reagents  $\text{RCu}(\text{PPh}_2)\text{Li}$ ,  $\text{RCu}(\text{NR}'_2)\text{Li}$ , and  $\text{RCu}(\text{PR}'_2)\text{Li}$  ( $\text{R}' = \text{cyclohexyl}$ ) are more stable than  $\text{R}_2\text{CuLi}$  and can be used at higher temperatures,<sup>1558</sup> but they are rather reactive. Unactivated aryl triflates<sup>1559</sup>  $\text{ArOSO}_2\text{CF}_3$  react to give  $\text{ArR}$  in good yields when treated with  $\text{R}_2\text{Cu}(\text{CN})\text{Li}_2$ .<sup>1560</sup> Both OTf units in  $\text{RCH}(\text{OTf})_2$  can be replaced with  $\text{Me}_2(\text{CN})\text{CuLi}_2$ .<sup>1561</sup> With an allenic substrate, reaction with  $\text{R}(\text{CN})\text{CuLi}$  can give ordinary displacement (with retention of configuration)<sup>1562</sup> or an  $\text{S}_{\text{N}}2'$  reaction to produce an alkyne.<sup>1563</sup> In the latter case, a chiral allene (Sec. 4.C, category 5) gave a chiral alkyne. The structures of “higher order mixed” cuprates has been called into question<sup>1564</sup> by Bertz, who suggested the reagent actually existed as  $\text{R}_2\text{CuLi}\cdot\text{LiCN}$  in THF.<sup>1565</sup> This conclusion was contradicted by Lipshutz.<sup>1566</sup>

Grignard reagents may react with alkyl halides in the presence of certain metal catalysts,<sup>1567</sup> and stereocontrol is possible in these reactions.<sup>1568</sup> The reaction of  $\text{CuI}$  with Grignard reagents gives magnesium cuprates,<sup>1569</sup> and  $\text{CuCN}$  has been used to generate the cuprate.<sup>1570</sup> Magnesium cuprates give conjugate addition reactions (**15-21**), similar to Gilman reagents.<sup>1569,1570,1571</sup> Other metals used include  $\text{Ag}$ ,<sup>1572</sup>  $\text{Pd}$ ,<sup>1573</sup>  $\text{Co}$ ,<sup>1574</sup>  $\text{Fe}$ ,<sup>1575</sup> and an Fe–amine complex.<sup>1576</sup> Iron nanoparticles have also been employed to facilitate this type of coupling.<sup>1577</sup> Prochiral enyne chlorides reacted with Grignard reagents and  $\text{CuTC}$  [copper(I) thiophenecarboxylate] to give a chiral allylic enyne.<sup>1578</sup> Allenes were prepared by the cross coupling of propargylic bromides with Grignard reagents, using a Ni catalyst.<sup>1579</sup>

Inversion of configuration has been shown in the reaction of 2-bromobutane with  $\text{Ph}_2\text{CuLi}$ ,<sup>1580</sup> but the same reaction with 2-iodobutane was reported to proceed with racemization.<sup>1581</sup> The reaction at a vinylic substrate occurs stereospecifically, with retention of configuration.<sup>1582</sup> Many *gem*-dihalides do not react, but when the two halogens are on a carbon  $\alpha$  to an aromatic ring,<sup>1583</sup> or on a cyclopropane ring,<sup>1584</sup> both halogens can be replaced by R, for example,  $\text{PhCHCl}_2 \rightarrow \text{PhCHMe}_2$ . However, 1,2-dibromides give exclusive elimination (**17-22**).<sup>1585</sup> Vinylmagnesium halides, upon addition of a catalytic amount of  $\text{Li}_2\text{CuCl}_4$ , couple to alkyl halides.<sup>1585</sup>

When dialkylcopperzinc reagents ( $\text{R}_2\text{CuZnCl}$ ) couple with allylic halides, allylic rearrangement occurs ( $\text{S}_{\text{N}}2'$ ) almost completely, and the reaction is diastereoselective if the allylic halide contains a  $\delta$ -alkoxy group.<sup>1586</sup> Another type of Cu reagent was prepared from  $\text{RZnI/CuCN}$ , and was shown to couple with alkenyl halides.<sup>1587</sup> Diethylzinc in the presence of a catalytic amount of CuBr coupled to allylic chlorides.<sup>1588</sup>

OS IX, 502.

### 10-59 Reaction of Alkyl Halides and Sulfonate Esters With Other Organometallic Reagents

A variation of the Wurtz coupling uses other metals to mediate or facilitate the coupling.<sup>1589</sup> Other metals include Ag, Zn,<sup>1590</sup> Fe,<sup>1591</sup> activated Cu,<sup>1592</sup> In,<sup>1593</sup> La,<sup>1594</sup> and Mn compounds.<sup>1595</sup> Other metals are commonly used for coupling reaction, often with an organic ligand.<sup>1596</sup> Organoaluminum compounds couple very well with tertiary halides (to give products containing a quaternary carbon) and benzylic halides at  $-78^\circ\text{C}$ .<sup>1597</sup> This reaction can also be applied to allylic, secondary, and some primary halides, but the reaction may

be slow. Alkynylaluminum reagents react with alkyl halides using a copper catalyst.<sup>1598</sup> Organoaluminum reagents react with secondary benzylic bromides in a cross-coupling reaction.<sup>1599</sup> Vinylic aluminum compounds (in the presence of a suitable transition metal catalyst) couple with allylic halides, acetates, and alcohol derivatives to give 1,4-dienes,<sup>1600</sup> and with vinylic and benzylic halides to give 1,3-dienes and allylic arenes, respectively.<sup>1601</sup> Alkynylaluminum reagents have been coupled with benzylic halides using a Ni catalyst.<sup>1602</sup>

Diarylmanganese reagents react with a Co catalyst to give the cross-coupling product.<sup>1603</sup> Coupling that involves the C–F bond using main group elements has been reviewed.<sup>1604</sup> The Ir-catalyzed cross-coupling of allylic carbonates with 1,3-diarylpropenes has been reported.<sup>1605</sup> Allylic halides have been coupled with triaryliindium reagents in the presence of rhodium catalysts.<sup>1606</sup> A nickel-catalyzed cross-coupling of alkyl aziridines has been reported.<sup>1607</sup>

The mechanism of many of these reactions differs with the metal catalyst. Aryl tin compounds couple with vinyl halides<sup>1608</sup> or vinyl triflates when a Pd catalyst is present.<sup>1609</sup> Homocoupling of benzylic halides was also effected by alumina-supported Ni nanoparticles in aqueous media.<sup>1610</sup> The ultrasound homocoupling of benzylic halides in the presence of Mg has been reported.<sup>1611</sup>

Vinylic halides can be coupled to give buta-1,3-dienes by treatment with activated Cu powder in a reaction analogous to the *Ullmann reaction* (**13-10**).<sup>1612</sup> This reaction is stereospecific, with retention of configuration at both carbons, and with *n*-BuLi in ether in the presence of MnCl<sub>2</sub>.<sup>1613</sup> Alkyl and allylic halides are coupled under electrochemical conditions, in aqueous media under air, catalyzed by Pd(OAc)<sub>2</sub> and Cu(OAc)<sub>2</sub>•H<sub>2</sub>O, and mediated by Pt–Zn.<sup>1614</sup> The polymeric phosphine-mediated coupling of alkyl halides has been reported using flow conditions (Sec. 7.D).<sup>1615</sup> The photoreductive coupling of 2-aryllallyl bromides with visible light, in the presence of a Ru catalyst, a Hantzsch ester, and *i*-Pr<sub>2</sub>NET gave 2,5-diaryl-1,5-dienes.<sup>1616</sup>

The coupling reaction with vinyltin reagents and vinyl halides occurs with a Pd catalyst.<sup>1617</sup> When the vinyltin reagent is coupled with a vinyl triflate in the presence of a Pd catalyst, the reaction is known as the *Stille reaction* (**12-15**). In the Stille reaction, vinylic triflates, in the presence of a Pd catalyst and LiCl, couple with organotin compounds R'SnMe<sub>3</sub>, where R' can be alkyl, allylic, vinylic, or alkynyl.<sup>1618</sup> The reaction has been performed intramolecularly, to prepare large-ring lactones.<sup>1619</sup> Allyltributylstannane compounds react with benzyl chlorides using Pd nanoparticles as a catalyst.<sup>1620</sup>

Products containing a quaternary carbon can also be obtained by treatment of tertiary halides with dialkyl or diaryl zinc reagents in CH<sub>2</sub>Cl<sub>2</sub>.<sup>1621</sup> Diarylzinc reagents reacted with benzylic bromides to give the coupling product.<sup>1622</sup> This organozinc coupling reaction has been done in ionic liquids.<sup>1623</sup> Palladium-catalyzed variations are also known for alkyl or vinyl halides with organozinc compounds.<sup>1624</sup> Dimethylzinc was coupled to aryl halides with a Pd catalyst,<sup>1625</sup> and *Reformatsky-type* zinc derivatives (see **16-27**; **16-31**) have been coupled to aryl halides using a Pd catalyst and microwave irradiation.<sup>1626</sup>

Alkyl or aryl triflates (halides) couple with alkyl or ArZn(halide) reagents in the presence of a Pd catalyst.<sup>1627</sup> Alkenylzinc iodides have been coupled to allylic halides in the presence of a Cu catalyst to give 1,4-dienes.<sup>1628</sup> Aryl ketones have been prepared by the coupling of aryl acid chlorides with alkylzinc chlorides, in the presence of Pd nanoparticles.<sup>1629</sup> Aryl iodides and benzyl chlorides or benzoyl chlorides were coupled, with CO and Zn powder and a Pd catalyst, to give 1,2-diarylethanones.<sup>1630</sup> Vinyl halides have been coupled to benzylic halides in the presence of Zn dust, in water, with a Pd catalyst.<sup>1631</sup> An alkyl halide with a CF<sub>3</sub> group was coupled with arylzinc compounds in the presence of a Ni catalyst.<sup>1632</sup> Ruthenium catalysts have been used for the allylic alkylation of disubstituted allylic esters.<sup>1633</sup> Cross-coupling reactions with achiral alkylzinc reagents have been reported.<sup>1634</sup> Secondary alkylzinc halides have been coupled with aryl or heteroaryl halides using Pd-PEPPSI-IPent, where PEPPSI is pyridine-enhanced precatalyst preparation stabilization

and initiation (a group of Pd catalysts), and IPent is the 3-pentyl substituent attached at the *ortho* positions of the aromatic rings.<sup>1635</sup> Alkenyl halides have been coupled with alkylzinc halides with a Pd catalyst.<sup>1636</sup> Organozinc reagents have been coupled with heteroaryl iodides using a Cu catalyst.<sup>1637</sup>

The coupling of alkyl or alkenyl halides and organozinc compound with a Ni complex has come to be known as *Negishi coupling*.<sup>1638</sup> The Ni-catalyzed reaction of an allylic halide and an organozinc reagent to give the coupling product is a generalized example,<sup>1639</sup>

although geminal diiodo compounds can be coupled without a catalyst.<sup>1640</sup> Arylzinc compounds<sup>1641</sup> have been used, as have arylvinyl iodides.<sup>1642</sup> The structure of bis(iodozinc) methane in THF solution has been reported.<sup>1643</sup> Pyridylzinc compounds have been used in Negishi coupling.<sup>1644</sup> Arylzinc bromides have been coupled to acid chlorides with a Ni catalyst to give aryl ketones.<sup>1645</sup> Pyridylzinc reagents have been used in the Negishi reaction.<sup>1646</sup> Organozinc compounds add to  $\alpha$ -chloroaldimines.<sup>1647</sup>

Carbonylative cross-coupling reactions have been reported.<sup>1648</sup> Asymmetric variations are known using various chiral additives or chiral catalysts,<sup>1649</sup> including reactions of allylic chlorides.<sup>1650</sup> Coupling with propargylic substrates has also been reported.<sup>1651</sup> Aminoalkylation of arenes and alkenes has been reported using a Ni catalyst.<sup>1652</sup> The cross-coupling reaction of organotellurium compounds has been used for the preparation of biaryls and aryl acetylenes.<sup>1653</sup> The Co-catalyzed cross coupling of heteroarylzinc or arylzinc reagents

with heteroaryl or aryl halides has been reported.<sup>1654</sup> An Fe-catalyzed cross-coupling reaction has been reported.<sup>1655</sup> The homocoupling of benzylic halides to give diarylethanes was effected with  $\text{Me}_2\text{Zn}$  and  $\text{RhCl}(\text{PPh}_3)_3$ .<sup>1656</sup> A Ni-catalyzed reductive approach to the cross-coupling of two unactivated alkyl halides, of which at least one must be a bromide, has been reported using a Ni catalyst with 3 equivalents of zinc.<sup>1657</sup>

There have been mechanistic studies of the Cu-catalyzed coupling reactions.<sup>1658</sup> Vinyl halides can be coupled with vinyltin reagents in the presence of CuI.<sup>1659</sup> Copper compounds can also be used as catalysts with dialkylzinc reagents.<sup>1660</sup> Alkyl halides can be treated with  $\text{SmI}_2$  and then CuBr to give a reactive species that couples with other alkyl halides.<sup>1661</sup> Tri-alkylindium compounds couple to allylic bromides in the presence of  $\text{Cu}(\text{OTf})_2 \cdot \text{P}(\text{OEt})_3$ .<sup>1662</sup> and vinyl indium compounds are coupled to  $\alpha$ -halo esters with a  $\text{BEt}_3$  catalyst.<sup>1663</sup> Vinylzirconium reagents can be coupled to allylic halides in the presence of Cu(I) compounds.<sup>1664</sup> A  $\text{S}_{\text{N}}2'$  reaction of allylic phosphates with alkylaluminum reagents, in the presence of a Cu–NMC catalyst, gave the corresponding enyne.<sup>1665</sup>

Allylic, benzylic, vinylic, and aryl halides or triflates (trifluoromethylsulfonates) couple with organotin reagents in a reaction catalyzed by Pd complexes.<sup>1666</sup> The advantage of this procedure is that the aryl group may contain nitro, ester, or aldehyde groups, and so on, which cannot be present in a *Grignard reagent*. Functional groups such as  $\text{CO}_2\text{R}$ , CN, OH, and CHO may be present in either reagent, but the substrate may not bear a  $\beta$  hydrogen on an  $sp^3$  carbon, because that results in elimination. Indium metal has been used to mediate the coupling of an allylic halide and an arylpalladium complex,<sup>1667</sup> and organoindium compounds were coupled to 1-iodonaphthalene with a Pd catalyst.<sup>1668</sup> Aryl halides have been coupled to allylic silanes in the presence of a Pd catalyst.<sup>1669</sup> Alkyl halides couple with  $\text{ArMnCl}$  or  $\text{RMnCl}$  in the presence of a Pd catalyst.<sup>1670</sup> Cobalt-catalyzed coupling reactions are known.<sup>1671</sup> The conversion of an aryllithium to an arylzirconium reagent was followed by coupling to a aryl halide in the presence of a Pd catalyst.<sup>1672</sup> Vinyl iodides couple

with  $\text{RMnCl}$  with an iron catalyst<sup>1673</sup> and  $\text{Bu}_3\text{MnMgBr}$  reacted with a geminal dibromocyclopropane to give a dialkylated cyclopropane.<sup>1674</sup>  $\alpha$ -Haloketones are coupled with aryl halides using a Ni catalyst.<sup>1675</sup> Allylgallium reagents have been coupled to  $\alpha$ -bromo esters in the presence of  $\text{BEt}_3/\text{O}_2$ .<sup>1676</sup>

Because of the presence of the 1,5-diene moiety in many naturally occurring compounds, methods that couple<sup>1677</sup> allylic groups are quite important. In one of these methods, allylic halides, tosylates, and acetates can be symmetrically coupled by treatment with nickel carbonyl<sup>1678</sup> to give 1,5-dienes.<sup>1679</sup> The order of halide reactivity is  $\text{I} > \text{Br} > \text{Cl}$ . With unsymmetrical allylic substrates, coupling nearly always takes place at the less-substituted end. The mechanism of coupling likely involves reaction of the allylic compound with  $\text{Ni}(\text{CO})_4$  to give one or more  $\pi$  allyl complexes, one of which may be the  $\eta^3$  complex **120**. Loss of CO to give a  $\pi$ -allylnickel bromide (**121**) and ligand transfer leads to coupling and the final product. In some cases, the  $\eta^3$  complexes **121** can be isolated from the solution and crystallized as stable solids.

Unsymmetrical coupling can be achieved by treating an alkyl halide directly with **121**, in a polar aprotic solvent,<sup>1680</sup> and coupling occurs at the less substituted end. There is evidence that free radicals are involved in such couplings.<sup>1681</sup> Hydroxy or carbonyl groups in the alkyl halide do not interfere. When **121** reacts with an allylic halide, a mixture of three products is obtained because of halogen–metal interchange.

### 10-60 Coupling of Organometallic Reagents With Carboxylic Esters

Several organometallic reagents react with allylic esters and carbonates to give the coupling product. Lithium dialkylcopper reagents couple with allylic acetates to give normal

coupling products or those resulting from allylic rearrangement, depending on the substrate.<sup>1682</sup> A mechanism involving a  $\sigma$ -allylic copper(III) complex has been suggested.<sup>1683</sup> Propargylic acetates reacted with cuprates to give an allene. Silyl cuprates have also been used with benzoate esters, to give allylsilanes.<sup>1684</sup> Interestingly, allylic silanes have been coupled to acetates using  $B(C_6F_5)_3$ <sup>1685</sup> or  $BF_3$ .<sup>1686</sup>

Lithium dialkylcopper reagents give normal coupling products with enol acetates of  $\beta$ -dicarbonyl compounds.<sup>1687</sup> It is also possible to carry out the coupling of allylic acetates with Grignard reagents, if catalytic amounts of cuprous salts are present.<sup>1688</sup> Yields are better with this method, and regioselectivity can be controlled by the choice of cuprous salts.

Several metal-catalyzed coupling reactions are known. Allylic, benzylic, and cyclopropylmethyl acetates couple with trialkylaluminums,<sup>1689</sup> and allylic acetates couple with aryl and vinylic tin reagents, in the presence of a Pd catalyst.<sup>1690</sup> Many Ni(0) coupling reactions are known.<sup>1691</sup> Titanium-mediated,<sup>1692</sup> Ir-catalyzed,<sup>1693</sup> and Fe-catalyzed<sup>1694</sup> reactions are also known. Allylic phosphonates have been used as substrates for displacement by higher order cuprates<sup>1695</sup> (see **10-58**) or dialkylzinc reagents.<sup>1696</sup>

A now common coupling reaction is the reaction of  $\eta^3$ - $\pi$ -allyl Pd complexes<sup>1697</sup> (Sec. 3.C.i) with various nucleophiles,<sup>1698</sup> where the complex is obtained from allylic esters (acetate is the most common) or allylic carbonates (also see **10-30**). This coupling reaction is often called the *Tsuji-Trost* reaction.<sup>1699</sup> The mechanism of such  $\pi$ -allyl palladium reactions has been discussed.<sup>1700</sup> The structure and nature of the ligands associated with the

metal are important to the reaction, particularly with respect to stereoselectivity of a given reaction.<sup>1701</sup> A typical transformation is shown for the reaction of an allylic acetate with diethyl malonate, BSA (*N,O*-bis(trimethylsilyl)acetamide) and potassium acetate, which gives a coupling product in the presence of the Pd catalyst.<sup>1702</sup>

This reaction is a variation of the basic transformation reported several years ago by Trost.<sup>1703</sup>

Enolate anions of active methylene compounds<sup>1704</sup> and also sulfone anions<sup>1705</sup> have been used as nucleophiles much of the time. In most reported cases, the R'M species is the anion of an active methylene compound (such as sodium, potassium, or lithium dimethylmalonate), or *Knoevenagel-type* carbanions (see **16-38**), or amino acid surrogates.<sup>1706</sup> Enolate anions (see **10-67**) have also been used.<sup>1707</sup> The Pd catalyst used, the reaction conditions, and the nature of the organometallic compounds varies widely. Although two allylic coupling products are possible via the  $\pi$ -allyl intermediate, attack at the less-substituted position is generally favored. This transformation has been done in ionic liquids<sup>1708</sup> and ionic liquids have been used as additives in catalytic amounts in other solvents.<sup>1709</sup> The reaction has been done in water, using a Pd catalyst and micellar catalysts that use a photochromic surfactant.<sup>1710</sup>  $S_N2'$  reactions with allylic substrates have been reported.<sup>1711</sup> Benzoate esters have been used successfully in lieu of the acetate.<sup>1712</sup> Catalyst metals other than Pd have been used for this reaction with allylic acetates.<sup>1713</sup> The Ni-catalyzed reaction is known for the coupling of allylic acetates with alkyl halides.<sup>1714</sup> The reaction has been done using continuous flow techniques (Sec. 7.D) using a Pd-C catalyst.<sup>1715</sup> The use of chiral

ligands<sup>1716</sup> or chiral additives that may act as ligands<sup>1717</sup> leads to asymmetric induction in the coupling product.<sup>1718</sup>

As mentioned above, a common variation is to replace the acetate leaving group with a carbonate ( $-\text{OCO}_2\text{R}$ ), where methyl carbonate ( $-\text{OCO}_2\text{Me}$ ) is most common.<sup>1719</sup> A generalized reaction is the transformation of an allylic carbonate to the malonate derivative:<sup>1720</sup>

As with allylic acetates, chiral ligands and chiral additives lead to asymmetric induction.<sup>1721</sup> A variety of active methylene compounds can be used as nucleophiles,<sup>1722</sup> including enolate anions.<sup>1723</sup> Other nucleophiles can be used to displace allylic carbonates,<sup>1724</sup> often in conjunction with chiral ligands to give the product with enantioselectivity. Polymer-supported phosphine ligands have been used successfully,<sup>1725</sup> and catalyst systems other than Pd have been used for this reaction with allylic carbonates.<sup>1726</sup> Potassium vinyltrifluoroborates (**10-72**) have also been used in Pd-catalyzed coupling reactions with allylic acetates.<sup>1727</sup>

Intramolecular cyclization is possible when the active methylene compound and an allylic acetate or carbonate is incorporated into the same molecule.<sup>1728</sup> Propargylic esters have been used in Pd-catalyzed coupling reactions, including a reaction with trialkylindium reagents.<sup>1729</sup>

## 10-61 Coupling of Organometallic Reagents With Miscellaneous Substrates

Leaving groups other than halide, esters or carbonates, or sulfonate esters are sometimes used. Sulfates, sulfonates, and epoxides give the expected products. The reactions of sodium sulfonates and alkyl halides in ionic liquids have been reported.<sup>1730</sup> The NR<sub>2</sub> group from *Mannich bases* such as RCOCH<sub>2</sub>CH<sub>2</sub>NR<sub>2</sub> can also act as a leaving group in this reaction (elimination–addition mechanism, Sec. 10.F). A nitro group can be displaced<sup>1731</sup> from α-nitro esters, ketones, nitriles, and α,α-dinitro compounds,<sup>1732</sup> and even from simple tertiary nitro compounds of the form R<sub>3</sub>CNO<sub>2</sub><sup>1733</sup> or ArR<sub>2</sub>CNO<sub>2</sub><sup>1734</sup> by salts of nitroalkanes, for example:

These reactions take place by SET mechanisms.<sup>1735</sup> However, with α-nitro sulfones it is the sulfone group that is displaced, rather than the nitro group.<sup>1736</sup> The SO<sub>2</sub>R group of allylic sulfones can be replaced by CHZZ'

if a Mo(CO)<sub>6</sub> catalyst is used.<sup>1737</sup>

*tert*-Butyl sulfones react with organolithium reagents, in the presence of a catalytic amount of an Fe complex, to give coupling.<sup>1738</sup> Treatment with phenyliodonium bis(trifluoroacetate) gave the five-membered ring lactone.<sup>1739</sup> Similar displacement of TolSO<sub>2</sub> was observed with tolylsulfones and diethylzinc.<sup>1740</sup> Phosphonic esters, ROPO(OR)<sub>2</sub>, react with allylic Grignard reagents to give the coupling product.<sup>1741</sup>

## 10-62 The Bruylants Reaction

The *Bruylants reaction* is the reaction of an amino nitrile with a *Grignard reagent* to give a substituted amine.<sup>1742</sup> This reaction is most often used for the preparation of aliphatic amines via aliphatic Grignard reagents. In a few cases, vinylic Grignard reagents can be used to prepare allylic amines.<sup>1743</sup> The use of  $\text{AgBF}_4$  to convert amino nitriles to the corresponding iminium ion facilitates the Bruylants reaction with vinylic Grignard reagents.<sup>1744</sup> Replacement of the cyano group in a tertiary nitrile is also possible.<sup>1745</sup>

## 10-63 Coupling Involving Alcohols

In some cases, it is possible to couple an alcohol in the presence of an organometallic compound.<sup>1746</sup> Allylic alcohols are coupled with alkylmagnesium bromides in the presence of  $\text{Ti}(\text{O}i\text{-Pr})_4$ , for example.<sup>1747</sup> Benzylic alcohols have been coupled to Grignard reagents as an alkyl or aryl source, in the presence of a Ni catalyst.<sup>1748</sup> Benzylic alcohols have been converted to benzylic Grignard reagents using hexylmagnesium chloride using an Fe, Ni, or Co catalyst.<sup>1748</sup> Using an Ir catalyst, the enantioselective reaction of secondary allylic alcohols with potassium alkynyltrifluoroborates, a chiral ligand, trifluoroacetic acid, and  $\text{KHF}_2$  give the corresponding enyne.<sup>1749</sup> The Pd-catalyzed reaction of active methylene compounds with allylic alcohols<sup>1750</sup> or benzylic alcohols<sup>1751</sup> is also known. The coupling of an alcohol to the  $\alpha$  carbon of a ketone to give a  $\beta$ -substituted alcohol is possible in the presence of a Ru catalyst.<sup>1752</sup> Alcohols are coupled to allenes in the presence of an Ir catalyst.<sup>1753</sup> Allylic carbonates are coupled to allylic alcohols with a Ni catalyst.<sup>1754</sup>

Allylic or benzylic alcohols can be symmetrically coupled<sup>1755</sup> by treatment with methyl-lithium and titanium trichloride at  $-78\text{ }^{\circ}\text{C}$ <sup>1756</sup> or by heating with  $\text{TiCl}_3$  and  $\text{LiAlH}_4$ .<sup>1757</sup> When the substrate is an allylic alcohol, the reaction is not regiospecific, but a mixture of normal coupling and allylic rearranged products is found. A free-radical mechanism is involved.<sup>1758</sup> The  $\text{TiCl}_3\text{-LiAlH}_4$  reagent can also convert 1,3-diols to cyclopropanes, provided that at least one phenyl group is present.<sup>1759</sup>

A catalyst has been developed with magnetite impregnated with Ir that catalyzes the cross-alkylation of primary alcohols; the catalyst can be removed from the reaction medium by magnetic sequestering.<sup>1760</sup> The Ru-catalyzed coupling of two alcohols with KOH gave the ketone, whereas reaction with  $\text{Mg}_3\text{N}_2$  gave the corresponding ester.<sup>1761</sup> Alcohols reacted with  $\text{CH}_2=\text{CHCH}_2\text{SiMe}_3$  in the presence of 15% iodine and an iodoimidazolium catalyst to give the allyl coupling product.<sup>1762</sup> The  $\text{Al}(\text{OTf})_3$ -catalyzed reaction of propargylic alcohols with molecules such as alcohols, aromatic compounds, amides, and thiols to give replacement of the hydroxyl unit with the nucleophile has been conducted.<sup>1763</sup> The cross coupling of alcohols in the presence of  $\text{NaHSO}_4/\text{SiO}_2$  gave the corresponding substituted alkenes.<sup>1764</sup> The stereospecific coupling of alkenes with alcohols to give the corresponding substituted (*E*)-alkenes was reported with an Fe catalyst.<sup>1765</sup>  $\text{Me}_2\text{TiCl}_2$  reacts with tertiary alcohols in the same way.<sup>1766</sup>  $\beta$ -Alkylation of secondary alcohols has been reported using alcohol substrates in the presence of an Ir complex.<sup>1767</sup> Allylic alcohols couple with a reagent prepared from  $\text{MeLi}$ ,  $\text{CuI}$ , or  $\text{R}'\text{Li}$  in the presence of  $(\text{Ph}_3\text{PNMePh})^+ \text{I}^-$  to give alkenes that are products of allylic rearrangement.<sup>1768</sup> Allylic alcohols also couple with certain Grignard reagents<sup>1769</sup> in the presence of a Ni complex to give both normal products and the products of allylic rearrangement. Allylic alcohols reacted with 3 equivalents of  $\text{EtMgBr}$  via a  $\text{S}_{\text{N}}2'$  alkylation in the presence of  $\text{CITi}(\text{O}i\text{-Pr})_3$ , then treated with iodomethane, to give the corresponding alkene.<sup>1770</sup>

The reaction gives good yields with primary, secondary, and tertiary alcohols, and with alkyl and aryllithium reagents.<sup>1771</sup> The Co-catalyzed coupling of secondary alcohols and

primary alcohols gave the alkylated mono alcohol.<sup>1772</sup> Allenic alcohols couple with allyl indium reagents at 140 °C to give allylic alcohol products.<sup>1773</sup> Secondary benzylic alcohols have been coupled to primary benzylic alcohols with a ruthenacycle catalyst, in the presence of base, to give the coupling product, an alcohol.<sup>1774</sup> Alcohols react with 1,3-ketones in the presence of a sulfuric acid catalyst at 101 °C.<sup>1775</sup> Alcohols react with acetonitrile to give the corresponding nitrile in the presence of Cs<sub>2</sub>CO<sub>3</sub> and an Ir catalyst, under microwave irradiation.<sup>1776</sup> The Pd-catalyzed coupling of allylic alcohols with cyclic 1,3-diones, in water, gave the corresponding allylated products.<sup>1777</sup> Alcohols react with allylsilanes, in the presence of an InCl<sub>3</sub><sup>1778</sup> or InBr<sub>3</sub><sup>1779</sup> catalyst, to give the corresponding coupling product. Propargylic alcohols have been coupled to allylic silanes using an Au catalyst<sup>1780</sup> or a Rh catalyst.<sup>1781</sup>

### 10-64 Coupling of Organometallic Reagents With Compounds Containing the Ether Linkage<sup>1782</sup>

Acetals,<sup>1783</sup> ketals, and ortho esters<sup>1784</sup> react with Grignard reagents to give, respectively, ethers and acetals (or ketals). The latter can be hydrolyzed to aldehydes or ketones (**10-6**). This procedure is a way of converting a halide R''X (which may be alkyl, aryl, vinylic, or alkynyl) to an aldehyde R''CHO, increasing the length of the carbon chain by one carbon (see also **10-77**). The ketone synthesis generally gives lower yields. Acetals, including allylic acetals, also give this reaction with organocopper compounds and BF<sub>3</sub>.<sup>1785</sup> Dihydropyrans react with Grignard reagents in the presence of a Ni catalyst.<sup>1786</sup> Acetals also undergo substitution when treated with silyl enol ethers or allylic silanes, with a Lewis acid catalyst,<sup>1787</sup> to give a β-alkoxy ketone. ω-Ethoxy lactams react with Grignard reagents to give ω-substituted lactams.<sup>1788</sup>

Ordinary ethers are not cleaved by Grignard reagents (in fact, diethyl ether and THF are the most common solvents for Grignard reagents), although more active organometallic compounds can cleave ethers.<sup>1789</sup> However, a Ni-catalyzed coupling reaction of ROME with MeMgBr led to replacement of the OMe group with a methyl group from the Grignard reagent.<sup>1790</sup>

Oxetanes have been opened with organolithium reagents and  $\text{BF}_3 \cdot \text{OEt}_2$ <sup>1791</sup> and also with excess Li metal with a biphenyl catalyst.<sup>1792</sup> Allylic ethers can be cleaved by Grignard reagents in THF if CuBr is present.<sup>1793</sup> The reaction can take place either with or without allylic rearrangement.<sup>1794</sup> Vinylic ethers can also be cleaved by Grignard reagents in the presence of a Ni catalyst.<sup>1795</sup> Silyl enol ethers  $\text{R}_2\text{C}=\text{CROSiMe}_3$  behave similarly.<sup>1796</sup> Bicyclic benzofurans can be opened by dialkylzinc reagents in the presence of a Pd catalyst.<sup>1797</sup> Benzylic methoxy compounds are converted to the methyl derivative by reaction with methylmagnesium iodide and a Ni catalyst.<sup>1798</sup>

### 10-65 The Reaction of Organometallic Reagents With Epoxides (Oxiranes) or Oxetanes

The reaction between *Grignard reagents* or organolithium reagents and epoxides is very valuable and is often used to increase the length of a carbon chain by two carbons.<sup>1799</sup> The Grignard reagent may be aromatic or aliphatic, although tertiary Grignard reagents give low yields. As expected for an  $\text{S}_{\text{N}}2$  process, attack is at the less substituted carbon. With allylic Grignard reagents, the addition of a catalytic amount of  $\text{Yb}(\text{OTf})_3$  facilitated

alkylation.<sup>1800</sup> Organolithium reagents,<sup>1801</sup> in the presence of chiral additives, lead to the 2-substituted alcohol with good enantioselectivity. Similar reaction with a chiral *Schiff base* gave the same type of product, with excellent enantioselectivity.<sup>1802</sup>

Lithium dialkylcopper reagents also give the reaction<sup>1803</sup> as do higher order cuprates,<sup>1804</sup> which often give higher yields. Organocuprates have the additional advantage that they do not react with ester, ketone, or carboxyl groups so that the epoxide ring of epoxy esters, ketones, and carboxylic acids can be selectively attacked, often in a regioselective manner.<sup>1805</sup> The use of BF<sub>3</sub> increases the reactivity of R<sub>2</sub>CuLi, enabling the use with thermally unstable epoxides.<sup>1806</sup> Lithium diaminocyno cuprates have also been used.<sup>1807</sup>

The reaction has also been performed with other organometallic compounds,<sup>1808</sup> and epoxides or oxetanes are ring opened by reaction with various reagents in the presence of transition metal catalysts.<sup>1809</sup> Terminal epoxides react with aryl halides using a NiI<sub>2</sub>·xH<sub>2</sub>O/2,2'-bipyridine catalyst, with 20% pyridine, 25% NaI, 2 equivalents of Zn, and Et<sub>3</sub>H<sup>+</sup> Cl<sup>-</sup> to give the corresponding alcohol.<sup>1810</sup> Arenes react with terminal epoxides in the presence of a Pd catalyst to give the alcohol.<sup>1811</sup> Aryl iodides ring-open terminal epoxides in the presence of selenium and CuCl as a catalyst to give a β-arylselenyl alcohol.<sup>1812</sup> Styryl epoxides reacted with butyllithium and LiCH<sub>2</sub>CN to give 1-hydroxymethylstyrene derivatives in an α-methenylation reaction.<sup>1813</sup> 2,3-Epoxyamines reacted with TMSN<sub>3</sub> in the presence of a Lewis acid to give 3-azido-2-hydroxyamines or 2-azido-3-hydroxyamines.<sup>1814</sup> Catalysis with BF<sub>3</sub>·OEt<sub>2</sub> or ZnCl<sub>2</sub> gives the 3-azido-2-hydroxyamines whereas Ti(O-*i*-Pr)<sub>4</sub> gave the 2-azido-3-hydroxyamines.<sup>1814</sup> The reaction of anisole derivatives with butyllithium in the presence of a catalytic amount of TMEDA, for 16 h at 0 °C, followed by reaction with terminal epoxides at -78 °C gave the *ortho*-2-hydroxyalkylanisole derivative with high regioselectivity.<sup>1815</sup>

Epoxides are opened to give the corresponding alcohols by treatment with  $\text{Ti}(\text{O-}i\text{-Pr})_4$ ,  $\text{Me}_3\text{SiCl}$ , and  $\text{Mg}$ .<sup>1816</sup> Epoxides reacted with potassium alkyltrifluoroborates in the presence of TFAA to give ring opening and the corresponding alcohols.<sup>1817</sup> Epoxides reacted with 3 equivalents of trimethylsulfoxonium iodide and 3 equivalents of  $\text{KO-}t\text{-Bu}$ , in the presence of a cobalt catalyst, to give a homoallylic alcohol.<sup>1818</sup> A symmetric ring opening of 3-substituted oxetanes with nucleophiles leads to ring opening and the alcohol.<sup>1819</sup> The epoxides of dihydrofurans and dihydropyrans reacted with organolithium reagents to give unsaturated diols.<sup>1820</sup>

Trialkylaluminum reagents open epoxides with delivery of the alkyl group to carbon.<sup>1821</sup> In the presence of a Lewis acid catalyst such as  $\text{BF}_3$ , alkylation can occur at the more substituted carbon.<sup>1822</sup> *Friedel-Crafts-type alkylation* (see **11-11**) is possible when an aromatic compound reacts with an epoxide and  $\text{AlCl}_3$ .<sup>1823</sup> Epoxides react with allyl bromide in the presence of In metal with the expected delivery of allyl to the less-substituted carbon.<sup>1824</sup> When a substituted epoxide was treated with  $\text{CO}$ ,  $\text{BF}_3 \cdot \text{OEt}_2$ , and a Co catalyst, carbonylation occurred and the final product was a  $\beta$ -lactone.<sup>1825</sup> Similar  $\beta$ -lactone-forming reactions were reported using substituted epoxides,  $\text{CO}$ , and a metal compound- $\text{BF}_3$  complex.<sup>1826</sup> Five-membered ring lactams were formed from substituted epoxides using  $\text{BF}_3 \cdot \text{OEt}_2$  followed by treatment with  $\text{KHF}_2$ .<sup>1827</sup> Ring opening of epoxides with Ti compounds has been shown to be selective for the more substituted carbon.<sup>1828</sup> Epoxides react with Ag salts of alkynes, in the presence of Zr compounds, to give the rearrangement product, a propargylic alcohol.<sup>1829</sup> A Ga/Sm-induced ring opening with alkyl halides has been reported.<sup>1830</sup> In the presence of a Sc catalyst, chiral allylic boranes open epoxides at the less-substituted position to generate chiral, homoallylic alcohols.<sup>1831</sup>

When the substrate is a vinylic epoxide,<sup>1832</sup> Grignard reagents generally give a mixture of the normal product of attack at the less substituted carbon atom and the product of allylic rearrangement (**122**).<sup>1833</sup>

### 10-66 Reaction of Organometallics With Aziridines or Azetidines

Aziridines have been opened by organometallic reagents to give amines.<sup>1836</sup> It is also possible to open aziridines, with organometallic reagents particularly, when there is a *N*-sulfonyl group such as tosyl (formally making it a sulfonamide), although they are less reactive than epoxides.<sup>1837</sup> Transition metals have been used with three-membered ring heterocycles.<sup>1838</sup> Grignard reagents react with *N*-tosyl 2-phenylaziridine to give the corresponding *N*-tosyl amine.<sup>1839</sup> Organocuprates (**10-58**) reaction with *N*-alkyl aziridines to give the corresponding amine.<sup>1840</sup> Aziridines react with benzene, in the presence of  $In(OTf)_3$ , to give the  $\beta$ -aryl amine.<sup>1841</sup>

*N*-Tosyl aziridines have also been opened with enolate anions, which led to a pyrroline derivative.<sup>1842</sup> Allylic alcohols open *N*-tosyl aziridines with KSF-Montmorillonite clay.<sup>1843</sup> C-Arylation is possible, giving a ring-opened amine derivative with a  $Ag(I)$  catalyst.<sup>1844</sup> *N*-Sulfonyl aziridines react with the enolate anions of  $\beta$ -keto esters under phase-transfer conditions.<sup>1845</sup> *N*-Tosyl aziridines react with  $InCl_3$  to give the chloro *N*-tosylamine.<sup>1846</sup> *N*-Sulfonyl aziridines react with aromatic or heteroaromatic compounds with a catalytic amount  $Zn(OT)_2$  and  $Sc(OTf)_3$ , leading to ring opening and formation of the sulfonamide derivative.<sup>1847</sup> A similar reaction has been reported using TMSNCS to give the thiocyanate

product.<sup>1848</sup> Aziridines react with alkyl diselenides in the presence of zinc and HCl, to give the  $\beta$ -alkylseleno amine.<sup>1849</sup>

Aziridines react with nucleophiles other than carbon nucleophiles. *N*-Benzylic aziridines are opened by trimethylsilyl azide in the presence of a Cr catalyst.<sup>1850</sup> Mediated by Lewis bases, aziridines react with silylated nucleophiles.<sup>1851</sup> *N*-Protected azetidines reacted with aryl thiols in the presence of a chiral phosphoric acid catalyst to give the protected amine derivative.<sup>1852</sup> Azetidines containing a basic ring nitrogen atom reacted with alkyl bromides and acyl chlorides to give 3-halo-1-amino propane derivatives.<sup>1853</sup>

### 10-67 Alkylation and Arylation at a Carbon Bearing an Active Hydrogen

This section will focus on the general reaction of a suitable base with active methylene compounds such as malonate derivatives,<sup>1854</sup> acetoacetic ester derivatives, and 1,3-diketone derivatives, and with substrates bearing a leaving group, not necessarily allylic substrates or metal catalyzed. Both Z and Z' may be COOR', CHO, COR',<sup>1855</sup> CONR'<sub>2</sub>, COO<sup>-</sup>, CN,<sup>1856</sup> NO<sub>2</sub>, SOR', SO<sub>2</sub>R',<sup>1857</sup> SO<sub>2</sub>OR', SO<sub>2</sub>NR'<sub>2</sub>, or similar groups.<sup>1858</sup> When compounds contain two or three strong electron-withdrawing groups on a carbon atom bearing a proton (the so-called  $\alpha$  proton), that proton is more acidic than in compounds without such groups (Sec. 5.B.i, category 1). Treatment with a base that has a conjugate acid with a  $pK_a$  greater than the  $\alpha$  proton removes the  $\alpha$  proton and generates the corresponding enolate anion (**10-68**). These enolate anions react as carbon nucleophiles and attack alkyl halides, resulting in their alkylation.<sup>1859</sup> Some commonly used bases are sodium ethoxide and potassium tert-butoxide, each in its respective alcohol as solvent. With particularly acidic compounds (e.g.,  $\beta$ -diketones, Z, Z' = COR'), sodium hydroxide (in water, aqueous alcohol or acetone), or even sodium carbonate,<sup>1860</sup> are strong enough bases for the reaction. If at least one Z group

is COOR', saponification is a possible side reaction. In addition to the groups listed above, Z may also be phenyl, but if two phenyl groups are on the same carbon, the acidity is less than in the other cases and a stronger base must be used. Diphenylmethane was deprotonated using NaNH<sub>2</sub> as the base.<sup>1861</sup>

If the solvent used in the reaction is a stronger acid than the substrate that reacts with the base, it is acidic enough to protonate either the enolate anion or the base. In such a case, an equilibrium will be established leading to only small amounts of the enolate anion (thermodynamic conditions). Such solvents are usually protic solvents that include water, alcohols, or amines. Aprotic solvents can be used in some cases to avoid this reaction. The use of polar aprotic solvents (e.g., DMF or DMSO) markedly increases the rate of alkylation<sup>1862</sup> but also increases the extent of alkylation at the oxygen rather than the carbon with highly reactive species such as iodomethane (Sec. 10.G.viii). In general, enolate anions such as those described here react with alkyl halides via C-alkylation, although *tri-alkylsilyl halides and anhydrides tend to react via O-alkylation*. Phase-transfer catalysis has also been used,<sup>1863</sup> and the use of chiral phase-transfer catalysts led to enantioselectivity in the alkylated product.<sup>1864</sup> Various functional groups may be present in RX as long as they are not sensitive to base. Side reactions that may cause problems are the above-mentioned competing O-alkylations, elimination (if the enolate anion is a strong enough base), and dialkylation.

With substrates such as ZCH<sub>2</sub>Z' it is possible to alkylate twice. Initial removal of the proton with a base followed by alkylation of the resulting enolate anion with RX, can be followed by subsequent removal of the proton from ZCHRZ' and then alkylation with the same or a different RX. When ω,ω'-dihalides are used, ring closures can be effected:<sup>1865</sup> This method has been used to close rings of from three (*n* = 0) to seven members, although five-membered ring closures proceed in highest yields. Another ring-closing method involves internal alkylation.<sup>1866</sup> This method has been shown to be applicable to medium rings (10 to 14 members) without the use of high-dilution techniques.<sup>1867</sup>

An important example of this reaction is the *malonic ester synthesis*, in which both Z groups are COOEt. The product can be hydrolyzed and decarboxylated (**12-40**) to give a carboxylic acid. An illustration is the preparation of 2-ethylpentanoic acid (**123**) from malonic ester.

<sup>1867</sup> See Deslongchamps, P.; Lamothe, S.; Lin, H. *Can. J. Chem.* **1987**, *65*, 1298.

A variation of this alkylation sequence employs 1,2-dibromoethane as the alkylating agent, and subsequent treatment with DBU (1,8-diazabicyclo[5.4.0]undec-7-ene) leads to incorporation of a vinyl group on the  $\alpha$  carbon.<sup>1868</sup> Another variation involved coupling of a dimalonate with an allylic carbonate (see **10-60**), using a polymer-supported Pd catalyst.<sup>1869</sup>

Another important example is the *acetoacetic ester synthesis*, in which Z is CO<sub>2</sub>Et and Z' is COCH<sub>3</sub>. In this case, the product can be decarboxylated with acid or dilute base (**12-39**) to give a ketone (**124**) or cleaved with concentrated base (**12-42**) to give a carboxylic ester (**125**) and a salt of acetic acid. This reaction has been done in *tert*-butanol in the presence of alumina, *in vacuo*, to give the alkylated keto acid directly from the keto ester.<sup>1870</sup>

Another way of preparing ketones involves alkylation<sup>1871</sup> of  $\beta$ -keto sulfoxides<sup>1872</sup> or sulfones,<sup>1873</sup> to give **126**. The sulfoxide group in the product (**126**) is easily reduced (desulfurized, see **19-70**) to give the ketone in high yields using aluminum amalgam or by electrolysis.<sup>1874</sup>  $\beta$ -Keto sulfoxides such as **126** or sulfones ( $-\text{SO}_2-$ ) are easily prepared (**16-82**). When one group attached to the sulfur atom is chiral, the alkylation proceeds with reasonable enantioselectivity.<sup>1875</sup>

In another method for the coupling of two different allylic groups,<sup>1876</sup> a carbanion derived from a  $\beta,\gamma$ -unsaturated thioether couples with an allylic halide to give **127**.<sup>1877</sup> The product **127** contains an SPh group that must be removed (with Li in ethylamine) to give the 1,5-diene. Unlike most of the methods previously discussed, this method has the advantage that the coupling preserves the original positions and configurations of the two double bonds; no allylic rearrangements take place.

Alkylation takes place at the most acidic position of a reagent molecule. For example, acetoacetic ester ( $\text{CH}_3\text{COCH}_2\text{COOEt}$ ) is alkylated at the methylene and not at the methyl group; this is because the former is more acidic than the latter and hence gives up its proton to the base. However, if 2 molar equivalents of base are used, then not only is the most acidic proton removed but also the second most acidic. Alkylation of this doubly charged anion (a dianion) occurs at the less acidic position, in this case the second most acidic position<sup>1878</sup> (Sec. 10.G.vii). The first and second ion pair acidities of  $\beta$ -diketones has been studied.<sup>1879</sup>

The reaction is not limited to  $\text{Z}-\text{CH}_2-\text{Z}'$  compounds. Other compounds have acidic C-H hydrogen atoms. Some examples are the methyl hydrogen atoms of  $\alpha$ -aminopyridines, the methyl hydrogen atoms of ynamines of the form  $\text{CH}_3\text{C}\equiv\text{CNR}_2$ <sup>1880</sup> (the product in this case can be hydrolyzed to an amide  $\text{RCH}_2\text{CH}_2\text{CONR}_2$ ), the  $\text{CH}_2$  hydrogen atoms of cyclopentadiene and its derivatives (Sec. 2.I.ii), hydrogen atoms connected to a triple-bond carbon (**10-74**), and the hydrogen of HCN (**10-76**), which can also be removed with a base and the resulting ion alkylated (see also **10-68** to **10-72**).  $\alpha$ -Imino esters have been used since treatment with a strong base with a Ti catalyst followed by an aldehyde leads to hydroxy amino esters.<sup>1881</sup>

The mechanism of these reactions is usually  $\text{S}_{\text{N}}2$  with inversion taking place at a chiral RX, although an SET<sup>1882</sup> mechanism may be involved in certain cases,<sup>1883</sup> especially where the nucleophile is an  $\alpha$ -nitro carbanion<sup>1884</sup> and/or the substrate contains a nitro or cyano<sup>1885</sup> group. Alkylation  $\alpha$  to a nitro group can be achieved with the *Katritzky pyrylium-pyridinium reagents*.<sup>1886</sup> This reaction probably has a free-radical mechanism.<sup>1887</sup> Tertiary alkyl groups can be introduced by an  $\text{S}_{\text{N}}1$  mechanism if the  $\text{ZCH}_2\text{Z}'$  compound (not the enolate anion) is treated with a tertiary carbocation generated *in situ* from an alcohol or alkyl halide and  $\text{BF}_3$  or  $\text{AlCl}_3$ ,<sup>1888</sup> or with a tertiary alkyl perchlorate.<sup>1889</sup>

Cyclohexa-1,3-diones reacted with a Cu catalyst and diisopropylethylamine in the presence of a chiral tridentate *P,P,N*-ketimine ligand to give the  $\alpha$ -alkylated product.<sup>1890</sup> Propargylic pivalates reacted with  $\text{HC}(\text{CO}_2\text{Et})_3$  in the presence of a Cu catalysts and a chiral

### 10-68 Alkylation of Ketones, Aldehydes, Nitriles, and Carboxylic Esters, etc.

Ketones,<sup>1895</sup> nitriles,<sup>1896</sup> and carboxylic esters<sup>1897</sup> can be alkylated in the  $\alpha$  position in a reaction similar to **10-67**.<sup>1898</sup> Current literature contains several hundred examples of work in this area, and only a handful can be presented here. The chosen new literature citations are simply meant to show some of the newer research in this area. The  $pK_a$  of the proton  $\alpha$  to the carbonyl or CN is in the range of 19–25, depending on the number of substituents (see Chapter 8, Table 8.1), and a base that has a conjugate acid with a  $pK_a$  greater than that proton must be employed. Note that since only one activating group is present, compared with two activating groups for the substrates in **10-67**, the  $pK_a$  of the  $\alpha$  proton is higher (a weaker acid) and so a stronger base is required. The mechanism for this deprotonation reaction has been studied,<sup>1899</sup> as has the rate of deprotonation.<sup>1900</sup> Reaction of the  $\alpha$  proton with the base generates the key nucleophilic intermediate, a *resonance-stabilized enolate anion*.<sup>1901</sup> The most common bases<sup>1902</sup> are lithium diethylamide ( $\text{Et}_2\text{NLi}$ ), lithium diisopropylamide [ $(\text{Me}_2\text{CH})_2\text{NLi}$ , LDA],<sup>1903</sup> lithium hexamethyldisilazide [ $\text{LiN}(\text{SiMe}_3)_2$ ], *t*-BuOK,  $\text{NaNH}_2$ ,

and KH. The base lithium *N*-isopropyl-*N*-cyclohexylamide (LICA) is particularly successful for carboxylic esters<sup>1904</sup> and nitriles.<sup>1905</sup> Lithium enolate anions exist as aggregates in solution.<sup>1906</sup> The structure of lithium enolates has been reviewed.<sup>1907</sup> Short-lived chiral enolate anions with a chiral C—O axis have been reported.<sup>1908</sup> The solution structures of Evan's enolates has been examined.<sup>1909</sup> Lithium enolates derived from Weinreb amides have been discussed.<sup>1910</sup> Enolate anion formation with lithium amides can also be regioselective (see **12-22**).<sup>1911</sup>

Solid KOH in DMSO has been used to methylate ketones, in high yields.<sup>1912</sup> Some bases are strong enough to convert the ketone, nitrile, or ester completely to its enolate anion conjugate base in an effectively irreversible manner, while others (especially *t*-BuOK) leads to an equilibrium that favors a significant fraction of the molecules. In the latter case, the *aldol reaction* (**16-34**) or *Claisen condensation* (**16-81**) may be side reactions, since under the thermodynamic (equilibrium) conditions associated with this base, both the free molecule and its conjugate base are present at the same time. Protic solvents generally favor the equilibrium or thermodynamic conditions because they protonate the base. Some common aprotic solvents are 1,2-dimethoxyethane, THF, and DMF, while protic solvents include water, alcohols, and liquid NH<sub>3</sub>. Phase-transfer catalysis has been used to alkylate many nitriles, as well as some esters and ketones.<sup>1913</sup>

Aldehydes bearing only one  $\alpha$  hydrogen have been alkylated with allylic and benzylic halides in good yields using the base KH to prepare the potassium enolate,<sup>1914</sup> or alkylated in moderate yields by the use of a phase-transfer catalyst.<sup>1915</sup> Even the use of amide bases (such as lithium diisopropylamide, LDA, lithium hexamethyldisilazide, LHMDs, or lithium tetramethylpiperidide, LTMP) to generate the enolate anion in an aprotic solvent (such as ether or THF) cannot completely suppress rapid aldol side reactions, although with modern techniques the side reactions are usually not a problem.

As in **10-67**, the alkyl halide that reacts with the enolate anion may be primary or secondary, while tertiary halides give elimination. If the enolate anion is a strong enough base (e.g., the enolate anion from Me<sub>3</sub>CCOMe), even primary and secondary halides may give predominant elimination,<sup>1916</sup> but this is unusual. If the reaction is performed on a silyl enol

ether (see **128**)<sup>1917</sup> of a ketone, aldehyde, or ester with a Lewis acid catalyst, tertiary alkyl as well as other groups that normally give S<sub>N</sub>1 reactions can be introduced.<sup>1918</sup>

Tertiary alkyl fluorides were coupled to silyl enol ethers with BF<sub>3</sub>•etherate.<sup>1919</sup> Silyl enol ethers can be converted to the enolate anion, which can then be alkylated in the usual manner.<sup>1920</sup> Metal-catalyzed alkylation reactions are known with silyl enol ethers, including an In-catalyzed<sup>1921</sup> reaction. An Ir-catalyzed regioselective and enantioselective alkylation of silyl enol ethers using allylic carbonates as a substrate has been reported.<sup>1922</sup> Enol acetates react with alcohols with a Re-complex catalyst.<sup>1923</sup> Enol ethers react with allylic bromides in water using SnCl<sub>2</sub> and KI.<sup>1924</sup> Enol acetates undergo direct alkylation with an InI<sub>3</sub>/Me<sub>3</sub>SiI catalyst.<sup>1925</sup> Zinc enolates were allylated using an Fe catalyst.<sup>1926</sup> Enol carbonates react with alkylating agents in the presence of a Pd catalyst.<sup>1927</sup>

Efficient enantioselective alkylations are known,<sup>1928</sup> including the use of a chiral base to form the enolate anion.<sup>1929</sup> Alternatively, a chiral auxiliary can be attached. Many auxiliaries are based on the use of chiral amides<sup>1930</sup> or esters.<sup>1931</sup> Subsequent formation of the enolate anion allows alkylation to proceed with high enantioselectivity. A subsequent step is required to convert the chiral amide or ester to the corresponding carboxylic acid. Chiral additives can also be used,<sup>1932</sup> and the influence of chelating ligands and hydrocarbon co-solvents has been studied for LiN(TMS)<sub>2</sub>-mediated enolization reactions.<sup>1933</sup> The addition of triethylamine influences the (*E/Z*) selectivity of the enolate anion.<sup>1934</sup> Dynamic kinetic

resolution has been used for the asymmetric alkylation of malonate derivatives using allenyl acetates.<sup>1935</sup>

When the compound to be alkylated is an unsymmetrical ketone, the question arises as to which side will be alkylated (regioselectivity). Which product is found in higher yield depends on the nature of the substrate, the base,<sup>1936</sup> the cation, and the solvent. In any case, di- and tri-substitution are frequent<sup>1937</sup> and it is often difficult to stop with the introduction of just one alkyl group.<sup>1938</sup> Several methods have been developed for ensuring that alkylation takes place regioselectively on the *desired* side of a ketone.<sup>1939</sup> Among these are the following.

1. Block one side of the ketone by introducing a removable group. Alkylation takes place on the other side and the blocking group is then removed. A common reaction for this purpose is formylation with ethyl formate (**16-82**), which generally blocks the less hindered side. The formyl group is easily removed by alkaline hydrolysis (**12-42**).
2. Introduce an activating group on one side; alkylation then takes place on that side (**10-67**); the activating group is then removed.
3. Reaction with the desired one of the two possible enolate anions.<sup>1940</sup> Of the two ions, for example, there will be a less-substituted enolate anion (the *kinetic enolate*) and a more-substituted enolate anion (the *thermodynamic enolate*). Here these are shown for heptan-2-one:

The two ions are in equilibrium as they are formed by an acid–base reaction. In the presence of the parent ketone or any stronger acid, each enolate anion is reprotonated and then deprotonated again, and the subsequent equilibrium favors the more stable product, the thermodynamic enolate anion.<sup>1941</sup> In the absence of such acids, with an aprotic solvent and a strong base, the dynamic equilibrium is suppressed since the enolate anion does not react with an acid and the kinetic enolate anion predominates.<sup>1942</sup> Therefore, by controlling the base and the solvent it is possible to react with the kinetic enolate or the thermodynamic enolate. One can thus achieve selective alkylation on either side of the ketone.<sup>1941,1943</sup> An alternative approach traps the predominate enolate anion by reaction with acetic anhydride or

trimethylsilyl chloride,<sup>1944</sup> to give the enol acetate or the silyl enol ether.<sup>1945</sup> Such treatment generally gives a mixture of the two enol acetates in which one or the other predominates, depending on the reagent. The mixtures are easily separable<sup>1946</sup> and subsequent treatment of the corresponding enol acetate or the silyl enol ether with 2 equivalents of methyllithium in 1,2-dimethoxyethane regenerates the desired enolate anion. Alkylation of an unsymmetrical ketone at the more substituted position was reported using an alkyl bromide, NaOH, and a calix[*n*]arene catalyst (Sec. 4.H, category 2, for calixarenes).<sup>1947</sup>

Metal-catalyzed alkylations that are related to this reaction are known. Monoalkylation is possible using Pd catalysts,<sup>1948</sup> and Pd-catalyzed asymmetric allylic alkylation is known.<sup>1949</sup>  $\alpha$ -Alkylation of ketones with alcohols uses a Ru catalyst<sup>1950</sup> or Ni nanoparticles.<sup>1951</sup> A recyclable Pd catalyst is available.<sup>1952</sup> Zinc enolate anions have been used in enantioselective Pd-catalyzed alkylation reactions.<sup>1953</sup> An interesting allylic substitution at a tertiary center involves the reaction of tertiary 2-bromonitriles with *i*-PrMgBr and allyl bromide to give the 2-allyl nitrile.<sup>1954</sup>  $\alpha$ -Alkylation of ketones with primary alcohols is possible using polymer-associated nanoparticulate Pd.<sup>1955</sup>

Enolate anions react with allylic acetates with a Pd catalyst.<sup>1956</sup> Both lactones<sup>1957</sup> and lactams are alkylated via the enolate anion.<sup>1958</sup>  $\beta,\gamma$ -Unsaturated carbonyl compounds are generated by reaction of an enolate anion and an alkenyl halide with a Pd catalyst.<sup>1959</sup> Ruthenium catalysts have been used.<sup>1960</sup> The Mo-catalyzed allylic alkylation of cyanoesters was reported to proceed with good enantioselectivity.<sup>1961</sup> The In-catalyzed propargylation of aldehydes has been reported via a  $S_N1$ -type reaction in water.<sup>1962</sup> Aldehydes have been converted to the  $\alpha$ -allyl product via a dual Ir–amine catalyst,<sup>1963</sup> or other  $\alpha$ -alkyl

A decarboxylative alkylation of an  $\alpha$ -allylic unit to a cyclopentanone was reported, proceeding from an  $\alpha$ -allylic ester with a Pd catalyst and a *t*-BuPHOX ligand.<sup>1979</sup> Acetophenone derivatives and aryl iodides react in the presence of excess KO*t*-Bu in DMF to give the  $\alpha$ -aryl derivative.<sup>1980</sup>

Hydrazones and other compounds with C=N bonds can be similarly alkylated.<sup>1929</sup> Both sides of acetone have been alkylated with different alkyl groups, in one operation, by treatment of the *N,N*-dimethylhydrazone of acetone with *n*-BuLi, followed by a primary alkyl, benzylic, or allylic bromide or iodide; then another mole of *n*-BuLi, a second halide, and finally hydrolysis of the hydrazone.<sup>1981</sup> The use of chiral amines or hydrazines,<sup>1982</sup> followed by hydrolysis (16-2) of the alkylated imine, can lead to chiral alkylated ketones in high optical yields<sup>1983</sup> (for an example, see Sec. 4.J). Lithiated imines are generated by the treatment of an imine with a suitable base, and reaction with an alkyl halide gives the alkylated imine.<sup>1984</sup>  $\alpha$ -Magnesio imines also react with alkyl halides.<sup>1985</sup> Imine alkylation can also be applied to the preparation of substituted amine derivatives. This reaction has also been done in the ionic liquid Bmim tetrafluoroborate (Sec. 9.D.iii).<sup>1986</sup>

In  $\alpha,\beta$ -unsaturated ketones, nitriles, and esters (e.g., **129**), the  $\gamma$  hydrogen assumes the acidity normally held by the position  $\alpha$  to the carbonyl group, especially when R is not hydrogen and so cannot compete. This principle, called *vinyllogy* (Sec. 6.B), operates because the resonance effect is transmitted through the double bond. However, because of the resonance, alkylation at the  $\alpha$  position (with allylic rearrangement) competes with alkylation at the  $\gamma$  position and usually predominates.

$\alpha$ -Hydroxynitriles (cyanohydrins), protected by conversion to acetals<sup>1987</sup> with ethyl vinyl ether (**15-5**), can be easily alkylated with primary or secondary alkyl or allylic

halides.<sup>1988</sup> The R group can be aryl or a saturated or unsaturated alkyl and the product is easily hydrolyzed to a ketone,<sup>1989</sup> so this is a method for converting an aldehyde RCHO to a ketone RCOR'.<sup>1990</sup> In this procedure the normal mode of reaction of a carbonyl carbon is reversed. The C atom of an aldehyde molecule is normally electrophilic and is attacked by nucleophiles (Chapter 16), but by conversion to the protected cyanohydrin this carbon atom has been induced to perform as a nucleophile.<sup>1991</sup> The German word *Umpolung*<sup>1992</sup> is used to describe this kind of reversal (another example is found in **10-71**). This method fails for formaldehyde (R = H), but other masked formaldehydes have proved successful.<sup>1993</sup>

Carboxylic acids were first converted to silyl ketene acetals. Subsequent reaction with aryl triflates in the presence of a Pd catalyst, followed by treatment with trifluoroacetic acid, gave the corresponding  $\alpha$ -aryl carboxylic acid.<sup>1994</sup>

### 10-69 The Stork Enamine Reaction<sup>1995</sup>

When enamines are treated with alkyl halides, an alkylation occurs to give an iminium salt via electron transfer from the electron pair on nitrogen, through the C=C to the electrophilic carbon of the alkyl halide.<sup>1996</sup> In effect, an enamine behaves as a “nitrogen enolate anion” and generally reacts as a carbon nucleophile.<sup>1997</sup> Hydrolysis of the iminium salt gives a ketone. Since the enamine is normally formed from a ketone (**16-12**), the net result is alkylation of the ketone at the  $\alpha$  position. Known as the *Stork enamine reaction*,<sup>1998</sup> this method is an alternative to the ketone alkylation described in **10-68**, and generally gives monoalkylation of the ketone. Alkylation usually takes place on the less-substituted side of the original

ketone. The most commonly used amines are the cyclic amines piperidine, morpholine, and pyrrolidine. There are metal-catalyzed enamine alkylation reactions, including the use of Ir catalysts.<sup>1999</sup> The Pd-catalyzed reaction of  $\beta$ -enaminines, with microwave irradiation, led to the allyl product.<sup>2000</sup> Enamides have been coupled to alkenes in the presence of  $\text{Cu}(\text{OAc})_2$  and  $\text{Pd}(\text{OAc})_2$  catalysts, in the presence of oxygen, to give the corresponding dienamide product.<sup>2001</sup>

The method is not used as much nowadays, but it has proven to be useful for particularly active alkyl halides, such as allylic, benzylic, and propargylic halides, and for  $\alpha$ -halo ethers and esters. Other primary and secondary halides can show sluggish reactivity. Tertiary halides do not give the reaction at all and elimination predominates. The reaction can also be applied to activated aryl halides (e.g., 2,4-dinitrochlorobenzene; see Chapter 13), to epoxides,<sup>2002</sup> and to activated alkenes, such as acrylonitrile. The latter is a *Michael-type reaction* (**15-20**) with respect to the alkene. Enamines react with carboxylic acids in a PhIO-mediated reaction to give the  $\beta$ -acyloxy enamine, which undergoes a cyclodehydration reaction to give an oxazole.<sup>2003</sup> Acylation<sup>2004</sup> can be accomplished by reaction with acyl halides or with anhydrides. Hydrolysis of the resulting iminium salt leads to a 1,3-diketone. The acylation of the enamine can take place by the same mechanism as alkylation.

*N*-Alkylation can be a problem, particularly with enamines derived from aldehydes. An alternative method, which gives good yields of alkylation with primary and secondary halides, is alkylation of enamine *salts*, which are prepared by treating an imine with ethylmagnesium bromide in THF.<sup>2005</sup> The enamine salt method has also been used to give good yields of mono  $\alpha$  alkylation of  $\alpha,\beta$ -unsaturated ketones.<sup>2006</sup> Enamines prepared from aldehydes and butylisobutylamine can be alkylated by simple primary alkyl halides in good yields.<sup>2007</sup> *N*-Alkylation in this case is presumably prevented by steric hindrance.

When the nitrogen of the substrate contains a chiral R group, both the Stork enamine synthesis and the enamine salt method can be used to perform enantioselective syntheses.<sup>2008</sup> The use of *S*-proline can generate a chiral enamine *in situ*, thus allowing alkylation to occur, giving the alkylated product with good enantioselectivity. It is noted that reactions are catalyzed by enamines, including asymmetric reactions.<sup>2009</sup> The reaction has been done intramolecularly.<sup>2010</sup> Conjugate addition (*Michael addition*) occurs when enamines react with conjugated ketones. This reaction is discussed in **15-20**.

## 10-70 Alkylation of Carboxylic Acid Salts

Carboxylic acids can be alkylated in the  $\alpha$  position by conversion of their salts to dianions (which have resonance contributors<sup>2011</sup>) by treatment with a strong base such as LDA.<sup>2012</sup> The use of  $\text{Li}^+$  as the counterion increases the solubility of the dianionic salt. The reaction has been applied<sup>2013</sup> to primary alkyl, allylic, and benzylic halides, and to carboxylic acids of the form  $\text{RCH}_2\text{CO}_2\text{H}$  and  $\text{RR}^2\text{CHCO}_2\text{H}$ .<sup>1896</sup> This procedure is an alternative to the malonic ester synthesis (**10-67**) as a means of preparing carboxylic acids and has the advantage that acids of the form  $\text{RR}'\text{R}^2\text{CCO}_2\text{H}$  can also be prepared. In a related reaction, methylated aromatic acids can be alkylated at the methyl group by a similar procedure,<sup>2014</sup> thus 2-methylbenzoic acid was treated with LDA and then an alkyl halide to give the 2-alkylbenzoate anion.

OS V, 526; VI, 517; VII, 249. See also OS VII, 164.

10-71 Alkylation at a Position  $\alpha$  to a Heteroatom

The presence of a sulfur atom on a carbon enhances the acidity of a proton on that carbon, and in dithioacetals and dithioketals that proton ( $\text{RSCH}_2\text{SR}$ ) is even more acidic. 1,3-Dithianes can be alkylated<sup>2015</sup> if a proton is removed by treatment with butyllithium in THF in a reaction that is quite slow at  $-78^\circ\text{C}$ .<sup>2016</sup> Since 1,3-dithianes can be prepared by treatment of an aldehyde or its acetal (see OS VI, 556) with 1,3-propanedithiol (**16-10**) and can be hydrolyzed (**10-7**), this is a method for the conversion of an aldehyde to a ketone<sup>2017</sup> (see also **10-68** and **18-9**).

The formation and reactivity of the dithiane anion makes the anion an “acyl anion equivalent,” and constitutes an Umpolung.

If a stabilizing group other than sulfur is attached to the S—CH<sub>2</sub> unit of a thioether (RSCH<sub>2</sub>X, where X is a stabilizing group), formation of the anion and alkylation is more efficient. For example, benzylic and allylic thioethers (RSCH<sub>2</sub>Ar and RSCH<sub>2</sub>CH=CH<sub>2</sub>)<sup>2018</sup> and thioethers of the form RSCH<sub>3</sub> (R = tetrahydrofuranyl or 2-tetrahydropyranyl)<sup>2019</sup> have been successfully alkylated at the carbon adjacent to the sulfur atom.<sup>2020</sup> Stabilization by one thioether group has also been used in a method for the homologation of primary halides.<sup>2021</sup>

Vinyl sulfides containing an  $\alpha$  hydrogen can also be alkylated<sup>2022</sup> by alkyl halides or epoxides. This is a method for converting an alkyl halide RX to an  $\alpha,\beta$ -unsaturated aldehyde, which is the synthetic equivalent of the unknown  $\text{HC}=\text{CH}-\text{CHO}$  ion; another Umpolung.<sup>2023</sup> Even simple alkyl aryl sulfides RCH<sub>2</sub>SAr and RR'CHSAr have been alkylated  $\alpha$  to the sulfur.<sup>2024</sup> Sulfones<sup>2025</sup> and sulfonic esters can also be alkylated in the  $\alpha$  position if strong enough bases are used.<sup>2026</sup> Sulfones and sulfonamides have been  $\alpha$ -arylated using a Pd catalyst.<sup>2027</sup> Alkylation at the  $\alpha$  position of selenoxides allows the formation of alkenes, since selenoxides easily undergo elimination (**17-10**).<sup>2028</sup>

Alkylation can also be carried out, in certain compounds, at positions  $\alpha$  to other heteroatoms,<sup>2029</sup> for example, at a position  $\alpha$  to the nitrogen of tertiary amines.<sup>2030</sup> Alkylation  $\alpha$  to the nitrogen of primary or secondary amines is not generally feasible because an NH hydrogen is usually more acidic than a CH hydrogen.  $\alpha$ -Lithiation of *N*-Boc amines has been accomplished and these react with halides in the presence of a Pd catalyst.<sup>2031</sup> Alkylation  $\alpha$  to the nitrogen atom of a carbamate occurs when the carbamate is treated with a Grignard reagent under electrolysis conditions.<sup>2032</sup>  $\alpha$ -Methoxy amides also react with allyl halides and zinc metal to give alkylation via replacement of the OMe unit.<sup>2033</sup> It has been accomplished, however, by replacing the NH hydrogens with other (removable) groups.<sup>2034</sup> In one example, a secondary amine is converted to its *N*-nitroso derivative

(**12-49**).<sup>2035</sup> The *N*-nitroso product is easily hydrolyzed to the product amine (**19-55**).<sup>2036</sup> Alkylation of secondary and primary amines has also been accomplished with > 10 other protecting groups, involving conversion of amines to amides, carbamates,<sup>2037</sup> formamidines,<sup>2038</sup> and phosphoramides.<sup>2033</sup> In the case of formamidines (R–N–C=N–R), use of a chiral R' leads to a chiral amine, in high enantiomeric excess, even when R is not chiral.<sup>2039</sup>

A proton can be removed from an allylic ether by treatment with an alkyl lithium at about –70 °C (at higher temperatures the Wittig rearrangement, **18-22**, takes place) to give the alkoxy allylic ion, which reacts with alkyl halides. The  $\alpha$ -arylation of cyclic ethers has been reported using 2 equivalents of a persulfate salt, an Ir complex photocatalyst, and TFA,<sup>2040</sup> to give the two products shown in the equation:<sup>2041</sup>

Similar reactions<sup>2042</sup> have been reported for allylic<sup>2043</sup> and vinylic tertiary amines.<sup>2044</sup>

*N*-Aryltetrahydroisoquinolines react with a variety of nucleophiles, including allyl tin reagents, nitromethane, cyanide, etc., with excess acetic acid, and exposure to oxygen gave the  $\alpha$ -substituted amine.<sup>2045</sup> Amines have been converted to  $\alpha$ -alkyl amines using a copper(I) carboxylate catalyst.<sup>2046</sup>

Benzylic phosphonates react with aryl bromides with excess NaOt-Bu with a Pd(OAc)<sub>2</sub>/CataCium A-based catalyst (a water-soluble organophosphorus compound derived from fluorene) to give the  $\alpha$ -aryl phosphonate.<sup>2047</sup> Phosphonates and phosphine oxides have been converted to the  $\alpha$ -amine derivative using a Cu catalyst.<sup>2048</sup> The Umpolung chemistry of boron and phosphorus has been reviewed.<sup>2049</sup>

## 10-72 Alkylation of Dihydro-1,3-Oxazine: The Meyers Synthesis

A synthesis of aldehydes<sup>2050</sup> developed by Meyers and co-workers<sup>2051</sup> begins with the commercially available dihydro-1,3-oxazine derivatives **130** (A = H, Ph, or COOEt).<sup>2052</sup> Removal of a proton from the pendant carbon in **130** leads to the resonance-stabilized and bidentate anion **131**. Alkylation occurs regioselectively at carbon using many alkyl bromides and iodides. The R group of RX can be primary or secondary alkyl, allylic, or benzylic and can carry another halogen or a CN group.<sup>2053</sup> The alkylated oxazine **132** is then reduced and hydrolyzed to give an aldehyde containing two more carbons than the starting RX. This method thus complements **10-71**, which converts RX to an aldehyde containing one more carbon. Since A can be H, mono- or disubstituted acetaldehydes can be produced by this method.

The ion **131** also reacts with epoxides, to form  $\gamma$ -hydroxy aldehydes after reduction and hydrolysis,<sup>2054</sup> and reacts with aldehydes and ketones (**16-38**). Similar aldehyde synthesis has also been carried out with thiazoles<sup>2055</sup> and thiazolines<sup>2056</sup> (five-membered rings containing N and S in the 1 and 3 positions).

The reaction has been extended to the preparation of ketones:<sup>2057</sup> Treatment of a dihydro-1,3-oxazine (**133**) with iodomethane forms the iminium salt which, when treated with a Grignard reagent or organolithium compound, produces **134**. Hydrolysis gives a ketone.

<sup>2050</sup> Larock, R.C. *Comprehensive Organic Transformations*, 2nd ed., Wiley-VCH, NY, **1999**, pp. 1461–1465.

<sup>2051</sup> Meyers, A.I.; Nabeya, A.; Adickes, H.W.; Politzer, I.R.; Malone, G.R.; Kovelesky, A.C.; Nolen, R.L.; Portnoy, R.C. *J. Org. Chem.* **1973**, *38*, 36.

<sup>2052</sup> See Schmidt, R.R. *Synthesis* **1972**, 333; Collington, E.W. *Chem. Ind. (London)* **1973**, 987.

<sup>2053</sup> Meyers, A.I.; Malone, G.R.; Adickes, H.W. *Tetrahedron Lett.* **1970**, 3715.

<sup>2054</sup> Adickes, H.W.; Politzer, I.R.; Meyers, A.I. *J. Am. Chem. Soc.* **1969**, *91*, 2155.

<sup>2055</sup> Altman, L.J.; Richheimer, S.L. *Tetrahedron Lett.* **1971**, 4709.

<sup>2056</sup> Meyers, A.I.; Durandetta, J.L. *J. Org. Chem.* **1975**, *40*, 2021.

<sup>2057</sup> Meyers, A.I.; Smith, E.M. *J. Org. Chem.* **1972**, *37*, 4289.

Note that the heterocycles **130**, **133**, and **135** do not react directly with Grignard reagents. In another procedure, 2-oxazolines<sup>2058</sup> (e.g., **135**) can be alkylated to give **136**,<sup>2059</sup> which are easily converted directly to the esters by heating in 5–7% ethanolic sulfuric acid.

By this reaction, 2-oxazolines **135** and **136** are synthons for carboxylic acids; this is another indirect method for the  $\alpha$ -alkylation of a carboxylic acid.<sup>2060</sup> The method can be adapted to the preparation of optically active carboxylic acids by the use of a chiral reagent.<sup>2061</sup> Note that **135** can be alkylated even if R is alkyl. However, the C=N bond of **135** and **136** cannot be effectively reduced, so that aldehyde synthesis is not feasible here.<sup>2062</sup>

OS VI, 905.

### 10-73 Alkylation With Boranes, Boronic Acids, and Boronates

The alkylation of activated halogen compounds is one of several reactions of trialkylboranes developed by H.C. Brown<sup>2063</sup> (see also **15-11**, **15-23**, **18-23**, **18-24**, and **18-25**). Trialkylboranes react rapidly and in high yields with  $\alpha$ -halo ketones,<sup>2064</sup>  $\alpha$ -halo esters sulfonyl derivatives (sulfones, sulfonic esters, sulfonamides)<sup>2065</sup> react with boranes in the presence of a base to give, respectively, alkylated ketones, esters, and sulfonyl derivatives.<sup>2066</sup> Potassium *tert*-butoxide is often a suitable base, but potassium 2,6-di-*tert*-butylphenoxide at 0 °C in THF gives better results in most cases, possibly because the large bulk of the two *tert*-butyl groups prevents the base from coordinating with the R<sub>3</sub>B.<sup>2067</sup> With appropriate boranes, the

R group transferred to  $\alpha$ -halo ketones, nitriles, and esters can be vinylic,<sup>2068</sup> or (for  $\alpha$ -halo ketones and esters) aryl.<sup>2069</sup> Allylic boranes reacted with allylic chlorides, with a Pd catalyst, to give the corresponding 1,5-diene.<sup>2070</sup> Trialkylboranes reacted with allylic chlorides with a Cu catalyst and in the presence of KOMe to give the cross-coupling product with displacement of the pinanylborane unit.<sup>2071</sup>

The reaction can be extended to  $\alpha,\alpha$ -dihalo esters<sup>2072</sup> and  $\alpha,\alpha$ -dihalo nitriles.<sup>2073</sup> It is possible to replace just one halogen or both. In the latter case, the two alkyl groups can be the same or different. When dialkylation is applied to dihalo nitriles, the two alkyl groups can be primary or secondary, but with dihalo esters, dialkylation is limited to primary R.

Another extension is the reaction of boranes ( $\text{BR}_3$ ) with  $\gamma$ -halo- $\alpha,\beta$ -unsaturated esters.<sup>2074</sup> Alkylation takes place in the  $\gamma$  position, but the double bond migrates out of conjugation with the  $\text{CO}_2\text{Et}$  unit.<sup>2075</sup> The mechanism is not known with certainty,<sup>2076</sup> but the first step is probably removal of the acidic proton by the base to give an enolate anion that combines with the borane (Lewis acid–base reaction). An R group then migrates, displacing the halogen leaving group.<sup>2077</sup> Another migration follows, this time of  $\text{BR}_2$  from carbon to oxygen to give the enol borinate,<sup>2078</sup> which is hydrolyzed. Configuration at the alkyl group R is retained.<sup>2079</sup>

Alkylboranes are coupled to alkyl halides in the presence of a Ni catalyst.<sup>2080</sup> Note that alkylboronic acids are coupled in the presence of  $\text{Ag}_2\text{O}$  and a catalytic amount of  $\text{CrCl}_2$  to give the symmetrical alkyl derivative.<sup>2081</sup> The Pd-catalyzed coupling of allylB(pin) with allylic electrophiles as been reported.<sup>2082</sup> Allylic chlorides reacted with 1,1-diborylalkanes, with a Cu catalyst, to give alkylboronates.<sup>2083</sup> Organoboranes also react with diazo compounds to give the corresponding ketone.<sup>2084</sup> The reaction of vinylmagnesium chloride with R-B(pin) in the presence of a catalytic amount of Pd and NaOTf gave chiral nonracemic chiral organoboronic esters.<sup>2085</sup>

Alkenylboranes ( $\text{R}'_2\text{C}=\text{CHBZ}_2$ ; Z = various groups) couple in high yields with vinylic,<sup>2086</sup> alkynyl, aryl, benzylic, and allylic halides or triflates in the presence of a Pd catalyst and a base to give  $\text{R}'_2\text{C}=\text{CHR}$ .<sup>2087</sup> 9-Alkyl-9-BBN compounds (**15-11**) also

couple with vinylic and aryl halides<sup>2088</sup> as well as with  $\alpha$ -halo ketones, nitriles, and esters.<sup>2089</sup>

The reaction has also been applied to compounds with other leaving groups. Diazo ketones, diazo esters, diazo nitriles, and diazo aldehydes<sup>2090</sup> react with trialkylboranes in a similar manner. The mechanism is probably similar. In this case a base is not needed since the carbon already has an available pair of electrons. The reaction with diazo aldehydes<sup>2091</sup> is especially notable, since successful reactions cannot be obtained with  $\alpha$ -halo aldehydes.<sup>2092</sup>

Boranes

Boronic acids

Boronates

Boronic acids also react with benzylic ammonium triflates to give the coupling product.<sup>2093</sup> Alkyl<sup>2094</sup> and aryl<sup>2095</sup> boronic acids  $[\text{RB}(\text{OH})_2]$  react with allylic acetates to give the alkylated product in the presence of a Pd catalyst.<sup>2096</sup> A cyclopropylboronic acid was coupled to an allylic bromide with silver oxide/KOH and a Pd catalyst.<sup>2097</sup> Alkylboronic acids can also be coupled to aromatic compounds in the presence of  $\text{Cu}(\text{OAc})_2$  and a Pd catalyst.<sup>2098</sup> The Pd-catalyzed coupling of vinyl halides and alkylboronic acids<sup>2099</sup> gives substituted alkenes and is related to the *Suzuki-Miyara coupling* (13-11).

The Ni-catalyzed cross-coupling between boronic acids and redox-active esters has been reported.<sup>2100</sup> The reaction of styryl epoxides with arylboronic acids using a Ni catalyst complexed with a biaryldialkyl monophosphine ligand opens the epoxide to give the 1,2-diarylethanol derivative.<sup>2101</sup> Cyclopropylboronic esters react with aromatic and aliphatic secondary acyclic amides, in the presence of  $\text{Cu}(\text{OAc})_2$ ,  $\text{Cs}_2\text{CO}_3$ , with excess pyridine, and when heated in the presence of dry air.<sup>2102</sup> Secondary alcohols react with alkyl boronic esters in the presence of *in situ* generated *N*-heterocyclic carbene–Ni catalysts to generate

a variety of tertiary alcohols.<sup>2103</sup> The CuBr-catalyzed coupling of amides and alkylboronic acids using the mild base NaOSiMe<sub>3</sub> and di-*tert*-butyl peroxide gives *N*-alkyl amides.<sup>2104</sup> The Cu-catalyzed *N*-arylation of lactams with arylboronic acids occurs under base and ligand-free conditions.<sup>2105</sup> bis-Aryl maleimides have been prepared using maleimide and arylboronic acids using a Pd catalyst.<sup>2106</sup> Arylboronic acids undergo a coupling reaction with epoxides in the presence of a Pd catalyst.<sup>2107</sup> Allylic alcohols can be coupled with arylboronic acids in an ionic liquid solvent and a Rh catalyst.<sup>2108</sup>

It has been reported that BrCH<sub>2</sub>Li reacts in poor yield with *tert*-alkylboronic esters due to the *O*-migratory propensity of the alkyl unit on boron, but reacted with alkyl boronic esters to give a good yield of the corresponding alcohol. The conversion of **137** to **138** in 73% yield is one example.<sup>2109</sup>

Boronic esters reacted with acyltrimethylsilanes, photochemically, to give the B–C bond insertion product, which was hydrolyzed with 1 M HCl in air to give the corresponding ketone.<sup>2110</sup> Phenols react with vinyl boronates and a Cu catalyst to give aryl vinyl ethers.<sup>2111</sup> Epoxides and also *N*-tosyl aziridines (**10-66**) react with alkylboronates and with a Cu catalyst to give the ring-opened alcohol (or amine).<sup>2112</sup> Arylation of *sp*<sup>3</sup> C–H positions can be done using arylboronates and a Rh catalyst.<sup>2113</sup>

Potassium alkyl, aryl, and 1-alkenyltrifluoroborates (RBF<sub>3</sub>K, ArBF<sub>3</sub>K, and RBF<sub>3</sub>K) are easily prepared from organoboronic acids or esters. In general, the trifluoroborates have greater air stability and greater nucleophilicity<sup>2114</sup> when compared to the corresponding organoboranes and organoboronic acid derivatives. Potassium alkyltrifluoroborates undergo the Pd-catalyzed coupling reaction with arenediazonium tetrafluoroborates,<sup>2115</sup> diaryliodonium salts,<sup>2116</sup> aryl halides,<sup>2117</sup> as well as with aryl triflates. An example of the latter reaction converted potassium benzyltrifluoroborate, **139**, to diphenylmethane via coupling with phenyl triflate.<sup>2118</sup> Alkenyltrifluoroborates can be

coupled to aryl halides.<sup>2119</sup> Potassium alkynyltrifluoroborates have been coupled to 2-chloroacetates or 2-chloroacetamides using a Pd catalyst.<sup>2120</sup> Trifluoroborates are methylated in reactions catalyzed by a Ru catalyst.<sup>2121</sup> Potassium alkyltrifluoroborates such as **139** undergo C–H alkylation in the presence of MnF<sub>3</sub> and a Pd(OAc)<sub>3</sub> catalyst.<sup>2122</sup> Note that dppf = diphenylphosphinoferrocene.

OS VI, 919; IX, 107.

### 10-74 Alkylation at an Alkynyl Carbon

The reaction between alkyl halides and acetylide ions is useful but of limited scope.<sup>2123</sup> Only primary halides unbranched in the β position give good yields, although allylic halides can be used if CuI is present.<sup>2124</sup> If acetylene is the reagent, two different groups can be successively attached. Sulfates, sulfonates, and epoxides<sup>2125</sup> are sometimes used as substrates. The acetylide ion is often prepared by treatment of an alkyne with a strong base such as NaNH<sub>2</sub>. Magnesium acetylides (prepared as in **12-22**) are also frequently used, although they react only with active substrates, such as allylic, benzylic, and propargylic halides, and not with primary alkyl halides. Alternatively, the alkyl halide can be treated with a lithium acetylide–ethylenediamine complex.<sup>2126</sup> If 2 equivalents of a very strong base are used, alkylation can be effected at a carbon α to a terminal triple bond.<sup>2127</sup>

For another method of alkylating at an alkynyl carbon, see **18-26**. As an alternative method for generating an alkyne anion, a trialkylsilyl alkyne was treated with potassium carbonate in methanol, and then MeLi/LiBr.<sup>2128</sup> In the presence of an alkyl iodide, alkylation at the alkynyl carbon occurred.

Catalytic asymmetric propargylation has been reviewed.<sup>2129</sup> The chemistry of alkynyl copper compounds has been reviewed.<sup>2130</sup> Terminal alkynes react with alkylzinc reagents

### 10-75 Ring Opening of Cyclopropane Derivatives

Cyclopropanes with ketone, diester, or dinitrile substituents are ring opened and converted to 1,3-dichlorides upon treatment with  $PhICl_2$  (iodobenzenedichloride).<sup>2161</sup> Dicarboalkoxycyclopropanes react with thiols in the presence of  $Ca(acac)_2$  or proline to give the  $\gamma$ -thioalkyl derivative.<sup>2162</sup> Similar cyclopropanes are ring opened and isomerized to (2-arylalkylidene)malonates in the presence of  $GaCl_3$ .<sup>2163</sup>

Functionalized cyclic  $\beta$ -enamino esters have been formed by the reaction of 1,1-carbomethoxycyclopropanes with malonitrile derivatives, in the presence of  $NaH$  and a  $Yb(OTf)_3$  catalyst.<sup>2164</sup> Similarly substituted cyclopropane derivatives react with  $RSX$  or  $RSeX$  to give the  $\alpha$ -thioalkyl or  $\alpha$ -selenoalkyl  $\gamma$ -halo diester.<sup>2165</sup> 2,2-difluorocyclopropyl ketones were opened by reaction with Lewis acids such as  $BX_3$  to give  $\beta$ - $CF_2X$  ketones.<sup>2166</sup> Bicyclic nitrocyclopropanes reacted with zinc powder under acidic conditions to give

double cleavage of C—C bonds in the cyclopropane to give a vinyl nitrile.<sup>2167</sup> The ring opening and isomerization reaction of cyclopropane derivatives catalyzed by B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub> has been reported to give the corresponding alkene.<sup>2168</sup>

The synthetic applications of vinylcyclopropane ring opening have been reviewed.<sup>2169</sup> The 1,5 addition of alcohols to dimethyl 2-vinylcyclopropane-1,1-dicarboxylate, catalyzed by Lewis acids [Sn(OTf)<sub>2</sub>, GaCl<sub>3</sub>, Sc(OTf)<sub>3</sub>, and Al(OTf)<sub>3</sub>] gave methyl 4-alkoxy-2-methoxycarbonyl-5-hexenoates.<sup>2170</sup> Cyclopropene derivatives react with a Ag<sup>+</sup> catalyst in the presence of amines to give the allylic amine.<sup>2171</sup> Vinylidene cyclopropanes reacted with secondary amines to give the corresponding α,β-unsaturated amide.<sup>2172</sup>

Cyclopropanol reacted with 1-bromoalkynes to give alk-4-yn-1-ones upon treatment with Et<sub>2</sub>Zn and CuCN•2LiCl.<sup>2173</sup> Cyclopropanol derivatives reacted with alkynyl iodonium compounds in the presence of AgNO<sub>3</sub> and K<sub>2</sub>S<sub>2</sub>O<sub>8</sub> to give β-alkynyl ketones.<sup>2174</sup> Cyclopropyl derivatives also reacted with trifluoromethyl iodonium compounds with LiCl and a CuCl catalyst to give β-trifluoromethyl ketones.<sup>2175</sup>

## 10-76 Preparation of Nitriles

The reaction between cyanide ion and alkyl halides is a convenient method for the preparation of nitriles.<sup>2176</sup> The reaction proceeds by an S<sub>N</sub>2 mechanism,<sup>2177</sup> so primary, benzylic, and allylic halides give good yields of nitriles; secondary halides give moderate yields. The reaction fails for tertiary halides, which give elimination under these conditions. Many other groups on the molecule do not interfere. A number of solvents have been used, but the high yields and short reaction times observed with DMSO make it a very good solvent for this reaction.<sup>2178</sup> In general, polar aprotic solvents are the best choice. Other ways to obtain high yields under mild conditions are to use a phase-transfer catalyst<sup>2179</sup> in alternative solvents, such as PEG 400 (a polyethylene glycol),<sup>2180</sup> or with ultrasound.<sup>2181</sup> This is

an important way of increasing the length of a carbon chain by one carbon, since nitriles are easily hydrolyzed to carboxylic acids (**16-4**). Substrates that react with cyanide may contain leaving groups other than halides, such as esters of sulfuric and sulfonic acids (sulfates and sulfonates, respectively). Vinylic triflates give vinylic cyanides when treated with LiCN, a crown ether, and a palladium catalyst.<sup>2182</sup> Vinylic bromides can be converted to vinylic cyanides with CuCN,<sup>2183</sup> with KCN, a crown ether, and a Pd complex,<sup>2184</sup> or with KCN and a Ni(0) catalyst.<sup>2185</sup>

The cyanide ion is an ambident nucleophile (it can react via N or via C) and isonitriles (also called isocyanides, R–N≡C) may be side products.<sup>2186</sup> If the preparation of isocyanides is desired (see **10-39**), they can be made the main products by the use of reagents with more covalent metal–carbon bonds, such as AgCN or CuCN<sup>2187</sup> (Sec. 10.G.vii, category 3). However, the use on an excess of LiCN in acetone/THF gave the nitrile as the major product.<sup>2188</sup> Tosyl cyanide (TolSO<sub>2</sub>CN) has been used in some cases.<sup>2189</sup> A radical cyanation of alkyl iodides has been reported using diethylphosphoryl cyanide<sup>2190</sup> (see Chapter 14). Halides can be converted to the corresponding nitriles by treatment with trimethylsilyl cyanide in the presence of catalytic amounts of SnCl<sub>4</sub>.<sup>2191</sup>

Alkyl nitriles were generated by the reaction of alkyl chlorides with tetrabutylammonium cyanide under photolytic conditions, using a CuI catalyst.<sup>2192</sup> Benzylic chlorides reacted with K<sub>4</sub>[Fe(CN)<sub>6</sub>] with a Pd catalyst to give benzyl nitriles.<sup>2193</sup> Allylic compounds were converted to the corresponding nitrile by reaction with Me<sub>3</sub>SiCN and a Cu catalyst.<sup>2194</sup> Primary halides have been converted to nitriles via a Pd-catalyzed reaction with NaN<sub>3</sub>.<sup>2195</sup> Benzonitriles have been formed from aryl iodides using DMF and ammonium carbonate, with a Cu catalyst.<sup>2196</sup> Styrene was converted to benzonitrile by reaction with NBS and Cu-promoted reaction via C=C double bond cleavage.<sup>2197</sup>

### 10-77 Direct Conversion of Alkyl Halides to Aldehydes and Ketones

The direct conversion of alkyl bromides to aldehydes, with an increase in the chain length by one carbon, can be accomplished<sup>2219</sup> by treatment with sodium tetracarbonylferrate(−2)<sup>2220</sup> (*Collman's reagent*) in the presence of triphenylphosphine and subsequent quenching of  $\text{RCOFe}(\text{CO})_3\text{PPh}_3$  with acetic acid. The reagent  $\text{Na}_2\text{Fe}(\text{CO})_4$  can be prepared by treatment of iron pentacarbonyl,  $\text{Fe}(\text{CO})_5$ , with sodium amalgam in THF. Good yields are obtained from primary alkyl bromides; secondary bromides give lower yields. The reaction is generally not satisfactory for benzylic bromides, but a good yield of the ketone was obtained using benzyl chloride and aryl iodides.<sup>2221</sup> The initial species produced from RX and  $\text{Na}_2\text{Fe}(\text{CO})_4$  is the ion  $\text{RFe}(\text{CO})_4^-$  (which can be isolated<sup>2222</sup>); it then reacts with  $\text{Ph}_3\text{P}$  to give  $\text{RCOFe}(\text{CO})_3\text{PPh}_3$ .<sup>2223</sup>

The synthesis can be extended to the preparation of ketones in six distinct ways.<sup>2224</sup> These include: (i) quenching  $\text{RCOFe}(\text{CO})_3\text{PPh}_3$  with a second alkyl halide (R'X) rather than acetic acid; (ii) omitting  $\text{PPh}_3$  with first RX and then adding the second R'X; (iii) treatment with RX in the presence of CO,<sup>2220</sup> followed by treatment with R'X'; (iv) treatment with an acyl halide followed by treatment with an alkyl halide or an epoxide, which gives an  $\alpha,\beta$ -unsaturated ketone.<sup>2225</sup> The final variations involve reaction of alkyl halides or tosylates with  $\text{Na}_2\text{Fe}(\text{CO})_4$  in the presence of ethylene to give alkyl ethyl ketones;<sup>2226</sup> when 1,4-dihalides are used, five-membered cyclic ketones are prepared.<sup>2227</sup> Electrolysis conditions with the alkyl chloride,  $\text{Fe}(\text{CO})_5$ , and a Ni catalyst gives the ketone directly, in one step.<sup>2228</sup>

Symmetrical ketones  $R_2CO$  can be prepared by treatment of a primary alkyl or benzylic halide with  $Fe(CO)_5$  and a phase-transfer catalyst,<sup>2229</sup> or can be prepared from a halide  $RX$  ( $R$  = primary alkyl, aryl, allylic, or benzylic) and  $CO$  by an electrochemical method involving a Ni complex.<sup>2230</sup> Aryl, benzylic, vinylic, and allylic halides have been converted to aldehydes by treatment with  $CO$  and  $Bu_3SnH$ , with a Pd catalyst.<sup>2231</sup> Various other groups do not interfere. Vinylic halides reacted with vinylic tin reagents in the presence of  $CO$  to give unsymmetrical divinyl ketones.<sup>2232</sup> In addition,  $SmI_2$  can be used to convert alkyl chlorides to ketones, in the presence of 50 atm of  $CO$ .<sup>2233</sup>

Other acyl organometallic reagents are known. An acyl zirconium reagent, such as  $RCOZr(Cl)Cp_2$ , reacted with allylic bromide in the presence of  $CuI$  to give the corresponding ketone, but with allylic rearrangement.<sup>2234</sup> The reaction of benzoyl chloride and alkyl iodides with a Ni catalyst, 3 equivalents of Zn, and 1.5 equivalents of  $MgCl_2$  gave the corresponding phenyl alkyl ketone.<sup>2235</sup>

A method for the conversion of halides to acid derivatives has been reported that also makes use of  $Na_2Fe(CO)_4$ . Treatment of  $RFe(CO)_4^-$  or  $RCOFe(CO)_4^-$  with oxygen or sodium hypochlorite gives, after hydrolysis, a carboxylic acid.<sup>2236</sup> Alternatively,  $RFe(CO)_4^-$  or  $RCOFe(CO)_4^-$  reacts with a halogen (e.g.,  $I_2$ ) in the presence of an alcohol to give a carboxylic ester,<sup>2236</sup> or in the presence of a secondary amine or water to give, respectively, the corresponding amide or free acid. Carboxylic esters  $RCO_2R'$  have also been prepared by treating primary alkyl halides  $RX$  with alkoxides  $R'O^-$  in the presence of  $Fe(CO)_5$ .<sup>2237</sup>  $RCOFe(CO)_4^-$  is presumably an intermediate.

OS VI, 807.

## 10-78 Carbonylation of Alkyl Halides, Alcohols, Amines, or Alkanes

A direct method for preparing a carboxylic acid treats an alkyl halide with  $NaNO_2$  in acetic acid and DMSO.<sup>2238</sup> Reaction of an alkyl halide with  $ClCOCO_2Me$  and  $(Bu_3Sn)_2$  under photochemical conditions leads to the corresponding methyl ester.<sup>2239</sup>

Several methods, all based on carbon monoxide or metal carbonyls, have been developed for converting an alkyl halide to a carboxylic acid or an acid derivative with the chain

extended by one carbon.<sup>2240</sup> When an alkyl halide is treated with  $\text{SbCl}_5\text{-SO}_2$  at  $-70^\circ\text{C}$ , it dissociates into the corresponding carbocation (Sec. 5.A.ii), and if CO and an alcohol are present, a carboxylic ester is formed.<sup>2241</sup> This conversion has also been accomplished with concentrated  $\text{H}_2\text{SO}_4$  saturated with CO.<sup>2242</sup> Not surprisingly, only tertiary halides perform satisfactorily; secondary halides give mostly rearrangement products. An analogous reaction takes place with alkanes possessing a tertiary hydrogen atom, using  $\text{HF-SbF}_5\text{-CO}$ .<sup>2243</sup>

Carboxylic acids or esters are the products, depending on whether the reaction mixture is solvolyzed with water or an alcohol. Alcohols with more than seven carbons are cleaved into smaller fragments by this procedure.<sup>2244</sup> Similarly, tertiary alcohols<sup>2245</sup> react with  $\text{H}_2\text{SO}_4$  and CO (which is often generated from  $\text{HCOOH}$  and the  $\text{H}_2\text{SO}_4$  in the solution) to give trisubstituted acetic acids in a process called the *Koch-Haaf reaction* (see also **15-31**).<sup>2246</sup> If a primary or secondary alcohol is the substrate, the carbocation initially formed rearranges to a tertiary ion before reacting with the CO. Better results are obtained if trifluoromethanesulfonic acid ( $\text{F}_3\text{CSO}_2\text{OH}$ ) is used instead of  $\text{H}_2\text{SO}_4$ .<sup>2247</sup> Iodo alcohols were transformed into lactones under radical conditions ( $\text{AIBN}$ ,  $\text{allylSnBu}_3$ ) and 45 atmospheres of CO.<sup>2248</sup>

Another method<sup>2249</sup> for the conversion of alkyl halides to carboxylic esters is treatment of a halide with nickel carbonyl,  $\text{Ni(CO)}_4$ , in the presence of an alcohol and its conjugate base.<sup>2250</sup> When  $\text{R}'$  is primary,  $\text{RX}$  may only be a vinylic or an aryl halide; retention of configuration is observed at a vinylic R. Consequently, a carbocation intermediate is not involved here. When  $\text{R}'$  is tertiary, R may be primary alkyl as well as vinylic or aryl. This is thus one of the few methods for preparing esters of tertiary alcohols. Alkyl iodides give the best results, then bromides. In the presence of an amine, an amide can be isolated directly, at least in some instances.

Palladium complexes also catalyze the carbonylation of halides.<sup>2251</sup> Aryl (see **13-15**),<sup>2252</sup> vinylic,<sup>2253</sup> benzylic, and allylic halides (especially iodides) can be converted to carboxylic

$\alpha$ -keto amides,<sup>2273</sup> and the R is usually aryl or vinylic.<sup>2274</sup> The formation of  $\alpha$ -keto acids<sup>2275</sup> or  $\alpha$ -keto esters<sup>2276</sup> requires more severe conditions.  $\alpha$ -Hydroxy acids were obtained from aryl iodides when the reaction was carried out in the presence of an alcohol, which functioned as a reducing agent.<sup>2277</sup> Cobalt catalysts have also been used and require lower CO pressures.<sup>2272</sup>

OS V, 20, 739.

### 10-79 Carboxylation of Alkyl, Alkenyl, and Alkynyl Substrates with CO<sub>2</sub> or CO

The carboxylation and carbonylation of organic substrates leads to carboxylic acid derivatives or ketone derivatives.<sup>2278</sup> Other C—C bond-forming reactions have been discussed.<sup>2279</sup> The reaction of alkynes with CO<sub>2</sub> and allylic, propargylic, or benzylic chlorides in the presence of Cs<sub>2</sub>CO<sub>3</sub> and a AgI catalyst gave functionalized 2-alkynoates.<sup>2280</sup> The reaction of bromostyrenes with CO<sub>2</sub> using electrolysis with a Ag electrode, followed by reaction with iodomethane, gave the corresponding vinyl benzoic acid methyl ester. Aryl terminal alkynes reacted with benzylic halides in the presence of CO<sub>2</sub>, Cs<sub>2</sub>CO<sub>3</sub>, and a AgI catalyst to give the corresponding benzylic ester.<sup>2281</sup>

Allylic tin or allylborates<sup>2282</sup> react with CO<sub>2</sub> in the presence of a Pd catalyst to give the corresponding ester.<sup>2283</sup>  $\alpha$ -Substituted propargylic bromides are carboxylated with CO<sub>2</sub> in the presence of zinc to give the corresponding carboxylic acid.<sup>2284</sup> The carboxylation of (hetero)arenes with CO<sub>2</sub> has been reported using Au and Cu complexes of *N*-heterocyclic carbenes.<sup>2285</sup> Propargyl acetates reacted with CO<sub>2</sub> and Mn, with a Co catalyst, to give the corresponding carboxylic acid.<sup>2286</sup> Cycloalkanes were coupled with amides in the presence of CO and a Cu catalyst to give the corresponding imide.<sup>2287</sup>

Allylic alcohols reacted with alcohols in the presence of CO, with a Pd catalyst and 10% of TFA, to give  $\beta,\gamma$ -unsaturated esters.<sup>2288</sup> Alcohols react with alcohols and CO, with a Pd catalyst and a catalytic amount of sulfuric acid, to give the corresponding ester.<sup>2289</sup> Alcohols reacted with allyl chloride, with CO, triethylamine, and a Pd catalyst, to give the corresponding ester.<sup>2290</sup>

## Aromatic Substitution, Electrophilic

Most substitutions at an aliphatic carbon are by nucleophiles. In aromatic systems the situation is reversed, because the high electron density at the aromatic ring leads to its reactivity as a Lewis base or a Brønsted-Lowry base, depending on the positive species. In electrophilic substitutions, a positive ion or the positive end of a dipole or induced dipole is attacked by the aromatic ring. The leaving group (the electrofuge) must necessarily depart without its electron pair. In nucleophilic substitution reactions, the chief leaving groups are those best able to carry the unshared pair:  $\text{Br}^-$ ,  $\text{H}_2\text{O}$ ,  $\text{OTs}^-$ , and so on, that is, the weakest bases. In electrophilic substitution reactions the most important leaving groups are those that can best exist *without* the pair of electrons necessary to fill the outer shell, that is, the weakest Lewis acids. The influence of solvents will vary with the reaction in many cases, and such details are discussed where appropriate in the reactions section (Sec. 11.F).<sup>1</sup>

### 11.A. MECHANISMS

Electrophilic aromatic substitutions<sup>2</sup> largely proceed by the *arenium ion mechanism*,<sup>3</sup> where the electrophile (which can be viewed as a Lewis acid) is attacked by the  $\pi$  electrons of the aromatic ring (which can be viewed as a Lewis base) in the first step. This reaction leads to formation of a new C–X bond and a new  $sp^3$  carbon in a positively charged intermediate called an arenium ion, where X is the electrophile. The positively charged intermediate (the arenium ion) is resonance stabilized, but not aromatic. The second mechanistic step is the loss of a proton from the  $sp^3$  carbon that is “adjacent” to the positive carbon in the arenium ion, in what is effectively an E1 process (Sec. 17.A.ii), driven by rearomatization of the ring from the arenium ion to give the aromatic substitution product. A proton therefore becomes the leaving group in this overall transformation, where X replaces H. The IUPAC designation for this mechanism is  $\text{A}_\text{E} + \text{D}_\text{E}$ . Hyperaromatic stabilization of arenium

<sup>1</sup> For a review of electrophilic aromatic reactions in ionic liquids, see Borodkin, G.I.; Cubin, V.G. *Russ. J. Org. Chem.* **2006**, *42*, 1745.

<sup>2</sup> See Galabov, B.; Nalbantova, D.; Schleyer, P.v.R.; Schaefer III, H.F. *Acc. Chem. Res.* **2016**, *49*, 1191.

<sup>3</sup> See Taylor, R. *Electrophilic Aromatic Substitution*, Wiley, NY, **1990**; Katritzky, A.R.; Taylor, R. *Electrophilic Substitution of Heterocycles: Quantitative Aspects* (Vol. 47 of *Adv. Heterocycl. Chem.*), Academic Press, NY, **1990**; Taylor, R. in Bamford, C.H.; Tipper, C.F.H. *Comprehensive Chemical Kinetics*, Vol. 13, Elsevier, NY, **1972**, pp. 1–406.

ions has been discussed.<sup>4</sup> Another mechanism, much less common, consists of the opposite behavior: a leaving group departs *before* the electrophile arrives. In this case, a substituent (*not* H) is attached to the aromatic ring, and the substituent is lost prior to incorporation of the electrophile. This mechanism, the  $S_E\text{Ar}$  mechanism, corresponds to the  $S_N\text{Ar}$  mechanism of nucleophilic substitution. Simultaneous attack and departure mechanisms (corresponding to  $S_N2$ ) are not found at all. An addition–elimination mechanism has been postulated in one case (see **11-4**).

### 11.A.i. The Arenium Ion Mechanism<sup>5</sup>

In the arenium ion mechanism the electrophilic species may be produced in various ways, but when H is replaced by X, conversion of the aromatic ring to an arenium ion is basically the same in all cases. For this reason most attention in the study of this mechanism centers on the identity of the electrophilic entity and how it is produced. This mechanism is *electrophilic aromatic substitution*, known as the  $S_E\text{Ar}$  mechanism.

The electrophile may be a positive ion ( $X^+$ ) or a molecule that has a positive dipole. If it is a positive ion, it is attacked by the ring (a pair of electrons from the aromatic sextet is donated to the electrophile) and the product is a resonance-stabilized carbocation, **1**, which is sometimes represented as in **2**. In other words, the electron-rich aromatic ring donates electrons to the electron-deficient carbocation. Ions of this type<sup>6</sup> have been called *Wheland intermediates*<sup>7</sup> and  $\sigma$  *complexes*, but nowadays *arenium ions*<sup>8</sup> is the appropriate designation. The arenium ion is a highly reactive intermediate, although there are cases in which it has been isolated (see below). For this type of ion the most likely pathway<sup>9</sup> is loss of either  $X^+$  or  $H^+$  but this reaction proceeds with loss of the proton and rearomatization of the final product **3**. The second step is nearly always faster than the first, making the first step rate determining, and the reaction is second order. The electrostatic modulation of aromatic rings via the solvation of substituents has been discussed.<sup>10</sup>

If the electrophilic species is not an ion but a molecule with a polarized covalent bond, the product must have a negative charge unless part of the dipole, with its pair of electrons, is broken off somewhere in the process, as in the conversion of **4** to **2**. Note that when the aromatic ring attacks X, Z may be lost directly to give **2**. However, benzene is a rather

weak electron-donating species unless electron-releasing substituents are attached, and in most cases a cation such as  $X^+$  must be generated in the presence of the benzene ring for a reaction to occur.

The electrophilic entities,  $X^+$ , and how they are formed, are discussed for each reaction in the reactions section of this chapter.

The evidence for the arenium ion mechanism is mainly of two kinds:

1. *Isotope effects.* If the hydrogen ion departs before the arrival of the electrophile ( $S_E1$  mechanism) or if the arrival and departure are simultaneous, there should be a substantial isotope effect (i.e., deuterated substrates should undergo substitution more slowly than nondeuterated compounds) because, in each case, the C–H bond is broken in the rate-determining step. However, in the arenium ion mechanism, the C–H bond is not broken in the rate-determining step, so no isotope effect should be found. Many such studies have been carried out and, in most cases, especially in the case of nitrations, there is no isotope effect.<sup>11</sup> This result is incompatible with either the  $S_E1$  or the simultaneous mechanism.

However, in many instances, isotope effects have been found. Since the values are generally much lower than expected for either the  $S_E1$  or the simultaneous mechanisms (e.g., 1–3 for  $k_H/k_D$  instead of 6–7), there must be another explanation. For the case where hydrogen is the leaving group, the arenium ion mechanism can be summarized as:

The small isotope effects found most likely arise from the reversibility of step 1 by a *partitioning effect*.<sup>12</sup> The rate at which  $\text{ArHY}^+$  reverts to  $\text{ArH}$  should be essentially the same as that at which  $\text{ArDY}^+$  (or  $\text{ArTY}^+$ ) reverts to  $\text{ArD}$  (or  $\text{ArT}$ ), since the Ar–H bond is not being cleaved. However,  $\text{ArHY}^+$  should go to  $\text{ArY}$  faster than either  $\text{ArDY}^+$  or  $\text{ArTY}^+$ , since the Ar–H bond is broken in this step. If  $k_2 \gg k_{-1}$ , this does not matter; since a large majority of the intermediates go to product, the rate is determined only by the slow step ( $k_2 I[\text{ArH}][\text{Y}^+]$ ), and no isotope effect is predicted. However, if  $k_2 \leq k_{-1}$ , reversion to starting materials is important. If  $k_2$  for  $\text{ArDY}^+$  (or  $\text{ArTY}^+$ ) is  $< k_2$  for  $\text{ArHY}^+$ , but  $k_{-1}$  is the same, then a larger proportion

<sup>11</sup> Berglund-Larsson, U.; Melander, L. *Ark. Kemi* **1953**, *6*, 219. See also, Zollinger, H. *Adv. Phys. Org. Chem.* **1964**, *2*, 163.

<sup>12</sup> See Hammett, L.P. *Physical Organic Chemistry*, 2nd ed., McGraw-Hill, NY, **1970**, pp. 172–182.

of  $\text{ArDY}^+$  reverts to starting compounds. That is,  $k_2/k_{-1}$  (the *partition factor*) for  $\text{ArDY}^+$  is less than that for  $\text{ArHY}^+$ . Consequently, the reaction is slower for  $\text{ArD}$  than for  $\text{ArH}$  and an isotope effect is observed.

One circumstance that could affect the  $k_2/k_{-1}$  ratio is steric hindrance. Thus, diazonium coupling of **5** gave no isotope effect, while coupling of **7** gave a  $k_{\text{H}}/k_{\text{D}}$  ratio of 6.55.<sup>13</sup> For steric reasons, it is much more difficult for **8** to lose a proton (it is harder for a base to approach) than it is for **6**, so  $k_2$  is greater for the latter. Since no base is necessary to remove  $\text{ArN}_2^+$ ,  $k_{-1}$  does not depend on steric factors<sup>14</sup> and is about the same for each. Thus the partition factor  $k_2/k_{-1}$  is sufficiently different for **7** and **8** that **7** exhibits a large isotope effect and **5** exhibits none.<sup>15</sup> Base catalysis can also affect the partition factor, since an increase in base concentration increases the rate at which the intermediate goes to product without affecting the rate at which it reverts to starting materials. In some cases, isotope effects can be diminished or eliminated by a sufficiently high concentration of base.

Evidence for the arenium ion mechanism has also been obtained from other kinds of isotope-effect experiments, involving substitutions of the type

where M is Si, Ge, Sn, or Pb, and R is methyl or ethyl. In these reactions the proton is the electrophile. If the arenium ion mechanism is operating, then the use of  $\text{D}_3\text{O}^+$  should give rise to an isotope effect, since the D—O bond would be broken in the rate-determining step. Isotope effects of 1.55–3.05 were obtained,<sup>16</sup> in accord with the arenium ion mechanism.

2. *Isolation of arenium ion intermediates.* Very strong evidence for the arenium ion mechanism comes from the isolation of arenium ions in a number of instances.<sup>17</sup> Compound **9** was isolated as a solid with a melting point of  $-15^\circ\text{C}$  by treatment of mesitylene with fluoroethane using a  $\text{BF}_3$  catalyst at  $-80^\circ\text{C}$ .

<sup>16</sup> Bott, R.W.; Eaborn, C.; Greasley, P.M. *J. Chem. Soc.* **1964**, 4803.

<sup>17</sup> See Koptuyug, V.A. *Top. Curr. Chem.* **1984**, 122, 1; Shteingarts, V.D. *Russ. Chem. Rev.* **1981**, 50, 735; Farcasiu, D. *Acc. Chem. Res.* **1982**, 15, 46.

When **9** was heated, the normal substitution product, 2-ethyl-1,3,5-trimethylbenzene, was obtained.<sup>18</sup> Even the simplest such ion, the benzenonium ion (**10**) has been prepared in  $\text{HF-SbF}_5\text{-SO}_2\text{ClF-SO}_2\text{F}_2$  at  $-134^\circ\text{C}$ , where it could be studied spectrally.<sup>19</sup> The  $^{13}\text{C}$  NMR spectra of the benzenonium ion<sup>20</sup> and the pentamethylbenzenonium ion<sup>21</sup> give graphic evidence for the charge distribution shown in **1** (as represented in the electron-density map for the arenium ion, **11**). According to this, the 1, 3, and 5 carbons, each of which bears a positive charge of  $\sim+1/3$  [note that C-1, C-3, and C-5 (numbering from **10**) are lighter, indicating less electron density in **11** whereas C-2 and C-4 are darker for higher electron density], should have a greater chemical shift in the NMR than the 2 and 4 carbons, which are unchanged. Support for this electron distribution is seen in the  $^{13}\text{C}$  NMR chemical shifts for **10** are C-3: 178.1; C-1 and C-5: 186.6; C-2 and C-4: 136.9, and C-6: 52.2.<sup>20</sup>

In Chapter 3, it was mentioned that positive ions can form addition complexes with  $\pi$  systems. Since the initial step of electrophilic substitution involves attack of a positive ion by an aromatic ring, it has been suggested<sup>22</sup> that such a complex, called a  $\pi$  complex (represented as **12**), is formed first, and then is converted to the arenium ion **13**.<sup>23</sup>

Stable solutions of arenium ions or  $\pi$  complexes (e.g., with  $\text{Br}_2$ ,  $\text{I}_2$ , picric acid,  $\text{Ag}^+$ , or  $\text{HCl}$ ) can be formed.<sup>24</sup> For example,  $\pi$  complexes are formed when aromatic hydrocarbons are treated with  $\text{HCl}$  alone, but the use of  $\text{HCl}$  plus a Lewis acid (e.g.,  $\text{AlCl}_3$ ) gives arenium ions. The two types of solution have very different properties. For example, a solution of an arenium ion is colored and conducts electricity, which shows that positive and negative

ions are present, while a  $\pi$  complex formed from HCl and benzene is colorless and does not conduct a current. Furthermore, when DCl is used to form a  $\pi$  complex, no deuterium exchange takes place (because there is no covalent bond between the electrophile and the ring), while formation of an arenium ion with DCl and AlCl<sub>3</sub> gives deuterium exchange.

The relative stabilities of some methylated arenium ions and  $\pi$  complexes are shown in Table 11.1. The arenium ion stabilities listed were determined by the relative basicity of the substrate toward HF.<sup>25</sup> The  $\pi$ -complex stabilities are relative equilibrium constants for the reaction<sup>26</sup> between the aromatic hydrocarbon and HCl. As shown in Table 11.1, the relative stabilities of the two types of species are very different: the  $\pi$  complex stability changes very little with methyl substitution, but the arenium ion stability changes a great deal. It is noted that stable arenium ions have been obtained from large methylene-bridged polycyclic aromatic hydrocarbons.<sup>27</sup>

How can we tell if **12** is present on the reaction path? If it is present, there are two possibilities: (i) the formation of **12** is rate determining (the conversion of **12** to **13** is much faster), or (ii) the formation of **12** is rapid, and the conversion **12** to **13** is rate determining. One way to ascertain which species is formed in the rate-determining step in a given reaction is to use the stability information given in Table 11.1. The relative rates of reaction of a given electrophile are measured with the series of compounds listed in Table 11.1. If the relative rates resemble the arenium ion stabilities, we conclude that the arenium ion is formed in the slow step; but if they resemble the stabilities of the  $\pi$  complexes, the latter are formed in the slow step.<sup>28</sup> When such experiments are carried out, it is found in most cases that the relative rates are similar to the arenium ion and not similar to the  $\pi$  complex stabilities.

<sup>25</sup> Kilpatrick, M.; Luborsky, F.E. *J. Am. Chem. Soc.* **1953**, *75*, 577.

<sup>26</sup> Brown, H.C.; Brady, J.D. *J. Am. Chem. Soc.* **1952**, *74*, 3570.

<sup>27</sup> Laali, K.K.; Okazaki, T.; Harvey, R.G. *J. Org. Chem.* **2001**, *66*, 3977.

<sup>28</sup> Condon, F.E. *J. Am. Chem. Soc.* **1952**, *74*, 2528.

For example, Table 11.1 lists chlorination rates.<sup>26</sup> Similar results were obtained in room-temperature bromination with Br<sub>2</sub> in acetic acid<sup>29</sup> and in acetylation with CH<sub>3</sub>CO<sup>+</sup> SbF<sub>6</sub><sup>-</sup>.<sup>30</sup> It is clear that in these cases the π complex either does not form at all, or, if it does, its formation is not rate determining (unfortunately, it is very difficult to distinguish between these two possibilities).

On the other hand, in nitration with the powerful electrophile NO<sub>2</sub><sup>+</sup> (in the form of NO<sub>2</sub><sup>+</sup> BF<sub>4</sub><sup>-</sup>), the relative rates resembled π complex stabilities much more than arenium ion stabilities.<sup>31</sup> Similar results were obtained for bromination with Br<sub>2</sub> and FeCl<sub>3</sub> in nitromethane.

These results were taken to mean<sup>32</sup> that in these cases π-complex formation is rate determining. However, graphical analysis of the NO<sub>2</sub><sup>+</sup> data showed that a straight line could not be drawn when the nitration rate was plotted against π-complex stability,<sup>33</sup> which casts doubt on the rate-determining formation of a π complex in this case.<sup>34</sup> There is other evidence, from positional selectivities (discussed in Sec. 11.D), that *some* intermediate is present before the arenium ion is formed, whose formation can be rate determining with powerful electrophiles. Not much is known about this intermediate, which is given the non-descriptive name *encounter complex* and generally depicted as Y<sup>+</sup>ArH. The arenium complex mechanism is therefore written as<sup>35</sup>

For the reason given above and for other reasons, it is unlikely that the encounter complex is a π complex, but just what kind of attraction exists between Y<sup>+</sup> and ArH is not known, other than the presumption that they are together within a solvent cage (see also, Sec. 11.D). There is evidence (from isomerizations occurring in the alkyl group, as well as other observations) that π complexes are present on the pathway from substrate to arenium ion in the gas phase protonation of alkylbenzenes.<sup>36</sup>

### 11.A.ii. The S<sub>E</sub>1 Mechanism

The S<sub>E</sub>1 mechanism (*substitution electrophilic unimolecular*) is rare, being found only in certain cases in which carbon is the leaving atom (see **11-33**, **11-35**) or when a very strong

base is present (see **11-1**, **11-10**, and **19-58**).<sup>37</sup> It consists of two steps with an intermediate carbanion. The IUPAC designation is  $D_E + A_E$ .

Reactions **12-40**, **12-44**, and **12-45** also take place by this mechanism when applied to aryl substrates.

## 11.B. ORIENTATION AND REACTIVITY

### 11.B.i. Orientation and Reactivity in Monosubstituted Benzene Rings<sup>38</sup>

When an electrophilic substitution reaction is performed on a monosubstituted benzene, the new group may be directed primarily to the *ortho*, *meta*, or *para* position and the substitution may be slower or faster than with benzene itself.<sup>39</sup> The group already on the ring determines which position the new group will take and whether the reaction will be slower or faster than with benzene. Groups that are electron donating increase the reaction rate and are called *activating*; groups that are electron withdrawing slow the reaction rate and are called *deactivating*. Electron-withdrawing groups are predominantly *meta* directing whereas electron-donating groups are *ortho/para* directing. Halogen substituents are weakly deactivating but are *ortho/para* directing. Groups direct *predominantly*, but usually not *exclusively*, so the electrophilic substitution reaction is regioselective and not regiospecific. For example, nitration of nitrobenzene gave 93% *m*-dinitrobenzene, 6% of the *ortho* isomer, and 1% of the *para* isomer.

The orientation and reactivity effects are explained on the basis of resonance and field effects of each group on the stability of the intermediate arenium ion formed from each compound. To understand why this approach can be used, it is necessary to know that in these reactions the product is usually kinetically controlled and not thermodynamically controlled (Sec. 6.F). There are three possible intermediates, resulting from reaction of the aromatic ring with the “X” group at C2, C3, or C4 relative to the carbon bearing the “X” group, the so-called *ipso* carbon<sup>40</sup>. Which of the three possible intermediates is formed is dependent not on the thermodynamic stability of the products, but on the activation energy necessary to form each of the three intermediates. It is necessary to make the assumption that the free-energy profile resembles either Figure 6.2(a) or (b). In either case, the transition state is closer in energy to the arenium ion intermediate than to the starting compounds. Invoking the *Hammond postulate* (Sec. 6.G), assume that the geometry of the transition state also resembles that of the intermediate and that anything that increases the stability of the intermediate will also lower the activation energy necessary to attain it. Formation of the

<sup>37</sup> Also see Eaborn, C.; Hornfeld, H.L.; Walton, D.R.M. *J. Chem. Soc. B* **1967**, 1036.

<sup>38</sup> See Hoggett, J.G.; Moodie, R.B.; Penton, J.R.; Schofield, K. *Nitration and Aromatic Reactivity*, Cambridge University Press, Cambridge, **1971**, pp. 122–145, 163–220.

<sup>39</sup> For a computational approach to evaluate substituent constants, see Galabov, B.; Ilieva, S.; Schaefer III, H.F. *J. Org. Chem.* **2006**, *71*, 6382.

<sup>40</sup> Perrin, C.L.; Skinner, G.A. *J. Am. Chem. Soc.* **1971**, *93*, 3389; Traynham, J.G. *J. Chem. Educ.* **1983**, *60*, 937.

intermediate is the slow step (the rate-determining step) and, once formed, the intermediate is rapidly converted to products. The relative stabilities of the three intermediates can be used as guides to predict which products will predominantly form. Of course, if reversible reactions are allowed to proceed to equilibrium, product ratios that are quite different may be obtained. For example, the sulfonation of naphthalene at 80 °C, where the reaction does not reach equilibrium, gives mostly  $\alpha$ -naphthalenesulfonic acid,<sup>41</sup> while at 160 °C, where equilibrium is attained, the  $\beta$  isomer predominates<sup>42</sup> (the  $\alpha$  isomer is thermodynamically less stable because of steric interaction between the SO<sub>3</sub>H group and the hydrogen at the 8 position).

The nine possible ions from incorporation of Y at each of the *ortho*, *meta*, and *para* positions are shown below, and each arenium ion obviously has a positive charge in the ring. Any group, Z, that has an electron-donating field effect (+I, Z will have a  $\delta^-$  charge or a  $\delta^-$  dipole in most cases) should stabilize all ions (relative to **1**), since electron donation to a positive center is stabilizing.

However, examination of the three resonance contributors show that the (+) charge is adjacent to the electron-donating ( $\delta^-$ ) X group only with the intermediate arising from *ortho* or *para* attack, but not *meta* attack, so the *ortho* and *para* intermediates are particularly stabilized (opposite charges attract). On the other hand, electron-withdrawing groups ( $-I$ , Z will have a  $\delta^+$  charge or a  $\delta^+$  dipole in most cases) will increase the positive charge on the ring (like charges repel), and destabilize the arenium ion. Examination of the three resonance contributors show that the (+) charge is adjacent to the electron-withdrawing ( $\delta^+$ ) X group only with the intermediate arising from *ortho* or *para* attack, but not *meta* attack and so those two intermediates are particularly destabilized (like charges repel).

Formation of a stabilized ion should be faster than benzene (which generates **1**), or activating, but formation of a destabilized ion should be slower, or deactivating. Such field effects should taper off with distance and are thus strongest at the carbon connected to the group Z (known as the ipso carbon). Since none of the canonical forms of the *meta* ion has a positive charge at the ipso carbon, +I groups should stabilize all three ions but mostly the *ortho* and *para*, so they should be not only activating but *ortho/para* directing as well. On the other hand,  $-I$  groups, by removing electron density, should destabilize all three ions but mostly the *ortho* and *para*, and should be not only deactivating but also *meta* directing. In many cases, there is *resonance interaction* between Z and the ring; this also affects the relative stability, in some cases in the same direction as the field effect, in others differently.

<sup>41</sup> Fierz, H.E.; Weissenbach, P. *Helv. Chim. Acta* **1920**, 3, 312.

<sup>42</sup> Witt, O.N. *Ber.* **1915**, 48, 743.

Some substituents have a pair of electrons (usually unshared) that may be contributed *toward* the ring. The *ortho* and *para* arenium ions would then have a fourth resonance contributor. The same three canonical forms can be drawn for each ion as before, but now an extra form for the *ortho* and *para* ions can be drawn. The stability of these two intermediate ions is increased by the extra form not only because it is another canonical form, but also because it is more stable than the others and makes a greater contribution to the hybrid. Every atom (except of course hydrogen) in these forms (**C** and **D**) has a complete octet, while all the other forms have one carbon atom with a sextet. No corresponding form can be drawn for the *meta* isomer. The inclusion of this form in the hybrid lowers the energy not only because of rule 6 (see Sec. 2.E), but also because it spreads the positive charge over a larger area, out onto the group Z. Groups with a pair of electrons to contribute (e.g., the halogens) would be expected, then, in the absence of field effects, not only to direct *ortho* and *para*, but also to activate these positions for electrophilic attack.

On the basis of these discussions, we can distinguish three types of groups.

1. *Groups that contain an unshared pair of electrons on the atom connected to the ring are electron donating with a (-) charge or ( $\delta^-$ ) dipole.* In this category are  $O^-$ ,  $NR_2$ ,  $NHR$ ,  $NH_2$ ,<sup>43</sup>  $OH$ ,  $OR$ ,  $NHCOR$ ,  $OCOR$ ,  $SR$ , and the four halogens.<sup>44</sup> The halogens deactivate the aromatic ring to substitution (the rate of reaction is slower than that of benzene), and this effect may arise from the unique energy level of the halogen lone pair orbital, which is higher than the adjacent  $\pi$ -molecular orbital of benzene ( $\pi_1$ ).<sup>45</sup> The resonance explanation predicts that all these groups should be *ortho/para* directing, and they are, though all except  $O^-$  are electron withdrawing by the field effect (Sec. 1.I). Therefore, for these groups, resonance is more important than the field effect. This is especially true for  $NR_2$ ,  $NHR$ ,  $NH_2$ , and  $OH$ , which are *strongly* activating, as is  $O^-$ .

Halogen substituents are deactivating since they are polarized  $\delta^+$  relative to the electron rich aromatic ring. However, the halogens are polarizable and this property allows the halogens to have a  $-I$  effect because once the arenium ion is formed and the ring has a formal (+) charge the halogen takes a  $\delta^-$  dipole and thus the *ortho* arenium ions are more stabilized than the *meta* arenium ions. Thus, the halogens are *ortho/para* directing. The  $SH$  group would probably belong here too, except that in the case of thiophenols electrophiles usually attack the sulfur rather than the ring, and ring substitution is not feasible with these substrates.<sup>46</sup> Fluorine<sup>47</sup> is the least deactivating, and fluorobenzenes usually show a reactivity approximating that of benzene itself. The other three halogens deactivate about equally.

2. *Groups that lack an unshared pair on the atom connected to the ring are electron withdrawing with a (+) charge or ( $\delta^+$ ) dipole.* In this category are, in approximate order of decreasing deactivating ability,  $NR_3^+$ ,  $NO_2$ ,  $CF_3$ ,<sup>48</sup>  $CN$ ,  $SO_3H$ ,  $CHO$ ,  $COR$ ,  $CO_2H$ ,  $CO_2R$ ,  $CONH_2$ ,  $CCl_3$ , and  $NH_3^+$ . Also in this category are all other groups with a positive charge on the atom directly connected to the ring<sup>49</sup> ( $SR_2^+$ ,  $PR_3^+$ , etc.) and many groups with positive charges on atoms farther away, since these are often still powerful  $-I$  groups. The field-effect explanation predicts that these should all be *meta* directing and deactivating, and (except for  $NH_3^+$ ) this is the case. The  $NH_3^+$  group is an anomaly, since this group directs *para* about as much as or a

<sup>43</sup> It must be remembered that in acidic solutions amines are converted to their conjugate acids, which for the most part are *meta* directing (type 2). However, unless the solution is highly acidic, there will be a small amount of free amine present, and since amino groups are activating and the conjugate acids deactivating, *ortho/para* direction is often found even under acidic conditions.

*para*, since there are two *ortho* positions and only one *para*. However, the phenonium ion **10**, which arises from protonation of benzene, has the approximate charge distribution shown<sup>57</sup> (see **11** as well).

If this model were accepted for the arenium ion in aromatic substitution, a *para* substituent would have a greater stabilizing effect on the adjacent carbon than an *ortho* substituent. If other effects are absent, this would mean that >33% *para* and <67% *ortho* substitution would be found. In hydrogen exchange (reaction **11-1**), where other effects are absent, it has been found for a number of substituents that the average ratio of the logarithms of the partial rate factors for these positions (Sec. 11.C for a definition of partial rate factor) was close to 0.865,<sup>58</sup> which is close to the value predicted from the ratio of charge densities in **10**. This picture is further supported by the fact that *meta*-directing groups, which destabilize a positive charge, give *ortho/para* ratios >67:33<sup>59</sup> (of course the total amount of *ortho* and *para* substitution with these groups is small, but the *ratios* are generally >67:33). Another important factor is the steric effect. If either the group on the attacking ring or the group on the electrophile is large, steric hindrance inhibits formation of the *ortho* product and increases the amount of the *para* isomer. An example may be seen in the nitration, under the same conditions, of toluene and *tert*-butylbenzene. The former gave 58% of the *ortho* compound and 37% of the *para*, while the more bulky *tert*-butyl group gave 16% of the *ortho* product and 73% of the *para*.<sup>60</sup> Some groups are so large that they direct almost entirely *para*.

When the *ortho/para*-directing group is one with an unshared pair (this of course applies to most of them), there is another effect that increases the amount of *para* product at the expense of the *ortho*. A comparison of the intermediates involved (Sec. 11.B.i) shows that **C** is a canonical form with an *ortho* quinoid structure, while **D** has a *para* quinoid structure. *para*-Quinones are more stable than the *ortho* isomers, so it seems reasonable to assume that **D** is more stable than **C**, and therefore contributes more to the hybrid and increases its stability compared to the *ortho* intermediate.

It has been shown that it is possible to compel regiospecific *para* substitution by enclosing the substrate molecules in a cavity from which only the *para* position projects. Anisole was chlorinated in solutions containing a cyclodextrin, a molecule in which the anisole is almost entirely enclosed (see Figure 3.4). With a high-enough concentration of

cyclodextrin, it was possible to achieve a *para/ortho* ratio of 21.6<sup>61</sup> (in the absence of the cyclodextrin the ratio was only 1.48). This behavior is a model for the regioselectivity found in the action of enzymes. The *Bell-Evans-Polanyi principle* states that the difference in activation energy between two reactions of the same family is proportional to the difference of their enthalpy.<sup>62</sup> This principle has been linked to the regioselectivity of electrophilic aromatic substitution.<sup>63</sup>

### 11.B.iii. Ipso Attack

Orientation has been discussed previously in the case of monosubstituted benzenes entirely in terms of attachment at the *ortho*, *meta*, and *para* positions, but attachment at the position bearing the substituent (called the *ipso position*) can also be important. Ipso attack has mostly been studied for nitration.<sup>64</sup> When attack of  $\text{NO}_2^+$  leads to incorporation at the ipso position there are at least five possible fates for the resulting arenium ion (**14**).

- Path **a**. The arenium ion can lose  $\text{NO}_2^+$  and revert to the starting compounds, resulting in no net reaction and is often undetectable.
- Path **b**. The arenium ion can lose  $\text{Z}^+$ , in which case this is simply aromatic substitution with a leaving group other than H (see **11-33** to **11-38**).
- Path **c**. The electrophilic group (in this case  $\text{NO}_2^+$ ) can undergo a 1,2-migration, followed by loss of the proton. The product in this case is the same as that obtained by direct attachment of  $\text{NO}_2^+$  at the *ortho* position of  $\text{PhZ}$ . It is not always easy to tell how much of the *ortho* product in any individual case arises from this pathway,<sup>65</sup> though there is evidence that it can be a considerable proportion. Because of this possibility, many of the reported conclusions about the relative reactivity of the *ortho*, *meta*, and *para* positions are cast into doubt, since some of the product may have arisen not from

direct attachment at the *ortho* position, but from attachment at the ipso position followed by rearrangement.<sup>66</sup>

- Path **d**. The ipso substituent (**Z**) can undergo 1,2-migration, which also produces the *ortho* product (although the rearrangement would become apparent if there were other substituents present). The evidence is that this pathway is very minor, at least when the electrophile is  $\text{NO}_2^+$ .<sup>67</sup>
- Path **e**. Attack of a nucleophile on **14**. In some cases, the products of such an attack (cyclohexadienes) have been isolated<sup>68</sup> (this is 1,4-addition to the aromatic ring), but further reactions are also possible.

#### 11.B.iv. Orientation in Benzene Rings With More Than One Substituent<sup>69</sup>

When two or more substituents are attached to the benzene ring, it is often possible to predict the correct isomer resulting from electrophilic substitution. Activating substituents lead to faster reactions at the *ortho/para* position relative to the activating group, and the more powerful activating group controls the substitution compared to a group with a lesser electron-withdrawing effect. In many cases, the groups already on the ring reinforce each other. Thus, 1,3-dimethylbenzene is substituted at the 4 position (*ortho* to one group and *para* to the other), but not at the 5 position (*meta* to both). Likewise, the incoming group in *p*-chlorobenzoic acid goes to the position *ortho* to the chloro and *meta* to the carboxyl group. 1,3,5-Trifluorobenzene was used as a starting material for a regioselective approach to multisubstituted benzene derivatives.<sup>70</sup>

When the groups oppose each other with respect to electron donating vs. electron withdrawing, the activating group dominates the regioselectivity when compared to an electron-withdrawing group. However, when both groups are relatively weak or have about the same directing strength, predictions may be more difficult. Consider *N*-acetyl-2-methoxyaniline. Here, the two groups of about equal directing ability are in competing positions, so all four products can be expected, and it is not easy to predict the proportions, except that steric hindrance should probably reduce the yield of substitution *ortho* to the acetamido group, especially for large electrophiles. Mixtures of about equal proportions are frequent in such cases. Nevertheless, even when groups on a ring oppose each other, there are some regularities.

1. If a strong activating group competes with a weaker one or with a deactivating group, the former controls. Thus *o*-cresol gives substitution mainly *ortho* and *para* to the *hydroxyl* group and not to the methyl. For this purpose we can arrange the groups in the following order:  $\text{NH}_2$ , OH,  $\text{NR}_2$ ,  $\text{O}^- > \text{OR}$ , OCOR, NHCOR  $> \text{R}$ , Ar  $>$  halogen  $>$  *meta*-directing groups.
2. All other things being equal, a third group is least likely to enter between two groups in the *meta* relationship. This is the result of steric hindrance and increases in

<sup>66</sup> This was first pointed out by Myhre, P.C. *J. Am. Chem. Soc.* **1972**, *94*, 7921.

<sup>67</sup> See Hartshorn, M.P.; Readman, J.M.; Robinson, W.T.; Sies, C.W.; Wright, G.J. *Aust. J. Chem.* **1988**, *41*, 373.

<sup>68</sup> See Banwell, T.; Morse, C.S.; Myhre, P.C.; Vollmar, A. *J. Am. Chem. Soc.* **1977**, *99*, 3042; Fischer, A.; Greig, C.C. *Can. J. Chem.* **1978**, *56*, 1063.

<sup>69</sup> For a quantitative discussion, see Sec. 11.C.

<sup>70</sup> Seo, H.; Ohmori, K.; Suzuki, K. *Chem. Lett.* **2011**, *40*, 744.

importance with the size of the groups on the ring and with the size of the attacking species.<sup>71</sup>

3. When a *meta*-directing group is *meta* to an *ortho/para*-directing group, the incoming group primarily goes *ortho* to the *meta*-directing group rather than *para*. For example, chlorination of **15** gives mostly **16**. The importance of this effect is underscored by the fact that **17**, which is in violation of the preceding rule, is formed in smaller amounts, but **18** is not formed at all. This is called the *ortho effect*,<sup>72</sup> and many such examples are known.<sup>73</sup>

Another is the nitration of *p*-bromotoluene, which gives 2,3-dinitro-4-bromotoluene. In this case, once the first nitro group came in, the second was directed *ortho* to it rather than *para*, even though this means that the group has to come in between two groups in the *meta* position. There is no good explanation yet for the *ortho effect*, though possibly there is intramolecular assistance from the *meta*-directing group.

It is interesting that chlorination of **15** illustrates all three rules. Of the four positions open to the electrophile, the 5 position violates rule 1, the 2 position violates rule 2, and the 4 position violates rule 3. The principal attachment is therefore at position 6.

### 11.B.v. Orientation in Other Ring Systems<sup>74</sup>

In fused ring systems, the positions are not equivalent and there is usually a preferred orientation, even in the unsubstituted hydrocarbon. The preferred positions may often be predicted as for benzene rings. Thus it is possible to draw more canonical forms for the arenium ion when attack by naphthalene leads to attachment of the electrophile at the  $\alpha$  position than when attack by naphthalene leads to attachment of the electrophile at the  $\beta$  position. Therefore, the  $\alpha$  position is the preferred site of attachment,<sup>75</sup> although, as previously mentioned (Sec. 11.B.i), the isomer formed by substitution at the  $\beta$  position is thermodynamically more stable and is the product if the reaction is reversible and equilibrium is reached. Because of the more extensive delocalization of charges in the corresponding arenium ions, naphthalene is more reactive than benzene and substitution is faster at both positions. Similarly,

<sup>71</sup> See Kruse, L.I.; Cha, J.K. *J. Chem. Soc., Chem. Commun.* **1982**, 1333.

<sup>72</sup> This is not the same as the *ortho effect* mentioned at the end of Sec. 9.C.

<sup>74</sup> See Hafner, H.; Moritz, K.L. in Olah, G.A. *Friedel-Crafts and Related Reactions*, Vol. 4, Wiley, NY, **1965**, pp. 127–183; Bublitz, D.E.; Rinehart Jr., K.L. *Org. React.* **1969**, *17*, 1.

<sup>75</sup> See de la Mare, P.B.D.; Ridd, J.H. *Aromatic Substitution, Nitration and Halogenation*, Academic Press, NY, **1959**, pp. 169–209.

anthracene, phenanthrene, and other fused polycyclic aromatic hydrocarbons are also substituted faster than benzene.

Heterocyclic compounds, too, have nonequivalent positions, and the principles are similar,<sup>76</sup> in terms of mechanism, and rate data is available.<sup>77</sup> Furan, thiophene, and pyrrole are chiefly substituted at the 2 position, and all are substituted faster than benzene.<sup>78</sup> Pyrrole is particularly reactive, with a reactivity approximating that of aniline or the phenoxide ion. For pyridine,<sup>79</sup> it is not the free base that must attack the electrophile but the conjugate acid (the pyridinium ion),<sup>80</sup> making the reactivity much less than that of benzene, being similar to that of nitrobenzene. The 3 position is most reactive in electrophilic substitution reactions of pyridine. However, groups can be introduced into the 4 position of a pyridine ring indirectly, by performing the reaction on the corresponding pyridine *N*-oxide.<sup>81</sup> Note that calculations show that the 2-pyridyl and 2-pyrimidyl cations are best represented as *ortho* hetaryinium ions, being more stable than their positional, nonconjugated isomers by as much as 18–28 kcal mol<sup>-1</sup> (75–117 kJ mol<sup>-1</sup>).<sup>82</sup>

When fused ring systems contain substituents, successful predictions can often be made by using a combination of the above principles. Thus, ring A of 2-methylnaphthalene is activated by the methyl group; ring B is not (although the presence of a substituent in a fused ring system affects all the rings,<sup>83</sup> the effect is generally greatest on the ring to which it is attached). Substitution is therefore expected in ring A. The methyl group activates positions 1 and 3, which are *ortho* to itself, but not position 4, which is *meta* to it. However, substitution at the 3 position gives rise to an arenium ion for which it is impossible to write a low-energy canonical form in which ring B has a complete sextet. Only forms like **19** are possible, in which the sextet is no longer intact. In contrast, substitution at the 1 position gives rise to a more stable arenium ion, for which two canonical forms (one of them is **20**) can be written in which ring B is benzenoid.

<sup>83</sup> See Ansell, H.V.; Sheppard, P.J.; Simpson, C.F.; Stroud, M.A.; Taylor, R. *J. Chem. Soc., Perkin Trans. 2* **1979**, 381.

We thus predict predominant substitution at C-1, and that is what is generally found.<sup>84</sup> However, in some cases predictions are much harder to make. For example, chlorination or nitration of 1-(*N*-acetyl)-2-ethoxynaphthalene gave mainly the 4 derivative, but bromination yielded chiefly the 6 compound.<sup>85</sup>

For fused heterocyclic systems too, predictions can be made based on the above principles, although many exceptions are known. Thus, indole is chiefly substituted in the pyrrole ring (at position 3) and reacts faster than benzene, while quinoline and isoquinoline generally react in the benzene ring, at the 5 and 8 positions, and react slower than benzene but faster than pyridine.

When strain due to a ring fused on an aromatic ring deforms that ring out of planarity, the molecule is more reactive to electrophilic aromatic substitution.<sup>86</sup> This effect has been explained by the presence of a shortened bond for the  $sp^2$ -hybridized carbon, increasing the strain at that position, and this is known as the *Mills-Nixon effect*.<sup>87</sup> There is EPR evidence (Sec. 5.C.i) for 3,6-dimethyl-1,2,4,5-tetrahydrobenzo-*bis*-cyclobutene (**21**) that supports the Mills-Nixon effect,<sup>88</sup> and a theoretical study supports this.<sup>89</sup> However, *ab initio* studies of triannulated benzene rings shows *no evidence* for the Mills-Nixon effect, and a new motif for bond-alternating benzenes was proposed.<sup>90</sup> Indeed, it is argued that the Mills-Nixon effect is not real.<sup>91</sup>

### 11.C. QUANTITATIVE TREATMENTS OF REACTIVITY IN THE SUBSTRATE

Quantitative rate studies of aromatic substitutions are complicated by the fact that there are usually several hydrogen atoms that can leave, so that measurements of overall rate ratios

<sup>84</sup> Kim, J.B.; Chen, C.; Krieger, J.K.; Judd, K.R.; Simpson, C.C.; Berliner, E. *J. Am. Chem. Soc.* **1970**, *92*, 910. See Gore, P.H.; Siddiquei, A.S.; Thorburn, S. *J. Chem. Soc., Perkin Trans. 1* **1972**, 1781.

<sup>91</sup> Siegel, J.S. *Angew. Chem. Int. Ed.* **1994**, *33*, 1721.

do not give a complete picture as they do in nucleophilic substitutions, where it is easy to compare substrates that have only one possible leaving group in a molecule. What is needed is not, say, the overall rate ratio for acetylation of toluene versus that for benzene, but the *rate ratio at each position*. These can be calculated from the overall rates and a careful determination of the proportion of isomers formed, provided that the products are kinetically controlled, as is usually the case. The *partial rate factor* may be defined for a given group and a given reaction as the rate of substitution at a single position relative to a single position in benzene. For example, for acetylation of toluene the partial rate factors are: for the *ortho* position  $o_f^{\text{Me}} = 4.5$ , for the *meta*  $m_f^{\text{Me}} = 4.8$ , and for the *para*  $p_f^{\text{Me}} = 749$ .<sup>92</sup> This means that toluene is acetylated at the *ortho* position 4.5 times as fast as a single position in benzene, or 0.75 times as fast as the overall rate of acetylation of benzene.<sup>93</sup> A partial rate factor  $> 1$  for a given position indicates that the group in question activates that position for the given reaction. Partial rate factors differ from one reaction to another and are even different, though less so, for the same reaction under different conditions.

Once the partial rate factors are known, the proportions of isomers to be obtained when two or more groups are present on a ring can be predicted, *if the assumption is made that the effect of substituents is independent*. For example, if the two methyl groups in *m*-xylene have the same effect as the methyl group in toluene, the theoretical partial rate factors at each position can be calculated by multiplying those from toluene. It is therefore possible to calculate the overall theoretical rate ratio for acetylation of *m*-xylene relative to benzene, since this is one-sixth the sum of the partial rate factors and the isomer distribution if the reaction is kinetically controlled.<sup>94</sup> The calculated agreement can be fairly good, but many cases are known where the effects are not additive (as in Sec. 11.B.ii).<sup>95</sup> For example, this treatment predicts that for 1,2,3-trimethylbenzene there should be 35% 5 substitution and 65% 4 substitution, but acetylation gave 79% 5 substitution and 21% of the 4 isomer. The treatment is thrown off by steric effects, such as those mentioned earlier (Sec. 11.B.iv), by products arising from ipso attack (Sec. 11.B.ii), and by resonance interaction *between* groups (e.g., **22**), which must make the results deviate from simple additivity of the effects of the groups.

Another approach that avoids the problem created by having competing leaving groups present in the same substrate is the use of substrates that contain only one leaving group. This is most easily accomplished by the use of a leaving group other than hydrogen. By this means overall rate ratios can be measured for specific positions.<sup>96</sup> Results obtained in this way<sup>97</sup> give a reactivity order quite consistent with that for hydrogen as leaving group.

<sup>97</sup> See Eaborn, C.; Jackson, P.M. *J. Chem. Soc. B* **1969**, 21.

A quantitative scale of reactivity for aromatic substrates (fused, heterocyclic, and substituted rings) has been devised, based on the hard–soft acid–base concept (Sec. 8.E).<sup>98</sup> From molecular orbital theory, a quantity called *activation hardness* can be calculated for each position of an aromatic ring. The smaller the activation hardness, the faster the attachment at that position; hence the treatment predicts the most likely orientations for incoming groups.

#### 11.D. A QUANTITATIVE TREATMENT OF REACTIVITY OF THE ELECTROPHILE: THE SELECTIVITY RELATIONSHIP

Not all electrophiles are equally reactive. The nitronium ion is attacked not only by benzene but also by aromatic rings that contain a strongly deactivating group. On the other hand, diazonium ions couple only with rings containing a powerful activating group. Attempts have been made to correlate the influence of substituents with the reactivity of the group being attacked. The most obvious way to do this is with the *Hammett equation* (Sec. 8.G):

$$\log F(k/k_0) = \rho\sigma$$

For aromatic substitution,<sup>99</sup>  $k_0$  is divided by 6 and, for *meta* substitution,  $k$  is divided by 2, so that comparisons are made for only one position (consequently,  $k/k_0$  for, say, the methyl group at a *para* position is identical to the partial rate factor  $p_f^{\text{Me}}$ ). It was soon found that, while this approach worked fairly well for electron-withdrawing groups, it failed for those that are electron donating. However, if the equation is modified by the insertion of the Brown  $\sigma^+$  values instead of the Hammett  $\sigma$  values (because a positive charge develops during the transition state), more satisfactory correlations can be made, even for electron-donating groups.<sup>100</sup> Groups with a negative value of  $\sigma_p^+$  or  $\sigma_m^+$  are activating for that position; groups with a positive value are deactivating. The  $\rho$  values correspond to the susceptibility of the reaction to stabilization or destabilization by the Z group and to the reactivity of the electrophile. The  $\rho$  values vary not only with the electrophile, but also with conditions. A large negative value of  $\rho$  means an electrophile of relatively low reactivity. Of course, this approach is completely useless for *ortho* substitution, since the Hammett equation does not apply there.

A modification of the Hammett approach, suggested by Brown, called the *selectivity relationship*,<sup>101</sup> is based on the principle that reactivity of a species varies inversely with selectivity. The selectivity was measured by two indexes: (i) their selectivity in attacking toluene rather than benzene, and (ii) their selectivity between the *meta* and *para* positions in toluene.<sup>101</sup> An electrophile that is more selective in one respect is also more selective in the other. In many cases, electrophiles known to be more stable (hence less reactive) than others show a higher selectivity, as would be expected. For example, the *tert*-butyl cation is more stable and more selective than the isopropyl (Sec. 5.A.ii), and  $\text{Br}_2$  is more selective than  $\text{Br}^+$ . However, deviations from the relationship are known.<sup>102</sup> Selectivity depends not

<sup>102</sup> See Olah, G.A.; Olah, J.A.; Ohyama, T. *J. Am. Chem. Soc.* **1984**, *106*, 5284.

only on the nature of the electrophile but also on the temperature. As expected, it normally decreases with increasing temperature.

Brown assumed that a good measurement of selectivity was the ratio of the *para* and *meta* partial rate factors in toluene. He defined the selectivity  $S_f$  of a reaction as

$$S_f = \log F \left( p_f^{\text{Me}}, m_f^{\text{Me}} \right)$$

That is, the more reactive the reactive species, the less preference it has for the *para* position compared to the *meta*. If we combine the Hammett-Brown  $\sigma^+\rho$  relationship with the linearity between  $\log S_f$  and  $\log p_f^{\text{Me}}$  and between  $\log S_f$  and  $\log m_f^{\text{Me}}$ , it is possible to derive the following expressions:

$$\log p_f^{\text{Me}} = \frac{\sigma_p^+}{\sigma_p^+ - \sigma_m^+} S_f$$

$$\log m_f^{\text{Me}} = \frac{\sigma_m^+}{\sigma_p^+ - \sigma_m^+} S_f$$

$S_f$  is related to  $\rho$  by  $S_f = \rho(\sigma_p^+ - \sigma_m^+)$ .

The general validity of these equations is supported by a great deal of experimental data on aromatic substitution reactions of toluene.<sup>103</sup> For other substituents, the treatment works well with groups that, like methyl, are not very polarizable. For more polarizable groups the correlations are sometimes satisfactory and sometimes not, probably because each electrophile in the transition state makes a different demand on the electrons of the substituent group. Not only are there substrates for which the treatment is poor, but it fails with very powerful electrophiles, which is why it is necessary to postulate the encounter complex mentioned in Sec. 11.A.i. For example, relative rates of nitration of *p*-xylene, 1,2,4-trimethylbenzene, and 1,2,3,5-tetramethylbenzene were 1.0, 3.7, and 6.4,<sup>104</sup> though the extra methyl groups should enhance the rates much more (*p*-xylene itself reacted 295 times faster than benzene). The explanation is that with powerful electrophiles the reaction rate is so rapid (reaction taking place at virtually every encounter<sup>105</sup> between an electrophile and substrate molecule)<sup>106</sup> that the presence of additional activating groups can no longer increase the rate.<sup>107</sup>

Given this behavior (little selectivity in distinguishing between different substrate molecules), the selectivity relationship would predict that positional selectivity should also be very small. However, it is not. For example, under conditions where nitration of *p*-xylene and 1,2,4-trimethylbenzene takes place at about equal rates, there was no corresponding lack of selectivity at positions *within* the latter.<sup>108</sup> Although steric effects are about the same

<sup>103</sup> Stock, L.M.; Brown, H.C. *Adv. Phys. Org. Chem.* **1963**, *1*, 35 presents many tables of these kinds of data. See also, DeHaan, F.P.; Chan, W.H.; Chang, J.; Ferrara, D.M.; Wainschel, L.A. *J. Org. Chem.* **1986**, *51*, 1591, and other papers in this series.

at both positions, > 10 times as much 5-nitro product was formed as 6-nitro product. It is clear that the selectivity relationship has broken down and it becomes necessary to explain why such an extremely rapid reaction should occur with positional selectivity. The explanation offered is that the rate-determining step is formation of an encounter complex (**12**, Sec. 11.B.ii).<sup>109</sup> Since the position of attachment is not determined in the rate-determining step, the 5:6 ratio is not related to the reaction rate. Essentially the same idea was suggested earlier<sup>110</sup> and for the same reason (failure of the selectivity relationship in some cases), but the earlier explanation specifically pictured the complex as a  $\pi$  complex, and there is evidence against this (Sec. 11.B.ii).

One interesting proposal<sup>111</sup> is that the encounter pair is a radical pair  $\text{NO}_2^\bullet \text{ArH}^{+\bullet}$  formed by an electron transfer (SET), which would explain why the electrophile, once in the encounter complex, can acquire the selectivity that the free  $\text{NO}_2^+$  lacked (it is not proposed that a radical pair is present in all aromatic substitutions; only in those that do not obey the selectivity relationship). The radical pair subsequently collapses to the arenium ion. There is evidence both for<sup>112</sup> and against this proposal.<sup>113</sup>

### 11.E. THE EFFECT OF THE LEAVING GROUP

In the vast majority of aromatic electrophilic substitutions, the leaving group is  $\text{H}^+$ , as indicated above, and very little work has been done on the relative electrofugal ability of other leaving groups. However, the following orders of leaving-group ability have been suggested:<sup>114</sup> (i) for leaving groups that depart without assistance ( $\text{S}_{\text{N}}1$  process with respect to the leaving group),  $\text{NO}_2^+ < i\text{-Pr}^+ \sim \text{SO}_3^+ < t\text{-Bu}^+ \sim \text{ArN}_2^+ < \text{ArCHOH}^+ < \text{NO}^+ < \text{CO}_2^+$ ; (ii) for leaving groups that depart with assistance from an outside nucleophile ( $\text{S}_{\text{N}}2$  process),  $\text{Me}^+ < \text{Cl}^+ < \text{Br}^+ < \text{D}^+ \sim \text{RCO}^+ < \text{H}^+ \sim \text{I}^+ < \text{Me}_3\text{Si}^+$ . This kind of list can be used to help predict which group, X or Y, will cleave from an arenium ion **23** (see **1**, where  $\text{Y} = \text{H}$ ) once it has been formed, and so obtain an idea of which electrophilic substitutions are feasible. However, a potential leaving group can also affect a reaction in another way,

which is by influencing the rate at which attack of the original electrophile leads to attachment directly at the ipso position. Partial rate factors for electrophilic attack at a position substituted by a group other than hydrogen are called ipso partial rate factors ( $i_f^X$ ).<sup>114</sup> Such factors for the nitration of *p*-haloanisoles are 0.18, 0.08, and 0.06, for *p*-iodo-, *p*-bromo-, and *p*-chloroanisole, respectively.<sup>116</sup> This means, for example, that attack at the electrophile in this case leads to attachment at the 4 position of 4-iodoanisole 0.18 times as fast as a single position of benzene. Note that this is far slower than attachment at the 4 position resulting from attack of anisole itself so that the presence of the iodo group greatly slows the reaction at that position. A similar experiment on *p*-cresol showed that ipso attack at the methyl position was 6.8 times slower than attack of phenol leading to attachment at the *para* position.<sup>117</sup> Thus, in these cases, both an iodo and a methyl group deactivate the ipso position.<sup>118</sup>

## 11.F. REACTIONS

The reactions in this chapter are classified according to leaving group. Hydrogen replacements are treated first, and then rearrangements in which the attacking entity is first cleaved from another part of the molecule (hydrogen is also the leaving group in these cases), and finally replacements of other leaving groups.

### 11.F.i. Hydrogen as the Leaving Group in Simple Substitution Reactions

#### A. Hydrogen as the Electrophile

##### 11-1 Hydrogen Exchange

Aromatic compounds can exchange hydrogen atoms when treated with acids. The reaction is used chiefly to study mechanistic questions<sup>119</sup> (including substituent effects), but can also be useful to deuterate (add <sup>2</sup>H) or tritiate (add <sup>3</sup>H) aromatic rings selectively. The usual directive effects apply and, for example, phenol treated with D<sub>2</sub>O gives slow exchange on heating, with only *ortho* and *para* hydrogen atoms being exchanged.<sup>120</sup> Strong acids, of course, exchange faster with aromatic substrates, and this exchange must be taken into account when studying the mechanism of any aromatic substitution catalyzed by acids. There is evidence that exchange takes place by the ordinary arenium ion mechanism, including the orientation effects noted above and the finding that the reaction is general acid catalyzed, which means that a proton is transferred in the slow

step<sup>121</sup> (Sec. 8.D). Furthermore, many examples have been reported of stable solutions of arenium ions formed by attack of a proton on an aromatic ring.<sup>8</sup> Simple aromatic compounds can be extensively deuterated in a convenient fashion by treatment with D<sub>2</sub>O and BF<sub>3</sub>.<sup>122</sup> It has been shown that tritium exchange takes place readily at the 2 position of **24**, despite the fact that this position is hindered by the bridge, and that the rates were not very different from the comparison compound 1,3-dimethylnaphthalene.<sup>123</sup>

Hydrogen exchange can also be effected with strong bases,<sup>124</sup> such as NH<sub>2</sub><sup>-</sup>. In these cases the slow step is the proton transfer:<sup>125</sup> so the S<sub>E</sub>I mechanism and not the usual arenium ion mechanism is operating.<sup>126</sup> Aromatic rings can also be deuterated by treatment with D<sub>2</sub>O and a rhodium(III) chloride<sup>127</sup> or a Pt<sup>128</sup> catalyst or with C<sub>6</sub>D<sub>6</sub> and an alkylaluminum dichloride catalyst,<sup>129</sup> though rearrangements may take place during the latter procedure. Tritium (<sup>3</sup>H, abbreviated T) can be introduced by treatment with T<sub>2</sub>O and an alkylaluminum dichloride catalyst.<sup>129</sup> Tritiation at specific sites (e.g. >90% *para* in toluene) has been achieved with T<sub>2</sub> gas and a microporous aluminophosphate catalyst.<sup>130</sup>

The mechanisms of hydride abstraction by quinones has been discussed.<sup>131</sup>

## B. Nitrogen Electrophiles

### 11-2 Nitration

Most aromatic compounds, whether of high or low reactivity, can be nitrated, and a wide variety of nitrating agents are available.<sup>132</sup> For benzene, the simple alkylbenzenes, and less

reactive compounds, the most common reagent is a mixture of concentrated nitric and sulfuric acids,<sup>133</sup> but for active substrates, the reaction can be carried out with nitric acid alone,<sup>134</sup> or in water, acetic acid, acetic anhydride, or chloroform.<sup>135</sup> Milder conditions are necessary for active compounds, such as amines, phenols, and pyrroles, since reaction with mixed nitric and sulfuric acids would oxidize these substrates. With active substrates, such as anilines<sup>136</sup> and phenols,<sup>137</sup> reagents used for nitration include a mixture of dilute nitrous and nitric acids,<sup>138</sup> NaNO<sub>2</sub> and trifluoroacetic acid,<sup>139</sup> ceric ammonium nitrate,<sup>140</sup> urea nitrate and nitrourea,<sup>141</sup> NBS/AgNO<sub>3</sub>,<sup>142</sup> NaNO<sub>2</sub>, and a hypervalent iodine compound with a Rh catalyst.<sup>143</sup> Phenol can also be nitrated in an ionic liquid.<sup>144</sup> Nitric acid, in the presence of P<sub>2</sub>O<sub>5</sub> supported on SiO<sub>2</sub>, is useful for the nitration of aromatic compounds under solvent-free conditions.<sup>145</sup> Arylboronic acids have been shown to react with ammonium nitrate and trifluoroacetic acid to give the corresponding nitrobenzene.<sup>146</sup> Arylboronic acids reacted with *t*-butyl nitrite at 8 °C in the air to give the corresponding nitro aryl compound.<sup>147</sup>

Phenols are converted to the 2-pyridinyloxy derivative,<sup>148</sup> then reaction with Pd(OAc)<sub>2</sub>, AgNO<sub>2</sub>, and K<sub>2</sub>S<sub>2</sub>O<sub>8</sub> at 110 °C led to the *ortho*-selective nitration, and the 2-pyridinyloxy group was removed by reaction with (i) MeOTf, 100 °C and (ii) 24 equivalents of Na in MeOH at reflux.<sup>149</sup> The reagent NO<sub>2</sub><sup>+</sup> BF<sub>4</sub><sup>-</sup> has been used for the nitration of toluene and the dynamics of the reaction were discussed.<sup>150</sup> Green procedures for the nitration of phenol have been reviewed.<sup>151</sup> An alternative route for the nitration of activated aromatic compounds, such as anisole, used a nitrate ester (RONO<sub>2</sub>) with triflic acid in an ionic liquid for *ortho*-selective nitration.<sup>152</sup> The nitration reaction of 1,2- and 1,4-dimethoxybenzene led

to the regioselective 1,2-dinitration product or the 1,4-dinitration product.<sup>153</sup> Aromatic, as well as aliphatic, carboxylic acids reacted with  $\text{NO}_2\text{BF}_4$  in the presence of  $\text{Ag}_2\text{CO}_3$  at 90 °C to give the aromatic nitro compound or the aliphatic nitro compound.<sup>154</sup> Since the nitro group is deactivating, it is usually easy to stop the reaction after one group has been added, if no activating group is present.

When anilines are nitrated under low-acid conditions, the free amine is nitrated and the orientation is *ortho/para*. Under strong-acid conditions, *meta* orientation is generally observed, because the ammonium salt is the species undergoing nitration, which is the conjugate acid of the amine. Although the free base may be present in much smaller amounts than the conjugate acid, it is far more susceptible to aromatic substitution (see also, Sec. 11.B.i). Because of these factors and because they are vulnerable to oxidation by nitric acid, primary aromatic amines are often protected before nitration by treatment with acetyl chloride (**16-71**) or acetic anhydride (**16-72**). *Nitration of the resulting acetanilide derivative avoids all the problems mentioned here.* There is evidence that when the reaction takes place on the free amine, it is the nitrogen that is attacked to give an *N*-nitro compound ( $\text{Ar-NH-NO}_2$ ) which rapidly undergoes rearrangement (see **11-28**) to give the product.<sup>155</sup>

With most of the reagents mentioned, the attacking species is the nitronium ion  $\text{NO}_2^+$ . There is a great deal of evidence that  $\text{NO}_2^+$  is present in most nitration reactions and that it is the attacking entity.<sup>156</sup>

1. Nitric acid has a peak in the Raman spectrum. When nitric acid is dissolved in concentrated sulfuric acid, the peak disappears and two new peaks appear, one at  $1400\text{ cm}^{-1}$ , attributable to  $\text{NO}_2^+$ , and one at  $1050\text{ cm}^{-1}$ , due to  $\text{HSO}_4^-$ .<sup>157</sup>
2. On addition of nitric acid, the freezing point of sulfuric acid is lowered about four times the amount expected if no ionization has taken place.<sup>158</sup> This means that the addition of one molecule of nitric acid results in the production of four particles, which is strong evidence for the ionization reaction between nitric and sulfuric acids given above.
3. Nitronium salts generally nitrate aromatic compounds, which shows that this ion does attack the ring.
4. The rate of the reaction with most reagents is proportional to the concentration of  $\text{NO}_2^+$ , not to the concentration of other species.<sup>159</sup> When the reagent produces this ion in small amounts, the attack is slow and only active substrates can be nitrated. In concentrated and aqueous mineral acids, the kinetics are second order: first order each in aromatic substrate and in nitric acid (unless pure nitric acid is used in which case there are pseudo-first-order kinetics). But in organic solvents such as nitromethane, acetic acid, and  $\text{CCl}_4$ , the kinetics are first order in nitric acid alone

and zero order in aromatic substrate, because the rate-determining step is formation of  $\text{NO}_2^+$  and the aromatic substrate does not take part in this.

The nitronium ion can be produced by several methods.

1. In concentrated sulfuric acid, it is produced by an acid–base reaction in which nitric acid is the base, and the ionization is essentially complete.

2. In concentrated nitric acid alone,<sup>160</sup> it is produced by a similar acid–base reaction in which one molecule of nitric acid is the acid and another the base. This equilibrium lies to the left (~4% ionization), but enough  $\text{NO}_2^+$  is formed for nitration to occur. This equilibrium occurs to a small extent even in organic solvents.

3. With  $\text{N}_2\text{O}_5$  in  $\text{CCl}_4$ , there is spontaneous dissociation to  $\text{NO}_2^+$  and  $\text{NO}_3^-$ , but in this case there is evidence that some nitration also takes place with undissociated  $\text{N}_2\text{O}_5$  as the electrophile.
4. When nitronium salts are used,  $\text{NO}_2^+$  is of course present to begin with.
5. Esters and acyl halides of nitric acid ionize to form  $\text{NO}_2^+$ .

In a few cases, depending on the substrate and solvent, there is evidence that the arenium ion is not formed directly, but via the intermediacy of a radical pair (Sec. 11.D) such as **25**.<sup>161</sup>

Functionalized aromatic compounds reacted with  $\text{Cu}(\text{NO}_3)_2 \cdot 3\text{H}_2\text{O}$  with a Ru catalyst to give the *meta*-substituted nitro compound.<sup>162</sup> The Cu-catalyzed ipso nitration of haloarenes or heterocyclic haloarenes has been reported.<sup>163</sup> The ipso nitration of arylboronic acids has been reported using bismuth nitrate and perdisulfate,<sup>164</sup> and sodium nitrite and  $\text{ClSiMe}_3$  has also been used.<sup>165</sup> The nitration of arynes by 2 equivalents of  $\text{NaNO}_2$  in water/MeCN

### 11-3 Nitrosation

Ring nitrosation<sup>171</sup> with nitrous acid is normally carried out only with active substrates, such as amines and phenols. However, primary aromatic amines give diazonium ions (**13-19**) when treated with nitrous acid,<sup>172</sup> and secondary amines tend to give *N*-nitroso rather than *C*-nitroso compounds (**12-49**). Therefore, this reaction is normally limited to phenols and tertiary aromatic amines. Nevertheless, secondary aromatic amines can be *C*-nitrosated in two ways. The *N*-nitroso compound first obtained can be isomerized to a *C*-nitroso compound (**11-29**), or it can be treated with another equivalent of nitrous acid to give an *N,C*-dinitroso compound. Also, a successful nitrosation of anisole has been reported, where the solvent was  $\text{CF}_3\text{COOH}-\text{CH}_2\text{Cl}_2$ .<sup>173</sup>

Much less work has been done on the mechanism of this reaction than on **11-2**.<sup>174</sup> In some cases, the attacking entity is  $\text{NO}^+$ , but in others it is apparently  $\text{NOCl}$ ,  $\text{NOBr}$ ,  $\text{N}_2\text{O}_3$ , and so on, in each of which there is a carrier of  $\text{NO}^+$ . Both  $\text{NOCl}$  and  $\text{NOBr}$  are formed during the normal process of making nitrous acid (the treatment of sodium nitrite with  $\text{HCl}$  or  $\text{HBr}$ ). Nitrosation requires active substrates because kinetic studies have shown that  $\text{NO}^+$  is at least  $10^{14}$  times less reactive than  $\text{NO}_2^+$ .<sup>175</sup> A consequence of the relatively high stability of  $\text{NO}^+$  is that this species is easily cleaved from the arenium ion, so that  $k_{-1}$  competes with  $k_2$  (Sec. 11.A.i) and isotope effects are found.<sup>176</sup> With phenols, there is evidence that nitrosation may first take place at the OH group, after which the nitrite ester thus formed

rearranges to the *C*-nitroso product.<sup>177</sup> Tertiary aromatic amines substituted in the *ortho* position generally do not react with HONO, probably because the *ortho* substituent prevents planarity of the dialkylamino group, without which the ring is no longer activated. This is an example of steric inhibition of resonance (Sec. 2.F).

OS I, 214, 411, 511; II, 223; IV, 247.

#### 11-4 Amination or Phosphination<sup>178</sup> (*N*-Arylation)

Aromatic compounds can be converted to primary aromatic amines<sup>179</sup> by treatment with hydrazoic acid  $\text{HN}_3$  in the presence of  $\text{AlCl}_3$  or  $\text{H}_2\text{SO}_4$ .<sup>180</sup> Higher yields (>90%) have been reported with trimethylsilyl azide ( $\text{Me}_3\text{SiN}_3$ ) and triflic acid ( $\text{F}_3\text{CSO}_2\text{OH}$ ).<sup>181</sup> Tertiary amines have been prepared by treatment of aromatic hydrocarbons with *N*-chlorodialkylamines, by heating in 96% sulfuric acid, with  $\text{AlCl}_3$  or  $\text{FeCl}_3$  in nitroalkane solvents, or by irradiation.<sup>182</sup> Treatment of an aryl halide with an amine and a Pd catalyst leads to the aniline derivative.<sup>183</sup> The ligand-free amination of haloarenes by reaction with an amine and  $\text{Pd}_2(\text{dba})_3$  as a catalyst, with microwave irradiation, has been reported.<sup>184</sup> Recyclable Pd catalysts for this reaction have been developed.<sup>185</sup>

The Ni-catalyzed reaction of aryl halides and ammonia has been reported.<sup>186</sup> Aryl halides reacted with aqueous ammonia when heated with PG-400 and CuI to give the arylamine.<sup>187</sup> Magnetically separable  $\text{CuFe}_2\text{O}_4$  nanoparticles in PEG have been used for the reaction of aryl halides and ammonia to give the arylamine.<sup>188</sup> Arylzinc reagents react with benzyloxyamines with a Cu catalyst to give the arylamine.<sup>189</sup> A *meta*-selective C–H amination reaction has been reported by the reaction of aniline derivatives with *N*-benzyloxyamines with a Pd catalyst and hydroxypyridine ligands and a modified norbornene mediator.<sup>190</sup>

Diphenyliodonium salts react with amines in the presence of a Cu catalyst. Diphenyliodonium tetrafluoroborate,  $\text{Ph}_2\text{I}^+ \text{BF}_4^-$ , reacts with indole in DMF at 150 °C

with a  $\text{Cu}(\text{OAc})_2$  catalyst, for example, to give *N*-phenylindole.<sup>191</sup> Aryliodonium compounds reacted directly with amides, without a metal catalyst but with NaH, to give the *N*-arylamide.<sup>192</sup> The amination of arenes with heteroaromatic amines and hypervalent iodine(III) reagents to give a new arylamine has been reported.<sup>193</sup>

Benzoxazoles are converted to the 2-amino compound by reaction with an amine and a NIS catalyst, with 2 equivalents of acetic acid and 2 equivalents of aq.  $\text{H}_2\text{O}_2$ .<sup>194</sup> Aryl halides reacted with  $\text{NH}_4\text{OH}$  in the presence of a CuI catalyst to give the arylamine.<sup>195</sup> The reaction of aryl halides with secondary amines, catalyzed by a Pd catalyst, with heating and an air-stable ligand, provided the arylamine.<sup>196</sup> Aromatic compounds have been converted to the corresponding arylamine via initial treatment with NBS in the presence of  $\text{FeCl}_3$  in  $(\text{bmim})_2\text{NTf}_2$  to form the aryl bromide in situ, and subsequent treatment with an amine in the presence of CuI gave the amine.<sup>197</sup> Arylsilanes reacted with amines in the presence of 3 equivalents of CuI, and 2 equivalents each of  $\text{Na}_2\text{CO}_3$  and NaF, in the presence of air, to give the arylamine.<sup>198</sup> Aryl halides reacted with amides in the presence of a Pd catalyst to give the corresponding *N*-arylamine.<sup>199</sup> Aryl halides also reacted with amines in the presence of a *N*-heterocyclic carbene Pd catalyst to give the arylamine.<sup>200</sup>

The reaction of heteroarenes with butyllithium and then  $\text{ClAlEt}_2$  gave the heteroaryl- $\text{AlEt}_2$  derivative, and reaction with benzyloxyamines and a Pt catalyst gave the heteroarylamine.<sup>201</sup> Aryl boroxines react with *O*-benzoyl amines with heating and 2 equivalents of  $\text{K}_2\text{CO}_3$  to give *N*-arylamines.<sup>202</sup> The metal-free anodic oxidation of arenes with pyridine and  $\text{Bu}_4\text{NBF}_4$  gave the corresponding pyridinium salt, which was heated with piperidine to give the arylamine.<sup>203</sup> Aryl halides have also been coupled to *N*-trimethylsilylamines using a Pd catalyst to give arylamines.<sup>204</sup>

Aryl- and heteroaryl compounds were first treated with an iodonium compound and then an amine, in the presence of a Cu catalyst, to give the arylamine or the heteroarylamine.<sup>205</sup> Aryl or heteroaryl chlorides reacted with amines in the presence of CuI and oxalic diamide ligands to give the arylamine or the heteroarylamine.<sup>206</sup> The Cu-catalyzed reaction of arylboronic acids with amines has been reported.<sup>207</sup> The Cu-catalyzed reaction of boronic acids and amines is known to give the corresponding arylamine.<sup>208</sup> Aromatic compounds reacted

with  $\text{NaN}_3$  and  $\text{BF}_3\text{--H}_2\text{O}$  to give the arylamine.<sup>209</sup> Aryl or heteroaryl chlorides or sulfonate esters reacted with amines with a Ni catalyst to give the corresponding aryl or heteroarylamine.<sup>210</sup>

Tertiary (and to a lesser extent, secondary) aromatic amines can also be prepared in moderate to high yields by amination with an *N*-chlorodialkylamine (or an *N*-chloroalkylamine) and a metallic-ion catalyst (e.g.,  $\text{Fe}^{2+}$ ,  $\text{Ti}^{3+}$ ,  $\text{Cu}^+$ ,  $\text{Cr}^{2+}$ ) in the presence of sulfuric acid.<sup>211</sup> The attacking species in this case is the aminium radical ion  $\text{R}_2\text{NH}\cdot$  formed by reaction of dialkylammonium chloride and the metal.<sup>212</sup> When an alkyl group is present, attack at the benzylic position competes with ring substitution. Aromatic rings containing only *meta*-directing groups do not give the reaction at all. Fused ring systems react well.<sup>213</sup>

Aryl hydrazines have been prepared by the copper-catalyzed cross-coupling of aryl bromides and hydrazine, in water.<sup>214</sup> The reaction with hydrazine has also been done using continuous flow techniques (Sec. 7.D).<sup>215</sup>

Direct *amidation* can be carried out if an aromatic compound is heated with a hydroxamic acid ( $\text{RCONHOH}$ ) in polyphosphoric acid, but the scope is essentially limited to phenolic ethers.<sup>216</sup> Naphthol reacted with a substituted hydrazine to give the 1-amino derivative.<sup>217</sup> Arenes reacted with 2 equivalents of  $\text{TsNH}_2$  in the presence of  $\text{Cu}(\text{OAc})_2$  to give the aryl tosylamide when heated to 130 °C.<sup>218</sup> *N*-Arylbenzamides reacted with *O*-benzoyl hydroxylamines using Pd catalysts to give the *ortho*-dialkylamino *N*-arylbzamide.<sup>219</sup>

Potassium aryltrifluoroborates were converted to the corresponding arylamine by reaction with  $\text{NH}_4\text{OH}$  in the presence of  $\text{CuSO}_4$  as the catalyst.<sup>220</sup>

Aryl, vinyl, benzylic, and allyl esters react with phosphorus compounds in the presence of a Ni catalyst gave C—O bond cleavage and formation of the organophosphorus compound.<sup>221</sup> The Cu-catalyzed arylation of secondary phosphine oxides with diaryliodonium salts gave tertiary phosphine oxides with good enantioselectivity.<sup>222</sup> The Ni-catalyzed reaction of aryl iodides and H-phosphinates gave the corresponding aryl phosphinate.<sup>223</sup> Aryl

iodides reacted with  $\text{Ph}_2\text{PCL}$  using  $\text{PdCl}_2$  and tetrabutylammonium bromide to give the corresponding arylphosphine.<sup>224</sup> 4-Tosyl or mesyl functionalized aryl derivatives reacted with phosphites in the presence of a Pd catalyst to give the phosphorylated aryl derivative.<sup>225</sup>

Also see, **13-5**, **13-16**.

### 11-5 Direct Introduction of the Diazonium Group

Diazonium salts can be prepared directly by replacement of an aromatic hydrogen without the necessity of going through the amino group.<sup>226</sup> The reaction is essentially limited to active substrates (amines and phenols), since otherwise poor yields are obtained. Since the reagents and the substrate are the same as in reaction **11-3**, the first species formed is the nitroso compound. In the presence of excess nitrous acid, this is converted to the diazonium ion.<sup>227</sup> A synthesis of solid aryldiazonium chlorides is now available.<sup>228</sup> Aryldiazomethanes have been prepared using continuous flow synthesis (sec.7.D).<sup>229</sup>

### 11-6 Diazonium Coupling

Aromatic diazonium ions normally couple only with active substrates such as amines and phenols.<sup>230</sup> Many of the products of this reaction are used as dyes (*azo dyes*).<sup>231</sup> The mechanism of (*Z/E*)-isomerization in  $\text{Ar}-\text{N}=\text{N}-\text{Ar}$  systems has been studied.<sup>232</sup> Substitution is mostly *para* to the activating group, unless that position is already occupied, in which case *ortho* substitution takes place. The pH of the solution is important both for phenols and amines. For amines, the solutions may be mildly acidic or neutral. The fact that amines give *ortho* and *para* products shows that even in mildly acidic solution they react in their un-ionized form. If the acidity is too high, the reaction does not occur, because the concentration of free amine becomes too small. Phenols must be coupled in slightly alkaline solution where they are converted to the more reactive phenoxide ions, because phenols themselves are not active enough for the reaction. However, neither phenols nor amines react in moderately alkaline solution, because the diazonium ion is converted to a diazo hydroxide  $\text{Ar}-\text{N}=\text{N}-\text{OH}$ .

<sup>230</sup> See Szele, I.; Zollinger, H. *Top. Curr. Chem.* **1983**, 112, 1; Hegarty, A.F. in Patai, S. *The Chemistry of Diazonium and Diazo Groups*, pt. 2, Wiley, NY, **1978**, pp. 545–551.

<sup>231</sup> See Zollinger, H. *Color Chemistry*, VCH, NY, **1987**, pp. 85–148; Gordon, P.F.; Gregory, P. *Organic Chemistry in Colour*, Springer, NY, **1983**, pp. 95–162.

<sup>232</sup> Asano, T.; Furuta, H.; Hofmann, H.-J.; Cimiraglia, R.; Tsuno, Y.; Fujio, M. *J. Org. Chem.* **1993**, 58, 4418.

Primary and secondary amines face competition from attack at the nitrogen.<sup>233</sup> However, the resulting *N*-azo compounds (aryl triazenes) can be isomerized to *C*-azo compounds (**11-30**). In at least some cases, even when the *C*-azo compound is isolated, it is the result of initial *N*-azo compound formation followed by isomerization. It is therefore possible to synthesize the *C*-azo compound directly in one laboratory step.<sup>234</sup> Acylated amines and phenolic ethers and esters are ordinarily not active enough for this reaction, though it is sometimes possible to couple them (as well as such polyalkylated benzenes as mesitylene and pentamethylbenzene) to diazonium ions containing electron-withdrawing groups in the *para* position, since such groups increase the concentration of the positive charge and thus the electrophilicity of the  $\text{ArN}_2^+$ . Phase-transfer catalysis has also been used.<sup>235</sup>

Coupling of a few aliphatic diazonium compounds to aromatic rings has been reported, involving cyclopropanediazonium ions and bridgehead diazonium ions, in which loss of  $\text{N}_2$  would lead to very unstable carbocations.<sup>236</sup>

## C. Sulfur Electrophiles

### 11-7 Sulfonation

Aromatic derivatives are converted to the corresponding aryl sulfonic acid. The sulfonation reaction is very broad in scope and many aromatic hydrocarbons (including fused ring systems), aryl halides, ethers, carboxylic acids, amines,<sup>237</sup> acylated amines, ketones, nitro compounds, and sulfonic acids have been sulfonated.<sup>238</sup> Phenols can also be successfully sulfonated, but attack at oxygen may compete.<sup>239</sup> Sulfonation is often accomplished with concentrated sulfuric acid, but it can also be done with fuming sulfuric acid,  $\text{SO}_3$ ,<sup>240</sup>  $\text{ClSO}_2\text{OH}$ ,  $\text{ClSO}_2\text{NMe}_2/\text{In}(\text{OTf})_3$ ,<sup>241</sup> or other reagents.<sup>242</sup> A  $\text{FeCl}_3$ -based ionic liquid has been used for the sulfonation of aromatic compounds.<sup>243</sup> Since this is a reversible reaction (see **19-74**), it may be necessary to drive the reaction to completion. However, at low temperatures the reverse reaction is very slow and the forward reaction is practically irreversible.<sup>244</sup> Sulfur trioxide reacts much more rapidly than sulfuric acid with benzene; the reaction is nearly instantaneous. Sulfones are often side products. When sulfonation is carried out on a benzene ring containing four or five alkyl and/or halogen groups, rearrangements usually occur (see **11-36**). The mechanism has been discussed, comparing a concerted mechanism versus

the  $S_EAr$  mechanism.<sup>245</sup> Molecular mechanics showed that in nonpolar media and “in the absence of catalysts the mechanism of aromatic sulfonation with a single  $SO_3$  is concerted and does not involve the conventionally depicted 1:1  $\sigma$  complex (Wheland) intermediate. In polar, higher dielectric  $SO_3$ -complexing media, the calculations favor an  $S_EAr$  mechanism for the 2:1 reaction involving a Wheland-type arene- $(SO_3)_2$  dimer intermediate.”<sup>245</sup>

A great deal of work has been done on the mechanism,<sup>246</sup> chiefly by Cerfontain and co-workers. Mechanistic study is made difficult by the complicated nature of the solutions. Indications are that the electrophile varies with the reagent, though  $SO_3$  is involved in all cases, either free or combined with a carrier. In aqueous  $H_2SO_4$  solutions, the electrophile is thought to be  $H_3SO_4^+$  (or a combination of  $H_2SO_4$  and  $H_3O^+$ ) at concentrations below ~80–85%  $H_2SO_4$ , and  $H_2S_2O_7$  (or a combination of  $H_2SO_4$  and  $SO_3$ ) at concentrations higher than this<sup>247</sup> (the changeover point varies with the substrate<sup>248</sup>). Evidence for a change in electrophile is that in both the dilute and the concentrated solutions the rate of the reaction was proportional to the activity of  $H_3SO_4^+$  and  $H_2S_2O_7$ , respectively. Further evidence is that with toluene as substrate the two types of solution gave very different *ortho/para* ratios. The mechanism is essentially the same for both electrophiles and may be shown as:<sup>247</sup>

The other product of the first step is  $HSO_4^-$  or  $H_2O$  from  $H_2S_2O_7$  or  $H_3SO_4^+$ , respectively. Path *a* is the principal route, except at very high  $H_2SO_4$  concentrations, when path *b* becomes important. With  $H_3SO_4^+$  the first step is rate determining under all conditions, but with  $H_2S_2O_7$  the first step is the slow step only up to ~96%  $H_2SO_4$ , when a subsequent proton transfer becomes partially rate determining.<sup>249</sup> The  $H_2S_2O_7$  is more reactive than  $H_3SO_4^+$ . In fuming sulfuric acid ( $H_2SO_4$  containing excess  $SO_3$ ), the electrophile appears to be dependent on the concentration.<sup>250</sup> Finally, when pure  $SO_3$  is the reagent in aprotic solvents,  $SO_3$  itself is the actual electrophile.<sup>251</sup> Free  $SO_3$  is the most reactive of all these species, so that attack here is generally fast and a subsequent step is usually rate determining, at least in some solvents.

## 11-8 Halosulfonation

Aromatic sulfonyl chlorides can be prepared directly, by treatment of aromatic rings with chlorosulfuric acid.<sup>252</sup> Since sulfonic acids can also be prepared by the same reagent (**11-7**), it is likely that they are intermediates, being converted to the halides by excess chlorosulfuric acid.<sup>253</sup> The reaction has also been effected with bromo- and fluorosulfuric acids. Sulfonyl chlorides (ArSOCl) have been prepared by the reaction of thionyl chloride and an aromatic compound on Montmorillonite K-10 clay.<sup>254</sup>

OS I, 8, 85.

## 11-9 Sulfonylation

Diaryl sulfoxides can be prepared by the reaction of aromatic compounds with thionyl chloride and triflic acid.<sup>255</sup> Diaryl sulfones have also been prepared using thionyl chloride with the ionic liquid [bmim]Cl•AlCl<sub>3</sub>.<sup>256</sup> Diaryl sulfones can be formed by treatment of aromatic compounds with aryl sulfonyl chlorides and a *Friedel-Crafts catalyst*.<sup>257</sup> This reaction is analogous to *Friedel-Crafts acylation* with carboxylic acid halides (**11-17**). In a better procedure, the aromatic compound is treated with an aryl sulfonic acid and P<sub>2</sub>O<sub>5</sub> in polyphosphoric acid.<sup>258</sup> Indium *tris*(triflate)<sup>259</sup> and indium trichloride<sup>260</sup> lead to sulfonylation of aromatic compounds in the presence of sulfonyl chlorides. Indium bromide was used with indoles.<sup>261</sup> A ferric chloride-catalyzed reaction with microwave irradiation has also been reported,<sup>262</sup> as has the use of zinc metal with microwave irradiation.<sup>263</sup> The reaction can be extended to the preparation of alkyl aryl sulfones by the use of a sulfonyl fluoride.<sup>264</sup>

the reaction with anilines before all the available *ortho* and *para* positions are substituted, because the initially formed haloamines are weaker bases than the original amines and are less likely to be protonated by the liberated HX.<sup>279</sup> For this reason, the corresponding anilides (*N*-acylaniline derivatives) are used if monosubstitution is desired. With phenols it is possible to stop after one group has entered.<sup>280</sup> The rapid room-temperature reaction with amines and phenols is often used as a test for these compounds. In general, for active substrates (including anilines, phenols, naphthalene, and polyalkylbenzenes<sup>281</sup> such as mesitylene and isodurene), no catalyst is needed. The overall effectiveness of reagents in aromatic substitution is  $\text{Cl}_2 > \text{BrCl} > \text{Br}_2 > \text{ICl} > \text{I}_2$ . A mixture of  $\text{ZnBr}_2$ /diazene has been suggested for the regioselective *para* bromination of activated aromatic substrates.<sup>282</sup>

When chlorination or bromination is carried out at high temperatures (e.g., 300–400 °C), *ortho/para*-directing groups direct *meta* and vice versa.<sup>283</sup> A different mechanism operates here, which is not completely understood. It is also possible for bromination to take place by the  $\text{S}_{\text{E}}1$  mechanism. An example is the *t*-BuOK-catalyzed bromination of 1,3,5-tribromobenzene.<sup>284</sup>

For reactions in the absence of a catalyst, the reactive species is  $\text{Br}_2$  or  $\text{Cl}_2$  that has been polarized by the ring (remember that halogens are polarizable).<sup>285</sup> Evidence for molecular chlorine or bromine as the attacking species in these cases is that acids, bases, and other ions, especially chloride ion, accelerate the rate about equally, though if chlorine dissociated into  $\text{Cl}^+$  and  $\text{Cl}^-$ , the addition of chloride should decrease the rate and the addition of acids should increase it. Intermediate **26** has been detected spectrally in the aqueous bromination of phenol.<sup>286</sup>

For less activated aromatic rings, Fe was commonly used at one time for halogenation, but the real catalyst was shown not to be the iron itself, but rather the  $\text{FeBr}_3$  or  $\text{FeCl}_3$  formed in small amounts from the reaction between iron and the reagent. Indeed, ferric chloride and other Lewis acids are typically directly used as catalysts, as is iodine. Many Lewis acids can be used, including thallium(III) acetate, which promotes bromination with high regioselectivity *para* to an *ortho/para*-directing group.<sup>287</sup>

<sup>287</sup> McKillop, A.; Bromley, D.; Taylor, E.C. *J. Org. Chem.* **1972**, *37*, 88.

When a Lewis-acid catalyst<sup>288</sup> is used with chlorine or bromine, the attacking entity may be  $\text{Cl}^+$  or  $\text{Br}^+$ , formed by  $\text{FeCl}_3 + \text{Br}_2 \rightarrow \text{FeCl}_3\text{Br}^- + \text{Br}^+$ , or it may be  $\text{Cl}_2$  or  $\text{Br}_2$ . With other reagents, the attacking entity in brominations may be  $\text{Br}^+$  or a species, such as  $\text{H}_2\text{OBr}^+$  (the conjugate acid of HOBr), in which  $\text{H}_2\text{O}$  is a carrier of  $\text{Br}^+$ .<sup>289</sup>

Other reagents can be used to promote chlorination or bromination. The Cu-catalyzed chlorination has been reported using dioxygen as an oxidant.<sup>290</sup> *N*-Bromosuccinimide (NBS) under photochemical conditions<sup>291</sup> brominates aromatic compounds, as does pyridinium bromide perbromide,<sup>292</sup> and NBS in acetic acid with ultrasound is effective.<sup>293</sup> Both NCS and NBS with aqueous  $\text{BF}_3$  gave the respective chloride or bromide.<sup>294</sup> NBS in an ionic liquid<sup>295</sup> gave the brominated aromatic, and *para* bromination of aniline was reported by mixing aniline with the ionic liquid, bmim  $\text{Br}_2$ .<sup>296</sup> Similarly, hmim  $\text{Br}_3$ ,<sup>297</sup> without another reagent, is a brominating agent. Majetich and co-workers reported the use of HBr/DMSO for the remarkably selective bromination of aniline.<sup>298</sup> Highly *para*-selective bromination was accomplished using dioxane dibromide, under solvent-free conditions.<sup>299</sup>

If the substrate contains alkyl groups, side-chain halogenation (**14-1**) is possible with most of the reagents mentioned above, including chlorine and bromine. Since side-chain halogenation is catalyzed by light, the reactions should be run in the absence of light wherever possible. Sulfuryl chloride ( $\text{SO}_2\text{Cl}_2$ ) in acetic acid chlorinates anisole derivatives.<sup>300</sup> A mixture of KCl and Oxone chlorinated activated aromatic compounds<sup>301</sup> and *para* bromination of anisole was reported using  $\text{KBr}^{302}$  or  $\text{NH}_4\text{Br}$ .<sup>303</sup> Conversion of aniline to the *N*- $\text{SnMe}_3$  derivative allowed *in situ* bromination with bromine, with high *para* selectivity after conversion to the free amine with aqueous  $\text{KF}$ .<sup>304</sup>

Both bromination<sup>305</sup> and iodination<sup>306</sup> of arenes have been reviewed. Arenes have been converted to *ortho* halo derivatives by reaction with NBS or NIS in the presence of Rh catalyst.<sup>307</sup> Aryl chlorides and aryl bromides are formed by the reaction of aryl triflates

with KCl or KBr, with a Pd catalyst and the addition of 0.5 equivalents of KF.<sup>308</sup> Arenes reacted with NBS or NIS to give the corresponding aryl halide with ball milling, without solvent, catalyst, or additives.<sup>309</sup> Arylboronic acids reacted with iodide or bromide to give aryl bromides or aryl iodides with a CuBr<sub>2</sub> catalyst in the presence of oxygen.<sup>310</sup>

The Ir-catalyzed borylation of arenes led to *meta* halogenation.<sup>311</sup> Certain alkylated phenols can be brominated in the *meta* positions with Br<sub>2</sub> in the superacid solution SbF<sub>5</sub>–HF.<sup>312</sup> It is likely that the *meta* orientation is the result of conversion by the superacid of the OH group to the OH<sub>2</sub><sup>+</sup> group, which should be *meta* directing because of its positive charge. Bromination and the *Sandmeyer reaction* (**13-22**) can be carried out in one laboratory step to give 3,4,5-tribromonitrobenzene by treatment of an aromatic primary amine with CuBr<sub>2</sub> and *tert*-butyl nitrite.<sup>313</sup> With deactivated aromatic derivatives, NBS and sulfuric acid is an effective reagent, giving the *meta*-brominated product.<sup>314</sup> Bromination at C-6 of 2-aminopyridine was accomplished with NBS.<sup>315</sup>

Aryl and heteroaryl bromides have been converted to the corresponding chloride with Me<sub>4</sub>NCl and a Cu<sub>2</sub>O catalyst.<sup>316</sup> The *ortho* chlorination of phenols has been reported by reaction with SO<sub>2</sub>Cl<sub>2</sub> in the presence of 2,2,6,6-tetramethylpiperidine.<sup>317</sup> The bromination of arenes was reported using an ionic liquid as both the catalyst and the solvent.<sup>318</sup> The reaction of 2-phenylpyridine with NBS or Br<sub>2</sub>, with a Ru catalyst and a catalytic amount of mesitoic acid, gave 1-pyridyl-3-bromobenzene.<sup>319</sup>

Furan and thiophene are known to polymerize in the presence of strong acids, both Brønsted-Lowry and Lewis. For such highly reactive heteroaromatic systems, alternative halogenating reagents are commonly used. Furan was converted to 2-bromofuran with a bromine•dioxane complex, for example, at <0 °C.<sup>320</sup> 3-Butylthiophene reacted with NBS/acetic acid to give 2-bromo-3-butylthiophene.<sup>321</sup> With NBS and a catalytic amount of PBr<sub>3</sub> at –78 °C to –10 °C, *N*-methylpyrrole gave *N*-methyl-3-bromopyrrole.<sup>322</sup>

**Iodine** Iodine is the least reactive of the halogens in aromatic substitution.<sup>323</sup> Except for active substrates, an oxidizing agent must normally be present to oxidize I<sub>2</sub> to a better electrophile.<sup>324</sup> Examples of such oxidizing agents used with I<sub>2</sub> are HNO<sub>3</sub>, hypervalent

iodine compounds such as  $\text{PhI}(\text{OTf})_2$ ,<sup>325</sup>  $\text{NaIO}_4$ ,<sup>326</sup>  $\text{NH}_4\text{I}$  and  $\text{H}_2\text{O}_2$ ,<sup>327</sup> and a mixture of  $\text{NaIO}_4/\text{KI}/\text{NaCl}$ .<sup>328</sup> The reagent  $\text{ICl}$  is a better iodinating agent than iodine itself.<sup>329</sup> A mixture of  $\text{ICl}/\text{In}(\text{OTf})_3$  has also been used.<sup>330</sup> Iodination can also be accomplished by treatment of the substrate with  $\text{KI}/\text{KIO}_3$  in aqueous methanol,<sup>331</sup> and  $\text{NaI}$  with an  $\text{Fe}$  catalyst.<sup>332</sup>

A solvent-free iodination was accomplished using  $\text{NaICl}_2$  and an *N*-bromoammonium salt.<sup>333</sup> A solvent-free iodination used  $\text{I}_2$  and  $\text{AgNO}_3$ .<sup>334</sup> Another solvent-free iodination used  $\text{I}_2$  with  $\text{Bi}(\text{NO}_3)_3$  on silica gel.<sup>335</sup> A mixture of iodine/pyridine/dioxane leads to selective *para* iodination of aniline derivatives.<sup>336</sup> Selective *ortho* cyanation allows the reaction with iodine to give the corresponding aryl iodide.<sup>337</sup> *N*-Iodosuccinimide and *p*-toluenesulfonic acid give regioselective iodination of phenol and related compounds.<sup>338</sup>

The actual attacking species is less clear than with bromine or chlorine. Iodine itself is too unreactive. This is except for active species such as phenols, where there is good evidence that  $\text{I}_2$  is the attacking entity.<sup>339</sup> There is evidence that  $\text{AcOI}$  may be the reactive entity when peroxyacetic acid is the oxidizing agent,<sup>340</sup> and  $\text{I}_3^+$  when  $\text{SO}_3$  or  $\text{HIO}_3$  is the oxidizing agent.<sup>341</sup> The  $\text{I}^+$  ion has been implicated in several procedures.<sup>342</sup> For an indirect method for accomplishing aromatic iodination, see **12-30**.

Benzamides and  $\alpha$ -arylacetamides reacted with  $\text{I}_2$  and  $\text{CsOAc}$  with a  $\text{Pd}$  catalyst to give the corresponding *ortho* iodide.<sup>343</sup> Aryl iodides were prepared from arenes by reaction with  $\text{NIS}$  and  $\text{AgNTf}_2$  as catalyst.<sup>344</sup> Aromatic compounds have been converted to aryl iodides by reaction with  $\text{NIS}$  and  $\text{FeCl}_3/(\text{bmim})\text{NTf}_2$ .<sup>345</sup> Toluene reacted with iodo-saccharin in  $(\text{bmim})\text{BF}_4$  to give 4-iodotoluene.<sup>346</sup> Arylboronic acids were converted to the corresponding aryl iodide by reaction with molecular iodine and  $\text{KF}$ .<sup>347</sup> Arylboronic acids also reacted

with iodine in aqueous solution in the presence of cetyltrimethylammonium bromide to give the corresponding aryl iodide.<sup>348</sup> A *meta*-selective iodination of activated arenes was reported using NIS and a gold catalyst.<sup>349</sup> Iodination of deactivated arenes was reported using triiodoisocyanuric acid in concentrated sulfuric acid.<sup>350</sup>

**Fluorine** Direct fluorination of aromatic rings with F<sub>2</sub> is not feasible at room temperature, because of the extreme reactivity of F<sub>2</sub>.<sup>351</sup> It has been accomplished at low temperatures (e.g., -70 to -20 °C, depending on the substrate),<sup>352</sup> but the reaction is not yet of preparative significance. Fluorination has also been reported with acetyl hypofluorite CH<sub>3</sub>CO<sub>2</sub>F (generated from F<sub>2</sub> and sodium acetate).<sup>353</sup> However, none of these methods seems likely to displace the *Schiemann reaction* (**13-23**; heating diazonium tetrafluoroborates) as the most common method for introducing fluorine into aromatic rings.

Aryl chlorides have been converted to aryl fluorides using CsF and a Ru catalyst at 120–180 °C.<sup>354</sup> Aromatic triflates have been converted to the corresponding aryl fluoride by reaction with 3 equivalents of CsF and a Pd catalyst.<sup>355</sup> Aryltriethoxysilane reacted with 2 equivalents of Selectfluor and 2 equivalents of Ag<sub>2</sub>O, with BaO at 90 °C, to give the corresponding aryl fluoride.<sup>356</sup>

Aryl fluorides have been prepared from arylstannanes or aryl trifluoroborates by reaction with *N*-fluoro-2,4,6-trimethylpyridinium triflate.<sup>357</sup> For the conversion of aryltributylstannanes, their reaction with tetrabutylammonium triphenyldifluorosilicate (TBAT) and copper(II) triflate gave the aryl fluoride.<sup>358</sup> Aryl fluorides have been prepared by the Pd-catalyzed reaction from potassium aryltrifluoroborates.<sup>359</sup> The *para*-selective fluorination of anilides has been reported using hypervalent iodine reagents.<sup>360</sup> Aryldiazonium tetrafluoroborates were formed in situ using flow techniques (Sec. 7.D) and then converted to the final product, aryl fluorides.<sup>361</sup> Using continuous flow techniques (Sec. 7.D), aniline derivatives were converted to the corresponding aryl fluoride using TFA, LiBF<sub>4</sub>, and *t*-BuONO.<sup>362</sup>

## E. Carbon Electrophiles

In the reactions in this section, a new carbon–carbon bond is formed. With respect to the aromatic ring, such reactions are electrophilic substitutions, because a positive species is attacked by the electron-rich ring.

### 11-11 Friedel-Crafts Alkylation

The alkylation of aromatic rings, called *Friedel-Crafts alkylation*, is a reaction of very broad scope.<sup>363</sup> The most important reagents are alkyl halides, alkenes, and alcohols, but other types of reagent have also been employed.<sup>363</sup> Tertiary halides are particularly good substrates since they form relatively stable tertiary carbocations. When alkyl halides are used, the reactivity order is  $\text{F} > \text{Cl} > \text{Br} > \text{I}$ .<sup>364</sup>

Di- and trihalides, when all the halogens are the same, usually react with more than one molecule of an aromatic compound, and it is usually not possible to stop the reaction earlier.<sup>365</sup> Thus, benzene with  $\text{CH}_2\text{Cl}_2$  gives  $\text{Ph}_2\text{CH}_2$ , not  $\text{PhCH}_2\text{Cl}$ , and benzene with  $\text{CHCl}_3$  gives  $\text{Ph}_3\text{CH}$ . With  $\text{CCl}_4$ , however, the reaction stops when only three rings have been substituted to give  $\text{Ph}_3\text{CCl}$ .

In most cases, electron-withdrawing groups on the aromatic ring, *meta*-directing groups, make the ring too inactive for alkylation. In other words, a general observation is that benzene rings with a strong deactivating substituent do not undergo the Friedel-Crafts reaction. Nitrobenzene cannot be alkylated, and there are only a few reports of successful Friedel-Crafts alkylations when electron-withdrawing groups are present.<sup>366</sup> The difficulty in many cases is caused by the fact that, with inactive substrates, degradation and polymerization of the electrophile occurs before it can attack the ring. However, if an activating and a deactivating group are both present on a ring, Friedel-Crafts alkylation can be accomplished.<sup>367</sup> It is noted that aromatic nitro compounds can be methylated by a nucleophilic mechanism (13-12).

Heterocyclic rings tend to be poor substrates for the Friedel-Crafts reaction. Although some furans and thiophenes have been alkylated, polymerization is quite common, and a true alkylation of a pyridine or a quinoline may not be possible.<sup>368</sup> The reaction of isoquinoline with  $\text{ClCO}_2\text{Ph}$  and  $\text{AgOTf}$ , followed by reaction with an allylic silane, led to a 2-allylic dihydroisoquinoline.<sup>369</sup>

A catalyst is nearly always required.<sup>370</sup> Lewis acid catalysts such as  $\text{AlCl}_3$  and boron  $\text{BF}_3$  are the most common, but many other Lewis acids have been used.<sup>371</sup> Protonic acids,

such as HF and H<sub>2</sub>SO<sub>4</sub> are commonly used.<sup>372</sup> For active halides a trace of a less-active catalyst, such as ZnCl<sub>2</sub>, may be enough. For an unreactive halide, such as chloromethane, a more powerful catalyst such as AlCl<sub>3</sub> is needed, and in larger amounts. In some cases, especially with alkenes, a Lewis acid catalyst causes reaction only if a small amount of proton-donating co-catalyst is present. Catalysts have been arranged in the following order of overall reactivity: AlBr<sub>3</sub> > AlCl<sub>3</sub> > GaCl<sub>3</sub> > FeCl<sub>3</sub> > SbCl<sub>5</sub><sup>373</sup> > ZrCl<sub>4</sub>, SnCl<sub>4</sub> > BCl<sub>3</sub>, BF<sub>3</sub>, SbCl<sub>3</sub>,<sup>374</sup> but the reactivity order in each case depends on the substrate, reagent, and conditions. Calcium has been used to catalyze Friedel-Crafts alkylation reactions, at room temperature.<sup>375</sup>

In Friedel-Crafts alkylation reactions, the product is more reactive than the starting aromatic substrate, and di- and polyalkylation are frequently observed. However, the activating effect of simple alkyl groups (e.g., ethyl, isopropyl) is only ~1.5–3 times as fast as benzene for Friedel-Crafts alkylations,<sup>376</sup> so it is often possible to obtain high yields of monoalkyl product.<sup>377</sup> Actually, the fact that di- and polyalkyl derivatives are frequently obtained is not due to the small difference in reactivity but to the circumstance that alkylbenzenes are preferentially soluble in the catalyst layer, where the reaction actually takes place.<sup>378</sup> This factor can be removed by the use of a suitable solvent, by high temperatures, or by high-speed stirring. It is important to note that the OH, OR, NH<sub>2</sub>, and so on, groups do not facilitate the reaction, since most Lewis acid catalysts coordinate with these basic groups. Although phenols give the usual Friedel-Crafts reactions, orienting *ortho* and *para*, the reaction is very poor for aniline derivatives.

Alcohols are more active than alkyl halides, but if a Lewis acid catalyst is used more catalyst is required, since the catalyst complexes with the OH group. However, proton acids such as H<sub>2</sub>SO<sub>4</sub> are often used to catalyze alkylation with alcohols. An intramolecular cyclization was reported from an allylic alcohol, using P<sub>2</sub>O<sub>5</sub>, to give indene derivatives.<sup>379</sup> Secondary alcohols are coupled to aromatic compounds using a heterobimetallic Ir–Sn complex.<sup>380</sup> Molecular iodine has been used to catalyze benzylation of arenes with benzylic alcohols.<sup>381</sup> A “contra Friedel-Crafts” *tert*-butylation has been reported.<sup>382</sup> Allylic alcohols reacted with anisole derivatives in the presence of an iron(III) porphyrin catalyst to give the *para* allylic-substituted anisole derivative.<sup>383</sup> Aromatic compounds reacted with benzylic alcohols in the presence of triphenylphosphine ditriflate (Ph<sub>3</sub>P<sup>+</sup> OTf<sup>−</sup> OTf) to give the benzylic substituted arene.<sup>384</sup> 1,1-Diaryl compounds were prepared by the graphene oxide-mediated reaction of

arenes with benzylic alcohols.<sup>385</sup> Cycloalkanols reacted with aromatic compounds in the presence of  $\text{FeCl}_3/\text{AgSbF}_6$  to give the arylcycloalkane.<sup>386</sup>

When carboxylic esters are the reagents, there is competition between alkylation and Friedel-Crafts acylation (**11-17**). This competition can often be controlled by choice of catalyst, and alkylation is usually favored, but carboxylic esters are not often employed in Friedel-Crafts reactions. Other alkylating agents are ethers,<sup>387</sup> thiols, sulfates, sulfonates, alkyl nitro compounds,<sup>388</sup> and even alkanes and cycloalkanes, under conditions where these are converted to carbocations. Notable are oxirane, which puts the  $\text{CH}_2\text{CH}_2\text{OH}$  group onto the ring,<sup>389</sup> and cyclopropyl<sup>390</sup> units. Arenes reacted with cycloalkanes in the presence of a Ru catalyst and 2 equivalents of *tert*-butylperoxide to give the arylcycloalkane.<sup>391</sup> Arylboronic acids reacted with cycloalkanes in the presence of a Ni catalyst to give the arylcycloalkane. For all types of reagent the reactivity order is allylic  $\approx$  benzylic > tertiary > secondary > primary.

Benzylic halides reacted with arylboronic acids in the presence of  $\text{CsCO}_3$  in aqueous benzotrifluoride to give the benzylic substituted arene.<sup>392</sup> Benzene, toluene, or chlorobenzene reacted with bromoalkanes in the presence of  $\text{AlCl}_3$  and microwave irradiation to give the arene.<sup>393</sup> Alkyl iodides reacted with arenes to give the alkylated aryl compounds with *meta* selectivity using a Pd catalyst and a functionalized norbornene compound.<sup>394</sup> It is noted that tertiary alkylbenzenes, which are generally not available via Friedel-Crafts reactions due to rearrangement of the intermediate cation, are available via a two-step process: (i) react with  $\text{SOCl}_2$  and (ii) reaction with 2 equivalents of  $\text{Me}_3\text{Al}$ .<sup>395</sup>

Alkyl mesylates undergo alkylation reaction with benzene rings in the presence of  $\text{Sc}(\text{OTf})_3$ .<sup>396</sup> Arenes reacted with alkylcarboxylic acids in the presence of  $\text{Pd}(\text{OAc})_2$  and  $\text{PhI}(\text{OAc})_2$ ; heating led to decarboxylative alkylation to give the alkylated aromatic compound.<sup>397</sup> 1-Functionalized naphthalenes reacted with  $\text{Me}_3\text{Al}$  or the  $\text{Me}_3\text{Al}$  diamine complex with 2,3-dichlorobutane and an Fe complex to give the 8-methyl 1-functionalized naphthalene.<sup>398</sup> *N*-Pyrimidylindoles reacted with alkylarenes in the presence of a Cu

catalyst and with 2 equivalents of di-*tert*-butylbenzoyl peroxide to give the 2-benzylic indole derivative.<sup>399</sup>

An important use of the Friedel-Crafts alkylation reaction is to effect ring closure,<sup>400</sup> via an intramolecular process.<sup>401</sup> The most common method is to heat an aromatic compound having a halogen, hydroxy, or alkene group in the proper position with aluminum chloride. Another way of effecting ring closure through Friedel-Crafts alkylation is to use a reagent containing two halogens. These reactions are most successful for the preparation of six-membered rings,<sup>402</sup> though five- and seven-membered rings have also been closed in this manner. For other Friedel-Crafts ring-closure reactions, see **11-15**, **11-13**, and **11-17**.

The electrophile in Friedel-Crafts alkylation is a carbocation, at least in most cases.<sup>403</sup> The cation is formed from the attacking reagent and the catalyst. For the three most important types of reagent these reactions are: (i) the reaction of alkyl halides with Lewis acids, such as AlCl<sub>3</sub>, (ii) the protonation and loss of water from alcohols to form a carbocation, (iii) the reaction of alcohols with Lewis acids, and (iv) the reaction of alkenes with an acid to form a carbocation.<sup>404</sup> Rearrangement of the alkyl substrate occurs frequently and is an important synthetic limitation of Friedel-Crafts alkylation. Rearrangement is usually in the order primary → secondary → tertiary and usually occurs by migration of the smaller group on the adjacent carbon. In the absence of special electronic or resonance influences on the migrating group (such as phenyl), H migrates before methyl, which migrates before ethyl, and so on (see discussion of rearrangement mechanisms in Chapter 18). It is therefore *not* usually possible to put a primary alkyl group (other than methyl<sup>405</sup> and ethyl) onto an aromatic ring by Friedel-Crafts alkylation. Because of these rearrangements, *n*-alkylbenzenes are often prepared by acylation (**11-17**), followed by reduction (**19-66**).

Rearrangement is possible even with a non-carbocation mechanism. The rearrangement could occur *before* the attack on the ring takes place. It has been shown that treatment of CH<sub>3</sub><sup>14</sup>CH<sub>2</sub>Br with AlBr<sub>3</sub> in the absence of any aromatic compound gave a mixture of the starting material and <sup>14</sup>CH<sub>3</sub>CH<sub>2</sub>Br.<sup>406</sup> Similar results were obtained with PhCH<sub>2</sub><sup>14</sup>CH<sub>2</sub>Br, in which case the rearrangement was so fast that the rate could be measured only below -0 °C.<sup>407</sup> Rearrangement could also occur *after* formation of the product, since alkylation is reversible (see **11-33**).<sup>408</sup>

There is direct evidence, from IR and NMR spectra, that the *tert*-butyl cation is quantitatively formed when *tert*-butyl chloride reacts with AlCl<sub>3</sub> in anhydrous liquid HCl.<sup>409</sup> In the case of alkenes, the more stable carbocation (*Markovnikov's rule*, Sec. 15.B.ii) is formed. Carbocation formation is particularly easy from some reagents, because of the

stability of the cations. Triphenylmethyl chloride<sup>410</sup> and 1-chloroadamantane<sup>411</sup> require no catalyst or solvent to react with activated aromatic rings (e.g., phenols, amines). Ions as stable as this are less reactive than other carbocations and often attack only active substrates. The tropylium ion, for example, alkylates anisole, but not benzene.<sup>412</sup> It was noted in Sec. 10.F that relatively stable vinylic cations can be generated from certain vinylic compounds. These have been used to introduce vinylic groups into aryl substrates.<sup>413</sup> Lewis acids, such as  $\text{BF}_3$ <sup>414</sup> or  $\text{AlEt}_3$ ,<sup>415</sup> can also be used to alkylate aromatic rings with alkene units.

There is considerable evidence that many Friedel-Crafts alkylations, especially with primary reagents, do not go through a completely free carbocation. The ion may exist as a tight ion pair with, say,  $\text{AlCl}_4^-$  as the counterion or as a complex. Among the evidence is the result that methylation of toluene by methyl bromide and methyl iodide gave different *ortho/para/meta* ratios,<sup>416</sup> although the same ratios are expected if the same species attacked in each case. Other evidence is that, in some cases, the reaction kinetics are third order; first order each in aromatic substrate, attacking reagent, and catalyst.<sup>417</sup> In these instances a mechanism in which the carbocation is slowly formed and then rapidly attacked by the aromatic ring is ruled out since, in such a mechanism, the substrate would not appear in the rate expression. Since it is known that free carbocations, once formed, are rapidly attacked by the ring (acting as a nucleophile), there are no free carbocations here. Another possibility (with alkyl halides) is that some alkylations take place by an  $\text{S}_{\text{N}}2$  mechanism (with respect to the halide), in which case no carbocations would be involved at all. However, a formal  $\text{S}_{\text{N}}2$  mechanism requires inversion of configuration. Most investigations of Friedel-Crafts stereochemistry, even where an  $\text{S}_{\text{N}}2$  mechanism might most be expected, have resulted in total racemization, or at best a few percent inversion. A few exceptions have been found,<sup>418</sup> most notably where the reagent was optically active propylene oxide, in which case 100% inversion was reported.<sup>419</sup>

Diastereoselective alkylation is possible from alcohol precursors, and high facial diastereoselectivity was reported with "chiral benzylic cations," for example.<sup>420</sup> Catalytic asymmetric Friedel-Crafts alkylation reactions are known.<sup>421</sup> An asymmetric Friedel-Crafts alkylation of indoles has been reported.<sup>422</sup> *N*-Methylpyrrole reacted with the  $\text{C}=\text{C}$  unit of methacrolein in the presence of a chiral catalyst to give the 2-alkylated pyrrole, with good enantioselectivity.<sup>423</sup>

### 11-12 Hydroxyalkylation: Cyclodehydration of Carbonyl-Containing Compounds

When an aldehyde, ketone, or other carbonyl-containing substrate is treated with a protonic or Lewis acid, an oxygen-stabilized cation is generated. In the presence of an aromatic ring, *Friedel-Crafts-type alkylation* occurs. The condensation of aromatic rings with aldehydes or ketones is called *hydroxyalkylation*.<sup>424</sup> The reaction can be used to prepare alcohols,<sup>425</sup> though more often the alcohol initially produced reacts with another molecule of aromatic compound (**11-11**) to give diarylation. The diarylation reaction is especially common with phenols (the diaryl product here is called a bisphenol). The reaction is normally carried out in alkaline solution on the phenolate ion.<sup>426</sup> Another variation involved Friedel-Crafts coupling of an aldehyde to an activated aromatic compound (an aniline derivative) to give diaryl carbinols that exhibited atropisomerism (Sec. 4.C, category 5).<sup>427</sup> The attacking species is the carbocation,  $\text{R}_2(\text{OH})\text{C}^+$ , formed from the aldehyde or ketone and the acid catalyst, except when the reaction is carried out in basic solution. When the reaction was done with a chiral aluminum complex, modest enantioselectivity was observed.

The hydroxymethylation of phenols with formaldehyde is called the *Lederer-Manasse reaction*. This reaction must be carefully controlled,<sup>428</sup> since it is possible for the *para* and both *ortho* positions to be substituted and for each of these to be rearylated, so that a polymeric structure is produced. However, such polymers, which are of the Bakelite type (phenol-formaldehyde resins), are of considerable commercial importance.<sup>429</sup>

Two methods, both involving boron-containing reagents, have been devised for the regioselective *ortho* hydroxymethylation of phenols or aromatic amines.<sup>430</sup> Conjugated aldehydes undergo Friedel-Crafts alkylation with aryltrifluoroborate salts, in the presence of a catalytic amount of an imidazolidinone.<sup>431</sup>

### 11-13 Cyclodehydration of Carbonyl-Containing Compounds

The reaction of a carbonyl and an aromatic ring can be carried out intramolecularly. When reaction with a Lewis acid leads to an oxygen-stabilized carbocation, *Friedel-Crafts alkylation* occurs to give an alcohol or an alkene, if dehydration occurs under the reaction

conditions. When the ring is formed the alcohol moiety is benzylic and treatment with acid results in cyclodehydration to form the alkene. Dehydration almost always takes place to give a double bond conjugated with the aromatic ring.<sup>432</sup> The method is very general and is widely used to close both carbocyclic and heterocyclic rings.<sup>433</sup> Polyphosphoric acid is a common reagent, but other acids have also been used.

An intramolecular cyclization of an aryl ether to the carbonyl of a pendant aryl ketone, on clay with microwave irradiation, led to a benzofuran via *Friedel-Crafts cyclization* and elimination of water.<sup>434</sup>

In a variation known as the *Bradsher reaction*,<sup>435</sup> diarylmethanes containing a carbonyl group in the *ortho* position can be cyclized to anthracene derivatives, **27**, and in this case 1,4-dehydration takes place, at least formally.

A variation of this reaction involves acylation of a  $\beta$ -keto ester to give **28**, followed by *Friedel-Crafts cyclization* of the ketone moiety. The product is a coumarin, **29**, in what is known as the *Pechmann condensation*.<sup>436</sup> Isolation of esters, such as **28**, is not always necessary, and protonic acids can be used rather than Lewis acids.

The Pechmann condensation is facilitated by the presence of hydroxyl (OH), dimethylamino (NMe<sub>2</sub>), and alkyl groups *meta* to the hydroxyl of the phenol.<sup>437</sup> The reaction has been accomplished using microwave irradiation on graphite/Montmorillonite K-10.<sup>438</sup> Pechmann condensation in an ionic liquid using ethyl acetate has also been reported.<sup>439</sup>

The reaction of resorcinol with ethyl 4,4,4-trifluoroacetoacetate and trifluorotoluene with heating led to a Pechmann condensation and formation of the 4-trifluoromethylcomarin.<sup>440</sup>

The carbonyl unit involved in the cyclization process is not restricted to aldehydes and ketones. The carbonyl of acid derivatives, such as amides, can also be utilized. One of the more important cyclodehydration reactions is applied to the formation of heterocyclic systems via cyclization of  $\beta$ -aryl amides, in what is called the *Bischler-Napieralski reaction*.<sup>441</sup> In this reaction amides of the type **30** are cyclized by reaction with phosphorus oxychloride or other reagents, including polyphosphoric acid, sulfuric acid, or phosphorus pentoxide, to give a dihydroisoquinoline, **31**.

The Bischler-Napieralski reaction has been done in ionic liquids using  $\text{POCl}_3$ .<sup>442</sup> The reaction has also been done using solid phase (Sec. 9.D.iv) techniques.<sup>443</sup> If the starting compound contains a hydroxyl group in the  $\alpha$  position, an additional dehydration takes place and the product is an isoquinoline.<sup>444</sup>

Another useful variation is the *Pictet-Spengler isoquinoline synthesis*, also known as the *Pictet-Spengler reaction*.<sup>445</sup> When a  $\beta$ -arylamine reacts with an aldehyde, the product is an iminium salt, which cyclizes with an aromatic ring to complete the reaction and generate a tetrahydroisoquinoline.<sup>446</sup> The reactive intermediate is an iminium ion **32** rather than an oxygen-stabilized cation, but attack at the electrophilic carbon of the  $\text{C}=\text{N}$  unit (see **16-31**) leads to an isoquinoline derivative, **33**.

Metal-catalyzed reactions are known, including the use of  $\text{AuCl}_3/\text{AgOTf}$ .<sup>447</sup> A variety of aldehydes can be used, and substitution on the aromatic ring leads to many derivatives. When the reaction is done in the presence of a chiral catalyst, good enantioselectivity was observed.<sup>448</sup> An organocatalyst, (*R*)-3,3'-bis(2,4,6-triisopropylphenyl)-BINOL-phosphoric acid, has been used for a Pictet-Spengler approach to the synthesis of several

natural products.<sup>449</sup> An  $\text{In}(\text{OTf})_3$ -catalyzed intramolecular reaction has been reported.<sup>450</sup> 3-Hydroxyethylindole derivatives were treated with an aldehyde with a dual catalyst composed of a secondary amine derivatives that contain thiourea unit, in the presence of MS 4Å, that generated an oxocarbenium ion for an enantioselective oxa-Pictet-Spengler reaction.<sup>451</sup> An oxa-Pictet-Spengler reaction was reported using a nitrated confined imidodiphosphoric acid catalyst.<sup>452</sup>

Another variation in this basic procedure leads to tetrahydroisoquinolines. When phenethylamine was treated with *N*-hydroxymethylbenzotriazole and then  $\text{AlCl}_3$  in chloroform, cyclization occurred. Reduction with sodium borohydride gave the 1,2,3,4-tetrahydro-*N*-methylisoquinoline.<sup>453</sup>

### 11-14 Haloalkylation

When certain aromatic compounds are treated with formaldehyde and HCl, the  $\text{CH}_2\text{Cl}$  group is introduced into the ring in a reaction called *chloromethylation*. The reaction has also been carried out with other aldehydes and with HBr and HI. The more general term *haloalkylation* covers these cases.<sup>454</sup> The reaction is successful for benzene, and alkyl-, alkoxy-, and halobenzenes, but is greatly hindered by *meta*-directing groups, which reduce yields or completely prevent the reactions. Amines and phenols are too reactive and usually give polymers unless deactivating groups are also present, but phenolic ethers and esters successfully undergo the reaction. Compounds of lesser reactivity can often be chloromethylated with chloromethyl methyl ether ( $\text{ClCH}_2\text{OMe}$ ), or methoxyacetyl chloride  $\text{MeOCH}_2\text{COCl}$ .<sup>455</sup> Zinc chloride is the most common catalyst, but other Friedel-Crafts catalysts are also employed. As with reaction **11-12**, and for the same reason, an important side product is the diaryl compound  $\text{Ar}_2\text{CH}_2$  (from formaldehyde).

Apparently, the initial step involves reaction of the aromatic compound with the aldehyde to form the hydroxyalkyl compound, exactly as in **11-12**, and then the HCl converts this to the chloroalkyl compound.<sup>456</sup> The acceleration of the reaction by  $\text{ZnCl}_2$  has been attributed<sup>457</sup> to the raising of the acidity of the medium, causing an increase in the concentration of  $\text{HOCH}_2^+$  ions.

## 11-15 Friedel-Crafts Arylation

The coupling of two aromatic molecules by treatment with a Lewis acid and a proton acid is called the *Scholl reaction*.<sup>458</sup> Yields are low and the synthesis is seldom useful. High temperatures and strong-acid catalysts are required, and the reaction fails for substrates that are destroyed by these conditions. The reaction becomes important with large fused ring systems, so ordinary *Friedel-Crafts reactions* (**11-11**) on these systems are rare. Yields can be increased by the addition of a salt such as  $\text{CuCl}_2$  or  $\text{FeCl}_3$ , which acts as an oxidant.<sup>459</sup> Rhodium<sup>460</sup> and Ru catalysts<sup>461</sup> have also been used. Twisted polycyclic arenes have been prepared by intramolecular Scholl reactions.<sup>462</sup>

Intramolecular Scholl reactions, such as formation of **34** from triphenylmethane, are much more successful than the intermolecular reaction. The mechanism is not clear, but it may involve attack by a proton to give an arenium ion of the type **13** (Sec. 11.A.i, category 2), which would be the electrophile that attacks the other ring.<sup>463</sup> An “intramolecular Scholl reaction of 1-benzoylpyrene gave 8*H*-dibenzo[*def,qr*]chrysen-8-one and 11*H*-indeno[2,1-*a*]pyren-11-one in a 1:2 ratio.”<sup>464</sup> A molecular modeling study indicated that the arenium-cation mechanism predicted the regioselectivity and that the reaction was under kinetic control.<sup>464</sup>

## 11-16 Arylation of Aromatic Compounds By Metalated Aryls

Many metalated aryl compounds are known to couple with aromatic compounds. Aniline derivatives react with  $\text{ArPb}(\text{OAc})_3$ , for example, to give the 2-arylaniline.<sup>465</sup> Phenolic anions also react to form biaryls, with modest enantioselectivity, in the presence of

<sup>458</sup> See Kovacic, P.; Jones, M.B. *Chem. Rev.* **1987**, *87*, 357; Balaban, A.T.; Nenitzescu, C.D. in Olah, G.A. *Friedel-Crafts and Related Reactions*, Vol. 2, Wiley, NY, **1964**, pp. 979–1047.

brucine.<sup>466</sup> A Mn(III)-mediated synthesis of biaryls used microwave irradiation for the coupling reaction.<sup>467</sup> The homocoupling reaction of aryl Grignard reagents in the presence of TEMPO is known.<sup>468</sup> A Cu-catalyzed coupling reaction with hypervalent arylated iodine derivatives is known.<sup>469</sup>

Heating benzene with arylpalladium(II) carboxylate and K<sub>2</sub>CO<sub>3</sub> led to the biaryl.<sup>470</sup> A fluorocation surrogate such as Selectfluor mediates the coupling of arenes with *N*-arylbenzamide derivatives to give the corresponding biaryl with heating and a Pd catalyst.<sup>471</sup> Biaryls were prepared by the electrochemical coupling of phenol derivatives with arenes in a methanol/fluorinated alcohol solvent.<sup>472</sup>

Phenols reacted with aryl iodides in the presence of a Pd catalyst and CO<sub>2</sub> to give the *meta* aryl phenol.<sup>473</sup> Functionalized aromatic compounds reacted with aryl iodides in the presence of Pd(Ac)<sub>2</sub> and a 2-hydroxypyridine compound as ligand, and mediated by norbornene, to give the *meta* aryl compound.<sup>474</sup>

Heteroaromatic compounds reacted with bromoheteroarenes with a Pd catalyst and 30% of pivalic acid, with microwave irradiation, to give the heteroaryl–heteroaryl compound.<sup>475</sup> Heteroaromatic compounds reacted with diaryliodonium salts in the presence of NaOH to give the aryl-substituted heteroaromatic compound.<sup>476</sup>

See reactions **13-9**, **13-10**, **13-11**.

### 11-17 Aryl Ketone Formation: Friedel-Crafts Acylation

A traditional method for the preparation of aryl ketones is known as *Friedel-Crafts acylation*.<sup>477</sup> Reagents other than acyl halides can be used,<sup>478</sup> including carboxylic acids,<sup>479</sup> anhydrides, and ketenes. Oxalyl chloride has been used to give diaryl 1,2-diketones.<sup>480</sup> Carboxylic esters usually give alkylation as the predominant product (see **11-11**).<sup>481</sup>

The alkyl group (R in RCOCl) may be aryl as well as alkyl.<sup>482</sup> The major disadvantages of Friedel-Crafts alkylation, which are polyalkylation and rearrangement of the intermediate carbocation, are not a problem in Friedel-Crafts acylation because (i) the intermediate is an acylium ion (an acylium ion,  $\text{RC}\equiv\text{O}^+$ ) that is stabilized by resonance and (ii) the RCO group is deactivating (the carbonyl is electron withdrawing), so the reaction stops cleanly after one group is introduced because the ketone product is less reactive than the aromatic precursor. All four acyl halides can be used, and the order of activity is usually, but not always,  $\text{I} > \text{Br} > \text{Cl} > \text{F}$ .<sup>483</sup> However, acyl chlorides are most commonly employed because they are usually the easiest and cheapest to prepare, but primarily because they are sufficiently reactive in most cases. With active substrates (e.g., aryl ethers, fused ring systems, thiophenes), Friedel-Crafts acylation can be carried out with very small amounts of catalyst, often just a trace, or even sometimes with no catalyst at all.

Protonic acids can be used as catalysts when the reagent is a carboxylic acid.<sup>484</sup> Other catalysts can be used. Triflic anhydride promotes dehydrative acylation of carboxylic acids,<sup>485</sup> as does  $\text{P}_2\text{O}_5/\text{SiO}_2$ .<sup>486</sup> The mixed carboxylic sulfonic anhydrides  $\text{RCOOSO}_2\text{CF}_3$  are extremely reactive acylating agents and can smoothly acylate benzene without a catalyst.<sup>487</sup> A solvent-free method is also available using tosic acid/graphite.<sup>488</sup> Acyl halides are coupled to arylboronic acids under microwave irradiation.<sup>489</sup> Friedel-Crafts acylation using a carboxylic acid with a catalyst called Envirocat-EPIC (an acid-treated clay-based material) was reported.<sup>490</sup> Acylation has been accomplished in carbon disulfide.<sup>491</sup> An interesting variation couples a conjugated acid chloride with benzene, in the presence of  $\text{AlCl}_3$  and microwave irradiation, to give an indanone.<sup>492</sup> Potassium iodide or lithium iodide has been used as an activating agent for the reaction of acid chlorides with arenes.<sup>493</sup>

The reaction is quite successful for many types of substrate, including fused ring systems which give poor results in **11-11**. Compounds containing electron-donating (*ortho/para*-directing) groups, including alkyl, hydroxy, alkoxy, halogen, and acetamido groups, are easily acylated and give mainly or exclusively the *para* products, because of the relatively large size of the acyl group. However, aromatic amines give poor results. With amines and phenols there may be competition from *N*- or *O*-acylation, and the Fries rearrangement may compete with *O*-acylated phenols. *Friedel-Crafts acylation is usually not possible for aromatic rings with only deactivating (meta-directing) groups*. Indeed, nitrobenzene is often used as a solvent for the reaction. Most five-membered ring heterocyclic systems, including

furans, thiophenes, and pyrroles,<sup>494</sup> can be acylated in good yield, but not six-membered ring heterocycles, such as pyridines or quinolines. Initial reaction of indole with  $\text{Et}_2\text{AlCl}$ <sup>495</sup> or  $\text{SnCl}_4$ ,<sup>496</sup> followed by acetyl chloride, leads to 3-acetylindole; the reaction is in the more active five-membered ring. When an electron-withdrawing group is on the nitrogen, as in *N*-acetylindole, reaction with acetic anhydride and  $\text{AlCl}_3$  gave *N*,6-diacetylindole.<sup>497</sup> Gore presents an extensive summary of the substrates to which acylation has been applied.<sup>498</sup>

Friedel-Crafts acylation can be carried out with cyclic anhydrides,<sup>499</sup> in which case the product contains a carboxyl group in the side chain. When succinic anhydride is used, the product is  $\text{ArCOCH}_2\text{CH}_2\text{CO}_2\text{H}$ . This product can be reduced (**19-66**) to  $\text{ArCH}_2\text{CH}_2\text{CH}_2\text{CO}_2\text{H}$ , and then be cyclized by an internal Friedel-Crafts acylation to give a tetralone. The total process is called the *Haworth reaction*.<sup>500</sup> When a mixed anhydride  $\text{RCOOCOR}'$  is the reagent, two products are possible:  $\text{ArCOR}$  and  $\text{ArCOR}'$ . Which product predominates depends on two factors. If R contains electron-withdrawing groups, then  $\text{ArCOR}'$  is chiefly formed, but if this factor is approximately constant in R and R', the ketone with the larger R group predominantly forms.<sup>501</sup> This means that *formylations* of the ring do not occur with mixed anhydrides of formic acid  $\text{HCOOCOR}$ .

As noted, an important use of the Friedel-Crafts acylation is to effect ring closure.<sup>502</sup> This closure can be accomplished if an acyl halide, anhydride, or carboxylic acid<sup>503</sup> group is in the proper position. An example is the conversion of 3-phenylpropanoyl chloride to indanone. The reaction is used mostly to close six-membered rings. Even large rings can be closed by high-dilution techniques.<sup>504</sup> Tricyclic and larger systems are often made by using substrates containing one of the acyl groups on a ring, and many fused ring systems are made in this manner. If the bridging group is CO, the product is a quinone.<sup>505</sup> One of the most common catalysts for intramolecular Friedel-Crafts acylation is polyphosphoric acid<sup>506</sup> (because of its high potency), but  $\text{AlCl}_3$ ,  $\text{H}_2\text{SO}_4$ , and other Lewis and proton acids are also used, though acylations with acyl halides are not generally catalyzed by proton acids.

The mechanism of Friedel-Crafts acylation has been studied,<sup>507</sup> and at least two mechanisms probably operate, depending on the conditions.<sup>508</sup>

In most Friedel-Crafts acylation reactions, the catalyst is a Lewis acid,<sup>516</sup> similar to those in reaction **11-11**. In acylation a little more than 1 equivalent of catalyst is required per mole of reagent, because the first equivalent coordinates with the oxygen of the reagent [as in  $R(Cl)C=O^+ - AlCl_3$ ].<sup>517</sup> A reusable catalyst [ $Ln(OTf)_3 - LiClO_4$ ] has been developed.<sup>518</sup> Ferric chloride in an ionic liquid has also been used.<sup>519</sup> Work continues using myriad catalysts for Friedel-Crafts acylation. Aryl iodides reacted with aldehydes, with  $Pd(OAc)_2$  and  $Ag_2O$ , in the presence of TBHP, to give the acyl ketone.<sup>520</sup> Aryl methyl ketones have been prepared by the cross coupling of aryl bromides or heteroaryl bromides and acetyltrimethylsilane, in the presence of a Pd catalyst.<sup>521</sup> The erbium trifluoromethanesulfonate-catalyzed acylation using aromatic carboxylic acids has been reported, using microwave irradiation.<sup>522</sup> Aryl methyl ketones reacted with aryl halide to give diaryl ketones using a Pd catalyst and then exposure to oxygen.<sup>523</sup> Arylthio esters reacted with arylzinc chlorides ( $ArZnCl$ ) to give the diaryl ketone using a Pd catalyst.<sup>524</sup> Triphenylbismuth reacted with 3 equivalents of benzoyl chloride to give 3 equivalents of benzophenone using a Pd catalyst on a mobile crystalline material.<sup>525</sup> Aromatic compounds reacted with acyl chlorides in the presence of  $AgNO_3$  to give the aryl ketone.<sup>526</sup> Friedel-Crafts acylation has been accomplished with arenes and acyl halides using  $Bi(OTf)_3$  in  $(bmi)PF_6$  with microwave irradiation or with heating.<sup>527</sup> A catalytic, regioselective Friedel-Crafts acylation has been reported, using nanopowder  $CuFe_2O_4$  catalyst that is moisture insensitive. Note that the magnetic properties of the catalyst render it magnetically separable.<sup>528</sup> Biaryl-2-tosylamines reacted with aryl aldehydes in the presence of a Pd catalyst and 2 equivalents each of TBHP and acetic acid give the 2'-aryl ketone 2-tosylaminebiaryl.<sup>529</sup> Functionalized arenes treated with acetamide and  $SO_2Cl_2$  gave the Friedel-Crafts acylation product including using sonication or microwave irradiation.<sup>530</sup> 4-Fluorobenzoic acid

## 11-18 Aromatic Aldehyde Formation: Formylation

Direct formylation of an aromatic ring leads to an aldehyde.<sup>538</sup> Reaction **11-17** has not been used for formylation, since neither formic anhydride nor formyl chloride is stable at ordinary temperatures. Formyl chloride has been shown to be stable in chloroform solution for 1 h at -60 °C,<sup>539</sup> but it is not useful for formylating aromatic rings under these conditions. Formic anhydride has been prepared in solution, but has not been isolated.<sup>540</sup> Mixed anhydrides of formic and other acids are known<sup>541</sup> and can be used to formylate amines (see **16-72**) and alcohols, but no formylation takes place when they are applied to aromatic rings. See **13-12** for a nucleophilic method for the formylation of aromatic rings.

The reaction with disubstituted formamides R<sub>2</sub>N-CHO and phosphorus oxychloride, called the *Vilsmeier* or the *Vilsmeier-Haack reaction*,<sup>542</sup> is the most common method for the

formylation of aromatic rings.<sup>543</sup> However, it is applicable only to active substrates, such as amines and phenols. An intramolecular version is also known.<sup>544</sup> Aromatic hydrocarbons and heterocycles can also be formylated, but only if they are much more active than benzene (e.g., azulenes, ferrocenes). Although *N*-phenyl-*N*-methylformamide is a common reagent, other arylalkyl amides and dialkyl amides are also used.<sup>545</sup> Phosgene (COCl<sub>2</sub>) has been used in place of POCl<sub>3</sub>. The reaction has also been carried out with other amides to give ketones (actually an example of **11-17**), but not often. The reactive species<sup>546</sup> is **38**,<sup>547</sup> and the mechanism is probably that shown to give **39**, which is unstable and easily hydrolyzes to the product. Either formation of **38** or the reaction of **38** with the substrate can be rate determining, depending on the reactivity of the substrate.<sup>548</sup>

In a related reaction, paraformaldehyde can be used, with MgCl<sub>2</sub>/NEt<sub>3</sub>, to convert phenol to phenol 2-carbaldehyde.<sup>549</sup> Another variation treated acetanilide with POCl<sub>3</sub>/DMF and generated 2-chloroquinoline-3-carboxaldehyde.<sup>550</sup> Used in conjunction with conjugated hydroxylamines, a tandem *Vilsmeier-Beckman reaction* (see **18-17** for the *Beckman rearrangement*) leads to pyridines (2-chloro-3-carbaldehyde).<sup>551</sup> A chain-extension variation has been reported in which an aryl alkyl ketone is treated with POCl<sub>3</sub>/DMF on silica with microwave irradiation to give a conjugated aldehyde:<sup>552</sup>

When (CF<sub>3</sub>SO<sub>2</sub>)<sub>2</sub>O was used instead of POCl<sub>3</sub>, the reaction was extended to some less-active compounds, including naphthalene and phenanthrene.<sup>553</sup> The reaction of aryl ethers, phenol, and also arenes with 3 equivalents of AgOTf and 3 equivalents of Cl<sub>2</sub>CHOMe

gave the *ortho* formyl derivative.<sup>554</sup> Aryl halides reacted with *t*-BuNC and Et<sub>3</sub>SiH in DMF, with Pd(OAc)<sub>2</sub> and JohnPhos, to give the aryl aldehyde.<sup>555</sup> Aryl iodides reacted with CO and H<sub>2</sub> with a Pd catalyst to give the aryl carbaldehyde.<sup>556</sup> Aryl bromides reacted with paraformaldehyde and Et<sub>3</sub>SiH with a Pd catalyst gave the aryl carbaldehyde.<sup>557</sup> Aryl iodides reacted with CO, base, and a Pd catalyst in PEG-400 to give the aryl carbaldehyde.<sup>558</sup> The Pd-catalyzed formylation of aryl iodides used formic acid.<sup>559</sup> Arylzinc halides reacted with *S*-phenylthioformate and a Pd catalyst to give the corresponding aryl carbaldehyde.<sup>560</sup> Aromatic iodides are formylated using CO<sub>2</sub> with a Pd catalyst on nanoparticles grafted onto amino-functionalized nanostarch. The reaction of aryl halides with CO<sub>2</sub> and PMHS, in the presence of a Pd catalyst and DBU, gave aryl aldehydes.<sup>561</sup>

Indoles reacted with *N*-methylaniline and TBHP with a RuCl<sub>3</sub> catalyst to give the 3-formylindole.<sup>562</sup> Indoles reacted with DMSO and 4 equivalents of ammonium acetate in water, at 150 °C, to give the 3-formylindole.<sup>563</sup> Indoles and quinolines reacted with formic acid and a Pd/C catalyst to give the formyl derivative.<sup>564</sup> Hexamethylenetetramine and air was used for the iodine-catalyzed C3-formylation of indole derivatives.<sup>565</sup> *N*-Alkyldihydropyrroles reacted with DMSO in air, with 60% FeCl<sub>3</sub>, to give the corresponding 2-formylpyrrole.<sup>566</sup>

OS I, 217; III, 98, IV, 331, 539, 831, 915.

Several other formylation methods are known.<sup>567</sup> Dichloromethyl methyl ether formylates aromatic rings with *Friedel-Crafts catalysts*, giving the aldehyde.<sup>568</sup> The ArCHClOMe compound is probably an intermediate. Orthoformates have also been used.<sup>569</sup> In another method, aromatic rings are formylated with formyl fluoride (HCOF) and BF<sub>3</sub>.<sup>570</sup> Unlike formyl chloride, formyl fluoride is stable enough for this purpose. This reaction was successful for benzene, alkylbenzenes, PhCl, PhBr, and naphthalene. Phenols can be regioselectively formylated in the *ortho* position in high yields by treatment with 2 molar equivalents of paraformaldehyde in aprotic solvents in the presence of SnCl<sub>4</sub> and a tertiary amine.<sup>571</sup>

Formylation with  $\text{Zn}(\text{CN})_2$  and  $\text{HCl}$  is called the *Gatterman reaction*.<sup>572</sup> It can be applied to alkylbenzenes, phenols and their ethers, and many heterocyclic compounds. However, it cannot be applied to aromatic amines. In the original version of this reaction the substrate was treated with  $\text{HCN}$ ,  $\text{HCl}$ , and  $\text{ZnCl}_2$ , but the use of  $\text{Zn}(\text{CN})_2$  and  $\text{HCl}$  ( $\text{HCN}$  and  $\text{ZnCl}_2$  are generated *in situ*) makes the reaction more convenient to carry out and yields are not diminished. The mechanism of the Gatterman reaction has not been investigated very much, but it is known that an initially formed but not isolated nitrogen-containing product is hydrolyzed to aldehyde. This product is presumed to be  $\text{ArCH}=\text{NH}_2^+ \text{Cl}^-$ , as shown. When benzene was treated with  $\text{NaCN}$  under superacid conditions ( $\text{F}_3\text{CSO}_2\text{OH}-\text{SbF}_5$ , Sec. 5.A.ii), a good yield of product was obtained, leading to the conclusion that the electrophile in this case was  $^+\text{C}(\text{H})=\text{N}^+\text{H}_2$ .<sup>573</sup> The Gatterman reaction may be regarded as a special case of 11-24.

Another method, formylation with  $\text{CO}$  and  $\text{HCl}$  in the presence of  $\text{AlCl}_3$  and  $\text{CuCl}$ <sup>574</sup> (the *Gatterman-Koch reaction*), is limited to benzene and alkylbenzenes.<sup>575</sup> Aryl halides are converted to aryl aldehydes with  $\text{CO}/\text{H}_2$  in the presence of a  $\text{Pd}$  catalyst.<sup>576</sup>

OS II, 583; III, 549.

In the *Reimer-Tiemann reaction*, aromatic rings are formylated by reaction with chloroform and hydroxide ion.<sup>577</sup> The method is useful only for phenols and certain heterocyclic compounds such as pyrroles and indoles. Unlike the previous formylation methods (in this section), this one is conducted in basic solution. Yields are generally low, seldom rising above 50%.<sup>578</sup> The incoming group is directed *ortho*, unless both *ortho* positions are filled, in which case the attack is *para*.<sup>579</sup> Certain substrates have been shown to give abnormal products instead of or in addition to the normal ones.<sup>580</sup>

A method closely related to the Reimer-Tiemann reaction is the *Duff reaction*, in which hexamethylenetetramine  $(\text{CH}_2)_6\text{N}_4$  is used instead of chloroform. This reaction can be applied only to phenols and amines; *ortho* substitution is generally observed and yields

<sup>572</sup> See Truce, W.E. *Org. React.* **1957**, 9, 37; Tanaka, M.; Fujiwara, M.; Ando, H. *J. Org. Chem.* **1995**, 60, 2106 for rate studies.

are low. A mechanism<sup>581</sup> has been proposed that involves initial aminoalkylation (**11-22**) to give  $\text{ArCH}_2\text{NH}_2$ , followed by dehydrogenation to  $\text{ArCH}=\text{NH}$  and hydrolysis of this to the aldehyde product. When  $(\text{CH}_2)_6\text{N}_4$  is used in conjunction with  $\text{F}_3\text{CCO}_2\text{H}$ , the reaction can be applied to simple alkylbenzenes; yields are much higher and a high degree of regioselective *para* substitution is found.<sup>582</sup> In this case too an imine seems to be an intermediate. Reaction **11-19** is the direct carboxylation<sup>583</sup> of aromatic rings.<sup>584</sup>

OS III, 463; IV, 866.

### 11-19 Aryl Carboxylic Acid Formation

Phosgene, in the presence of *Friedel-Crafts catalysts*, can carboxylate the ring. This process is analogous to **11-17**, but the  $\text{ArCOCl}$  product initially produced hydrolyzes to the carboxylic acid. However, in most cases the reaction does not take this course, but instead the  $\text{ArCOCl}$  is attacked by another ring to give a ketone  $\text{ArCOAr}$ . A number of other reagents have been used to get around this difficulty, including oxalyl chloride, urea hydrochloride, chloral ( $\text{Cl}_3\text{CCHO}$ ),<sup>585</sup> carbamoyl chloride ( $\text{H}_2\text{NCOCl}$ ), and *N,N*-diethylcarbamoyl chloride.<sup>586</sup> With carbamoyl chloride the reaction is called the *Gatterman amide synthesis* and the product is an amide. Among compounds carboxylated by one or another of these reagents are benzene, alkylbenzenes, and fused ring systems.<sup>587</sup>

Although mechanistically different, other methods are available to convert aromatic compounds to aromatic carboxylic acids. The Pd-catalyzed reaction of aromatic compounds and formic acid leads to benzoic acid derivatives.<sup>588</sup> Diphenyliodonium tetrafluoroborate,  $\text{Ph}_2\text{I}^+ \text{BF}_4^-$  reacts with CO and indium in DMF, with a Pd catalyst, to give benzophenone.<sup>589</sup> The Ni-catalyzed reaction of  $\text{CO}_2$  with aryl bromides and aryl triflates led to carboxylation.<sup>590</sup> 2-Phenylpyridine reacted with  $\text{CO}_2$  and 2 equivalents of  $\text{AlMe}_2(\text{OMe})$ , in the presence of a Rh catalyst, to give the 2-pyridylbenzoic acid.<sup>591</sup> Aryl or vinyl chlorides reacted with  $\text{CO}_2$  and a Ni catalyst, mediated by Mn, to give the corresponding carboxylic acid.<sup>592</sup> Aryl iodides reacted with CO and  $\text{K}_2\text{CO}_3$  with a Pd catalyst to give the benzoic acid derivative.<sup>593</sup> Aryl bromides reacted with epoxides and an alcohol in the presence of

Pd/C at 150 °C to give the corresponding aryl ester.<sup>594</sup> Arylboronic esters reacted with CO<sub>2</sub> and a Ag catalyst to give the aryl carboxylic acid.<sup>595</sup>

The reaction of indoles with CO<sub>2</sub> and 5 equivalents of LiOtBu in DMF at 100 °C gave the indole 3-carboxylic acid.<sup>596</sup> Indole 3-carboxylate esters were prepared from indoles and CO and an alcohol in the presence of K<sub>2</sub>S<sub>2</sub>O<sub>8</sub> and a Rh catalyst.<sup>597</sup>

OS V, 706; VII, 420.

Sodium phenoxides can be carboxylated, mostly in the *ortho* position, by carbon dioxide (the *Kolbe-Schmitt reaction*). The mechanism is not clearly understood, but apparently some kind of a complex is formed between the reactants (Ar–O•••Na•••O=C=O),<sup>598</sup> making the carbon of the CO<sub>2</sub> more positive and putting it in a good position to attack the ring. Potassium phenoxide, which is less likely to form such a complex, chiefly reacts at the *para* position. There is evidence that, in the complex formed from potassium salts, the bonding is between the aromatic compound and the carbon atom of CO<sub>2</sub>.<sup>599</sup> Carbon tetrachloride can be used instead of CO<sub>2</sub>, under *Reimer-Tiemann* (**11-18**) conditions.

A Pd-catalyzed reaction has been used to directly prepare acyl fluorides.<sup>600</sup> Molybdovanadophosphates have been used for the carboxylation of anisole in the presence of CO and O<sub>2</sub>.<sup>601</sup> Sodium or potassium phenoxide can be carboxylated regioselectively in the *para* position in high yield by treatment with Na<sub>2</sub>CO<sub>3</sub> or K<sub>2</sub>CO<sub>3</sub> and CO.<sup>602</sup> <sup>14</sup>C labeling showed that it is the carbonate carbon that appears in the *p*-hydroxybenzoic acid product.<sup>603</sup> The CO is converted to sodium formate or potassium formate. Carbon monoxide has also been used to carboxylate aromatic rings with Pd compounds as catalysts.<sup>604</sup> A Pd-catalyzed carboxylation has been reported using Ag<sub>2</sub>CO<sub>3</sub> and CO.<sup>605</sup>

An enzymatic carboxylation was reported, in supercritical CO<sub>2</sub> (Sec. 9.D.ii), in which exposure of pyrrole to *Bacillus megaterium* PYR2910 and KHCO<sub>3</sub> gave the potassium salt of pyrrole 2-carboxylic acid.<sup>606</sup>

## 11-20 Carboxylation: Amidation

*N*-Substituted amides can be prepared by direct attack of isocyanates on aromatic rings.<sup>607</sup> The R group may be alkyl or aryl but, if the latter, dimers and trimers are also obtained. Isothiocyanates similarly give thioamides.<sup>608</sup> The reaction has been carried out intramolecularly both with aralkyl isothiocyanates and acyl isothiocyanates.<sup>609</sup> In the latter case, the product is easily hydrolyzable to a dicarboxylic acid; this is a way of putting a carboxyl group on a ring *ortho* to one already there. The reaction gives better yields with substrates such as ArCH<sub>2</sub>CONCS, where six-membered rings are formed.

There are interesting transition metal-catalyzed reactions that lead to aryl amides.<sup>610</sup> The use of POCl<sub>3</sub> and DMF, with a Pd catalyst, converts aryl iodides to benzamides.<sup>611</sup> Carbonylation is another method that generates amides. Aminocarbonylation is accomplished with microwave irradiation using hydroxylamine as an ammonia equivalent.<sup>612</sup>

Benzamide derivatives and heteroaryl carboxamide derivatives reacted with TsNH<sub>2</sub> and Cu(OAc)<sub>2</sub> in the air to give the *ortho* *N*-anilide derivative.<sup>613</sup> Arenes reacted with formamides and POCl<sub>3</sub> and Pd(OAc)<sub>2</sub>/Xantiphos to give the corresponding benzamide derivative.<sup>614</sup> An indole reacted with *N*-phenylacetamide to give the *N*-phenyl-*N*-acetylindole using 2 equivalents of *t*-butyl peroxide and 20% CuBr.<sup>615</sup> Phenol derivatives reacted with CO, ammonia, DBU, and C<sub>4</sub>H<sub>9</sub>SO<sub>2</sub>F, with a Pd catalyst, to give the benzamide derivative.<sup>616</sup> The reaction of aryl bromides, CO, and ammonium carbamate gave benzamide derivatives in the presence of a Pd catalyst.<sup>617</sup>

Arylboronic acids reacted with benzonitrile and with KO*t*-Bu and a Cu catalyst to give the *N*-arylbenzamide derivative.<sup>618</sup> Aryl halides reacted with alkyl isonitriles in the presence of Cu<sub>2</sub>O and Cs<sub>2</sub>CO<sub>3</sub> in 80% aqueous DMSO to give the *N*-alkylbenzamide derivative.<sup>619</sup> Aryl halides also reacted with isocyanides using a polymer-supported Pd/*N*-heterocyclic carbene complex to give the benzamide derivative.<sup>620</sup> Aryl iodides reacted with primary amines in the presence of CO and a Pd catalyst to give the corresponding benzamide

### 11-21 Carbonylation: Formation of Aryl Ketones

When a nucleophile adds to the carbonyl of carboxylic acid derivatives such as acid chlorides and esters, the resulting tetrahedral intermediate has the leaving groups Cl and OR. Loss of  $\text{Cl}^-$  or  $\text{RO}^-$  regenerates the  $\text{C}=\text{O}$  unit and the overall result of this process is a substitution reaction in which the nucleophile replaces chlorine or alkoxy on the carbonyl. This reaction with carboxylic acid derivatives (acid chlorides, esters, anhydrides, amides) is therefore called *nucleophilic acyl substitution*. Grignard reagents react with acid derivatives to give a ketone. However, ketones are slightly more reactive than the ester, so there is a competition for reaction with the Grignard reagent. In a typical reaction, all of the ester and Grignard reagent will be consumed, and there will be a mixture of the ketone and alcohol products. Esters, anhydrides, and amides give similar products via acyl substitution. The best leaving group is chloride, followed closely by carboxylate (acid chlorides and anhydrides, respectively), and then the alkoxy group from an ester. Organolithium reagents generally behave similarly. Organometallics other than Grignard reagents or organolithium reagents have been used that give the ketone directly.

Gilman and co-workers<sup>624</sup> discovered that a Grignard reagent reacts with cadmium chloride ( $\text{CdCl}_2$ ) to give a dialkylcadmium reagent ( $\text{R}_2\text{Cd}$ ), and this less reactive organometallic is more selective in its reactions with carbonyl derivatives.<sup>625</sup> Apart from the reaction of organocadmium reagents, organocuprates react with acid chlorides to give the ketone, and this reaction is discussed as reaction **16-29**. The reaction of organometallic compounds with carboxylic acid derivatives or with aryl halides and  $\text{CO}$ <sup>626</sup> leads to the corresponding ketone, and alternative methods for the preparation of aryl ketones have been reported.

Heteroaryl iodides reacted with heteroarenes and  $\text{CO}$ , in the presence of a Pd catalyst, to give the diaryl ketone.<sup>627</sup> Aryl halides reacted with potassium monoethyl malonate in the presence of  $\text{Pd}(\text{OAc})_2$ , imidazole,  $\text{MgCl}_2/\text{NEt}_3$ , and  $\text{Co}_2(\text{CO})_8$ , with microwave irradiation, to give the corresponding  $\beta$ -keto ester.<sup>628</sup> 4-Aminophenyl zinc iodide and 3-aminophenyl zinc iodide were generated from the corresponding aryl iodide by reaction with zinc metal, and reaction with acid chlorides gave the diaryl ketone.<sup>629</sup> Aryl halides reacted with phenylboronic acids and benzene-1,3,5-triyl triformate as the  $\text{CO}$  source, with a Pd catalyst, to give the diaryl ketone.<sup>630</sup> Functionalized aromatic compounds reacted with aryl aldehydes in air, with a Pd catalyst, to give the diaryl ketone.<sup>631</sup> Aryl aldehydes reacted with aryl iodonium

compounds, in the presence of a Rh or Ir catalyst, to give the diaryl ketone.<sup>632</sup> Aryl iodides reacted with CO and a nucleophile to give the 1,2-diketone derivative in the presence of a Pd catalyst.<sup>633</sup>

### 11-22 Aminoalkylation and Amidoalkylation

Phenols, secondary and tertiary aromatic amines,<sup>634</sup> pyrroles, and indoles can be aminomethylated by treatment with formaldehyde and a secondary amine. Other aldehydes have sometimes been employed. Aminoalkylation is a special case of the *Manich reaction* (16-17). When phenols and other activated aromatic compounds are treated with *N*-hydroxymethylchloroacetamide, *amidomethylation* takes place<sup>635</sup> to give the aminomethyl derivative, which is often hydrolyzed *in situ* to the aminoalkylated product. Other *N*-hydroxyalkyl and *N*-chlorinated compounds have also been used.<sup>417</sup> Nitroethane in polyphosphoric acid can be used for the acetamidation of aromatic compounds.<sup>636</sup> Aldimines reacted with pyridine derivatives in the presence of a secondary amine and a lanthanum complex that resulted in the *ortho* aminomethyl pyridine.<sup>637</sup> Aryl halides are aminomethylated with potassium organotrifluoroborates.<sup>638</sup>

OS I, 381; IV, 626; V, 434; VI, 965; VII, 162.

### 11-23 Thioalkylation

A methylthiomethyl group can be inserted into the *ortho* position of phenols by heating with dimethyl sulfoxide and 1,3-dicyclohexylcarbodiimide (DCC).<sup>639</sup> Other reagents can be used instead of DCC, among them  $\text{SOCl}_2$ <sup>640</sup> or acetic anhydride.<sup>641</sup> Alternatively, the phenol can be treated with dimethyl sulfide and *N*-chlorosuccinimide (NCS), followed by triethylamine.<sup>642</sup>

## 11-24 Acylation with Nitriles: The Hoesch Reaction

Friedel-Crafts acylation with nitriles and HCl is called the *Hoesch* or the *Houben-Hoesch reaction*.<sup>643</sup> In most cases, a Lewis acid is necessary, and zinc chloride is the most common. The reaction is generally useful only with phenols, phenolic ethers, and some reactive heterocyclic compounds such as pyrrole, but it can be extended to aromatic amines by the use of  $\text{BCl}_3$ .<sup>644</sup> Acylation in the case of aniline derivatives is regioselectively *ortho*. Monohydric phenols, however, generally do not give ketones<sup>645</sup> but are attacked at the oxygen to produce imino esters. Many nitriles have been used. Even aryl nitriles give good yields if they are first treated with HCl and  $\text{ZnCl}_2$  and then the substrate added at 0 °C.<sup>646</sup> In fact, this procedure increases yields with any nitrile. If thiocyanates  $\text{RSCN}$  are used, thiol esters  $\text{ArCOSR}$  can be obtained. The *Gatterman reaction* (11-18) is a special case of the Hoesch synthesis.

The reaction mechanism is complex and not completely settled.<sup>647</sup> The first stage consists of an attack on the substrate by a species containing the nitrile and HCl (and the Lewis acid, if present) to give an imine salt (an imino ester, **42**). Among the possible reactive species are **40** and **41**. In the second stage, the salts are hydrolyzed to the products, first the iminium salt, and then the ketone.

Ketones can also be obtained by treating phenols or phenolic ethers with a nitrile in the presence of  $\text{F}_3\text{CSO}_2\text{OH}$ .<sup>648</sup> The mechanism in this case is different.

OS II, 522.

## 11-25 Cyanation

Aromatic hydrocarbons (including benzene), phenols, and phenolic ethers can be cyanated with trichloroacetonitrile,  $\text{BrCN}$ , or mercury fulminate  $\text{Hg}(\text{ONC})_2$ .<sup>649</sup> In the case of

<sup>643</sup> See Ruske, W. in Olah, G.A. *Friedel-Crafts and Related Reactions*, Vol. 3, Wiley, NY, **1964**, pp. 383–497.

## 11-26 Hydroxylation

There have been only a few reports of direct hydroxylation<sup>665</sup> by an electrophilic process (see, however, **14-4**).<sup>666</sup> In general, poor results are obtained, partly because the introduction of an OH group activates the ring, which suppresses further reaction, and quinone formation is common. However, alkyl-substituted benzenes, such as mesitylene or durene, can be hydroxylated in good yield with  $\text{CF}_3\text{CO}_3\text{H}$  and  $\text{BF}_3$ .<sup>667</sup> In the case of mesitylene, the product, 2,4,6-trimethylphenol, is not subject to further attack. In a related procedure, even benzene and substituted benzenes (e.g., PhMe, PhCl, xylenes) can be converted to phenols in good yields with sodium perborate/ $\text{F}_3\text{CSO}_2\text{OH}$ .<sup>668</sup> Aromatic amines, *N*-acyl amines, and phenols were hydroxylated with  $\text{H}_2\text{O}_2$  in  $\text{SbF}_5/\text{HF}$ .<sup>669</sup>

Another hydroxylation reaction is the *Elbs reaction*.<sup>670</sup> In this method phenols can be oxidized to *p*-diphenols with  $\text{K}_2\text{S}_2\text{O}_8$  in alkaline solution.<sup>671</sup> Primary, secondary, or tertiary aromatic amines give predominant or exclusive *ortho* substitution unless both *ortho* positions are blocked, in which case *para* substitution is found. The reaction with amines is called the *Boylan-Sims oxidation*. Yields are low with either phenols or amines, generally <50%. The mechanisms are not clear<sup>672</sup> but have been reviewed.<sup>673</sup>

Electrolysis of benzene, in the presence of trifluoroacetic acid and triethylamine, leads to a 73% yield of phenol.<sup>674</sup> Photolytic hydroxylation of benzene has been reported in the presence of mesoporous  $\text{TiO}_2$ .<sup>675</sup> Nitrous oxide has been used as an oxidant, in the presence of  $\text{FeAlPO}$  catalysts.<sup>676</sup>

## G. Metal Electrophiles

Reactions in which a metal replaces the hydrogen of an aromatic ring are considered along with their aliphatic counterparts in reactions **12-22** and **12-23**.

## 11.F.ii. Hydrogen as the Leaving Group In Rearrangement Reactions

In these reactions a group is detached from a *side chain* and then reattached the ring, but in other aspects they resemble the reactions already treated in this chapter.<sup>677</sup> Since a group moves from one position to another in a molecule, these are rearrangements (also see Chapter 18). When considering if a given rearrangement is intermolecular or intramolecular, there is evidence that, at least in some cases, an intermolecular mechanism can still result in a high degree of *ortho* migration.<sup>678</sup>

### A. Groups Cleaving from Oxygen

#### 11-27 The Fries Rearrangement

Phenolic esters can be rearranged by heating with *Friedel-Crafts catalysts* in a synthetically useful reaction known as the *Fries rearrangement*.<sup>679</sup> Both *o*- and *p*-acylphenols can be produced, and it is often possible to select conditions so that one predominates. The *ortho/para* ratio is dependent on the temperature, solvent, and amount of catalyst used. Exceptions are known, but low temperatures generally favor the *para* product and high temperatures the *ortho* product. The R group may be aliphatic or aromatic. Any *meta*-directing substituent on the ring interferes with the reactions, as might be expected for a Friedel-Crafts process. In the case of aryl benzoates treated with  $F_3CSO_2OH$ , the Fries rearrangement was shown to be reversible and an equilibrium was established.<sup>680</sup> Transition metal-catalyzed Fries rearrangements have been reported.<sup>681</sup> Methanesulfonic acid has been used to initiate a Fries rearrangement of aryl phenylacetate to hydroxy aryl ketones.<sup>682</sup>

Questions remain about the exact mechanism.<sup>683</sup> Opinions have been expressed that it is completely intermolecular,<sup>684</sup> completely intramolecular,<sup>685</sup> and partially inter- and intramolecular.<sup>686</sup> One way to decide between inter- and intramolecular processes is to

run the reaction of the phenolic ester in the presence of another aromatic compound, say, toluene. If some of the toluene is acylated, the reaction must be, at least in part, intermolecular. If the toluene is not acylated, the presumption is that the reaction is intramolecular, although this is not certain, for it may be that the toluene is not attacked because it is less active than the first reactant. A number of such experiments (called *crossover experiments*) have been carried out; sometimes crossover products have been found and sometimes not. As in **11-17**, an initial complex ( $\text{ArO}(\text{R})\text{C}=\text{O}^+-\text{AlCl}_3^-$ ) is formed between the substrate and the catalyst, so that a catalyst/substrate molar ratio of at least 1:1 is required. In the presence of aluminum chloride, the Fries rearrangement can be induced with microwave irradiation,<sup>687</sup> but simply heating phenyl acetate with microwave irradiation gives the Fries rearrangement.<sup>688</sup> The Fries rearrangement has been carried out in ionic melts.<sup>689</sup>

The Fries rearrangement can also be carried out with UV light, in the absence of a catalyst.<sup>690</sup> This reaction, called the *photo-Fries rearrangement*,<sup>691</sup> is predominantly an intramolecular free-radical process. Both *ortho* and *para* migration are observed.<sup>692</sup> Unlike the Lewis acid-catalyzed Fries rearrangement, the photo-Fries reaction can be accomplished, though often in low yields, when *meta*-directing groups are on the ring. The available evidence strongly suggests the following mechanism involving formation of the excited state ester followed by dissociation to a radical pair in a solvent cage<sup>693</sup> for the photo-Fries rearrangement<sup>694</sup> (illustrated for formation of the *para* product).

The phenol  $\text{ArOH}$  is always a side product, resulting from some  $\text{ArO}\cdot$  that leaks from the solvent cage and abstracts a hydrogen atom from a neighboring molecule. When the reaction was performed on phenyl acetate in the gas phase, where there are no solvent molecules to form a cage (but in the presence of isobutane as a source of abstractable hydrogen atoms), phenol was the chief product and virtually no *o*- or *p*-hydroxyacetophenone was found.<sup>695</sup> Other evidence<sup>696</sup> for the mechanism is that CIDNP has been observed during the course

<sup>687</sup> Khadilkar, B.M.; Madyar, V.R. *Synth. Commun.* **1999**, *29*, 1195.

<sup>696</sup> See Shine, H.J.; Subotkowski, W. *J. Org. Chem.* **1987**, *52*, 3815.

of the reaction<sup>697</sup> and that the ArO• radical has been detected by flash photolysis<sup>698</sup> and by nanosecond time-resolved Raman spectroscopy.<sup>699</sup>

A lithium diisopropylamide (LDA)-mediated anionic Fries rearrangement of aryl carbamates has been reported.<sup>700</sup> So-called *anionic Snieckus-Fries rearrangement* has also been discussed.<sup>701</sup> Treatment of *O*-arylsulfonate esters with AlCl<sub>3</sub>/ZnCl<sub>2</sub> on silica with microwave irradiation, leads to 2-sulfonyl phenols in a thia-Fries rearrangement.<sup>702</sup> A similar reaction was reported with *O*-arylsulfonamides.<sup>703</sup>

OS II, 543; III, 280, 282.

## B. Groups Cleaving from Nitrogen<sup>704</sup>

It has been shown that PhNH<sub>2</sub>D<sup>+</sup>Cl<sup>-</sup> rearranges to *o*- and *p*-deuterioaniline.<sup>705</sup> The migration of OH, formally similar to reactions **11-28** to **11-32**, is a nucleophilic substitution and is treated in **13-33**.

### 11-28 Migration of the Nitro Group

*N*-Nitro aromatic amines rearrange on treatment with acids to *o*- and *p*-nitroamines, with the *ortho* compounds predominating.<sup>706</sup> Aside from this indication of an intramolecular process, there is also the fact that virtually no *meta* isomer is produced in this reaction,<sup>707</sup> although direct nitration of an aromatic amine generally gives a fair amount of *meta* product. Thus, a mechanism in which NO<sub>2</sub><sup>+</sup> is dissociated from the ring and then is attacked by another molecule must be ruled out. Further results indicating an intramolecular process include the observation that rearrangement of several substrates in the presence of K<sup>15</sup>NO<sub>3</sub> gave products containing no <sup>15</sup>N,<sup>708</sup> and that rearrangement of a mixture of PhNH<sup>15</sup>NO<sub>2</sub> and unlabeled *p*-MeC<sub>6</sub>H<sub>4</sub>NHNO<sub>2</sub> gave 2-nitro-4-methylaniline containing no <sup>15</sup>N.<sup>709</sup> On

the other hand, rearrangement of **43** in the presence of unlabeled PhNMeNO<sub>2</sub> gave labeled **44**, which did not arise by displacement of F.<sup>710</sup>

The R group may be hydrogen or alkyl. Two principal mechanisms have been suggested, one involving cyclic attack by the oxygen of the nitro group at the *ortho* position before the group cleaves,<sup>711</sup> and the other involving a cleavage into a radical and a radical ion held together in a solvent cage.<sup>712</sup> Among the evidence for the latter view<sup>713</sup> are the effects of substituents on the rate of the reaction,<sup>714</sup> Kinetic isotope effects using <sup>15</sup>N and <sup>14</sup>C that show nonconcertedness,<sup>715</sup> as do the fact that both *N*-methylaniline and nitrous acid are produced in sizable and comparable amounts in addition to the normal products *o*- and *p*-nitro-*N*-methylaniline.<sup>716</sup> These side products are formed when the radicals escape from the solvent cage.

### 11-29 Migration of the Nitroso Group: The Fischer-Hepp Rearrangement

The migration of a nitroso group, formally similar to **11-28**, is important because *p*-nitroso secondary aromatic amines cannot generally be prepared by direct *C*-nitrosation of secondary aromatic amines (see **12-49**). The reaction, known as the *Fischer-Hepp rearrangement*,<sup>717</sup> is brought about by treatment of *N*-nitroso secondary aromatic amines with HCl. Other acids give poor or no results. In benzene systems the *para* product is usually formed

exclusively.<sup>718</sup> The mechanism of the rearrangement is not completely understood. The fact that the reaction takes place in a large excess of urea<sup>719</sup> shows that it is intramolecular<sup>720</sup> since, if  $\text{NO}^+$ ,  $\text{NOCl}$ , or some similar species were free in the solution, they would be captured by the urea, preventing the rearrangement.

### 11-30 Migration of an Arylazo Group

Rearrangement of aryl triazenes can be used to prepare azo derivatives of primary and secondary aromatic amines.<sup>721</sup> These are first diazotized at the amino group (see **11-6**) to give triazenes, which are then rearranged by treatment with acid. The rearrangement always gives the *para* isomer, unless that position is occupied.

### 11-31 Migration of Halogen: The Orton Rearrangement

Migration of a halogen from a nitrogen side chain to the ring by treatment with  $\text{HCl}$  is called the *Orton rearrangement*.<sup>722</sup> The main product is the *para* isomer, though some *ortho* product may also be formed. The reaction has been carried out with *N*-chloroamines and *N*-bromoamines and less often with *N*-iodo compounds. The amine must be acylated, except that  $\text{PhNCl}_2$  gives 2,4-dichloroaniline. The reaction is usually performed in water or acetic acid. There is considerable evidence (cross-halogenation, labeling, etc.) that this is an intermolecular process.<sup>723</sup> First, the  $\text{HCl}$  reacts with the starting material to give  $\text{ArNHCOCH}_3$  and  $\text{Cl}_2$ ; then the chlorine halogenates the ring as in **11-10**. Among the evidence is that chlorine has been isolated from the reaction mixture.

The Orton rearrangement can also be brought about photochemically<sup>724</sup> and by heating in the presence of benzoyl peroxide.<sup>725</sup> These two reactions are free-radical processes.

11-32 Migration of an Alkyl or Aryl Group<sup>726</sup>

When HCl salts of arylalkylamines are heated at  $\sim 200\text{--}300\text{ }^\circ\text{C}$ , migration occurs in what is called the *Hofmann-Martius reaction*. It is an intermolecular reaction, since crossing is found. For example, methylanilinium bromide gave not only the normal products *o*- and *p*-toluidine but also aniline and di- and trimethylanilines.<sup>727</sup> As expected for an intermolecular process, there is isomerization when R is primary.

With primary R, the reaction probably goes through the alkyl halide formed initially in an  $\text{S}_{\text{N}}2$  reaction:

Evidence for this view is that alkyl halides have been isolated from the reaction mixture and that  $\text{Br}^-$ ,  $\text{Cl}^-$ , and  $\text{I}^-$  gave different *ortho/para* ratios, which indicates that the halogen is involved in the reaction.<sup>727</sup> Further evidence is that the alkyl halides isolated are not rearranged (as would be expected if they are formed by an  $\text{S}_{\text{N}}2$  mechanism), even though the alkyl groups in the ring are rearranged. Once the alkyl halide is formed, it reacts with the substrate by a normal *Friedel-Crafts alkylation* process (11-11), accounting for the rearrangement. When R is secondary or tertiary, carbocations may be directly formed so that the reaction does not go through the alkyl halides.<sup>728</sup>

It is also possible to carry out the reaction by heating the amine (not the salt) at a temperature between 200 and 350  $^\circ\text{C}$  with a metal halide, such as  $\text{CoCl}_2$ ,  $\text{CdCl}_2$ , or  $\text{ZnCl}_2$ . When this is done, the reaction is called the *Reilly-Hickinbottom rearrangement*. Primary R groups larger than ethyl give both rearranged and unrearranged products.<sup>729</sup> The reaction is not generally useful for secondary and tertiary R groups, which are usually cleaved to alkenes under these conditions.

When acylated arylamines are photolyzed, migration of an acyl group takes place<sup>730</sup> in a process that resembles the photo-Fries reaction (11-27). The migration of phenyl groups is known via ipso arenium ions.<sup>731</sup>

## 11.F.iii. Other Leaving Groups

Three types of reactions are considered in this section.

1. Reactions in which hydrogen replaces another leaving group:

<sup>726</sup> See Grillot, G.F. *Mech. Mol. Migr.* **1971**, 3, 237; Shine, H.J. *Aromatic Rearrangements*, Elsevier, NY, **1967**, pp. 249–257.

<sup>728</sup> Hart, H.; Kosak, J.R. *J. Org. Chem.* **1962**, 27, 116.

<sup>729</sup> See Birchall, J.M.; Clark, M.T.; Goldwhite, H.; Thorpe, D.H. *J. Chem. Soc., Perkin Trans. 1* **1972**, 2579.

<sup>730</sup> See Nassetta, M.; de Rossi, R.H.; Cosa, J.J. *Can. J. Chem.* **1988**, 66, 2794.

<sup>731</sup> Ajaz, A.; McLaughlin, E.C.; Skraba, S.L.; Thammatam, R.; Johnson, R.P. *J. Org. Chem.* **2012**, 77, 9487.

2. Reactions in which an electrophile other than hydrogen replaces another leaving group:

3. Reactions in which a group (other than hydrogen) migrates from one position in a ring to another. Such migrations can be either inter- or intramolecular, as in the migration of an *ortho* X group to the *para* position.

The three types are not treated separately, but reactions are classified by leaving group.

## A. Carbon Leaving Groups

### 11-33 Reversal of Friedel-Crafts Alkylation

Alkyl groups can be cleaved from aromatic rings by treatment with proton acids and/or Lewis acids. Tertiary R groups are the most easily cleaved; because this is true, the *tert*-butyl group is occasionally introduced into a ring, used to direct another group, and then removed.<sup>732</sup> For example, 4-*tert*-butyltoluene (**45**) reacted with benzoyl chloride and AlCl<sub>3</sub> to give the acylated product, and subsequent treatment with AlCl<sub>3</sub> led to loss of the *tert*-butyl group to give **46**.<sup>733</sup>

Because of this reaction, care must be taken when using Friedel-Crafts catalysts (Lewis acids or proton acids) on aromatic compounds containing alkyl groups. Secondary R groups are harder to cleave, and primary R harder still. True cleavage, in which the R becomes an alkene, occurs only at high temperatures, >400 °C.<sup>734</sup> At ordinary temperatures, the R group attacks another ring, so that the bulk of the product may be dealkylated, but there is a residue of heavily alkylated material.

The isomerization reaction, in which a group migrates from one position in a ring to another or to a different ring, is more important than true cleavage. In these reactions, the *meta* isomer is generally the most favored product among the dialkylbenzenes; and the 1,3,5 product the most favored among the trialkylbenzenes, because they have the highest thermodynamic stabilities.

Alkyl migrations can be inter- or intramolecular, depending on the conditions and on the R group. The following experiments can be cited:

<sup>732</sup> Tashiro, M. *Synthesis* **1979**, 921; Tashiro, M.; Fukata, G. *Org. Prep. Proced. Int.* **1976**, 8, 51.

<sup>733</sup> Hofman, P.S.; Reiding, D.J.; Nauta, W.T. *Recl. Trav. Chim. Pays-Bas* **1960**, 79, 790.

<sup>734</sup> Olah, G.A. in Olah, G.A. *Friedel-Crafts and Related Reactions*, Vol. 1, Wiley, NY, **1963**, pp. 36–38.

- Ethylbenzene treated with HF and BF<sub>3</sub> gave, almost completely, benzene and diethylbenzenes<sup>735</sup> (entirely intermolecular).
- Propylbenzene labeled in the β position gave benzene, propylbenzene, and di- and tripropylbenzenes, but the propylbenzene recovered was partly labeled in the α position and not at all in the γ position<sup>736</sup> (both intra- and intermolecular).
- *o*-Xylene treated with HBr and AlBr<sub>3</sub> gave a mixture of *o*- and *m*- but no *p*-xylene, while *p*-xylene gave *p*- and *m*- but no *o*-xylene, and no trimethyl compounds could be isolated in these experiments<sup>737</sup> (exclusively intramolecular rearrangement).

Apparently, methyl groups migrate only intramolecularly, while other groups may follow either path.<sup>738</sup>

The mechanism<sup>739</sup> of intermolecular rearrangement can involve free alkyl cations, but there is much evidence to show that this is not necessarily the case. For example, many of them occur without rearrangement within the alkyl group.<sup>740</sup> Evidence for this mechanism is that optically active PhCHDCH<sub>3</sub> labeled in the ring with <sup>14</sup>C and treated with GaBr<sub>3</sub> in the presence of benzene gave ethylbenzene containing no deuterium and also ethylbenzene that contained two deuterium atoms. The rate of loss of radioactivity was about equal to the rate of loss of optical activity.<sup>740</sup> The mechanism of intramolecular rearrangement is not very clear. 1,2 shifts of this kind have been proposed.<sup>741</sup> There is evidence from <sup>14</sup>C labeling that intramolecular migration occurs only through 1,2 shifts.<sup>742</sup> Any 1,3 or 1,4 migration takes place by a series of two or more 1,2 shifts.

Phenyl groups have also been found to migrate. Thus *o*-terphenyl, heated with AlCl<sub>3</sub>/H<sub>2</sub>O, gave a mixture containing 7% *o*-, 70% *m*-, and 23% *p*-terphenyl.<sup>743</sup> Alkyl groups have also been replaced by groups other than hydrogen (e.g., nitro groups).

Unlike alkylation, *Friedel-Crafts acylation* has been generally considered to be irreversible, but a number of instances of electrofugal acyl groups have been reported,<sup>744</sup> especially where there are two *ortho* substituents, for example the hydro-debenzoylation of **47**.<sup>745</sup>

**11-34** Decarbonylation of Aromatic Aldehydes

The decarbonylation of aromatic aldehydes with sulfuric acid<sup>746</sup> is the reverse of the *Gatterman-Koch reaction* (**11-18**). It has been carried out with trialkyl- and trialkoxybenzaldehydes. The reaction takes place by the ordinary arenium ion mechanism: the attacking species is H<sup>+</sup> and the leaving group is HCO<sup>+</sup>, which can lose a proton to give CO or combine with OH<sup>-</sup> from the water solvent to give formic acid.<sup>747</sup> Aromatic aldehydes have also been decarbonylated with basic catalysts.<sup>748</sup> When basic catalysts are used, the mechanism is probably similar to the S<sub>E</sub>1 process of **11-35**. See also, **14-26**. A Ni-catalyzed decarbonylation reaction has been reported.<sup>749</sup> The extrusion of CO from ketones using a Rh catalyst was used to produce biaryls and alkyl/alkenyl arenes.<sup>750</sup>

**11-35** Decarboxylation of Aromatic Acids

The decarboxylation of aromatic acids is most often carried out by heating with Cu and quinoline. However, two other methods can be used with certain substrates. In one method the salt of the acid (ArCOO<sup>-</sup>) is heated, and in the other the carboxylic acid is heated with a strong acid, often sulfuric. The latter method is accelerated by the presence of electron-donating groups in *ortho* and *para* positions and by the steric effect of groups in the *ortho* positions; in benzene systems it is generally limited to substrates that contain such groups. In this method, decarboxylation takes place by the arenium ion mechanism,<sup>751</sup> with H<sup>+</sup> as the electrophile and CO<sub>2</sub> as the leaving group.<sup>752</sup> Evidently, the order of electrofugal ability is CO<sub>2</sub> > H<sup>+</sup> > COOH<sup>+</sup>, so that it is necessary, at least in most cases, for the COOH to lose a proton before it can cleave.

When carboxylate *ions* are decarboxylated, the mechanism is entirely different, being of the S<sub>E</sub>1 type. Evidence for this mechanism is that the reaction is first order and that electron-withdrawing groups, which would stabilize a carbanion, facilitate the reaction.<sup>753</sup>

Despite its synthetic importance, the mechanism of the Cu-quinoline method has been studied very little, but it has been shown that the actual catalyst is cuprous ion (Cu<sup>+</sup>).<sup>754</sup> In fact, the reaction proceeds much faster if the acid is heated in quinoline with cuprous

<sup>746</sup> See Taylor, R. in Bamford, C.H.; Tipper, C.F.H. *Comprehensive Chemical Kinetics*, Vol. 13, Elsevier, NY, **1972**, pp. 316–323; Schubert, W.M.; Kintner, R.R. in Patai, S. *The Chemistry of the Carbonyl Group*, Vol. 1, Wiley, NY, **1966**, pp. 695–760.

<sup>752</sup> See Willi, A.V.; Cho, M.H.; Won, C.M. *Helv. Chim. Acta* **1970**, *53*, 663.

<sup>753</sup> See Segura, P.; Bunnett, J.F.; Villanova, L. *J. Org. Chem.* **1985**, *50*, 1041.

<sup>754</sup> Cohen, T.; Schambach, R.A. *J. Am. Chem. Soc.* **1970**, *92*, 3189. See also, Aalten, H.L.; van Koten, G.; Tromp, J.; Stam, C.H.; Goubitz, K.; Mak, A.N.S. *Recl. Trav. Chim. Pays-Bas* **1989**, *108*, 295.

oxide ( $\text{Cu}_2\text{O}$ ) instead of Cu, provided that atmospheric oxygen is rigorously excluded. A mechanism has been suggested in which it is the cuprous salt of the acid that actually undergoes the decarboxylation.<sup>754</sup> It has been shown that cuprous salts of aromatic acids are easily decarboxylated by heating in quinoline<sup>755</sup> and that arylcopper compounds are intermediates that can be isolated in some cases.<sup>756</sup> Metallic silver has been used in place of copper, with higher yields.<sup>757</sup> Silver acetate has also been used to promote decarboxylation.<sup>758</sup> A photolytic decarboxylation has also been reported, under a dioxygen atmosphere in the presence of  $\text{HgF}_2$ .<sup>759</sup> The *ortho* position exerts dual effects in the decarboxylation event: *ortho* substituents destabilize but an *ortho* electron-withdrawing group adds stabilization, with the net effect that the decarboxylation energy barrier is lowered.<sup>760</sup> The photochemical decarboxylation of aryl carboxylic acids has been reported using a silver compound and  $\text{K}_2\text{S}_2\text{O}_8$ .<sup>761</sup> A decarboxylative coupling reaction of aryl halides and arylcarboxylic acids has been reported, using Pd and Cu catalysts, to give the corresponding biaryl.<sup>762</sup>

Rearrangements are also known to take place. For example, when the phthalate ion is heated with a catalytic amount of cadmium, the terphthalate ion is produced.<sup>763</sup> In a similar process, potassium benzoate heated with Cd salts disproportionates to benzene and the dianion of terephthalic acid. The term *Henkel reaction* (named for the company that patented the process) is used for these rearrangements.<sup>764</sup> An  $\text{S}_{\text{E}}1$  mechanism has been suggested.<sup>765</sup> The terphthalate is the main product because it crystallizes from the reaction mixture, driving the equilibrium in that direction.<sup>766</sup>

A decarboxylative etherification reaction has been reported in which a potassium arylcarboxylate reacted with  $\text{Si}(\text{OR})_4$ , in the presence of  $\text{Ag}_2\text{CO}_3$ ,  $\text{Cu}(\text{OAc})_2$ , and oxygen, and gave the aryl alkyl ether.<sup>767</sup> Arylamines have been prepared by the decarboxylative coupling of aryl carboxylic acids and hydroxylamines, in the presence of DCC and a Pd catalyst.<sup>768</sup> Aryl carboxylic acids reacted with  $\text{CuX}_2$  at 110 °C, with  $\text{Ag}_2\text{CO}_3$  and a Pd catalyst, to give the ipso-substituted halo aromatic compound.<sup>769</sup> A decarboxylative aryl–aryl coupling reaction was reported in which aryl carboxylic acids were coupled with arylboroxins or aryl(trialkoxo)silanes, with a silver compound and a Pd catalyst, in air.<sup>770</sup> The decarboxylative coupling of aryl carboxylic acids and benzene to give the biaryl used a silver(I) compound and 3 equivalents of  $\text{K}_2\text{S}_2\text{O}_8$ , heated to 120 °C.<sup>771</sup>

### 11-36 The Jacobsen Reaction

When polyalkyl- or polyhalobenzenes are treated with sulfuric acid, the ring is sulfonated, but rearrangement also takes place. The reaction, known as the *Jacobsen reaction*, is limited to benzene rings that have at least four substituents, which can be any combination of alkyl and halogen groups, where the alkyl groups can be ethyl or methyl and the halogens can be iodo, chloro, or bromo. When isopropyl or *tert*-butyl groups are on the ring, these groups are cleaved to give alkenes. Since a sulfo group can later be removed (19-74), the Jacobsen reaction can be used as a means of rearranging polyalkylbenzenes. The rearrangement always brings the alkyl or halo groups closer together than they were originally. Side products in the case illustrated above are pentamethylbenzenesulfonic acid, 2,4,5-trimethylbenzenesulfonic acid, and so on, indicating an intermolecular process, at least partially.

The mechanism of the Jacobsen reaction is not established,<sup>772</sup> but there is evidence, at least for polymethylbenzenes, that the rearrangement is intermolecular, and that the species to which the methyl group migrates is a polymethylbenzene, not a sulfonic acid. Sulfonation takes place after the migration.<sup>773</sup> It has been shown by labeling that ethyl groups migrate without internal rearrangement.<sup>774</sup> Isomerization of alkyl groups in substituted biphenyls has been observed<sup>775</sup> when the medium is a superacid (Sec. 5.A.ii).

### C. Metal Leaving Groups

#### 11-38 Hydrolysis of Organometallic Compounds

Organometallic compounds can be hydrolyzed by acid treatment. For active metals, such as Mg, Li, and so on, water is sufficiently acidic. The most important example of this reaction is hydrolysis of Grignard reagents, but M may be many other metals or metalloids. Examples are SiR<sub>3</sub>, HgR, Na, and B(OH)<sub>2</sub>. Since aryl Grignard and aryllithium compounds are fairly easy to prepare, they are often used to prepare salts of weak acids, such as alkynes.

Where the bond between the metal and the ring is covalent, the usual arenium ion mechanism operates.<sup>784</sup> Where the bonding is essentially ionic, this is a simple acid–base reaction.

For the aliphatic counterpart of this reaction, see reaction **12-24**.

Other reactions of aryl organometallic compounds are treated with their aliphatic analogs: see reactions **12-25** to **12-27** and **12-29** to **12-36**.

# Aliphatic, Alkenyl, and Alkynyl Substitution: Electrophilic and Organometallic

The reactivity of a proton in a chemical reaction usually depends on the acidity. Protons in saturated alkanes are very unreactive, but electrophilic substitutions are often easily carried out at more acidic positions, for example,  $\alpha$  to a carbonyl group, or at an alkynyl position ( $\text{RC}\equiv\text{CH}$ ). Since metallic ions are easily able to bear positive charges, organometallic compounds should be especially susceptible to electrophilic substitution, and this is indeed the case.<sup>1</sup> Another important type of electrophilic substitution, known as *anionic cleavage*, involves the breaking of C–C bonds; in these reactions there are carbon leaving groups (12-39 to 12-45). A number of electrophilic substitutions at a nitrogen atom are treated at the end of this chapter.

Since a carbanion is generated when an atom or group is removed as a positive species from a carbon atom, the subject of carbanion structure and stability (Chapter 5) is inevitably related to the material in this chapter. Also related is the subject of very weak acids and very strong bases (Chapter 8), because the weakest acids are those in which the hydrogen is bonded to carbon.

## 12.A. MECHANISMS

For aliphatic electrophilic substitution, at least four possible major mechanisms can be distinguished,<sup>2</sup>  $\text{S}_{\text{E}}1$ ,  $\text{S}_{\text{E}}2$  (front),  $\text{S}_{\text{E}}2$  (back), and  $\text{S}_{\text{E}}\text{i}$ . The  $\text{S}_{\text{E}}1$  is unimolecular; the other three

Chem.* 1978, 50, 717; *Tetrahedron* 1978, 34, 2827.

are bimolecular. It is noted that the term “S<sub>E</sub>Ar” has been proposed to represent electrophilic aromatic substitution, so that the term “S<sub>E</sub>2” refers exclusively to electrophilic substitutions where a steric course is possible.<sup>3</sup> To describe the steric course of an aliphatic substitution reaction, the suffixes “ret” and “inv” were proposed, referring to retention and inversion of configuration, respectively.

### 12.A.i. Bimolecular Mechanisms. S<sub>E</sub>2 and S<sub>E</sub>i

Reactions in which an electrophile (an electron-deficient species) removes a functional group are termed electrophilic aliphatic substitution reactions. The electrophilic substitution *bimolecular* mechanisms are termed S<sub>E</sub>2 mechanisms. This mechanism appears to be most prevalent for some organometallic compounds. The most extensive body of work involving substantiated S<sub>E</sub>2 processes, based on both kinetic and stereochemical studies, deals with electrophilic cleavages of organomercurials.<sup>4</sup> Retention of configuration is the normal course of electrophilic cleavage of the carbon–mercury bond.<sup>5</sup> These results with mercurials have been generalized, leading to the conclusion that the normal stereochemical course of electrophilic substitution is retention of configuration on carbon. So far, no inversion has been found with an organomercury substrate. It may be that still other examples of backside attack exist,<sup>6</sup> but have escaped detection because of the difficulty in preparing compounds with a configurationally stable carbon–metal bonds.

The bimolecular mechanisms for electrophilic aliphatic substitution are analogous to the S<sub>N</sub>2 mechanism in that the new bond forms as the old one breaks. However, in the S<sub>N</sub>2 mechanism the incoming group brings with it a pair of electrons (see Chapter 10), and this orbital can overlap with the central carbon only to the extent that the leaving group takes away its electrons; otherwise the carbon would have more than eight electrons at one time in its outer shell. Since electron clouds repel, this means also that the incoming group attacks backside, at a position 180° from the leaving group, resulting in inversion of configuration. When the nucleophilic species attacks (donates electrons to) an electrophile, it brings to the substrate only a vacant orbital. Predicting the direction of the attack is not as straightforward. Two main possibilities can be imagined: delivery of the electrophile to the front, which is S<sub>E</sub>2 (front), or delivery of the electrophile to the rear, which is S<sub>E</sub>2 (back).

Both the S<sub>E</sub>2 (front) and S<sub>E</sub>2 (back) mechanisms are designated D<sub>E</sub>A<sub>E</sub> in the IUPAC system. With substrates in which these possibilities may be distinguished, the former mechanism should result in retention of configuration and the latter in inversion. The reaction of allylsilanes with adamantyl chloride and TiCl<sub>4</sub>, for example, gives primarily the *anti* product via a S<sub>E</sub>2' reaction.<sup>7</sup> When the electrophile reacts from the front, there is a third

possibility. A portion of the electrophile may assist in the removal of the leaving group, forming a bond with it at the same time that the new C–Y bond is formed:

This mechanism, which is called the  $S_{Ei}$  mechanism<sup>8</sup> (IUPAC designation: *cyclo-D<sub>E</sub>A<sub>E</sub>D<sub>n</sub>A<sub>n</sub>*), also results in retention of configuration.<sup>9</sup> Plainly, where a second-order mechanism involves this kind of internal assistance, backside attack is impossible.

It is evident that these three mechanisms are not easy to distinguish. All three give second-order kinetics, and two result in retention of configuration.<sup>10</sup> In fact, although much work has been done on this question, there are few cases in which one can unequivocally establish that another mechanism is not actually taking place. Clearly, a study of the stereochemistry can distinguish between  $S_{E2}$  (back) on the one hand and  $S_{E2}$  (front) or  $S_{Ei}$  on the other. Many such investigations have been made. In the overwhelming majority of second-order electrophilic substitutions, the result has been retention of configuration or some other indication of frontside attack, indicating an  $S_{E2}$  (front) or  $S_{Ei}$  mechanism.

Another indication of frontside attack is that second-order electrophilic substitutions proceed very easily at *bridgehead* carbons (Sec. 10.A.i).<sup>11</sup> Still another indication is the behavior of neopentyl as a substrate.  $S_N2$  reactions at neopentyl are extremely slow (Sec. 10.G.i), because attack from the rear is blocked and the transition state for the reaction lies very high in energy. The fact that neopentyl systems undergo electrophilic substitution only slightly more slowly than ethyl<sup>12</sup> is further evidence for frontside attack.

Inversion of configuration has been found in certain cases, demonstrating that the  $S_{E2}$  (back) mechanism can take place. For example, the reaction of optically active *sec*-butyltrineopentyltin with bromine (**12-39**) gives inverted *sec*-butyl bromide.<sup>13</sup> A number of other organometallic compounds have also been shown to give inversion when treated with halogens,<sup>14</sup> although others do not.<sup>15</sup>

Compounds that are chiral because of a stereogenic carbon at which a carbon–metal bond is located<sup>16</sup> are often difficult to resolve and once resolved are often easily racemized.

<sup>8</sup> The names for these mechanisms vary throughout the literature. For example, the  $S_{Ei}$  mechanism has also been called the  $S_{E2}$ , the  $S_{E2}$  (closed), and the  $S_{E2}$  (cyclic) mechanism. The original designations,  $S_{E1}$ ,  $S_{E2}$ , and so on, were devised by the Hughes-Ingold school.

<sup>9</sup> It has been contended that the  $S_{Ei}$  mechanism violates the principle of conservation of orbital symmetry (see **15-60**, A), and that the  $S_{E2}$  (back) mechanism partially violates it: Slack, D.A.; Baird, M.C. *J. Am. Chem. Soc.* **1976**, *98*, 5539.

The resolution has been accomplished most often with organomercury compounds,<sup>17</sup> and most stereochemical investigations have therefore been made with these substrates. Only a few optically active *Grignard reagents* (**12-37**) have been prepared<sup>18</sup> (i.e., in which the only stereogenic center is the carbon bonded to the magnesium). Because of this, the steric course of electrophilic substitutions at the C—Mg bond has not often been determined. However, in one such case, the reaction of both the *exo* and *endo* isomers of the 2-norbornyl Grignard reagent with HgBr<sub>2</sub> (to give 2-norbornylmercuric bromide) has been shown to proceed with retention of configuration.<sup>19</sup> It is likely that inversion takes place only when steric hindrance prevents reaction on the frontside and when the electrophile does not carry an electron-withdrawing group.

The S<sub>E</sub>2 (back) mechanism can be identified in certain cases (if inversion of configuration is found), but it is plain that stereochemical investigations cannot distinguish between the S<sub>E</sub>2 (front) and the S<sub>E</sub>i mechanisms and that, in the many cases where configurationally stable substrates cannot be prepared, such investigations are of no help at all in distinguishing among all three of the second-order mechanisms. Unfortunately, there are not many other methods that lead to unequivocal conclusions. One method that has been used in an attempt to distinguish between the S<sub>E</sub>i mechanism on the one hand and the S<sub>E</sub>2 pathways on the other involves the study of salt effects on the rate. It may be recalled (Sec. 10.G.iv) that reactions in which neutral starting molecules acquire charges in the transition state are aided by an increasing concentration of added ions. Thus the S<sub>E</sub>i mechanism would be less influenced by salt effects than would either of the S<sub>E</sub>2 mechanisms. On this basis Abraham and co-workers<sup>20</sup> concluded that the reactions

take place by S<sub>E</sub>2 and not by S<sub>E</sub>i mechanisms. Similar investigations involve changes in solvent polarity<sup>21</sup> (see also, Sec. 12.C.i). In the case of the reactions where R = R' = *i*-Pr and R = *i*-Pr, R' = neopentyl, the use of polar solvents gave predominant inversion, while nonpolar solvents gave predominant retention.<sup>22</sup>

On the basis of evidence from reactivity studies, it has been suggested<sup>23</sup> that a variation of the S<sub>E</sub>i mechanism is possible in which the group Z becomes attached to X before the latter becomes detached. This process has been called the S<sub>E</sub>C or S<sub>E</sub>2 (co-ord) mechanism<sup>22,24</sup> (IUPAC designation A<sub>n</sub> + cyclo-D<sub>E</sub>A<sub>E</sub>D<sub>n</sub>).

It has been shown that in certain cases (e.g.,  $\text{Me}_4\text{Sn} + \text{I}_2$ ) the reactants in an  $\text{S}_{\text{E}}2$  reaction, when mixed, give rise to an immediate charge-transfer spectrum (Sec. 3.C.i), showing that an electron donor–acceptor (EDA) complex has been formed.<sup>25</sup> In these cases it is likely that the EDA complex is an intermediate in the reaction.

### 12.A.ii. The $\text{S}_{\text{E}}1$ Mechanism

The  $\text{S}_{\text{E}}1$  mechanism is analogous to the  $\text{S}_{\text{N}}1$ . It involves two steps: a slow ionization and a fast combination. The IUPAC designation is  $\text{D}_{\text{E}} + \text{A}_{\text{E}}$ .

First-order kinetics are predicted and many such examples have been found. Other evidence for the  $\text{S}_{\text{E}}1$  mechanism was obtained in a study of base-catalyzed tautomerization. In the reaction the rate of deuterium exchange was the same as the rate of racemization<sup>26</sup> and there was an isotope effect.<sup>27</sup> It is known that  $\text{S}_{\text{N}}1$  reactions do not proceed at strained bridgehead carbons (e.g., in [2.2.1] bicyclic systems, Sec. 10.A.ii) because planar carbocations cannot form at these carbons. However, carbanions not stabilized by resonance are probably not planar, and  $\text{S}_{\text{E}}1$  reactions readily occur with this type of substrate. Indeed, the question of carbanion structure is intimately tied into the problem of the stereochemistry of the  $\text{S}_{\text{E}}1$  reaction. If a carbanion is planar, racemization should occur. If it is pyramidal and *can hold its structure*, the result should be retention of configuration, or at least partial retention. On the other hand, even a pyramidal carbanion will give racemization if it cannot hold its structure (this means that there is pyramidal inversion, as with amines, Sec. 4.C, category 3). Unfortunately, the only carbanions that can be studied easily are those stabilized by resonance, which makes them planar, as expected (Sec. 5.B.i). For simple alkyl carbanions, the main approach to deduce the structure has been to study the stereochemistry of  $\text{S}_{\text{E}}1$  reactions rather than the other way around. Racemization is almost always observed, but whether this is caused by planar carbanions or by oscillating pyramidal carbanions is not known. In either case, racemization occurs whenever a carbanion is completely free or is symmetrically solvated.

However, even planar carbanions need not give racemization. Cram found that retention and even inversion can occur in an alkoxide (see **1**) cleavage reaction (**12-40**), which is a first-order  $\text{S}_{\text{E}}1$  reaction involving resonance-stabilized planar carbanions (here designated  $\text{R}^-$ ).<sup>28</sup> By changing the solvent, Cram was able to produce products ranging from

<sup>25</sup> Fukuzumi, S.; Kochi, J.K. *J. Am. Chem. Soc.* **1980**, *102*, 2141, 7290.

<sup>26</sup> Hsu, S.K.; Ingold, C.K.; Wilson, C.L. *J. Chem. Soc.* **1938**, 78.

<sup>27</sup> Wilson, C.L. *J. Chem. Soc.* **1936**, 1550.

<sup>28</sup> See Hoffman, T.D.; Cram, D.J. *J. Am. Chem. Soc.* **1969**, *91*, 1009. For a discussion, see Cram, D.J. *Fundamentals of Carbanion Chemistry*, Academic Press, NY, **1965**, pp. 138–158.

99% retention to 60% inversion and including complete racemization. These results are explained by a carbanion that is not completely free but is solvated. In nondissociating, nonpolar solvents, such as benzene or dioxane, the alkoxide ion exists as an ion pair, solvated by the solvent BH:

In the course of the cleavage, the proton of the solvent moves in to solvate the newly forming carbanion. This solvation is asymmetrical since the solvent molecule is already on the front side of the carbanion. When the carbanion actually bonds with the proton, the result is retention of the original configuration. In protic solvents, such as diethylene glycol, a good deal of inversion is found. In these solvents, the *leaving group* solvates the carbanion, so the solvent can solvate it only from the opposite side:

When C-H bond formation occurs, the result is inversion. Racemization occurs in polar aprotic solvents such as DMSO. In these solvents, the carbanions are relatively long lived (because the solvent has no proton to donate) and symmetrically solvated. Similar behavior was found for carbanions generated by base-catalyzed hydrogen exchange (reaction **12-1**).<sup>29</sup> In this case information was obtained from measurement of the ratio of  $k_e$  (rate constant for isotopic exchange) to  $k_a$  (rate constant for racemization). A  $k_e/k_a$  ratio substantially  $> 1$  means retention of configuration, since many individual isotopic exchanges are not producing a change in configuration. A  $k_e/k_a$  ratio of  $\sim 1$  indicates racemization and a ratio of  $\frac{1}{2}$  corresponds to inversion (Sec. 10.A.i). All three types of steric behavior were found, depending on R, the base, and the solvent. As with the alkoxide cleavage reaction, retention was generally found in solvents of low dielectric constant, racemization in polar aprotic solvents, and inversion in protic solvents. However, in the proton-exchange reactions, a fourth type of behavior was encountered. In aprotic solvents, with aprotic bases like tertiary amines, the  $k_e/k_a$  ratio was found to be *less* than 0.5, indicating that racemization took place *faster* than isotopic exchange (this process is known as *isoracemization*). Under these conditions, the conjugate acid of the amine remains associated with the carbanion as an ion pair. Occasionally, the ion pair dissociates long enough for the carbanion to turn over and recapture the proton. Thus, inversion (and hence racemization, which is

<sup>29</sup> See Roitman, J.N.; Cram, D.J. *J. Am. Chem. Soc.* **1971**, *93*, 2225, 2231 and references cited therein; Cram, J.M.; Cram, D.J. *Intra-Sci. Chem. Rep.* **1973**, *7*(3), 1; Cram, D.J. *Fundamentals of Carbanion Chemistry*, Academic Press, NY, **1965**, pp. 85-105.

produced by repeated acts of inversion) occurs without exchange. A single act of inversion without exchange is called *isoinversion*.

The isoinversion process can take place by a pathway in which a positive species migrates in a stepwise fashion around a molecule from one nucleophilic position to another. For example, in the exchange reaction of 3-carboxamido-9-methylfluorene (2) with  $Pr_3N$  in *t*-BuOH, it has been proposed that the amine removes a proton from the 9 position of 2 and via 3 conducts the proton out to the C=O oxygen (4), around the molecule, and back to C-9 on the opposite face of the anion. Collapse of 5 gives the inverted product 6. Of course 4 could also go back to 2 via 3, but a molecule that undergoes the total process 2  $\rightarrow$  3  $\rightarrow$  4  $\rightarrow$  5  $\rightarrow$  6 has experienced an inversion without an exchange. Evidence for this pathway, called the *conducted tour mechanism*,<sup>30</sup> is that the 12-carboxamido isomer of 2 does not give isoracemization. In this case, the negative charge on the oxygen atom in the anion corresponding to 6 is less, because a canonical form in which oxygen acquires a full negative charge (7) results in disruption of the aromatic sextet in both benzene rings (cf. 8 where one benzene ring is intact). Whether the isoracemization process takes place by the conducted tour mechanism or a simple nonstructured contact ion-pair mechanism depends on the nature of the substrate (e.g., a proper functional group is necessary for the conducted tour mechanism) and of the base.<sup>31</sup>

It is known that vinylic carbanions *can* maintain configuration, so that  $S_E1$  mechanisms should produce retention, which is the case. For example, *trans*-2-bromobut-2-ene was converted to 64–74% angelic acid (*trans*-2-methylbut-2-enoic acid).<sup>32</sup> Only ~5% of the *cis* isomer, tiglic acid, was produced. In addition, certain carbanions in which the negative charge is stabilized by *d*-orbital overlap can maintain configuration (Sec. 5.B.ii) and  $S_E1$  reactions involving them proceed with retention of configuration.

## 12.A.iii. Electrophilic Substitution Accompanied by Double-Bond Shifts

When electrophilic substitution is carried out at an allylic substrate, the product may be rearranged (**9**  $\rightarrow$  **10**). This type of process is analogous to the nucleophilic allylic rearrangements discussed in Sec. 10.D. There are two principal pathways. The first of these is analogous to the  $S_E1$  mechanism in that the leaving group is first removed, giving a resonance-stabilized allylic carbanion, which then attacks the electrophile Y. In the other pathway, the Y group is first attacked by the  $\pi$  bond, giving a carbocation, which then loses X with formation of the alkene unit. These mechanisms are more fully discussed under reaction **12-2**.

Most electrophilic allylic rearrangements involve loss of hydrogen, but they have also been observed with metallic leaving groups.<sup>33</sup> Sleezer, Winstein, and Young found that crotylmercuric bromide reacted with HCl  $\sim 10^7$  times faster than *n*-butylmercuric bromide and the product was >99% but-1-ene.<sup>34</sup> These facts point to an  $S_{E1'}$  mechanism (IUPAC designation cyclo-1/3/ $D_E A_E D_n A_n$ ):

The reaction of the same compound with acetic acid/perchloric acid seems to proceed by an  $S_{E2'}$  mechanism (IUPAC designation 1/3/ $D_E A_E$ ):<sup>34</sup>

The geometry of electrophilic allylic rearrangement has not been studied very much (cf. the nucleophilic case, Sec. 10.E), but in most cases the rearrangement takes place with *anti*

<sup>33</sup> See Courtois, G.; Miginiac, L. *J. Organomet. Chem.* **1974**, 69, 1.

stereoselectivity,<sup>35</sup> although *syn* stereoselectivity has also been demonstrated.<sup>36</sup> In one case, use of the electrophile H<sup>+</sup> and the leaving group SnMe<sub>3</sub> gave both *syn* and *anti* stereoselectivity, depending on whether the substrate was *cis* or *trans*.<sup>37</sup>

#### 12.A.iv. Other Mechanisms

Addition–elimination (12-16) and cyclic mechanisms (12-39) are also known. Much less work has been done on electrophilic aliphatic substitution mechanisms than on nucleophilic substitutions, and the exact mechanisms of many of the reactions in this chapter are in doubt. For many of them, not enough work has been done to allow a decision as to which of the mechanisms described in this chapter is operating, if indeed any is. There may be other electrophilic substitution mechanisms, and some of the reactions in this chapter may not even be electrophilic substitutions at all.

### 12.B. REACTIVITY

Only a small amount of work has been done in this area, compared to the vast amount done for aliphatic nucleophilic substitution and aromatic electrophilic substitution. Therefore, only a few conclusions can be drawn, most of them sketchy or tentative.<sup>38</sup>

1. *Effect of substrate.* For S<sub>E</sub>1 reactions, electron-donating groups decrease rates and electron-withdrawing groups increase them. This is expected for a reaction in which the rate-determining step is analogous to the cleavage of a proton from an acid. For the S<sub>E</sub>2 (back) mechanism, Jensen and Davis<sup>13</sup> showed that the reactivity of alkyl groups is similar to that for the S<sub>N</sub>2 mechanism (i.e., Me > Et > Pr > *i*-Pr > neopentyl), as is expected, since both involve backside attack and both are equally affected by steric hindrance. In fact, this pattern of reactivity can be regarded as evidence for the occurrence of the S<sub>E</sub>2 (back) mechanism in cases where stereochemical investigation is not feasible.<sup>39</sup> For S<sub>E</sub>2 reactions that proceed with retention, several studies have been made with varying results, depending on the reaction.<sup>40</sup> One such study, which examined the reaction R<sub>Hg</sub>Br + Br<sub>2</sub> → RBr catalyzed by Br<sup>-</sup>, showed *t*-Bu to have a relative rate of 43370 whereas Me had a relative rate of 1, but neopentyl had a relative rate of 0.173.<sup>41</sup> This data shows that branching increased the rates, while β branching decreased them. Sayre and Jensen<sup>41</sup> attributed the decreased rates to steric hindrance, although attack here was definitely frontside, and the increased rates to the electron-donating effect of the alkyl groups, which

stabilized the electron-deficient transition state.<sup>42</sup> Of course, steric hindrance should also be present with the  $\alpha$ -branched groups, so these workers concluded that if it were not, the rates would be even greater. The Br electrophile is a rather large one and it is likely that smaller steric effects are present with smaller electrophiles. The rates of certain second-order substitutions of organotin compounds have been found to increase with increasing electron withdrawal by substituents. This behavior has been ascribed<sup>43</sup> to an  $S_E2$  mechanism involving ion pairs, analogous to Snee's ion-pair mechanism for nucleophilic substitution (Sec. 10.A.iv). Solvolysis of 2-bromo-1,1,1-trifluoro-2-(*p*-methoxyphenyl)ethane in water proceeds via a free carbocation intermediate, but ion pairing influences the reaction in the presence of bromide ion.<sup>44</sup>

2. *Effect of leaving group.* For both  $S_E1$  and second-order mechanisms, the more polar<sup>45</sup> the C—X bond, the easier it is for the electrofuge to cleave. For metallic leaving groups in which the metal has a valence  $>1$ , the nature of the other group or groups attached to the metal thus has an effect on the reaction. For example, consider a series of organomercurials RHgW. Because a more electronegative W decreases the polarity of the C—Hg bond and furthermore results in a less stable HgW<sup>+</sup>, the electrofugal ability of HgW decreases with increasing electronegativity of W. Thus, HgR' (from RHgR') is a better leaving group than HgCl (from RHgCl). Also in accord with this is the leaving-group order Hg-*t*-Bu  $>$  Hg-*i*-Pr  $>$  HgEt  $>$  HgMe, reported for acetolysis of R<sub>2</sub>Hg,<sup>42</sup> since the more highly branched alkyl groups better help to spread the positive charge. It might be expected that, when metals are the leaving groups,  $S_E1$  mechanisms would be favored, while with carbon leaving groups, second-order mechanisms would be found. However, the reported results have been just about the reverse of this. For carbon leaving groups the mechanism is usually  $S_E1$  while for metallic leaving groups the mechanism is almost always  $S_E2$  or  $S_Ei$ . A number of reports of  $S_E1$  reactions with metallic leaving groups have appeared,<sup>46</sup> but the mechanism is not easy to prove and many of these reports have been challenged.<sup>47</sup> Reutov and co-workers<sup>46</sup> expressed the view that in such reactions a nucleophile (which may be the solvent) must assist in the removal of the electrofuge and they refer to such processes as  $S_E1(N)$  reactions.
3. *Effect of solvent.*<sup>48</sup> In addition to the solvent effects on certain  $S_E1$  reactions, mentioned earlier (Sec. 12.A.ii), solvents can influence the mechanism that is preferred. As with nucleophilic substitution (Sec. 10.G.iv), an increase in solvent polarity increases the possibility of an ionizing mechanism, in this case  $S_E1$ , in comparison with the second-order mechanisms, which do not involve ions. As previously mentioned (Sec. 12.A.ii), the solvent can also exert an influence between the  $S_E2$  (front or back) and  $S_Ei$  mechanisms, in that the rates of  $S_E2$  mechanisms should be increased by an increase in solvent polarity, while  $S_Ei$  mechanisms are much less affected.

## 12.C. REACTIONS

The reactions in this chapter are arranged in order of leaving group: hydrogen, metals, halogen, and carbon. Electrophilic substitutions at a nitrogen atom are treated last.

### 12.C.i. Hydrogen as Leaving Group

#### A. Hydrogen as the Electrophile

##### 12-1 Hydrogen Exchange

Hydrogen exchange can be accomplished by treatment with acids or bases. As with **11-1**, the exchange reaction is mostly used to study mechanistic questions, such as relative acidities, but it can be used synthetically to prepare deuterated or tritiated molecules. When ordinary strong acids (such as  $\text{H}_2\text{SO}_4$ ) are used, only fairly acidic protons on carbon can exchange (for example, acetylenic and allylic). However, primary, secondary, and tertiary hydrogen atoms of alkanes can be exchanged by treatment with superacids (Sec. 5.A.ii).<sup>49</sup> The order of hydrogen reactivity is tertiary > secondary > primary. Where C–C bonds are present, they may be cleaved also (**12-46**). The mechanism of the exchange (illustrated for methane) has been formulated as involving reaction of  $\text{H}^+$  with the C–H bond to give the pentavalent methanonium ion, which loses  $\text{H}_2$  to give a trivalent carbocation.<sup>50</sup>

The methanonium ion  $\text{CH}_5^+$  has a three-center, two-electron bond.<sup>51</sup> It is not known whether the methanonium ion is a transition state or a true intermediate, but an ion  $\text{CH}_5^+$  has been detected in the mass spectrum.<sup>52</sup> The IR spectrum of the ethanonium ion  $\text{C}_2\text{H}_7^+$  has been measured in the gas phase.<sup>53</sup> Note that the two electrons in the three-center, two-electron bond can move in three directions, in accord with the threefold symmetry of such a structure. The electrons can move to unite the two hydrogen atoms, leaving the  $\text{CH}_3^+$  free (the forward reaction), or they can unite the  $\text{CH}_3$  with either of the two hydrogen atoms, leaving the other hydrogen as a free  $\text{H}^+$  ion (the reverse reaction). Actually, the methyl cation is not stable under these conditions. It can go back to  $\text{CH}_4$  by the route shown (leading to  $\text{H}^+$  exchange), or it can react with additional  $\text{CH}_4$  molecules (**12-20**) to eventually

yield the *tert*-butyl cation, which is stable in these superacid solutions. Hydride ion can also be removed from alkanes (producing trivalent carbocations) by treatment with pure  $\text{SbF}_5$  in the absence of any source of  $\text{H}^+$ .<sup>54</sup> Complete or almost complete perdeuteration of cyclic alkenes has been achieved by treatment with dilute  $\text{DCI/D}_2\text{O}$  in sealed Pyrex tubes at 165–280 °C.<sup>55</sup>

Exchange with bases involves an  $\text{S}_{\text{E}}1$  mechanism. Of course, such exchange is most successful for relatively acidic protons, such as those  $\alpha$  to a carbonyl group, but even weakly acidic protons can exchange with bases if the bases are strong enough (Sec. 5.B.i). Alkanes and cycloalkanes, of both low and high molecular weight, can be fully perdeuterated by treatment with  $\text{D}_2$  gas and a catalyst, such as Rh, Pt, or Pd.<sup>56</sup>

OS VI, 432.

## 12-2 Migration of Double Bonds

The double bonds of many unsaturated compounds may be isomerized<sup>57</sup> upon treatment with strong bases.<sup>58</sup> In many cases equilibrium mixtures are obtained and the thermodynamically most stable isomer predominates.<sup>59</sup> If the new double bond can be in conjugation with one already present or with an aromatic ring, *the conjugated compound is favored*.<sup>60</sup> If the choice is between an exocyclic and an endocyclic double bond (particularly with six-membered rings), *endocyclic is usually preferred*. In the absence of such considerations, *Zaitsev's rule* (Sec. 17.B) applies and the double bond goes to the carbon with the fewest hydrogen atoms (the thermodynamically more stable alkene). All these considerations lead to predictions that terminal alkenes can be isomerized to internal ones, nonconjugated alkenes to conjugated, *exo* six-membered-ring alkenes to *endo*, and so on, and not the other way around.

The term *prototropic rearrangement* is sometimes used as an example of electrophilic substitution with accompanying allylic rearrangement. The mechanism involves abstraction by a base to give a resonance-stabilized allylic carbanion and then reaction with a proton at the position that will give the more stable alkene.<sup>61</sup> This mechanism is exactly analogous to the allylic-rearrangement mechanism for nucleophilic substitution (Sec. 10.D). UV spectra of allylbenzene and 1-propenylbenzene in solutions containing  $\text{NH}_2$  are identical, showing

<sup>61</sup> See Pollack, R.M.; Mack, J.P.G.; Eldin, S. *J. Am. Chem. Soc.* **1987**, *109*, 5048.

that the same carbanion is present in both cases, as required by this mechanism.<sup>62</sup> A protonic acid  $BH^+$  protonates the carbanion and the more stable product will predominate, although the ratio of the two possible products can vary with the identity of  $BH^+$ .<sup>63</sup> It has been shown that base-catalyzed double-bond shifts are partially intramolecular, at least in some cases.<sup>64</sup> The intramolecular nature has been ascribed to a *conducted tour mechanism* (Sec. 12.A.iii) in which the base leads the proton from one carbanionic site to the other (**11**  $\rightarrow$  **12**).<sup>65</sup>

Double bond rearrangements can also take place on treatment with acids. Both proton acids and Lewis acids<sup>66</sup> can be used. The mechanism in the case of proton acids is the reverse of the previous one; first a proton is gained on but-1-ene by reaction with  $H^+$ , giving an allylic carbocation, and then another is lost, so the but-1-ene to but-2-ene isomerization is complete. As in the case of the base-catalyzed reaction, the thermodynamically more stable alkene is the one predominantly formed. However, the acid-catalyzed reaction is much less synthetically useful because carbocations give rise to many side products. If the substrate has several possible locations for a double bond, mixtures of all possible isomers are usually obtained. Isomerization of dec-1-ene, for example, gave a mixture that contains not only dec-1-ene and *cis*- and *trans*-dec-2-ene but also the *cis* and *trans* isomers of 3-, 4-, and 5-decene as well as branched alkenes resulting from rearrangement of carbocations. It is true that the most stable alkenes predominate, but many of them have stabilities that are close together.

Double bond isomerization can take place in other ways. Nucleophilic allylic rearrangements were discussed in Sec. 10.E. Electrocyclic and sigmatropic rearrangements are treated at **18-27** to **18-35**. Double bond migrations have also been accomplished photochemically,<sup>67</sup> and by means of metallic ion (most often complex ions containing Pt, Rh, or Ru) or metal carbonyl catalysts.<sup>68</sup> With metal compounds there are at least two possible mechanisms. One of these, which requires external hydrogen, is called the *metal hydride addition-elimination mechanism*:

React.* **1972**, 3, 1 (pp. 133–149).

The other mechanism, called the  $\pi$ -allyl complex mechanism, does not require external hydrogen and proceeds by hydrogen abstraction to form the  $\eta^3$ - $\pi$ -allyl complex **13** (Sec. 3.C.i, category 1, and **10-60**).

Another difference between the two mechanisms is that the former involves 1,2 shifts and the latter 1,3 shifts. The Rh-catalyzed isomerization of but-1-ene is an example of a reaction that takes place by the metal hydride mechanism,<sup>69</sup> while an example of the  $\pi$ -allyl complex mechanism is found in the  $\text{Fe}_3(\text{CO})_{12}$ -catalyzed isomerization of 3-ethylpent-1-ene.<sup>70</sup> The reaction of an en-yne with  $\text{HSiCl}_3$  and a Pd catalyst generated an allene with moderate enantioselectivity (Sec. 4.C, category 5 for chiral allenes).<sup>71</sup>

No matter which of the electrophilic methods of double bond shifting is employed, the thermodynamically most stable alkene is usually formed in the largest amount, although a few anomalies are known. Since the migration reaction is always toward the end of a chain (see **14**),

terminal alkenes can be produced from internal ones. The rearranged borane can be converted directly to the terminal alkene by heating with an alkene of molecular weight higher than that of the product (**17-13**). Photochemical isomerization can also lead to the thermodynamically less stable isomer.<sup>72</sup>

Triple bonds can also migrate in the presence of bases,<sup>73</sup> but through an allene intermediate:<sup>74</sup>

In general, strong bases, for example,  $\text{NaNH}_2$ , convert internal alkynes to terminal alkynes. A particularly good base for this purpose is potassium 3-aminopropylamide  $\text{NH}_2\text{CH}_2\text{CH}_2\text{CH}_2\text{NHK}$ <sup>75</sup>, because the equilibrium is shifted by formation of the acetylide

ion. With weaker bases, such as NaOH (which are not strong enough to remove the acetylenic proton), the internal alkynes are favored because of their greater thermodynamic stability. In some cases the reaction can be stopped at the allene stage.<sup>76</sup> The reaction then becomes a method for the preparation of allenes.<sup>77</sup> Long-chain terminal alkynes that have a distal methyl group, an isobranch, were shown to isomerize to the internal alkyne faster than similar straight-chain terminal alkynes.<sup>78</sup>

The reaction of propargylic alcohols with tosylhydrazine, PPh<sub>3</sub>, and DEAD also generates allenes.<sup>79</sup> Acid-catalyzed migration of triple bonds (with allene intermediates) can be accomplished if very strong acids (e.g., HF/PF<sub>5</sub>) are used.<sup>80</sup> If the mechanism is the same as that for double bonds, vinyl cations are intermediates.

### 12-3 Keto-Enol Tautomerization

The tautomeric equilibrium between enols and ketones or aldehydes (keto-enol tautomerism) is a form of prototropy.<sup>81</sup> For some ketones, both forms can be prepared (Sec. 2.N.i, category 3 for a discussion of this and other types of tautomerism). Keto-enol tautomerism occurs in systems containing one or more carbonyl groups linked to *sp*<sup>3</sup> carbon atoms bearing one or more hydrogen atoms. *The keto tautomer is generally more stable than the enol tautomer for neutral systems*, and for most ketones and aldehydes only the keto form is detectable under ordinary conditions. The availability of additional intramolecular stabilization through hydrogen bonding or complete electron delocalization (as in phenol), may cause the enol tautomer to be favored.

Keto-enol tautomerism is usually a slow process, but it can be catalyzed by a trace of acid or base.<sup>82</sup> In this equilibrium, the heteroatom is the basic site in the reaction with an acid whereas the proton is the acidic site in the presence of a suitable base. For tautomerism in general (Sec. 2.N.i),<sup>83</sup> the presence of an acid or a base is not necessary to initiate the isomerization since each tautomeric substance possesses amphiprotic properties.<sup>83</sup> Polar protic solvents such as water or alcohol may participate in the proton transfer by forming a cyclic

or a linear complex with the tautomers.<sup>84</sup> Whether the complex formed is cyclic or linear depends on the conformation and configuration of the tautomers. In a strongly polar aprotic solvent and in the presence of an acid or a base, the tautomeric molecule may lose or gain a proton and form the corresponding mesomeric anion or cation, which, in turn, may gain or lose a proton, respectively, and yield a new tautomeric form.<sup>85</sup> The structural features of the carbonyl compound influences the equilibrium.<sup>86</sup> Differing conjugative stabilization by CH- $\pi$  orbital overlap does not directly influence stereoselectivity, and steric effects are generally not large enough to cause the several kcal mol<sup>-1</sup> energy difference seen between transition structures unless there is exceptional crowding.<sup>87</sup> It is noted that sterically stabilized enols are known,<sup>88</sup> including arylacetaldehydes.<sup>89</sup> Torsional strain involving vicinal bonds does contribute significantly to stereoselectivity in enolate formation.<sup>88</sup>

The acid- and base-catalyzed mechanisms are identical to those in **12-2**.<sup>90</sup>

- Acid catalyzed

- Base catalyzed<sup>91</sup>

For each catalyst, the mechanism for one direction is the exact reverse of the other, by the principle of *microscopic reversibility*.<sup>92</sup> As expected from mechanisms in which the C-H bond is broken in the rate-determining step, substrates of the type RCD<sub>2</sub>COR show deuterium isotope effects (of ~5) in both the basic<sup>93</sup> and the acid-catalyzed<sup>94</sup> processes. The keto-enol/enolate anion equilibrium has been studied in terms of the influence

of  $\beta$ -oxygen<sup>95</sup> or  $\beta$ -nitrogen<sup>96</sup> substituents. The stereochemistry of enol protonation can be controlled by varying the proximal group and by changing the acidity of the medium.<sup>97</sup>

The base-induced reaction generates an enolate anion rather than an enol, and the formation of and reactions of enolate anions are discussed further in **10-60**, **10-67**, **16-22**, and **16-34**. It should be noted that ring strain plays no significant role on the rate of base-catalyzed enolization.<sup>98</sup> In certain cases such as benzofuranones, base-induced enolate anion formation may give a transition state in which aromaticity can play a role. One study showed that aromatic stabilization of the transition state is ahead of proton transfer, and aromaticity appears to lower the intrinsic barrier to this reaction.<sup>99</sup> Enolizable hydrogen atoms can be replaced by deuterium (and <sup>16</sup>O by <sup>18</sup>O) by passage of a sample through a deuterated (or <sup>18</sup>O-containing) gas chromatography column.<sup>100</sup>

Although the conversion of an aldehyde or a ketone to its enol tautomer is not generally a preparative procedure for most relatively simple aldehydes or ketones, the reactions do have their preparative aspects. When enol ethers or esters are hydrolyzed, the initially formed enols immediately tautomerize to the aldehydes or ketones. In addition, the overall processes (forward plus reverse reactions) are often used for equilibration purposes. When an optically active compound in which the chirality is due to a stereogenic carbon  $\alpha$  to a carbonyl group, as in 2-methylpentan-2-one, is treated with acid or base, racemization results.<sup>101</sup> If there is another stereogenic center in the molecule, the less stable diastereomer can be converted to the more stable one in this manner. For example, *cis*-decalone can be equilibrated to the *trans* isomer. Isotopic exchange can similarly be accomplished at the  $\alpha$  position of an aldehyde or ketone. In cyclic compounds such as *cis*- or *trans*-decalone, *cis* to *trans* isomerization can occur via the enol.<sup>102</sup> The role of additives, such as ZnCl<sub>2</sub>, on the stereogenic enolization reactions using chiral cases has been discussed.<sup>103</sup>

If a full equivalent of base per equivalent of ketone is used, the enolate ion is formed and can be isolated<sup>104</sup> (see, e.g., the alkylation reaction in **10-68**).<sup>105</sup> Enantioselective enolate anion protonation reactions have been studied.<sup>106</sup> Enolate protonation is discussed in reaction **16-34**. For the acid-catalyzed process, exchange or equilibration is accomplished only if the carbonyl compound is completely converted to the enol and then back. However, in the base-catalyzed process exchange or equilibration can take place if only the first step (conversion to the enolate ion) takes place. The difference is usually academic. Aggregation behavior of stereoselective enolizations mediated by Mg and calcium bis(amides) have been studied.<sup>107</sup> It is noted that chiral magnesium amides have been developed.<sup>108</sup>

In the case of 2,6-dimethylcyclohexanone, a racemic mixture was converted to an optically active mixture (optical yield 46%) by treatment with the chiral lithium dialkylamide.<sup>109</sup> The chiral base reacted with one enantiomer of the racemic ketone faster than with the other (an example of *kinetic resolution*) to give the enolate anion as the conjugate base and the amine as the conjugate acid. It is presumed that the enolate anion remained coordinated with the chiral amine, and it is the amine (rather than an added proton source) that re-protonates the enolate anion to give the optically active 2,6-dimethylcyclohexanone.

## B. Halogen Electrophiles

Halogenation of unactivated hydrocarbons is discussed in **14-1**.

### 12-4 Halogenation of Aldehydes and Ketones

Aldehydes and ketones can be halogenated in the  $\alpha$  position with bromine,<sup>110</sup> chlorine, or iodine,<sup>111</sup> although the reaction is less successful with fluorine.<sup>112</sup> Sulfuryl chloride,<sup>113</sup>  $\text{Me}_3\text{SiCl-Me}_2\text{SO}$ ,<sup>114</sup> and *N*-chlorosuccinimide (NCS)<sup>115</sup> have been used as reagents for chlorination.  $\alpha$ -Chloro aldehydes are formed with  $\text{Cl}_2$  and a catalytic amount of tetraethylammonium chloride.<sup>116</sup> Bromination methods include reaction with *N*-bromosuccinimide (see **14-3**),<sup>117</sup> or bromine•dioxane on silica with microwave irradiation.<sup>118</sup>  $\alpha$ -Chlorination<sup>119</sup> and also bromination<sup>120</sup> have been reported in ionic liquids. Enantioselective chlorination<sup>121</sup> and bromination<sup>122</sup> methods are known, including

<sup>122</sup> See Bertelsen, S.; Halland, N.; Bachmann, S.; Marigo, M.; Braunton, A.; Jørgensen, K.A. *Chem. Commun.* **2005**, 4821.

methods that use enolate anions as intermediates.<sup>123</sup> Organocatalyzed asymmetric  $\alpha$ -halogenation methods are known that can be applied to the incorporation of virtually any halogen.<sup>124</sup>  $\beta$ -Keto esters and 1,3-diketones are  $\alpha$ -brominated using bromodimethylsulfonium bromide.<sup>125</sup> 1,3-Diketones,  $\beta$ -keto esters, and malonates are chlorinated using sodium hypochlorite or brominated using sodium hypobromite.<sup>126</sup>

Iodination has been accomplished by the direct reaction of ketones with molecular iodine,<sup>127</sup> NCS/NaI,<sup>128</sup> or ICl/NaI/FeCl<sub>3</sub>.<sup>129</sup> Methyl ketones react with *N*-iodosuccinimide (NIS) and tosic acid with microwave irradiation without solvent to give the  $\alpha$ -iodo ketone.<sup>130</sup> An asymmetric iodination of aldehydes used NIS, with a catalytic amount of benzoic acid and a chiral biaryl amine.<sup>131</sup>

Although less prevalent than those noted above, several methods have been reported for the preparation of  $\alpha$ -fluoro aldehydes and ketones,<sup>132</sup> including enantioselective fluorination protocols.<sup>133</sup> Organocatalytic  $\alpha$ -fluorination is known for aldehydes and ketones.<sup>134</sup> Selectfluor [1-fluoro-4-hydroxy-1,4-diazoniabicyclo[2.2.2]octane *bis*(tetrafluoroborate)] has been used for the monofluorination of ketones.<sup>135</sup> Active compounds, such as  $\beta$ -keto esters and  $\beta$ -diketones, have been fluorinated with an *N*-fluoro-*N*-alkylsulfonamide.<sup>136</sup> Note that this reaction can result in enantioselective fluorination, if an optically active *N*-fluorosulfonamide is used.<sup>137</sup> Aldehydes have been  $\alpha$ -fluorinated using *N*-fluorobenzenesulfonimide as an electrophilic source of fluorine and an imidazolidinone as an organocatalyst.<sup>138</sup> The enantioselective  $\alpha$ -fluorination of oxindoles has been reported using *N*-fluorobenzenesulfonimide, a Pd catalyst, and a chiral ligand,<sup>139</sup> and also with an organocatalyst.<sup>140</sup>

For unsymmetrical ketones, the preferred position of halogenation is usually the more substituted: a CH group, then a CH<sub>2</sub> group, and then CH<sub>3</sub>;<sup>141</sup> however, mixtures are frequent. When basic catalysts are used, one  $\alpha$  position of a ketone is completely halogenated before the other is attacked, and the reaction cannot be stopped until all the hydrogen atoms of the first carbon have been replaced (see below). If one of the groups is methyl, the

haloform reaction (**12-43**) can take place. With acid catalysts, it is usually possible to stop the reaction after only one halogen has been incorporated, although a second halogen can be introduced by the use of excess reagent. In chlorination the second halogen generally appears on the same side as the first,<sup>142</sup> while in bromination the  $\alpha,\alpha'$ -dibromo product is found.<sup>143</sup> Actually, with both halogens it is the  $\alpha,\alpha'$ -dihalo ketone that is formed first, but in the case of bromination this compound isomerizes under the reaction conditions to the  $\alpha,\alpha'$  isomer.<sup>142</sup>

When chlorine, bromine, or iodine is used as the halogenating reagent, it is not the aldehyde or ketone itself that is halogenated, but the corresponding enol or enolate ion. The purpose of the catalyst is to provide a small amount of enol or enolate (**12-3**). The reaction is often done without addition of acid or base, but traces of acid or base are always present, and these are enough to catalyze formation of the enol or enolate. With acid catalysis the mechanism is enol formation, reaction with the halogen, and trapping the halide ion to give the product.

There is a great deal of evidence for this mechanism: (i) the rate is first order in substrate; (ii) bromine does not appear in the rate expression at all,<sup>144</sup> a fact consistent with a rate-determining first step;<sup>145</sup> (iii) the reaction rate is the same for bromination, chlorination, and iodination under the same conditions;<sup>146</sup> (iv) the reaction shows an isotope effect; and (v) the rate of the step 2–step 3 sequence has been independently measured (by starting with the enol) and found to be very fast.<sup>147</sup>

With basic catalysts the mechanism probably involves formation of the enolate ion without formation of the enol, and then reaction with the halogen gives the product.

It was mentioned above that in the base-catalyzed reaction, if the substrate has two or three  $\alpha$  halogens on the same side of the C=O group, it is not possible to stop the reaction after just one halogen atom has entered. The reason is that the electron-withdrawing field effect of the first halogen increases the acidity of the remaining hydrogen atoms, that is, a CHX group is more acidic than a CH<sub>2</sub> group, so that the initially formed halo ketone is converted to enolate ion (and hence halogenated) more rapidly than the original substrate.

Regioselectivity in the halogenation of unsymmetrical ketones can be attained by treatment of the appropriate enol borinate of the ketone with *N*-bromo- or

## 12-5 Halogenation of Carboxylic Acids and Acyl Halides

The  $\alpha$ -hydrogen atoms of carboxylic acids are replaced by bromine or chlorine using a phosphorus halide as catalyst.<sup>174</sup> The reaction, known as the *Hell-Volhard-Zelinskii reaction*, is not applicable to iodine or fluorine. When there are two  $\alpha$ -hydrogen atoms, one or both may be replaced, although it is often hard to stop with just one. The reaction actually takes place on the acyl halide formed initially from the carboxylic acid and the halogenating reagent. This means that each molecule of acid is  $\alpha$ -halogenated while it is in the acyl halide stage. Carboxylic acids with relatively high enol content, such as malonic acid, are the most reactive. Less than one full molar equivalent of catalyst (per molar equivalent of substrate) is required, because of the exchange reaction between carboxylic acids and acyl halides (see **16-78**). The halogen from the catalyst is *not* transferred to the  $\alpha$  position. For example, the use of  $\text{Cl}_2$  and  $\text{PBr}_3$  results in  $\alpha$ -chlorination, not bromination. Acyl halides undergo  $\alpha$  halogenation without a catalyst. An enantioselective  $\alpha$ -halogenation was reported to give chiral  $\alpha$ -halo esters via an alkaloid-catalyzed reaction of acyl halides with perhaloquinone-derived reagents.<sup>175</sup> The mechanism is usually regarded as proceeding through the enol, as in **12-4**.<sup>176</sup> If chlorosulfuric acid  $\text{ClSO}_2\text{OH}$  is used as a catalyst, carboxylic acids can be  $\alpha$ -iodinated,<sup>177</sup> as well as chlorinated or brominated.<sup>178</sup> *N*-Bromosuccinimide in a mixture of sulfuric acid/trifluoroacetic acid can mono-brominate simple carboxylic acids.<sup>179</sup>

A number of other methods exist for the  $\alpha$ -halogenation of carboxylic acids or their derivatives.<sup>180</sup> Under electrolytic conditions with NaCl, malonates are converted to 2-chloro

## 12-6 Halogenation of Sulfoxides and Sulfones

Sulfoxides can be chlorinated in the α position<sup>187</sup> by treatment with Cl<sub>2</sub><sup>188</sup> or *N*-chlorosuccinimide,<sup>189</sup> in the presence of pyridine. These methods involve basic conditions. The reaction can also be accomplished in the absence of base with SO<sub>2</sub>Cl<sub>2</sub> in CH<sub>2</sub>Cl<sub>2</sub>,<sup>190</sup> or with TsNCl<sub>2</sub>.<sup>191</sup> The bromination reactions of sulfoxides with bromine<sup>192</sup> and with NBS/bromine<sup>193</sup> have also been reported. The α-fluorination of sulfoxides was reported via treatment with diethylaminosulfur trifluoride, Et<sub>2</sub>NSF<sub>3</sub> (DAST), to give an α-fluoro thioether, usually in high yield. Oxidation of this compound with *m*-chloroperoxybenzoic acid gave the sulfoxide.<sup>194</sup>

applied to compounds of the form  $Z-CH_2-Z'$ , where  $Z$  and  $Z'$  are electron-withdrawing groups, as defined in reaction **16-38**; for example,  $\beta$ -keto esters,  $\beta$ -keto amides, malonic ester.

The mechanism is probably of the simple  $S_E1$  type where the enolate anion reacts with the diazo compound to give the  $R_2CH-N=N-Ar$ , in which the carbon containing the azo group is attached to a hydrogen. This compound is unstable and tautomerizes to the isomeric hydrazone product,  $R_2C=N-NH-Ar$ .

When the reaction is carried out on a compound of the form  $Z-CHR-Z'$ , the azo compound does not have a hydrogen that can lead to tautomerism. If at least one  $Z$  is acyl or carboxyl, cleavage of the azo group leads to the hydrazone and not the azo compound. The overall process in this case is called the *Japp-Klingemann reaction*<sup>196</sup> and involves conversion of a ketone or a carboxylic acid to a hydrazone. When an acyl and a carboxyl group are both present, the leaving group order has been reported to be  $MeCO > COOH > PhCO$ .<sup>197</sup> When there is no acyl or carboxyl group present, the aliphatic azo compound is stable.

OS **III**, 660; **IV**, 633.

## 12-8 Nitrosation at a Carbon Bearing an Active Hydrogen

Carbons adjacent to a  $Z$  group (an electron-withdrawing group) can be nitrosated with nitrous acid or alkyl nitrites.<sup>198</sup> The initial product is the  $C$ -nitroso compound, but these are stable only when there is no hydrogen that can undergo tautomerism. When there is hydrogen that can undergo tautomerism, the product is the more stable oxime. The situation is analogous to that with azo compounds and hydrazones (**12-7**). The mechanism is similar to that in **12-7**:<sup>199</sup>

The reactive species is either  $NO^+$  or a carrier of it. When the substrate is a simple ketone, the mechanism goes through the enol (as in halogenation **12-4**).

Evidence shows that the reaction, in the presence of  $X^-$  ( $Br^-$ ,  $Cl^-$ , or  $SCN^-$ ) is first order in ketone and in  $H^+$ , but zero order in  $HNO_2$  and  $X^-$ .<sup>200</sup> Furthermore, the rate of the nitrosation was about the same as that for enolization of the same ketones. The species  $NOX$  is formed by

<sup>196</sup> For a review, see Phillips, R.R. *Org. React.* **1959**, *10*, 143.

<sup>197</sup> Neplyuev, V.M.; Bazarova, I.M.; Lozinskii, M.O. *J. Org. Chem. USSR* **1989**, *25*, 2011. This paper also includes a sequence of leaving group ability for other  $Z$  groups.

<sup>198</sup> See Williams, D.L.H. *Nitrosation*, Cambridge University Press, Cambridge, **1988**, pp. 1–45.

<sup>199</sup> For a review, see Williams, D.L.H. *Adv. Phys. Org. Chem.* **1983**, *19*, 381. See also, Williams, D.L.H. *Nitrosation*, Cambridge University Press, Cambridge, **1988**.

<sup>200</sup> Leis, J.R.; Peña, M.E.; Williams, D.L.H.; Mawson, S.D. *J. Chem. Soc., Perkin Trans. 2* **1988**, 157.

In the cases of  $F_3CCOCH_2COCF_3$  and malononitrile the nitrosation went entirely through the enolate ion rather than the enol.<sup>201</sup>

As in the *Japp-Klingemann reaction*, when Z is an acyl or carboxyl group (in the case of  $R_2CH-Z$ ), the azo group can be cleaved. Since oximes and nitroso compounds can be reduced to primary amines, this reaction often provides a route to amino acids. As in the case of **12-4**, the silyl enol ether of a ketone can be used instead of the ketone itself.<sup>202</sup>

Imines can be prepared in a similar manner, by treatment of an active hydrogen compound with a nitroso compound,  $R'-NO$ . Alkanes can be nitrosated photochemically, by treatment with  $NOCl$  and UV light.<sup>203</sup> For nitration at an activated carbon, see **12-9**.

OS **II**, 202, 204, 223, 363; **III**, 191, 513; **V**, 32, 373; **VI**, 199, 840. Also see, OS **V**, 650.

## 12-9 Nitration of Alkanes

Nitration of alkanes<sup>204</sup> can be carried out in the gas phase at  $\sim 400^\circ C$  or in the liquid phase. The reaction is not practical for the production of pure products for any alkane except methane. For other alkanes, not only does the reaction produce mixtures of the mono-, di-, and polynitrated alkanes at every combination of positions, but extensive chain cleavage occurs.<sup>205</sup> A free-radical mechanism is involved.<sup>206</sup>

Activated positions (e.g.,  $ZCH_2Z'$  compounds) can be nitrated by fuming nitric acid in acetic acid, by acetyl nitrate and an acid catalyst,<sup>207</sup> or by alkyl nitrates ( $RONO_2$ ) under alkaline conditions.<sup>208</sup> In the latter case, it is the carbanionic form of the substrate that is actually nitrated. The conjugate base of the nitro compound is isolated under these alkaline conditions, but yields are not high. Of course, the mechanism in this case is not of the free-radical type, but is electrophilic substitution with respect to the carbon (similar to the mechanisms of **12-7** and **12-8**). Positions activated by only one electron-withdrawing group, for example,  $\alpha$  positions of simple ketones, nitriles, sulfones, or *N,N*-dialkyl amides, can be nitrated with alkyl nitrates if a very strong base, e.g., *t*-BuOK or  $NaNH_2$ , is present to convert the substrate to the carbanionic form.<sup>209</sup> The reaction of alkanes with nitric acid and *N*-hydroxysuccinimide (NHS), however, gave moderate to good yields of the corresponding nitroalkane.<sup>210</sup> Similar nitration was accomplished with  $NO_2$ , NHS, and air.<sup>211</sup>

### 12-10 Direct Formation of Diazo Compounds From Ketones, Aldehydes, and Active Methylene Compounds

Active methylene compounds (two Z groups) can be converted to diazo compounds<sup>212</sup> upon treatment with tosyl azide in the presence of a base.<sup>213</sup> The use of phase-transfer catalysis increases the convenience of the method.<sup>214</sup> Sulfonyl azides also give the reaction.<sup>215</sup> The *diazo transfer reaction* can also be applied to other reactive positions, e.g., the 5 position of cyclopenta-1,3-diene.<sup>216</sup> The mechanism is probably as follows:

A diazo group can be introduced adjacent to a single carbonyl group indirectly by first converting the ketone to an  $\alpha$ -formyl ketone (**16-81**) and then treating it with tosyl azide and the formyl group is cleaved during the reaction.<sup>217</sup> Hydrazones have been oxidized to diazo compounds using *N*-iodo *p*-toluenesulfonamide.<sup>218</sup> A phosphino ester was used to mediate the conversion of azides into diazo compounds in phosphate buffer at neutral pH and room temperature.<sup>219</sup>

OS V, 179; VI, 389, 414.

The reaction between acyl halides and diazomethane is of wide scope and is the best way to prepare diazo ketones.<sup>220</sup> Diazomethane must be present in excess or the HX produced will react with the diazo ketone (**10-51**). This reaction is the first step of the *Arndt-Eistert synthesis* (**18-8**). Diazo ketones can also be prepared directly from a carboxylic acid and diazomethane or diazoethane in the presence of DCC.<sup>221</sup>

12-11 Conversion of Carboxylic Acid Derivatives to  $\alpha$ -Azido Derivatives

In reaction **12-10**, treatment of  $Z-CH_2-Z'$  with tosyl azide gave the  $\alpha$ -diazo compound via diazo transfer. When this reaction is performed on a compound with a single Z group (such as an amide), formation of the azide becomes a competing process via the enolate anion.<sup>222</sup> Factors favoring azide formation rather than diazo transfer include  $K^+$  as the enolate counterion rather than  $Na^+$  or  $Li^+$  and the use of 2,4,6-triisopropylbenzenesulfonyl azide rather than  $TsN_3$ .

The synthesis of  $\alpha$ -diazo ketones was achieved by simply stirring the mixture of 1,3-diketone,  $TsN_3$ , and  $MeNH_2$  in  $EtOH$ .<sup>223</sup> Using microflow reactor technology (Sec. 7.D) and the Bamford-Stevens reaction (**17-11**), *N*-arylsulfonyl hydrazones reacted with triethylamine to give the  $\alpha$ -diazo ester, which was converted to an  $\alpha$ -amino ester derivative or an  $\alpha$ -alkoxy ester derivative.<sup>224</sup>

## 12-12 Direct Amination at an Activated Position

Allylic amination of alkenes<sup>225</sup> has been reported by treatment with solutions of imido selenium compounds,  $R-N=Se=N-R$ .<sup>226</sup> The reaction, which is similar to the allylic oxidation of alkenes with  $SeO_2$  (see **19-14**), has been performed with  $R = t-Bu$  and  $R = Ts$ . The imido sulfur compound  $TsN=S=NTs$  has also been used.<sup>227</sup> Enantioselective allylic amination has been reported using organocatalysts.<sup>228</sup> A Rh-catalyzed amination of benzylic positions has also been reported.<sup>229</sup>

Tertiary alkyl hydrogen can be replaced in some cases via C–H nitrogen insertion. The reaction of sulfamate ester **15** with  $PhI(OAc)_2$ ,  $MgO$ , and a dinuclear Rh carboxylate catalyst, for example, generated oxathiazinane **16**.<sup>230</sup> This transformation

is a formal oxidation, and primary carbamates have been similarly converted to oxazolidin-2-ones.<sup>231</sup>

The asymmetric amination of  $\alpha$ -substituted cyclic ketones by reaction with di-*tert*-butyl azodicarboxylate was catalyzed by a chiral phosphoric acid to give  $\alpha$ -branched ketones, the *N*-containing quaternary stereocenter as a di-*tert*-butyl hydrazine-1,2-dicarboxylate derivative.<sup>232</sup> The enantioselective addition of anilines to azoalkenes using a chiral phosphoric acid catalyst gave  $\alpha$ -arylamino hydrazones and subsequent hydrolysis gave enantioenriched  $\alpha$ -arylamino ketones.<sup>233</sup>  $\alpha$ -Hydroxy ketones reacted with aniline derivatives in the presence of  $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ , solvent free at 80 °C or with microwave irradiation, to give the  $\alpha$ -amino ketone.<sup>234</sup> The reaction of amides and simple azides in the presence of  $\text{Tf}_2\text{O}$  gave stereoselective  $\alpha$ -amination of amides and formation of the  $\alpha$ -amino amide.<sup>235</sup> The reaction of phosphates that have an  $\alpha$  carbon with  $\text{Zn}(\text{2,2,6,6-tetramethylpiperidinyl})_2$  generated an organozinc compound *in situ*, which reacts with *O*-acylhydroxylamines and a Cu catalyst to give the corresponding  $\alpha$ -aminophosphonate.<sup>236</sup>

## 12-13 Insertion by Nitrenes

Nitrenes,<sup>237</sup>  $\text{R}-\text{N}$ , are the nitrogen analogs of carbenes, and most of the comments about carbenes also applies to them. Nitrenes are too reactive for isolation under ordinary conditions.<sup>238</sup> As stated in Sec. 5.E, one of the important reactions of nitrenes is insertion,

especially insertion into C–H bonds as well as some other bonds. A mechanism study of the chemoselectivity of metal-catalyzed N-atom transfer reactions of styryl azide has been reported.<sup>239</sup>

Carbonyl nitrenes, :NCOW (W = R', Ar, or OR'), are very reactive species (Sec. 5.E) and insert into the C–H bonds of alkanes to give amides (W = R' or Ar) or carbamates (W = OR').<sup>240</sup> The nitrenes are generated as discussed in Sec. 5.E. The order of reactivity among alkane C–H bonds is tertiary > secondary > primary.<sup>241</sup> Nitrenes are much more selective (and less reactive) in this reaction than carbenes (**12-17**).<sup>242</sup> It is likely that only singlet and not triplet nitrenes insert.<sup>243</sup> Retention of configuration is found at a stereogenic carbon.<sup>244</sup> The mechanism is presumably similar to the simple one-step mechanism for insertion of carbenes (**12-21**).

Other nitrenes [e.g., cyanonitrene (NCN)<sup>245</sup> and aryl nitrenes (NAr)<sup>246</sup>] can also insert into C–H bonds, but alkyl nitrenes usually undergo rearrangement before they can react with the alkane. The Au(III)-catalyzed insertion of nitrenes into aromatic and benzylic C–H groups has been reported.<sup>247</sup> N-Carbamoyl nitrenes undergo insertion reactions that often lead to mixtures of products, but exceptions are known,<sup>248</sup> chiefly in cyclizations.<sup>249</sup> Enantioselective nitrene insertion reactions are known.<sup>250</sup>

The reaction of an  $\alpha$ -nitro- $\alpha$ -diazo ester with a urea catalyst led to insertion into the N–H bonds of anilines.<sup>251</sup> A myoglobin-catalyzed N–H insertion reaction of  $\alpha$ -diazo esters with aryl amines gave the corresponding  $\alpha$ -amino ester.<sup>252</sup> Aryl and aliphatic aldehydes were converted to the corresponding amides using an Fe catalyst and reaction with PhI=NTs.<sup>253</sup> Intermolecular N–H insertion of  $\alpha$ -diazocarbonyl compounds into dibenzenesulfonimide gave the corresponding protected amino ester.<sup>254</sup> Heating aryl diazoacetates gave the corresponding carbene, and N–H insertion with primary and secondary amines, without a metal catalyst, gave  $\alpha$ -amino esters.<sup>255</sup> The reactivity of a triplet vinyl nitrene has been discussed.<sup>256</sup> The asymmetric reaction of  $\alpha$ -diazo esters led to N–H insertion with anilines, catalyzed by Cu complexes of chiral spiro bisoxazoline ligands.<sup>257</sup>

## D. Sulfur Electrophiles

### 12-14 Sulfenylation, Sulfonation, and Selenylation of Ketones and Carboxylic Esters

Ketones, carboxylic esters (including lactones),<sup>258</sup> and amides (including lactams)<sup>259</sup> can be sulfenylated<sup>260</sup> in the  $\alpha$  position by conversion to the enolate anion (Sec. 8.F, part 7) and subsequent treatment with a disulfide.<sup>261</sup> The reaction, shown above for ketones, involves nucleophilic substitution at sulfur.  $\alpha$ -Phenylseleno ketones,  $\text{RCH}(\text{SePh})\text{COR}'$ , and  $\alpha$ -phenylseleno esters,  $\text{RCH}(\text{SePh})\text{COOR}'$ , can be similarly prepared<sup>262</sup> by treatment of the corresponding enolate anions with  $\text{PhSeBr}$ ,<sup>263</sup>  $\text{PhSeSePh}$ ,<sup>264</sup> or benzeneseleninic anhydride,  $\text{PhSe}(\text{O})\text{OSe}(\text{O})\text{Ph}$ .<sup>265</sup> Another method for the introduction of a phenylseleno group into the  $\alpha$  position of a ketone involves simple treatment of an ethyl acetate solution of the ketone with  $\text{PhSeCl}$  (but not  $\text{PhSeBr}$ ) at room temperature.<sup>266</sup> This procedure is also successful for aldehydes but not for carboxylic esters. *N*-Phenylselenophthalimide has been used to convert ketones<sup>267</sup> and aldehydes<sup>268</sup> to the  $\alpha$ -PhSe derivative.

The  $\alpha$ -seleno and  $\alpha$ -sulfenyl carbonyl compounds prepared by this reaction can be converted to  $\alpha,\beta$ -unsaturated carbonyl compounds (**17-10**). The sulfenylation reaction has also been used<sup>269</sup> as a key step in a sequence for moving the position of a carbonyl group to an adjacent carbon.<sup>270</sup>

Aldehydes, ketones, and carboxylic acids containing  $\alpha$ -hydrogen atoms can be sulfonated with sulfur trioxide.<sup>271</sup> The mechanism is presumably similar to that of **12-4**. Sulfonation has also been accomplished at vinylic hydrogen.

## E. Carbon Reagents

### 12-15 Coupling of Alkene to Alkene, Alkene to Alkyne (Stille Coupling)

Vinyl triflates ( $\text{C}=\text{C}-\text{OSO}_2\text{CF}_3$ ) react with vinyl tin derivatives in the presence of a Pd catalyst to form dienes, in what is known as *Stille coupling*.<sup>272</sup> Phosphine or bis(phosphine) ligands are most commonly used with the Pd catalyst,<sup>273</sup> but other ligands have been used,<sup>274</sup> including triphenylarsine.<sup>275</sup> Vinyl triflates can be prepared from the enolate anion by reaction with *N*-phenyl triflimide.<sup>276</sup> Vinyltin compounds are generally prepared by the reaction of an alkyne with a trialkyltin halide (see **15-12** and **15-16**).<sup>277</sup> Stille cross-coupling reactions are an important variation of the basic reaction,<sup>278</sup> including cross-coupling reactions of unactivated secondary halides and mono-organotin reagents.<sup>279</sup> Aryl halides,<sup>280</sup> heteroaryl halides,<sup>281</sup> and heteroaryl triflates<sup>282</sup> can be coupled to vinyltin reagents<sup>283</sup> using a Pd catalyst. A Mo-catalyzed variation is known.<sup>284</sup> A Cu-catalyzed cross-coupling variation<sup>285</sup> has been reported in ionic liquids.<sup>286</sup> Vinyl halides can be coupled to alkenes to form dienes.<sup>287</sup> Diazo esters were coupled with aryltrimethylstannanes using a Rh catalyst.<sup>288</sup> Vinyl halides can be used,<sup>289</sup> and allenic tin compounds have been used.<sup>290</sup> Intramolecular reactions are possible.<sup>291</sup> Stille coupling has been done using microwave irradiation,<sup>292</sup>

in ionic liquids,<sup>293</sup> in fluorous solvents,<sup>294</sup> and in supercritical CO<sub>2</sub> (Sec. 9.D.ii).<sup>295</sup> Stille coupling using alkynes as a substrate are known.<sup>296</sup>

The accepted mechanism for the Stille reaction involves a catalytic cycle<sup>297</sup> in which the oxidative addition<sup>298</sup> and a reductive elimination steps<sup>299</sup> are fast, relative to the Sn/Pd-transmetalation (the rate-determining step).<sup>300</sup> It appears that the greater coordinating ability of the unsaturated species is important, and a coordinated solvent molecule is likely involved in the electrophilic substitution at tin. Another mechanism has been proposed, in which oxidative addition of the vinyl triflate to the ligated Pd gives a *cis* Pd complex that isomerizes rapidly to *trans* Pd complex, which then reacts with the organotin compound following a S<sub>E</sub>2 (cyclic) mechanism, with release of a ligand.<sup>301</sup> This pathway gives a bridged intermediate, and subsequent elimination of XSnBu<sub>3</sub> yields a three-coordinate species *cis* Pd complex, which readily gives the coupling product.<sup>301</sup> Most of the major intermediates have been intercepted, isolated, and characterized using electrospray ionization mass spectrometry.<sup>302</sup>

This reaction is highly stereoselective, and proceeds with a retention of geometry of the C=C units, and is usually regioselective with respect to the newly formed C–C σ bond.<sup>303</sup> Cine substitution is known with this reaction, and its mechanism has been studied.<sup>304</sup> It is noted that the origin of cine substitution has been examined.<sup>305</sup> Carbonylative Stille coupling reactions are known.<sup>306</sup> Stille coupling to enols has been reported.<sup>307</sup> The coupling of vinyl silanes<sup>308</sup> to give the symmetrically conjugated dienes using CuCl and air was reported.<sup>309</sup>

The coupling of alkenes or alkenes to alkynes usually requires a transition metal catalyst. The Pd-catalyzed dehydrative coupling of terminal alkynes with allylic alcohols assisted by Ti(Oi-Pr)<sub>4</sub> gave 1,4-enynes.<sup>310</sup> Conjugated dienes were prepared by the Pd-catalyzed reaction of unactivated alkenes with allylic esters and acrylates.<sup>311</sup> Conjugated enynes such as **17** were prepared via the Cu-catalyzed coupling between vinyl halides and terminal alkynes.<sup>312</sup>

Styrene was dimerized to give 1,4-diphenylbuta-1,3-diene upon treatment with a Pd catalyst and a cupric acetate oxidant and benzyl chloride.<sup>313</sup> 1,3-Enynes were prepared by coupling of vinyl halides and alkynes in the presence of Cu iodide.<sup>314</sup> The Ir-catalyzed dehydrogenative coupling of vinyl arenes gave predominantly (*E,E*)-1,4-diarylbuta-1,3-dienes.<sup>315</sup>

Cyclopropylboronic acids (**12-27**) couple with vinylic halides<sup>316</sup> or vinyl triflates<sup>317</sup> to give vinylcyclopropanes, using a Pd catalyst. Vinyl borates (**12-27**) were coupled to vinyl triflates using a Pd catalyst.<sup>318</sup> Vinyltrifluoroborates can be coupled to allylic chlorides using microwave irradiation<sup>319</sup> and vinyl halides react with vinyltrifluoroborates to give dienes with high stereoselectivity.<sup>320</sup>

Alkyl groups can be coupled to a vinyl unit to give substituted alkenes. The reaction of vinyl iodides and EtZnBr, with a Pd catalyst, gave the ethylated alkene (C=C–Et).<sup>321</sup> Aliphatic alkyl bromides reacted with vinyltin compounds to give the alkylated alkene using a Pd catalyst.<sup>322</sup> Allylic tosylates were coupled to conjugated alkenes to give a nonconjugated diene using a Pd catalyst.<sup>323</sup>

Alkynes are added to propargyl acetates using a Pd catalyst to give an alkyne allene.<sup>324</sup> Alkyne-alkenes were formed by coupling terminal alkynes and allenes in the presence of a Pd catalyst.<sup>325</sup> An alkyne was coupled internally to an allene using a Pd catalyst, to give a product that has an exocyclic methylene group and a vinyltin derivative.<sup>326</sup>

## 12-16 Acylation at Aliphatic or Alkenyl Carbon

Alkenes can be acylated with an acyl halide and a Lewis acid catalyst in what is essentially a *Friedel-Crafts reaction* (**11-17**) at an aliphatic carbon.<sup>327</sup> The product can arise by two

Rev.* **1972**, 1, 73; Satchell, D.P.N.; Satchell, R.S. in Patai, S. *The Chemistry of the Carbonyl Group*, Vol. 1, Wiley, NY, **1966**, pp. 259–266, 270–273; Nenitzescu, C.D.; Balaban, A.T. in Olah, G.A. *Friedel-Crafts and Related Reactions*, Vol. 3, Wiley, NY, **1964**, pp. 1033–1152.

paths. The initial attack is by the  $\pi$  bond of the alkene unit on the acyl cation ( $\text{RCO}^+$ ; or on the acyl halide free or complexed; see **11-17**) to give a carbocation, where the positive carbon atom is  $\beta$  relative to the carbonyl. Loss of a proton from the carbocation gives an unsaturated ketone. If the carbocation combines with chloride, the product is a  $\beta$ -halo ketone, which can be isolated, so that the result is addition to the double bond (see **15-43**). On the other hand, the  $\beta$ -halo ketone may, under the conditions of the reaction, lose HCl to give the unsaturated ketone, this time by an addition–elimination mechanism. In the case of unsymmetrical alkenes, the more stable alkene is formed (the more highly substituted and/or conjugated alkene, following *Markovnikov's rule*, Sec. 15.B.ii).

Anhydrides and carboxylic acids (the latter with a protonic acid such as anhydrous HF,  $\text{H}_2\text{SO}_4$ , or polyphosphoric acid as a catalyst) are sometimes used instead of acyl halides. With some substrates and catalysts double-bond migrations are occasionally encountered so that, for example, when 1-methylcyclohexene was acylated with acetic anhydride and zinc chloride, the major product was 6-acetyl-1-methylcyclohexene.<sup>328</sup> Acylation of vinylic ethers has been accomplished with aromatic acyl chlorides, a base, and a Pd catalyst.<sup>329</sup>

*Formylation* of alkenes can be accomplished with *N*-disubstituted formamides and  $\text{POCl}_3$ .<sup>330</sup> This is an aliphatic *Vilsmeier reaction* (see **11-18**). Vilsmeier formylation can also be performed on the  $\alpha$  position of acetals and ketals, so that hydrolysis of the products gives keto aldehydes or dialdehydes.<sup>331</sup> Aromatic compounds were treated with  $\text{POCl}_3/\text{DMF}$  to form an aryl-type Vilsmeier reaction, and subsequent treatment with iodine in aqueous ammonia gave the aryl nitrile.<sup>332</sup> Acetylation of acetals or ketals can be accomplished with acetic anhydride and  $\text{BF}_3$ -etherate.<sup>333</sup> The mechanism with acetals or ketals also involves attack at an alkenyl carbon, since enol ethers are intermediates.<sup>331</sup> Ketones can be formylated in the  $\alpha$  position by treatment with CO and a strong base.<sup>334</sup>

Silyl enol ethers,<sup>335</sup> important reagents with a number of synthetic uses (see, for example, **10-68**, **12-4**, **15-20**, **15-60**, and **16-36**), can be prepared by base treatment of a ketone (converting it to its enolate anion) followed by addition of a trialkylchlorosilane. Other silylating agents have also been used.<sup>336</sup> Both strong bases (such as lithium diisopropylamide, LDA) and weaker bases (Et<sub>3</sub>N) have been used for this purpose.<sup>337</sup> In some cases, the base and the silylating agent can be present at the same time.<sup>338</sup>

The reaction can be applied to aldehydes by the use of the base KH in 1,2-dimethoxyethane.<sup>339</sup> A particularly mild method for conversion of ketones or aldehydes to silyl enol ethers uses Me<sub>3</sub>SiI and the base hexamethyldisilazane, (Me<sub>3</sub>Si)<sub>2</sub>NH.<sup>340</sup> *bis*-(Trimethylsilyl)acetamide is an effective reagent for the conversion of ketones to the silyl enol ether, typically giving the thermodynamic product (see below).<sup>341</sup> Silyl enol ethers have also been prepared by the direct reaction of a ketone and a silane (R<sub>3</sub>SiH) with a Pt catalyst.<sup>342</sup>

For substituted ketones, (*E*) and (*Z*) isomers are usually formed. A silyl enol ether is (*Z*) when R<sup>1</sup> is the priority group but (*E*) when R<sup>2</sup> is the priority group. In some cases it is possible to control the selectivity to favor more of one isomer than the other. Treatment of 2-methylpentan-3-one with LDA (THF, -78 °C), for example, gave a 60:40 mixture of the (*Z*) and (*E*) enolates.<sup>343</sup> The base used to generate an enolate anion, the solvent and temperature, the conjugate acid of the base used, and the nature of the carbonyl substrate will all play a role in the selectivity. In general, equilibrating (thermodynamic) conditions (protic solvents, e.g., ethanol, water, or ammonia, a base generating a conjugate acid stronger than the starting ketone, more ionic counterions, e.g., K or Na, higher temperatures, and longer reaction times) are expected to give more of the (*E*) isomer. Conversely, kinetic conditions (aprotic solvents, such as ether or THF, a base generating a

<sup>343</sup> Heathcock, C.H.; Buse, C.T.; Kleschick, W.A.; Pirrung, M.A.; Sohn, J.E.; Lampe, J. *J. Org. Chem.* **1980**, 45, 1066.

conjugate acid weaker than the starting ketone, more covalent counterions, e.g., Li, lower temperatures, and relatively short reaction times) usually give more of the (*Z*) isomer. It is not always easy to predict the ratio, however. Either isomer is possible from aldehydes using the proper Rh catalyst.<sup>344</sup> Magnesium diisopropylamide has been used to prepare kinetic silyl enol ethers in virtual quantitative yield.<sup>345</sup> Reaction with Me<sub>3</sub>SiCl/KI in DMF gives primarily the thermodynamic silyl enol ether.<sup>346</sup>

The protonation of silyl enol ethers with a chiral sulfonamide/achiral sulfonic acids as a co-catalyst gave the chiral  $\alpha$ -aryl cyclic ketone.<sup>347</sup> The reaction of  $\alpha,\beta$ -unsaturated acylsilanes with BuCu or a Grignard reagent/*t*-BuOCu and then an alkyl halide gave the silyl enol ether with a  $\gamma$  stereocenter.<sup>348</sup>

An interesting synthesis of silyl enol ethers involves chain extension of an aldehyde. Aldehydes are converted to the silyl enol ether of a ketone upon reaction with lithium (trimethylsilyl)diazomethane and then a dirhodium catalyst.<sup>349</sup> For example, initial reaction of lithium (trimethylsilyl)diazomethane [LTMSD, prepared *in situ* by reaction of butyllithium with (trimethylsilyl)diazomethane] with the aldehyde (**18**) gave the alkoxide addition product. Protonation, then capture by a transition metal catalyst, and a 1,2-hydride migration gave the silyl enol ether, **19**.

Enol acetates are generally prepared by the reaction of an enolate anion with a suitable acylating reagent such as acetic anhydride.<sup>350</sup> Enolate anions react with acyl halides and with anhydrides to give the acylated product. Both *C*-acylation and *O*-acylation are possible, but in general *O*-acylation predominates.<sup>351</sup> Note that the extent of *O*- versus *C*-acylation is very dependent on the local environment and electronic effects within the enolate anion.<sup>352</sup> *O*-Benzoate enols are formed in good yield from aldehydes or 1,3-diketones in the presence of CuBr and *tert*-butylhydroperoxide.<sup>353</sup> A polymer-supported triflating agent was used to prepare silyl enol triflate from ketones, in the presence of diisopropylethylamine.<sup>354</sup>

When a silyl enol ether is the trimethylsilyl derivative (Me<sub>3</sub>Si—O—C=C), treatment with methyl lithium will regenerate the lithium enolate anion and the volatile trimethylsilane (Me<sub>3</sub>SiH).<sup>355</sup>

### 12-18 Conversion of Aldehydes to $\beta$ -Keto Esters or Ketones

$\beta$ -Keto esters have been prepared in moderate to high yields by treatment of aldehydes with diethyl diazoacetate in the presence of a catalytic amount of a Lewis acid, such as  $\text{SnCl}_2$ ,  $\text{BF}_3$ , or  $\text{GeCl}_2$ .<sup>357</sup> The reaction was successful for both aliphatic and aromatic aldehydes, but the former react more rapidly than the latter, and the difference is great enough to allow selective reactivity. In a similar process, aldehydes react with certain carbanions stabilized by boron ( $\text{Ar}_2\text{BCH}^-\text{R}'$ ), in the presence of  $(\text{F}_3\text{CCO})_2\text{O}$  or NCS, to give ketones.<sup>358</sup>

Ketones can be prepared from aryl aldehydes ( $\text{ArCHO}$ ) by treatment with a Rh complex  $(\text{Ph}_3\text{P})_2\text{Rh}(\text{CO})\text{Ar}'$ , whereby the Ar group is transferred to the aldehyde, producing the ketone,  $\text{Ar}-\text{CO}-\text{Ar}'$ .<sup>359</sup> In another Rh-catalyzed reaction, aryl aldehydes ( $\text{ArCHO}$ ) react with  $\text{Me}_3\text{SnAr}'$  to give the diaryl ketone  $\text{Ar}-\text{CO}-\text{Ar}'$ .<sup>360</sup> Acylation of aryl halides with aldehydes gives aryl ketones in the presence of a Pd catalyst.<sup>361</sup>

### 12-19 Cyanation

There are several reactions in which a C–H unit is altered to C–CN. In virtually all cases, the hydrogen being replaced is on a carbon  $\alpha$  to a heteroatom or functional group. There are several examples. Introduction of a cyano group  $\alpha$  to the carbonyl group of a ketone can be accomplished by prior formation of the enolate anion with LDA in THF and addition of this solution to *p*-TsCN at  $-78^\circ\text{C}$ .<sup>362</sup> The products are formed in moderate to high yields but the reaction is not applicable to methyl ketones. Treatment of  $\text{TMSCH}_2\text{N}(\text{Me})\text{C}=\text{N}t\text{-Bu}$  with *sec*-butyllithium and  $\text{R}_2\text{C}=\text{O}$ , followed by iodomethane and NaOMe, leads to the nitrile,  $\text{R}_2\text{CH}-\text{CN}$ .<sup>363</sup>

Cyanation has been shown to occur  $\alpha$  to a nitrogen, specifically in *N,N*-dimethylaniline derivatives. Treatment with a catalytic amount of  $\text{RuCl}_3$  in the presence of oxygen and NaCN leads to the corresponding cyanomethylamine.<sup>364</sup> Conversion of tertiary amines to the  $\alpha$ -cyanoamine has been reported in the presence of  $\text{FeCl}_2$  and *t*-BuOOH.<sup>365</sup>

<sup>365</sup> Han, W.; Ofial, A.R. *Chem. Commun.* **2009**, 5024.

Allylic tertiary amines reacted with tropylium tetrafluoroborate and KCN to give the  $\alpha$ -cyanoamine.<sup>366</sup> Vinyl halides reacted with cyanohydrins with a Pd catalyst to give the vinyl nitrile.<sup>367</sup> Vinylic boronic acids reacted with  $\alpha$ -cyanoacetates in the presence of O<sub>2</sub> and a Cu catalyst to give the vinyl nitrile.<sup>368</sup> The Au-catalyzed oxidative  $\alpha$  cyanation of tertiary amines has been reported.<sup>369</sup>

In a different kind of reaction, nitro compounds are  $\alpha$  cyanated by treatment with <sup>-</sup>CN and K<sub>3</sub>Fe(CN)<sub>6</sub>.<sup>370</sup> The mechanism probably involves ion radicals. In still another reaction, secondary amines are converted to  $\alpha$ -cyanoamines by treatment with phenylseleninic anhydride and NaCN or Me<sub>3</sub>SiCN.<sup>371,372</sup>

## 12-20 Alkylation of Alkanes

Alkanes can be alkylated by treatment with solutions of stable carbocations<sup>373</sup> (Sec. 5.A.ii), but the availability of such carbocations is limited and mixtures are usually obtained. In a typical experiment, the treatment of propane with isopropyl fluoroantimonate (Me<sub>2</sub>HC<sup>+</sup> SbF<sub>6</sub><sup>-</sup>) gave 26% 2,3-dimethylbutane, 28% 2-methylpentane, 14% 3-methylpentane, and 32% *n*-hexane, as well as some butanes, pentanes (formed by **12-46**), and higher alkanes. Mixtures arise in part because intermolecular hydrogen exchange

is much faster than alkylation, so that alkylation products are also derived from the new alkanes and carbocations formed in the exchange reaction. Furthermore, the carbocations present are subject to rearrangement (Chapter 18), giving rise to new carbocations. Products result from all the hydrocarbons and carbocations present in the system. As expected from their relative stabilities, secondary alkyl cations alkylate alkanes more readily than tertiary alkyl cations (the *tert*-butyl cation does not alkylate methane or ethane). Stable primary alkyl cations are not available, but alkylation has been achieved with complexes formed between CH<sub>3</sub>F or C<sub>2</sub>H<sub>5</sub>F and SbF<sub>5</sub>.<sup>374</sup> The mechanism of alkylation can be formulated (similar to that shown in hydrogen exchange with superacids, **12-1**) as that shown. It is by means of successive reactions of this sort that simple alkanes like methane and ethane give *tert*-butyl cations in superacid solutions (Sec. 5.A.ii).<sup>375</sup>

Intramolecular insertion has been reported.<sup>376</sup> The reaction of alkyl halides with the unactivated  $sp^3$  C–H bonds of aliphatic amides used a N catalyst and a bidentate directing group.<sup>377</sup>

## 12-21 Insertion by Carbenes

The highly reactive species methylene ( $\text{:CH}_2$ ) inserts into C–H bonds,<sup>378</sup> both aliphatic and aromatic,<sup>379</sup> although with aromatic compounds subsequent ring expansion is also possible (see **15-60**). This is effectively a homologation reaction.<sup>380</sup> The insertion reactions of dimethylcarbene have been reviewed.<sup>381</sup> The methylene insertion reaction has limited utility because of its nonselectivity (Sec. 5.D.i). The carbenes can be generated in any of the ways mentioned in Sec. 5.D.ii. Alkylcarbenes usually rearrange rather than give insertion (Sec. 5.D.ii, category 4), but, when this is impossible, *intramolecular* insertion<sup>382</sup> is found, rather than intermolecular.<sup>383</sup> Methylene ( $\text{:CH}_2$ ) generated by photolysis of diazomethane ( $\text{CH}_2\text{N}_2$ ) in the liquid phase is indiscriminate (totally nonselective) in its reactivity (Sec. 5.D.ii, category 2). Methylene ( $\text{:CH}_2$ ) generated in other ways and monoalkyl and dialkyl carbenes are less reactive and insert in the order tertiary > secondary > primary.<sup>384</sup> Carbenes have been generated using ultrasound.<sup>385</sup> Carbene insertion with certain allylic systems can proceed with rearrangement of the double bond.<sup>386</sup> Halocarbenes ( $\text{:CCl}_2$ ,  $\text{:CBr}_2$ , etc.) insert much less readily, although a number of instances have been reported.<sup>387</sup> Generation of triplet carbenes has been discussed.<sup>388</sup>

Dirhodium-catalyzed insertion into H—C(*sp*<sup>2</sup>) bonds is known,<sup>389</sup> and also into H—C(*sp*) bonds.<sup>390</sup> It is noted that cyclopropanation may compete with C—H insertion with electron-rich highly substituted alkenes.<sup>391</sup> Insertion of diazoalkane and diazocarbonyl compounds can be catalyzed by Cu compounds<sup>392</sup> and Ag compounds<sup>393</sup> as well. Insertion at an allylic carbon of alkenes has been reported.<sup>394</sup> Insertion into the α-C—H bond of an aldehyde gives an α-substituted aldehyde.<sup>395</sup> Intramolecular insertion at the α carbon of a ketone by a diazo ketone, using TiCl<sub>4</sub>, gives a bicyclic 1,3-diketone.<sup>396</sup> A Au-catalyzed reaction is known that uses alkynes as an α-diazo ketone equivalent.<sup>397</sup>

The metal carbene insertion reaction, in contrast to the methylene insertion reaction, can be highly selective,<sup>398</sup> and is useful in synthesis.<sup>399</sup> There are numerous examples, usually requiring a transition metal catalyst.<sup>400</sup> The catalyst typically converts a diazoalkane or diazocarbonyl compound to the metal carbene *in situ*, allowing the subsequent insertion reaction. Intermolecular reactions are known, including a diazoalkane insertion reaction with a dirhodium catalyst.<sup>401</sup> Good enantioselectivity is observed in the insertion product when chiral ligands are present.<sup>402</sup>

The mechanism<sup>403</sup> of the insertion reaction is not known with certainty, but there seem to be at least two possible pathways.

1. A simple one-step process involving a three-center cyclic transition state:

The most convincing evidence for this mechanism is that in the reaction between isobutene-1-<sup>14</sup>C and carbene the product 2-methylbut-1-ene was labeled only in the C-1 position.<sup>404</sup> This rules out a free radical or a carbocation or carbanion

intermediate. If an allylic radical such as **20** (or a corresponding ion) were an intermediate, resonance would ensure that some carbene attacked at the C-1 position:

Other evidence is that retention of configuration, which is predicted, has been found in a number of instances.<sup>405</sup> An ylid intermediate was trapped in the reaction of  $\text{:CH}_2$  with allyl alcohol.<sup>406</sup>

2. A free-radical process in which the carbene directly abstracts a hydrogen atom from the substrate to generate a pair of free radicals:

One fact supporting this mechanism is that among the products obtained (beside butane and 2-methylpropane) on treatment of propane with  $\text{CH}_2$  (generated by photolysis of diazomethane and ketene) were propene and ethane,<sup>407</sup> which could arise, respectively, by disproportionation of the propane radical to prop-1-ene and propane. Note that disproportionation refers to a reaction in which a compound is simultaneously oxidized and reduced to give two different products such as the alkene and the alkane. Alternatively, propane can react with  $\text{:CH}_2$  to give the propyl radical and the methyl radical, and the methyl radical can couple with a second methyl radical to give ethane.

The disproportionation mechanism can take place under suitable conditions, as has been demonstrated by isotopic labeling<sup>408</sup> and by other means.<sup>409</sup> However, the formation of disproportionation and dimerization products does not always mean that the free-radical abstraction process takes place. In some cases these products arise in a different manner.<sup>410</sup> The product of the reaction between a carbene and a molecule may have excess energy (Sec. 5.D.ii). Therefore, it is possible for the substrate and the carbene to react by mechanism 1 (the direct-insertion process) and for the excess energy to cause the compound thus formed to cleave to free radicals. When this pathway is in operation, the free radicals are formed *after* the actual insertion reaction. The mechanism of

cyclopropylcarbene reactions has also been discussed.<sup>411</sup> Migratory carbene insertion reactions have been discussed.<sup>412</sup>

It has been suggested<sup>413</sup> that singlet carbenes insert by the one-step direct-insertion process and triplets (which, being free radicals, are more likely to abstract hydrogen) by the free-radical process. In support of this suggestion, CIDNP signals<sup>414</sup> (Sec. 5.C.i) were observed in the ethylbenzene produced from toluene and triplet CH<sub>2</sub>, but not from the same reaction with singlet CH<sub>2</sub>.<sup>415</sup> Carbenoids (e.g., compounds of the form R<sub>2</sub>CMCl, see 12-39) can insert into a C—H bond by a different mechanism, similar to pathway 2, but involving abstraction of a hydride ion rather than a hydrogen atom.<sup>416</sup>

There are many types of insertion reactions, including insertion into C—H bonds, O—H or O—C bonds, or N—H bonds, and there are many variations. The insertion of  $\alpha$ -diazo esters into aryl aldehydes gave the  $\alpha$ -carbomethoxy aldehyde in the presence of a chiral oxazaborolidinium catalyst.<sup>417</sup> The insertion of  $\alpha$ -diazo esters into benzocyclobutenols gave indanol derivatives.<sup>418</sup> *ortho*-Alkylbromobenzene derivatives undergo insertion reactions with diazoalkanes and a Pd catalyst to produce indane derivatives.<sup>419</sup> The carbonylation of carbenes can give ketenes.<sup>420</sup>

$\alpha$ -Diazo esters, in the presence of a Cu catalyst, generated a carbene that reacted via insertion with alkynes with a distal ester unit to give the corresponding alkenyl ester.<sup>421</sup> The Rh-catalyzed insertion of the carbene derived from  $\alpha$ -diazocarbonyl compounds into primary alkyl C—H bonds has been reported.<sup>422</sup> The alkylidene carbene reagents,<sup>423</sup> generated from the reaction of ketone with TMSCHN<sub>2</sub> and BuLi, gave an intramolecular insertion reaction that generated cyclopentene derivatives.<sup>424</sup> Benzylic diazo compounds reacted with aldehydes to give chiral  $\alpha$ -aryl ketones using a chiral oxazaborolidinium catalyst.<sup>425</sup> The Rh-catalyzed insertion reaction of  $\alpha$ -diazo esters with functionalized aromatic compounds gave the *ortho*-substituted CHRCO<sub>2</sub>R' product.<sup>426</sup> The insertion reaction of  $\alpha$ -aryl- $\alpha$ -diazo ketones with a Rh catalyst gave  $\alpha$ -aryl cyclohexanone derivatives.<sup>427</sup> Gold vinylidene reagents, formed *in situ* from alkynyl ketones by treatment with *N*-bromoacetamide, a Au catalyst, and 10% AgSbF<sub>6</sub>, gave 2-bromocyclopentenone derivatives.<sup>428</sup>  $\alpha$ -Diazo esters reacted with benzylic aromatic compounds in the presence of an immobilized Cu

catalyst to give the  $\alpha$ -aryl ester.<sup>429</sup>  $\alpha$ -Oxo gold carbenes were trapped by carboxylic acids.<sup>430</sup>

Intramolecular insertion reactions are well known,<sup>431</sup> and tolerate a variety of functional groups.<sup>432</sup> The insertion of the diazocarbonyl unit into the C–H bond of an  $\alpha$ -diazo amide gives the lactam shown in the reaction.<sup>433</sup>

Insertion into a 2-pyrrolidinone derivative using  $\text{Me}_3\text{SiCH}_2\text{N}_2$  followed by  $\text{AgCO}_2\text{Ph}$  with ultrasound gave the ring-expanded 2-piperidone derivative.<sup>434</sup> An intramolecular insertion reaction was reported for  $\alpha$ -diazo keto esters with a distal phenyl substituent, using a Rh catalyst to give a dihydronaphthalene derivative.<sup>435</sup> The intramolecular insertion reaction of  $\alpha$ -diazo- $\beta$ -keto esters or  $\alpha$ -diazo- $\beta$ -keto phosphonates with  $\text{CuCl}_2$  and sodium tetrakis[3,5-bis(trifluoromethyl)phenyl]borate gave the cyclopentanone derivative.<sup>436</sup>

Insertion into the O–H bond of alcohols, to produce ethers, has been reported using a diazocarbonyl compound and an  $\text{In}(\text{OTf})_3$  catalyst.<sup>437</sup> The Cu-catalyzed insertion of a diazo ester into an oxetane gives the ring-expanded tetrahydrofuran derivative.<sup>438</sup> Insertion is also possible with other ethers, including silyl ethers.<sup>439</sup> Metal-catalyzed silylene insertion into allylic ethers leads to allylic silanes.<sup>440</sup> Similar insertion at the  $\alpha$  carbon of an ether leads to cyclic ethers, with high enantioselectivity when a chiral ligand is used with a Rh catalyst.<sup>441</sup>

Phenyl diazoacetates, when heated, gave the carbene, which reacted via N–H insertion with aniline, in the presence of Cinchona alkaloids, to give chiral  $\alpha$ -amino esters.<sup>442</sup> The

intramolecular insertion reaction of  $\alpha$ -diazo esters with a distal amino, ether, or methylene unit gave the corresponding cyclic amine, cyclic ether, or cyclic hydrocarbon in the presence of a Pd catalyst.<sup>443</sup>

The carbenoid alkene insertion reactions of oxiranyllithium reagents have been reported.<sup>444</sup> A computational study has been carried out for a carbenoid mechanism for the reaction of geminal dihalocyclopropanes with metals or alkyllithiums to give carbenoids that are converted to allenes.<sup>445</sup> The Pd-catalyzed insertion of carbenoids into amins has been reported.<sup>446</sup> Lithium chloride carbenoids have been used in bond activation reactions.<sup>447</sup> Carbenoid insertion reactions into Si–H and S–H bonds has been reported using  $\alpha$ -diazo ketones and  $\alpha$ -diazo esters with a Cu catalyst.<sup>448</sup> Alkyldenecyclobutanes have been prepared by the reaction of cyclobutylmagnesium carbenoids with vinyl sulfones.<sup>449</sup> Allenyl carbenoids reacted via insertion with organozirconium bonds to give homopropargyl alcohols.<sup>450</sup>

OS VII, 200.

## F. Metal Electrophiles

### 12-22 Metalation With Organometallic Compounds

Many organic compounds can be metalated by treatment with an organometallic compound.<sup>451</sup> In general, the reaction can be performed only with organometallics of active metals such as Li, Na, and K, but Grignard reagents abstract protons from sufficiently acidic C–H bonds, as in  $\text{R}-\text{C}\equiv\text{C}-\text{H} \rightarrow \text{R}-\text{C}\equiv\text{C}-\text{MgX}$ . This is the best method for the preparation of alkynyl Grignard reagents.<sup>452</sup> Lewis acids have been used to promote  $\alpha$ -lithiation of amines.<sup>453</sup> Triethylgallium has been used to generate enolate anions from ketones.<sup>454</sup> Note that organolithium compounds are aggregated species and can form hetero-aggregates containing different organic groups.<sup>455</sup> *N*-Lithio-*N*-(trialkylsilyl)allylamines are deprotonated in ether solvents at the *cis*-vinylic position

to give 3,*N*-dilithio-*N*-(trialkylsilyl)allylamines.<sup>456</sup> Since the reaction involves a proton transfer, the equilibrium lies on the side of the weaker acid.<sup>457</sup> The most common reagent is probably butyllithium.<sup>458</sup> Reductive lithiation is an important method for the preparation of organolithium reagents.<sup>459</sup> Normally, only active aromatic rings react with butyllithium. Benzene itself reacts with lithium very slowly and in low yield, although benzene can be metalated by butyllithium in the presence of *tert*-BuOK<sup>460</sup> or by coordination with various diamines.<sup>461</sup> Metalation of aliphatic RH is most successful when the carbanions are stabilized by resonance (allylic, benzylic, propargylic,<sup>462</sup> etc.) or when the negative charge is at an *sp* carbon (at triple bonds). Trimethylsilylmethyl potassium (Me<sub>3</sub>SiCH<sub>2</sub>K)<sup>463</sup> and also a combination of an organolithium compound with a bulky alkoxide (LICKOR superbases)<sup>464</sup> are very good reagents for allylic metalation. The former is also useful for benzylic positions. A combination of BuLi, *t*-BuOK, and tetramethylethylenediamine has been used to convert ethylene to vinylpotassium.<sup>465</sup> The reaction can be used to determine relative acidities of very weak acids by allowing two R–H compounds to compete for the same R'M and to determine which proton in a molecule is the most acidic.<sup>466</sup>

When a heteroatom, such as N, O, S,<sup>467</sup> or a halogen,<sup>468</sup> is present in a molecule containing an aromatic ring or a double bond, lithiation is usually quite regioselective.<sup>469</sup> The reaction of methoxyethene with *t*-butyllithium generates 1-lithio-1-methoxyethene.<sup>470</sup> It has been shown that fluorine is more effective for stabilization of carbanions when compared to the heavier halogens.<sup>471</sup> In such compounds, the lithium usually bonds with the *sp*<sup>2</sup> carbon closest to the heteroatom, probably because the attacking species coordinates with the heteroatom.<sup>472</sup> This type of reaction with compounds such as anisole are often called directed metalations.<sup>473</sup> In the case of aromatic rings this means attack at the *ortho*

<sup>473</sup> Slocum, D.W.; Coffey, D.S.; Siegel, A.; Grimes, P. *Tetrahedron Lett.* **1994**, *35*, 389.

position,<sup>474</sup> but this is considered in **13-12**. In the case of  $\gamma,\delta$ -unsaturated disubstituted amides, the lithium does not go to the closest position, but in this case too the regiochemistry is controlled by coordination to the oxygen.<sup>475</sup> Cyclopropyllithium reagents are rather stable.<sup>476</sup>

The mechanism involves an attack by  $R'^-$  (or a polar  $R'$ ) on the *hydrogen*<sup>477</sup> (an *acid-base reaction*). Evidence is that resonance effects of substituents in R seem to make little difference. When R is aryl, OMe and  $CF_3$  *both* direct *ortho*, while isopropyl directs *meta* and *para* (mostly *meta*).<sup>478</sup> These results are exactly what would be expected from pure field effects, with no contribution from resonance effects, which implies that attack occurs at the hydrogen and not at R. Other evidence for the involvement of H in the rate-determining step is that there are large isotope effects.<sup>479</sup> The nature of  $R'$  also has an effect on the rate. In the reaction between triphenylmethane and  $R'Li$ , the rate decreased in the order  $R' = \text{allyl} > \text{Bu} > \text{Ph} > \text{vinyl} > \text{Me}$ , although this order changed with changing concentration of  $R'Li$ , because of varying degrees of aggregation of the  $R'Li$ .<sup>480</sup> With respect to the reagent, this reaction is a special case of **12-24**.

Enantioselective reactions are known. The preparation of chlorodeuteriomethylithium proceeds with inversion from the corresponding enantiopure stannyl derivative.<sup>481</sup> Although highly reactive chemically, it is configurationally stable at temperatures up to  $-78^\circ\text{C}$ . Enantioselective catalytic deprotonation with chiral ligands has been used for the deprotonation of *N*-Boc amines to give chiral  $\alpha$ -trimethylsilyl derivatives.<sup>482</sup> A barrier to enantiomerization has been observed for unstabilized, chelated, and dipole-stabilized organolithium compounds. Studies of lithiopyrrolidines show free energies for enantiomerization in the range of  $19\text{--}22 \text{ kcal mol}^{-1}$  ( $79.5\text{--}92.1 \text{ kJ mol}^{-1}$ ) at  $0^\circ\text{C}$ .<sup>483</sup>

acids (Sec. 5.B.i). The conversion of terminal alkynes to acetylide ions is one important application.<sup>485</sup> A Au-catalyst conversion of trimethylsilyl-substituted esters and carbonates to the corresponding enolate anion has been reported.<sup>486</sup> Synthetically, an important use of the method is to convert aldehydes and ketones,<sup>487</sup> carboxylic esters, and similar compounds to their enolate forms,<sup>488</sup> including  $\beta$ -keto esters and malonate derivatives.

## 12.C.ii. Metals as Leaving Groups

### A. Hydrogen as the Electrophile

#### 12-24 Replacement of Metals by Hydrogen

Organometallic compounds, including enolate anions, react with compounds that have an acidic hydrogen in reactions that replace the metal with hydrogen.<sup>489</sup> The R group may be aryl (see 11-38). The reaction is often used to introduce deuterium or tritium into susceptible positions. For *Grignard reagents*, water is usually a strong enough acid, but stronger acids are also used. An important method for the reduction of alkyl halides consists of the process:

The organometallic compounds that are hydrolyzed by water are the ones high in the electromotive series: Na, K, Li, Zn, and so on. In other words, this reaction is an acid–base reaction and these organometallics are very basic, and react with the relatively weak acid, water ( $\text{p}K_{\text{a}}$ , 15.7). Enantioselective protonation of lithium enolates<sup>490</sup> and cyclopropyllithium compounds<sup>491</sup> have been reported. When the metal is less active, the organometallic is less basic and stronger acids are required. For example,  $\text{R}_2\text{Zn}$  compounds react explosively with water, slowly with  $\text{R}_2\text{Cd}$ , and not at all with  $\text{R}_2\text{Hg}$ , although the latter can be cleaved with concentrated HCl. However, this general statement has many exceptions, some hard to explain. For example,  $\text{BR}_3$  compounds are completely inert to water,  $\text{GaR}_3$  at room temperature cleaves just one R group, but  $\text{AlR}_3$  reacts violently with water. However,  $\text{BR}_3$  can be converted to RH with carboxylic acids.<sup>492</sup> Organometallic compounds of less active

metals and metalloids (e.g., Si,<sup>493</sup> Sb, and Bi) are quite inert to water. Alkyl–Si bonds are cleaved by H<sub>2</sub>SO<sub>4</sub>, for example:<sup>494</sup>

## B. Oxygen Electrophiles

### 12-25 The Reaction between Organometallic Reagents and Oxygen<sup>495</sup>

Oxygen reacts with *Grignard reagents* to give either hydroperoxides<sup>496</sup> or alcohols. The reaction can be used to convert alkyl halides to alcohols without side reactions. With aryl Grignard reagents, yields are lower and only phenols are obtained, not hydroperoxides. Because of this reaction, oxygen should be excluded when Grignard reagents are prepared and used in various reactions.

Most other organometallic compounds also react with oxygen. In addition, trialkylboranes and alkyldichloroboranes (RBCl<sub>2</sub>) can be conveniently converted to hydroperoxides by treatment with oxygen followed by hydrolysis.<sup>497</sup> Dilithiated carboxylic acids (see **10-70**) react with oxygen to give α-hydroxy carboxylic acids (after hydrolysis).<sup>498</sup> There is evidence that the reaction between Grignard reagents and oxygen involves a free-radical mechanism.<sup>499</sup>

OS V, 918. See also, OS VIII, 315.

### 12-26 Reaction between Organometallic Reagents and Peroxides

A convenient method of preparation of *tert*-butyl ethers consists of treating *Grignard reagents* with *tert*-butyl acyl peroxides.<sup>500</sup> Both alkyl and aryl Grignard reagents can

<sup>500</sup> Lawesson, S.; Frisell, C.; Denney, D.B.; Denney, D.Z. *Tetrahedron* **1963**, 19, 1229. See Brilkina, T.G.; Shushunov, V.A. *Reactions of Organometallic Compounds with Oxygen and Peroxides*, CRC Press, Boca Raton,

be used. The application of this reaction to Grignard reagents prepared from cyclopropyl halides permits cyclopropyl halides to be converted to *tert*-butyl ethers of cyclopropanols,<sup>501</sup> which can then be easily hydrolyzed to the cyclopropanols. The direct conversion of cyclopropyl halides to cyclopropanols by **10-1** is not generally feasible, because cyclopropyl halides do not generally undergo nucleophilic substitutions without ring opening.

Vinyl lithium reagents react with silyl peroxides to give high yields of silyl enol ethers with retention of configuration.<sup>502</sup> Dialkyl ethers have been prepared from organotrifluoroborates and acetals.<sup>503</sup>

OS V, 642, 924.

## 12-27 Preparation of Boranes, Boronic Acids, and Borates

Work continues on the preparation of organoborane and derivatives. Alkyl bromides reacted with  $B_2Pin_2$  in the presence of a Pd catalyst to give RBPIn.<sup>504</sup> Aniline derivatives *t*-BuONO and  $B_2Pin_2$  give the arylboronate.<sup>505</sup> Aryl halides reacted with bis(pinacolato)diboron and then irradiation with visible light with tributylamine and an Ir catalyst and then exposure to air is give the phenol.<sup>506</sup>

Organoboron compounds, including alkylboronic acids and arylboronic acids<sup>507</sup> [ $RB(OH)_2$  and  $ArB(OH)_2$ , respectively], are increasingly important in organic chemistry.<sup>508</sup> The Pd-catalyzed coupling reaction of aryl halides and aryl triflates with arylboronic acids (the *Suzuki-Miyaura reaction*, **13-11**) is probably the most notable example. A simple synthesis involves the reaction of a *Grignard reagent*, such as phenylmagnesium bromide, with an alkyl borate to give phenylboronic acid.<sup>509</sup> Alkylboronic acids are similarly prepared.<sup>510</sup> Note that boronic acids are subject to cyclic trimerization with loss of water to form boroxines. Tetrahydroxydiboron has been used to prepare allylboronic acids, as well as potassium trifluoro(allyl)borates.<sup>511</sup> Alkylboronic acids are oxidized to the corresponding alcohol by treatment with hydrogen peroxide and dimethyl carbonate.<sup>512</sup> Borinic acids and borinates were prepared using amine–borane complexes as a water- and air-insensitive

borylating agent.<sup>513</sup> Boronic acids have been prepared using continuous flow techniques (Sec. 7.D).<sup>514</sup>

Alkeneboronic esters and acids are also readily available, for example, by the addition of vinylmagnesium chloride<sup>515</sup> to trimethyl borate below  $-50\text{ }^{\circ}\text{C}$ , followed by hydrolysis.<sup>516</sup> A nonaqueous workup procedure has been reported for the preparation of arylboronic esters  $[\text{ArB}(\text{OR}')_2]$ .<sup>517</sup> Uncontrollable polymerization or oxidation of much of the boronic acid occurred during the final stages of the isolation procedure, but could be avoided by *in situ* conversion to the dibutyl ester by adding the crude product to butan-1-ol. The Sm-catalyzed hydroboration of olefins with catecholborane is a good synthesis of boronate esters.<sup>518</sup>

The reaction of alkenes with borane, monoalkylboranes, and dialkylboranes leads to a new organoborane (see **15-11**). Treatment of organoboranes with alkaline  $\text{H}_2\text{O}_2$  oxidizes trialkylboranes to esters of boric acid.<sup>519</sup> This reaction does not affect double or triple bonds, aldehydes, ketones, halides, or nitriles that may be present elsewhere in the molecule. While the R group migrates from boron to oxygen,<sup>465</sup> as shown, which led to the B—O—R unit, there is no rearrangement of the R group itself. This reaction is a step in the hydroboration method of converting alkenes to alcohols (**15-11**). The mechanism has been formulated as involving initial formation of an “ate” complex when the hydroperoxide anion attacks the electrophilic boron atom. Rearrangement follows:

Similar migration of the other two R groups and hydrolysis of the B—O bonds leads to the alcohol and boric acid. Retention of configuration is observed in R. Boranes can also be oxidized to borates in good yields with oxygen,<sup>520</sup> with sodium perborate ( $\text{NaBO}_3$ ),<sup>521</sup> and with trimethylamine oxide, either anhydrous<sup>522</sup> or in the form of the dihydrate.<sup>523</sup> The reaction with oxygen is free radical in nature.<sup>524</sup>

OS V, 918; VI, 719, 852, 919.

Trimethylborate,  $\text{B}(\text{OMe})_3$ , can be used in place of tri-*n*-butylborate.<sup>525</sup> Newer methods involve the Pd-mediated borylation of alcohols with bis(pinacolato)diboron<sup>526</sup> or pinacolborane,<sup>527</sup> but deprotection of the boronate esters can be a problem. Diolboranes, such

as catecholborane **21**,<sup>528</sup> are prepared by the reaction of a diol with borane. Boronate esters are often prepared as a means to purify the organoboron species, but some of these esters are hydrolytically unstable and difficult to deal with upon completion of the reaction.<sup>529</sup>

Trialkyl borates (sometimes called orthoborates) can be prepared by heating the appropriate alcohol with boron trichloride in a sealed tube, but the procedure works well only for relatively simple alkyl groups.<sup>530</sup> Heating alcohols with boron trioxide ( $B_2O_3$ ) in an autoclave at 110–170 °C gives the trialkyl borate.<sup>531</sup>

Alkenyl boronic esters have been prepared from alkenes using a modified Heck reaction (**13-13**).<sup>532</sup> 3-Nitrophenyl allylic ethers reacted with a Cu/N-heterocyclic carbene catalyst and  $B_2Pin_2$ , 30% NaOt-Bu, and 2 equivalents of methanol to give the allyl boronate.<sup>533</sup> Cyclopropenes reacted with  $B_2Pin_2$  and a Cu catalyst and in the presence of the ligand (*R*)-di(3,5-di-*t*-butyl-4-methoxyphenyl)-Segphos in methanol to give the cyclopropylboronate.<sup>534</sup> Benzylic ammonium triflates reacted with  $B_2Pin_2$  using a Ni catalyst to give the benzylic boronate.<sup>535</sup> 3,3-Disubstituted allyl boronates have been prepared for the construction of quaternary centers.<sup>536</sup> Stereospecific functionalization and transformation of boronic esters has been discussed.<sup>537</sup> Chiral organoboronates have been prepared using a Suzuki reaction (**13-11**).<sup>538</sup> Allylic chlorides have been converted to allylic boronates with a Pd catalyst and  $B_2Pin_2$ , whereas the use of a Ni catalyst allowed allylic acetates to be converted to allylic boronates.<sup>539</sup> Hydroboration of 1,3-enyne compounds with  $B_2Pin_2$  and a Cu catalyst gave 1,2-addition of the alkyne unit and formation of the vinylboronate diene when triphenylphosphine was used as the ligand, whereas the use of diphosphine led to addition of the C=C unit and formation of the homopropargyl boronate.<sup>540,541</sup>

Potassium organotrifluoroborates ( $RBF_3K$ ) are readily prepared by the addition of inexpensive  $KHF_2$  to a variety of organoboron intermediates.<sup>542</sup> They are monomeric crystalline solids that are readily isolated and indefinitely stable in the air. These reagents can be used

in several of the applications where boronic acids or esters are used.<sup>543</sup> Note that vinylboronic acid and even vinylboronate esters are unstable to polymerization,<sup>544</sup> whereas the analogous vinyltrifluoroborate is readily synthesized and completely stable.<sup>545</sup> Aryl chlorides reacted with diboronic acid [B<sub>2</sub>(OH)<sub>4</sub>] and a Pd catalyst to give the arylboronic acid, and subsequent reaction with KHF<sub>2</sub> gave the potassium aryltrifluoroborate.<sup>546</sup> Acyltrifluoroborates have been prepared.<sup>547</sup>

OS 13, 16; 8I, 134.

## 12-28 Oxygenation of Organometallic Reagents and Other Substrates to O-Esters and Related Compounds

In some cases, it is possible to oxygenate a nonaromatic carbon atom using various reagents, where the product is an *O*-ester rather than an alcohol. In one example, a vinyl iodonium salt was heated with DMF to product the corresponding formate ester.<sup>548</sup>

## C. Sulfur Electrophiles

### 12-29 Conversion of Organometallic Reagents to Sulfur Compounds

Thiols and sulfides are occasionally prepared by treatment of *Grignard reagents* with sulfur.<sup>549</sup> Analogous reactions are known for selenium and tellurium compounds. Grignard reagents and other organometallic compounds<sup>550</sup> react with sulfuryl chloride to give sulfonyl chlorides,<sup>551</sup> with esters of sulfinic acids to give (stereospecifically) sulfoxides,<sup>552</sup> with disulfides to give sulfides,<sup>553</sup> and with SO<sub>2</sub> to give sulfinic acid salts<sup>554</sup> that can be hydrolyzed to sulfinic acids or treated with halogens to give sulfonyl halides.<sup>555</sup>

## D. Halogen Electrophiles

### 12-30 Halo-de-metalation

*Grignard reagents* react with halogens to give alkyl halides. The reaction is useful for the preparation of iodo compounds from the corresponding chloro or bromo compounds. The reaction is not useful for preparing chlorides, since the reagents RMgBr and RMgI react with Cl<sub>2</sub> to give mostly RBr and RI, respectively.<sup>556</sup>

Most organometallic compounds, both alkyl and aryl, also react with halogens to give alkyl or aryl halides.<sup>557</sup> The reaction can be used to convert acetylide ions to 1-haloalkynes.<sup>558</sup> Vinylidonium tetrafluoroborates were converted to vinyl fluorides by heating.<sup>559</sup> Similarly, vinyl trifluoroborates were converted to the vinyl iodide with NaI and chloramine-T in aqueous THF.<sup>560</sup> The reaction of an alkene with CuO•BF<sub>4</sub>, iodine, and triethylsilane gave the 2-iodoalkane.<sup>561</sup> Vinylzirconate reagents react with I<sub>2</sub> to give the corresponding vinyl iodide.<sup>562</sup>

Trialkylboranes react rapidly with I<sub>2</sub><sup>563</sup> or Br<sub>2</sub><sup>564</sup> in the presence of NaOMe in methanol, or with FeCl<sub>3</sub> or other reagents,<sup>565</sup> to give alkyl iodides, bromides, or chlorides, respectively. Combined with the hydroboration reaction (15-11), this is an indirect way of adding HBr, HI, or HCl to a double bond to give products with an anti-Markovnikov orientation (see 15-1). Trialkylboranes can also be converted to alkyl iodides by treatment with allyl iodide and air in a free-radical process.<sup>566</sup> *trans*-1-Alkenylboronic acids were prepared by hydroboration of terminal alkynes with catecholborane (15-11) followed by hydrolysis,<sup>567</sup> and subsequent reaction with I<sub>2</sub> in the presence of NaOH at 0 °C in ethereal solvents to give *trans*-vinylic iodides.<sup>568</sup> Treatment with ICl also gives the vinyl iodide.<sup>569</sup> This is an indirect way of accomplishing the anti-Markovnikov addition of HI to a terminal triple bond. The reaction cannot be applied to alkenylboronic acids prepared from internal alkynes.

However, alkenylboronic acids prepared from both internal and terminal alkynes react with  $\text{Br}_2$  (2 molar equivalents of  $\text{Br}_2$  must be used), followed by base, to give the corresponding vinylic bromide, but in this case with *inversion* of configuration; so the product is the *cis* vinylic bromide.<sup>570</sup> Alkenylboronic acids also give vinylic bromides and iodides when treated with a mild oxidizing agent and NaBr or NaI, respectively.<sup>571</sup> Vinylic boranes can be converted to the corresponding vinylic halide by treatment with NCS or NBS.<sup>572</sup> Vinylic halides can also be prepared from vinylic silanes<sup>573</sup> and from vinylic copper reagents. The latter react with  $\text{I}_2$  to give iodides,<sup>574</sup> and with NCS or NBS at  $-45^\circ\text{C}$  to give chlorides or bromides.<sup>575</sup> Boronic acids can be fluorinated in a reaction mediated by silver(I) triflate.<sup>576</sup>

The conversion of terminal alkynes to 1-iodo-1-alkynes was reported using NaI under electrochemical conditions.<sup>577</sup> 1-Bromo-1-alkynes were converted to the 1-iodo-1-alkyne with CuI.<sup>578</sup> 1-Trialkyldisilylalkynes were converted to the corresponding 1-bromoalkyne via reaction with NBS and AgF.<sup>579</sup> Terminal alkynes react with (diacetoxyiodo)benzene, KI, and CuI to give 1-iodoalkynes.<sup>580</sup> Trichloroisocyanuric acid has been used to convert terminal alkynes to 1-chloroalkynes.<sup>581</sup>

It is unlikely that a single mechanism suffices to cover all conversions of organometallic compounds to alkyl halides.<sup>582</sup> In a number of cases, the reaction has been shown to involve inversion of configuration (Sec. 12.A.i), indicating an  $\text{S}_{\text{E}}2$  (back) mechanism, while in other cases retention of configuration has been shown,<sup>583</sup> implicating an  $\text{S}_{\text{E}}2$  (front) or  $\text{S}_{\text{E}}\text{i}$  mechanism. In still other cases, complete loss of configuration as well as other evidence demonstrated the presence of a free-radical mechanism.<sup>583,584</sup>

There are several methods for the conversion of alkyl- or aryllithium compounds to primary amines.<sup>585</sup> The two most important are treatment with hydroxylamine derivatives and with certain azides.<sup>586</sup> First, treatment of RLi with methoxyamine and MeLi in ether at  $-78\text{ }^{\circ}\text{C}$  gives  $\text{RNH}_2$ .<sup>587</sup> Grignard reagents from aliphatic halides give lower yields. The reaction can be extended to give secondary amines by the use of *N*-substituted methoxyamines  $\text{CH}_3\text{ONHR}'$ .<sup>588</sup> There is evidence<sup>589</sup> that the mechanism involves the direct displacement of  $\text{OCH}_3$  by R on an intermediate  $\text{CH}_2\text{ONR}'^-$ :

Tosyl azide ( $\text{TsN}_3$ ) is a highly useful azide.<sup>590</sup> The initial product is usually  $\text{RN}_3$ , but this is easily reduced to the amine (**19-55**). With some azides, such as azidomethyl phenyl sulfide ( $\text{PhSCH}_2\text{N}_3$ ), the group attached to the  $\text{N}_3$  is a poor leaving group, so the initial product is a triazene (in this case  $\text{ArNHN}=\text{NCH}_2\text{SPh}$  from  $\text{ArMgX}$ ), which can be hydrolyzed to the amine.<sup>591</sup>

Organoboranes react with a mixture of aqueous  $\text{NH}_3$  and  $\text{NaOCl}$  to produce primary amines.<sup>592</sup> It is likely that the actual reagent is chloramine ( $\text{NH}_2\text{Cl}$ ). Chloramine itself,<sup>593</sup> hydroxylamine-*O*-sulfonic acid in diglyme,<sup>594</sup> and trimethylsilyl azide<sup>595</sup> also give the reaction. Since the boranes can be prepared by the hydroboration of alkenes (**15-11**), this is an indirect method for the addition of  $\text{NH}_3$  to a double bond with *anti*-Markovnikov orientation. Secondary amines can be prepared<sup>596</sup> by the treatment of alkyl- or aryl dichloroboranes or dialkylchloroboranes with alkyl or aryl azides. The use of an optically active  $\text{R}^*\text{BCl}_2$  gave secondary amines of essentially 100% optical purity.<sup>597</sup> Aryllead triacetates,  $\text{ArPb}(\text{OAc})_3$ , give secondary amines ( $\text{ArNHAr}'$ ) when treated with primary aromatic amines  $\text{Ar}'\text{NH}_2$  and  $\text{Cu}(\text{OAc})_2$ .<sup>598</sup>

Metal-catalyzed amination reactions are increasingly important in organic methodology. In a typical reaction, an amine is coupled to an alkyl, vinyl, or aryl halide (or with a different leaving group) in the presence of a transition metal, usually Pd. Presumably, the amination occurs via reaction with a transient organometallic species. In one example, a vinyl triflate is converted to an enamine via reaction with pyrrole in the presence of a Pd catalyst.<sup>599</sup>

Aryl and heteroaryl aluminum compounds reacted with *N,N*-dialkyl-*O*-benzoylhydroxylamines, in the presence of a CuI catalyst, to give the arylamine.<sup>600</sup> The reaction of secondary amines with NCS and then arylmagnesium halides with Ti(Oi-Pr)<sub>4</sub> gave the arylamine.<sup>601</sup> Secondary amines have been converted to tertiary amines by treatment with lithium dialkylcuprate reagents.<sup>602</sup>

The reaction was also used to convert primary amines to secondary ones, but yields were lower.<sup>603</sup>

Terminal alkynes reacted with chlorodiphenylphosphine (Ph<sub>2</sub>PCl) and a Ni catalyst to give the 1-diphenylphosphino alkyne (R–C≡C–PPh<sub>2</sub>).<sup>604</sup> Alkynyl halides can be used for a similar reaction. Treatment of methyl carbamates with KHMDS and CuI, followed by 2 equivalents of 1-bromo phenylacetylene gave the *N*-substituted alkyne, Ph–C≡C–N(CO<sub>2</sub>Me)R.<sup>605</sup>

### 12-32 The Conversion of Organometallic Compounds to Ketones, Aldehydes, Carboxylic Esters, or Amides

Symmetrical ketones<sup>606</sup> can be prepared in good yields by the reaction of organomercuric halides<sup>607</sup> with dicobalt octacarbonyl in THF,<sup>608</sup> or with nickel carbonyl in DMF or certain other solvents.<sup>609</sup> The R group may be aryl or alkyl. However, when R is alkyl, rearrangements may intervene in the Co<sub>2</sub>(CO)<sub>8</sub> reaction, although the Ni(CO)<sub>4</sub> reaction seems to be free from such rearrangements.<sup>610</sup> Divinylic ketones (useful in the *Nazarov cyclization*, **15-15**) have been prepared in high yields by treatment of vinylic mercuric halides with CO and a Rh catalyst.<sup>610</sup>

<sup>607</sup> See Larock, R.C. *Organomercury Compounds in Organic Synthesis*, Springer, NY, **1985**; Larock, R.C. *Tetrahedron* **1982**, *38*, 1713; *Angew. Chem. Int. Ed.* **1978**, *17*, 27.

<sup>608</sup> Seyferth, D.; Spohn, R.J. *J. Am. Chem. Soc.* **1969**, *91*, 3037.

<sup>609</sup> Ryu, I.; Ryang, M.; Rhee, I.; Omura, H.; Murai, S.; Sonoda, N. *Synth. Commun.* **1984**, *14*, 1175 and references cited therein. For another method, see Hatanaka, Y.; Hiyama, T. *Chem. Lett.* **1989**, 2049.

<sup>610</sup> Larock, R.C.; Hershberger, S.S. *J. Org. Chem.* **1980**, *45*, 3840.

In a more general synthesis of unsymmetrical ketones, tetraalkyltin compounds ( $R_4Sn$ ) are treated with a halide  $R'X$  ( $R' = \text{aryl, vinylic, benzylic}$ ), CO, and a Pd-complex catalyst.<sup>611</sup> Similar reactions use *Grignard reagents*,  $Fe(CO)_5$ , and an alkyl halide.<sup>612</sup>

Grignard reagents react with formic acid to give good yields of aldehydes. Two molar equivalents of  $RMgX$  are used; the first converts  $HCO_2H$  to  $HCOO^-$ , which reacts with the second equivalent to give  $RCHO$ .<sup>613</sup> Alkyl lithium reagents and Grignard reagents react with CO to give symmetrical ketones.<sup>614</sup> An interesting variation reacts  $CO_2$  with an organolithium, which is then treated with a different organolithium reagent to give the unsymmetrical ketone.<sup>615</sup>  $\alpha,\beta$ -Unsaturated aldehydes can be prepared by treatment of vinylic silanes with dichloromethyl methyl ether and  $TiCl_4$  at  $-90^\circ C$ .<sup>616</sup> Continuous flow techniques (Sec. 7.D) were used to prepare ketones with  $CO_2$  and organolithium reagents or Grignard reagents.<sup>617</sup> Alkyl and aryl Grignard reagents can be converted to carboxylic esters with  $Fe(CO)_5$  instead of CO.<sup>618</sup>

$\alpha,\beta$ -Unsaturated esters can be prepared by treating boronic esters with CO,  $PdCl_2$ , and  $NaOAc$  in MeOH.<sup>619</sup> The synthesis of  $\alpha,\beta$ -unsaturated esters has also been accomplished by treatment of vinylic mercuric chlorides with CO at atmospheric pressure and a Pd catalyst in an alcohol as solvent, for example.<sup>620</sup>

Amides have been prepared by the treatment of trialkyl or triarylboranes with CO and an imine, in the presence of catalytic amounts of cobalt carbonyl.<sup>621</sup> In another method for the conversion  $RM \rightarrow RCONR$ , *Grignard reagents* and organolithium compounds are treated with a formamide ( $HCONR'_2$ ) to give the intermediate  $RCH(OM)NR'_2$ , which is not isolated but instead is treated with  $PhCHO$  or  $Ph_2CO$  to give the product  $RCONR'_2$ .<sup>622</sup>

Direct conversion of a hydrocarbon to an aldehyde

was reported by treatment of the hydrocarbon with  $GaCl_3$  and CO.<sup>623</sup>

OS IX, 548.

## G. Metal Electrophiles

### 12-34 Transmetalation With a Metal

Many organometallic compounds are best prepared by this reaction, which involves replacement of one metal in an organometallic compound by another metal. The  $\text{RM}'$  compound can be successfully prepared only when  $\text{M}'$  is above  $\text{M}$  in the electromotive series, unless some other way is found to shift the equilibrium. That is,  $\text{RM}$  is usually an unreactive compound and  $\text{M}'$  is a metal more active than  $\text{M}$ . Most often,  $\text{RM}$  is  $\text{R}_2\text{Hg}$ , since mercury alkyls<sup>607</sup> are easy to prepare and mercury is far down in the electromotive series.<sup>629</sup> Alkyls of Li, Na, K, Be, Mg, Al, Ga, Zn, Cd, Te, Sn, and so on, have been prepared this way. An important advantage of this method over **12-37** is that it ensures that the organometallic compound will be prepared free of any possible halide. This method can be used for the isolation of solid sodium and potassium alkyls.<sup>630</sup> If the metals lie too close together in the series, it may not be possible to shift the equilibrium. For example, alkylbismuth compounds cannot be prepared in this way from alkylmercury compounds.

OS V, 1116.

### 12-35 Transmetalation with a Metal Halide

In contrast to **12-34**, the reaction between an organometallic compound and a metal halide is successful only when  $\text{M}'$  is below  $\text{M}$  in the electromotive series.<sup>631</sup> The two

reactions considered together therefore constitute a powerful tool for preparing all kinds of organometallic compounds. In this reaction, the most common substrates are Grignard reagents and organolithium compounds.<sup>632</sup>

The MgX of *Grignard reagents*<sup>633</sup> can migrate to terminal positions in the presence of small amounts of TiCl<sub>4</sub>.<sup>634</sup> The proposed mechanism consists of metal exchange (12-34), elimination–addition, and metal exchange:

The addition step is similar to 15-11 or 15-12 and follows Markovnikov's rule, so the positive titanium goes to the terminal carbon.

Among others, alkyls of Be, Zn,<sup>635</sup> Cd, Hg, Al, Sn, Pb, Co, Pt, and Au have been prepared by treatment of *Grignard reagents* with the appropriate halide.<sup>636</sup> The reaction has been used to prepare alkyls of almost all nontransition metals and even of some transition metals. Alkyls of metalloids and of nonmetals, including Si, B,<sup>637</sup> Ge, P, As, Sb, and Bi, can also be prepared in this manner.<sup>638</sup> Except for alkali metal alkyls and Grignard reagents, the reaction between RM and M'X is the most common method for the preparation of organometallic compounds.<sup>639</sup> Boranes can also be prepared. In the presence of Ir catalysts,<sup>640</sup> or Pd catalysts,<sup>641</sup> aromatic compounds react with boranes to give the corresponding arylborane.

Lithium dialkylcopper reagents are prepared from 2 molar equivalents of RLi with 1 molar equivalent of a cuprous halide in ether at low temperatures.<sup>642</sup> The formation of organocuprates of this type are discussed in more detail in reaction 10-58, in connection with the coupling reaction of organocuprates with alkyl halides. Another way is to dissolve

### 12-36 Transmetalation With an Organometallic Compound

This type of metallic exchange is used much less often than 12-34 and 12-35. It is an equilibrium reaction and is useful only if the equilibrium lies in the desired direction. Usually the goal is to prepare a lithium compound that is not prepared easily in other ways.<sup>646</sup> For example, it can be used to prepare a vinylic or an allylic lithium, most commonly from an organotin substrate. Examples are the preparation of vinyl lithium from phenyllithium and tetra vinyltin and the formation of  $\alpha$ -dialkylamino organolithium compounds from the corresponding organotin compounds.<sup>647</sup>

The reaction has also been used to prepare 1,3-dilithiopropanes<sup>648</sup> and 1,1-dilithiomethylenecyclohexane<sup>649</sup> from the corresponding mercury compounds. In general, the equilibrium lies in the direction in which the more electropositive metal is bonded to that alkyl or aryl group that is the more stable carbanion (Sec. 5.B.i). The reaction proceeds with retention of configuration;<sup>650</sup> an  $S_Ei$  mechanism is likely.<sup>651</sup>

OS V, 452; VI, 815; VIII, 97.

### 12.C.iii. Halogen as Leaving Group

The reduction of alkyl halides is considered in 19-57.

### 12-37 Metalo-de-halogenation

Alkyl halides react directly with certain metals to give organometallic compounds.<sup>652</sup> The most common metal is Mg, and of course this is by far the most common method for

the preparation of *Grignard reagents*.<sup>653</sup> The Grignard reaction with aldehydes or ketones is discussed in **16-22**. The order of halide activity is  $I > Br > Cl$ . The reaction can be applied to many alkyl halides (primary, secondary, and tertiary) and to aryl halides, although aryl *chlorides* require the use of THF or another higher-boiling solvent instead of the usual ether, or special entrainment methods.<sup>654</sup> Aryl iodides and bromides can be treated in the usual manner. Allylic Grignard reagents can also be prepared in the usual manner (or in THF),<sup>655</sup> although in the presence of excess halide these may give *Wurtz-type coupling* products (see **10-56**).<sup>656</sup> Like aryl chlorides, vinylic halides require higher-boiling solvents (see OS **IV**, 258). For benzylic and allylic halides, activated magnesium turnings have also been used.<sup>657</sup> Alkynyl Grignard reagents are generally prepared by the method in **12-22**.

Dihalides<sup>658</sup> can be converted to Grignard reagents if the halogens are different and are at least three carbons apart. If the halogens are the same, it is possible to obtain dimagnesium compounds (e.g.,  $\text{BrMg}(\text{CH}_2)_4\text{MgBr}$ ).<sup>659</sup> 1,2-Dihalides give elimination<sup>660</sup> rather than Grignard reagent formation (**17-20**), and the reaction is seldom successful with 1,1-dihalides, although the preparation of *gem*-disubstituted compounds, such as  $\text{CH}_2(\text{MgBr})_2$ , has been accomplished.<sup>661</sup> Alkylmagnesium fluorides can be prepared by refluxing alkyl fluorides with Mg in the presence of appropriate catalysts (e.g.,  $\text{I}_2$  or EtBr) in THF for several days.<sup>662</sup> Nitrogen-containing Grignard reagents have been prepared.<sup>663</sup>

The presence of other functional groups in the halide usually affects the preparation of the Grignard reagent. Groups that contain active hydrogen (defined as any hydrogen that will react with a Grignard reagent), such as OH,  $\text{NH}_2$ , and  $\text{CO}_2\text{H}$ , can be present in the molecule, but only if they are converted to the salt form ( $\text{O}^-$ ,  $\text{NH}^-$ ,  $\text{COO}^-$ , respectively). Groups that react with Grignard reagents, such as  $\text{C}=\text{O}$ ,  $\text{C}\equiv\text{N}$ ,  $\text{NO}_2$ ,  $\text{CO}_2\text{R}$ , cannot be in the molecule. It is known that  $\beta$ -halo ethers generally give  $\beta$  elimination when treated with Mg (see **17-22**), and Grignard reagents from  $\alpha$ -halo ethers<sup>664</sup> can only be formed in THF or dimethoxymethane at a low temperature,<sup>665</sup> because such reagents immediately undergo  $\alpha$  elimination (see **12-38**) at room temperature in ether solution.

Grignard reagents are strong bases so they react with water (**12-24**), and they also react with oxygen (**12-25**), it is generally best to prepare them in an anhydrous nitrogen atmosphere. Grignard reagents are generally neither isolated nor stored and solutions of Grignard reagents are used directly for the required synthesis. However, it is possible to obtain Grignard reagents in powdered form, by complexing them with tris(3,6-dioxaheptyl)amine

$N(\text{CH}_2\text{CH}_2\text{OCH}_2\text{CH}_2\text{OCH}_3)_3$ , a chelating agent (see OS VI, 845).<sup>666</sup> Grignard reagents can also be prepared in benzene or toluene, if a tertiary amine is added to complex with the  $\text{RMgX}$ .<sup>667</sup> This method eliminates the need for an ether solvent. With certain primary alkyl halides it is even possible to prepare alkylmagnesium compounds in hydrocarbon solvents in the absence of an organic base.<sup>668</sup>

The efficiency of the organometallic formation can often be improved by use of the metal in its powdered<sup>669</sup> or vapor<sup>670</sup> form. This approach has permitted the preparation of some organometallic compounds that cannot be prepared by the standard procedures. Among the metals produced in an activated form are  $\text{Mg}$ ,<sup>671</sup>  $\text{Ca}$ ,<sup>672</sup>  $\text{Zn}$ ,<sup>673</sup>  $\text{Al}$ ,  $\text{Sn}$ ,  $\text{Cd}$ ,<sup>674</sup>  $\text{Ni}$ ,  $\text{Fe}$ ,  $\text{Ti}$ ,  $\text{Cu}$ ,<sup>675</sup>  $\text{Pd}$ , and  $\text{Pt}$ .<sup>676</sup>

The mechanism of Grignard reagent formation involves free radicals.<sup>677</sup> There is much evidence for this, from CIDNP<sup>678</sup> (Sec. 5.C.i) and from stereochemical, rate, and product studies.<sup>679</sup> Further evidence is that free radicals have been trapped,<sup>680</sup> and that experiments that studied the intrinsic reactivity of  $\text{MeBr}$  on a magnesium single-crystal surface showed that Grignard reagent formation does not take place by a single-step insertion mechanism.<sup>681</sup> The following SET mechanism has been proposed:<sup>678</sup>

Other evidence has been offered to support a SET-initiated radical process for the second step of this mechanism.<sup>682</sup> The species  $-\text{X}^{\bullet-}$  and  $\text{Mg}_s^{\bullet+}$  are radical ions.<sup>683</sup> The subscript "s" in the mechanism is meant to indicate that the species so marked are bound to the surface of

the magnesium. It is known that this is a surface reaction.<sup>684</sup> It has been suggested that some of the R• radicals diffuse from the magnesium surface into the solution and then return to the surface to react with the XMg•. There is evidence both for<sup>685</sup> and against<sup>686</sup> this suggestion. Another proposal is that the fourth step is not the one shown here, but that the R• is reduced by Mg<sup>+</sup> to the carbanion R<sup>-</sup>, which combines with MgX<sup>+</sup> to give RMgX.<sup>687</sup>

There are too many preparations of Grignard reagents in *Organic Syntheses* to list here. Chiral Grignard reagents are rare, since they are configurationally unstable in most cases, but a few chiral Grignard reagents are known.<sup>688</sup> Use of the reaction to prepare other organometallic compounds can be found in OS **I**, 228; **II**, 184, 517, 607; **III**, 413, 757; **VI**, 240; **VII**, 346; **VIII**, 505. The preparation of unsolvated butylmagnesium bromide is described at OS **V**, 1141.

Next to the formation of Grignard reagents, the most important application of this reaction is the conversion of alkyl and aryl halides to organolithium reagents (RLi),<sup>689</sup> but it has also been carried out with many other metals (e.g., Na, Be, Zn, Hg, As, Sb, and Sn). With Na, the *Wurtz reaction* (**10-56**) is an important side reaction. In some cases where the reaction between a halide and a metal is too slow, an alloy of the metal with K or Na can be used instead. The most important example is the preparation of tetraethyl lead from ethyl bromide and a Pb/Na alloy.

Organolithium reagents are usually written as R–Li, but this simple representation does not describe their actual structure.<sup>690</sup> The extent of association of the organolithium is important since it can affect the rate of metal–halogen or metal–hydrogen exchange, as well as the product distribution. The degree of association of several common organolithium reagents in various solvents has been reported,<sup>690,691,692</sup> and it was shown that the degree of association decreases as the coordinating ability of the solvent increases. This observation can loosely be compared with increasing solvent polarity. Some physical data<sup>690</sup> suggest that the C–Li bond in an organolithium reagent is highly covalent, and it is known that organolithium reagents exist as associated aggregates, due in part to this covalent character. Both methyllithium (CH<sub>3</sub>Li)<sup>693</sup> and ethyllithium (CH<sub>3</sub>CH<sub>2</sub>Li)<sup>694</sup> have been obtained in crystalline form and their crystal structure determined by X-ray crystallography. The crystal structure of isopropyllithium was reported by Siemeling and co-workers,<sup>695</sup> and it was shown to exist as a hexamer, (*i*-PrLi)<sub>6</sub>.

Methyl lithium and ethyl lithium are tetrameric in the solid state,<sup>694,696</sup> and most organolithium reagents are highly associated in solution.<sup>690,697</sup> The structure of an unsymmetrical heptalithium cage complex has been reported.<sup>698</sup> The degree of association is related to the solvent and structure of the organolithium, but tends to be higher for straight chain reagents when compared with branched (secondary and tertiary) organolithium reagents.

### 12-38 Replacement of a Halogen by a Metal from an Organometallic Compound

The exchange reaction between halides and organometallic compounds occurs most readily when M is lithium and X is bromide or iodide,<sup>699</sup> although it has been shown to occur with magnesium.<sup>700</sup> The R' group is usually, although not always, alkyl, and often butyl; R is usually aromatic.<sup>701</sup> Alkyl halides are generally not reactive enough, while allylic and benzylic halides usually give Wurtz coupling. Of course, the R that becomes bonded to the halogen is the one for which RH is the weaker acid. Despite the preponderance of reactions with bromides and iodides, 1-octyllithium has been prepared.<sup>702</sup> Vinylic halides react with retention of configuration.<sup>703</sup> The reaction can be used to prepare  $\alpha$ -halo organolithium<sup>704</sup> and  $\alpha$ -halo organomagnesium compounds.<sup>705</sup> Such compounds can also be prepared by hydrogen-metal exchange, for example.<sup>706</sup> These  $\alpha$ -halo organometallic compounds are stable (and configurationally stable as well<sup>707</sup>) only at low temperatures (ca.  $-100^\circ\text{C}$ ) and only in THF or mixtures of THF and other solvents (e.g., HMPA). At ordinary temperatures they lose MX ( $\alpha$ -elimination) to give carbenes (which then react further) or carbenoid reactions. The  $\alpha$ -chloro- $\alpha$ -magnesium sulfones  $\text{ArSO}_2\text{CH}(\text{Cl})\text{MgBr}$  are exceptions, being stable in solution at room temperature and even under reflux.<sup>708</sup> Compounds in which a halogen and a transition metal are on the same carbon can be more stable than the ones with lithium.<sup>709</sup>

There is evidence that the mechanism<sup>710</sup> of the reaction of alkyllithium compounds with alkyl and aryl iodides involves free radicals.<sup>711</sup>

Among the evidence is the fact that coupling and disproportionation products are obtained from R• and R'• and the observation of CIDNP.<sup>711,712</sup> However, in the degenerate exchange between PhI and PhLi the ate complex Ph<sub>2</sub>I<sup>-</sup> Li<sup>+</sup> has been shown to be an intermediate,<sup>713</sup> and there is other evidence that radicals are not involved in all instances of this reaction.<sup>714</sup>

### 12.C.iv. Carbon Leaving Groups

In these reactions (12-39 to 12-47), a carbon-carbon bond cleaves. The substrate is the side that retains the electron pair; hence the reactions are considered electrophilic substitutions. The incoming group is hydrogen in all but one (12-41) of the cases. The reactions in groups A and B are sometimes called *anionic cleavages*,<sup>715</sup> although they do not always occur by mechanisms involving free carbanions (S<sub>E</sub>1). When they do, the reactions are facilitated by increasing stability of the carbanion.

#### A. Carbonyl-Forming Cleavages

Any carbon leaving group must be stabilized because C-C, C-O, and C-N bonds are relatively strong. With respect to the leaving group, the reaction is elimination to form a C=O bond. Retrograde aldol reactions (16-34) and cleavage of cyanohydrins (16-51) belong to this classification but are treated in Chapter 16 under their more important reverse reactions. Other eliminations to form C=O bonds are discussed in 17-30.

### 12-39 Decarboxylation of Aliphatic Acids

Many carboxylic acids that have a suitable group at the β position can be successfully decarboxylated, either as the free acid or in the salt form, but not simple aliphatic acids.<sup>716</sup> An exception is acetic acid, which as the acetate, heated with base, gives good yields of methane. Malonic acid derivatives are the most common substrates for decarboxylation, giving the corresponding monocarboxylic acid. Decarboxylation of 2-substituted malonic

<sup>716</sup> March, J. *J. Chem. Educ.* **1963**, 40, 212.

acids has been reported using microwave irradiation.<sup>717</sup> Aliphatic acids that do undergo successful decarboxylation have certain functional groups or double or triple bonds in the  $\alpha$  or  $\beta$  position.<sup>718</sup> Some acids can also be decarboxylated directly and, in most of these cases, there is a cyclic, six-center mechanism:

Here too there is an enol that tautomerizes to the product. The mechanism is illustrated for the case of  $\beta$ -keto acids,<sup>719</sup> but it is likely that malonic acids,  $\alpha$ -cyano acids,  $\alpha$ -nitro acids, and  $\beta,\gamma$ -unsaturated acids<sup>720</sup> behave similarly, since similar six-membered transition states can be written for them.

When the carboxylate *ion* is decarboxylated, the mechanism can be either  $S_E1$  or  $S_E2$ . In the case of the  $S_E1$  mechanism, the reaction is of course aided by the presence of electron-withdrawing groups, which stabilize the carbanion.<sup>721</sup> Decarboxylation of carboxylate ions can be accelerated by the addition of a suitable crown ether, which in effect removes the metallic ion.<sup>722</sup> The reaction without the metallic ion has also been performed in the gas phase.<sup>723</sup> Some  $\alpha,\beta$ -unsaturated acids are also decarboxylated by this mechanism by isomerizing to the  $\beta,\gamma$  isomers before they actually decarboxylate.<sup>724</sup> Evidence is bicyclic  $\beta$ -keto acids where the COOH moiety is attached to a bridgehead carbon atom, as in **22**, resist decarboxylation.<sup>725</sup>

In such compounds, the six-membered cyclic transition state cannot form for steric reasons,<sup>726</sup> and formation of the intermediate enol would violate *Bredt's rule* (Sec. 4.Q.iii). Some of the structural features observed for the decarboxylation of acids are shown in Table 12.1.

For decarboxylation of aromatic acids, see **11-35**. Decarboxylation of an  $\alpha$ -cyano acid can give a nitrile or a carboxylic acid, since the cyano group may or may not be hydrolyzed in the course of the reaction. In addition to the compounds listed in Table 12.1,

decarboxylation can be carried out on  $\alpha,\beta$ -unsaturated<sup>727</sup> and  $\alpha,\beta$ -acetylenic acids. Glycidic acids give aldehydes on decarboxylation. The mechanism shown has been suggested.<sup>728</sup>

The direct product is an enol that tautomerizes to the aldehyde.<sup>729</sup> This is the usual last step in the *Darzens reaction* (16-40).

Krapcho and co-workers developed a mild decarboxylation procedure of esters<sup>730</sup> that involved heating with LiCl in aqueous DMSO. This mild procedure is an  $S_N2$ -type reaction and is referred to as *Krapcho decarboxylation*.<sup>731</sup> A microwave-assisted decarboxylation procedure has been reported.<sup>732</sup>

$\beta$ -Keto acids<sup>733</sup> are easily decarboxylated, but such acids are usually prepared from  $\beta$ -keto esters, and the esters are easily decarboxylated themselves on hydrolysis without isolation of the acids.<sup>734</sup> This decarboxylation of  $\beta$ -keto esters involving cleavage on the carboxyl side of the substituted methylene group is carried out under acidic, neutral, or slightly basic conditions to yield a ketone. When strongly basic conditions are used, cleavage occurs on the other side of the  $\text{CR}_2$  group (**12-42**).  $\beta$ -Keto esters can be decarboxylated without passing through the free-acid stage by treatment with boric anhydride  $\text{B}_2\text{O}_3$  at 150 °C.<sup>735</sup> The alkyl portion of the ester ( $\text{R}'$ ) is converted to an alkene or, if it lacks a  $\beta$  hydrogen, to an ether  $\text{R}'\text{OR}'$ . Another method for the decarbalkoxylation of  $\beta$ -keto esters, malonic esters, and  $\alpha$ -cyano esters consists of heating the substrate in wet DMSO containing  $\text{NaCl}$ ,  $\text{Na}_3\text{PO}_4$ , or some other simple salt.<sup>736</sup> In this method, too, the free acid is probably not an intermediate, but here the alkyl portion of the substrate is converted to the corresponding alcohol.  $\alpha$ -Amino acids have been decarboxylated by treatment with a catalytic amount of cyclohexen-2-one.<sup>737</sup> Amino acids are decarboxylated by sequential treatment with NBS at pH 5 followed by  $\text{NaBH}_4$  and  $\text{NiCl}_2$ .<sup>738</sup> Certain decarboxylations can also be accomplished photochemically.<sup>739</sup> See also, the decarbonylation of acyl halides, mentioned in **14-26**. In some cases, decarboxylations can give organometallic compounds.<sup>740</sup>

The Cu-catalyzed decarboxylation of 2-alkynoic acids to terminal alkynes has been reported.<sup>741</sup>

Research continues for decarboxylation techniques. Fatty acids were decarboxylated to give terminal alkenes by treatment with Cytochrome P450 OleT<sub>JE</sub>.<sup>742</sup> An Fe-catalyzed decarbonylation of aliphatic carboxylic acids has been reported, leading to an alkene.<sup>743</sup> The reaction of N-Boc amino acids with aryl halides under photoredox and Ni catalysis led to decarboxylation with the formation of  $\alpha$ -arylamines.<sup>744</sup> Aliphatic carboxylic acids were treated with TMS and  $\text{Me}_3\text{SiBr}$ , with a catalytic amount of  $\text{InBr}_3$ , and gave the alkyl bromide, whereas the reaction with  $\text{I}_2$  under the same conditions led to the alkyl iodide.<sup>745</sup> A Ag-catalyzed decarboxylative bromination from aliphatic carboxylic acids has been reported.<sup>746</sup> Allylic carboxylic acids reacted with  $\text{PhI}(\text{OAc})_2$  to give the allylic acetate via decarboxylation, and reacted with hypervalent iodine reagents containing an

amine unit to give allylic amines.<sup>747</sup> Conjugated ketones were produced by the reaction of  $\alpha$ -oxocarboxylic acids with allyl  $\alpha$ -oxocarboxylates and a Pd catalyst via decarboxylative allylation.<sup>748</sup> Propiolic acids reacted with alkyl halides in the presence of CuI as a catalyst to give the alkyne via decarboxylative alkylation.<sup>749</sup> The mechanism of the silver-catalyzed decarboxylative fluorination has been discussed.<sup>750</sup> Barton decarboxylation using ultrasonic flow conditions (Sec. 7.D) has been reported.<sup>751</sup>

Some carboxylic acids that cannot form a six-membered transition state in accord with the six-centered transition state shown above can still be decarboxylated, presumably via an  $S_E1$  or  $S_E2$  mechanism.<sup>752</sup> Further evidence for the cyclic mechanism is that the reaction rate varies very little with a change from a nonpolar to a polar solvent (even from benzene to water<sup>753</sup>), and is not subject to acid catalysis.<sup>754</sup> The rate of decarboxylation of a  $\beta,\gamma$ -unsaturated acid was increased  $\sim 10^5$ – $10^6$  times by introduction of a  $\beta$ -methoxy group, indicating that the cyclic transition state has dipolar character.<sup>755</sup> Rate constants for decarboxylation reactions have been calculated using no barrier theory.<sup>756</sup>

Decarboxylative alkylation and arylation reactions are known. In the presence of a Ru catalyst and a *B*-phenyl borinate, decarboxylation of proline esters leads to 2-phenylpyrrolidine derivatives.<sup>757</sup> In the presence of a Pd catalyst, esters undergo decarboxylation with coupling between the alkyl groups on the carbonyl and the ester oxygen to give the corresponding hydrocarbon fragment.<sup>758</sup>

groups are simple unbranched alkyl groups, for example, the alkoxide of triethylcarbinol. Cleavage is accomplished with branched alkoxides, such as the alkoxides of diisopropylneopentylcarbinol or tri-*tert*-butylcarbinol.<sup>760</sup> Allylic,<sup>761</sup> benzylic,<sup>762</sup> and aryl groups also cleave; for example, the alkoxide of triphenylcarbinol gives benzene and benzophenone. Studies in the gas phase show that the cleavage is a simple one, giving the carbanion and ketone directly in one step.<sup>763</sup> However, with some substrates in solution, substantial amounts of dimer R–R have been found, indicating a radical pathway.<sup>764</sup> Hindered alcohols (not the alkoxides) also lose one R group by cleavage, also by a radical pathway.<sup>765</sup>

The retro-aldol (see **16-34**) is another example. The reaction has been used for extensive mechanistic studies (Sec. 12.A.ii).

OS VI, 268.

### 12-41 Replacement of a Carboxyl Group by an Acyl Group

When an  $\alpha$ -amino acid is treated with an anhydride in the presence of pyridine, the carboxyl group is replaced by an acyl group and the  $\text{NH}_2$  becomes acylated. This decarboxylation is called the *Dakin-West reaction*.<sup>766</sup> The mechanism involves formation of an oxazolone.<sup>767</sup> The reaction sometimes takes place on carboxylic acids even when an  $\alpha$ -amino group is not present. A number of *N*-substituted amino acids,  $\text{RCH}(\text{NHR}')\text{COOH}$ , give the corresponding *N*-alkylated products.

OS IV, 5; V, 27.

## B. Acyl Cleavages

Formally, these reactions could be placed in Chapter 16, but because carbanion leaving groups are involved the reactions are placed here. In these reactions (**12-42** to **12-45**), a carbonyl group is attacked by a hydroxide ion (or an amide ion), giving an intermediate that undergoes cleavage to a carboxylic acid (or an amide). With respect to the leaving group, the carbanion must be stabilized. This is nucleophilic substitution at a carbonyl group and

the mechanism is the tetrahedral one discussed in Sec. 16.A.i. With respect to R this is of course electrophilic substitution. The mechanism is usually  $S_E1$ .

### 12-42 Basic Cleavage of $\beta$ -Keto Esters and $\beta$ -Diketones

When  $\beta$ -keto esters are treated with concentrated base, cleavage occurs, but on the keto side of the  $\text{CR}_2$  group in contrast to the acid cleavage mentioned in **12-39**. The products are a carboxylic ester and the salt of an acid. However, the utility of the reaction is somewhat limited by the fact that decarboxylation is a side reaction, even under basic conditions.  $\beta$ -Diketones behave similarly to give a ketone and the salt of a carboxylic acid. With both  $\beta$ -keto esters and  $\beta$ -diketones,  $^-\text{OEt}$  can be used instead of  $^-\text{OH}$ , in which case the ethyl esters of the corresponding acids are obtained instead of the salts. In the case of  $\beta$ -keto esters, this is the reverse of the *Claisen condensation* (**16-81**). The related cleavage of cyclic  $\alpha$ -cyano ketones, in an intramolecular fashion, has been used in a synthesis of macrocyclic lactones.<sup>768</sup> Activated  $\text{F}^-$  (from KF and a crown ether) has been used as the base to cleave an  $\alpha$ -cyano ketone.<sup>769</sup> Treatment with ceric ammonium nitrate led to cleavage of  $\beta$ -diketones to give a carboxylic acid.<sup>770</sup>

OS **II**, 266, 531; **III**, 379; **IV**, 415, 957; **V**, 179, 187, 277, 533, 747, 767.

### 12-43 Haloform Reaction

In the *haloform reaction*, methyl ketones (and the only methyl aldehyde, acetaldehyde) are cleaved with halogen and a base.<sup>771</sup> The halogen can be bromine, chlorine, or iodine. What takes place is actually a combination of two reactions. The first is an example of **12-4**, in which, under the basic conditions employed, the methyl group is trihalogenated. Then the resulting trihalo ketone is attacked by hydroxide ion to give tetrahedral intermediate **23**.<sup>772</sup> The  $\text{X}_3\text{C}^-$  group is a sufficiently good leaving group (not  $\text{HX}_2\text{C}^-$  or  $\text{H}_2\text{XC}^-$ ) that a carboxylic acid is formed, which quickly reacts with the carbanion to give the final products. Primary or secondary methylcarbinols also give the reaction, because they are oxidized to the carbonyl compounds under the conditions employed.

<sup>770</sup> Zhang, Y.; Jiao, J.; Flowers II, R.A. *J. Org. Chem.* **2006**, *71*, 4516.

<sup>771</sup> See Chakrabarty, S.K. in Trahanovsky, W.S. *Oxidation in Organic Chemistry*, pt. C, Academic Press, NY, **1978**, pp. 343–370.

<sup>772</sup> See Zucco, C.; Lima, C.F.; Rezende, M.C.; Vianna, J.F.; Nome, F. *J. Org. Chem.* **1987**, *52*, 5356.

As with **12-4**, the rate-determining step is the preliminary enolization of the methyl ketone.<sup>773</sup> A side reaction is  $\alpha$ -halogenation of the nonmethyl R group. Sometimes these groups are also cleaved.<sup>774</sup> The reaction cannot be applied to  $\text{F}_2$ , but ketones of the form  $\text{RCOFC}_3$  (R = alkyl or aryl) give fluoroform and  $\text{RCOO}^-$  when treated with base.<sup>775</sup> Rate constants for cleavage of  $\text{X}_3\text{CCOPh}$  (X = F, Cl, Br) were found to be in the ratio  $1:5.3 \times 10^{10}:2.2 \times 10^{13}$ , showing that an  $\text{F}_3\text{C}^-$  group cleaves much more slowly than the others.<sup>776</sup> In the past, the haloform reaction was used as a test for methylcarbinols and methyl ketones. Iodine was most often used as the test reagent, since iodoform ( $\text{CHI}_3$ ) is an easily identifiable yellow solid. The reaction can be used for synthetic purposes. Methyl ketones  $\text{RCOCH}_3$  can be converted directly to methyl esters  $\text{RCO}_2\text{CH}_3$  by an electrochemical reaction.<sup>777</sup> Trifluoromethyl ketones have been converted to ethyl esters via treatment with  $\text{NaH}$  in aqueous DMF followed by reaction with bromoethane.<sup>778</sup>

OS I, 526; II, 428; III, 302; IV, 345; V, 8. Also see, OS VI, 618.

#### 12-44 Cleavage of Nonenolizable Ketones

Ordinary ketones are generally much more difficult to cleave than trihalo ketones or  $\beta$ -diketones. However, nonenolizable ketones can be cleaved by treatment with a 10:3 mixture of  $t\text{-BuOK-H}_2\text{O}$  in an aprotic solvent such as ether, DMSO, 1,2-dimethoxyethane (glyme),<sup>779</sup> or with solid  $t\text{-BuOK}$  in the absence of a solvent.<sup>780</sup> When the reaction is applied to monosubstituted diaryl ketones, the aryl group that preferentially cleaves comes off as the more stable carbanion, except that aryl groups substituted in the *ortho* position are more readily cleaved than otherwise because of the steric effect (relief of strain).<sup>780,781</sup> In certain cases, cyclic ketones can be cleaved by base treatment, even if they are enolizable.<sup>782</sup>

## 12-45 The Haller-Bauer Reaction

Cleavage of ketones with sodium amide is called the *Haller-Bauer reaction*.<sup>783</sup> As with **12-44**, which is exactly analogous, the reaction is usually applied only to nonenolizable ketones, most often to ketones of the form  $\text{ArCOCR}_3$ , where the products  $\text{R}_3\text{CCONH}_2$  (after hydrolysis) are not easily attainable by other methods. However, many other ketones have been used, although benzophenone is virtually unaffected.

It has been shown that the configuration of optically active alkyl groups (R) is retained.<sup>784</sup> The  $\text{NH}_2$  loses its proton from the tetrahedral intermediate **24** before the R group is cleaved.<sup>785</sup>

An extension of this cleavage process involves the reaction of  $\alpha$ -nitro ketones ( $\text{RCOCHRNO}_2$ ) with a primary amine, neat, to give the corresponding amide,  $\text{RCONHR}$ .<sup>786</sup>

OS V, 384, 1074.

## C. Other Cleavages

## 12-46 The Cleavage of Alkanes

The C—C bonds of alkanes can be cleaved by treatment with superacids (Sec. 5.A.ii). For example, neopentane in  $\text{FSO}_3\text{H}/\text{SbF}_5$  can cleave to give methane and the *tert*-butyl cation. A competing reaction of C—H cleavage (see **12-1**), for example of neopentane, can give  $\text{H}_2$  and the *tert*-pentyl carbocation (formed by rearrangement of the initially formed neopentyl cation) by this pathway. In general, the order of reactivity is tertiary C—H > C—C > secondary C—H  $\gg$  primary C—H, although steric factors cause a shift in favor of C—C cleavage in such a hindered compound as tri-*tert*-butylmethane. The mechanism is similar to that shown in **12-1** and **12-20** and involves attack by  $\text{H}^+$  on the C—C bond to give a pentavalent cation.

Catalytic hydrogenation seldom breaks unactivated C—C bonds, i.e.,

<sup>783</sup> See Gilday, J.P.; Paquette, L.A. *Org. Prep. Proced. Int.* **1990**, 22, 167.

<sup>784</sup> See Paquette, L.A.; Ra, C.S. *J. Org. Chem.* **1988**, 53, 4978.

<sup>786</sup> Ballini, R.; Bosica, G.; Fiorini, D. *Tetrahedron* **2003**, 59, 1143.

but methyl and ethyl groups have been cleaved from substituted adamantanes by hydrogenation with a Ni/Al<sub>2</sub>O<sub>3</sub> catalyst at about 250 °C.<sup>787</sup> Certain C—C bonds have been cleaved by alkali metals.<sup>788</sup>

### 12-47 Decyanation

The cyano group of alkyl nitriles can be removed<sup>789</sup> by treatment with metallic Na, either in liquid ammonia,<sup>790</sup> or together with tris(acetylacetonato)iron(III) [Fe(acac)<sub>3</sub>].<sup>791</sup> The two procedures are complementary. Although both can be used to decyanate many kinds of nitriles, the Na/NH<sub>3</sub> method gives high yields with R groups such as trityl, benzyl, phenyl, and tertiary alkyl, but lower yields (~35–50%) when R = primary or secondary alkyl. On the other hand, primary and secondary alkyl nitriles are decyanated in high yields by the Na/Fe(acac)<sub>3</sub> procedure. Sodium in liquid ammonia is known to be a source of solvated electrons, and the reaction may proceed through the free radical R• that would then be reduced to the carbanion R<sup>-</sup>, which by abstraction of a proton from the solvent, would give RH. The mechanism with Fe(acac)<sub>3</sub> is presumably different. Another procedure,<sup>792</sup> which is successful for R = primary, secondary, or tertiary, involves the use of potassium metal and the crown ether dicyclohexano-18-crown-6 in toluene.<sup>793</sup>

α-Amino nitriles [RCH(CN)NR'<sub>2</sub>] and α-amido nitriles [RCH(CN)NHCOR'] can be decyanated in high yield by treatment with NaBH<sub>4</sub>.<sup>794</sup>

### 12.C.v. Electrophilic Substitution At Nitrogen

In most of the reactions in this section, an electrophile bonds with the unshared electron pair of a nitrogen atom. The electrophile may be a free positive ion or a positive species attached to a carrier that breaks off in the course of the attack or shortly after:

Further reaction of the ammonium ion depends on the nature of Y and of the other groups attached to the nitrogen.

**12-48** The Conversion of Hydrazines to Azides

Monosubstituted hydrazines treated with nitrous acid give azides in a reaction exactly analogous to the formation of aliphatic diazo compounds mentioned in **13-19**. Examples of reagents used for this conversion are  $\text{N}_2\text{O}_4$ <sup>795</sup> and nitrosyl tetrafluoroborate ( $\text{NOBF}_4$ ).<sup>796</sup> OS **III**, 710; **IV**, 819; **V**, 157.

**12-49** *N*-Nitrosation

When secondary amines are treated with nitrous acid (typically formed from sodium nitrite and a mineral acid),<sup>797</sup> *N*-nitroso compounds (also called nitrosamines) are formed.<sup>798</sup> The reaction can be accomplished with dialkyl-, diaryl-, or alkylarylamines, and even with mono-*N*-substituted amides:<sup>799</sup>

Tertiary amines have also been *N*-nitrosated, but in these cases one group cleaves, so that the product is the nitroso derivative of a secondary amine.<sup>800</sup> The group that cleaves appears as an aldehyde or ketone product. Other reagents have also been used, for example,  $\text{NOCl}$ , which is useful for amines or amides that are not soluble in an acidic aqueous solution or where the *N*-nitroso compounds are highly reactive. *N*-Nitroso compounds can be prepared in basic solution by treatment of secondary amines with gaseous  $\text{N}_2\text{O}_3$ ,  $\text{N}_2\text{O}_4$ ,<sup>801</sup> or alkyl nitrites,<sup>802</sup> and, in aqueous or organic solvents, by treatment with  $\text{BrCH}_2\text{NO}_2$ .<sup>803</sup> Secondary amines are converted to the *N*-nitroso compound with  $\text{H}_5\text{IO}_6$  on wet silica.<sup>804</sup>

The mechanism of nitrosation is essentially the same as in **13-19** up to the point where  $\text{Ar}(\text{R})\text{N}-\text{N}=\text{O}$  is formed. Since this species cannot lose a proton, it is stable and the reaction ends there. The attacking entity can be any of those mentioned in **13-19**. The mechanism suggested for the reaction with tertiary amines involves reaction with  $\text{HONO}$  to give the

*N*-nitrosoamine, which loses HNO to give an iminium salt.<sup>805</sup> The iminium salt fragments to a ketone and an ammonium salt, and final reaction with HONO gives the final product, R<sub>2</sub>N=N=O.<sup>805</sup> The evidence for this mechanism includes the facts that nitrous oxide is a product (formed by 2HNO → H<sub>2</sub>O + N<sub>2</sub>O) and that quinuclidine, where the nitrogen is at a bridgehead and cannot give elimination, does not react. Tertiary amines have also been converted to nitrosamines with nitric acid in Ac<sub>2</sub>O<sup>806</sup> and with N<sub>2</sub>O<sub>4</sub>.<sup>807</sup>

Amines and amides can be *N*-nitrated<sup>808</sup> with nitric acid,<sup>809</sup> or NO<sub>2</sub><sup>+</sup>,<sup>810</sup> and aromatic amines can be converted to triazenes with diazonium salts. Aliphatic primary amines can also be converted to triazenes if the diazonium salts contain electron-withdrawing groups.<sup>811</sup>

## 12-50 Conversion of Nitroso Compounds to Azoxy Compounds

In a reaction similar to **13-24**, azoxy compounds can be prepared by the condensation of a nitroso compound with a hydroxylamine.<sup>812</sup> The position of the oxygen in the final product is determined by the nature of the R groups, not by which R groups came from which starting compound. Both R and R' can be alkyl or aryl, but when two different aryl groups are involved, mixtures of azoxy compounds (ArNONAr, ArNONAr', and Ar'NONAr') are obtained<sup>813</sup> and the unsymmetrical product (ArNONAr') is likely to be formed in the smallest amount. This behavior is probably caused by an equilibration between the starting compounds prior to the actual reaction.<sup>814</sup>

The mechanism<sup>815</sup> has been investigated in the presence of base. Under these conditions both reactants are converted to radical anions, which couple:

<sup>814</sup> Knight, G.T.; Saville, B. *J. Chem. Soc., Perkin Trans. 2* **1973**, 1550.

<sup>815</sup> For discussions of the mechanism in the absence of base, see Becker, A.R.; Sternson, L.A. *J. Org. Chem.* **1980**, 45, 1708. See also, Pizzolatti, M.G.; Yunes, R.A. *J. Chem. Soc., Perkin Trans. 1* **1990**, 759.

These radical anions have been detected by ESR.<sup>816</sup> This mechanism is consistent with the following result: when nitrosobenzene and phenylhydroxylamine are coupled, <sup>18</sup>O and <sup>15</sup>N labeling show that the two nitrogen atoms and the two oxygen atoms become equivalent.<sup>817</sup> Unsymmetrical azoxy compounds can be prepared<sup>818</sup> by combination of a nitroso compound with an *N,N*-dibromoamine. Symmetrical and unsymmetrical azo and azoxy compounds are produced when aromatic nitro compounds react with aryliminodimagnesium reagents ArN(MgBr)<sub>2</sub>.<sup>819</sup>

### 12-51 *N*-Halogenation

The use of *N*-haloamines in organic synthesis has been reviewed.<sup>820</sup> Treatment with sodium hypochlorite or hypobromite converts primary amines into *N*-halo- or *N,N*-dihaloamines. Secondary amines can be converted to *N*-halo secondary amines. Similar reactions can be carried out on unsubstituted and *N*-substituted amides and on sulfonamides. With unsubstituted amides, the *N*-halogen product is seldom isolated but usually rearranges (see **18-13**); however, *N*-halo-*N*-alkyl amides and *N*-halo imides are quite stable. The important reagents NBS and NCS are made in this manner. *N*-Halogenation has also been accomplished with other reagents (e.g., sodium bromite NaBrO<sub>2</sub>),<sup>821</sup> benzyltrimethylammonium tribromide (PhCH<sub>2</sub>NMe<sub>3</sub><sup>+</sup>Br<sub>3</sub><sup>-</sup>),<sup>822</sup> NaCl with Oxone,<sup>823</sup> and NCS.<sup>824</sup> Sodium hypohalite in the presence of *tert*-butanol and acetic acid is an efficient method for the preparation of *N*-haloamines.<sup>825</sup> The mechanisms of these reactions<sup>826</sup> involve attack by a positive halogen and are probably similar to those of **13-19** and **12-49**.<sup>827</sup> *N*-Fluorination can be accomplished by direct treatment of amines<sup>828</sup> or amides<sup>829</sup> with F<sub>2</sub>. Trichloroisocyanuric acid converts primary amines to the *N,N*-dichloroamine.<sup>830</sup> Amides are *N*-chlorinated with

## 12-52 The Reaction of Amines With Carbon Monoxide or Carbon Dioxide

Three types of product can be obtained from the reaction of amines with carbon monoxide, depending on the catalyst.

1. Both primary and secondary amines react with CO in the presence of various catalysts [e.g.,  $\text{Cu}(\text{CN})_2$ ,  $\text{Me}_3\text{N-H}_2\text{Se}$ , and Rh or Ru complexes] to give *N*-substituted and *N,N*-disubstituted formamides, respectively.<sup>836</sup> Primary aromatic amines react with ammonium formate to give the formamide.<sup>837</sup> Tertiary amines react with CO and a Pd catalyst to give an amide.<sup>838</sup>
2. Symmetrically substituted ureas can be prepared by treatment of a primary amine (or ammonia) with CO<sup>839</sup> in the presence of Se<sup>840</sup> or S.<sup>841</sup> R can be alkyl or aryl. The same thing can be done with secondary amines, using  $\text{Pd}(\text{OAc})_2\text{-I}_2\text{-K}_2\text{CO}_3$ .<sup>842</sup> Treatment of a secondary amine with nitrobenzene, selenium, and carbon monoxide leads to the unsymmetrical urea.<sup>843</sup>
3. When  $\text{PdCl}_2$  is the catalyst, primary amines yield isocyanates.<sup>844</sup> Isocyanates can also be obtained by treatment of CO with azides:<sup>845</sup>

or with an aromatic nitroso or nitro compound and a Rh complex catalyst.<sup>846</sup>

Lactams are converted to the corresponding *N*-chloro lactam with  $\text{Ca}(\text{OCl})_2$  with moist alumina in dichloromethane.<sup>847</sup> Ring-expanded lactams are obtained from cyclic amines via a similar reaction<sup>848</sup> (see also, **16-20**). Intramolecular carbonylation of amines also leads to lactams.<sup>849</sup>

Another type of product, a carbamate ( $\text{RNHCOOR}'$ ), can be obtained from primary or secondary amines, if these are treated with  $\text{CO}$ ,  $\text{O}_2$ , and an alcohol ( $\text{R}'\text{OH}$ ) in the presence of a catalyst.<sup>850</sup> Primary amines react with dimethyl carbonate in supercritical  $\text{CO}_2$  (Sec. 9.D.ii) to give a carbamate.<sup>851</sup> Carbamates can also be obtained from nitroso compounds, by treatment with  $\text{CO}$ ,  $\text{R}'\text{OH}$ ,  $\text{Pd}(\text{OAc})_2$ , and  $\text{Cu}(\text{OAc})_2$ ,<sup>852</sup> and from nitro compounds.<sup>853</sup> When allylic amines ( $\text{R}_2\text{C}=\text{CHRCHRNR}'_2$ ) are treated with  $\text{CO}$  and a Pd-phosphine catalyst, the  $\text{CO}$  inserts to produce the  $\beta,\gamma$ -unsaturated amides ( $\text{R}_2\text{C}=\text{CHRCHRCONR}'_2$ ) in good yields.<sup>854</sup> Silyloxy carbamates ( $\text{RNHCO}_2\text{SiR}'_3$ ) can be prepared by the reaction of a primary amine with carbon dioxide and triethylamine, followed by reaction with triisopropylsilyl triflate and tetrabutylammonium fluoride.<sup>855</sup>

Carbon dioxide reacts with amines ( $\text{ArNH}_2$ ) and alkyl halides, under electrolysis conditions, to give the corresponding carbamate ( $\text{ArNHCO}_2\text{Et}$ ).<sup>856</sup> Secondary amines react with all halides and an onium salt in supercritical  $\text{CO}_2$  (Sec. 9.D.ii) to give the carbamate.<sup>857</sup> *N*-Phenylthioamines react with  $\text{CO}$  and a Pd catalyst to give a thiocarbamate ( $\text{ArSCO}_2\text{NR}'_2$ ).<sup>858</sup> Urea derivatives were obtained from amines,  $\text{CO}_2$ , and an Sb catalyst.<sup>859</sup>

Aziridines can be converted to cyclic carbamates (oxazolidinones) by heating with carbon dioxide and a Cr-salen catalyst.<sup>860</sup> The reaction of aziridines with  $\text{LiI}$  and then  $\text{CO}_2$  also generates oxazolidinones.<sup>861</sup>

## Aromatic Substitution: Nucleophilic and Organometallic

In Sec. 10.G, category 2, it was pointed out that nucleophilic substitutions proceed so slowly at an aromatic carbon that the reactions of Chapter 10 are not feasible for aromatic substrates. There are, however, exceptions to this statement, and these exceptions form the subject of this chapter.<sup>1</sup> Reactions that *are* successful at an aromatic substrate are largely of five kinds: (i) reactions activated by electron-withdrawing groups *ortho* and *para* to the leaving group; (ii) reactions catalyzed by very strong bases and proceeding through aryl anion intermediates; (iii) reactions initiated by electron donors; (iv) reactions in which the nitrogen of a diazonium salt is replaced by a nucleophile; and (v) coupling reactions<sup>2</sup> catalyzed by transition metals,<sup>3</sup> primarily Pd,<sup>4</sup> Cu, Ni, Pt,<sup>5</sup> Co,<sup>6</sup> Mo,<sup>7</sup> Fe,<sup>8</sup> etc. There are also transition metal-free coupling reactions.<sup>9</sup> It is noted that solvent effects can be important.<sup>10</sup> The transition metal-catalyzed coupling reactions are included because they involve replacement of a leaving group on an aromatic ring.

### 13.A. MECHANISMS

There are four principal mechanisms for aromatic nucleophilic substitution.<sup>11</sup> Each of the four is similar to one of the aliphatic nucleophilic substitution mechanisms discussed in Chapter 10.

#### 13.A.i. The S<sub>N</sub>Ar Mechanism<sup>12</sup>

By far the most important mechanism for nucleophilic aromatic substitution consists of two steps: (i) attack of the nucleophilic species at the *ipso* carbon of the aromatic ring (the carbon bearing the leaving group in this case), followed (ii) by elimination of the leaving group and regeneration of the aromatic ring.<sup>13</sup>

The reaction with the nucleophilic Y<sup>-</sup> is usually, but not always, rate determining because an electron-rich species donating electrons to an electron-rich aromatic ring should be slow. The attacking species forms a bond with the substrate, giving an intermediate such as **1**, and then the leaving group departs. This is the S<sub>N</sub>Ar mechanism.<sup>14</sup> The IUPAC designation is A<sub>N</sub> + D<sub>N</sub> (the same as for the tetrahedral mechanism; compare the designation A<sub>E</sub> + D<sub>E</sub> for the arenium ion mechanism). This mechanism is generally found where activating groups are present on the ring (Sec. 13.B.i).

There is a great deal of evidence for the mechanism.<sup>11</sup> Probably the most convincing evidence was the isolation, as long ago as 1902, of the intermediate **2** in the reaction between 2,4,6-trinitrophenetole and methoxide ion.<sup>15</sup> Intermediates of this type are stable

salts, called *Meisenheimer* or *Meisenheimer-Jackson salts*,<sup>16</sup> and many more have been isolated.<sup>17</sup> The structures of several of these intermediates have been proved by NMR<sup>18</sup> and by X-ray crystallography.<sup>19</sup> Further evidence comes from studies of the effect of the leaving group on the reaction. If the mechanism were similar to either the S<sub>N</sub>1 or S<sub>N</sub>2 mechanisms described in Chapter 10, the Ar–X bond would be broken in the rate-determining step. In the S<sub>N</sub>Ar mechanism this bond is not broken until after the rate-determining step (i.e., if step 1 is rate determining). There is some evidence that electron transfer may be operative during this process.<sup>20</sup> If the S<sub>N</sub>Ar mechanism is operating, a change in leaving group should not have much effect on the reaction rate. In the reaction of dinitro compounds such as **3** with piperidine, when X was Cl, Br, I, SOPh, SO<sub>2</sub>Ph, or *p*-nitrophenoxy, the rates differed only by a factor of ~5.<sup>21</sup>

This behavior would not be expected in a reaction in which the Ar–X bond is broken in the rate-determining step. The rates are not expected to be *identical*, because the nature of X affects the rate at which Y attacks.<sup>22</sup> An increase in the electronegativity of X causes a decrease in the electron density at the site of attack, resulting in a faster attack by a nucleophile. Thus, in the reaction just mentioned, when X = F, the relative rate was 3300 (compared with I = 1). The very fact that fluoro is the best leaving group among the halogens in most aromatic nucleophilic substitutions is good evidence that the mechanism is different from the S<sub>N</sub>1 and the S<sub>N</sub>2 mechanisms, where fluoro is by far the poorest leaving group of the halogens. This is an example of the element effect (Sec. 10.F).

The pattern of base catalysis of reactions with amine nucleophiles provides additional evidence. Bases only catalyze these reactions when a relatively poor leaving group (e.g., OR) is present (not Cl or Br) and only when relatively bulky amines are nucleophiles.<sup>23</sup> Bases could not catalyze step 1, but if amines are nucleophiles, bases can catalyze step 2. Base catalysis is found precisely in those cases where the amine moiety cleaves easily but X does not, so that  $k_1$  is large and step 2 is rate determining. This is evidence for the S<sub>N</sub>Ar mechanism because it implies two steps. Furthermore, in cases where bases *are* catalysts, they catalyze only at low base concentrations: a plot of the rate against the base concentration shows that small increments of base rapidly increase the rate until a certain

concentration of base is reached, after which further base addition no longer greatly affects the rate. This behavior, based on a partitioning effect (Sec. 11.A.i), is also evidence for the  $S_NAr$  mechanism. At low base concentration, each increment of base, by increasing the rate of step 2, increases the fraction of intermediate that goes to product rather than reverting to reactants. At high base concentration the process is virtually complete: there is very little reversion to reactants and the rate becomes dependent on step 1. Just how bases catalyze step 2 has been investigated. For protic solvents two proposals have been presented. One is that step 2 consists of two steps: rate-determining deprotonation of **4** followed by rapid loss of X, and that bases catalyze the reaction by increasing the rate of the deprotonation step.<sup>24</sup> According to the other proposal, loss of X assisted by  $BH^+$  is rate determining.<sup>25</sup>

Two mechanisms, both based on kinetic evidence, have been proposed for aprotic solvents, such as benzene.<sup>26</sup> In both proposals the ordinary  $S_NAr$  mechanism operates, but in one the attacking species involves two molecules of the amine (the *dimer mechanism*),<sup>27</sup> while in the other there is a cyclic transition state.<sup>28</sup> Further evidence for the  $S_NAr$  mechanism has been obtained from  $^{18}O/^{16}O$  and  $^{15}N/^{14}N$  isotope effects.<sup>29</sup> The  $S_NAr$  reaction has been reported in water by micellar catalysis.<sup>30</sup>

The  $S_NAr$  mechanism has been studied for the reaction between picryl chloride (as well as other substrates) and  $^-OH$  ions (**13-1**), and spectral evidence has been reported<sup>31</sup> for two intermediates, one a  $\pi$  complex (Sec. 11.A.i), and the other a radical ion–radical pair.

As with the tetrahedral mechanism at an acyl carbon, nucleophilic catalysis (Sec. 16.A.i) has been demonstrated with an aryl substrate, in certain cases.<sup>32</sup> There is also evidence of an interaction of anions with the  $\pi$  cloud of aromatic compounds.<sup>33</sup> Nucleophilic aromatic substitution of heterocycles has been reported using flow conditions (Sec.7.D).<sup>34</sup>

### 13.A.ii. The S<sub>N</sub>1 Mechanism

For aryl halides and sulfonates, even active ones, a unimolecular S<sub>N</sub>1 mechanism (IUPAC: D<sub>N</sub> + A<sub>N</sub>) is very rare; it has only been observed for aryl triflates in which both *ortho* positions contain bulky groups (*tert*-butyl or SiR<sub>3</sub>).<sup>35</sup> This mechanism seems to be observed in reactions with diazonium salts,<sup>36</sup> with slow loss of N<sub>2</sub> to give an aryl cation that reacts with the nucleophile, Y<sup>-</sup>.<sup>37</sup> Among the evidence for the S<sub>N</sub>1 mechanism<sup>38</sup> with aryl cations as intermediates,<sup>39,40</sup> is the following:<sup>41</sup>

1. The reaction rate is first order in diazonium salt and independent of the concentration of Y.
2. When high concentrations of halide salts are added, the product is an aryl halide but the rate is independent of the concentration of the added salts.
3. The effects of ring substituents on the rate are consistent with a unimolecular rate-determining cleavage.<sup>42</sup>
4. When reactions were run with substrate deuterated in the *ortho* position, isotope effects of ~1.22 were obtained.<sup>43</sup> It is difficult to account for such high secondary isotope effects in any other way except that an incipient phenyl cation is stabilized by hyperconjugation (Sec. 2.M),<sup>44</sup> which is diminished when hydrogen is replaced by deuterium.
5. The first step is reversible cleavage,<sup>45</sup> demonstrated by the observation that when Ar<sup>15</sup>N<sup>+</sup>≡N was the reacting species, recovered starting material contained not only Ar<sup>15</sup>N<sup>+</sup>≡N but also ArN<sup>+</sup>≡<sup>15</sup>N.<sup>46,47</sup> This observation could arise only if the nitrogen breaks away from the ring and then returns. Additional evidence was obtained by treating PhN<sup>+</sup>≡<sup>15</sup>N with unlabeled N<sub>2</sub> at various pressures. At 300 atm, the recovered product had lost ~3% of the labeled nitrogen, indicating that PhN<sub>2</sub><sup>+</sup> was exchanging with atmospheric N<sub>2</sub>.<sup>47</sup>

There is kinetic and other evidence<sup>48</sup> that the first step is more complicated and involves two steps, both reversible, where ArN<sub>2</sub><sup>+</sup> is in equilibrium with [Ar<sup>+</sup> N<sub>2</sub>], which is in

equilibrium with  $\text{Ar}^+ + \text{N}_2$ . The  $[\text{Ar}^+ \text{N}_2]$  intermediate, which is probably some kind of a tight ion–molecule pair, has been trapped with carbon monoxide.<sup>49</sup>

### 13.A.iii. The Benzyne Mechanism<sup>50</sup>

Some aromatic nucleophilic substitutions are clearly different in character from those that occur by the  $\text{S}_{\text{N}}\text{Ar}$  mechanism (or the  $\text{S}_{\text{N}}1$  mechanism). These substitutions occur with aryl halides that have no activating groups; stronger bases are required than those normally used and the incoming group does not always take the position vacated by the leaving group. The validity of the latter statement was elegantly demonstrated by the reaction of 1-<sup>14</sup>C-chlorobenzene with potassium amide:

The product consisted of almost equal amounts of aniline labeled in the 1 position and in the 2 position.<sup>51</sup>

A mechanism that can explain all these facts involves elimination followed by addition. A suitable base removes the *ortho* hydrogen, with subsequent (or concomitant) loss of the chlorine (leaving group) to generate a symmetrical intermediate **5** called *benzyne*.<sup>52</sup> Subsequently, benzyne is attacked by the  $\text{NH}_3$  at either of two positions, which explains why about half of the aniline produced from the radioactive chlorobenzene was labeled at the 2 position.<sup>53</sup> The fact that the 1 and 2 positions were not labeled equally is the result of a small isotope effect.

Other evidence for this mechanism is the following:

1. If the aryl halide contains two *ortho* substituents, the reaction should not be able to occur. This is indeed the case.<sup>49</sup>
2. It had been known many years earlier that aromatic nucleophilic substitution occasionally results in substitution at a different position. This is called *cine substitution*<sup>54</sup> and can be illustrated by the conversion of *o*-bromoanisole to *m*-aminoanisole.<sup>55</sup> In

<sup>53</sup> The electrophilicity of benzyne and related intermediates has been quantified, see Nathel, N.F.F.; Morrill, L.A.; Mayr, H.; Garg, N.K. *J. Am. Chem. Soc.* **2016**, *138*, 10402.

<sup>54</sup> See Suwinski, J.; Swierczek, K. *Tetrahedron* **2001**, *57*, 1639.

<sup>55</sup> See Gilman, H.; Avakian, S. *J. Am. Chem. Soc.* **1945**, *67*, 349. For a table of many such examples, see Bunnett, J.F.; Zahler, R.E. *Chem. Rev.* **1951**, *49*, 273 (pp. 385).

this particular case, only the *meta* isomer is formed. The reason a 1 : 1 mixture is not formed is that the intermediate **6** is not symmetrical and the methoxy group directs the incoming group *meta*, but not *ortho* (Sec. 13.B.i). However, not all *cine* substitutions proceed by this kind of mechanism (see **13-31**). A study of the influence of structure on the formation of substituted benzyne, along with rate studies, has been reported.<sup>56</sup>

3. The fact that the order of halide reactivity is  $\text{Br} > \text{I} > \text{Cl} > \text{F}$  (when the reaction is performed with  $\text{KNH}_2$  in liquid  $\text{NH}_3$ ) shows that the  $\text{S}_{\text{N}}\text{Ar}$  mechanism is not operating here.<sup>51</sup>

In the conversion of the substrate to **6**, either proton removal or subsequent loss of halide ion can be rate determining. In fact, the unusual leaving-group order just mentioned ( $\text{Br} > \text{I} > \text{Cl}$ ) stems from a change in the rate-determining step. When the leaving group is Br or I, proton removal is rate determining and the rate order for this step is  $\text{F} > \text{Cl} > \text{Br} > \text{I}$ . When Cl or F is the leaving group, cleavage of the C–X bond is rate determining and the order for this step is  $\text{I} > \text{Br} > \text{Cl} > \text{F}$ . Confirmation of the latter order was found in a direct competitive study. *meta*-Dihalobenzenes in which the two halogens are different were treated with  $\text{NH}_2^-$ .<sup>57</sup> In such compounds, the most acidic hydrogen is the one between the two halogens; when it leaves, the remaining anion can lose either halogen. Therefore a study of which halogen is preferentially lost provides a direct measure of leaving-group ability. The order was found to be  $\text{I} > \text{Br} > \text{Cl}$ .<sup>57,58</sup>

Species such as **5** and **6** are *benzyne*s (sometimes dehydrobenzenes) but the more general term is *arynes*,<sup>59</sup> and the mechanism in which such species are intermediates is known as the *benzyne mechanism*. Benzyne is very reactive, and neither benzyne nor any other aryne has yet been isolated under ordinary conditions,<sup>60</sup> but benzyne has been isolated in an argon matrix at 8 K,<sup>61</sup> and its IR spectrum observed. In addition, benzyne can be trapped; for example, they undergo the *Diels-Alder reaction* (**15-56**). Note that the extra pair of electrons does not affect the aromaticity. However, evaluation by a series of aromaticity indicators, including magnetic susceptibility anisotropies and exaltations,

nucleus-independent chemical shifts (NICS), aromatic stabilization energies, and valence bond Pauling resonance energies point to the *o*-benzyne > *m*-benzyne > *p*-benzyne aromaticity order.<sup>62</sup> The relative order with respect to benzene depends on the aromaticity criterion.<sup>58</sup> It is noted that tunable reactivity for *meta*-benzynes has been demonstrated.<sup>63</sup> The aromatic sextet from the aromatic precursor functions as a closed ring, and the two additional electrons are merely located in a  $\pi$  orbital that covers only two carbons. Benzynes do not have a formal triple bond, since two canonical forms (**A** and **B**) contribute to the hybrid. The IR spectrum, mentioned above, indicates that **A** contributes more than **B**.

Not only benzene rings but also other aromatic rings,<sup>64</sup> and even nonaromatic rings (Sec. 10.F), can react through this kind of intermediate. Of course, the nonaromatic rings do have a formal triple bond. When a benzyne unit is fused to a small ring, strain-induced regioselectivity is observed in its reactions.<sup>65</sup> 2-(Trimethylsilyl)phenyl trimethylsilyl ethers have been used as benzyne precursors.<sup>66</sup> The reaction of alcohols with *ortho*-benzynes has been studied.<sup>67</sup> Insertion reactions into C–C,<sup>68</sup> C–O, O–H,<sup>69</sup> C–I,<sup>70</sup> and I–I bonds<sup>71</sup> have been observed.<sup>72</sup> A photo-induced, benzyne click reaction has been reported.<sup>73</sup>

#### 13.A.iv. The S<sub>RN</sub>1 Mechanism

When 5-iodo-1,2,4-trimethylbenzene was treated with KNH<sub>2</sub> in NH<sub>3</sub>, 2,3,5-trimethylaniline and 2,4,5-trimethylaniline were formed in the ratio 0.63:1. The presence of an unactivated substrate, a strong base, and the occurrence of *cine* substitution along with normal substitution are strong indications of a benzyne mechanism. Yet if that were so, 6-iodo-2,4-trimethylbenzene should have given 2,3,5-trimethylaniline and 2,4,5-trimethylaniline in the same ratio (because the same aryne intermediate would be formed in both cases), but in this case the ratio of 2,3,5-trimethylaniline and 2,4,5-trimethylaniline

was 5.9 : 1 (the chloro and bromo analogs did give the same ratio, 1.46 : 1, showing that the benzyne mechanism may be taking place there). To explain the iodo result, it has been proposed<sup>74</sup> that in addition to the benzyne mechanism, a free-radical mechanism is also operating:

Followed by termination steps

This sequence is called the  $S_{RN}1$  mechanism,<sup>75</sup> and many other examples are known (13-2, 13-3, 13-5, 13-15). The IUPAC designation is T + D<sub>N</sub> + A<sub>N</sub>.<sup>76</sup> Note that the last step of the mechanism produces  $\text{ArI}^{\bullet-}$  radical ions, so the process is a chain mechanism<sup>77</sup> (Sec. 14.A.i). An electron donor is required to initiate the reaction, and in the case above it was solvated electrons from  $\text{KNH}_2$  in  $\text{NH}_3$ . Evidence for the mechanism was that the addition of potassium metal (a good producer of solvated electrons in ammonia) completely suppressed the *cine* substitution. Further evidence for the  $S_{RN}1$  mechanism was that addition of radical scavengers (which would suppress a free-radical mechanism) led to 2,3,5-trimethylaniline and 2,4,5-trimethylaniline ratios much closer to 1.46 : 1. Numerous other observations of  $S_{RN}1$  mechanisms that were stimulated by solvated electrons and inhibited by radical scavengers have also been recorded.<sup>78</sup> Further evidence for the  $S_{RN}1$  mechanism in the case above was that some 1,2,4-trimethylbenzene was found among the products. This could easily be formed by abstraction by  $\text{Ar} \bullet$  of H from the solvent  $\text{NH}_3$ . Besides initiation by solvated electrons,<sup>79</sup>  $S_{RN}1$  reactions have been initiated photochemically,<sup>80</sup> electrochemically,<sup>81</sup> and even thermally.<sup>82</sup>

The  $S_{RN}1$  reactions have a fairly wide scope. The efficiency of the reaction has been traced to the energy level of the radical anion of the substitution product.<sup>83</sup> There is no requirement for activating groups or strong bases, but in DMSO haloarenes are less reactive as the stability of the anion increases.<sup>84</sup> The reaction has also been done in liquid ammonia,

promoted by ultrasound (Sec. 7.B),<sup>85</sup> and ferrous ion has been used as a catalyst.<sup>86</sup> Alkyl, alkoxy, aryl, and COO<sup>-</sup> groups do not interfere, although Me<sub>2</sub>N, O<sup>-</sup>, and NO<sub>2</sub> groups do interfere. *Cine* substitution is not found.

### 13.A.v. Other Mechanisms

There is no clearcut proof that a one-step S<sub>N</sub>2 mechanism, so important at a saturated carbon, ever actually occurs with an aromatic substrate. The hypothetical aromatic S<sub>N</sub>2 process is sometimes called the *one-stage* mechanism to distinguish it from the *two-stage* S<sub>N</sub>Ar mechanism. A “clean” example of a S<sub>RN</sub>2 reaction has been reported, the conversion of 2,3,4,5,6-pentafluoronitrobenzene to 2,3,5,6-tetrafluoro-4-nitroanisole in methanol.<sup>87</sup> Both S<sub>RN</sub>1 and S<sub>RN</sub>2 reactions have been reviewed.<sup>88</sup>

Some of the reactions in this chapter operate by still other mechanisms, among them an addition–elimination mechanism (see 13-12). A new mechanism has been reported in aromatic chemistry, a reductively activated “polar” nucleophilic aromatic substitution.<sup>89</sup> The reaction of phenoxide with *p*-dinitrobenzene in DMF shows radical features that cannot be attributed to a radical anion, and it is not S<sub>RN</sub>2. The new designation was proposed to account for these results.

## 13.B. REACTIVITY

### 13.B.i. The Effect of Substrate Structure

In the discussion of electrophilic aromatic substitution (Chapter 11) equal attention was paid to the effect of substrate structure on reactivity (activation or deactivation) and on orientation. The question of orientation was important because in a typical substitution there are four or five hydrogen atoms that could serve as leaving groups. This type of question is much less important for aromatic nucleophilic substitution, since in most cases there is only one potential leaving group in a molecule. Therefore attention is largely focused on the reactivity of one molecule compared with another and not on the comparison of the reactivity of different positions within the same molecule.

### S<sub>N</sub>Ar Mechanism

These substitutions are accelerated by electron-withdrawing groups, especially in positions *ortho* and *para* to the leaving group<sup>90</sup> and are hindered by electron-attracting groups. This is, of course, opposite to the effects of these groups on electrophilic substitutions, and the reasons are similar to those discussed in Sec. 11.A.i. When attached to a benzene ring, the rate of reaction depends on the substituent.<sup>91</sup> Activating groups include

<sup>85</sup> Manzo, P.G.; Palacios, S.M.; Alonso, R.A. *Tetrahedron Lett.* **1994**, 35, 677.

<sup>88</sup> Rossi, R.A.; Palacios, S.M. *Tetrahedron* **1993**, 49, 4485.

<sup>89</sup> Marquet, J.; Casado, F.; Cervera, M.; Espín, M.; Gallardo, I.; Mir, M.; Niat, M. *Pure Appl. Chem.* **1995**, 67, 703.

<sup>90</sup> With *meta* substituents, electron-withdrawing groups also increase the rate: see Nurgatin, V.V.; Shamin, G.P.; Ginzburg, B.M. *J. Org. Chem. USSR* **1983**, 19, 343.

<sup>91</sup> See Miller, J. *Aromatic Nucleophilic Substitution*, Elsevier, NY, **1968**, pp. 61–136.

2-nitro,<sup>92,93</sup>  $N_2^+$ , NO, or C=N units with strong nucleophiles. When a nitro group is attached  $SO_2Me$ ,  $NMe_3$ ,  $CF_3$ , CN, CHO, COR,  $CO_2H$ ,  $SO_3$ , halogen, H, Me, or OMe activate.<sup>91</sup> Nitrogen atoms are also strongly activating (especially to the  $\alpha$  and  $\gamma$  positions) and are even more so when quaternized.<sup>94</sup> Both 2- and 4-chloropyridine, for example, are often used as substrates. Heteroaromatic amine *N*-oxides are readily attacked by nucleophiles in the 2 and 4 positions, but the oxygen is generally lost in these reactions.<sup>95</sup> The most highly activating group,  $N_2^+$ , is seldom deliberately used to activate a reaction, but it sometimes happens that in the diazotization of a compound such as *p*-nitroaniline or *p*-chloroaniline, the group *para* to the diazonium group is replaced by OH from the solvent or by X from  $ArN_2^+ X^-$  untouched. By far the most common activating group is the nitro group and the most common substrates are 2,4-dinitrophenyl halides and 2,4,6-trinitrophenyl halides (also called picryl halides).<sup>96</sup> Polyfluorobenzenes<sup>97</sup> (see **11**) also undergo aromatic nucleophilic substitution quite well.<sup>98</sup> Benzene rings that lack activating substituents are generally not useful substrates for the  $S_NAr$  mechanism, because the two extra electrons in **1** are in an antibonding orbital (Sec. 2.A). Activating groups, by withdrawing electron density, are able to stabilize the intermediates and the transition states leading to them. Reactions taking place by the  $S_NAr$  mechanism are also accelerated when the aromatic ring is coordinated with a transition metal.<sup>99</sup>

Just as electrophilic aromatic substitutions were found more or less to follow the *Hammett relationship* (with  $\sigma^+$  instead of  $\sigma$ ; Sec. 9.C) so do nucleophilic substitutions, with  $\sigma^-$  instead of  $\sigma$  for electron-withdrawing groups.<sup>100</sup>

## Benzyne Mechanism

Two factors affect the position of the incoming group, the first being the direction in which the aryne forms.<sup>101</sup> When there are groups *ortho* or *para* to the leaving group, there is no choice:

<sup>92</sup> For reviews of reactivity of nitrogen-containing heterocycles, see Illuminati, G. *Adv. Heterocycl. Chem.* **1964**, 3, 285; Shepherd, R.G.; Fedrick, J.L. *Adv. Heterocycl. Chem.* **1965**, 4, 145.

<sup>100</sup> See Bartoli, G.; Todesco, P.E. *Acc. Chem. Res.* **1977**, 10, 125; there is a list of  $\sigma^-$  values in Table 9.4 in Sec. 9.C.

<sup>101</sup> From Roberts, J.D.; Vaughan, C.W.; Carlsmith, L.A.; Semenov, D.A. *J. Am. Chem. Soc.* **1956**, 78, 611. See Hoffmann, R.W. *Dehydrobenzene and Cycloalkynes*, Academic Press, NY, **1973**, pp. 134–150.

but when a *meta* group is present, the aryne can form in two different ways:

In such cases, the more acidic hydrogen is removed. Since acidity is related to the field effect of Z, it can be stated that an electron-attracting Z favors removal of the *ortho* hydrogen while an electron-donating Z favors removal of the *para* hydrogen. The second factor is that the aryne, once formed, can be attacked at two positions. The favored position for nucleophilic attack is the one that leads to the more stable carbanion intermediate, and this in turn also depends on the field effect of Z. For  $-I$  groups, the more stable carbanion is the one in which the negative charge is closer to the substituent.

These principles are illustrated by the reaction of the three dichlorobenzenes (**13-16**) with alkali metal amides to give the predicted products shown. In each case, the predicted product was the one chiefly formed.<sup>102</sup> The observation that *m*-aminoanisole is obtained, mentioned in Sec. 13.A.iii, is also in accord with these predictions.

### 13.B.ii. The Effect of the Leaving Group<sup>103</sup>

The common leaving groups in aliphatic nucleophilic substitution (halide, sulfate, sulfonate,  $\text{NR}_3^+$ , etc.) are also common leaving groups in aromatic nucleophilic substitutions, but the groups  $\text{NO}_2$ , OR, OAr,  $\text{SO}_2\text{R}$ ,<sup>104</sup> and SR, which are not generally lost in aliphatic systems, are leaving groups when attached to aromatic rings. Surprisingly,  $\text{NO}_2$  is a particularly good leaving group.<sup>105</sup> An approximate order of leaving-group ability<sup>106</sup> is  $\text{F} > \text{NO}_2 > \text{OTs} > \text{SOPh} > \text{Cl}, \text{Br}, \text{I} > \text{N}_3 > \text{NR}_3^+ > \text{OAr}, \text{OR}, \text{SR}, \text{NH}_2$ . However, this depends greatly on the nature of the nucleophile, as illustrated by the fact that  $\text{C}_6\text{Cl}_5\text{OCH}_3$  treated with  $\text{NH}_2^-$  gives mostly  $\text{C}_6\text{Cl}_5\text{NH}_2$ ; that is, the one methoxy group is replaced in preference to the five chlorines.<sup>107</sup> As usual, OH can be a leaving group if it is converted to an inorganic ester. Among the halogens, fluoro is generally a much better leaving group than the other halogens, which have reactivities fairly close together. The order is usually  $\text{Cl} > \text{Br} > \text{I}$ , but not always.<sup>108</sup> The leaving-group order is quite different from that for the  $\text{S}_{\text{N}}1$  or  $\text{S}_{\text{N}}2$  mechanisms. The most likely explanation is that the first step of the  $\text{S}_{\text{N}}\text{Ar}$  mechanism is usually rate determining, and this step is promoted by groups with strong  $-I$  effects. This would explain why fluoro and nitro are such good leaving groups when this mechanism is operating. Fluoro is the poorest leaving group of the halogens when the second step of the  $\text{S}_{\text{N}}\text{Ar}$  mechanism is rate determining or when the benzyne mechanism is

operating. The four halogens, as well as SPh,  $\text{NMe}_3^+$ , and  $\text{OPO}(\text{OEt})_2$ , have been shown to be leaving groups in the  $\text{S}_{\text{RN}}1$  mechanism.<sup>77</sup> The only important leaving group in the  $\text{S}_{\text{N}}1$  mechanism is  $\text{N}_2^+$ .

### 13.B.iii. The Effect of the Attacking Nucleophile<sup>109</sup>

It is not possible to construct an invariant nucleophilicity order because different substrates and different conditions lead to different orders of nucleophilicity, but an overall approximate order is  $\text{NH}_2^- > \text{Ph}_3\text{C}^- > \text{PhNH}^-$  (aryne mechanism)  $> \text{ArS}^- > \text{RO}^- > \text{R}_2\text{NH} > \text{ArO}^- > \text{OH}^- > \text{ArNH}_2 > \text{NH}_3 > \text{I}^- > \text{Br}^- > \text{Cl}^- > \text{H}_2\text{O} > \text{ROH}$ .<sup>110</sup> As with aliphatic nucleophilic substitution, nucleophilicity is generally dependent on base strength and nucleophilicity increases as the attacking atom moves down a column of the periodic table, but there are some surprising exceptions; for example,  $\text{OH}^-$ , a stronger base than  $\text{ArO}^-$ , is a poorer nucleophile.<sup>111</sup> In a series of similar nucleophiles, such as substituted anilines, nucleophilicity is correlated with base strength. Oddly, the cyanide ion is not a nucleophile for aromatic systems, except for sulfonic acid salts and in the *von Richter* (**13-31**) and *Rosenmund-von Braun* (**13-8**) reactions, which are special cases. Studies on the nature of the nucleophile continue. Indeed, the second-order rate constants for vicarious nucleophilic substitution reactions of some carbanions were measured to define electrophilicity parameters for electron-deficient heteroarenes.<sup>112</sup>

## 13.C. REACTIONS

In the first part of this section, reactions are classified according to the attacking species, with all leaving groups considered together, except for hydrogen and  $\text{N}_2^+$ , which are treated subsequently. Finally, a few rearrangement reactions are discussed.

### 13.C.i. All Leaving Groups Except Hydrogen And $\text{N}_2^+$

#### A. Oxygen Nucleophiles

##### 13-1 Hydroxylation of Aromatic Compounds

Direct hydroxylation of aryl halides to give phenols generally requires the presence of activating groups or exceedingly strenuous reaction conditions.<sup>113</sup> When the reaction is carried out at high temperatures, *cine* substitution is observed, indicating a benzyne

mechanism.<sup>114</sup> However, phenols are prepared from aryl halides using KOH and a Pd catalyst at 100 °C.<sup>115</sup> Formation of phenols is possible using AgNO<sub>3</sub> with microwave irradiation,<sup>116</sup> or CuI.<sup>117</sup> Other microwave-promoted phenol-forming reactions are known.<sup>118</sup> A slightly related reaction involves the amino group of naphthylamines, which can be replaced by a hydroxyl group by treatment with aqueous bisulfite.<sup>119</sup>

Continuous flow techniques (Sec. 7.D) have been applied to the synthesis of phenols.<sup>120</sup> Phenols have been obtained from unactivated aryl halides by treatment with borane and a metal such as lithium, followed by oxidation with alkaline H<sub>2</sub>O<sub>2</sub>.<sup>121</sup> Arylboronic acids, ArB(OH)<sub>2</sub>, are oxidized by aqueous hydrogen peroxide to give the corresponding phenol.<sup>122</sup> Aryllithium reagents have been converted to phenols by treatment with oxygen.<sup>123</sup> Arylboronic acids reacted with aqueous hydrogen peroxide and acidic alumina to give phenols,<sup>124</sup> or with iron(III) oxide as a photocatalyst to give phenols.<sup>125</sup> Benzene was converted to phenol by reaction with O<sub>2</sub> and a NADH analog,<sup>126</sup> or by using H<sub>2</sub>O<sub>2</sub> and a specialized molecular sieve.<sup>127</sup> The oxidative hydroxylation of arylboronic acids by visible light photoredox catalysis has been reported.<sup>128</sup> Metal-free conversion of aryl halides to phenols have been reported.<sup>129</sup>

Many metal-catalyzed transformations that produce phenols have been reported. The Cu-catalyzed reaction of aryl halides with CsOH in aqueous DMSO gave phenols.<sup>130</sup> Aryl and heteroaryl halides reacted with KOH or CsOH in the presence of a Pd catalyst<sup>131</sup> to give the hydroxylated derivative.<sup>132</sup> Benzene derivatives were hydroxylated to give the phenol by reaction with H<sub>2</sub>O<sub>2</sub> and a Mn complex incorporated into mesoporous silica alumina.<sup>133</sup>

OS I, 455; II, 451; V, 632. Also see, OS V, 918.

Aryl sulfonic acids can be converted, through their salts, to phenols, by alkali fusion. In spite of the extreme conditions, the reaction gives fairly good yields, except when the substrate contains other groups that are attacked by alkali at the fusion temperatures. Milder conditions can be used when the substrate contains activating groups, but the presence of deactivating groups hinders the reaction. The mechanism is not clear, but a benzyne intermediate has been ruled out by the finding that *cine* substitution does not occur.<sup>134</sup>

OS I, 175; III, 288.

### 13-2 Replacement by OR or OAr

This reaction is similar to **13-1** and so generally requires activated substrates.<sup>113,135</sup> With unactivated substrates, side reactions predominate, although aryl methyl ethers have been prepared from unactivated chlorides by treatment with MeO<sup>-</sup> in HMPA.<sup>136</sup> This reaction gives better yields than **13-1** and is used more often. A good solvent is liquid ammonia. Aryl chlorides react with phenol and KOH with microwave irradiation to give the diaryl ether.<sup>137</sup> The metal-free preparation of aryl ethers has been reported in water.<sup>138</sup> Phenols reacted with alcohols in the presence of Phenofluor and TMS-imidazole to give the corresponding ether.<sup>139</sup>

Phenols reacted with aryl fluorides<sup>140</sup> or aryl chlorides<sup>141</sup> to give the diaryl ether. Intramolecular versions are known that produce benzofurans.<sup>142</sup> Heating aryl iodides and

## B. Sulfur Nucleophiles

### 13-3 Replacement by SH or SR

Aryl thiols (mercaptans) and thioethers (sulfides) can be prepared by reactions that are similar to **13-1** and **13-2**.<sup>168</sup> Activated aryl halides generally give good results, but side reactions are occasionally important. Some reagents give the thiol directly. 4-Bromonitrobenzene reacts with Na<sub>3</sub>SPO<sub>3</sub>, in refluxing methanol, to give 4-nitrothiophenol, for example.<sup>169</sup> Thiophenols have been prepared by the reaction of formate anion via transfer hydrogenation of aryl sulfonamides and sulfonyl chlorides.<sup>170</sup>

Diaryl sulfides can also be prepared (in high yields) by treatment of unactivated aryl iodides with ArS<sup>-</sup> in liquid ammonia under irradiation.<sup>171</sup> Even unactivated aryl halides react with ArS<sup>-</sup> if polar aprotic solvents, for example, DMF,<sup>172</sup> DMSO,<sup>173</sup> or HMPA,<sup>174</sup> are used. Aryl halides reacted with aryl thiols in the presence of Cs<sub>2</sub>CO<sub>3</sub> and visible light to give the diaryl sulfide.<sup>175</sup> Aryl sulfides were formed by the reaction of thiols with diaryliodonium salts.<sup>176</sup> The reaction of dialkyl, diaryl, or alkyl aryl sulfides with diaryliodonium salt, in the presence of trifluoroacetic acid, gave aryl thioethers.<sup>177</sup> Alkyl thiols reacted with alkyl-diazonium tetrafluoroborates in the presence of a catalytic amount of Eosin Y (an acidic

red stain for highlighting cytoplasmic material) and also air and green LEDs to give the corresponding sulfide.<sup>178</sup> Aryl diazonium salts were reduced by ascorbic acid to generate an aryl radical, which reacted with disulfides to yield aryl sulfides.<sup>179</sup>

Metal-catalyzed reactions of aromatic compounds give thioethers, and such reactions have been reviewed.<sup>180</sup> Catalysis in aqueous media has been reported.<sup>181</sup> The more common metals used are Pd,<sup>182</sup> Cu,<sup>183</sup> Rh,<sup>184</sup> Ni,<sup>185</sup> or In catalysts.<sup>186</sup>

A significant amount of work continues with Cu catalysts. Arylboronic acids, ArB(OH)<sub>2</sub>, react with thiols and copper(II) acetate to give the corresponding alkyl aryl sulfide.<sup>187</sup> Diaryl sulfides have been prepared by the photo-induced, Cu-catalyzed coupling of aryl thiols with aryl halides, using CuI as a precatalyst.<sup>188</sup> Diaryl sulfides were prepared by the reaction of triarylbismuth reagents with diaryl sulfides in the presence of a Cu catalyst.<sup>189</sup> Aryl- and alkenylboronic acids reacted with thiosulfonates using a Cu catalyst to give the aryl thioether.<sup>190</sup> Heating aryl thiols and aryl halides with a Cu catalyst gave the diaryl sulfide.<sup>191</sup> The Cu-catalyzed reaction of aryl halides and potassium thiocyanate gave diaryl sulfides.<sup>192</sup>

Other metals are continuing to be examined as catalysts. Aryl thioethers have been prepared by the reaction of thiols and Grignard reagents, promoted by NCS.<sup>193</sup> A Mn-catalyzed cross-coupling reaction of thiols with aryl iodides gave the aryl thioether.<sup>194</sup> In the presence of a Pd catalyst, thiophenols react with diaryliodonium salts, Ar<sub>2</sub>I<sup>+</sup> BF<sub>4</sub><sup>-</sup>, to give the unsymmetrical diaryl sulfide.<sup>195</sup> The reaction of aniline derivatives with thiols using a Ru photoredox catalyst and *t*-BuONO gave the aryl sulfide under flow conditions (Sec.7.D).<sup>196</sup> Aryl chlorides reacted with thiophenols to give the corresponding sulfide using an Ir catalyst.<sup>197</sup>

Other sulfur nucleophiles also react with activated aryl halides. Aryl sulfones have been prepared from sulfinic acid salts, aryl iodides, and CuI.<sup>198</sup> The Cu-catalyzed reaction of

### C. Nitrogen Nucleophiles

#### 13-4 Replacement of Halogen by NH<sub>2</sub>, NHR, or NR<sub>2</sub>

Aryl halides can be converted to amines by the use of NaNH<sub>2</sub>, NaNHR, or NaNR<sub>2</sub>.<sup>211</sup> The reaction of an amine, an aryl halide, and potassium *tert*-butoxide generates the *N*-arylamine.<sup>212</sup> Activated aryl halides react with ammonia and with primary and secondary amines to give the corresponding arylamines.<sup>213</sup> Primary and secondary amines usually give better results than ammonia, with piperidine especially reactive. Lithium dialkylamides

also react with aryl halides to give the *N*-arylamine.<sup>214</sup> With amide base reagents, the benzyne mechanism generally operates, so *cine* substitution (Sec. 13.A.iii, category 2) is often found. Triarylamines have been prepared in a similar manner from ArI and Ar'<sub>2</sub>NLi, even with unactivated ArI.<sup>215</sup> Arylation of amines with aryl halides has also been done in ionic liquids<sup>216</sup> and in supercritical CO<sub>2</sub>.<sup>217</sup> Flow reactor technology (Sec. 7.D) has been used for the direct, uncatalyzed amination of 2-chloropyridine.<sup>218</sup> Aryl triflates react directly with secondary amines in *N*-methylpyrrolidine solvent using microwave irradiation.<sup>219</sup>

Aryl fluorides react with amines in the presence of potassium carbonate/DMSO and ultrasound,<sup>220</sup> and aryl chlorides react on basic alumina with microwave irradiation.<sup>221</sup> Aryl fluorides react in the presence of KF-alumina and 18-crown-6 in DMSO.<sup>222</sup>

Intramolecular versions of this reaction generate bicyclic or polycyclic amines.<sup>223</sup> An example is the conversion of **7** to the tetrahydroquinoline.<sup>224</sup> Larger ring amines can be prepared using this approach, giving 8- and even 12-membered products.

Organometallics are important intermediates for the preparation of arylamines. Aryl halides can be converted to the corresponding Grignard reagent (**12-37**) and subsequent reaction with allyl azide followed by hydrolysis leads to the corresponding aniline derivative.<sup>225</sup> Aryl Grignard reagents react with nitroaryl compounds to give, after reduction with FeCl<sub>3</sub>/NaBH<sub>4</sub>, a diaryl amine.<sup>226</sup>

Both aliphatic amines and aniline derivatives and amide bases have been coupled to aryl halides using Pd catalysts and an appropriate ligand. This Pd-catalyzed amination has come to be called the *Buchwald-Hartwig cross-coupling reaction*.<sup>227</sup> A considerable amount of

work<sup>228</sup> has been done to vary the nature of the ligand and the Pd catalyst, as well as the base.<sup>229</sup> Ligands have been prepared that facilitate the dynamic kinetic asymmetric version of the Buchwald-Hartwig reaction.<sup>230</sup> Other ligands have been developed that are important in this reaction.<sup>231</sup> The role of the base in the amination reaction has been discussed.<sup>232</sup> The reaction has been done in water using surfactants.<sup>233</sup> Work to discern the mechanism of this reaction has also received considerable attention.<sup>234</sup> The metal-catalyzed reaction with ammonia or amines likely proceeds by the  $S_NAr$  mechanism,<sup>235</sup> although, in certain cases, the  $S_{RN}1$  mechanism has been found (**10-26**). When the substrate is a heterocyclic aromatic nitrogen compound, a different mechanism still [the  $S_N(ANRORC)$  mechanism], involving opening and reclosing of the aromatic ring, has been shown to take place.<sup>236</sup>

Polymer-supported Pd catalysts,<sup>237</sup> polymer-bound phosphine ligands used in conjunction with a Pd catalyst,<sup>238</sup> and polymer-bound amines<sup>239</sup> have been used for *N*-arylation. These reactions have been carried out in ionic liquids using a Pd catalyst,<sup>240</sup> and with microwave irradiation.<sup>241</sup> Catalysts are available for the amination of aryl halides in aqueous media.<sup>242</sup> The Pd-catalyzed amination of aryl substrates is not limited to halides, and the reaction with mesylates lead to arylamines.<sup>243</sup> Arylamines with chiral substituents on nitrogen can be prepared using a Pd catalyst with optically active ligands.<sup>244</sup>

Aryl tosylates reacted with secondary amines to give the corresponding arylamine in the presence of a Pd catalyst.<sup>245</sup> The Pd-catalyzed coupling of aryl halides with ammonia and gaseous amines as their ammonium salts gave arylamines.<sup>246</sup> Amines react with

$\text{Ph}_2\text{I}^+ \text{BF}_4^-$ , in the presence of Pd catalysts<sup>247</sup> or a CuI catalyst,<sup>248</sup> to give the *N*-phenylamine. Aminoalkylation of heteroaromatic rings is possible, as in the reaction of 3-bromothiophene with a primary amine and a Pd catalyst.<sup>249</sup> 2-Halopyridines react to give the 2-aminoalkyl pyridine.<sup>250</sup>

Copper catalysts have been extensively explored for this coupling reaction.<sup>251</sup> The selectivity of *O*- versus *N*-arylation for reactions of amino alcohols has been discussed.<sup>252</sup> The Cu-catalyzed reaction of aryl halides and amines,<sup>253</sup> or of aryl halides and  $\alpha$ -amino acids, led to the formation of arylamines.<sup>254</sup> The Cu-catalyzed *N*-arylation of indoles has been reported.<sup>255</sup> The *N*-arylation of amines used a Cu catalyst in water.<sup>256</sup> Aryl halides in liquid ammonia gave the primary aromatic amine when catalyzed by a Cu-salt/ascorbate system.<sup>257</sup>

Arylboronic acids react with aliphatic amines<sup>258</sup> or aqueous ammonia<sup>259</sup> in the presence of a Cu catalyst. The Cu-catalyzed reaction of an arylboronic acid (BPin) (Pin = pinacolato) and secondary amines gave arylamines.<sup>260</sup> The *N*-arylation of imidazolines has been reported using arylboronic acids and a Cu catalyst.<sup>261</sup> Arylboronic acids reacted with aryl azides in the presence of indium and  $\text{Cu}(\text{OAc})_2$  to give diarylamines.<sup>262</sup> The  $\text{S}_{\text{N}}\text{Ar}$  amination of functionalized pyrimidines has been reported.<sup>263</sup>

Nickel catalysts have been used in the reaction of aryl halides with *N*-alkyl aniline derivatives<sup>264</sup> and also with aliphatic amines.<sup>265</sup> An intramolecular reaction of a pendant aminoalkyl unit with an aryl chloride moiety, catalyzed by Ni(0), gave a dihydroindole.<sup>266</sup>

Aryl ethers reacted with imines, in the presence of a Ni catalyst, to give arylamines after acid hydrolysis.<sup>267</sup>

Several other transition metal-catalyzed reactions have been examined. The amination of arenes with phthalimide used an iodine(III) oxidant in the presence of a Au(I) catalyst, to give phthalimide-substituted aniline derivatives.<sup>268</sup> The Au-catalyzed direct amination of arenes with azodicarboxylates gave *N*-arylhydrazine derivatives.<sup>269</sup> Indoles have been prepared by intramolecular C–H amination using an Fe catalyst.<sup>270</sup> The reaction of arenes with azide in water used an Fe catalyst and DDQ and gave the amides.<sup>271</sup> 2-Chloropyridine reacted with *N*-(MgCl)-pyrrolidine in the presence of a Cr catalyst to give 2-pyrrolidinopyridine.<sup>272</sup> A Mo(CO)<sub>6</sub>-mediated, Pd-catalyzed reaction is known for allylamines and aryl halides.<sup>273</sup>

Amides react with aryl halides in the presence of a Pd<sup>274</sup> or a Cu catalyst.<sup>275</sup> *N*-Aryl lactams are prepared by the reaction of a lactam with an aryl halide in the presence of a Pd catalyst.<sup>276</sup> β-Lactams also react.<sup>277</sup> The Ru-catalyzed amidation of heteroaryl arenes has been reported.<sup>278</sup> *N*-Aryl imides have been prepared, using a Cu catalyst, from arylboronic acids.<sup>279</sup> In the *Goldberg reaction*, an aryl bromide reacts with an acetanilide in the presence of K<sub>2</sub>CO<sub>3</sub> and CuI to give an *N*-acetyldiarylamine, which can be hydrolyzed to a diarylamine.<sup>280</sup>

*N*-Arylation of urea is possible using a Cu catalyst.<sup>281</sup> The Pd-catalyzed amidation of aryl halides by reaction with isocyanides has been reported.<sup>282</sup> The Cu-catalyzed, intramolecular amidation of benzamide derivatives led to isoindolinones.<sup>283</sup> Functionalized arenes reacted with phthalimide in the presence of oxygen and a Cu catalyst to give the *ortho* amide derivative.<sup>284</sup> Arylamines were produced by the Ir-catalyzed *ortho* C–H amidation of arenes by reaction of arenes with sulfonyl and aryl azides.<sup>285</sup>

### 13-5 Replacement of a Hydroxy Group by an Amino Group

The reaction of naphthols with ammonia and sodium bisulfite is called the *Bucherer reaction*. Primary amines can be used instead of ammonia, in which case *N*-substituted naphthylamines are obtained. The mechanism of the Bucherer reaction amounts to a kind of overall addition–elimination, via initial sulfonation at C-3 to give an enol and loss of proton with dearomatization to give the 1-oxo-3-sodium sulfonate. Addition of the amine to the ketone moiety gives the imine, which tautomerizes to the enamine and aromatization then gives the 1-naphthylamine derivative.<sup>294</sup>

Evidence for this mechanism was (i) the isolation of 1-oxo-3-sodium sulfonate<sup>295</sup> and (ii) the demonstration that for  $\beta$ -naphthol treated with ammonia and  $\text{HSO}_3^-$ , the rate of the reaction depends only on the substrate and on  $\text{HSO}_3^-$ , indicating that ammonia is not involved in the rate-determining step.<sup>296</sup> If the starting compound is a  $\beta$ -naphthol, the intermediate is a 2-keto-4-sulfonic acid compound, so the sulfur of the bisulfite in either case attacks *meta* to the OH or  $\text{NH}_2$ .<sup>297</sup>

Hydroxy groups on benzene rings can be replaced by  $\text{NH}_2$  groups if they are first converted to aryl diethyl phosphates. Treatment of these with  $\text{KNH}_2$  and potassium metal in

liquid ammonia gives the corresponding primary aromatic amines.<sup>298</sup> The mechanism of the second step is  $S_{RN}1$ .<sup>299</sup>

OS III, 78.

## D. Halogen Nucleophiles

### 13-6 The Introduction of Halogens

It is possible to replace a halogen on an aromatic ring by another halogen,<sup>300</sup> if the ring is activated. In such cases there is equilibrium, which is usually shifted in the desired direction by the use of an excess of added halide ion.<sup>301</sup> A phenolic hydroxy group can be replaced by chloro with  $\text{PCl}_5$  or  $\text{POCl}_3$ , but only if the ring is activated. Unactivated phenols give phosphates when treated with  $\text{POCl}_3$

Phenols, even unactivated ones, can be converted to aryl bromides by treatment with  $\text{Ph}_3\text{PBr}_2$ <sup>302</sup> (see **10-46**) and to aryl chlorides by treatment with  $\text{PhPCl}_4$ .<sup>303</sup> *meta*-Chlorophenols were formed by the reaction of phenol derivatives with iodonium salts followed by treatment with HCl in dioxane.<sup>304</sup>

Halide exchange can also be accomplished with copper halides. Since the leaving-group order in this case is  $\text{I} > \text{Br} > \text{Cl} \gg \text{F}$  (which means that iodides cannot normally be made by this method), the  $S_{\text{N}}\text{Ar}$  mechanism is probably not operating.<sup>305</sup> However, aryl iodides have been prepared from bromides, (i) with an excess of NaI and a Cu catalyst,<sup>306</sup> and (ii) by treatment with excess KI and a Ni catalyst.<sup>307</sup> Interestingly, aryl chlorides have been prepared from aryl iodides using 2 molar equivalents of  $\text{NiCl}_2$  in DMF, with microwave irradiation.<sup>308</sup> Aryl and vinyl triflates can be converted to the corresponding bromide or chloride using a Pd catalyst.<sup>309</sup> The Rh-catalyzed selective bromination and iodination of electron-rich heterocycles with NIS or *N*-bromophthalimide (NBP) gave the corresponding halogenated heterocycle.<sup>310</sup>

Treatment of  $\text{PhB(OH)}_2$  with *N*-iodosuccinimide gives iodobenzene.<sup>311</sup> Arylboronic acids (**12-27**) can be converted to the corresponding aryl bromides by reaction with

1,3-dibromo-5,5-dimethylhydantoin and 5 mol % NaOMe.<sup>312</sup> Other aryl halides can be prepared using 1,3-dihalo-5,5-dimethylhydantoin.

Halide exchange is particularly useful for putting fluorine into a ring, since there are fewer alternate ways of doing this than for the other halogens. Activated aryl chlorides give fluorides when treated with KF in DMF, DMSO, or dimethyl sulfone.<sup>313</sup> Reaction of aryl halides with Bu<sub>4</sub>PF/HF is also effective for exchanging a halogen with fluorine.<sup>314</sup> Aryl alcohols (phenol derivatives) reacted with CsF and aryl nonafluorobutylsulfonates, and subsequent treatment with a Pd catalyst and heating with microwave irradiation gave the corresponding aryl fluoride.<sup>315</sup> The S<sub>N</sub>Ar fluorination used anhydrous tetraalkylammonium fluoride salts, generated by several approaches.<sup>316</sup>

### 13-7 Replacement by Boron

Arylboronic acids and aryl boronates have become important synthetic targets due to their extensive application in organic syntheses, especially for the transition metal-catalyzed C–C, C–O, and C–N bond-forming reactions. Aryl halides and also arenes<sup>317</sup> have been converted to arylboranes, aryl boronates and other arylboron compounds.<sup>318</sup> Aryl halides reacted with B<sub>2</sub>(OR)<sub>4</sub> in the presence of 4-phenylpyridine and KOMe to give the borate, ArB(OR)<sub>2</sub>.<sup>319</sup> The reaction of aryl aldehydes with B<sub>2</sub>Pin<sub>2</sub> (Pin = pinacolato) gave *ortho* borylation using *tert*-butylamine with 8-aminoquinoline whereas *meta* borylation proceeds by using a 1,10-phenanthroline.<sup>320</sup> Aryl boronates have been prepared from aryllithium halides or arylmagnesium halides using flow techniques (Sec. 7.D).<sup>321</sup> Heteroarylboronic acids have also been prepared.<sup>322</sup>

Transition metal-catalyzed reactions are an important area of research. The Ir-catalyzed reaction of B<sub>2</sub>Pin<sub>2</sub> and aromatic compounds gave the *ortho* borylation product.<sup>323</sup> The Ru catalyst is known.<sup>324</sup> The BPin product was formed by reaction of sterically congested arenes with B<sub>2</sub>Pin<sub>2</sub> and a Pt *N*-heterocyclic carbene catalyst.<sup>325</sup> The borylation of arenes has used an Fe catalyst,<sup>326</sup> and the Mn-catalyzed reaction of aryl chlorides.<sup>327</sup> A Zn/NHC

system catalyzed the borylation of aryl halides with diboron reagents in the presence of KOMe.<sup>328</sup> The Ni-catalyzed aromatic borylation is known,<sup>329</sup> and the Ni-catalyzed reaction of aryl fluorides and B<sub>2</sub>(nep)<sub>2</sub> (nep = 5,5-dimethyl-1,3,2-dioxaborolane) gave ArB(nep).<sup>330</sup> Aryl ethers and benzylic ethers were converted to the *ipso*-substituted borylation product by reaction with B<sub>2</sub>(nep)<sub>2</sub> or B<sub>2</sub>Pin<sub>2</sub> and a Ni catalyst.<sup>331</sup> Aryl bromides reacted with pinacolborane using an Fe/Cu co-catalyst system to give the aryl boronate.<sup>332</sup> Aryl thioethers reacted with B<sub>2</sub>Pin<sub>2</sub> and a Rh catalyst to give *ipso* substitution and formation of the aryl boronate.<sup>333</sup> Aryl halides reacted with B<sub>2</sub>(NMe<sub>2</sub>)<sub>4</sub> in the presence of a diol and a Pd catalyst to give the aryl boronate.<sup>334</sup>

Aryl nitriles reacted with B<sub>2</sub>Pin<sub>2</sub> with a Rh catalyst and with DABCO at 100 °C to give the corresponding aryl boronate via replacement of the cyano group.<sup>335</sup> *N*-Heterocyclic carbenes were used to convert aryl halides and B<sub>2</sub>Pin<sub>2</sub> to the corresponding arylboron compound.<sup>336</sup> Arylboronic acids were prepared by the treatment of aryl halides with Mg and LiCl, followed by the *in situ* reaction with B(OMe)<sub>3</sub>.<sup>337</sup>

Organotrifluoroborates have been prepared and used in many reactions described for organoboronic acids and esters.<sup>338</sup> Potassium aryltrifluoroborates have been prepared using electrochemical synthesis.<sup>339</sup> Aryl halides or triflates reacted with bis(boronic acid) [(OH)<sub>2</sub>B–B(OH)<sub>2</sub>] in the presence of a Pd catalyst, and subsequent treatment with KHF<sub>2</sub> gave the potassium aryltrifluoroborate.<sup>340</sup> Aryl diazonium tetrafluoroborates reacted with diisopropylaminoborane with either a Ti or a Zr catalyst to give aryl boronates, arylboronic acids, or potassium aryltrifluoroborates.<sup>341</sup>

## E. Carbon Nucleophiles<sup>342</sup>

Some formations of new aryl–carbon bonds from aryl substrates have been considered in **10-57**, **10-68**, **10-77**, and **10-78**.

### 13-8 Cyanation of Aromatic Rings: Aryl Nitriles

Aryl halides react with metal cyanides, often with another transition metal catalyst, to give aryl nitriles (aryl cyanides). The reaction between aryl halides and cuprous cyanide is called the *Rosenmund-von Braun reaction*.<sup>343</sup> Reactivity of the aryl halide is in the order

I > Br > Cl > F, indicating that the S<sub>N</sub>Ar mechanism does not apply.<sup>344</sup> Cyanides alone such as KCN and NaCN do not react with aryl halides, even activated ones, but CuCN catalyzed the reaction in ionic liquids.<sup>345</sup> The reaction has also been done in water using CuCN, a phase-transfer catalyst, and microwave irradiation.<sup>346</sup> L-Proline has been used to promote the reaction.<sup>347</sup> Metal-free methods include conversion of an aromatic compound to the corresponding iminium salt using POCl<sub>3</sub> and DMF, and subsequent reaction with I<sub>2</sub> in aqueous ammonia gave the nitrile.<sup>348</sup>

Aryl nitriles were formed by initial formation of a Grignard reagent from aryl halides, followed by reaction with *N,N*-dimethyl formamide adducts, and then treatment with molecular iodine (I<sub>2</sub>) in aqueous NH<sub>3</sub> at room temperature.<sup>349</sup> Aryl bromides and other aromatic compounds have been converted to aryl nitriles via the corresponding aryllithium and the DMF adduct.<sup>350</sup> The reaction of an aromatic ring with *tert*-butyllithium, followed by reaction with PhOCN (phenyl cyanate) gave the aryl nitrile.<sup>351</sup> Aromatic ethers (ArOR)<sup>352</sup> have been photochemically converted to ArCN.

Alkali cyanides convert aryl halides to nitriles<sup>353</sup> in dipolar aprotic solvents in the presence of Pd,<sup>354</sup> Cu,<sup>355</sup> or Ni<sup>356</sup> complexes. Several different sources of cyanide may be used with the Pd-catalyzed reaction, including Zn(CN)<sub>2</sub>,<sup>357</sup> CuCN,<sup>358</sup> potassium ferricyanide,<sup>359</sup> and KCN.<sup>360</sup> Microwave irradiation has been used to facilitate Pd-catalyzed cyanation.<sup>361</sup> Aryl triflates may be used in aryl cyanation reactions as well as aryl halides.<sup>362</sup> Benzylthiocyanate reacts with boronic acids to give aryl cyanides in a “cyanide-free” reaction, catalyzed by a Pd complex and mediated by Cu(I).<sup>363</sup> The reaction of aryl halides with CuSCN and a Pd catalyst gave the aryl nitrile.<sup>364</sup> Ethyl cyanoacetate has been used for the Pd-catalyzed conversion of aryl halides to aryl nitriles.<sup>365</sup> Aryl halides have been converted to aryl nitriles using K<sub>4</sub>[Fe(CN)<sub>6</sub>] and ZnO-supported Pd nanoparticles as a

unsymmetrical biaryls,<sup>381</sup> and couple to halopyridines to give the arylated pyridine.<sup>382</sup> Aryl Grignard reagents are coupled to arylodonium salts, with ZnCl<sub>2</sub> and a Pd catalyst, to give the biaryl.<sup>383</sup>

A number of methods involving transition metals have been used to prepare unsymmetrical biaryls<sup>384</sup> (see also, **13-10**). The uncatalyzed coupling of aryl halides and metalated aryls (particularly aryllithium reagents) is also known, including cyclization of organolithium reagents to aromatic rings.<sup>385</sup> Noncatalyzed coupling reactions of aryllithium reagents and haloarenes can proceed via the well-known aryne route, but a novel addition–elimination pathway is possible when substituents facilitate a chelation-driven nucleophilic substitution pathway.<sup>386</sup> Such noncatalyzed coupling reactions often proceed with high regioselectivity and high yield.<sup>386</sup> 2-Bromopyridine reacts with pyrrolidine, at 130 °C with microwave irradiation, to give 2-(2-pyrrolidino)pyridine.<sup>387</sup> Aryl iodides undergo homocoupling to give the biaryl by heating with triethylamine in an ionic liquid.<sup>388</sup> The arylation of anilines has been reported using flow conditions (Sec. 7.D).<sup>389</sup>

Transition metal catalysts have been used to effect the aryl coupling. Aryl halides undergo homocoupling to give the biaryl with a Pd catalyst<sup>390</sup> or a Ni catalyst.<sup>391</sup> Homocoupling occurs with aryl triflates under electrolysis conditions with a Pd catalyst.<sup>392</sup> A recyclable Pd catalyst for use in ionic liquids has been developed.<sup>393</sup> Thiophene derivatives,<sup>394</sup> pyrrole,<sup>395</sup> azoles,<sup>396</sup> quinoline,<sup>397</sup> and indolizine<sup>398</sup> have been coupled to aryl halides using a Pd catalyst. A related reaction is the Pd-catalyzed decarboxylative coupling of arylcarboxylic acids with aryl iodides.<sup>399</sup>

Palladium catalysts are often used in conjunction with another metal compound or complex. Arylgermanium compounds are coupled with aryl iodides using tetrabutylammonium fluoride and a Pd catalyst.<sup>400</sup> Homocoupling of triphenylbismuth is known,<sup>401</sup> as is the coupling of arylbismuth reagents to arylodonium salts<sup>402</sup> and to aryltin compounds<sup>403</sup> with Pd compounds or complexes. Aryl triflates were coupled to triphenylbismuth using

a Pd catalyst.<sup>404</sup> Specialized arylbismuth compounds have been used with a Pd catalyst to convert aryl chlorides to biaryls.<sup>405</sup> An aryltin–aryl halide coupling has been done in ionic liquids.<sup>406</sup>

The homocoupling of arylzinc iodides, with a Pd catalyst, has been reported.<sup>407</sup> In a related reaction, arylsulfonyl chlorides also react with ArSnBu<sub>3</sub>, with Pd and Cu catalysts, to give the biaryl.<sup>408</sup> Biaryls were prepared by heating thiophenol and ArZnCl with MeZnCl, Mg<sup>2+</sup>, and Li<sup>+</sup>.<sup>409</sup> Aryl halides were cross coupled with arylmagnesium bromides to give the biaryl, catalyzed by *N*-heterocyclic carbene nickel complexes.<sup>410</sup>

OS VI, 916; VIII, 430, 586; X, 9, 448.

### 13-10 Homo-coupling of Aryl Halides: The Ullmann Reaction

The homocoupling of aryl halides with copper is called the *Ullmann reaction*.<sup>411</sup> The reaction is clearly related to **13-9**, but involves aryl Cu intermediates. The reaction is of broad scope and has been used to prepare many symmetrical and unsymmetrical biaryls.<sup>412</sup> There are three possible products when a mixture of two different aryl halides is used, but often only one is obtained. The best leaving group is iodo, and the reaction is most often done on aryl iodides, but bromides, chlorides, and even thiocyanates have been used. New ligands have been developed to promote the reaction, including an air-stable diazaphospholane ligand.<sup>413</sup> Intramolecular reactions are known.<sup>414</sup> The coupling reaction can be applied to heterocyclic compounds.<sup>415</sup> Ullmann-type couplings have been promoted by potassium *tert*-butoxide.<sup>416</sup>

The effects of other groups on the ring are not easily predicted. The nitro group is strongly activating, but only in the *ortho* (not *meta* or *para*) position.<sup>417</sup> Both R and OR groups activate in all positions. Not only do OH, NH<sub>2</sub>, NHR, and NHCOR inhibit the reaction, as would be expected for aromatic nucleophilic substitution. However, so do CO<sub>2</sub>H (but not CO<sub>2</sub>R), SO<sub>2</sub>NH<sub>2</sub>, and similar groups, for which the reaction fails completely by causing side reactions.

<sup>417</sup> Forrest, J. *J. Chem. Soc.* **1960**, 592.

The mechanism is not known with certainty. It seems likely that it is basically a two-step process, similar to that of the *Wurtz reaction* (**10-56**), and which can be represented schematically by:

Organocopper compounds have been trapped by coordination with organic bases.<sup>418</sup> In addition, aryl copper compounds (ArCu) have been independently prepared and shown to give biaryls (Ar–Ar') when treated with aryl iodides Ar'I.<sup>419</sup> A similar reaction has been used for ring closure.<sup>420</sup>

A modified Cu(0)–Cu(I) mediated reaction that gave biaryls was reported.<sup>421</sup> *N*-phenylpicolinamide (NPPA) was shown to be an effective ligand for Ullmann-type homo-coupling reactions of aryl iodides and bromides to give the biaryl derivative.<sup>422</sup> A green procedure using a reusable Pd/ZrO<sub>2</sub> catalyst has been reported.<sup>423</sup> A microwave-assisted reaction has been reported in alkaline water.<sup>424</sup>

An alternative to the Ullmann method is the use of Ni complexes.<sup>425</sup> Aryl halides, ArX, can also be converted to Ar–Ar'<sup>426</sup> by treatment with activated Ni metal,<sup>427</sup> with Zn and Ni complexes,<sup>428</sup> and in an electrochemical process catalyzed by a Ni complex.<sup>429</sup> An asymmetric Ullmann reaction has been reported.<sup>430</sup>

OS III, 339; V, 1120.

### 13-11 Coupling of Aryl Compounds and Alkenyl Compounds With Arylboronic acid Derivatives

Arylboronic acids, ArB(OH)<sub>2</sub> (**12-27**),<sup>431</sup> are coupled to aryl halides using a Pd catalyst to give the biaryl<sup>432</sup> in what is called *Suzuki coupling* (or *Suzuki-Miyaura coupling*).<sup>433</sup>

Aryl triflates react with arylboronic acids,<sup>434,435</sup> or with organoboranes,<sup>436</sup> in the presence of a Pd catalyst.<sup>437</sup> Even hindered boronic acids give good yields of the coupled product.<sup>438</sup> Homocoupling of arylboronic acids has been reported.<sup>439</sup> Some aromatic compounds are so reactive that a catalyst may not be required. Arylation of heterocycles with unreactive and hindered aryl chlorides<sup>440</sup> or aryl bromides<sup>441</sup> have been reported; these reactions use a Pd catalyst. Biocatalysis has been used to prepare biaryls.<sup>442</sup> Decarboxylative oxidative cross coupling has been applied to biaryl synthesis.<sup>443</sup> The intramolecular reaction is well known.<sup>444</sup> Radical arylation reactions are known.<sup>445</sup> Aryl boronates also react with  $\pi$ -allyl palladium complexes to form the alkylated aromatic compound.<sup>446</sup> Transition metal-free cross-coupling reactions have been reported.<sup>447</sup> Chemoselective cross-coupling strategies have been explored.<sup>448</sup>

Different conditions (including additives and solvent) for the reaction have been reported,<sup>449</sup> often focusing on the catalyst<sup>450</sup> or the ligand.<sup>451</sup> Phosphine-free conditions<sup>452</sup> and ligand-free conditions<sup>453</sup> have been developed. A ligand-free In-catalyzed

Alkyl groups may be coupled to aryls, as in the Pd-catalyzed reaction of arylboronic acids with benzylic carbonates.<sup>495</sup> Alkyl/alkyl Suzuki reactions using alkyl chlorides are known, using a Ni catalyst,<sup>496</sup> and asymmetric reactions are known.<sup>497</sup> Arylboronic acids also couple with alkyl halides using either a Pd<sup>498</sup> or a Ni catalyst.<sup>499</sup> Conversely, arylboronic acids can be coupled to aliphatic halides.<sup>500</sup> Arylboronic acids can be coupled to allylic alcohols as well.<sup>501</sup> Benzylic phosphonates have also been used.<sup>502</sup> Double Suzuki coupling reactions are known.<sup>503</sup>

Since many biaryls are chiral due to atropisomerism (Sec. 4.C, category 5), the use of a chiral catalyst, and/or a chiral ligand can lead to enantioselectivity in the Suzuki coupling.<sup>504</sup> The asymmetric synthesis of axially chiral heterobiaryls is known.<sup>505</sup> The choice of ligand has important effects on the stereochemistry.<sup>506</sup> The chemoselective and enantioselective cross coupling of benzylic organoboronic esters has been reported.<sup>507</sup>

For a mechanistic viewpoint,<sup>508</sup> the Suzuki coupling proceeds via oxidative addition of areneboronic acids to give a Pd species, followed by 1,2-arene migration to an electron-deficient Pd atom, eventually leading to very fast reductive elimination to afford biaryls.<sup>509</sup> This mechanism is discussed in detail.<sup>510</sup> Several intermediates of the oxidative coupling

and alkoxymethyltrifluoroborates have been coupled to heteroaryls.<sup>555</sup> Potassium Boc-protected aminomethyltrifluoroborate has been coupled to aryl and heteroaryl halides.<sup>556</sup> Photoredox coupling of trifluoroborates and aryl bromides has been reported using flow conditions (Sec. 7.D).<sup>557</sup> Trifluoro(*N*-methylheteroaryl)borates<sup>558</sup> and potassium 2-pyridyl trifluoroborates<sup>559</sup> have also been used. Suzuki coupling with trifluoroborates has also been done using microwave irradiation<sup>560</sup> and in water.<sup>561</sup> Aryl tellurides have been used in this reaction.<sup>562</sup> A Pd-catalyzed reaction with enamino ketones, mediated by Cu(II) salts, led to coupling to give the aryl derivative.<sup>563</sup> Ruthenium catalysts have also been used.<sup>564</sup>

OS 75, 53, 61.

The coupling reactions of alkylboronic acids are covered in 13-17.

### 13-12 Alkylation of Aryl Compounds

Alkyl halides or alkyl sulfonate esters react with aryl organometallics to give the corresponding arene, sometimes directly but often using a transition metal catalyst. *Grignard reagents* couple with aryl halides without a catalyst, by the benzyne mechanism,<sup>565</sup> but metal-catalyzed reactions are known. Typical catalysts include Fe,<sup>566</sup> Ni,<sup>567</sup> Co,<sup>568</sup> Ti,<sup>569</sup> and Pd.<sup>570</sup> Benzene, naphthalene, and phenanthrene have been alkylated with alkyllithium reagents, although the usual reaction with these reagents is 12-22,<sup>571</sup> and *Grignard reagents* have been used to alkylate naphthalene.<sup>572</sup> The addition-elimination mechanism apparently applies in these cases. Formation of the *ortho* arylmagnesium compound has been accomplished with bases of the form (R<sub>2</sub>N)<sub>2</sub>Mg.<sup>573</sup> It is noted that the transition metal-free alkylation of pyridines has been reported.<sup>574</sup> The transition metal-free cross coupling of allylic bromides with aryl- and vinylboronic acids has been reported.<sup>575</sup>

The reaction of an aromatic ring with an organolithium reagent can give H–Li exchange to form an aryllithium.<sup>576</sup> This reaction tends to be slow if there are activating substituents on the aryl halide or in the absence of diamine additives.<sup>577</sup> When heteroatom substituents are present on the aromatic ring, however, the reaction is facile and the Li goes into the 2 position.<sup>578</sup> This regioselectivity can be quite valuable synthetically, and is now known as *directed ortho metalation*<sup>579</sup> (see 10-57). The reaction occurs by an addition–elimination mechanism and the adduct can be isolated.<sup>580</sup> Upon heating of the adduct, elimination of LiH occurs and an alkylated product is obtained. The alkylation of heterocyclic nitrogen compounds<sup>581</sup> with aryllithium reagents is called *Ziegler alkylation*. Note that H–Li exchange can be faster than Cl–Li exchange. The reaction of *N*-triisopropylsilyl indole with *tert*-butyllithium and then iodomethane gave the 3-methyl derivative.<sup>582</sup> Heteroaromatic compounds can be alkylated. Pyrrole, for example, reacts with an allylic halide and zinc to give primarily the 3-substituted pyrrole.<sup>583</sup>

With TMEDA/*n*-butyllithium-mediated arene lithiation reactions, the viability of directive effects (complex-induced proximate effects) has been questioned,<sup>584</sup> although it is not clear if this extends to other systems (particularly when there is a strong coordinating group such as carbamate).<sup>585</sup> The 2 position is much more acidic than the 3 position (see Table 8.1), but a negative charge at C-3 is in a more favorable position to be stabilized by the Li<sup>+</sup>. Lithiation reactions do not necessarily rely on a complex-induced proximity effect.<sup>586</sup>

The metal-catalyzed reaction of aryl derivatives leads to alkylated aromatic compounds.<sup>587</sup> The coupling of alkyl substrates and alkene substrates using transition metal catalysis is also known. The transition metal-catalyzed  $\alpha$ -arylation reaction is known.<sup>588</sup> The trifluoromethylation of aryl and heteroaryl halides has been reviewed.<sup>589</sup>

The development of transition metal-catalyzed reactions is a very active area of research, and a sampling of current work follows. The Ni-catalyzed cross-coupling reaction of Grignard reagents such as butylmagnesium bromide and an alkyl or aryl halide such as

chlorobenzene to give butylbenzene,<sup>590</sup> is called *Kumada coupling*.<sup>591</sup> Pd catalysts have also been used.

The Ni-catalyzed reaction of alkyl Grignard reagents with aryl bromides or triflates has also been reported.<sup>592</sup> The Ni-catalyzed reaction of aryl, heteroaryl, or vinyl chlorides gave the coupling product.<sup>593</sup> Alkenyl halides were coupled to Grignard reagents using a Pd catalyst.<sup>594</sup> Both the intermolecular and the intramolecular Fe-mediated cross coupling of alkyl chlorides and aryl bromides has been reported.<sup>595</sup> An Fe-catalyzed Kumada cross-coupling reaction has been reported using flow conditions (Sec. 7.D).<sup>596</sup> An asymmetric Kumada cross-coupling reaction for the enantioselective arylation of  $\alpha$ -bromo esters catalyzed by a Co-bis(oxazoline) complex gave chiral  $\alpha$ -aryl alkanolic esters with excellent enantioselectivity.<sup>597</sup>

There are many current examples of Pd-catalyzed reactions. The lithium enolate anion of an ester was coupled to an aryl halide using a Pd catalyst.<sup>598</sup> Ketones can be coupled to aryl triflates, in the presence of a Pd catalyst, and with good enantioselectivity.<sup>599</sup> Aryl halides reacted with acetone to give  $\alpha$ -aryl acetone in the presence of a Pd catalyst.<sup>600</sup> Aryl halides led to  $\beta$ -arylation of simple ketones using a Pd catalyst, in the presence of AgTFA.<sup>601</sup> The Pd-catalyzed  $\alpha$ -arylation of  $\alpha$ -fluoro ketones has been reported, with high enantioselectivity.<sup>602</sup>  $\alpha$ -Allyl acetoxy cyclic ketones reacted with  $\alpha$ -aryl derivatives, and subsequent treatment with Meldrum's acid and a Pd catalyst gave the tertiary  $\alpha$ -aryl ketones.<sup>603</sup> Indium homoenolates<sup>604</sup> reacted with aryl halides to give  $\beta$ -aryl ketones in the presence of a Pd

catalyst.<sup>605</sup> The direct reaction of a ketone, a vinyl halide, sodium *tert*-butoxide, and a Pd catalyst also gave the  $\alpha$ -vinyl ketone.<sup>606</sup>

Organolithium reagents are coupled to aryl bromides in the presence of a Ni catalyst,<sup>607</sup> as are arylzinc compounds.<sup>608</sup> The mechanism of the Ni-catalyzed cross-coupling reaction of aryl halides and alkyl halides has been examined.<sup>609</sup> The Ni-catalyzed cross coupling of heteroaryl iodides and  $\alpha$ -chloronitriles is known.<sup>610</sup> Aryl halides reacted with secondary alkyl bromides or with allylic acetates, in the presence of Zn and a Ni catalyst, to give the alkylated aryl compound.<sup>611</sup> Alkyl halides are coupled to aryl halides using a Ni-catalyzed reductive cross coupling.<sup>612</sup> The Ni-catalyzed coupling of aryl bromides and tertiary alkyl halides has been reported.<sup>613</sup> Aryl halides reacted with methyl tosylate using a Ni catalyst.<sup>614</sup> The Ni-catalyzed  $\alpha$ -arylation of ketones has been reported using phenol derivatives.<sup>615</sup> The Ni-catalyzed trifluoromethylation of arylboronic acids has been reported.<sup>616</sup>

The decarboxylative coupling of simple alkyl carboxylic acids with aryl zinc reagents, using a Ni catalyst, has been reported.<sup>617</sup> An electrochemical method for reducing catalytic Ni complexes allowed the coupling of aryl bromides with alkyl bromides to give the arene.<sup>618</sup> Aryl halides and alkyl halides gave the photo-coupled product in the presence of a Ni catalyst, an Ir photosensitizer, and an amine electron donor.<sup>619</sup> The Ni-catalyzed synthesis of  $\alpha$ -aryl nitriles was reported by the cross coupling of  $\alpha$ -bromonitriles and arylboronic acids.<sup>620</sup> Vinylic and aryl halides can be used to vinylate or arylate carboxylic esters (but not ketones) by the use of NiBr<sub>2</sub> as a catalyst.<sup>621</sup>

The Pd-catalyzed coupling of arylboronic acids with alkyl  $\alpha$ -bromoacetates gave aryl acetic acid esters.<sup>622</sup> The Pd-catalyzed 2-alkylation reaction of N-H indoles relies on a norbornene-mediated cascade activation of the indole C-H.<sup>623</sup> The Zn-mediated, Pd-catalyzed coupling of benzylic halides with heteroaryl halides gave arylheteroarylmethanes in aqueous media.<sup>624</sup> The Pd-catalyzed reaction of aryl halides and cyclic alkyl halides has

been reported using a zinc mediator and octanoic acid as a surfactant.<sup>625</sup> Alkylzinc reagents were coupled to heteroaryl halides using a Pd catalyst.<sup>626</sup> Organozinc compounds, available by reaction of an alkyl halide and zinc metal, are coupled to aryl halides using a Pd catalyst.<sup>627</sup> Specialized alkyl In complexes have been used with a Pd catalyst to give arenes.<sup>628</sup> The intramolecular alkylation of aryl and heteroaryl amine derivatives using a Pd catalyst gave the corresponding carbocycle and/or heterocycle.<sup>629</sup>

Copper compounds are important in these coupling reactions. The cross coupling of organoboron compounds with primary alkyl halides was catalyzed by Cu catalysts. Arylmagnesium bromide with Cu(acac)<sub>2</sub> reacts in an S<sub>N</sub>2' reaction, displacing a pyridyl ester unit to give an allylic aryl compound.<sup>630</sup> The Cu–N-heterocyclic carbene-catalyzed allylation and alkenylation of heteroarenes has been reported.<sup>631</sup> The enantioselective α-arylation of aldehydes has been reported using diaryliodonium salts and a combination of Cu and organic catalysts.<sup>632</sup> The Cu-mediated trifluoromethylation of aryl and heteroaryl boronic acids with F<sub>3</sub>C<sup>−</sup> has been reported, in the presence of oxygen.<sup>633</sup> Silyl enol ethers react with diaryliodonium triflates in the presence of a Cu(I)-bisoxazoline catalyst, to give the α-aryl ester or amide.<sup>634</sup>

Cobalt compounds<sup>635</sup> and Fe compounds<sup>636</sup> have been used to catalyze aryl/alkyl coupling. Alkyl halides are coupled to alkenes to form substituted alkenes using a Co catalyst, promoted by Me<sub>3</sub>SiCH<sub>2</sub>MgCl.<sup>637</sup> Alkylation requires that the alkyl group lacks a β-hydrogen, and the reaction is successful for the introduction of methyl, benzyl, and neopentyl groups.<sup>638</sup> Cobalt has been used to catalyze aryl/allyl cross-coupling reactions.<sup>639</sup> The Co-catalyzed intramolecular cross coupling of alkyl iodides with alkenes upon irradiation with visible light in the presence of a tertiary amine base gave alkylated alkenes.<sup>640</sup> Cycloalkyl iodides were coupled to alkynyl or aryl or heteroaryl Grignard reagents with a Co catalyst.<sup>641</sup> The C4 alkylation of pyridines was reported using a Co catalyst.<sup>642</sup> Alkyl Grignard reagents were coupled to aryl sulfamates or tosylates using an Fe catalyst.<sup>643</sup> The Fe-catalyzed reaction of alkyl, benzyl, or allyl halides led to coupling with arylboronic esters.<sup>644</sup> Potassium vinyltrifluoroborates were trifluoromethylated using an Fe catalyst.<sup>645</sup>

### 13-13 Aryl-Alkene Coupling: The Heck Reaction

Arylation of alkenes,<sup>656</sup> catalyzed by an *in situ*-generated Pd complex, has become an important reaction in organic chemistry.<sup>657</sup> The Pd-catalyzed aryl-alkene coupling reaction is known as *the Heck reaction*.<sup>658</sup> Mizoroki had earlier described the coupling between iodobenzene and styrene to form stilbene in methanol at 120 °C in the presence

of potassium acetate and a PdCl<sub>2</sub> catalyst,<sup>659</sup> leading many to call this the *Mizoroki-Heck reaction*. The reaction works best with aryl iodides, but conditions are available for aryl bromides and aryl chlorides.<sup>660</sup> Aryldiazonium salts (see **13-25** and **13-27**) have also been used.<sup>661</sup> Activated aromatic compounds couple readily<sup>662</sup> but unactivated aromatic compounds often require special reaction conditions. The Heck reaction can be done with heterocyclic compounds,<sup>663</sup> and heteroaryl halides can be used in the coupling reaction.<sup>664</sup>

Phosphine-free catalysts,<sup>665</sup> halogen-free reactions,<sup>666</sup> and base-free reactions<sup>667</sup> have been developed for the Heck reaction. Ligand-free and base-free Heck reactions with heteroaryl halides have been reported.<sup>668</sup> Improvements to the Pd catalyst system are constantly being reported,<sup>669</sup> including polymer-supported catalysts,<sup>670</sup> silica-supported catalysts,<sup>671</sup> and recoverable catalysts.<sup>672</sup>

The Heck reaction can be done in aqueous media,<sup>673</sup> in polyethylene glycol,<sup>674</sup> in supercritical CO<sub>2</sub> (Sec. 9.D.ii),<sup>675</sup> and in ionic liquids.<sup>676</sup> Heck reactions have been reported using flow conditions (Sec. 7.D)<sup>677</sup> and ball-milling techniques have been used

(Sec.7.E).<sup>678</sup> The reaction has been done on solid support,<sup>679</sup> on a reverse-phase silica support,<sup>680</sup> and using microwave irradiation.<sup>681</sup> A noncatalytic reaction was reported using supercritical water.<sup>682</sup> The effects of high pressure have been studied.<sup>683</sup> Aryl halides were coupled photochemically with styrene derivatives, in the presence of 18-crown-6, to give the aryl alkene. This reaction was transition metal-free and solvent-free.<sup>684</sup>

Control of regiochemistry is a serious problem in the coupling to unsymmetrical alkenes.<sup>685</sup> The presence of an auxiliary coordinating group,<sup>686</sup> or the use of special ligands and acrylate or styrene as substrates,<sup>687</sup> leads to improved regioselectivity. Steric effects are thought to control regioselectivity,<sup>688</sup> but electronic influences have also been proposed.<sup>689</sup> Steric effects generally improve 1,2-selectivity, and electronic effects can be used to favor 1,2- or 2,1-selectivity.<sup>690</sup> Neighboring group effects play a role in the Heck reaction.<sup>691</sup> Migration of the double bond is a problem in some cases, and reaction conditions play a significant role in such migrations.<sup>692</sup> Because the product is formed by an elimination step, double bond migration can occur with suitable substrates, resulting in allylic rearrangement, as in the reaction of cyclopentene and iodobenzene to give 3-phenylcyclopentene.<sup>693</sup> It has been reported that double bond isomerization can be suppressed in intramolecular Heck reactions done in supercritical CO<sub>2</sub> (Sec. 9.D.ii).<sup>694</sup> Intramolecular Heck reactions are increasingly important.<sup>695</sup> A silane-tethered, intramolecular Heck reaction is known.<sup>696</sup>

The Pd-catalyzed reactions are usually stereospecific,<sup>697</sup> yielding products expected from *syn* addition followed by *syn* elimination.<sup>698</sup> Asymmetric Heck reactions are

known,<sup>699</sup> including asymmetric intramolecular Heck reactions.<sup>700</sup> The intermolecular dehydrogenative Heck arylation of trisubstituted alkenes used a Pd catalyst and was used to construct quaternary stereocenters.<sup>701</sup>

In the conventionally accepted reaction mechanism,<sup>702</sup> which is shown,<sup>703</sup> a four-coordinate aryl-Pd(II) intermediate (a palladacycle)<sup>704</sup> is formed by oxidative addition of the aryl halide to a Pd(0) complex prior to alkene addition.<sup>705</sup>

This description suggests that cleavage of the dimeric precursor complex, reduction of Pd<sup>2+</sup>, and ligand dissociation combine to give a viable catalytic species.<sup>706</sup>  $\sigma$ -Alkyl Pd(II) intermediates are thought to be involved.<sup>707</sup> An analysis of reaction kinetics under dry conditions was reported.<sup>700</sup> In this study, the mechanism requires a first-order dependence on alkene concentration, and anomalous kinetics may be observed when the rate-limiting step is not directly on the catalytic cycle.<sup>700</sup> The mechanism requires a proton abstraction step, and there are substituent effects for this step.<sup>708</sup> A mechanistic study has been reported for the Pd-catalyzed decarboxylative reaction of alkenes and arylcarboxylic acids.<sup>709</sup> The

kinetics and mechanism of the Heck reaction promoted by a C–N palladacycle have been studied.<sup>710</sup> The mechanistic implications of asymmetric Heck reactions have been examined.<sup>711</sup> Mechanistic studies of the Ru-catalyzed<sup>712</sup> and the Pd-catalyzed<sup>713</sup> reactions of arenes and alkenes to give styryl derivatives have been reported.

Ethylene is the most reactive alkene, and increasing substitution lowers the reactivity. Coupling generally takes place at the less highly substituted side of the double bond.<sup>714</sup> Both electron-deficient alkenes, such as acrylates,<sup>715</sup> and electron-rich alkenes<sup>716</sup> undergo the Heck reaction. The substrate can be an unactivated alkene,<sup>717</sup> and the alkene can contain a variety of functional groups, such as esters, ether,<sup>718</sup> enol ethers,<sup>719</sup> enamides,<sup>720</sup> and carboxyl, phenolic, or cyano groups.<sup>721</sup> Silyl-Heck reactions are known.<sup>722</sup> The aryl halide or aryl triflate can be coupled to dienes,<sup>723</sup> allenes,<sup>724</sup> allylic acetates,<sup>725</sup> allylic silanes,<sup>726</sup> allylic amines,<sup>727</sup> and vinyl phosphonate esters.<sup>728</sup> Aryliodonium salts can be coupled to conjugated alkenes in a Heck-like manner using a Pd catalyst.<sup>729</sup> Heck-type reactions have been reported with imines.<sup>730</sup> The *para*-selective alkenylation of anilines has been reported.<sup>731</sup> The ligand acridine promoted a biomimetic aerobic oxidative cross coupling between arenes and alkenes under ambient oxygen pressure; this reaction gave alkenylarenes.<sup>732</sup> Heck reactions have been an important part of domino reactions.<sup>733</sup> The Pd-catalyzed arylation of  $\alpha,\beta$ -unsaturated Weinreb amides with arenes or aryl iodides gave  $\beta$ -aryl- $\alpha,\beta$ -unsaturated Weinreb amides.<sup>734</sup> Aryl triflates were coupled to alkenes at the

internal position using a Pd catalyst and a ferrocenyl ligand.<sup>735</sup> The cross coupling of indoles and conjugated alkenes using a Pd catalyst has been reported using flow conditions (Sec. 7.D).<sup>736</sup> There are a number of variations of this reaction, including the use of transition metal catalysts other than Pd. Catalysts used in this reaction include complexes with Rh,<sup>737</sup> Co,<sup>738</sup> Ru,<sup>739</sup> Ni,<sup>740</sup> and Fe.<sup>741</sup> Aryl halides have been coupled to allenyltin compounds ( $C=C=C-SnR_3$ ).<sup>742</sup>

Very many reactions catalyzed by various transition metals have been reported. The Ni-catalyzed reaction of alkenes with aryl sulfonates or chlorides is known.<sup>743</sup> Aryl halides reacted with Mn and a Co catalyst; subsequent treatment with vinyl halides gave the stilbene derivative.<sup>744</sup> Aryl pivalates were coupled to alkenes using a Ni(dppf) catalyst generated *in situ*.<sup>745</sup> Catalytic cationic Ru complexes with  $Cu(OAc)_2$  facilitated the coupling of benzoate derivatives and conjugated esters to give the *ortho* aryl-alkene coupling product.<sup>746</sup> The Rh-catalyzed coupling of phenols and alkenes to give the *ortho*-alkenyl product has been reported.<sup>747</sup> Arylaluminum reagents reacted with alkyl alkenes, in the presence of a ketone and a Rh catalyst, and gave give stilbene-type derivatives.<sup>748</sup> Aromatic compounds reacted with styrene-type derivatives in the presence of  $Cu(OAc)_2$  and a Rh catalyst to give diaryl alkenes.<sup>749</sup> The Rh-catalyzed reaction of anthracene-9-carboxylic acid derivatives and electron-deficient alkenes in the presence of  $Cu(OAc)_2$  has been reported.<sup>750</sup> 2-Alkenylfurans were prepared using a Bi catalyst.<sup>751</sup> The influence of trace metals on Mn-catalyzed cross-coupling reactions has been reported.<sup>752</sup>

Potassium vinyltrifluoroborates can be coupled to aryl halides in Heck-like coupling reactions.<sup>753</sup> Likewise, the reaction of aryltrifluoroborates with vinyl halides, in the presence of a Pd catalyst, leads to the aryl alkene.<sup>754</sup> In a related reaction, alkyltrifluoroborates react with aryl halides in the presence of a Pd catalyst and a Rh catalyst.<sup>755</sup>

## 13-14 Aryl-Alkyne Coupling Reactions

When aryl halides react with copper acetylides to give 1-aryl alkynes, the reaction is known as *Stephens-Castro coupling*.<sup>756</sup> Both aliphatic and aromatic substituents can be attached to the alkyne unit, and a variety of aryl iodides have been used. Coupling of the alkynes to form a diyne (see **14-16**) can be a problem in some cases, although the aryl-alkyne coupling usually predominates.<sup>757</sup>

A Pd-catalyzed reaction of aryl halides with a terminal alkyne to give 1-aryl alkynes is called *Sonogashira coupling*.<sup>758</sup> Terminal aryl alkynes react with aryl iodides and Pd(0)<sup>759</sup> to give the corresponding diaryl alkyne,<sup>760</sup> but monoalkynes are easily prepared.<sup>761</sup> Aryl iodides are more reactive than aryl fluorides.<sup>762</sup> Alkynes can be coupled to heteroaromatic compounds.<sup>763</sup> As with all of the metal-catalyzed reactions in this chapter, work has been done to vary reaction conditions, including the catalyst,<sup>764</sup> the ligand,<sup>765</sup> the solvent, and additives.<sup>766</sup> The reaction has been done using flow conditions (Sec. 7.D).<sup>767</sup> Copper catalysts have been used in water media,<sup>768</sup> and the reaction has been done in water

without Cu.<sup>769</sup> The coupling has been done in ionic liquids.<sup>770</sup> There are copper-free<sup>771</sup> and ligand-free variations.<sup>772</sup> Transition metal-free coupling<sup>773</sup> has been reported using 2,2,6,6-tetramethylpiperidine-*N*-oxyl radical as an oxidant.<sup>774</sup> Microwave irradiation is an important tool in this reaction.<sup>775</sup> Sonogashira coupling was reported on microbeads,<sup>776</sup> with nanoparticulate Ni powder,<sup>777</sup> and the aryl iodide was tethered to a polymer for a solid-state reaction.<sup>778</sup> The *N*-heterocyclic carbene Cu and Pd complex-catalyzed reactions have been reported.<sup>779</sup> Arylsulfonium salts have been used.<sup>780</sup>

There are variations of the Sonogashira reaction that use other metals as catalysts or co-catalysts. A Pd-free reaction is known, using Cu complexes as the catalyst.<sup>781</sup> Other metals used as catalysts include Zn,<sup>782</sup> Mn,<sup>783</sup> In,<sup>784</sup> Ag,<sup>785</sup> Au,<sup>786</sup> Rh,<sup>787</sup> Ni,<sup>788</sup> Fe,<sup>789</sup> alkynyl tin,<sup>790</sup> and alkynyl Au compounds.<sup>791</sup>

Lithium alkynyl trimethylborates are coupled to aryl chlorides as well.<sup>792</sup> Terminal alkynes are coupled to acylpyridinium salts in the presence of a Cu catalyst, giving a product

halides generally give good results.<sup>808</sup> Treatment of propanone with an aryl halide in liquid ammonia containing Na or K, for example, gave 1-arylpropan-2-one and 1-arylpropan-2-ol.<sup>809</sup> When the solution is irradiated with near-UV light, and the Na or K is omitted, the same products are obtained, but in different proportions.<sup>810</sup> In either case, other leaving groups can be used instead of halogens (e.g.,  $\text{NR}_3^+$ ,  $\text{SAr}$ ) and the mechanism is the  $\text{S}_{\text{RN}}1$  mechanism. *N*-Heterocyclic carbene ligands in the presence of alkoxide bases leads to coupling of ketones and aryl halides at the  $\alpha$  position of the ketone.<sup>811</sup> The reaction can also take place without an added initiator.  $\beta$ -Keto esters were coupled to aryl fluorides using CsOH and a chiral quaternary ammonium salt, leading to the aryl substitution product with good enantioselectivity.<sup>812</sup>

Even unactivated aryl halides can be employed if the reaction is carried out in the presence of a strong base, such as  $\text{NaNH}_2$ <sup>813</sup> or LDA. Compounds of the form  $\text{ZCH}_2\text{Z}'$ , and even simple ketones<sup>814</sup> or carboxylic esters, have been arylated in this manner. The reaction with unactivated halides proceeds by the benzyne mechanism and represents a method for extending the malonic ester (and similar) syntheses to aromatic compounds. The base performs two functions: (i) it removes a proton from  $\text{ZCH}_2\text{Z}'$  and (ii) it catalyzes the benzyne mechanism. The reaction has been used for ring closure to prepare an indole.<sup>815</sup>

Palladium catalysts have been developed for the  $\alpha$ -arylation of ketones<sup>816</sup> and the  $\alpha$ -arylation of esters.<sup>817</sup> Malonate esters are coupled to unactivated aryl halides using a Pd catalyst.<sup>818</sup> The coupling of active methylene compounds and unactivated aryl halides can also be done with copper halide catalysts<sup>119</sup> (the *Hurtley reaction*).<sup>819</sup> Similar coupling was accomplished with  $\text{CH}_2(\text{CN})_2$  and a Ni catalyst.<sup>820</sup> Malonic esters and  $\beta$ -keto esters can be arylated at the  $\alpha$  carbon in high yields by treatment with Bi reagents.<sup>821</sup> Arylzinc reagents<sup>822</sup> and iron(II) salts have also been used to initiate this reaction.<sup>823</sup> *Bis*-sulfones,

<sup>808</sup> There is evidence for both the  $\text{S}_{\text{N}}\text{Ar}$  mechanism (see Leffek, K.T.; Matinopoulos-Scordou, A.E. *Can. J. Chem.* **1977**, *55*, 2656, 2664) and the  $\text{S}_{\text{RN}}1$  mechanism (see Zhang, X.; Yang, D.; Liu, Y.; Chen, W.; Cheng, J. *Res. Chem. Intermed.* **1989**, *11*, 281).

$\text{CH}_2(\text{SO}_2\text{Ar})_2$ , reacted with aryl halides in the presence of a Pd catalyst.<sup>824</sup> A variation of  $\alpha$ -arylation reacts  $\alpha$ -halocarbonyl compounds with arylboronic acids in the presence of a Ni catalyst.<sup>825</sup>

The carbanions with a chlorine at the carbanionic carbon react with aromatic nitro compounds uses carbanion nucleophiles to give the *ortho*-substitution product.<sup>826</sup>

This type of process is called *vicarious nucleophilic substitution of hydrogen*.<sup>827</sup> The Z group is electron withdrawing (e.g.,  $\text{SO}_2\text{R}$ ,  $\text{SO}_2\text{OR}$ ,  $\text{SO}_2\text{NR}_2$ ,  $\text{COOR}$ , or  $\text{CN}$ ); it stabilizes the negative charge. The carbanion attacks the activated ring *ortho* or *para* to the nitro group.<sup>828</sup> The presence of the adjacent Cl allows the hydrogen to be replaced, so, Cl is a “vicarious” leaving group. Other leaving groups have been used (e.g., OMe, SPh), but Cl is generally the best. The reaction is also successful for di- and trinitro compounds, for nitronaphthalenes,<sup>829</sup> and for many nitro heterocycles;  $\text{Z}-\text{CR}-\text{Cl}$  may also be used.<sup>830</sup>

Enolate ions of ketones react with aryl iodides in the dark.<sup>831</sup> It has been suggested<sup>832</sup> that initiation takes place by formation of an  $\alpha$ -keto radical, so this reaction proceeds by an SET mechanism (Sec. 10.B). The photo-stimulated reaction has also been used for ring closure.<sup>833</sup> In certain instances of the intermolecular reaction there is evidence that the leaving group exerts an influence on the product ratios, even when it has already departed at the time that product selection takes place.<sup>834</sup>

The reaction of aryl halides with the enolate anions of ketones and aldehydes, generated *in situ* by addition of a suitable base, can be accomplished by treatment with a Pd catalyst.<sup>835</sup> Nickel-catalyzed  $\alpha$ -arylation of ketone enolate anions is also known.<sup>836</sup> The enolate anions of lactams will react with aryl halides in the presence of a Pd catalyst via the 3-aryl lactam.<sup>837</sup> When the enolate anion of a ketone is generated in the presence of a Pd catalyst and a chiral phosphine ligand, the  $\alpha$ -aryl ketone is formed with good enantioselectivity.<sup>838</sup>

### 13-16 Conversion of Aryl Substrates to Carboxylic Acids, Their Derivatives, Aldehydes, and Ketones<sup>839</sup>

Carbonylation of aryl halides<sup>840</sup> and aryl triflates<sup>841</sup> with carbon monoxide, an alcohol, and a base (which gives an alkoxide), using a Pd catalyst, gives carboxylic esters. Similar carbonylation reactions are possible with alkyl halides. Aryl carboxylic acids were also prepared from aryl iodides by heating in DMF with lithium formate, LiCl, acetic anhydride, and a Pd catalyst.<sup>842</sup> Even very sterically hindered alkoxides can be used to produce the corresponding ester.<sup>843</sup> The use of H<sub>2</sub>O, RNH<sub>2</sub>, or an alkali metal or calcium carboxylate in reactions with ArX,<sup>844</sup> instead of ROH, gives the carboxylic acid,<sup>845</sup> amide,<sup>846</sup> or mixed anhydride, respectively.<sup>847</sup> Ester formation via carbonylation was carried out in supercritical CO<sub>2</sub> (Sec. 9.D.ii).<sup>848</sup> Microwave-promoted carbonylation reactions have been reported.<sup>849</sup>

Variations include a silica-supported Pd reagent that has been used to convert iodobenzene to butyl benzoate, in the presence of CO and butan-1-ol.<sup>850</sup> 2-Chloropyridine was converted to butyl pyridine 2-carboxylate with this procedure.<sup>851</sup> Heating an aryl iodide and CO, in ethanol and DBU, with a Pd catalyst, gave the ethyl ester of the aryl carboxylic acid.<sup>852</sup> A similar result was obtained when an aryl iodide was heated in ethanol with triethylamine, CO, and Pd/C.<sup>853</sup> Phenols and aryl halides react with a Pd catalyst, and carbonylation leads to the phenyl ester.<sup>854</sup>

Modification of this approach allows the synthesis of ketones and aryl iodides can also be converted to aldehydes.<sup>855</sup> Aryllithium and *Grignard reagents* react with iron pentacarbonyl to give aldehydes, ArCHO.<sup>856</sup> The reaction of CO with aryllithium may occur by electron transfer.<sup>857</sup> Aryl iodides are carbonylated to give the aryl alkyl ketone with CO and R<sub>3</sub>In.<sup>858</sup> Aryl iodides are coupled with aryl acid chlorides in the presence of an In complex to form

a diaryl ketone.<sup>859</sup> Aryl iodides containing an *ortho* substituent that had a  $\beta$ -cyano group (which served as the source of a carbonyl group), were converted to bicyclic ketones with a Pd catalyst at 130 °C in aqueous DMF.<sup>860</sup>

Diaryl ketones can also be prepared by coupling aryl iodides with phenylboronic acid (**12-28**), in the presence of CO and a Pd catalyst.<sup>861</sup> This reaction has been extended to heteroaromatic systems, with the preparation of phenyl 4-pyridyl ketone from phenylboronic acid and 4-iodopyridine.<sup>862</sup> 2-Bromopyridine as coupled with phenylboronic acid, CO, and a Pd catalyst to give phenyl 2-pyridyl ketone.<sup>863</sup>

### 13-17 Arylation of Silanes

In the presence of transition metal catalysts, such as Pd, trialkoxysilanes [ $\text{HSi(OR)}_3$ ] react with aryl halides to give the corresponding arylsilane.<sup>864</sup> The influence of silicon substituents on the cross-coupling reaction has been studied.<sup>865</sup> Cyclic alkoxy silanes are prepared using Pd-catalyzed cross-coupling reactions.<sup>866</sup> Vinylsilanes are coupled to aryl halides to give the aryl alkene.<sup>867</sup> Disilanes have also been employed, using a Pd catalyst.<sup>868</sup> Arylsilanes can be coupled to aryl iodides using a Pd catalyst<sup>869</sup> and in aqueous media.<sup>870</sup> Similar coupling of aryl halides with trialkylsilanes,  $\text{HSiR}_3$ ,<sup>871</sup> in the presence of a Pd,<sup>872</sup> Rh,<sup>873</sup> PtO<sub>2</sub>,<sup>874</sup> Ru,<sup>875</sup> Sc,<sup>876</sup> or Ir catalyst,<sup>877</sup> gave the arylsilane.

The metal-free catalytic silylation of aromatic compounds with various hydrosilanes was reported, using commercially available  $\text{B(C}_6\text{F}_5)_3$  as a catalyst.<sup>878</sup> Functionalized arenes and heteroarenes were converted to the arylsilane derivative by reaction with  $\text{TMSCF}_3$ ,

activated by alkali metal fluoride.<sup>879</sup> 2-Aryl pyridines reacted with  $\text{HSiFR}_2$  in the presence of an Ir catalyst to give the 1-silyl-2-pyridylarene.<sup>880</sup>

### 13.C.ii. Hydrogen as Leaving Group<sup>881</sup>

#### 13-18 Amination of Nitrogen Heterocycles

Pyridine and other heterocyclic nitrogen compounds can be aminated with alkali metal amides in a process called the *Chichibabin reaction*.<sup>882</sup> The attack is always in the 2 position unless both such positions are filled, in which case the 4 position is attacked. Substituted alkali metal amides, e.g.,  $\text{RNH}^-$  and  $\text{R}_2\text{N}^-$ , have also been used. The mechanism is probably similar to that of **13-12**. The existence of intermediate ions, such as **8** (from quinoline) has been demonstrated by NMR spectra.<sup>883</sup>

A pyridyne type of intermediate was ruled out by several observations, including the facts that 3-ethylpyridine gave 2-amino-3-ethylpyridine<sup>884</sup> and that certain heterocycles that cannot form an aryne could nevertheless be successfully aminated. Nitro compounds do not give this reaction,<sup>885</sup> but they have been aminated ( $\text{ArH} \rightarrow \text{ArNH}_2$  or  $\text{ArNHR}$ ) via the vicarious substitution principle (see **13-17**), using 4-amino- or 4-alkylamino-1,2,4-triazoles as nucleophiles.<sup>886</sup> The vicarious leaving group in this case is the triazole ring. Note, however, that 3-nitropyridine was converted to 6-amino-3-nitropyridine by reaction with KOH, hydroxylamine, and  $\text{ZnCl}_2$ .<sup>887</sup>

Analogous reactions have been carried out with hydrazide ions,  $\text{R}_2\text{NNH}^-$ .<sup>888</sup> A mixture of  $\text{NO}_2$  and  $\text{O}_3$ , with excess  $\text{NaHSO}_3$ , converted pyridine to 3-aminopyridine.<sup>889</sup> For other methods of aminating aromatic rings, see **11-4**.

### 13.C.iii. Nitrogen as Leaving Group

The diazonium group can be replaced by a number of groups.<sup>891</sup> Some of these are nucleophilic substitutions, with S<sub>N</sub>1 mechanisms (Sec. 10.A.ii), but others are free-radical reactions and are treated in Chapter 14. The solvent in diazonium group reactions is usually water. With other solvents it has been shown that the S<sub>N</sub>1 mechanism is favored by solvents of low nucleophilicity, while those of high nucleophilicity favor free-radical mechanisms.<sup>892</sup> The N<sub>2</sub><sup>+</sup> group<sup>893</sup> can be replaced by Cl<sup>-</sup>, Br<sup>-</sup>, and CN<sup>-</sup> by a nucleophilic mechanism (see OS IV, 182). It must be kept in mind that the N<sub>2</sub><sup>+</sup> group can activate the removal of another group on the ring.

### 13-19 Diazotization

When primary aromatic amines are treated with nitrous acid, diazonium salts are formed.<sup>894</sup> The reaction also occurs with aliphatic primary amines, but aliphatic diazonium ions are extremely unstable, even in solution (Sec. 10.G.iii). Aromatic diazonium ions are more stable, because of the resonance interaction between the nitrogen atoms and the ring, as shown.

Incidentally, **9** contributes more than **10**, as shown by bond-distance measurements.<sup>895</sup> In benzenediazonium chloride, the C–N distance is  $\sim 1.42$  Å, and the N–N distance  $\approx 1.08$  Å,<sup>896</sup> and these values fit more closely to a single bond and a triple bond than to two double bonds (see Table 1.5). Even aromatic diazonium salts are unstable at temperatures other than about  $<5$  °C. A few are more stable, such as the diazonium salt obtained from sulfanilic acid, which is stable up to 10 or 15 °C. Diazonium salts are usually prepared

in aqueous solution and *used without isolation*.<sup>897</sup> While it is possible to prepare solid diazonium salts (see **13-22**), *many dry diazonium salts are explosive* if not handled with great care and extreme caution should be exercised. The stability of aryl diazonium salts can be increased by crown ether complexation.<sup>898</sup>

For aromatic amines, the reaction is very general. Since aliphatic amines do not react with nitrous acid below a pH of about 3, it is even possible, by working at a pH  $\sim 1$ , to diazotize an aromatic amine without disturbing an aliphatic amino group in the same molecule.<sup>899</sup> If an aliphatic amino group is  $\alpha$  to a COOR, CN, CHO, COR, and so on and has a hydrogen, treatment with nitrous acid gives not a diazonium salt, but a *diazo compound*<sup>900</sup> (e.g.,  $\text{EtO}_2\text{C}-\text{CH}=\text{N}^+=\text{N}$ ) Such diazo compounds can also be prepared, often more conveniently, by treatment of the substrate with isoamyl nitrite ( $\text{Me}_2\text{CHCH}_2\text{CH}_2\text{ONO}$ ) and a small amount of acid.<sup>901</sup> Certain heterocyclic amines also give diazo compounds rather than diazonium salts.<sup>902</sup>

Despite the fact that diazotization takes place in acid solution, the actual reactive species is not the salt of the amine, but the small amount of free amine present.<sup>903</sup> Because aliphatic amines are stronger bases than aromatic ones, at pH values  $< 3$ , there is not enough free amine present for the aliphatic amines to be diazotized, while the aromatic amines still undergo the reaction. In dilute acid the actual attacking species is  $\text{N}_2\text{O}_3$ , which acts as a carrier of  $\text{NO}^+$ . Evidence is that the reaction is second order in nitrous acid and, at sufficiently low acidities, the amine does not appear in the rate expression.<sup>904</sup> Under these conditions the mechanism is that shown.

Other evidence exists for this mechanism.<sup>905</sup> Other attacking species can be  $\text{NOCl}$  and  $\text{H}_2\text{NO}_2^+$  and, at high acidities, even  $\text{NO}^+$ . Nucleophiles (e.g.,  $\text{Cl}^-$ ,  $\text{SCN}^-$ , thiourea) catalyze the reaction by converting the HONO to a better electrophile, for example:<sup>906</sup>

There are many preparations of diazonium salts listed in *Organic Syntheses*, but they are always prepared for use in other reactions. They are listed under the reactions in which they are used. The preparation of aliphatic diazo compounds can be found in OS **III**, 392; **IV**, 424. See also, OS **VI**, 840.

### 13-20 Hydroxylation of Aryldiazonium Salts

This reaction is formally analogous to **13-1**, but with a  $\text{N}_2^+$  leaving group rather than a halide. Water is usually present whenever diazonium salts are made, but at these temperatures (0–5 °C) the reaction proceeds very slowly. When it is *desired* to have OH replace the diazonium group, the excess nitrous acid is destroyed and the solution is usually boiled. Some diazonium salts require even more vigorous treatment, for example, boiling with aqueous sulfuric acid or with trifluoroacetic acid containing potassium trifluoroacetate.<sup>907</sup> The reaction can be performed on solutions of any diazonium salts, but hydrogensulfates are preferred to chlorides or nitrates, since in these cases there is competition from the nucleophiles  $\text{Cl}^-$  or  $\text{NO}_3^-$ .

A better method, which is faster, avoids side reactions, takes place at room temperature, and gives higher yields, consists of adding  $\text{Cu}_2\text{O}$  to a dilute solution of the diazonium salt dissolved in a solution containing a large excess of  $\text{Cu}(\text{NO}_3)_2$ .<sup>908</sup> Aryl radicals are intermediates when this method is used. It has been shown that aryl radicals are at least partly involved when ordinary hydroxy de-diazonation is carried out in weakly alkaline aqueous solution.<sup>909</sup> Decomposition of arenediazonium tetrafluoroborates in  $\text{F}_3\text{CSO}_2\text{OH}$  gives aryl triflates directly, in high yields.<sup>910</sup>

OS **I**, 404; **III**, 130, 453, 564; **V**, 1130.

### 13-21 Replacement by Sulfur-Containing Groups

These reactions are convenient methods for incorporating a sulfur-containing group onto an aromatic ring. With  $\text{Ar}'\text{S}^-$ , diazosulfides  $\text{Ar}-\text{N}=\text{N}-\text{S}-\text{Ar}'$  are intermediates,<sup>911</sup> which can in some cases be isolated.<sup>912</sup> Thiophenols can be made as shown above, but more often the diazonium ion is treated with  $\text{EtO}-\text{CS}_2^-$  or  $\text{S}_2^{2-}$ , which give the expected products, and these are easily convertible to thiophenols. Aryldiazonium salts are prepared by the reaction of an aniline derivative with an alkyl nitrite ( $\text{RONO}$ ); when formed in the presence of dimethyl disulfide ( $\text{MeS}-\text{SMe}$ ), the product is the thioether,  $\text{Ar}-\text{S}-\text{Me}$ .<sup>913</sup> Aryl triflates

have been converted to the aryl thiol using NaST(P5) and a palladium catalyst, followed by treatment with tetrabutylammonium fluoride<sup>914</sup> (see also, **13-21**).

Thiocyanates have been generated from unactivated aryl halides using charcoal-supported copper(I) thiocyanate.<sup>915</sup> The visible light-promoted, aerobic, metal-free C3 thio-cyanation of indoles<sup>916</sup> or of imidazoheterocycles<sup>917</sup> has been reported.

OS II, 580; III, 809 (but see OS V, 1050). Also see, OS II, 238.

Diazonium salts can be converted to sulfonyl chlorides by treatment with sulfur dioxide in the presence of CuCl<sub>2</sub>.<sup>918</sup> The use of FeSO<sub>4</sub> and Cu metal instead of CuCl<sub>2</sub> gives sulfinic acids (ArSO<sub>2</sub>H).<sup>919</sup>

OS V, 60; VII, 508.

### 13-22 Replacement by Halogen

Treatment of diazonium salts with CuCl or CuBr leads to aryl chlorides or aryl bromides, respectively. In either case, the reaction is called the *Sandmeyer reaction*.<sup>920</sup> The reaction can also be carried out with copper and HBr or HCl, in which case it is called the *Gatterman reaction* (not to be confused with **11-18**). However, a Cu-catalyzed Sandmeyer bromination reaction is known.<sup>921</sup> The Sandmeyer reaction is not useful for the preparation of fluorides or iodides, but for bromides and chlorides it is of wide scope and is probably the best way of introducing bromine or chlorine into an aromatic ring. The yields are usually high.

The mechanism is believed to involve formation of an aryl radical.<sup>922</sup> The first step involves a reduction of the diazonium ion by the cuprous ion, which results in the formation of an aryl radical. In the second step, the aryl radical abstracts halogen from cupric chloride, reducing it. CuX is regenerated and is thus a true catalyst.

Aryl bromides and aryl chlorides can be prepared from primary aromatic amines in one step by several procedures,<sup>923</sup> including treatment of the amine (i) with *tert*-butyl nitrite and anhydrous CuCl<sub>2</sub> or CuBr<sub>2</sub> at 65 °C,<sup>924</sup> and (ii) with *tert*-butyl thionitrite or *tert*-butyl

<sup>923</sup> Also see Brackman, W.; Smit, P.J. *Recl. Trav. Chim. Pays-Bas* **1966**, 85, 857; Cadogan, J.I.G.; Roy, D.A.; Smith, D.M. *J. Chem. Soc. C* **1966**, 1249.

<sup>924</sup> Doyle, M.P.; Siegfried, B.; Dellaria Jr., J.F. *J. Org. Chem.* **1977**, 42, 2426.

thionitrate and  $\text{CuCl}_2$  or  $\text{CuBr}_2$  at room temperature.<sup>925</sup> A further advantage is that cooling to 0 °C is not needed. A mixture of  $\text{Me}_3\text{SiCl}$  and  $\text{NaNO}_2$  was used to convert aniline to chlorobenzene in a related reaction.<sup>926</sup> It is noted that the reaction of aryl diazonium salts with  $\text{CuCN}$  to give benzonitrile derivatives is also called the *Sandmeyer reaction*. It is usually conducted in neutral solution to avoid liberation of  $\text{HCN}$ .

OS I, 135, 136, 162, 170; II, 130; III, 185; IV, 160. Also see, OS III, 136; IV, 182. For the reaction with  $\text{CuCN}$  see OS I, 514.

One of the best methods for the introduction of iodine into aromatic rings (see 13-6) is the reaction of diazonium salts with iodide ions.<sup>927</sup> When other diazonium reactions are carried out in the presence of these ions, halides are usually side products. Aniline has also been converted to fluorobenzene by treatment with *t*-BuONO and  $\text{SiF}_4$  followed by heating.<sup>928</sup>

The actual attacking species is probably not only  $\text{I}^-$ , if it is  $\text{I}^-$  at all. The iodide ion is oxidized (by the diazonium ion, nitrous acid, or some other oxidizing agent) to iodine, which in a solution containing iodide ions is converted to  $\text{I}_3^-$ ; this is the actual attacking species, at least partly. This conclusion was deduced by isolation of  $\text{ArN}_2^+ \text{I}_3^-$  salts, which, on standing, gave  $\text{ArI}$ .<sup>929</sup> From this experiment, it can be inferred that the reason the other halide ions give poor results is *not* that they are poor nucleophiles but *rather* they are poor reducing agents (compared with iodide). There is also evidence for a free-radical mechanism.<sup>930</sup>

OS II, 351, 355, 604; V, 1120.

Heating diazonium tetrafluoroborates ( $\text{ArN}_2^+ \text{BF}_4^-$ ; the *Schiemann* or *Balz-Schiemann reaction*) is by far the best way to introduce fluorine into an aromatic ring.<sup>931</sup> In the most common procedure, the tetrafluoroborate salts are prepared by diazotizing as usual with nitrous acid and  $\text{HCl}$  and then adding a cold aqueous solution of  $\text{NaBF}_4$ ,  $\text{HBF}_4$ , or  $\text{NH}_4\text{BF}_4$ . A precipitate forms, which is dried, and the salt is heated in the dry state (*CAUTION!*). These salts are unusually stable for diazonium salts, and the reaction is usually successful. (Since diazonium salts are generally unstable, care should be exercised any time a diazonium salt is dried.) In general, any aromatic amine that can be diazotized will form a  $\text{BF}_4^-$  salt, usually with high yields. The diazonium fluoroborates can be formed directly from primary aromatic amines with *tert*-butyl nitrite and  $\text{BF}_3$ -etherate.<sup>932</sup> The reaction has also been carried out on  $\text{ArN}_2^+ \text{PF}_6^-$ ,  $\text{ArN}_2^+ \text{SbF}_6^-$ , and  $\text{ArN}_2^+ \text{AsF}_6^-$  salts, in many cases with better yields.<sup>933</sup> Aryl chlorides and bromides are commonly prepared by the *Sandmeyer reaction*. In an alternative procedure, aryl fluorides are prepared by treatment of aryltriazenes  $\text{Ar-N=N-NR}_2$  with 70%  $\text{HF}$  in pyridine.<sup>934</sup> The mechanism is of the  $\text{S}_{\text{N}}1$  type. That aryl cations are intermediates was shown by several experiments:<sup>935</sup>

<sup>935</sup> See also, Swain, C.G.; Sheats, J.E.; Harbison, K.G. *J. Am. Chem. Soc.* **1975**, 97, 783, 796; Becker, H.G.O.; Israel, G. *J. Prakt. Chem.* **1979**, 321, 579.

If an aryl cation is an intermediate in the Schiemann reaction, compounds containing *meta*-directing groups, that is *meta*-directing for *electrophilic* substitutions, should be *meta*-arylated and those containing *ortho/para*-directing groups should be *ortho*- and *para*-arylated, since an aryl cation should behave in this respect like any electrophile (see Chapter 11). Experiments have shown<sup>936</sup> that such orientation is observed, demonstrating that the Schiemann reaction has a positively charged intermediate. The attacking species, in at least some instances, is not F<sup>-</sup> but BF<sub>4</sub><sup>-</sup>.<sup>937</sup>

OS II, 188, 295, 299; V, 133.

### 13-23 Replacement of the Diazonium Group by Nitro

Nitro compounds can be formed in good yields by treatment of diazonium salts with sodium nitrite in the presence of cuprous ion. The reaction occurs only in neutral or alkaline solution. This is not usually called the *Sandmeyer reaction*, although it was discovered by Sandmeyer. Tetrafluoroborate (BF<sub>4</sub><sup>-</sup>) is often used as the negative ion since the diminished nucleophilicity avoids competition from the chloride ion.<sup>938</sup> If electron-withdrawing groups are present, the catalyst is not needed; NaNO<sub>2</sub> alone gives nitro compounds in high yields.<sup>939</sup>

OS II, 225; III, 341.

### 13-24 Conversion of Amines to Azo Compounds

Aromatic nitroso compounds combine with primary arylamines in glacial acetic acid to give symmetrical or unsymmetrical azo compounds (the *Mills reaction*).<sup>940</sup> A wide variety of substituents may be present in both aryl groups. Unsymmetrical azo compounds have also been prepared by the reaction between aromatic nitro compounds, ArNO<sub>2</sub>, and *N*-acyl aromatic amines, Ar'NHAc.<sup>941</sup> The use of phase-transfer catalysis increased the yields. The nano-Pd-catalyzed reaction of aromatic nitro compounds and KOH gave aromatic azo compounds.<sup>942</sup> Heating aryl nitro compounds and aniline derivatives with KOH gave the corresponding diaryl azo compound.<sup>943</sup>

A methyl group can be introduced onto an aromatic ring by treatment of diazonium salts with  $\text{Me}_4\text{Sn}$  and a Pd catalyst.<sup>944</sup> The reaction has been performed with Me, Cl, Br, and  $\text{NO}_2$  groups on the ring. A vinylic group can be introduced by using  $\text{CH}_2=\text{CHSnBu}_3$ . When an aryl amine is treated with *tert*-butyl hyponitrite (*t*-BuONO) and allyl bromide, the nitrogen is displaced to give allyl aryl compound.<sup>945</sup>

### 13-26 Conversion of Diazonium Salts to Aldehydes, Ketones, or Carboxylic Acids

Diazonium salts react with oximes to give aryl oximes, which are easily hydrolyzed to aldehydes ( $\text{R} = \text{H}$ ) or ketones.<sup>946</sup> A copper sulfate/sodium sulfite catalyst is essential. In most cases higher yields (40–60%) are obtained when the reaction is used for aldehydes than for ketones. In another method<sup>947</sup> for achieving the conversion  $\text{ArN}_2^+ \rightarrow \text{ArCOR}$ , diazonium salts are treated with  $\text{R}_4\text{Sn}$  and CO with palladium acetate as catalyst.<sup>948</sup> In a different kind of reaction, silyl enol ethers of aryl ketones  $\text{Ar}'\text{C}(\text{OSiMe}_3)=\text{CHR}$  react with solid diazonium fluoroborates ( $\text{ArN}_2^+ \text{BF}_4^-$ ) to give ketones ( $\text{Ar}'\text{CHRCOAr}'$ ).<sup>949</sup> This sequence is, in effect, an arylation of the aryl ketone.

Carboxylic acids can be prepared in moderate to high yields by treatment of diazonium fluoroborates with CO and palladium acetate<sup>950</sup> or  $\text{CuCl}_2$ .<sup>951</sup> The mixed anhydride  $\text{ArCOOCOME}$  is an intermediate that can be isolated. Other mixed anhydrides can be prepared by the use of other salts instead of sodium acetate.<sup>952</sup> An arylpalladium compound is probably an intermediate.<sup>368</sup>

OS V, 139.

### 13-27 Arylation of Activated Alkenes by Diazonium Salts: Meerwein Arylation

Alkenes activated by an electron-withdrawing group (Z may be  $\text{C}=\text{C}$ , halogen,  $\text{C}=\text{O}$ , Ar, CN, etc.) can be arylated by treatment with a diazonium salt and a  $\text{CuCl}_2$ <sup>953</sup> catalyst in what is called the *Meerwein arylation reaction*.<sup>954</sup> Addition of  $\text{ArCl}$  to the double bond [to give  $\text{Z}(\text{Cl})\text{C}-\text{CHAr}$ ] is a side reaction (15-42). In an improved procedure, an arylamine is treated

with an alkyl nitrite (generating  $\text{ArN}_2^+$  *in situ*) and a copper(II) halide in the presence of the alkene.<sup>955</sup>

The mechanism of reaction with an alkene is probably of the free-radical type, with  $\text{Ar}\cdot$  as seen in **13-22** and then (i) halogen transfer to give aryl addition with a  $\beta$ -chloro or (ii) elimination to give the styrene derivative.<sup>956</sup> Even when the addition pathway is taken, however, the substitution product may still be formed by subsequent elimination of HCl. Note that radical reactions are presented in Chapter 14, but the coupling of an alkene with an aromatic compound containing a leaving group prompted its placement here. Note the similarity to the *Heck reaction* (**13-13**).

OS IV, 15.

Esters with a distal terminal alkene unit were coupled with aryldiazonium tetrafluoroborates with a Pd catalyst to give the styryl derivative with high (*E*) selectivity.<sup>957</sup> The use of a Ru photoredox catalyst allows visible light to mediate the  $\alpha$ -arylation of enol acetates by aryl diazonium salts.<sup>958</sup> The Pd-catalyzed cross coupling of diazo compounds with vinyl boronic acids gave 1,3-dienes.<sup>959</sup>

A Heck-type reaction of alkenes with aryldiazonium salts using a Pd catalyst gave the aryl alkene in neat water.<sup>960</sup> The coupling of 4-phenol diazonium salts with styrenes gave 4'-hydroxy stilbenes using a Pd catalyst.<sup>961</sup> The flow diazotization (Sec. 7.D) of aniline derivatives has been reported for the Pd-catalyzed cross coupling of ethyl acrylate to give the  $\gamma$ -arylated alkene product.<sup>962</sup>

### 13-28 Arylation of Aromatic Compounds by Diazonium Salts

When the normally acidic solution of a diazonium salt is made alkaline, the aryl portion of the diazonium salt can couple with another aromatic ring. Known as the *Gomberg reaction* or the *Gomberg-Bachmann reaction*,<sup>963</sup> it has been performed on several types of aromatic rings and on quinones. Yields are not high (usually < 40%) because of the many side reactions undergone by diazonium salts, although higher yields have been obtained under phase-transfer conditions.<sup>964</sup> The conditions of the *Meerwein reaction* (**13-27**), treatment of the solution with a Cu-Fe catalyst, have also been used, as has the addition of sodium nitrite in DMSO (to benzenediazonium tetrafluoroborate).<sup>965</sup> When the Gomberg-Bachmann reaction is performed intramolecularly, either by the alkaline solution or by the copper ion procedure, it is called the *Pschorr reaction*<sup>966</sup> and yields are usually somewhat higher. Still

higher yields have been obtained by carrying out the Pschorr reaction electrochemically.<sup>967</sup> The Pschorr reaction has been carried out for  $Z = \text{CH}=\text{CH}$ ,  $\text{CH}_2\text{CH}_2$ ,  $\text{NH}$ ,  $\text{C}=\text{O}$ ,  $\text{CH}_2$ , and quite a few others. A rapid and convenient way to diazotize the amine substrate uses isopropyl nitrite in the presence of sodium iodide, in which case the ring-closed product is formed in one step.<sup>968</sup> Palladium-catalyzed arylation of arenediazonium salts is known.<sup>969</sup>

A Cu-catalyzed modification of Gomberg-Bachmann-Hey reaction gave biaryls by diazotization of anilines with a *p*-TSA and  $\text{NaNO}_2$  system at 50 °C, using aromatic liquids as solvents.<sup>970</sup> The ferrous salt-promoted homocoupling of arenediazonium salts gave biaryls.<sup>971</sup> Arenediazonium salts react with benzoic acids to give the *ortho* arylation product using an Ir catalyst.<sup>972</sup> A Au catalyst was used for the cross coupling of aryldiazonium salts with arylboronic acids, under photoredox conditions.<sup>973</sup> Aniline derivatives were arylated using aryl diazoacetates.<sup>974</sup> Aryldiazonium salts were coupled to heteroarenes photochemically in the presence of eosin.<sup>975</sup>

Other compounds with nitrogen–nitrogen bonds have been used instead of diazonium salts. Among these are *N*-nitroso amides  $[\text{ArN}(\text{NO})\text{COR}]$ , triazenes,<sup>976</sup> and azo compounds. Still another method involves treatment of an aromatic primary amine directly with an alkyl nitrite in an aromatic substrate as solvent.<sup>977</sup>

In each case, the mechanism involves generation of an aryl radical from a covalent azo compound. In acid solution, diazonium salts are ionic and their reactions are polar. When they cleave, the product is an aryl cation (Sec. 13.A.i). However, in neutral or basic solution, diazonium ions are converted to covalent compounds, and these cleave to give free radicals ( $\text{Ar}\cdot$  and  $\text{Z}\cdot$ ). Note that radical reactions are presented in Chapter 14, but the coupling of an aromatic ring with an aromatic compound containing a leaving group prompted its placement here. Under Gomberg-Bachmann conditions, the species that cleaves is the anhydride, **11**.<sup>978</sup> The aryl radical thus formed attacks the substrate to give the aryl cation<sup>979</sup> (intermediate **13**), from which the radical **12** abstracts hydrogen to give the product, a biaryl.

*N*-Nitroso amides probably rearrange to *N*-acyloxy compounds (**14**), which cleave to give aryl radicals.<sup>980</sup>

There is evidence that the reaction with alkyl nitrites also involves attack by aryl radicals.<sup>981</sup>

The *Pschorr reaction* can take place by two different mechanisms, depending on conditions: (i) attack by an aryl radical (as in the *Gomberg-Bachmann reaction*) or (ii) attack by an aryl cation (similar to the  $\text{S}_{\text{N}}1$  mechanism discussed in Sec. 13.A.ii).<sup>982</sup> Under certain conditions, the ordinary *Gomberg-Bachmann reaction* can also involve attack by aryl cations.<sup>983</sup>

OS I, 113; IV, 718.

### 13-29 Aryl Dimerization with Diazonium Salts

When diazonium salts are treated with cuprous ion (or with Cu and acid, in which case it is called the *Gatterman method*), two products are possible. If the ring contains electron-withdrawing groups, the main product is the biaryl, but the presence of electron-donating groups leads mainly to the azo compound. This reaction is different from **13-28** (and from **19-14**) in that *both* aryl groups in the product originate from  $\text{ArN}_2^+$ , that is, hydrogen is not a leaving group in this reaction. The mechanism probably involves free radicals.<sup>984</sup>

OS I, 222; IV, 872. Also see, OS IV, 273.

### 13-30 Replacement of Nitro

In some cases, the nitrogen group of an aromatic nitro compound can be replaced with an alkyl group. The reaction of 1,4-dinitrobenzene with potassium *tert*-butoxide in the presence of  $\text{BEt}_3$ , for example, gave 4-ethylnitrobenzene.<sup>985</sup>

Other nucleophiles can replace a nitrogen-containing group. The reaction of hydroxide with  $\text{Ar}-\text{Y}$ , where  $\text{Y} = \text{nitro}$ ,<sup>986</sup> azide,  $\text{NR}_3^+$ , and so on, gives the corresponding phenol.

<sup>986</sup> See Knudsen, R.D.; Snyder, H.R. *J. Org. Chem.* **1974**, 39, 3343.

This latter reaction works with alkoxide nucleophiles to give the corresponding aryl ether. The nitro can be replaced with chloro by use of  $\text{NH}_4\text{Cl}$ ,  $\text{PCl}_5$ ,  $\text{SOCl}_2$ ,  $\text{HCl}$ ,  $\text{Cl}_2$ , or  $\text{CCl}_4$ . Some of these reagents operate only at high temperatures and the mechanism is not always nucleophilic substitution. Activated aromatic nitro compounds can be converted to fluorides with fluoride ion.<sup>987</sup>

### 13.C.iv. Rearrangements

#### 13-31 The von Richter Rearrangement

When aromatic nitro compounds are treated with cyanide ion, the nitro group is displaced and a carboxyl group enters with *cine* substitution (Sec. 13.A.iii), always *ortho* to the displaced group, never *meta* or *para*. The scope of this reaction, called the *von Richter rearrangement*, is variable.<sup>988</sup> As with other nucleophilic aromatic substitutions, the reaction gives best results when electron-withdrawing groups are in *ortho* and *para* positions, but yields are low, usually <20% and never >50%.

At one time it was believed that a nitrile,  $\text{ArCN}$ , was an intermediate, since cyanide is the reagent and nitriles are hydrolyzable to carboxylic acids under the reaction conditions (**16-4**). However, a remarkable series of results proved this belief to be in error. Bunnett and Rauhut demonstrated<sup>989</sup> that  $\alpha$ -naphthyl cyanide is *not* hydrolyzable to  $\alpha$ -naphthoic acid under conditions at which  $\beta$ -nitronaphthalene undergoes the von Richter rearrangement to give  $\alpha$ -naphthoic acid. This proved that the nitrile couldn't be an intermediate. It was subsequently demonstrated that  $\text{N}_2$  is a major product of the reaction.<sup>990</sup> It had previously been assumed that all the nitrogen in the reaction was converted to ammonia, which would be compatible with a nitrile intermediate, since ammonia is a hydrolysis product of nitriles. At the same time it was shown that  $\text{NO}_2^+$  is not a major product. The discovery of nitrogen indicated that a N–N bond must be formed during the course of the reaction. Rosenblum proposed a mechanism in accord with all the facts.<sup>989</sup>

The 2-nitrobenzamide intermediate is a stable compound, and it was prepared and subjected to the conditions of the von Richter rearrangement, and this experiment gave the correct product.<sup>991</sup> When 4-chloro or 4-bromonitrobenzene was treated with cyanide in  $\text{H}_2^{18}\text{O}$ , half the oxygen in the product was labeled, showing that one of the oxygen atoms of the carboxyl group came from the nitro group and one from the solvent, as required by this mechanism.<sup>992</sup>

## 13-32 The Sommelet-Hauser Rearrangement

Benzylic quaternary ammonium salts undergo a rearrangement called the *Sommelet-Hauser rearrangement* when treated with alkali metal amides.<sup>993</sup> Since the product is a benzylic tertiary amine, it can be further alkylated and the product again subjected to the rearrangement. This process can be continued around the ring until an *ortho* position is blocked.<sup>994</sup>

The rearrangement occurs with high yields and can be performed with various groups present in the ring.<sup>995</sup> The reaction is most often carried out with three methyl groups on the nitrogen, but other groups can also be used. Note, though, that if a  $\beta$  hydrogen is present, *Hofmann elimination* (**17-6**) often competes. The *Stevens rearrangement* (**18-21**) is also a competing process.<sup>996</sup> When both rearrangements are possible, the Stevens rearrangement is favored at high temperatures and the Sommelet-Hauser at low temperatures.<sup>997</sup> The mechanism is:

The benzylic hydrogen is most acidic and is the one that first loses a proton to give the ylid **15**. However, **16**, which is present in a smaller amount, is the species that undergoes the rearrangement, shifting the equilibrium in its favor. This mechanism is an example of a [2,3]-sigmatropic rearrangement (see **18-35**). Another mechanism that might be proposed is one in which a methyl group actually breaks away (in some form) from the nitrogen and then attaches itself to the ring. That this is not so was shown by a product study.<sup>998</sup> If the second mechanism were true, **17** should give 1-(2,6-dimethylphenyl)-*N,N*-dimethylmethanamine, but the first mechanism predicts the formation of 1-(2,3-dimethylphenyl)-*N,N*-dimethylmethanamine, which is what was actually obtained.<sup>999</sup>

<sup>993</sup> See Pine, S.H. *Org. React.* **1970**, *18*, 403; Lepley, A.R.; Giumanini, A.G. *Mech. Mol. Migr.* **1971**, *3*, 297; Wittig, G. *Bull. Soc. Chim. Fr.* **1971**, 1921; Stevens, T.S.; Watts, W.E. *Selected Molecular Rearrangements*, Van Nostrand-Reinhold, Princeton, **1973**, pp. 81–88; Shine, H.J. *Aromatic Rearrangements*, Elsevier, NY, **1967**, pp. 316–326. <sup>998</sup> See Puterbaugh, W.H.; Hauser, C.R. *J. Am. Chem. Soc.* **1964**, *86*, 1105; Pine, S.H.; Sanchez, B.L. *Tetrahedron Lett.* **1969**, 1319; Shirai, N.; Watanabe, Y.; Sato, Y. *J. Org. Chem.* **1990**, *55*, 2767.

<sup>999</sup> Kantor, S.W.; Hauser, C.R. *J. Am. Chem. Soc.* **1951**, *73*, 4122.

The mechanism as shown can lead only to an *ortho* product. However, a small amount of *para* product has been obtained in some cases.<sup>1000</sup> A mechanism<sup>1001</sup> in which there is a dissociation of the ArC–N bond (similar to the ion-pair mechanism of the *Stevens rearrangement*, **18-21**) has been invoked to explain the *para* products that are observed. Dialkylation using the Sommelet-Hauser protocol is known.<sup>1002</sup>

OS IV, 585.

### 13-33 Rearrangement of Aryl Hydroxylamines

Aryl hydroxylamines treated with acids rearrange to aminophenols.<sup>1003</sup> Although this reaction (known as the *Bamberger rearrangement*) is similar in appearance to **11-28** to **11-32**, the attack on the ring is not electrophilic but nucleophilic. The rearrangement is intermolecular, with the following mechanism:

Among the evidence<sup>1004</sup> for this mechanism are the facts that other products are obtained when the reaction is run in the presence of competing nucleophiles, for example, *p*-ethoxyaniline is produced when ethanol is present, and that when the *para* position is blocked, compounds similar to **19** are isolated. In the case of 2,6-dimethylphenylhydroxylamine, the intermediate nitrenium ion **18** was trapped, and its lifetime in solution was measured.<sup>1005</sup> The reaction of **19** with water was found to be diffusion controlled.<sup>1006</sup>

## 13-34 The Smiles Rearrangement

The *Smiles rearrangement* actually comprises a group of rearrangements that follow the pattern shown above.<sup>1007</sup> A specific example is the reaction of **20** with hydroxide to give **21**.

Smiles rearrangements are simply intramolecular nucleophilic substitutions. In the example given,  $\text{SO}_2\text{Ar}$  is the leaving group and  $\text{ArO}^-$  the nucleophile, and the nitro group serves to activate its *ortho* position. Halogens also serve as activating groups.<sup>1008</sup> The ring at which the substitution takes place is nearly always activated, usually by *ortho* or *para* nitro groups. Here X is usually S, SO,  $\text{SO}_2$ ,<sup>1009</sup> O, or  $\text{CO}_2$ , and Y is usually the conjugate base of OH,  $\text{NH}_2$ , NHR, or SH. The reaction has even been carried out with  $\text{Y}=\text{CH}_2^-$  (phenyllithium was the base here).<sup>1010</sup>

The reaction rate is greatly enhanced by substitution in the 6 position of the attacking ring, for steric reasons. For example, a methyl, chloro, or bromo group in the 6 position of **20** caused the rate to be  $\sim 10^5$  times faster than when the same groups were in the 4 position,<sup>1011</sup> although electrical effects should be similar at these positions. The enhanced rate comes about because the most favorable conformation the molecule can adapt to suit the bulk of the 6 substituent is also the conformation required for the rearrangement. Thus, less entropy of activation is required.

Although the Smiles rearrangement is usually carried out on compounds containing two rings, this need not be the case, as in the formation of **22**.<sup>1012</sup>

<sup>1007</sup> See Truce, W.E.; Kreider, E.M.; Brand, W.W. *Org. React.* **1971**, *18*, 99; Shine, H.J. *Aromatic Rearrangements*, Elsevier, NY, **1967**, pp. 307–316; Stevens, T.S.; Watts, W.E. *Selected Molecular Rearrangements*, Van Nostrand-Reinhold, Princeton, **1973**, pp. 120–126. See Reyes-González, J.; Gómez, R.M.; Cortés-Guzmán, F. *J. Phys. Org. Chem.* **2012**, *25*, 230.

<sup>1008</sup> Grundon, M.F.; Matier, W.L. *J. Chem. Soc., B* **1966**, 266; Schmidt, D.M.; Bonvicino, G.E. *J. Org. Chem.* **1984**, *49*, 1664.

<sup>1009</sup> See Cerfontain, H. *Mechanistic Aspects in Aromatic Sulfonation and Desulfonation*, Wiley, NY, **1968**, pp. 262–274.

<sup>1010</sup> Truce, W.E.; Robbins, C.R.; Kreider, E.M. *J. Am. Chem. Soc.* **1966**, *88*, 4027; Drozd, V.N.; Nikonova, L.A. *J. Org. Chem. USSR* **1969**, *5*, 313.

<sup>1011</sup> Bunnett, J.F.; Okamoto, T. *J. Am. Chem. Soc.* **1956**, *78*, 5363.

<sup>1012</sup> Kent, B.A.; Smiles, S. *J. Chem. Soc.* **1934**, 422.

In this case the sulfenic acid (**22**) is unstable<sup>1013</sup> and the actual products isolated were the corresponding sulfinic acid ( $\text{RSO}_2\text{H}$ ) and disulfide ( $\text{R}_2\text{S}_2$ ).

In the Smiles rearrangement, the nucleophile Y is most often the conjugate base of SH,  $\text{SO}_2\text{NHR}$ ,  $\text{SO}_2\text{NH}_2$ ,  $\text{NH}_2$ ,  $\text{NHR}$ ,  $\text{OH}$ , or  $\text{OR}$ . There are few examples where Y is a carbanion, and the most common example is probably the *Truce-Smiles rearrangement*, where  $\text{L}-\text{YH}$  is an *o*-tolyl group.<sup>1014</sup> The prototypical Truce-Smiles rearrangement requires use of a strong base to form the benzylic carbanion that undergoes the rearrangement. When sulfone **23** was treated with butyllithium, for example, deprotonation led to the benzylic lithium compound **24**. Truce-Smiles rearrangement led to **25**, and hydrolysis gave the sulfinic acid, **26**.<sup>1015</sup>

Truce-Smiles rearrangements with stabilized benzylic carbanions are known,<sup>1015</sup> and rearrangements of carbanions in general fall under this category.<sup>1016</sup> Relatively few examples have been reported, however.<sup>1017</sup> Truce-Smiles rearrangements of sulfones that proceed through a six-membered transition state have been reported.<sup>1018</sup> In another example, displacement of an activated aryl fluoride with *o*-hydroxyacetophenone gave a product that was *C*-arylated adjacent to the ketone.<sup>1019</sup> Phenols were converted to anilines via a Smiles rearrangement.<sup>1020</sup> A benzyne Truce-Smiles rearrangement is known.<sup>1021</sup>

# Radical Reactions

This chapter discusses many types of radical reactions, including reactions in which radicals may be intermediates. Radicals are increasingly important in organic synthesis.<sup>1</sup> The formation, fate, and properties of radicals were introduced in Sec. 5.C. Additional information concerning radicals may be found in Sec. 7.A, in the discussion of photochemical processes.

For the most part, this chapter discusses radical substitution reactions, although some radical coupling reactions are discussed.<sup>2</sup> Free-radical additions to unsaturated compounds and rearrangements are discussed in Chapters 15 and 18, respectively. Fragmentation reactions are covered, in part, in Chapter 17. In addition, many of the oxidation–reduction reactions considered in Chapter 19 involve free-radical mechanisms. Several important types of free-radical reactions do not usually lead to reasonable yields of pure products and are not generally treated in this book.

## 14.A. MECHANISMS

### 14.A.i. Radical Mechanisms in General<sup>3</sup>

A free-radical process (or just a radical process) consists of at least two steps. Any radical reaction first involves the *formation* of free radicals, usually by homolytic cleavage of a bond, that is, a cleavage in which each fragment retains one electron:

See Huyser, E.S. in McManus, S.P. *Organic Reactive Intermediates*, Academic Press, NY, **1973**, pp. 1–59; Giese, B. *Radicals in Organic Synthesis: Formation of Carbon–Carbon Bonds*, Pergamon, Elmsford, NY, **1986**; Davies, D.I.; Parrott, M.J. *Free Radicals in Organic Synthesis*, Springer, NY, **1978**; Curran, D.P. *Synthesis* **1988**, 417, 489; Ramaiah, M. *Tetrahedron* **1987**, 43, 3541.

This reaction is called an *initiation* step. It may happen spontaneously or may be induced by heat<sup>4</sup> or light (Sec. 5.C.ii), depending on the type of bond.<sup>5</sup> Peroxides,<sup>6</sup> including hydrogen peroxide, dialkyl, diacyl, alkyl acyl peroxides, and peroxyacids are the most common source of free radicals. However, other organic compounds with low-energy bonds, such as azo compounds, are also used. Chlorine, bromine, and various ketones<sup>7</sup> (see Chapter 7) are most commonly cleaved by light. Radicals can also be formed by a one-electron transfer (loss or gain),<sup>8</sup> for example:

One-electron transfers usually involve inorganic ions or electrochemical processes.<sup>9</sup>

Dialkyl peroxides (ROOR) or alkyl hydroperoxides (ROOH) decompose to hydroxy radicals (HO•)<sup>10</sup> or alkoxy radicals (RO•)<sup>11</sup> when heated. Cumene hydroperoxide (PhCMe<sub>2</sub>OOH), bi-*tert*-butylperoxide (Me<sub>3</sub>COOCMe<sub>3</sub>),<sup>12</sup> and benzoyl peroxide [(PhCO)O<sub>2</sub>] undergo homolytic cleavage at temperatures compatible with many organic reactions, and they are reasonably soluble in organic solvents.<sup>13</sup> In general, when a peroxide decomposes, the oxygen radical remains in a “cage” for ~10<sup>-11</sup> seconds before diffusing away.<sup>14</sup> The radical can recombine (dimerize), or react with other molecules.

Azo compounds, characterized by a —N=N— bond, are free-radical precursors that liberate nitrogen gas (N≡N) upon decomposition. Azobisisobutyronitrile (AIBN, **1**) is a well-known example, which decomposes to give nitrogen gas and the cyano-stabilized radical, **2**.<sup>15</sup> Homolytic dissociation of symmetrical diazo compounds may be stepwise.<sup>16</sup> A derivative has been developed that decomposes at room temperature:

2,2'-azobis-(2,4-dimethyl-4-methoxyvaleronitrile), **3**.<sup>17</sup> Water-soluble azo compounds are known, and can be used as radical initiators.<sup>18</sup>

Alkyl hypochlorites (R–O–Cl) generate chlorine radicals (Cl•) and alkoxy radicals (RO•) when heated.<sup>19</sup> Heating *N*-alkoxydithiocarbamates is another useful source of alkoxy radicals, RO•.<sup>20</sup> Alkoxy radicals, particularly those derived from cyclic compounds, may undergo β-scission reactions to give carbonyl derivatives.<sup>21</sup>

It has been known for many years that boron compounds participate in radical reactions.<sup>22</sup> Trialkylboranes (R<sub>3</sub>B; see **15-23**, **12-27**), such as triethylborane (Et<sub>3</sub>B), can be used to initiate radical reactions. Indeed, Et<sub>3</sub>B is widely used.<sup>23</sup> In radical reactions, Et<sub>3</sub>B functions as both a radical initiator and also as a chain propagation agent.<sup>24</sup> Reactions are usually run in open vessels exposed to oxygen or under an oxygen atmosphere. It is known that O<sub>2</sub> reacts with BEt<sub>3</sub> to give Et<sub>2</sub>BOO• and Et• in the initiation step, and then an atom transfer reaction with an alkyl iodide<sup>25</sup> gives the alkyl radical, R•. In a second step, Et• reacts with R–I to give R• and Et–I. Trialkylborane/water-mediated radical reactions are also known.<sup>26</sup> 1-Chloroalkyl radicals have been generated from organoboranes.<sup>27</sup>

In general, the order of reactivity is R<sub>3</sub>B > R<sub>2</sub>BOR > RB(OR)<sub>2</sub> where R = alkyl.<sup>28</sup> Boronic acids are less reactive, presumably due to π bonding between B and O.<sup>23</sup> However, *B*-alkylcatecholboranes are very reactive, and are highly useful for initiating radical reactions.<sup>29</sup> Reaction conditions usually involve addition of catecholborane (**4**, abbreviated CatBH), and the *B*-alkyl derivative is presumably generated *in situ* by reaction with an

alkene.<sup>30</sup> It is noted that borole derivatives (the B analog of pyrrole, **5**) have been used to initiate radical reactions.<sup>31</sup>

Aldehydes can be a source of acyl radicals ( $\bullet\text{C}=\text{O}$ ) via reaction with transition metal salts such as Mn(III) acetate or Fe(II) compounds.<sup>32</sup>  $\alpha,\beta$ -Unsaturated acyl radicals are subject to an isomerization that generates  $\alpha$ -ketenyl radicals.<sup>33</sup> Another useful variation employs imidoyl radicals as synthons for unstable aryl radicals.<sup>34</sup> The formation of chirality in the reactions of  $\alpha$ -amide radicals has been reported.<sup>35</sup>

An important step in radical reactions involves the *destruction* of free radicals. This usually happens by a process opposite to the first, namely, a combination of two like or unlike radicals to form a new bond:<sup>36</sup>

This type of step is called *termination* because the product of the reaction is a neutral compound and not a radical.<sup>37</sup> Note that this reaction constitutes a radical coupling process. The termination step rarely follows initiation because most radicals are very reactive, and there are several radical processes that occur faster than the termination step. In the usual situation, in which the concentration of radicals is low, a radical is more likely to react with a molecule rather than another radical (i.e., the radical coupling reaction is usually slower). When a radical (which has an odd number of electrons) reacts with a molecule (which has an even number), the total number of electrons in the products must be odd. In other words, the product is another radical. When a radical reacts with a  $\pi$  bond,  $\text{R}\bullet + \text{C}=\text{C}$ , the product is a free radical,  $\text{R}-\text{C}-\text{C}\bullet$ . This is called *radical addition*. Another reaction constitutes an *atom-transfer reaction*. The abstraction of an atom such as hydrogen atom from an alkyl fragment gives two particles,  $\text{R}-\text{H}$  and the new radical  $\text{R}'\bullet$ :

This type of atom-transfer reaction is called a *hydrogen-transfer reaction*. Once again, the product is a free radical. This type of step is called *propagation*, since the newly formed radical can now react with another molecule and produce another radical, and so on, until

<sup>36</sup> For a review of stereochemistry, see Porter, N.A.; Krebs, P.J. *Top. Stereochem.* **1988**, *18*, 97.

<sup>37</sup> Another type of termination step is *disproportionation* (Sec. 5.C.ii).

two radicals undergo coupling and terminate the sequence. The process of initiation, propagation, and then termination constitutes what is called a *chain reaction*,<sup>38</sup> and there may be hundreds or thousands of propagation steps between an initiation and a termination. Two other types of propagation reactions do not involve a molecule at all. These are (i) cleavage of a radical into, necessarily, a radical and a molecule and (ii) rearrangement of one radical to another (see Chapter 18). When radicals are highly reactive, for example, alkyl radicals, chains are long, since reactions occur with many molecules; but with radicals of low reactivity, aryl radicals for example, the radical may be unable to react with anything until it meets another radical, so that chains are short. Alternatively, the reaction may be a nonchain process. In any particular chain process, there are usually a wide variety of propagation and termination steps so there may be many products.

Such reactions are often difficult to treat kinetically.<sup>39</sup>

Is it possible to terminate a radical reaction under controlled conditions? The answer is yes, using an atom-transfer reaction. When a carbon radical ( $\text{R}\cdot$ ) is generated in the presence of tributyltin hydride ( $n\text{-Bu}_3\text{SnH}$ ), a hydrogen atom is transferred to the radical to give  $\text{R-H}$  and a new radical,  $n\text{-Bu}_3\text{Sn}\cdot$ . The tin radical usually undergoes rapid coupling to another tin radical to give  $n\text{-Bu}_3\text{Sn-Sn-}n\text{-Bu}_3$ , which effectively terminates the chain radical process. The carbon radical is *reduced* ( $\text{R}\cdot \rightarrow \text{R-H}$ ) as a result of the hydrogen atom transfer, and the tin dimer can be removed from the reaction. Again, hydrogen atom transfer<sup>40</sup> is simply a variation of the radical reaction known as atom transfer. Silanes, such as triethylsilane ( $\text{Et}_3\text{SiH}$ ), have also been used as an effective radical reducing agent.<sup>41</sup> The rate constants for the reaction of both tributyltin hydride and  $(\text{Me}_3\text{Si})_3\text{Si-H}$  with acyl radical have been measured and the silane quenches the radical faster than the tin hydride.<sup>42</sup> Thermolysis of *bis*-(tri-*n*-butylstannyl)benzopinacolate has also been used as a source of  $n\text{-Bu}_3\text{Sn}\cdot$ , used to mediate radical reactions.<sup>43</sup>

The following are some general characteristics of free-radical reactions:<sup>44</sup>

1. Reactions are fairly similar whether they are occurring in the vapor or liquid phase, but solvation of free radicals in solution does cause some differences.<sup>45</sup>
2. They are largely unaffected by the presence of acids or bases or by changes in the polarity of solvents, except that nonpolar solvents may suppress competing ionic reactions.

3. They are initiated or accelerated by typical free-radical sources, such as the peroxides or diazo compounds noted above, or by light. In the latter case, the concept of quantum yield applies (Sec. 7.A.viii). Quantum yields can be quite high, for example, 1000, if each quantum generates a long chain, or low, in the case of nonchain processes.
4. Their rates are decreased or the reactions are suppressed entirely by substances that scavenge free radicals, for example, nitric oxide, molecular oxygen, or benzoquinone. These substances are called *inhibitors*.<sup>46</sup> Note that there are C-centered radicals in thermal equilibrium with their dimers that show poor reactivity with molecular oxygen but good reactivity with peroxy radicals.<sup>47</sup>

#### 14.A.ii. Free-Radical Substitution Mechanisms<sup>48</sup>

In a free-radical substitution reaction that transforms R–X to R–Y, there must first be homolytic cleavage of the substrate RX so that R• and X• radicals are produced.

This can happen by a spontaneous cleavage, or it can be caused by light or heat. More often, there is no actual cleavage, but R• is produced by an *abstraction* of another atom, X, by a radical W• produced by adding a compound, such as peroxide, that spontaneously forms free radicals.

Such a compound is called an *initiator* (see above). Once R• is formed, it can react with A–B to form R–A and a new radical B•, the products in this system.

Such an atom abstraction is known as an *atom transfer*.

Coupling is another reaction of radicals in which one radical reacts with another (R• + Y•) to form the neutral product R–Y.

In a reaction with a moderately long chain, much more of the product will be produced by abstraction than by coupling.

The cleavage steps have been called S<sub>H</sub>1 (H for homolytic), and abstraction steps have been called S<sub>H</sub>2; reactions can be classified as S<sub>H</sub>1 or S<sub>H</sub>2 on the basis of whether RX is converted to R by spontaneous cleavage or reaction with a radical source (W•).<sup>49</sup> Most chain substitution mechanisms follow the pattern cleavage then atom transfer. Chains are long and reactions go well where both cleavage and atom-transfer processes are energetically favored (no worse than slightly endothermic; Sec. 14.B.i, 14.C.i). The IUPAC designation of a chain reaction that follows this pattern is A<sub>r</sub>D<sub>R</sub> + A<sub>R</sub>D<sub>r</sub> (R stands for radical).

With certain radicals the transition state in an abstraction reaction has some polar character. Consider the abstraction of hydrogen from the methyl group of toluene by a bromine atom. Since bromine is more electronegative than carbon, it is reasonable to assume that there is a separation of charge in the transition state, with a partial negative charge on the halogen and a partial positive charge on the carbon:

Evidence for the polar character of the transition state is that electron-withdrawing groups in the *para* position of toluene (which would destabilize a positive charge) decrease the rate of hydrogen abstraction by bromine while electron-donating groups increase it.<sup>50</sup> However, substituents have a smaller effect here ( $\rho \approx -1.4$ ) than they do in reactions where a completely ionic intermediate is involved, e.g., the  $S_N1$  mechanism (Sec. 10.A.ii). Other evidence for polar transition states in radical abstraction reactions is mentioned in Sec. 14.B.i, category 4. For abstraction by radicals such as methyl or phenyl, polar effects are very small or completely absent. For example, rates of hydrogen atom abstraction from ring-substituted toluenes by methyl radical were relatively unaffected by the presence of electron-donating or electron-withdrawing substituents.<sup>51</sup> Those radicals (e.g.,  $\text{Br}\cdot$ ) that have a tendency to abstract electron-rich hydrogen atoms are called *electrophilic radicals*.

When the reaction step  $\text{R}-\text{X} \rightarrow \text{R}\cdot$  takes place at a stereogenic carbon, *racemization is almost always observed because free radicals do not retain configuration*. Exceptions to this rule are found with cyclopropyl substrates, where both inversion<sup>52</sup> and retention<sup>53</sup> of configuration have been reported, and in the reactions mentioned in Sec. 14.A.iv. Enantioselective radical processes have been reviewed.<sup>54</sup>

#### 14.A.iii. Mechanisms at an Aromatic Substrate<sup>55</sup>

When R in the reaction from  $\text{R}-\text{X}$  to  $\text{R}-\text{Y}$  is aromatic, the simple abstraction mechanism just discussed may be operating, especially in gas-phase reactions. However, mechanisms of this type cannot account for all reactions of aromatic substrates. In processes such as the following (see 13-28, 14-16, and 14-17), an aryl radical forms and coupling leads to a biaryl:

Coupling of this type can occur in solution, and generation of  $\text{H}\cdot$  by the free-radical mechanism:

is very unlikely (Sec. 14.B.i). Rather, the products can be explained by a mechanism similar to that of electrophilic and nucleophilic aromatic substitution. Initially, the aryl

<sup>50</sup> See Kim, S.S.; Choi, S.Y.; Kang, C.H. *J. Am. Chem. Soc.* **1985**, *107*, 4234.

<sup>55</sup> See Kobrina, L.S. *Russ. Chem. Rev.* **1977**, *46*, 348; Perkins, M.J. in Kochi, J.K. *Free Radicals*, Vol. 2, Wiley, NY, **1973**, 231–271; Bolton, R.; Williams, G.H. *Adv. Free Radical Chem.* **1975**, *5*, 1; Nonhebel, D.C.; Walton, J.C. *Free-Radical Chemistry*, Cambridge University Press, London, **1974**, pp. 417–469.

radical attacks the ring in much the same way as would an electrophile or a nucleophile to generate **5**.

The intermediate radical **5** is relatively stable because of the resonance and the overall reaction leads to a biaryl product. Three pathways are available for **5**. Simple coupling leads to **6**, whereas disproportionation would give the biaryl product and **7**.

If a species ( $R'\bullet$ ) is present, abstraction of hydrogen gives the biaryl product directly.<sup>56</sup>

Coupling product **6** is a partially hydrogenated *o*-quaterphenyl (an *o,o'*-diphenylbiphenyl). Of course, the coupling need not be *ortho-ortho*, and other isomers can also be formed. Compounds of types **6** and **7** were isolated, which is taken as evidence for these steps.<sup>57</sup> However, under the reaction conditions dihydrobiphenyls like **7** are normally oxidized to the corresponding biphenyls. Other evidence for this mechanism is the detection of the intermediate **5** by CIDNP<sup>58</sup> and the absence of isotope effects. (Isotope effects would be expected if the rate-determining step were coupling of  $Ar\bullet$  with  $Ar-H$ , which involves cleavage of the  $Ar-H$  bond.) In the mechanism just given, the rate-determining step is formation of **5**, and this reaction does not involve loss of hydrogen. The reaction between aromatic rings and the  $HO\bullet$  radical takes place by the same mechanism. Intramolecular hydrogen transfer reactions of aryl radicals are known.<sup>59</sup> A similar mechanism has been shown for substitution at some vinylic<sup>60</sup> and acetylenic substrates, giving the substituted alkene via formation of the radical, **8**.<sup>61</sup>

The kinetics of radical heterolysis reactions that form alkene radical cations has been studied.<sup>62</sup> This mechanism is reminiscent of the nucleophilic tetrahedral mechanism at a vinylic carbon (Sec. 10.F).

There are a number of transition metal-mediated coupling reactions of aromatic substrates that probably proceed by radical coupling. It is likely that many of these reactions do *not* proceed by free radicals but rather by metal-mediated radicals or by ligand transfer at the metal. Reactions in these categories were presented in Chapter 13 for convenient correlation with other displacement reactions of aryl halides, aryl diazonium salts, and so on.

#### 14.A.iv. Neighboring-Group Assistance in Free-Radical Reactions

In a few cases it has been shown that cleavage steps and abstraction steps were accelerated by the presence of neighboring groups. Photolytic halogenation (**14-1**) is a process that normally leads to mixtures of many products. However, bromination of carbon chains containing a bromine atom occurs with high regioselectivity. Bromination of alkyl bromides gave 84–94% substitution at the carbon adjacent to the bromine already in the molecule.<sup>63</sup> This result may seem surprising because, as will be seen (Sec. 14.B.i, category 3), positions close to a polar group, such as bromine, should actually be *deactivated* by the electron-withdrawing field effect of the bromine. However, the unusual regioselectivity is explained by a mechanism in which abstraction is assisted by a neighboring bromine atom, as in **9**.<sup>64</sup> In the normal mechanism,  $\text{Br}\cdot$  abstracts a hydrogen atom from  $\text{R}-\text{H}$ , leaving  $\text{R}\cdot$ . When a bromine is present in the proper position, it assists this process, giving a cyclic intermediate (a *bridged free radical*, **10**).<sup>65</sup> In the final step (very similar to  $\text{R}\cdot + \text{Br}_2 \rightarrow \text{RBr} + \text{Br}\cdot$ ) the ring is broken. If this mechanism is correct, the configuration at the substituted carbon (marked \*) should be retained.

Indeed, optically active 1-bromo-2-methylbutane gave 1,2-dibromo-2-methylbutane with retention of configuration.<sup>64</sup> When this reaction was carried out in the presence of  $\text{DBr}$ , the “recovered” 1-bromo-2-methylbutane was found to be deuterated in the 2 position, and its configuration was retained.<sup>66</sup> This result is just what would be predicted if some of the  $\text{C}=\text{C}-\text{R}$  that is present abstracted  $\text{D}$  from  $\text{DBr}$ . There is evidence that  $\text{Cl}$  can form bridged radicals,<sup>67</sup> although ESR spectra show that the bridging is not necessarily

The principal reason for this preference is steric. A univalent atom is much more exposed to attack by the incoming radical than an atom with a higher valence. Also, in many cases, abstraction of a univalent atom is energetically more favored. For example, in the reaction given above, a  $C_2H_5-H$  bond is broken ( $D = 100 \text{ kcal mol}^{-1}$ ,  $419 \text{ kJ mol}^{-1}$ , from Table 5.3) whichever pathway is taken, but in the former case an  $H-Cl$  bond is formed ( $D = 103 \text{ kcal mol}^{-1}$ ,  $432 \text{ kJ mol}^{-1}$ ) while in the latter case it is a  $C_2H_5-Cl$  bond ( $D = 82 \text{ kcal mol}^{-1}$ ,  $343 \text{ kJ mol}^{-1}$ ). Thus the first reaction is favored because it is exothermic by  $3 \text{ kcal mol}^{-1}$  ( $100-103$ ) [ $13 \text{ kJ mol}^{-1}$  ( $419-432$ )], while the latter is endothermic by  $18 \text{ kcal mol}^{-1}$  ( $100-82$ ) [ $76 \text{ kJ mol}^{-1}$  ( $419-343$ )].<sup>79</sup> However, the steric reason is more important, because even in cases where  $\Delta H$  is not very different for the two possibilities, the univalent atom is chosen.<sup>80</sup> *Ab initio* studies have probed the transition structures for radical hydrogen abstractions.<sup>81</sup>

Most studies of aliphatic reactivity have been made with hydrogen as the leaving atom and chlorine atoms as the abstracting species.<sup>82</sup> In these reactions, every hydrogen atom in the substrate is potentially replaceable and mixtures of several products may be obtained. However, the abstracting radical is not totally unselective, and some positions on a molecule lose hydrogen more easily than others. *Ab initio* studies have studied the factors controlling hydrogen abstraction by radicals.<sup>83</sup> For hydrogen abstraction by the *tert*-butoxy radical ( $t\text{-Bu-O}\bullet$ ) the factors that influence rate in their order of importance are structure of the radical > substituent effects<sup>84</sup> > solvent effects.<sup>85</sup> The position of attack will be discussed under several headings.<sup>86</sup>

1. *Alkanes*. If a tertiary hydrogen atom is present in an alkane, it is preferentially abstracted by almost any radical, with secondary hydrogen atoms being next preferred. This is in the same order as  $D$  values for these types of  $C-H$  bonds (Table 5.3). The extent of the preference depends on the selectivity of the abstracting radical and on the temperature. At high temperatures, and in the gas phase, selectivity for attack of  $Cl\bullet$  at  $3^\circ > 2^\circ > 1^\circ$  hydrogens decreases,<sup>87</sup> as might be expected.<sup>88</sup> An example of the effect of radical selectivity is the comparison of fluorine atoms with bromine atoms. For the former, the ratio of primary to tertiary abstraction (of hydrogen) is 1:1.4, while for the less reactive bromine atom this ratio is 1:1600. With certain large radicals there is a steric factor that may change the selectivity pattern.

<sup>79</sup> The parameter  $\Delta H$  for a free-radical abstraction reaction can be regarded simply as the difference in  $D$  values for the bond being broken and the one formed.

Chem. Int. Ed.* **1970**, *9*, 830; Poutsma, M.L. *Methods Free-Radical Chem.* **1969**, *1*, 79; Davidson, R.S. *Q. Rev. Chem. Soc.* **1967**, *21*, 249; Pryor, W.A.; Fuller, D.L.; Stanley, J.P. *J. Am. Chem. Soc.* **1972**, *94*, 1632.

<sup>87</sup> Hass, H.B.; McBee, E.T.; Weber, P. *Ind. Eng. Chem.* **1936**, *28*, 333.

<sup>88</sup> With phenyl radicals: Kopinke, F.; Zimmermann, G.; Anders, K. *J. Org. Chem.* **1989**, *54*, 3571.

For example, in the photochemical chlorination of 2-methylbutane in  $\text{H}_2\text{SO}_4$  with *N*-chloro-di-*tert*-butylamine and *N*-chloro-*tert*-butyl-*tert*-pentylamine, the primary hydrogen atoms are abstracted 1.7 times *faster* than the tertiary hydrogen.<sup>89</sup> In this case, the attacking radicals (the radical ions  $\text{R}_2\text{NH}^{\bullet+}$ , see **14-1**) are bulky enough for steric hindrance to become a major factor.

Cyclopropylcarbinyl radicals (**11**) are alkyl radicals, but because of the cyclopropane ring with its relatively weak bonds, they undergo rapid ring opening to give butenyl radicals.<sup>90</sup> The rate constant for this process has been measured by picosecond radical kinetic techniques to be in the range of  $10^7 \text{ M}^{-1} \text{ s}^{-1}$  for the parent<sup>91</sup> to  $10^{10} \text{ M}^{-1} \text{ s}^{-1}$  for substituted derivatives.<sup>92</sup>

Cyclobutylcarbinyl radicals undergo the cyclobutylcarbinyl to 4-pentenyl radical process,<sup>93</sup> but examples are generally limited to the parent system and phenyl-substituted derivatives.<sup>94</sup> Cyclization of the 4-pentenyl radical is usually limited to systems where a stabilized radical can be formed.<sup>95</sup> The effect of substituents has been studied.<sup>96</sup> Note that 2-aziridinylmethyl radicals also undergo ring opening via C–N or C–C cleavage to give a nitrogen or carbon radical respectively, and the ring opening is strongly influenced by substituents at C1 rather than those on nitrogen.<sup>97</sup> An alkyl substituent at C1 generally leads to C–N cleavage, whereas a carbonyl substituent at C1 usually favors C–C cleavage.<sup>97</sup>

The rates of the ring-opening reaction of **5** and other substrates<sup>98</sup> have been determined using an indirect method for the calibration<sup>99</sup> of fast radical reactions, applicable for radicals with lifetimes as short as 1 ps.<sup>100</sup> This “radical clock”<sup>101</sup> method is based on the use of pyridine-2-thione-*N*-oxycarbonyl esters as radical precursors and radical trapping by the highly reactive thiophenol and benzeneselenol.<sup>102</sup> A number of radical clock substrates are known.<sup>103</sup> Other radical clock processes include: (i)

racemization of radicals with chiral conformations,<sup>104</sup> (ii) one-carbon ring expansion in cyclopentanones,<sup>105</sup> norcarane, and spiro[2,5]octane,<sup>106</sup> (iii)  $\alpha$ - and  $\beta$ -thujone radical rearrangements,<sup>107</sup> (iv) cyclopropylcarbinyl radicals or alkoxy-carbonyl radicals containing stabilizing substituents,<sup>108</sup> and (v) cyclobutylcarbinyl radicals.<sup>109</sup> *Ab initio* and density functional theory have been used to study radical clock reactions.<sup>110</sup>

2. *Alkenes*. When the substrate molecule contains a double bond, treatment with chlorine or bromine usually leads to addition rather than substitution, as described in **15-35**. However, for other radicals (and even for chlorine or bromine atoms when they react by hydrogen transfer) the position of attack is at the allylic carbon. Vinylic hydrogen atoms are practically never abstracted, and allylic hydrogen atoms are greatly preferred to other positions of the molecule. Allylic hydrogen abstraction from a cyclic alkenes is usually faster than abstraction from a acyclic alkenes.<sup>111</sup> This is generally attributed<sup>112</sup> to resonance stabilization of an allylic radical:

As might be expected, allylic rearrangements (see **14-6**) are common in these cases.<sup>113</sup>

3. *Alkyl Side Chains of Aromatic Rings*. The preferential position of attack on a side chain is usually the one directly attached to the ring (the benzylic position). Both for active radicals, such as chlorine and phenyl, and for more selective ones, such as bromine, hydrogen exchange is faster than that at a primary carbon. For active radicals, hydrogen exchange at the benzylic position is slower than for tertiary positions, while for the selective ones it is faster. Two or three aryl groups on a carbon activate its hydrogen atoms even more, as would be expected from the resonance involved. These statements can be illustrated by the abstraction ratios shown:<sup>114</sup>

	Me-H	MeCH <sub>2</sub> -H	Me <sub>2</sub> CH-H	Me <sub>3</sub> C-H	PhCH <sub>2</sub> -H	Ph <sub>2</sub> CH-H	Ph <sub>3</sub> C-H
Br	0.0007	1	220	19,400	64,000	1.1 × 10 <sup>6</sup>	6.4 × 10 <sup>6</sup>
Cl	0.004	1	4.3	6.0	1.3	2.6	9.5

However, many anomalous results have been reported for these substrates. The benzylic position is not always the most favored. One thing certain is that *aromatic* hydrogen atoms are seldom abstracted if there are aliphatic ones to compete. (Note from Table 5.3, that *D* for Ph-H is higher than that for any C-H bond in an alkyl

group.) Several  $\sigma^*$  scales (similar to the  $\sigma$ ,  $\sigma^+$ , and  $\sigma^-$  scales discussed in Chapter 9) have been developed for benzylic radicals.<sup>115</sup>

4. *Compounds Containing Electron-Withdrawing Substituents.* In halogenations, electron-withdrawing groups greatly deactivate adjacent positions. Compounds of the type  $Z-CH_2-CH_3$  are attacked predominantly or exclusively at the  $\beta$  position when  $Z$  is  $CO_2H$ ,  $COCl$ ,  $COOR$ ,  $SO_2Cl$ , or  $CX_3$ . Compounds such as acetic acid and acetyl chloride are not attacked at all, in sharp contrast to electrophilic halogenations (12-4 to 12-6), where *only* the  $\alpha$  position is substituted. This deactivation of  $\alpha$  positions is also at variance with the expected stability of the resulting radicals, since they would be expected to be stabilized by resonance similar to that for allylic and benzylic radicals. This behavior is a result of the polar transition states discussed in Sec. 14.A.ii. Halogen atoms are electrophilic radicals and look for positions of high electron density. Hydrogen atoms on carbon atoms next to electron-withdrawing groups have low electron densities (because of the field effect of  $Z$ ) and are therefore shunned. Radicals that are not electrophilic do not display this behavior. For example, the methyl radical is essentially nonpolar and does not avoid positions next to electron-withdrawing groups; relative rates of abstraction at the C-2 and C-3 carbons of propionic acid are (i) 1 for C-2 and 78 for C-3 ( $Me\bullet$ ) and (ii) 1 for C-2 and 0.02 for C-3 ( $Cl\bullet$ ).<sup>116</sup>

It is possible to generate radicals adjacent to electron-withdrawing groups. Radical **12** can be generated and it undergoes coupling reactions with little selectivity. When **13** is generated, it rapidly disproportionates rather than couples, giving the corresponding alkene and alkane.<sup>117</sup> Such radicals have also been shown to have a conformational preference for orientation of the orbital containing the single electron. In such cases, hydrogen abstraction proceeds with good stereoselectivity.<sup>118</sup>

Some radicals, for example, *tert*-butyl,<sup>119</sup> benzyl,<sup>120</sup> and cyclopropyl,<sup>121</sup> are *nucleophilic* (they tend to abstract electron-poor hydrogen atoms).<sup>122</sup> The phenyl radical appears to have a very small degree of nucleophilic character.<sup>123</sup> For longer chains, the field effect continues, and the  $\beta$  position is also deactivated to attack by halogen, though much less so than the  $\alpha$  position. It was noted previously (in

Sec. 14.A.ii) that abstraction of an  $\alpha$ -hydrogen atom from ring-substituted toluenes can be correlated by the *Hammett equation*.

5. *Stereoelectronic Effects*. In Sec. 16.A.i, category 4, there is an example of a stereo-electronic effect. It has been shown that such effects are important where a hydrogen is abstracted from a carbon adjacent to a C—O or C—N bond. In such cases, hydrogen is abstracted from C—H bonds that have a relatively small dihedral angle ( $\approx 30^\circ$ ) with the unshared orbitals of the O or N much more easily than from those with a large angle ( $\approx 90^\circ$ ). For example, the starred hydrogen of **14** was abstracted about 8 times faster than the starred hydrogen of **15**.<sup>124</sup>

The presence of an OR or SiR<sub>3</sub> substituent  $\beta$  to the carbon bearing the radical accelerates the rate of halogen abstraction.<sup>125</sup> Tertiary arylcarbinoyloxy radicals undergo  $\beta$  scission to give a ketone.<sup>126</sup> Abstraction of a halogen has been studied much less,<sup>127</sup> but the order of reactivity is RI > RBr > RCl  $\gg$  RF.

There are now many cases where free-radical reactions are promoted by transition metals.<sup>128</sup>

#### 14.B.ii. Reactivity at a Bridgehead<sup>129</sup>

Many free-radical reactions have been observed at bridgehead carbons, for example, the formation of bromide **16** (see **14-24**),<sup>130</sup> demonstrating that the free radical need not be planar. However, treatment of norbornane with sulfuryl chloride and benzoyl peroxide gave mostly 2-chloronorbornane, although the bridgehead position is tertiary.<sup>131</sup> So, while bridgehead free-radical substitution is possible, it is not preferred, presumably because of the strain involved.<sup>132</sup>

### 14.B.iii. Reactivity in Aromatic Substrates

Free-radical substitution at an aromatic carbon seldom takes place by a mechanism in which a hydrogen atom is abstracted to give an aryl radical. Reactivity considerations here are similar to those in Chapters 11 and 13; i.e., which position on the ring will be attacked to give the intermediate, **17**.

The obvious way to obtain this information is to carry out reactions with various Z groups and to analyze the products for percent *ortho*, *meta*, and *para* isomers, as has so often been done for electrophilic substitution. However, this procedure is much less accurate in the case of free-radical substitutions because of the many side reactions. It may be, for example, that in a given case the *ortho* position is more reactive than the *para*, but the intermediate from the *para* attack may go on to product while that from *ortho* attack gives a side reaction. In such a case, analysis of the three products does not give a true picture of which position is most susceptible to attack. The following generalizations can nevertheless be drawn, although there has been much controversy over just how meaningful such conclusions are.<sup>133</sup>

1. All substituents increase reactivity at *ortho* and *para* positions over that of benzene. There is no great difference between electron-donating and electron-withdrawing groups.
2. Reactivity at *meta* positions is usually similar to that of benzene, perhaps slightly higher or lower. This fact, coupled with the preceding one, means that all substituents are activating and *ortho/para* directing; none are deactivating or (chiefly) *meta* directing.
3. Reactivity at *ortho* positions is usually somewhat greater than at *para* positions, except where a large group decreases *ortho* reactivity for steric reasons.
4. In direct competition, electron-withdrawing groups exert a somewhat greater influence than electron-donating groups. Arylation of *para*-disubstituted compounds  $\text{XC}_6\text{H}_4\text{Y}$  showed that substitution *ortho* to the group X became increasingly preferred as the electron-withdrawing character of X increases (with Y held constant).<sup>134</sup> The increase could be correlated with the Hammett  $\sigma_p$  values for X.
5. Substituents have a much smaller effect than in electrophilic or nucleophilic substitution; hence the partial rate factors (Sec. 11.C) are not great.<sup>135</sup> Partial rate factors for a few groups are given in Table 14.1.<sup>136</sup>
6. Although hydrogen is the leaving group in most free-radical aromatic substitutions, *ipso* attack (Sec. 11.B.iii) and *ipso* substitution (e.g., with Br,  $\text{NO}_2$ , or  $\text{CH}_3\text{CO}$  as the leaving group) have been found in certain cases.<sup>137</sup>

Note that interconvertible 1,4-hydrogen atom shifts are possible in radicals derived from biaryls.<sup>138</sup>

#### 14.B.iv. Reactivity in the Attacking Radical<sup>139</sup>

As seen above, some radicals are much more selective than others (Sec. 14.B.i). The bromine atom is so selective that when only primary hydrogen atoms are available, as in 2,2-dimethylpropane or *tert*-butylbenzene, the reaction is slow. Also, 2-methylpropane can be selectively brominated to give *tert*-butyl bromide in high yields. However, toluene reacts with bromine atoms instantly. Bromination of other alkylbenzenes, for example ethylbenzene and cumene (isopropylbenzene), takes place exclusively at the  $\alpha$  position,<sup>140</sup> emphasizing the selectivity of Br•. The dissociation energy *D* of the C–H bond is more important for radicals of low reactivity than for highly reactive radicals, since the energy required for bond breaking in the transition state is greater. Thus, bromine shows a greater tendency than chlorine to attack  $\alpha$  to an electron-withdrawing group because the energy of the C–H bond there is lower than in other places in the molecule.

Some radicals, for example, triphenylmethyl, are so unreactive that they abstract hydrogen atoms very poorly, if at all. Common free radicals have been discussed for their selectivity and approximate order of reactivity.<sup>141</sup> The bromine radical is nearly 708 times more reactive than the chlorine radical for removal of a tertiary alkyl hydrogen atom and is 4500 times more reactive than the fluorine radical. The methyl radical is 5.6 times more reactive than the chlorine radical, and the methoxy radical is 3 times more reactive than the chlorine radical for removal of a tertiary hydrogen atom. The activation energies for the reaction *i*-Pr• show that it is less active than Me• and *t*-Bu• is even less reactive.<sup>142</sup> It has been mentioned that some free radicals (e.g., chloro) are electrophilic and some (e.g., *tert*-butyl) are nucleophilic. It must be borne in mind that these tendencies are relatively slight compared with the electrophilicity of a positive ion or the nucleophilicity of a negative ion. The predominant character of a free radical is neutral, whether it has slight electrophilic or nucleophilic tendencies.

### 14.B.v. The Effect of Solvent on Reactivity<sup>143</sup>

As noted earlier, the solvent usually has little effect on free-radical substitutions in contrast to ionic substitution reactions: indeed, reactions in solution are often quite similar in character to those in the gas phase, where there is no solvent at all. However, in certain cases the solvent *can* make an appreciable difference.

Chlorination of 2,3-dimethylbutane in aliphatic solvents gave ~60%  $(\text{CH}_3)_2\text{CHCH}(\text{CH}_3)\text{CH}_2\text{Cl}$  and 40%  $(\text{CH}_3)_2\text{CHCCl}(\text{CH}_3)_2$ , while in aromatic solvents the ratio became about 10 : 90.<sup>144</sup> This result is attributed to complex formation between the aromatic solvent and the chlorine atom that makes the chlorine more selective.<sup>145</sup> This type of effect is not found in cases where the differences in ability to abstract the atom are caused by field effects of electron-withdrawing groups (Sec. 14.B.i). In such cases, aromatic solvents make little difference.<sup>146</sup> The aryl-Cl complex has been detected<sup>147</sup> as a very short-lived species by observation of its visible spectrum in the pulse radiolysis of a solution of benzene in  $\text{CCl}_4$ .<sup>148</sup>

Differences caused by solvents have also been reported in reactions of other radicals.<sup>149</sup> Some of the anomalous results obtained in the chlorination of aromatic side chains (Sec. 14.B.i) can also be explained by this type of complexing, in this case not with the solvent but with the reacting species.<sup>150</sup> Much smaller, but real, differences in selectivity have been found when the solvent in the chlorination of 2,3-dimethylbutane is changed from an alkane to  $\text{CCl}_4$ .<sup>151</sup> However, these differences are not caused by formation of a complex between  $\text{Cl}\cdot$  and the solvent. There are cases, however, where the rate of reaction for trapping a radical depends on the polarity of the solvent, particularly in water.<sup>152</sup>

## 14.C. REACTIONS

The reactions in this chapter are classified according to leaving group.

<sup>153</sup> For lists of reagents, with references, see Larock, R.C. *Comprehensive Organic Transformations*, 2nd ed., Wiley-VCH, NY, 1999, pp. 611–617.

Alkanes can be chlorinated or brominated by treatment with chlorine or bromine in the presence of visible or UV light, or with heat.<sup>154</sup> These reactions require an added chemical reagent as the radical chain initiator, or exposure to light, or higher temperatures.<sup>155</sup> The reaction can also be applied to alkyl chains containing many functional groups. The chlorination reaction is usually not useful for preparative purposes precisely because it is so general: not only does substitution take place at virtually every alkyl carbon in the molecule, but di- and polychloro substitution almost invariably occur even if there is a large molar ratio of substrate to halogen. A visible light-induced monochlorination of cyclohexane with NaCl and Oxone in H<sub>2</sub>O/CF<sub>3</sub>CH<sub>2</sub>OH gave chlorocyclohexane.<sup>156</sup> Note that benzylic halogenation, such as the *Wohl-Ziegler bromination*, is discussed in **14-3**.

When functional groups are present, the principles are those outlined in Sec. 14.B.i. Tertiary carbons are most likely to be functionalized and primary carbons least likely. Favored positions are those  $\alpha$  to aromatic rings, while positions  $\alpha$  to electron-withdrawing groups are least likely to be substituted. Hydrogen atoms  $\alpha$  to an OR group are very readily replaced. Nevertheless, mixtures are nearly always obtained. Of course, if a *mixture* of chlorides is wanted, the reaction is usually quite satisfactory. For obtaining pure compounds, the chlorination reaction is essentially limited to substrates with only one type of replaceable hydrogen (e.g., ethane, cyclohexane, 2,2-dimethylpropane). With methylbenzenes and other substrates with methyl groups on aromatic rings, few cases are known where halogen atoms substitute at an aromatic position.<sup>157</sup> Of course, ring substitution *does* take place in the presence of a positive ion-forming catalyst (**11-10**). In addition to mixtures of various alkyl halides, traces of other products are obtained. These include H<sub>2</sub>, alkenes, higher alkanes, lower alkanes, and halogen derivatives of these compounds. Solvent plays an important role in this process.<sup>158</sup>

The bromine atom is much more selective than the chlorine atom. As indicated in Sec. 14.B.iv, it is often possible to brominate tertiary and benzylic positions selectively. High regioselectivity can also be obtained where the neighboring-group mechanism (Sec. 14.A.iv) can operate. Reductive bromine atom transfer reactions have been reported.<sup>159</sup> Photobromination using molecular bromine has been done using flow conditions (Sec. 7.D).<sup>160</sup>

As already mentioned, halogenation can be performed with chlorine or bromine. Fluorine has also been used,<sup>161</sup> but seldom, because it is too reactive and hard to control.<sup>162</sup>

The reactions of fluorinated organic radicals have been studied.<sup>163</sup> Fluorination often breaks carbon chains down into smaller units, a side reaction that sometimes becomes troublesome in chlorinations too. Fluorination<sup>164</sup> has been achieved by the use of chlorine trifluoride  $\text{ClF}_3$  at  $-75^\circ\text{C}$ .<sup>165</sup> For example, cyclohexane gave 41% fluorocyclohexane and methylcyclohexane gave 47% 1-fluoro-1-methylcyclohexane. Fluoroxytrifluoromethane  $\text{CF}_3\text{OF}$  fluorinates tertiary positions of certain molecules in good yields with high regioselectivity.<sup>166</sup> Fluorine at  $-70^\circ\text{C}$ , diluted with  $\text{N}_2$ ,<sup>167</sup> and bromine trifluoride at  $25\text{--}35^\circ\text{C}$ <sup>168</sup> are also highly regioselective for tertiary positions. These reactions probably have an electrophilic mechanism<sup>169</sup> not a free-radical mechanism. In fact, the success of the  $\text{F}_2$  reactions depends on the suppression of free-radical pathways, by dilution with an inert gas, by working at low temperatures, and/or by the use of radical scavengers. Fluorination of 1,3-dicarbonyl compounds and activated aromatic compounds was achieved under solvent-free conditions using Selectfluor/TEDA/ $\text{BF}_4$ .<sup>170</sup>

Iodine can be used if the activating light has a wavelength of 184.9 nm,<sup>171</sup> but iodinations using  $\text{I}_2$  alone are seldom attempted, largely because the HI formed reduces the alkyl iodide. The direct free-radical halogenation of aliphatic hydrocarbons with iodine is significantly endothermic relative to the other halogens, and the requisite chain reaction does not occur.<sup>172</sup> The reaction of an alkane with *tert*-butylhypoiodite (*t*-BuOI) at  $40^\circ\text{C}$  gave the iodoalkane in good yield.<sup>173</sup> The reaction of alkanes with iodine and  $\text{PhI}(\text{OAc})_2$  generates the iodoalkane.<sup>174</sup> A radical protocol was developed using  $\text{Cl}_4$  with base. For example, cyclohexane could be iodinated with  $\text{Cl}_4$  in the presence of powdered NaOH.<sup>175</sup> The reaction led to the use of iodoform on solid NaOH as the iodination reagent of choice. A base-induced bromination has been reported. Hydrogen peroxide/HBr in water has been used for radical bromination.<sup>176</sup>

When chlorination is carried out with *N*-haloamines and sulfuric acid (catalyzed by either UV light or metal ions), selectivity is much greater than with other reagents.<sup>177</sup> In particular, alkyl chains are chlorinated with high regioselectivity at the position next to the end of the chain (the  $\omega - 1$  position).<sup>178</sup> Some typical selectivity values are given here:<sup>179</sup>

<sup>178</sup> The  $\omega - 1$  regioselectivity diminishes when the chains are  $>10$  carbons; see Deno, N.C.; Jedziniak, E.J. *Tetrahedron Lett.* **1976**, 1259; Konen, D.A.; Maxwell, R.J.; Silbert, L.S. *J. Org. Chem.* **1979**, *44*, 3594.

<sup>179</sup> See, however, Deno, N.C.; Pohl, D.G. *J. Org. Chem.* **1975**, *40*, 380.

Furthermore, di- and polychlorination are much less prevalent. Dicarboxylic acids are predominantly chlorinated in the middle of the chain,<sup>183</sup> and adamantane and bicyclo[2.2.2]octane are predominantly chlorinated at the bridgeheads<sup>184</sup> by this procedure. The reasons for the high  $\omega - 1$  specificity are not clearly understood.<sup>185</sup> Enhanced selectivity at a terminal position of *n*-alkanes has been achieved by absorbing the substrate onto a pentasil (five-membered ring) zeolite.<sup>186</sup>

In almost all cases, the mechanism involves a free-radical chain:

When the reagent is halogen, initiation occurs as shown above.<sup>187</sup> When it is another reagent, a similar cleavage occurs (catalyzed by light or, more commonly, peroxides), followed by propagation steps that do not necessarily involve abstraction by halogen. For example, the propagation steps for chlorination by *tert*-butyl hypochlorite (*t*-BuOCl) have been formulated as:<sup>188</sup>

and the abstracting radicals in the case of *N*-haloamines are the aminium radical cations  $R_2NH\bullet^+$  (**11-5**), with the following mechanism (in the case of initiation by  $Fe^{2+}$ ):<sup>177</sup>

The two propagation steps shown above for  $X_2$  are those that lead directly to the principal products ( $RX$  and  $HX$ ), but many other propagation steps are possible and many occur. Similarly, the only termination step shown is the one that leads to  $RX$ , but any two radicals ( $\bullet H$ ,  $\bullet CH_3$ ,  $\bullet Cl$ ,  $\bullet CH_2CH_3$ ) may combine in all combinations. Thus, products like  $H_2$ , higher alkanes, and higher alkyl halides can be accounted for.

When  $CH_4$  and  $CH_2CD_2$  are the substrates, the rate-determining step is removal of  $H$  by  $Cl\bullet$

and an isotope effect of 12.1 was observed at 0 °C.<sup>189</sup> For chlorinations, there are about  $10^4$ – $10^6$  propagations before a termination step takes place.

The order of reactivity of the halogens can be explained by energy considerations. For the substrate methane,  $\Delta H$  values for the two principal propagation steps are shown:

	$F_2$	$Cl_2$	$Br_2$	$I_2$	$F_2$	$Cl_2$	$Br_2$	$I_2$
	kcal mol <sup>-1</sup>				kJ mol <sup>-1</sup>			
$CH_4 + X\bullet \rightarrow CH_3\bullet + HX$	-31	+2	+17	+34	-132	+6	+72	+140
$CH_4 + X_2 \rightarrow CH_3X + X\bullet$	-70	-26	-24	-21	-293	-113	-100	-87

In each case  $D$  for  $CH_3-H$  is 105 kcal mol<sup>-1</sup> (438 kJ mol<sup>-1</sup>), while  $D$  values for the other bonds involved are given in Table 14.2.<sup>190</sup>  $F_2$  is so reactive<sup>191</sup> that neither UV light nor any other initiation is needed (total  $\Delta H = -101$  kcal mol<sup>-1</sup>,  $-425$  kJ mol<sup>-1</sup>);<sup>192</sup> while  $Br_2$  and  $I_2$  essentially do not react with methane. The second step is exothermic in all four cases, but it cannot take place before the first, and it is this step that is very unfavorable for  $Br_2$  and  $I_2$ . It is apparent that the most important single factor causing the order of halogen reactivity to be  $F_2 > Cl_2 > Br_2 > I_2$  is the decreasing strength of the  $HX$  bond in the order  $HF > HCl > HBr > HI$ . The increased reactivity of secondary and tertiary positions is in accord with the decrease in  $D$  values for  $R-H$  in the order primary > secondary > tertiary (Table 5.3). (Note that for chlorination the first step is exothermic for practically all substrates other than  $CH_4$ , since most other aliphatic  $C-H$  bonds are weaker than those in

CH<sub>4</sub>.) It is noted that the mechanism of triethylborane-initiated radical chain chlorination has been examined.<sup>193</sup>

Metal-mediated halogenation reactions are known. Heating alkenes with bromine in the presence of MnO<sub>2</sub> leads to monobromination.<sup>194</sup> Bromination and chlorination of alkanes and cycloalkanes can also take place by an electrophilic mechanism if the reaction is catalyzed by AgSbF<sub>6</sub>.<sup>195</sup> The Ag-catalyzed chlorination is known.<sup>196</sup> Polycomponent metal-catalyzed fluorination reactions are known.<sup>197</sup> Direct chlorination at a vinylic position by an electrophilic mechanism has been achieved with benzeneseleninyl chloride PhSe(O)Cl and AlCl<sub>3</sub> or AlBr<sub>3</sub>.<sup>198</sup> However, while some substituted alkenes give high yields of chloro substitution products, others (e.g., styrene) undergo addition of Cl<sub>2</sub> to the double bond (**15-39**).<sup>164</sup> The Pd-catalyzed fluorination has been reported.<sup>199</sup> Organocatalysts have been used for asymmetric fluorination.<sup>200</sup>

an  $\alpha$  hydrogen,  $\alpha$  halogenation occurs instead. The mechanisms are probably of the free-radical type. *N*-Bromosuccinimide (NBS), with AIBN (Sec. 14.A.i) as a catalyst, has been used to convert aldehydes to acyl bromides.<sup>201</sup> Many other halogenation agents have been employed, and a common reagent is sulfuryl chloride  $\text{SO}_2\text{Cl}_2$ .<sup>202</sup> Among other reagents used have been *N*-bromosuccinimide (see **14-3**),  $\text{CCl}_4$ ,<sup>203</sup>  $\text{PCl}_5$ ,<sup>204</sup> and *N*-haloamines and sulfuric acid.<sup>177</sup> In all these cases, an initiator is required, usually peroxides or UV light.<sup>205</sup> OS I, 155.

#### 14-2 Halogenation at Silicon

Just as free radical halogenation occurs at the carbon of an alkane, via hydrogen abstraction to form the radical, a similar reaction occurs at silicon. When triisopropylsilane (*i*- $\text{Pr}_3\text{Si-H}$ ) reacts with *tert*-butyl hypochlorite at  $-10^\circ\text{C}$ , the product is triisopropylchlorosilane (*i*- $\text{Pr}_3\text{Si-Cl}$ ).<sup>206</sup>

#### 14-3 Allylic and Benzylic Halogenation

This reaction is a special case of **14-1**, but is important enough to be treated separately.<sup>207</sup> Alkenes can be brominated in the allylic position and arenes in a benzylic position by a number of reagents, of which NBS<sup>208</sup> is by far the most common. When this reagent is used, the reaction is known as *Wohl-Ziegler bromination*.<sup>209</sup> A nonpolar solvent is used, most often  $\text{CCl}_4$ , but the reaction has also been done in an ionic liquid.<sup>210</sup> Other *N*-bromoamides have also been used. A radical initiator is needed, usually AIBN (**1**), but a peroxide such as di-*tert*-butyl peroxide, or benzoyl peroxide or, less often, UV light can be used. A light-induced benzylic bromination<sup>211</sup> has been reported using flow conditions, as

has benzylic fluorination<sup>212</sup> (Sec. 7.D). Boron tribromide in CCl<sub>4</sub> has been used for benzylic bromination.<sup>213</sup> Benzylic dibromides have been prepared from benzylic alcohols using 1,3-dibromo-5,5-dimethylhydantoin in THF.<sup>214</sup> The radical bromination of unsymmetrical dimethylated pyridines proceeds with good regioselectivity.<sup>215</sup>

Allylic chlorination has also been carried out<sup>216</sup> with *N*-chlorosuccinimide (NCS) and either arylselenenyl chlorides (ArSeCl), aryl diselenides (ArSeSeAr), or TsNSO as catalysts. Allylic chlorination has been carried out with *tert*-butyl hypochlorite<sup>217</sup> or with NaClO/CeCl<sub>3</sub>•7H<sub>2</sub>O.<sup>218</sup> The regioselective and enantioselective fluorination of cyclic allylic halides using Pd catalysts<sup>219</sup> is known, and Mn catalysts<sup>220</sup> have been reported. Iron compounds catalyze benzylic fluorination.<sup>221</sup> Iodohydantoins were used for benzylic iodination.<sup>222</sup> The reaction of allylic systems with an excess of elemental iodine in DMA gave the allylic iodide.<sup>223</sup>

The reaction is usually quite specific at an allylic or benzylic position and good yields are obtained. However, when the allylic radical intermediate is unsymmetrical, allylic rearrangements can take place, so that mixtures of both possible products are obtained, for example 1-bromobut-2-ene and 3-bromobut-1-ene are formed from but-1-ene. When a double bond has two different allylic positions (e.g., CH<sub>3</sub>CH=CHCH<sub>2</sub>CH<sub>3</sub>), a secondary position is substituted more readily than a primary. The relative reactivity of tertiary hydrogen is not clear, though many substitutions at allylic tertiary positions have been performed.<sup>224</sup> It is possible to brominate both sides of the double bond.<sup>225</sup> Because of the electron-withdrawing nature of bromine, the second bromine substitutes on the other side of the double bond rather than  $\alpha$  to the first bromine. Use of the selenium catalysts produces almost entirely the allylic rearranged chlorides in high yields. With TsNSO the products are the unrearranged chlorides in lower yields. Dichlorine monoxide (Cl<sub>2</sub>O), with no catalyst, also leads to allylic rearranged chlorides in high yields.<sup>226</sup> A free-radical mechanism is unlikely in these latter reactions.

Molecules with a benzylic hydrogen, such as toluene, react rapidly to give benzyl bromide (e.g., PhCH<sub>3</sub> → PhCH<sub>2</sub>Br).

*N*-Bromosuccinimide is a highly regioselective brominating agent at other positions, including positions  $\alpha$  to a carbonyl group,  $\alpha$  to a C≡C triple bond, or  $\alpha$  to an aromatic ring (the benzylic position). When both a double and a triple bond are in the same molecule, the preferred position is  $\alpha$  to the triple bond.<sup>227</sup>

Dauben and McCoy demonstrated that the mechanism of allylic bromination is of the free-radical type,<sup>228</sup> showing that the reaction is very sensitive to free-radical initiators and inhibitors and indeed does not proceed at all unless at least a trace of initiator is present. Subsequent work indicated that the species that actually abstracts hydrogen from the substrate is the bromine atom. The reaction is initiated by small amounts of Br•, and the main propagation steps are

and then

When NBS is used, the source of the Br<sub>2</sub> is a fast ionic reaction between NBS and the HBr:

The function of the NBS is therefore to provide a source of Br<sub>2</sub>, as shown in the reaction, in a low, steady state concentration, which effectively uses up the HBr liberated in step 1.<sup>229</sup> The main evidence for this mechanism is that NBS and Br<sub>2</sub> show similar selectivity<sup>230</sup> and that the various *N*-bromo amides also show similar selectivity,<sup>231</sup> which is consistent with the hypothesis that the same species is abstracting in each case.<sup>232</sup>

It may be asked why, if Br<sub>2</sub> is the reacting species, it does not add to the double bond, either by an ionic or by a free-radical mechanism (see 15-35). Apparently, the concentration is too low. In bromination of a double bond, only one atom of an attacking bromine molecule becomes attached to the substrate, whether the addition is electrophilic or free radical. The other bromine atom comes from another bromine-containing molecule or ion. This is clearly not a problem in reactions with benzylic species since the benzene ring is not prone to such addition reactions. If the concentration is sufficiently low, there is a low probability that the proper species will be in the vicinity once the intermediate forms. The intermediate in either case reverts to the initial species and the allylic substitution competes successfully. If this is true, it should be possible to brominate an alkene in the allylic position without competition from addition, even in the absence of NBS or a similar compound, if a very low concentration of bromine is used and if the HBr is removed as it is formed so that it is not available to complete the addition step. This pathway has indeed been demonstrated.<sup>233</sup>

When NBS is used to brominate nonalkenyl substrates, such as alkanes, another mechanism, involving abstraction of the hydrogen of the substrate by the succinimidyl radical<sup>234</sup> **18** can operate.<sup>235</sup> This mechanism is facilitated by certain solvents (e.g., CH<sub>2</sub>Cl<sub>2</sub>, CHCl<sub>3</sub>, or MeCN) in which NBS is more soluble, and by the presence of small amounts of an alkene that lacks an allylic hydrogen (e.g., ethene). The alkene serves to scavenge any Br• that forms from the reagent. Among the evidence for the mechanism involving **18** are abstraction selectivities similar to those of Cl• atoms and the isolation of β-bromopropionyl isocyanate (BrCH<sub>2</sub>CH<sub>2</sub>CONCO), which is formed by ring opening of **18**.

## B. Substitution by Oxygen

### 14-4 Hydroxylation at an Aromatic Carbon<sup>236</sup>

The hydroxylation of aromatic rings (e.g., formation of a phenol derivative) was discussed in **13-1**. However, another procedure is known that involves radicals. A mixture of hydrogen peroxide and ferrous sulfate,<sup>237</sup> called *Fenton's reagent*,<sup>238</sup> can be used to hydroxylate aromatic rings, although yields are usually not high.<sup>239</sup> Biaryls are typical side products. A mixture of ferrous ion, oxygen, ascorbic acid, and ethylenetetraaminetetraacetic acid (*Udenfriend's reagent*),<sup>240</sup> and peroxy acids such as peroxyxynitrous and trifluoroperoxyacetic acids have been used.

Much work has been done on the mechanism of the reaction with Fenton's reagent, and it is known that free aryl radicals (formed by a process such as HO• + ArH → Ar• + H<sub>2</sub>O) are *not* intermediates. The mechanism is essentially that outlined in Sec. 14.A.iii, with HO• as the attacking species,<sup>241</sup> formed by Fe<sup>2+</sup> + H<sub>2</sub>O<sub>2</sub> → Fe<sup>3+</sup> + <sup>-</sup>OH + HO•. The rate-determining step is formation of HO• and not its reaction with the aromatic substrate.

## 14-5 Formation of Cyclic Ethers

Alcohols with hydrogen in the  $\delta$  position (C-3 relative to the carbon bearing the OH) can be cyclized with lead tetraacetate.<sup>242</sup> The reaction is usually carried out at  $\sim 80^\circ\text{C}$  (most often in benzene at reflux), but can also be done at room temperature if the reaction mixture is irradiated with UV light. Tetrahydrofurans are formed in high yields. Little or no four- and six-membered cyclic ethers (oxetanes and tetrahydropyrans, respectively) are obtained even when  $\gamma$  and  $\epsilon$ -hydrogen atoms are present. The reaction has also been carried out with a mixture of halogen ( $\text{Br}_2$  or  $\text{I}_2$ ) and a salt or oxide of silver or mercury (especially  $\text{HgO}$  or  $\text{AgOAc}$ ),<sup>243</sup> with iodosobenzene diacetate and  $\text{I}_2$ ,<sup>244</sup> and with ceric ammonium nitrate (CAN).<sup>245</sup> The following mechanism is likely for the lead tetraacetate reaction:<sup>246</sup>

although **19** has never been isolated. The step marked **A** is a *1,5 internal hydrogen abstraction*. Such abstractions are well known (see **18-40**) and are greatly favored over 1,4 or 1,6 abstractions (the small amounts of tetrahydropyran formed result from 1,6 abstractions).<sup>247</sup>

Oxidation to the aldehyde or acid (**19-3** and **19-22**) and fragmentation of the substrate sometimes compete. When the OH group is on a ring of at least seven members, a transannular product can be formed, as in the cyclization reaction of octan-1-ol to **20**.<sup>248</sup>

#### 14-6 Formation of Hydroperoxides

The slow atmospheric oxidation (*slow* meaning without combustion) of C—H to C—O—O—H is called *autoxidation*.<sup>249</sup> The reaction occurs when compounds are allowed to stand in air and is catalyzed by light, so unwanted autoxidations can be greatly slowed by keeping the compounds in dark places. Most autoxidations proceed by free-radical chain processes that involve peroxy radicals.<sup>250</sup> To suppress autoxidation, an antioxidant can be added that will prevent or retard the reaction with atmospheric oxygen.<sup>251</sup> Although some lactone compounds are sold as antioxidants, many radicals derived from lactones show poor or no reactivity toward oxygen.<sup>251</sup> The hydroperoxides produced often react further to give alcohols, ketones, and more complicated products, so the reaction is not often used for preparative purposes, although in some cases hydroperoxides have been prepared in good yield.<sup>252</sup> Foods, rubber, paint, lubricating oils, and so on deteriorate on exposure to the atmosphere over periods of time due to autoxidation. On the other hand, a useful application of autoxidation is the atmospheric drying of paints and varnishes.

As with other free-radical reactions of C—H bonds, some bonds are attacked more readily than others,<sup>253</sup> and these are the ones seen before (Sec. 14.B.i), although the selectivity is very low at high temperatures and in the gas phase. The reaction can be carried out successfully at tertiary (to a lesser extent, secondary), benzylic,<sup>254</sup> and allylic R (though allylic rearrangements are common).<sup>255</sup> 2-Phenylpropane reacted with oxygen to give PhMe<sub>2</sub>C—OOH, for example. Another susceptible position is an aldehyde C—H, but the peroxy acids so produced are not easily isolated<sup>256</sup> since they are converted to the corresponding carboxylic acids (**19-23**). The  $\alpha$  positions of ethers are also easily attacked by oxygen [ RO—C—H  $\rightarrow$  RO—C—OOH ], but the resulting hydroperoxides are seldom isolated. However, this reaction constitutes a hazard in the storage of ethers since solutions of these hydroperoxides and their rearrangement products in ethers are potential spontaneous explosives.<sup>257</sup>

Oxygen itself (a diradical,  $\bullet\text{O}-\text{O}\bullet$ ) is not reactive enough to be the species that actually abstracts the hydrogen. But if even a trace of free radical (say R'•) is produced by some

<sup>249</sup> The term autoxidation actually applies to any slow oxidation with atmospheric oxygen. See Goosen, A.; Morgan, D.H. *J. Chem. Soc., Perkin Trans. 2* **1994**, 557. initiating process, it reacts with oxygen<sup>258</sup> to give R'-O-O•; and since this type of radical does abstract hydrogen, the chain is:

In at least some cases (in alkaline media)<sup>259</sup> the radical R• can be produced by formation of a carbanion and its oxidation (by O<sub>2</sub>) to a radical such as allylic radical.<sup>260</sup> Autoxidations in alkaline media can also proceed by a different mechanism:<sup>261</sup>

When alkenes are treated with oxygen that has been photosensitized (Sec. 7.A.vi, category 6), they are substituted by OOH in the allylic position in a synthetically useful reaction.<sup>262</sup> Although superficially similar to autoxidation, this reaction is clearly different because 100% allylic rearrangement always takes place. The reagent here is not the ground-state oxygen (a triplet), but an excited singlet state<sup>263</sup> (in which all electrons are paired; *singlet oxygen*). The function of the photosensitization is to promote the oxygen to this singlet state. Singlet oxygen can also be produced by nonphotochemical means,<sup>264</sup> for example, by the reaction between H<sub>2</sub>O<sub>2</sub> and NaOCl<sup>265</sup> or between ozone and triphenyl phosphite.<sup>266</sup> Calcium peroxide diperexohydrate (CaO<sub>2</sub>•2H<sub>2</sub>O<sub>2</sub>) has been reported as a storable compound used for the chemical generation of singlet oxygen.<sup>267</sup> The oxygen generated by either photochemical or nonphotochemical methods reacts with alkenes in the same way;<sup>268</sup> this is evidence that singlet oxygen is the reacting species in the photochemical reaction and not some hypothetical complex between triplet oxygen and the photosensitizer, as had previously been suggested. The fact that 100% allylic rearrangement always takes place is incompatible with a free-radical mechanism. Further evidence that free radicals are not involved comes from the treatment of optically active limonene

(21) with singlet oxygen. Among other products is the optically active hydroperoxide 22, though if 23 were an intermediate, it could not give an optically active product since it possesses a plane of symmetry.<sup>269</sup> In contrast, autoxidation of 21 gave optically inactive 22 (a mixture of four diastereomers in which the two pairs of enantiomers are present as racemic mixtures).

As this example shows, singlet oxygen reacts faster with more highly substituted alkenes than with less highly substituted alkenes. The order of alkene reactivity is tetrasubstituted > trisubstituted > disubstituted. Electron-withdrawing substituents deactivate the alkene.<sup>270</sup> In simple trisubstituted alkenes, there is a general preference for the hydrogen to be removed from the more highly congested side of the double bond.<sup>271</sup> With *cis*-alkenes of the form RCH=CHR', the hydrogen is removed from the larger R group.<sup>272</sup> Many functional groups in an allylic position cause the hydrogen to be removed from that side rather than the other (geminal selectivity).<sup>273</sup> Also, in alkyl-substituted alkenes, the hydrogen that is preferentially removed is the one geminal to the larger substituent on the double bond.<sup>274</sup>

Several mechanisms have been proposed for the reaction with singlet oxygen.<sup>275</sup> One of these is a pericyclic mechanism, similar to that of the *ene* synthesis (15-19).

However, there is strong evidence against this mechanism,<sup>276</sup> and a more likely mechanism involves addition of singlet oxygen to the double bond to give a perepoxide (24),<sup>277</sup> followed by internal proton transfer.<sup>278</sup> Still other proposed mechanisms involve diradicals or dipolar intermediates.<sup>279</sup>

**14-7** Formation of Peroxides

Peroxy groups (ROO) can be introduced into susceptible organic molecules by treatment with a hydroperoxide in the presence of cuprous chloride or other catalysts, for example, Co and Mn salts.<sup>280</sup> Very high yields can be obtained. The type of hydrogen replaced is similar to that with NBS (**14-3**), that is, mainly benzylic, allylic, and tertiary. The mechanism is therefore of the free-radical type, involving ROO• formed from ROOH and the metal ion. Biologically important chiral endoperoxides have been prepared by the catalytic peroxidation of conjugated aldehydes.<sup>281</sup>

**14-8** Acyloxylation

Susceptible positions of organic compounds can be directly acyloxylated<sup>282</sup> by *tert*-butyl peroxyesters, the most frequently used being acetic and benzoic (R' = Me or Ph).<sup>283</sup> The reaction requires a catalyst (cuprous ion is the actual catalyst, but a trace is all that is necessary, and such traces are usually present in cupric compounds, so that these are often used) and without the catalyst the reaction is not selective. Susceptible positions are similar to those in **14-5**: benzylic, allylic, and the  $\alpha$  position of ethers and sulfides. Terminal alkenes are substituted almost entirely in the 3 position, that is, with only a small amount of allylic rearrangement, but internal alkenes generally give mixtures containing a large amount of allylic-shift products. If the reaction with alkenes is carried out in an excess of another acid R''CO<sub>2</sub>H, the ester produced is of *that* acid ROCOR''. Aldehydes react to give anhydrides.

<sup>282</sup> For a list of reagents, with references, see Larock, R.C. *Comprehensive Organic Transformations*, 2nd ed., Wiley-VCH, NY, **1999**, pp. 1625–1630 ff, 1661–1663.

<sup>283</sup> See Rawlinson, D.J.; Sosnovsky, G. *Synthesis* **1972**, 1; Sosnovsky, G.; Rawlinson, D.J. in Swern, D. *Organic Peroxides*, Vol. 1, Wiley, NY, **1970**, pp. 585–608; Doumaux Jr, A.R. in Augustine, R.L. *Oxidation*, Vol. 2, Marcel Dekker, NY, **1971**, pp. 141–185.

Acyloxylation has also been achieved with metallic acetates, such as lead tetraacetate,<sup>284</sup> mercuric acetate,<sup>285</sup> and palladium(II) acetate.<sup>286</sup> In the case of the lead and mercuric acetates, not only does the reaction take place at allylic and benzylic positions and at those positions  $\alpha$  to an OR or SR group, but also at positions  $\alpha$  to the carbonyl groups of aldehydes, ketones, or esters and at positions  $\alpha$  to two carbonyl groups ( $ZCH_2Z'$ ). It is likely that in the latter cases it is the enol forms that react. Ketones can be  $\alpha$ -acyloxyated indirectly by treatment of various enol derivatives with metallic acetates, for example, silyl enol ethers with silver carboxylate/iodine,<sup>287</sup> enol thioethers with lead tetraacetate,<sup>288</sup> and enamines<sup>289</sup> with lead tetraacetate.<sup>290</sup> Lead tetraacetate even acyloxyates alkanes, in a slow reaction (10 days to 2 weeks), with tertiary and secondary positions greatly favored over primary ones.<sup>291</sup>  $\alpha,\beta$ -Unsaturated ketones can be acyloxyated in good yields in the  $\alpha'$  position with manganese triacetate.<sup>292</sup> Palladium acetate converts alkenes to vinylic and/or allylic acetates.<sup>293</sup> Acyloxylation of certain alkanes has also been reported with palladium(II) acetate.<sup>294</sup>

Studies of the mechanism of the cuprous-catalyzed reaction show that the most common mechanism is the one shown.<sup>295</sup>

This mechanism, involving a free radical  $\text{R}\cdot$ , is compatible with the allylic rearrangements found.<sup>296</sup> The fact that *tert*-butyl peroxyesters labeled with  $^{18}\text{O}$  in the carbonyl oxygen gave an ester with 50% of the label in each oxygen<sup>297</sup> is in accord with coupling of  $\text{R}\cdot$  with intermediate **34**, in which the Cu is ionically bound, so that the oxygen atoms are essentially equivalent. Other evidence is that *tert*-butoxy radicals have been trapped with

yields (80–90%) are obtained at  $-25$  to  $-20$  °C. In the nickel peroxide reaction the corresponding alcohols ( $\text{ArCH}_2\text{OH}$ ) have also been used as substrates.

Oxidative amidation of aldehydes has been done using  $\text{AgIO}_3$  in the presence of a Cu catalyst.<sup>308</sup> Similar oxidative amidation was accomplished using  $\text{H}_2\text{O}_2$  and a Pd catalyst.<sup>309</sup> Amides were prepared from aldehydes using NBS with a Cu catalyst.<sup>310</sup> Hypervalent iodine with a Fe catalyst has also been used.<sup>311</sup> Oxidative amidation of aromatic aldehydes using Oxone and ball milling without solvent gave the corresponding amide.<sup>312</sup>

Treatment of an aldehyde with iodine in aqueous ammonia, followed by oxidation with aqueous hydrogen peroxide, generates a primary amide.<sup>313</sup> Secondary amines react with aldehydes to give an amide using a Pd catalyst<sup>314</sup> or a Rh catalyst.<sup>315</sup> Thioamides  $\text{RCSNR}'_2$  have been prepared in good yield from thioaldehydes (produced *in situ* from phosphoranes and sulfur) and secondary amines.<sup>316</sup>

#### 14-11 Amidation and Amination at an Alkyl Carbon

When alkanes bearing a tertiary hydrogen are exposed to UV light in acetonitrile containing a heteropolytungstic acid, they are converted to an amide.<sup>317</sup> The oxygen in the product comes from the tungstic acid. When the substrate bears two adjacent tertiary hydrogen atoms, alkenes are formed (by loss of two hydrogen atoms), rather than amides (**19-2**). Amidyl radicals can be generated by other means.<sup>318</sup>

*N*-Methoxybenzamide reacts with ethers, with a Ni catalyst and di-*tert*-butyl peroxide, to give the *N*-( $\alpha$ -alkoxy) derivative via radical–radical coupling.<sup>319</sup> The activation of remote C–H bonds by photoredox-catalyzed radical translocation via *O*- and *N*-centered radicals has been reported.<sup>320</sup> The  $\alpha$ -C–H amination of ketones by reaction with amines using ammonium iodide as the catalyst and sodium percarbonate as the co-oxidant has been developed.<sup>321</sup> The Cu-catalyzed reaction of benzylic or simple hydrocarbons with benzamide and 2 equivalents of di-*tert*-butyl peroxide gave the corresponding amide.<sup>322</sup> A similar reaction has been reported using tetrabutylammonium iodide with TBHP as the oxidant.<sup>323</sup> A

Cu-catalyzed amidation reaction has been reported.<sup>324</sup> The visible-light photoredox-catalyzed reaction using DCA (9,10-dicyanoanthracene) as a visible light-absorbing photoredox catalyst and using *N*-methoxyacetamide as the nitrogen source gave the amide derivative.<sup>325</sup>

#### 14-12 Substitution by Nitro

In a reaction termed a “nitro-Hunsdiecker” (see **14-24**), vinyl carboxylic acids (conjugated acids) are treated with nitric acid and a catalytic amount of AIBN (**1**). The product is the vinyl nitro compound, generated via decarboxylation of a radical intermediate.<sup>326</sup>

Aryl halides are converted to aromatic nitro compounds via a Cu-catalyzed reaction with nitrite salts ( $\text{Ar-X} \rightarrow \text{Ar-NO}_2$ ).<sup>327</sup> Ceric ammonium nitrate in acetonitrile also facilitates this reaction.<sup>328</sup> Conjugated amides were coupled via the  $\gamma$  carbon to give good yields of the dimeric diamide, with an excess of samarium (II) iodide, and with modest enantioselectivity using a chiral additive.<sup>329</sup>

### E. Substitution by Carbon

In these reactions a new carbon–carbon bond is formed. These reaction may be given the collective title *coupling reactions*. In each case, an alkyl or aryl radical is generated and then combines with another radical (a termination process) or reacts with an aromatic ring or alkene to give the coupling product.<sup>330</sup>

#### 14-13 Simple Coupling at a Susceptible Position

Alkane and alkyl substrates  $\text{R-H}$  are treated with peroxides, which decompose to give a radical that abstracts a hydrogen from  $\text{R-H}$  to give  $\text{R}\cdot$ , which dimerizes by radical coupling. Dialkyl and diacyl peroxides have been used, as well as Fenton’s reagent (see **14-4**). This reaction is far from general, although in certain cases respectable yields have been obtained. Among susceptible positions are those at a tertiary carbon,<sup>331</sup> as well as those  $\alpha$  to a phenyl group (especially if there is also an  $\alpha$ -alkyl or  $\alpha$ -chloro group),<sup>332</sup> an ether

group,<sup>333</sup> a carbonyl group,<sup>334</sup> a cyano group,<sup>335</sup> a dialkylamino group,<sup>336</sup> or a carboxylic ester group (either the acid or alcohol side).<sup>337</sup> Cross coupling is possible in some cases. When toluene was heated with allyl bromide, in the presence of di-*tert*-butyl peroxide, 4-phenylbut-1-ene was formed quantitatively.<sup>338</sup>

Alkanes can be dimerized by vapor-phase mercury photosensitization<sup>339</sup> in a synthetically useful process that produces H<sub>2</sub> as a byproduct. Best results are obtained for coupling at tertiary positions, but compounds lacking tertiary hydrogen atoms (e.g., cyclohexane) also give good yields. Dimerization of *n*-alkanes gives secondary–secondary coupling in a nearly statistical distribution, with primary positions essentially unaffected. When a mixture of compounds is treated, cross-dimerization and homodimerization take place statistically. Even with the limitation on yield implied by the statistical process, cross-dimerization is still useful when one of the reactants is an alkane, because the products are easy to separate, and because of the few other ways to functionalize an alkane. The cross coupling of an alkane with trioxane is especially valuable, because hydrolysis of the product (**10-6**) gives an aldehyde, thus achieving the conversion RH → RCHO. The mechanism probably involves abstraction of H by the excited Hg atom, and coupling of the resulting radicals. Acylation of a tertiary alcohol gave the *tert*-alkyl *N*-phthalimidoyl oxalate, and subsequent exposure to visible light, with a Ru(bpy)<sub>3</sub>(PF<sub>6</sub>) catalyst, gave the tertiary carbon radical, which gave reductive coupling with alkenes or substitution reactions with allylic and vinylic halides.<sup>340</sup>

OS IV, 367; V, 1026; VII, 482.

#### 14-14 Coupling at a Susceptible Position Via Silanes

Under electrochemical conditions it is possible to couple two silanes. The reaction of 1-trimethylsilyl-1-methoxynonane and allyltrimethylsilane, for example, gave the corresponding homoallylic ether.<sup>341</sup>

#### 14-15 Coupling of Alkynes<sup>342</sup>

Terminal alkynes can be coupled by heating with stoichiometric amounts of cupric salts in pyridine or a similar base. This reaction, which produces symmetrical diynes

in high yields, is called the *Eglinton reaction*.<sup>343</sup> The large-ring annulenes (Sec. 2.K) were prepared by rearrangement and hydrogenation of cyclic polyynes,<sup>344</sup> prepared by the Eglinton reaction with terminal diynes, to give a cyclic trimer of 1,5-hexadiyne (cyclooctadeca-1,3,7,9,13,15-hexayne), and subsequent reaction with *Kt*-*OBu* and then catalytic hydrogenation gave cyclooctadeca-1,3,5,7,9,11,13,15,17-nonaene.<sup>345</sup> The corresponding tetramers ( $C_{24}$ ), pentamers ( $C_{30}$ ), and hexamers ( $C_{36}$ ) were also formed. The Eglinton reaction is of wide scope and many functional groups can be present on the alkyne. The oxidation is usually quite specific for triple-bond hydrogen. 1,4-Diynes have been prepared by the coupling of propargyl alcohols and terminal alkynes using cupric triflate as a catalyst and MS 4Å.<sup>346</sup>

Another common procedure is the use of catalytic amounts of cuprous salts in the presence of ammonia or ammonium chloride (this method is called the *Glaser reaction*). Atmospheric oxygen or some other oxidizing agent, such as permanganate or hydrogen peroxide, is required in the latter procedure. This method is not satisfactory for cyclic coupling. Hydrogen peroxide, potassium permanganate, potassium ferricyanide, iodine, or Cu(II) can be used as oxidants rather than oxygen.<sup>347</sup> Isolation of copper acetylide during the reaction can be avoided by doing the reaction in pyridine or cyclohexylamine, in the presence of catalytic amount of  $CuCl_2$ .<sup>348</sup> If the Glaser reaction is done with a *N,N,N',N'*-tetramethylethylenediamine/CuCl complex, the reaction proceeds in good yield in virtually any organic solvent.<sup>349</sup> A  $CuCl_2$ -catalyzed Glaser oxidative coupling has been reported.<sup>350</sup> When molecular oxygen is the oxidant, this modification of Glaser condensation is known as the *Hay reaction*. A microwave accelerated Glaser-Hay reaction is known.<sup>351</sup>

Unsymmetrical diynes can be prepared by *Cadiot-Chodkiewicz* coupling,<sup>352</sup> which is the Cu-catalyzed reaction of terminal alkynes with 1-bromoalkynes.

This reaction may be regarded as a variation of **10-74**, but it must have a different mechanism since acetylenic halides give the reaction but ordinary alkyl halides do not, which

<sup>351</sup> Bédard, A.-C.; Collins, S.K. *Chem. Commun.* **2012**, *48*, 6420.

<sup>352</sup> Chodkiewicz, W. *Ann. Chim. (Paris)* **1957**, [13] *2*, 819; Sindhu, K.S.; Thankachan, A.P.; Sajitha, P.S.; Anilkumar, G. *Org. Biomol. Chem.* **2015**, *13*, 6891.

is hardly compatible with a nucleophilic mechanism. However, the mechanism is not fully understood. Alkynes have also been coupled using CuI and a Pd catalyst.<sup>353</sup> A variation of the Cadiot-Chodkiewicz method consists of treating a haloalkyne ( $R'C\equiv CX$ ) with a copper acetylide ( $RC\equiv CCu$ ).<sup>354</sup> The Cadiot-Chodkiewicz procedure can be adapted to the preparation of diynes in which  $R' = H$  by the use of  $BrC\equiv CSiEt_3$  and subsequent cleavage of the  $SiEt_3$  group.<sup>355</sup> This protecting group can also be used in the Eglinton or Glaser methods.<sup>356</sup> The Au-catalyzed reaction was reported.<sup>357</sup>

The mechanism of the Eglinton and Glaser reactions probably begins with loss of a proton to give the alkyne anion since there is a base present and acetylenic protons are acidic. It is known, of course, that cuprous ion can form complexes with triple bonds. The final step is probably the coupling of two radicals that are formed *in situ*, but just how the carbanion becomes oxidized to the radical and what part the cuprous ion plays (other than forming the acetylide salt) are matters of considerable speculation,<sup>358</sup> and depend on the oxidizing agent. One proposed mechanism postulated Cu(II) as the oxidant.<sup>359</sup> It has been shown that molecular oxygen forms adducts with Cu(I) supported by tertiary amines, which might be the intermediates in the Glaser reaction where molecular oxygen is the oxidant.<sup>360</sup> For the *Hay reaction*, the mechanism involves a Cu(I)/Cu(III)/Cu(II)/Cu(I) catalytic cycle, and the key step for this reaction is the dioxygen activation during complexation of two molecules of acetylide with molecular oxygen, giving a Cu(III) complex.<sup>361</sup> This mechanism is supported by isolation and characterization of Cu(III) complexes formed under the conditions of the Glaser coupling.

A variation in the Glaser reaction couples terminal alkynes using  $CuCl_2$  in supercritical  $CO_2$  (Sec. 9.D.ii)<sup>362</sup> and in ionic liquids.<sup>363</sup> Coupling was also achieved using  $CuCl_2$  on  $KF/Al_2O_3$  with microwave irradiation.<sup>364</sup> A transition metal-free coupling reaction is known.<sup>365</sup> Coupling has been achieved under ambient conditions using cupric acetate.<sup>366</sup> Another variation is a Ni-catalyzed cross coupling.<sup>367</sup> Terminal alkynes give 1,3-diynes upon treatment with Cu/iodine.<sup>368</sup>

R = alkyl, the scope is more limited.<sup>385</sup> Only certain aromatic compounds, particularly benzene rings with two or more nitro groups, and fused ring systems, can be alkylated by this procedure. 1,4-Quinones can be alkylated with diacyl peroxides or with lead tetraacetate (methylation occurs with this reagent).

The mechanism is as shown in Sec. 14.A.iii and CIDNP has been observed.<sup>386</sup> The radicals are produced by cleavage of the O—O bond of diacyl peroxides (R(CO)O—O(CO)R) to give an acyl radical (RCO<sub>2</sub>•) that loses CO<sub>2</sub> to give R•. Since no relatively stable free radical is present, most of the product arises from dimerization and disproportionation.<sup>387</sup> The addition of a small amount of nitrobenzene increases the yield of arylation product because the nitrobenzene is converted to diphenyl nitroxide, which abstracts a hydrogen atom and diminishes the extent of side reactions.<sup>388</sup> The Pd-catalyzed methylation of aromatic rings in the presence of dicumyl peroxide is another variation.<sup>389</sup>

Aromatic compounds are converted to a biaryl by aryllead tricarboxylates such as ArPb(OAc)<sub>3</sub>.<sup>390</sup> Best yields (~70–85%) are obtained when the substrate contains alkyl groups; an electrophilic mechanism is likely. *O*-Phenylation is a possible side reaction. As with the aryllead tricarboxylate reactions, a free-radical mechanism is unlikely.<sup>391</sup>

OS V, 51. See also, OS V, 952; VI, 890.

#### 14-17 Photochemical Arylation of Aromatic Compounds

Another free-radical arylation method consists of the photolysis of aryl iodides in an aromatic solvent.<sup>392</sup> The role of directing substituents has been discussed.<sup>393</sup> Yields are generally higher than in **13-28** or **14-16**. The aryl iodide may contain OH or COOH groups. The coupling reaction of iodobenzene and azulene to give a phenylazulene was reported (41% conversion and 85% yield).<sup>394</sup> The mechanism is similar to that of **13-28**. The aryl radicals are generated by photolytic cleavage:

The reaction has been applied to intramolecular arylation (analogous to the *Pschorr reaction*).<sup>395</sup>

<sup>385</sup> See Tiecco, M.; Testaferri, L. *React. Intermed. (Plenum)* **1983**, 3, 61.

<sup>386</sup> Kaptein, R.; Freeman, R.; Hill, H.D.W.; Bargon, J. *J. Chem. Soc., Chem. Commun.* **1973**, 953.

<sup>387</sup> The mechanism is actually more complicated. See DeTar, D.F. *J. Am. Chem. Soc.* **1967**, 89, 4058. See also, Jandu, K.S.; Nicolopoulou, M.; Perkins, M.J. *J. Chem. Res. (S)* **1985**, 88.

Photoirradiation using a Xe lamp, promoted by tetrabutylammonium cyanoborohydride with air, led to radical biaryl coupling of iodoarenes and benzene.<sup>396</sup>

#### 14-18 Alkylation, Acylation, and Carbalkoxylation of Nitrogen Heterocycles<sup>397</sup>

Alkylation of protonated nitrogen heterocycles (e.g., pyridines, quinolines) can be accomplished by treatment with a carboxylic acid, silver nitrate, sulfuric acid, and ammonium peroxydisulfate.<sup>398</sup> The R group can be primary, secondary, or tertiary. The attacking species is  $\text{R}\cdot$ , formed by<sup>399</sup>

A hydroxymethyl group can be introduced ( $\text{ArH} \rightarrow \text{ArCH}_2\text{OH}$ ) by several variations of this method.<sup>400</sup> Alkylation of these substrates can also be accomplished by generating the alkyl radicals in other ways: from hydroperoxides and  $\text{FeSO}_4$ ,<sup>401</sup> from alkyl iodides and  $\text{H}_2\text{O}_2/\text{Fe(II)}$ ,<sup>402</sup> from carboxylic acids and lead tetraacetate, or from the photochemically induced decarboxylation of carboxylic acids by iodosobenzene diacetate.<sup>403</sup> Protonated nitrogen heterocycles can be carbalkoxylated<sup>404</sup> by treatment with esters of  $\alpha$ -keto acids and Fenton's reagent.

#### 14.C.ii. Metals as Leaving Groups

##### 14-19 Coupling of Grignard Reagents

This organometallic coupling reaction is clearly related to the *Wurtz coupling*, discussed in **10-56**, and the coupling of other organometallic compounds is discussed in **14-20**.

<sup>404</sup> See Heinisch, G.; Lötsch, G. *Angew. Chem. Int. Ed.* **1985**, *24*, 692.

Grignard reagents can be coupled to give symmetrical dimers<sup>405</sup> by treatment with either thallium(I) bromide<sup>406</sup> or with a transition metal halide such as Fe,<sup>407</sup> Cr, or Cu compounds.<sup>408</sup> The metallic halide is an oxidizing agent and becomes reduced. Both aryl and alkyl Grignard reagents can be dimerized by either procedure, though the TlBr method cannot be applied to R = primary alkyl or to aryl groups with *ortho* substituents. Vinylic and alkynyl Grignard reagents can be coupled (to give 1,3-dienes and 1,3-diynes, respectively) by treatment with SOCl<sub>2</sub>.<sup>409</sup> Primary alkyl, vinylic, aryl, and benzylic Grignard reagents give symmetrical dimers in high yield (≈90%) when treated with a silver(I) salt in the presence of a nitrogen-containing oxidizing agent such as lithium nitrate, methyl nitrate, or NO<sub>2</sub>.<sup>410</sup> This method has been used to close rings of four, five, and six members.<sup>411</sup> The mechanisms of the reactions with metal halides, at least in some cases, probably begin with conversion of RMgX to the corresponding RM (**12-35**), followed by its decomposition to free radicals.<sup>412</sup>

Work continues in this area. The Co-,<sup>413</sup> Cu-,<sup>414</sup> Fe-,<sup>415</sup> and Ni<sup>416</sup>-catalyzed couplings with Grignard reagents are known. The mechanism of the Cu-free asymmetric allylic allylation with Grignard reagents has been explored.<sup>417</sup> The Cu-catalyzed cross coupling of secondary alkyl halides or tosylates with secondary alkyl Grignard reagents, in the presence of TMEDA and LiOMe, has been reported.<sup>418</sup> The Co-catalyzed coupling of alkyl halides with tertiary alkyl Grignard reagents has been reported.<sup>419</sup> The Fe-catalyzed, enantioselective cross coupling of  $\alpha$ -chloro esters,<sup>420</sup> and also  $\alpha$ -bromo esters,<sup>421</sup> and aryl Grignard reagents has been reported. The *N*-heterocyclic carbene-based, Ni-catalyzed coupling of

aryl bromide with tertiary alkyl Grignard reagents is known.<sup>422</sup> Pyridinyl Grignard reagents have been coupled with secondary alkyl iodides using  $\text{CuLi}_2\text{Cl}_4$ .<sup>423</sup>

OS VI, 488.

#### 14-20 Coupling of Other Organometallic Reagents<sup>347</sup>

Lithium dialkylcopper reagents can be oxidized to symmetrical dimers by  $\text{O}_2$  at  $-78^\circ\text{C}$  in THF.<sup>424</sup> The reaction is successful for R = primary and secondary alkyl, vinylic, or aryl groups. Vinylic copper reagents dimerize on treatment with oxygen, or simply on standing at  $0^\circ\text{C}$  for several days or at  $25^\circ\text{C}$  for several hours, to yield 1,3-dienes.<sup>425</sup> Retention of configuration for this reaction has been observed, which demonstrates that free-radical intermediates are not involved.

There are Fe-catalyzed cross-coupling reactions.<sup>426</sup> Coupling products are obtained by treatment of vinylic mercury chlorides<sup>427</sup> with LiCl and a Rh catalyst<sup>428</sup> and by treatment of vinylic tin compounds with a Pd catalyst.<sup>429</sup> Unsymmetrical coupling of vinylic, alkynyl, and arylmercury compounds was achieved in moderate to good yields by treatment with alkyl and vinylic dialkylcopper reagents, for example,<sup>430</sup>

The Ni-catalyzed alkyl-alkyl cross-coupling reaction has been reported.<sup>431</sup> The homo-coupling of benzylic halides was catalyzed by Ni catalysts.<sup>432</sup> Bromoalkanes were coupled using a Au catalyst.<sup>433</sup> The Pd-catalyzed cross coupling of primary and secondary homoallylic electrophiles is known.<sup>434</sup> The cross coupling of organozinc reagents has been reported.<sup>435</sup>

Alkylboranes can be coupled by treatment with silver nitrate and base.<sup>436</sup> Since alkylboranes are easily prepared from alkenes (**15-11**), this is essentially a way of coupling and reducing alkenes; in fact, alkenes can be hydroborated and coupled in the same flask. For symmetrical coupling ( $R = R'$ ) yields range from 60 to 80% for terminal alkenes and from 35 to 50% for internal ones. Unsymmetrical coupling has also been carried out,<sup>437</sup> but with lower yields. Arylboranes react similarly, yielding biaryls.<sup>438</sup> The mechanism is probably of the free-radical type.

Dimerization of two vinylborane units to give a conjugated diene can be achieved by treatment of divinylchloroboranes (see **15-11**) with methylcopper. (*E,E*)-1,3-Dienes are prepared in high yields.<sup>439</sup>

Similarly, symmetrical conjugated diynes  $RC\equiv C-C\equiv CR$  can be prepared by reaction of lithium dialkyldialkynylborates,  $Li^+ [R'_2B(C\equiv CR)_2]^-$ , with iodine.<sup>440</sup>

The Pd-catalyzed cross coupling of racemic tertiary allylic carbonates and allylboronates gave all-carbon quaternary centers with high regioselectivity and enantioselectivity.<sup>441</sup>

### 14.C.iii. Halogen as Leaving Group

The conversion of  $RX$  to  $RH$  can occur by a free-radical mechanism, but this is treated at **19-57**.

### 14.C.iv. Sulfur as Leaving Group

#### 14-22 Desulfurization

Thiols and thioethers,<sup>442</sup> both alkyl and aryl, can be desulfurized by hydrogenolysis with Raney nickel.<sup>443</sup> The hydrogen is usually not applied externally, since Raney nickel already contains enough hydrogen for the reaction. Other sulfur compounds can be similarly

<sup>442</sup> See Block, E. in Patai, S. *The Chemistry of Functional Groups, Supplement E*, pt. 1, Wiley, NY, **1980**, pp. 585–600.

<sup>443</sup> See Belen'kii, L.I. in Belen'kii, L.I. *Chemistry of Organosulfur Compounds*, Ellis Horwood, Chichester, **1990**, pp. 193–228; Pettit, G.R.; van Tamelen, E.E. *Org. React.* **1962**, *12*, 356; Hauptmann, H.; Walter, W.F. *Chem. Rev.* **1962**, *62*, 347.

desulfurized,<sup>444</sup> among them disulfides (RSSR), thiono esters (RCSOR'),<sup>445</sup> thioamides (RCDNHR'), sulfoxides, and dithioacetals. The last reaction, which is an indirect way of accomplishing reduction of a carbonyl to a methylene group (see **19-66**), can also give the alkene if a hydrogen atom is present.<sup>446</sup> In most of the examples given, R can also be aryl. Other reagents<sup>447</sup> have also been used,<sup>448</sup> including Sm in acetic acid for desulfurization of vinyl sulfones.<sup>449</sup> A lanthanum-catalyzed desulfurization system has been developed in ionic liquids.<sup>450</sup> The Co-catalyzed desulfurization reaction has been applied to the preparation of isothiocyanates.<sup>451</sup>

An important special case of RSR reduction is desulfurization of thiophene derivatives. This proceeds with concomitant reduction of the double bonds. Many compounds have been made by alkylation of thiophene, followed by catalytic hydrogenation that led to desulfurization and formation of the corresponding alkane. Thiophenes can also be desulfurized to alkenes (RCH<sub>2</sub>CH=CHCH<sub>2</sub>R') with a nickel boride catalyst prepared from NiCl<sub>2</sub> and NaBH<sub>4</sub> in methanol.<sup>452</sup> It is possible to reduce just one SR group of a dithioacetal by treatment with borane/pyridine in trifluoroacetic acid or in CH<sub>2</sub>Cl<sub>2</sub> in the presence of AlCl<sub>3</sub>.<sup>453</sup> Phenyl selenides RSePh can be reduced to RH with Ph<sub>3</sub>SnH<sup>454</sup> or with nickel boride.<sup>455</sup>

It has been shown that reduction of thiophene proceeds through butadiene and butene, not through butane-1-thiol or other sulfur compounds. In other words, the sulfur is removed before the double bonds are reduced, as demonstrated by isolation of the alkenes and the failure to isolate any potential sulfur-containing intermediates.<sup>456</sup>

See Chapter 19 for other reduction reactions involving sulfur compounds.

OS **IV**, 638; **V**, 419; **VI**, 109, 581, 601. See also, OS **VII**, 124, 476.

Sulfides can be cleaved, with a phenylthio group replaced by a lithium,<sup>457</sup> by treatment with Li or lithium naphthalenide in THF.<sup>458</sup> Good yields have been obtained with R = primary, secondary, or tertiary alkyl, or allylic,<sup>459</sup> and containing groups such as double bonds or halogens. Dilithio compounds can be made from compounds containing two separated SPH groups, but it is also possible to replace just one SPH from a compound with two such groups on a single carbon, to give an  $\alpha$ -lithio sulfide.<sup>460</sup> The reaction has also been used to prepare  $\alpha$ -lithio ethers and  $\alpha$ -lithio organosilanes.<sup>457</sup> For some of these compounds

lithium 1-(dimethylamino)naphthalenide is a better reagent than either Li metal or lithium naphthalenide.<sup>461</sup> The mechanism is presumably of the free-radical type.

#### 14.C.v. Carbon as Leaving Group

##### 14-23 Decarboxylative Dimerization. The Kolbe Reaction

Electrolysis of carboxylate ions leads to decarboxylation, and combination of the resulting radicals to give the coupling product R–R. This coupling reaction is called the *Kolbe reaction* or the *Kolbe electrosynthesis*.<sup>462</sup> It is used to prepare symmetrical R–R, where R is straight chained, since little or no yield is obtained when there is branching. The reaction is not successful for R = aryl. Many functional groups may be present, though many others inhibit the reaction.<sup>462</sup> Unsymmetrical R–R' have been made by coupling mixtures of acid salts. The Kolbe reaction has been done using solid-supported bases.<sup>463</sup>

A free-radical mechanism is involved, via formation of RCOO•, loss of CO<sub>2</sub>, and formation of R•.

There is much evidence<sup>464</sup> for this mechanism, including side products (R–H, alkenes) that are characteristic of free-radical intermediates and the fact that electrolysis of acetate ion in the presence of styrene caused some of the styrene to polymerize to polystyrene (such polymerizations can be initiated by free radicals, Sec. 15.B.i). Other side products (ROH, RCO<sub>2</sub>R) are sometimes found, stemming from further oxidation of the radical R• to a carbocation R<sup>+</sup>.<sup>465</sup>

When the reaction is conducted in the presence of 1,3-dienes, additive dimerization can occur.<sup>466</sup> The radical R• adds to the conjugated system to give RCH<sub>2</sub>CH=CHCH<sub>2</sub>•, which dimerizes. Another possible product is RCH<sub>2</sub>CH=CHCH<sub>2</sub>R, from coupling of the two kinds of radicals.<sup>467</sup>

The synthesis of terminal allenes was reported using a Cu-catalyzed decarboxylative coupling of carboxylic acids.<sup>468</sup> A silver-catalyzed C–S cross-coupling reaction of aliphatic carboxylic acids has been reported.<sup>469</sup>

In a nonelectrolytic process, aryl acetic acids are converted to *vic*-diaryl compounds

by treatment with sodium persulfate ( $\text{Na}_2\text{S}_2\text{O}_8$ ) and a catalytic amount of  $\text{AgNO}_3$ .<sup>470</sup> Photolysis of carboxylic acids in the presence of  $\text{Hg}_2\text{F}_2$  leads to the dimeric alkane via decarboxylation.<sup>471</sup> Both of these reactions involve dimerization of free radicals.

OS III, 401; V, 445, 463; VII, 181.

#### 14-24 The Hunsdiecker Reaction

Reaction of a silver salt of a carboxylic acid with bromine is called the *Hunsdiecker reaction*<sup>472</sup> and is a method of decreasing the length of a carbon chain by one unit.<sup>473</sup> The reaction is of wide scope, giving good results for *n*-alkyl R from 2 to 18 carbons and for many branched R too, producing primary, secondary, and tertiary bromides. Many functional groups may be present as long as they are not  $\alpha$  substituted. R may also be aryl. However, if R contains unsaturation, the reaction seldom gives good results. Although bromine is the most often used halogen, chlorine and iodine have also been used. Catalytic Hunsdiecker reactions are known,<sup>474</sup> and microwave enhancement has been employed.<sup>475</sup> A transition metal-free Hunsdiecker reaction has been reported.<sup>476</sup>

When iodine is the reagent, the ratio between the reactants is very important and determines the products. A 1 : 1 ratio of salt/iodine gives the alkyl halide, as above. A 2 : 1 ratio, however, gives the ester  $\text{RCOOR}$ . This is called the *Simonini reaction* and is sometimes used to prepare carboxylic esters. The Simonini reaction can also be carried out with lead salts of acids.<sup>477</sup> A more convenient way to perform the *Hunsdiecker reaction* is by use of a mixture of the acid and mercuric oxide instead of the silver salt, since the silver salt must be very pure and dry and such pure silver salts are often not easy to prepare.<sup>478</sup>

A catalytic Hunsdiecker reaction of aliphatic carboxylic acids has been reported, catalyzed by  $\text{Ag}(\text{Phen})_2\text{OTf}$ , in which the reaction of carboxylic acids with *t*-butyl

hypochlorite gave the corresponding alkyl chloride.<sup>479</sup> Using  $\text{AgNO}_3$  as a catalyst, aliphatic carboxylic acids gave decarboxylative fluorination with Selectfluor in aqueous solution, leading to alkyl fluorides.<sup>480</sup>

The mechanism of the Hunsdiecker reaction is believed to involve formation of  $\text{R}\cdot$ . The first step is not a free-radical process, and its actual mechanism is not known.<sup>481</sup> Compound **25** is an acyl hypohalite and is presumed to be an intermediate, although it has never been isolated from the reaction mixture.

Among the evidence for the mechanism is that optical activity at R is lost (except when a neighboring bromine atom is present, Sec. 14.A.iv); if R is neopentyl, there is no rearrangement, which would certainly happen with a carbocation; and the side products, notably R-R, are consistent with a free-radical mechanism. There is evidence that the Simonini reaction involves the same mechanism as the Hunsdiecker reaction, but that the alkyl halide formed then reacts with excess  $\text{RCOOAg}$  (**10-17**) to give the ester<sup>482</sup> (see also, **19-12**).

Other methods for accomplishing the conversion  $\text{RCOOH} \rightarrow \text{RX}$  are<sup>483</sup> (i) treatment of thallium(I) carboxylates with bromine;<sup>484</sup> (ii) treatment of carboxylic acids with lead tetraacetate and halide ions ( $\text{Cl}^-$ ,  $\text{Br}^-$ , or  $\text{I}^-$ );<sup>485</sup> (iii) reaction of the acids with lead tetraacetate and NCS, which gives tertiary and secondary chlorides in good yields but is not good for R = primary alkyl or phenyl;<sup>486</sup> (iv) treatment of thiohydroxamic esters with  $\text{CCl}_4$ ,  $\text{BrCCl}_3$  (which gives bromination),  $\text{CH}_3$ , or  $\text{CH}_2\text{I}_2$  in the presence of a radical initiator;<sup>487</sup> (v) photolysis of benzophenone oxime esters of carboxylic acids in  $\text{CCl}_4$  ( $\text{RCON}=\text{CPh}_2 \rightarrow \text{RCl}$ ).<sup>488</sup> Alkyl fluorides can be prepared in moderate to good yields by treating carboxylic acids  $\text{RCOOH}$  with  $\text{XeF}_2$ .<sup>489</sup> This method works best for R = primary and tertiary alkyl, and benzylic. Aromatic and vinylic acids do not react.

#### 14-25 Decarboxylative Alkylation, Alkenylation, or Alkynylation

The COOH group of a  $\beta$ -keto acid is replaced by an allylic group when the acid is treated with an allylic acetate and a palladium catalyst at room temperature.<sup>492</sup> The reaction is successful for various substituted allylic groups. The less highly substituted end of the allylic group forms the new bond. Thus, both  $\text{CH}_2=\text{CHCHMeOAc}$  and  $\text{MeCH}=\text{CHCH}_2\text{OAc}$  gave  $\text{O}=\text{C}(\text{R})-\text{C}-\text{CH}_2\text{CH}=\text{CHMe}$  as the product.

The transition metal decarboxylative allylation and benzylation are well known.<sup>493</sup> Using  $\text{AgNO}_3$  as the catalyst and  $\text{K}_2\text{S}_2\text{O}_8$  as the oxidant, aliphatic carboxylic acids gave decarboxylative alkynylation to give alkylated alkynes using commercially available ethynylbenziodoxolones in aqueous solution.<sup>494</sup> The Ni-catalyzed decarboxylative coupling of alkynyl carboxylic acids and allylic acetates has been reported.<sup>495</sup> The  $\text{I}_2\text{O}_5$ -promoted decarboxylative trifluoromethylation of cinnamic acids has been reported.<sup>496</sup> A cationic  $[\text{Ru}-\text{H}]$  complex catalyzes selective coupling of  $\alpha$ - and  $\beta$ -amino acids with ketones via decarboxylation and deamination to form  $\alpha$ -alkylated ketone products.<sup>497</sup> Aromatic and heteroaromatic carboxylic acids have been used for decarboxylative coupling.<sup>498</sup> The Ir-catalyzed decarboxylative allylation of  $\beta$ -keto acids gave  $\gamma,\delta$ -unsaturated ketones.<sup>499</sup>

Aldehydes, both aliphatic and aromatic, can be decarbonylated<sup>500</sup> by heating with a Rh,<sup>501</sup> Pd,<sup>502</sup> or other catalysts such as RhCl(Ph<sub>3</sub>P)<sub>3</sub>, which is often called *Wilkinson's catalyst*.<sup>503</sup> In an older reaction aliphatic (but not aromatic) aldehydes are decarbonylated by heating with di-*tert*-butyl peroxide or other peroxides,<sup>504</sup> usually in a solution containing a hydrogen donor, such as a thiol. The reaction has also been initiated with light, and thermally (without an initiator) by heating at ~500 °C.

Wilkinson's catalyst has also been reported to decarbonylate aromatic acyl halides at 180 °C (ArCOX → ArX).<sup>505</sup> This reaction has been carried out with acyl iodides,<sup>506</sup> bromides, and chlorides. Aliphatic acyl halides that lack a hydrogen also give this reaction,<sup>507</sup> but if an α hydrogen is present, elimination takes place instead (**17-15**).

A cyanobacterial aldehyde decarbonylase was used to convert fatty aldehydes to alkanes.<sup>508</sup> The reaction of fatty aldehydes with cyanobacterial aldehyde decarbonylase gave the alkane and formate via decarbonylation.<sup>509</sup> The Ni/*N*-heterocyclic carbene-mediated decarbonylation of simple diaryl ketones gave biaryl compounds.<sup>510</sup> The Ru-catalyzed decarbonylation of alkynyl α-diones gave conjugated ynones and disubstituted alkynes.<sup>511</sup> The decarbonylation of tertiary aldehydes occurs "on-water" at room temperature in the presence of BHT (butylated hydroxytoluene) or in the absence of air, while no reaction takes place in organic solvents.<sup>512</sup> A Pd-catalyzed aldehyde decarbonylation has been reported.<sup>513</sup> Decarbonylation reactions have been done under flow conditions (Sec.7.D).<sup>514</sup>

It is possible to decarbonylate acyl halides in another way, to give alkanes (RCOCl → RH) by heating the substrate with tripropylsilane Pr<sub>3</sub>SiH in the presence of *tert*-butyl peroxide.<sup>515</sup> Yields are good for R = primary or secondary alkyl and poor for R = tertiary alkyl or benzylic. There is no reaction when R = aryl.

## Addition to Carbon–Carbon Multiple Bonds

There are four fundamental ways in which addition to a double or triple bond can take place.<sup>1</sup> Three of these are two-step processes, with (i) initial attack by a nucleophile<sup>2</sup> or (ii) attack upon an electrophile or (iii) attack upon a free radical. The second step consists of combination of the resulting intermediate with, respectively, a positive species, a negative species, or a neutral entity. In the fourth type of mechanism, attack at the two carbon atoms of the double or triple bond is simultaneous (concerted). Which of the four mechanisms is operating in any given case is determined by the nature of the substrate, the reagent, and the reaction conditions. Some of the reactions in this chapter can take place by all four mechanistic types. Note that the bond Fukui function has been suggested as a new reactivity index capable of predicting the evolution of bond-breaking and bond-formation processes during an organic reaction involving  $\pi$  conjugated systems.<sup>3</sup> The frontier electron densities proposed by Fukui<sup>4</sup> are local properties that depend on a function  $f(r)$  that differentiates one part of a molecule from another and serve as a reactivity index. The density functional expression of this idea is the Fukui function, defined by Parr and Yang.<sup>5</sup> The reactivity of alkenes and alkynes was probed using activation energies, enthalpies of protonation, and carbon  $1s$  ionization energies.<sup>6</sup>

## 15.A. MECHANISMS

15.A.i. Electrophilic Addition<sup>7</sup>

In the electrophilic addition mechanism, a positive species approaches the double or triple bond and, in the first step, forms a bond by donation of the  $\pi$  pair of electrons<sup>8</sup> to the electrophilic species to form a  $\sigma$  bond:

The IUPAC designation for this mechanism is  $A_E + A_N$  (or  $A_H + A_N$  if  $Y^+ = H^+$ ). As in electrophilic substitution (Sec. 11.A.i), the reactive species need not actually be a positive ion ( $Y^+$ ) but can be the positive end of a dipole or an induced dipole, but the electron-rich  $\pi$  bond donates two electrons to  $Y^+$ . The product of this reaction is a highly reactive intermediate, a carbocation (**1**). In a second step, carbocation **1** reacts with a species that can donate an electron pair and often bears a negative charge,  $W$ . This reaction of an electron-rich species with the electron-deficient carbocation is the same as the second step of the  $S_N1$  mechanism. The mechanism is called  $A_E2$  (electrophilic addition, bimolecular).

The most useful type of information for investigating the mechanism of addition to a double bond, is perhaps, the stereochemistry of the reaction.<sup>9</sup> The two carbons of the double bond and the four atoms immediately attached to them are all in a plane (Sec. 1.D); there are

<sup>7</sup> See de la Mare, P.B.D.; Bolton, R. *Electrophilic Additions to Unsaturated Systems*, 2nd ed., Elsevier, NY, **1982**. For reviews, see Schmid, G.H. in Patai, S. *The Chemistry of Double-Bonded Functional Groups, Supplement A*, Vol. 2, pt. 1, Wiley, NY, **1989**, pp. 679–731; Schmid, G.H.; Garratt, D.G. in Patai, S. *The Chemistry of Double-Bonded Functional Groups, Supplement A*, Vol. 1, pt. 2, Wiley, NY, **1977**, pp. 725–912; Freeman, F. *Chem. Rev.* **1975**, 75, 439.

<sup>8</sup> See Mayr, H.; Kempf, B.; Ofial, A.R. *Acc. Chem. Res.* **2003**, 36, 66; Meng, B.; Ma, S. *Org. Lett.* **2012**, 14, 2674; Zenz, I.; Mayr, H. *J. Org. Chem.* **2011**, 76, 9370.

<sup>9</sup> See Fahey, R.C. *Top. Stereochem.* **1968**, 3, 237; Bartlett, P.A. *Tetrahedron* **1980**, 36, 2 (pp. 3–15).

thus three possibilities. The reaction is stereospecific and there are two possible modes of addition. Both Y and W may enter from the same side of the plane (*syn* addition), in which case the *syn* diastereomer will be the major product, or they may enter from opposite sides (*anti* addition) and the *anti* diastereomer will be the major product. Another possibility is that the reaction may be nonstereospecific. In order to determine which of these possibilities is occurring in a given reaction, the following type of experiment is often done: Y–W is added to the *cis* and *trans* isomers of an alkene of the form ABC=CBA. Using the *cis* alkene as an example, if the addition is *syn*, the diastereomer formed will be the *erythro dl* pair, because each carbon has a 50% chance of being attacked by Y. On the other hand, if the addition is *anti*, the diastereomer formed will be the *threo dl* pair.

Of course, the *trans* isomer will give a different result for this stereospecific reaction: the *threo* pair if the addition is *syn* and the *erythro* pair if it is *anti*. The *threo* and *erythro* diastereomers have different physical properties, as expected. In the special case where Y = W (as in the addition of Br<sub>2</sub>), the *syn* addition gives only one compound via both modes of addition, and the *erythro* diastereomer is a *meso* compound. In addition to triple bond compounds of the type AC≡CA, *syn* addition results in a *cis* alkene and *anti* addition in a *trans* alkene. By the definition given in Sec. 4.N, addition to triple bonds cannot be stereospecific, although it can be, and often is, stereoselective. This contrasts with a circumstance that would favor *syn* addition: formation of an ion pair **2** after the addition of Y.<sup>10</sup> Since W is already on the same side of the plane as Y, collapse of the ion pair leads to *syn* addition.

Another possibility is that *anti* addition might, at least in some cases, be caused by the operation of a mechanism in which attack by W and Y are essentially *simultaneous* but from opposite sides:

This mechanism, called the Ad<sub>E</sub>3 mechanism (*termolecular addition*, IUPAC A<sub>N</sub>A<sub>E</sub>),<sup>11</sup> has the disadvantage that three molecules must come together in the transition state. Note that it is the reverse of the E2 mechanism for elimination, for which the transition state is known to possess this geometry (Sec. 17.A.i).

When the electrophile is a proton,<sup>12</sup> the mechanism is the simple A<sub>H</sub> + A<sub>N</sub> process shown before. This is an A-S<sub>E</sub>2 mechanism (see **10-6**). There is a great deal of evidence<sup>13</sup> for

<sup>10</sup> Heasley, G.E.; Bower, T.R.; Dougharty, K.W.; Easdon, J.C.; Heasley, V.L.; Arnold, S.; Carter, T.L.; Yaeger, D.B.; Gipe, B.T.; Shellhamer, D.F. *J. Org. Chem.* **1980**, *45*, 5150.

<sup>12</sup> See Sergeev, G.B.; Smirnov, V.V.; Rostovshchikova, T.N. *Russ. Chem. Rev.* **1983**, *52*, 259.

<sup>13</sup> Also see Hampel, M.; Just, G.; Pisanenko, D.A.; Pritzkow, W. *J. Prakt. Chem.* **1976**, *318*, 930; Allen, A.D.; Tidwell, T.T. *J. Am. Chem. Soc.* **1983**, *104*, 3145.

it, including the observation that the reaction is general acid, not specific acid-catalyzed, implying rate-determining proton transfer from the acid to the double bond.<sup>14</sup>

The existence of open carbocation intermediates as the electrophile<sup>15</sup> is supported by the contrast in the pattern of alkyl substituent effects<sup>16</sup> with that found in brominations, where cyclic intermediates are involved (see **15-35**). With respect to the alkene, more-substituted alkenes react with H<sup>+</sup> faster than less-substituted alkenes. An alkyl group on the positively charged carbon atom will stabilize the positive charge due to an inductive effect that leads to a  $\delta$ - dipole on that carbon.<sup>17</sup> Such inductive effects make a tertiary carbocation more stable than a secondary, which is more stable than a primary, and the rate of reaction of alkenes with H<sup>+</sup> follows the order tetrasubstituted > trisubstituted > disubstituted > monosubstituted > ethene, so formation of a 3° carbocation is faster than formation of a 2°, which is faster than formation of a 1° carbocation.<sup>18</sup>

Carbocations are prone to rearrangement to the more stable carbocation when a less stable carbocation is formed in the initial reaction (Chapter 18). Indeed, many rearrangements have been found to accompany additions of HX and H<sub>2</sub>O.<sup>19</sup> It may also be recalled that vinylic ethers react with proton donors in a similar manner (see **10-6**).

The addition of DBr to acenaphthylene as well as to indene and 1-phenylpropene gave predominant *syn* addition, as shown for acenaphthylene.<sup>20</sup>

Changing the reaction conditions can control the stereoselectivity of HCl addition. Addition of HCl to acenaphthylene in CH<sub>2</sub>Cl<sub>2</sub> at –98 °C gave predominantly *syn* addition, while in ethyl ether at 0 °C, the addition was mostly *anti*.<sup>21</sup>

Addition of HX to triple bonds has the same mechanism, although the intermediate in this case is a vinylic cation, **3**.<sup>22</sup>

In all these cases (except for the  $\text{Ad}_{\text{E}}3$  mechanism), it was assumed that formation of the carbocation intermediate is the slow step, and therefore rate determining, and attack by the nucleophile on the intermediate is rapid, and this is probably true in most cases. However, some additions have been found in which the second step is rate determining.<sup>23</sup>

### 15.A.ii. Nucleophilic Addition<sup>24</sup>

In the first step of nucleophilic addition a nucleophile donates a pair of electrons to one carbon atom of the double or triple bond, creating a carbanion, which reacts with a positive species,  $\text{W}^+$ , in the second step. The IUPAC label for this mechanism is  $\text{A}_{\text{N}} + \text{A}_{\text{E}}$  or  $\text{A}_{\text{N}} + \text{A}_{\text{H}}$ .

When the alkene contains a good leaving group (as defined for nucleophilic substitution), substitution is a side reaction (this is nucleophilic substitution at a vinylic substrate, Sec. 10.F).

In the case of addition of  $\text{HY}$  to a substrate of the form  $-\text{C}=\text{C}-\text{Z}$ , where  $\text{Z} = \text{CHO}$ ,  $\text{COR}$ <sup>25</sup> (including quinones<sup>26</sup>),  $\text{CO}_2\text{R}$ ,  $\text{CONH}_2$ ,  $\text{CN}$ ,  $\text{NO}_2$ ,  $\text{SOR}$ ,  $2\text{R}$ ,<sup>27</sup> and so on, addition nearly always follows a nucleophilic mechanism,<sup>28</sup> with the nucleophile ( $\text{Y}^-$ ) bonding with the carbon  $\beta$  to the carbonyl carbon to give a resonance-stabilized enolate anion. Subsequent protonation of the enolate ion is probably at the oxygen to give an enol, which tautomerizes to the ketone (Sec. 2.N.i).

<sup>27</sup> See Simpkins, N.S. *Tetrahedron* **1990**, 46, 6951; Fuchs, P.L.; Braish, T.F. *Chem. Rev.* **1986**, 86, 903.

<sup>28</sup> See Bernasconi, C.F. *Tetrahedron* **1989**, 45, 4017.

The mechanism is 1,4-nucleophilic addition to the C=C-C=O (or similar) system and is essentially that of the *Michael reaction* discussed in 15-20. Indeed, such reactions are often called *Michael reactions* or Michael-type reactions, and this is also known as *conjugate addition*. It is noted that 1,2-addition is the attack of the nucleophile at the carbonyl carbon, which is the normal mode of attack when there is no conjugating C=C unit (see Chapter 16).

The bond polarization that is induced in adjacent atoms by the carbonyl oxygen is shown, and leads to a  $\delta^+$  dipole on the  $\beta$  carbon. This extension of polarization, called vinylogy (Sec. 6.B), accounts for the attraction of the negatively charged nucleophile for the  $\beta$  carbon and 1,4-addition. Attack of the  $Y^-$  ion at the  $\alpha$  position is very difficult due to the  $\delta^-$  polarization and repulsion of the like charges, and the resulting carbanion would have no resonance stabilization.<sup>29</sup> Systems of the type C=C-C=C-Z can give 1,2-, 1,4-, or 1,6-addition.<sup>30</sup> *Michael-type reactions* are reversible, and compounds of the type  $YCH_2CH_2Z$  can often be decomposed to  $Y-H$  and  $CH_2=CHZ$  by heating, either with or without alkali.

Except for *Michael-type substrates*, the stereochemistry of nucleophilic addition to double bonds has been studied only in cyclic systems, where only the *cis* isomer exists. In these cases the reaction has been shown to be stereoselective, with *syn* addition reported in some cases<sup>31</sup> and *anti* addition in others.<sup>32</sup> When the reaction is performed on a Michael-type substrate, C=C-Z, the hydrogen does not arrive at the carbon directly but only through a tautomeric equilibrium. The product naturally assumes the most thermodynamically stable configuration, without relation to the direction of original attack of Y. In one such case (the addition of EtOD and of  $Me_3CSD$  to *trans*- $MeCH=CHCOOEt$ ) predominant *anti* addition was found; there is evidence that the stereoselectivity here results from the final protonation of the enolate, and not from the initial attack.<sup>33</sup> For obvious reasons, additions to triple bonds cannot be stereospecific. As with electrophilic additions, nucleophilic additions to triple bonds are usually stereoselective and *anti*,<sup>34</sup> although *syn* addition<sup>35</sup> and nonstereoselective addition<sup>36</sup> have also been reported.

### 15.A.iii. Free-Radical Addition

The mechanism of free-radical addition<sup>37</sup> follows the pattern discussed in Sec. 14.A.i. Principal-component analysis was used to analyze polar and enthalpic effect in radical addition reactions.<sup>38</sup> A radical is generated by photolysis or spontaneous dissociation:

<sup>38</sup> Héberger, K.; Lopata, A. *J. Chem. Soc., Perkin Trans. 2* **1995**, 91.

Alternatively,  $Y-W$  reacts with  $R\cdot$ , generated from another source, so that

For subsequent reaction with an alkene, propagation occurs by (i) addition of the radical  $Y\cdot$  to give a carbon radical as the product and (ii) abstraction (an atom transfer), where  $W$  is nearly always either hydrogen or halogen (Sec. 14.B.i) then leads to the product (addition of  $Y$  and  $W$  to  $C=C$ ) and the radical carrier  $Y\cdot$ , in a propagation step.

Termination of the chain can occur in any of the ways discussed in Sec. 14.A.i. If the carbon radical adds to another alkene molecule, a dimer is formed, which can add to still another alkene unit, and chains, long or short, may be built up via free-radical polymerization. Short polymeric molecules (called *telomers*), formed in this manner, are often troublesome side products in free-radical addition reactions.

When free radicals are added to 1,5- or 1,6-dienes, the initially formed radical (**4**) can add intramolecularly to the other bond, leading to a cyclic product (**5**) in a process known as radical cyclization (**15-26**).<sup>39</sup> Radicals of the type **4**, generated in other ways, also undergo these cyclizations. Both five- and six-membered rings can be formed (Sec. 15.B.i; **15-26**).

The free-radical addition mechanism just outlined predicts that the addition should be nonstereospecific, at least if a carbon radical has anything but an extremely short lifetime. However, the reactions may be stereoselective, for reasons similar to those discussed above for nucleophilic addition to alkenes. A few free-radical additions are selective. For example, propyne (at  $-78$  to  $-60$  °C) gave only *cis*-1-bromopropene (*anti* addition), making it stereospecific.<sup>40</sup> Selectivity was observed in radical cyclization reactions of functionalized alkenes, which proceeded via a *trans* ring closure.<sup>41</sup> An important case is probably addition of  $HBr$  to 2-bromobut-2-ene under free-radical conditions at  $-80$  °C. Under these conditions, the *cis* isomer gave 92% of the *meso* product, while the *trans* isomer gave mostly the *dl* pair.<sup>42</sup> This stereospecificity disappeared at room temperature, where both alkenes gave the same mixture of products ( $\sim 78\%$  of the *dl* pair and 22% of the *meso* compound), so the addition was still stereoselective but no longer stereospecific. The stereospecificity at low temperatures is probably caused by a stabilization of the intermediate radical through

<sup>42</sup> Goering, H.L.; Larsen, D.W. *J. Am. Chem. Soc.* **1959**, *81*, 5937. Also see, Skell, P.S.; Freeman, P.K. *J. Org. Chem.* **1964**, *29*, 2524.

the formation of a three-membered ring-bridged bromine radical (see the bromonium ion in **15-35**) rather than  $\text{Br}-\text{C}-\text{C}\cdot$ , which would normally be expected. Further evidence for the existence of such bridged radicals was obtained by addition of  $\text{Br}\cdot$  to alkenes at 77 K. The ESR spectra of the resulting species were consistent with bridged structures.<sup>43</sup>

For many radicals, step 1 ( $\text{C}=\text{C} + \text{Y}\cdot \rightarrow \cdot\text{C}-\text{C}-\text{Y}$ ) is reversible. In such cases free radicals can cause *cis*  $\rightarrow$  *trans* isomerization of a double bond by reversible formation of a carbon radical, which allows rotation about C-C bonds.<sup>44</sup>

#### 15.A.iv. Cyclic Mechanisms

There are some addition reactions where the initial reaction is not at one carbon of the double bond, but both carbons react simultaneously. Some of these are four-center mechanisms (**15-59**). In others, there is a five- or a six-membered transition state. In these cases the addition to the double or triple bond must be *syn*. The most important reaction of this type is the *Diels-Alder reaction* (**15-56**).

#### 15.A.v. Addition to Conjugated Systems

Michael addition, discussed in Sec. 15.A.ii and **15-20**, is one example of a reaction with a conjugated system, in that case a nucleophile reacted with the C=C unit of the conjugated ketone or other system. Conjugated systems such as buta-1-,3-dienes also react with electrophilic reagents such as HX or  $\text{X}_2$ . When electrophilic addition is carried out on a compound with two double bonds in conjugation, a 1,2-addition product is often obtained, but a 1,4-addition product is often formed in larger yield.<sup>45</sup> If the diene is unsymmetrical, there may be two 1,2-addition products. The competition between two types of addition product comes about because the carbocation resulting from attack of a C=C unit on  $\text{Y}^+$  is a resonance hybrid, with partial positive charges at C-2 (**6**) and C-4 (**7**). Nucleophilic reaction with **6** leads to the 1,2-addition product whereas nucleophilic reaction with **7** leads to the 1,4-addition product. The original reaction with  $\text{Y}^+$  is always at the end of the conjugated system because reaction at a middle carbon would give a cation unstabilized by resonance.

An example is the reaction of HBr with penta-1,3-diene to give 3-bromopent-2-ene via a symmetrical allylic carbocation.<sup>46</sup> For reaction with unsymmetrical dienes, more 1,4- than 1,2-addition product is obtained in most cases. This may be a consequence of thermodynamic control of products, as against kinetic, and is usually temperature dependent. It

was found that at low temperatures, buta-1,3-diene and HCl gave only 20–25% 1,4-adduct, while at high temperatures, where attainment of equilibrium is more likely, the mixture contained 75% 1,4-product.<sup>47</sup> 1,2-addition predominated over 1,4- in the reaction between DCl and penta-1,3-diene, where the intermediate was symmetrical (except for the D label).<sup>48</sup> Ion pairs were invoked to explain this result, since Cl<sup>-</sup> would attack a free ion equally well at both positions, except for the very small isotope effect.

Addition to conjugated systems can also be accomplished by any of the other three mechanisms. In each case, there is competition between 1,2- and 1,4-addition. In the case of nucleophilic or free-radical attack,<sup>49</sup> the intermediates are resonance hybrids and behave like the intermediate from electrophilic attack. Dienes can similarly give 1,4-addition by a cyclic mechanism. Other conjugated systems, including trienes, enynes, diynes, and so on, have been studied much less but behave similarly. 1,4-Addition to enynes is an important way of making allenes.

Radical addition to conjugated systems is an important part of chain propagation reactions. The rate constants for addition of cyclohexyl radical to conjugated amides have been measured, and shown to be faster than addition to styrene.<sup>50</sup> In additions to RCH=C(CN)<sub>2</sub> systems, where the R group has a stereogenic center, the Felkin-Anh model (Sec. 4.H, category 1) applies and the reaction proceeds with high selectivity.<sup>51</sup> Addition of some radicals, such as (Me<sub>3</sub>Si)<sub>3</sub>Si•, is reversible and this can lead to poor selectivity or isomerization.<sup>52</sup>

## 15.B. ORIENTATION AND REACTIVITY

### 15.B.i. Reactivity

As with electrophilic aromatic substitution (Chapter 11), electron-donating groups increase the reactivity of a double bond toward electrophilic addition and electron-withdrawing groups decrease it. This is illustrated in Tables 15.1<sup>53a</sup> and 15.2.<sup>53b</sup>

As a further illustration, the reactivity toward electrophilic addition of a group of alkenes increased in the order  $\text{CCl}_3\text{CH}=\text{CH}_2 < \text{Cl}_2\text{CHCH}=\text{CH}_2 < \text{ClCH}_2\text{CH}=\text{CH}_2 < \text{CH}_3\text{CH}_2=\text{CH}_2$ .<sup>54</sup> For nucleophilic addition the situation is reversed. These reactions are best carried out on substrates containing three or four electron-withdrawing groups, two of the most common being  $\text{F}_2\text{C}=\text{CF}_2$ <sup>55</sup> and  $(\text{NC})_2\text{C}=\text{C}(\text{CN})_2$ .<sup>56</sup> The effect of substituents is so great that it is possible to make the statement that *simple alkenes do not react by the nucleophilic mechanism, and polyhalo or polycyano alkenes do not generally react by the electrophilic mechanism.*<sup>57</sup> There are some reagents that attack only as nucleophiles (e.g., ammonia) that add only to substrates susceptible to nucleophilic attack. Other reagents react only as electrophiles (e.g.,  $\text{F}_2\text{C}=\text{CF}_2$ ) that do not react with other alkenes. In still other cases, the same reagent reacts with a simple alkene by the electrophilic mechanism and with a polyhalo alkene by a nucleophilic mechanism. For example,  $\text{Cl}_2$  and HF are normally electrophilic reagents, but it has been shown that  $\text{Cl}_2$  adds to  $(\text{N}=\text{C})_2\text{C}=\text{CHC}\equiv\text{N}$  with initial attack by  $\text{Cl}^-$ <sup>58</sup> and that HF adds to  $\text{F}_2\text{C}=\text{CClF}$  with initial attack by  $\text{F}^-$ .<sup>59</sup> Compounds that have a double bond conjugated with a Z group (as defined in Sec. 15.A.ii) nearly always react by a nucleophilic mechanism.<sup>60</sup> These are actually 1,4-additions, also discussed in Sec. 15.A.ii. A number of studies have been made of the relative activating abilities of various Z groups.<sup>61</sup> On the basis of these studies, the following order of decreasing activating ability has been suggested for Z:  $\text{NO}_2 > \text{COAr} > \text{CHO} > \text{COR} > \text{SO}_2\text{Ar} > \text{CN} > \text{CO}_2\text{R} > \text{SOAr} > \text{CONH}_2 > \text{CONHR}$ .<sup>62</sup>

It seems obvious that electron-withdrawing groups enhance nucleophilic addition and inhibit electrophilic addition because they lower the electron density of the double bond. Addition of electrophilic radicals to electron-rich alkenes has been reported,<sup>63</sup> so the

reaction is possible in some cases. This is probably true, and yet similar reasoning does not always apply to a comparison between double and triple bonds.<sup>64</sup> There is a higher concentration of electrons between the carbons of a triple bond than in a double bond, and yet triple bonds are *less* subject to attack at an electrophilic site and *more* subject to nucleophilic attack than double bonds.<sup>65</sup> This statement is not universally true, but it does hold in most cases. In compounds containing both double and triple bonds (nonconjugated), bromine, an electrophilic reagent, always adds to the double bond.<sup>66</sup> Addition of electrophilic H<sup>+</sup> (acid-catalyzed hydration, **15-3**; addition of hydrogen halides, **15-2**) takes place at about the same rates for alkenes as for corresponding alkynes.<sup>67</sup> Furthermore, the presence of electron-withdrawing groups lowers the alkene/alkyne rate ratio. For example, while styrene PhCH=CH<sub>2</sub> was brominated 3000 times faster than PhC≡CH, the addition of a second phenyl group (PhCH=CHPh versus PhC≡CPh) lowered the rate ratio to about 250.<sup>68</sup> In the case of *trans*-MeOOCCH=CHCOOMe versus MeOOC≡CCOOMe, the triple bond compound was actually brominated faster.<sup>69</sup>

As mentioned earlier, it is true that in general triple bonds are more susceptible to nucleophilic attack and less prone to reaction at an electrophilic site than double bonds, in spite of their higher electron density. One explanation is that the electrons in the triple bond are held more tightly because of the smaller carbon-carbon distance; it is thus harder to donate an electron pair to an electrophile. There is evidence from far-UV spectra to support this conclusion.<sup>70</sup> Another possible explanation has to do with the availability of the unfilled orbital in the alkyne. It has been shown that a π\* orbital of bent alkynes (e.g., cyclooctyne) has a lower energy than the π\* orbital of alkenes, and it has been suggested<sup>71</sup> that linear alkynes can achieve a bent structure in their transition states when reacting with an electrophile.

Although alkyl groups in general increase the rates of electrophilic addition, as mentioned in Sec. 15.A.i, category 1, there is a different pattern depending on whether the intermediate is a bridged ion or an open carbocation. For brominations and other electrophilic additions in which the first step of the mechanism is rate determining, the rates for substituted alkenes correlate well with the ionization potentials of the alkenes, which means that steric effects are not important.<sup>72</sup> Where the second step is rate determining [e.g., oxymercuration (**15-3**), hydroboration (**15-12**)], steric effects are important.<sup>73</sup>

Free-radical additions can occur with any type of substrate. The determining factor is the presence of a reactive free-radical species. Some reagents, e.g., HBr, RSH, attack by ionic mechanisms if no initiator is present, but in the presence of a free-radical initiator,

the mechanism changes and the addition is of the free-radical type. Nucleophilic radicals (Sec. 14.A.ii) behave like nucleophiles in that the rate is increased by the presence of electron-withdrawing groups in the substrate. The reverse is true for electrophilic radicals.<sup>74</sup> However, nucleophilic radicals react with alkynes more slowly than with the corresponding alkenes,<sup>75</sup> which is contrary to what might have been expected.<sup>76</sup>

Steric influences are important in some cases. In catalytic hydrogenation, where the substrate must be adsorbed onto the catalyst surface, the reaction becomes more difficult with increasing substitution. The hydrocarbon **8**, in which the double bond is entombed between the benzene rings, does not react with  $\text{Br}_2$ ,  $\text{H}_2\text{SO}_4$ ,  $\text{O}_3$ ,  $\text{BH}_3\text{:CBr}_2$ , or other reagents that react with most double bonds.<sup>77</sup>

A similarly inactive compound is tetra-*tert*-butylallene ( $(t\text{-Bu})_2\text{C}=\text{C}=\text{C}(t\text{-Bu})_2$ ), which is inert to  $\text{Br}_2$ ,  $\text{Cl}_2$ ,  $\text{O}_3$ , and catalytic hydrogenation.<sup>78</sup>

### 15.B.ii. Orientation

When an unsymmetrical reagent is added to an unsymmetrical substrate, the question arises is “Which side of the reagent goes to which side of the double or triple bond?” In other words, what is the *regioselectivity* of the reaction? *Regioselectivity is defined as one direction of bond making or breaking that occurs preferentially over all other possible directions.* The terms side and face are arbitrary, and a simple guide is shown to help understand the arguments used here.

For reaction with an electrophile, the traditional answer is given by *Markovnikov's rule*: *The positive portion of the reagent goes to the side of the double or triple bond that has more hydrogen atoms.*<sup>79</sup> Mechanistically, regioselectivity is predicted by attack of the  $\pi$

<sup>79</sup> See Isenberg, N.; Grdinic, M. *J. Chem. Educ.* **1969**, 46, 601; Grdinic, M.; Isenberg, N. *Intra-Sci. Chem. Rep.*, **1970**, 4, 145–162.

bond on  $Y^+$ , forming a bond to the carbon that will give the more stable carbocation. In this example, the secondary carbocation is more stable than the primary.

This mechanism is supported by evidence from core electron spectroscopy and by theoretical analysis.<sup>80</sup> The *Hammond postulate* is invoked to say that the lower energy carbocation is preceded by the lower energy transition state. *Markovnikov's rule* also applies for halogen substituents, and the mechanistic rationale is that the halogen stabilizes the carbocation by resonance, so the intermediate with the positive charge on the Cl-bearing carbon is more stable.

Alkenes containing strong electron-withdrawing groups may violate *Markovnikov's rule*, but formation of the more stable carbocation still controls the reaction. For example, attack at the Markovnikov position of  $\text{Me}_3\text{N}^+-\text{CH}=\text{CH}_2$  would give an ion with positive charges on adjacent atoms. The compound  $\text{CF}_3\text{CH}=\text{CH}_2$  has been reported to give electrophilic addition with acids in an *anti-Markovnikov* direction, but it has been shown<sup>81</sup> that, when treated with acids, this compound does not give simple electrophilic addition at all; the apparently anti-Markovnikov products are formed by other pathways. Molecular electrostatic potentials for the  $\pi$  region of substituted alkenes were studied, with electron-donating and electron-withdrawing substituents (based on the increase or decrease in the negative character of  $V_{\min}$ , the most negative-value point), and plots of  $V_{\min}$  shows a good linear correlation with the Hammett  $\sigma_p$  constants, suggesting similar substituent electronic effects for substituted ethylenes and substituted benzenes.<sup>82</sup>

In free-radical addition<sup>83</sup> the main effect seems to be steric.<sup>84</sup> All substrates  $\text{CH}_2=\text{CHX}$  preferentially react at the  $\text{CH}_2$ , regardless of the identity of X or of the radical. With a reagent such as HBr, which generates  $\text{Br}\cdot$  *in situ* via hydrogen atom exchange, this means that the addition is anti-Markovnikov:

Thus the observed orientation in both kinds of HBr addition (Markovnikov electrophilic and anti-Markovnikov free radical) is caused by formation of the more stable secondary intermediate.

For conjugated dienes, attack at a positive ion, by a negative ion, or reaction with a free radical is almost always at the *end* of the conjugated system, since in each case this gives an intermediate stabilized by resonance. In the case of an unsymmetrical diene, the more

<sup>84</sup> See, however, Gleicher, G.J.; Mahiou, B.; Aretakis, A.J. *J. Org. Chem.* **1989**, *54*, 308.

stable ion is formed. For example, isoprene ( $\text{CH}_2=\text{CMeCH}=\text{CH}_2$ ) treated with HCl gives only  $\text{Me}_2\text{CClCH}=\text{CH}_2$  and  $\text{Me}_2\text{C}=\text{CHCH}_2\text{Cl}$ , with none of the product arising from attack at the other end.  $\text{PhCH}=\text{CHCH}=\text{CH}_2$  gives only  $\text{PhCH}=\text{CHCHClCH}_3$  since it is the only one of the eight possible products that has a double bond in conjugation with the ring and that results from attack that places the proton at an end of the conjugated system.

When allenes attack electrophilic reagents,<sup>85</sup> Markovnikov's rule would predict that the formation of the new bond should be at the end of the system, since there are no hydrogen atoms in the middle.

Reaction at the center gives a carbocation stabilized by resonance, but not immediately. In order for such stabilization to be in effect, the three  $p$  orbitals must be parallel, and it requires a rotation about the C-C bond.<sup>86</sup> Therefore, the stability of the allylic cation has no effect on the transition state, which still has a geometry similar to that of the original allene (Sec. 4.C, category 5). Probably because of this, reaction of the unsubstituted  $\text{CH}_2=\text{C}=\text{CH}_2$  is most often at the end carbon, to give a vinylic cation, although reaction at the center carbon has also been reported. However, as alkyl or aryl groups are substituted on the allene carbons, reaction at the middle carbon becomes more favorable because the resulting cation is stabilized by the alkyl or aryl groups (it is now a secondary, tertiary, or benzylic cation). For example, allenes of the form  $\text{RCH}=\text{C}=\text{CH}_2$  react most often at the end, but  $\text{RCH}=\text{C}=\text{CHR}'$  usually gives reaction at the center carbon.<sup>87</sup> Free radicals<sup>88</sup> react with allenes most often at the end,<sup>89</sup> although reaction at the middle carbon has also been reported.<sup>90</sup> As with reactions that proceed via electrophilic intermediates, and for the same reason, the stability of the allylic radical has no effect on the transition state of the reaction between a free radical and an allene. Again, the presence of alkyl groups increases the extent of reaction by a radical at the middle carbon.<sup>91</sup>

### 15.B.iii. Stereochemical Orientation

It has already been pointed out that some additions are *syn*, with both groups approaching from the same side, and that others are *anti*, with the groups approaching from opposite sides of the double or triple bond. Steric orientation must be considered for cyclic compounds. In *syn* addition to an unsymmetrical cyclic alkene, the two groups can come in from the more-hindered face or from the less-hindered face of the double bond. The rule is that *syn* addition

<sup>85</sup> See Schuster, H.F.; Coppola, G.M. *Allenes in Organic Synthesis*, Wiley, NY, **1984**; Pasto, D.J. *Tetrahedron* **1984**, *40*, 2805; Smadja, W. *Chem. Rev.* **1983**, *83*, 263. <sup>89</sup> Griesbaum, K.; Oswald, A.A.; Quiram, E.R.; Naegele, W. *J. Org. Chem.* **1963**, *28*, 1952.

<sup>90</sup> See Pasto, D.J.; L'Hermine, G. *J. Org. Chem.* **1990**, *55*, 685.

<sup>91</sup> See Pasto, D.J.; Warren, S.E.; Morrison, M.A. *J. Org. Chem.* **1981**, *46*, 2837. See, however, Bartels, H.M.; Boldt, P. *Liebigs Ann. Chem.* **1981**, *40*.

is usually, although not always, from the less-hindered face. For example, epoxidation of 4-methylcyclopentene gave 76% addition from the less-hindered face and 24% from the more-hindered face.<sup>92</sup>

In *anti* addition to a cyclic substrate, the initial reaction with the electrophile is also from the less-hindered face. Many (but not all) electrophilic additions to norbornene and similar strained bicycloalkenes are *syn* additions,<sup>93</sup> where reaction is always from the *exo* side, as in formation of **9**,<sup>94</sup> unless the *exo* side is blocked by substituents in the 7 position, in which case *endo* attack may predominate; for example, 7,7-dimethylnorbornene undergoes *syn-endo* epoxidation (**15-46**) and hydroboration<sup>95</sup> (**15-11**).

However, addition of DCl and F<sub>3</sub>CCO<sub>2</sub>D to 7,7-dimethylnorbornene and oxymercuration (**15-2**) of 7,7-dimethylnorbornene proceeds *syn-exo* in spite of the methyl groups in the 7 position.<sup>96</sup> Similarly, free-radical additions to norbornene and similar molecules are often *syn-exo*, although *anti* additions and *endo* attacks are also known.<sup>97</sup>

Electronic effects can also play a part in determining which face reacts preferentially with the electrophilic species. In the adamantane derivative **10**, steric effects are about the same for each face of the double bond. Yet epoxidation, dibromocarbene reactions (**15-60**), and hydroboration (**15-11**) all take place predominantly from the face that is *syn* to the electron-withdrawing fluorine.<sup>98</sup> In the case shown, about twice as much **11** was formed, compared to **12**.

Similar results have been obtained on other substrates:<sup>99</sup> groups that are electron withdrawing by the field effect (*-I*) direct attack from the *syn* face; *+I* groups from the *anti* face,

for both electrophilic and nucleophilic attack. These results are attributed<sup>100</sup> to hyperconjugation (Sec. 2.M). For the adamantane case, there is overlap between the  $\sigma^*$  orbital of the newly forming bond (between the attacking species and C-2 in **10**) and the filled  $\sigma$  orbitals of the  $C_\alpha-C_\beta$  bonds on the opposite side. This is called the *Cieplak effect*. The  $\text{LiAlH}_4$  reduction of 2-axial methyl or methoxy cyclohexanones supports Cieplak's proposal.<sup>101</sup> In addition reactions of methanol to norbornanones, however, little evidence was found to support the Cieplak effect.<sup>102</sup> The four possible bonds are C-3-C-4 and C-1-C-9 on the *syn* side and C-3-C-10 and C-1-C-8 on the *anti* side. The preferred pathway is the one where the incoming group has the more electron-rich bonds on the side *opposite* to it (these are the ones it overlaps with). Since the electron-withdrawing F has its greatest effect on the bonds closest to it, the C-1-C-8 and C-3-C-10 bonds are more electron rich, and the group comes in on the face *syn* to the F.

In the reaction of  $\text{Br}_2$  and  $\text{HOBr}$  with a cyclohexene, the initially formed product is conformationally specific too, being mostly diaxial.<sup>103</sup> This is so because diaxial opening of the three-membered ring intermediate in these cases (reaction **15-35**) preserves a maximum co-planarity of the participating centers in the transition state; indeed, on opening, epoxides also give diaxial products.<sup>104</sup> However, the initial diaxial product may then pass over to the diequatorial conformer unless other groups on the ring render the latter less stable than the former. In free-radical additions to cyclohexenes in which cyclic intermediates are not involved, the initial reaction with the radical is also usually from the axial direction,<sup>105</sup> resulting in a diaxial initial product if the overall addition is *anti*. The direction from which unsymmetrical radicals react has also been studied.<sup>106</sup>

#### 15.B.iv. Addition to Cyclopropane Rings<sup>107</sup>

It was shown in Sec. 4.Q.iv that cyclopropane rings resemble double bonds in some aspects of their reactivity.<sup>108</sup> It is not surprising, therefore, that cyclopropanes undergo addition reactions analogous to those undergone by double bond compounds, resulting in the opening of the cyclopropane ring. The reaction

illustrates the relationship to the alkene reaction.

Additions to cyclopropanes can take place by any of the four mechanisms already discussed in this chapter, but the most important type involves reaction with an electrophile.<sup>109</sup> For substituted cyclopropanes, these reactions usually follow *Markovnikov's rule*, although exceptions are known and the degree of regioselectivity is often small.

The application of Markovnikov's rule to these substrates can be illustrated by the reaction of 1,1,2-trimethylcyclopropane with HX.<sup>110</sup> The rule predicts that the electrophile (in this case H<sup>+</sup>) goes to the carbon with the most hydrogen atoms and the nucleophile (X) goes to the carbon that can best stabilize a positive charge (in this case the tertiary rather than the secondary carbon).

The stereochemistry of the reaction can be investigated at two positions – the one that becomes connected to the electrophile and the one that becomes connected to the nucleophile. The results at the former position are mixed. Additions have been found to take place with 100% retention,<sup>111</sup> 100% inversion,<sup>112</sup> and with mixtures of retention and inversion.<sup>113</sup> At the carbon that becomes connected to the nucleophile the result is usually inversion, although retention has also been found,<sup>114</sup> and elimination, rearrangement, and racemization processes often compete, indicating that in many cases a positively charged carbon is generated at this position.

At least three mechanisms have been proposed for electrophilic addition (these mechanisms are shown for reaction with HX, but analogous mechanisms can be written for other electrophiles).

- The first mechanism involves a corner-protonated cyclopropane;<sup>115</sup> examples of such ions were seen in the 2-norbornyl and 7-norbornenyl cations (Sec. 10.C.i).
- The second mechanism involves an edge-protonated cyclopropane, in which a proton bridges two carbon atoms of the three-membered ring.
- A third mechanism is a one-step S<sub>E</sub>2-type attack on H<sup>+</sup> to give the classical carbocation that reacts with the nucleophile.

Although the three mechanisms show retention of configuration at the carbon that becomes attached to the proton, the first and third mechanisms can also result in inversion at this carbon. Unfortunately, the evidence on hand at present does not allow unequivocal selection of any of these as the exclusive mechanism in all cases. Matters are complicated by the possibility that more than one edge-protonated cyclopropane is involved, at least in some cases. There is strong evidence for the edge-protonated mechanism with the electrophiles Br<sup>+</sup> and Cl<sup>+</sup>.<sup>116</sup> There is evidence for the corner-protonated pathway for mechanism with D<sup>+</sup> and Hg<sup>2+</sup>.<sup>117</sup> *Ab initio* studies show that the corner-protonated pathway is slightly more stable (~1.4 kcal mol<sup>-1</sup>, 6 kJ mol<sup>-1</sup>) than the edge-protonated pathway.<sup>118</sup> There is some evidence against formation of a carbocation as suggest by the third mechanism.<sup>119</sup>

Free-radical additions to cyclopropanes have been much less studied, but it is known that  $\text{Br}_2$  and  $\text{Cl}_2$  add to cyclopropanes by a free-radical mechanism in the presence of UV light. The addition follows *Markovnikov's rule*, with the initial radical reacting at the least-substituted carbon and the second group going to the most-substituted position. Several investigations have shown that the reaction is stereospecific at one carbon, taking place with inversion there, but nonstereospecific at the other carbon.<sup>120</sup> A mechanism that accounts for this behavior is<sup>121</sup>

## 15.C. REACTIONS

### 15.C.i. Isomerization of Double and Triple Bonds

#### 15-1 Isomerization

Without a transition metal catalyst, there is usually a rather high energy barrier for the excited state required for *E/Z* isomerization.<sup>122</sup> However, double bonds that are conjugated to aromatic rings are known to isomerize from *Z* to *E*, sometimes spontaneously. An example is the conjugated diene isolated as a 2:1 *E:Z* mixture, but completely isomerized to the *E* isomer (**13**) upon standing at ambient temperature.<sup>123</sup>

The transition metal-catalyzed isomerization of an alkene from *E* to *Z* or *Z* to *E* is a well-studied reaction.<sup>124</sup> Among the metals examined, Pt is widely used, and rather selective.<sup>125</sup> A 1:1 mixture of *cis/trans*-styrene derivatives was isomerized to a 90% yield of the *trans*-styrene derivatives using a Pd catalyst.<sup>126</sup> Isomerization of cyclic alkenes is

difficult for rings of seven members and less, but *cis/trans* isomerization of cyclooctene is induced photochemically.<sup>127</sup> Radical-induced *E/Z* isomerization is known.<sup>128</sup> Isomerization of the C=C units in dienes is also induced photochemically.<sup>129</sup> (–)-Riboflavin has been used for the (*E*)- to (*Z*)-alkene isomerization.<sup>130</sup>

In general, there is an energetic preference of an  $\alpha,\beta$  versus  $\beta,\gamma$  double bond.<sup>131</sup> Allylic arenes (Ar–CH<sub>2</sub>CH=CH<sub>2</sub>) have been converted to the corresponding (*Z*)-1-propenyl arene (Ar–CH=CHMe) using a Ru catalyst<sup>132</sup> or a polymer-supported Ir catalyst.<sup>133</sup> The isomerization of allylbenzenes to 1-propenylbenzenes has been reviewed.<sup>134</sup> A computational study of the asymmetric alkene isomerization of  $\beta,\gamma$ - to  $\alpha,\beta$ -unsaturated butenolides, catalyzed by novel cinchona alkaloid derivatives, was reported.<sup>135</sup> Ruthenium hydrides promoted the positional isomerization of 1,3-dienes into more highly substituted 1,3-dienes.<sup>136</sup> A co-catalyst and organosilane led to irreversible isomerization of terminal alkenes by one position.<sup>137</sup> The synthesis of (*Z*)-alkenes has been reported, by the Rh-catalyzed isomerization of the alkene moiety of  $\beta,\gamma$ -unsaturated ketones to the conjugated ketone.<sup>138</sup> Using a Pd catalyst, the *exo* methylenes of 2,6-disubstituted bicyclo[3.3.1]nonan-9-ones were isomerized, under an atmosphere of hydrogen, to predominantly form the bis-endocyclic isomer with C<sub>2</sub> symmetry.<sup>139</sup> The La-catalyzed isomerization of allylic alcohols to homoallylic alcohols has been reported.<sup>140</sup> The isomerization of 1,3-dienes using [CoBr<sub>2</sub>(py-imine)] gave the (*Z*)-1,3-diene whereas [CoBr<sub>2</sub>(dpppMe<sub>2</sub>)] gave the (*2Z*),(*4E*)-configured 2,4-dienes.<sup>141</sup> The Rh-catalyzed isomerization of 4-pentenals into 3-pentenals has been reported.<sup>142</sup>

Propargylic systems were isomerized to 1,3-dienes using a Au complex,<sup>143</sup> and the 1,3-transposition of ynones used a Au catalyst.<sup>144</sup> The stereoselective rearrangement of allenic alcohols to (*E,E*)-1,3-dien-2-yl triflates and chlorides was reported using TMSOTf or TMSCl.<sup>145</sup> The cesium hydroxide-catalyzed isomerization of terminal alkynes to the corresponding allene has been reported.<sup>146</sup>

For conjugated carbonyl compounds that have a hydrogen atom at the  $\gamma$  position (C-4), it is possible to move a double bond *out* of conjugation. Photolysis of conjugated esters, at –40 °C in the presence of *N,N*-dimethylaminoethanol, gave the nonconjugated

ester.<sup>147</sup> Heating an *N*-allylic amide (N–C=C) with Fe(CO)<sub>5</sub>, neat, gave the enamide (N=C–C).<sup>148</sup> Conjugated aldehydes have been isomerized using thiourea in DMF.<sup>149</sup> Double bonds of atoms other than carbon are subject to isomerization. Azobenzenes (Ar–N=N–Ar) exist as *E* and *Z* isomers, and photochemical isomerization is possible.<sup>150</sup>

## 15.C.ii. Reactions in Which Hydrogen Adds to One Side

### A. Halogen on the Other Side

#### 15-2 Addition of Hydrogen Halides

Any of the four hydrogen halides can be added to double bonds.<sup>151</sup> Alkenes react as Brønsted-Lowry bases with HI, HBr, and HF<sup>152</sup> at room temperature, but reaction with HCl is more difficult and usually requires heat.<sup>12</sup> HCl adds easily in the presence of silica gel, however.<sup>153</sup> HF is difficult to handle, but a convenient method for the addition of HF involves the use of a poly(HF)/pyridine solution in THF.<sup>154</sup> An aprotic solution of HBr has been reported, HBr•DMPU.<sup>155</sup>

The addition of hydrogen halides to simple alkenes, in the absence of peroxides, takes place by an electrophilic mechanism, and the orientation is in accord with *Markovnikov's rule*.<sup>156</sup> In other words, the  $\pi$  bond of the alkene donates two electrons to the acidic proton of H–X such that a new C–H bond is formed that generates the more stable carbocation. The addition follows second-order kinetics.<sup>157</sup> Alkenes react with HBr in dioxane to give the alkyl bromide.<sup>158</sup> Hex-1-ene reacts with Me<sub>3</sub>SiCl in water to give 2-chlorohexane.<sup>159</sup>

When peroxides are added, the addition of HBr occurs by a free-radical mechanism in which Br• is generated and reacts with the C=C moiety to form the more stable radical, which reacts with H–Br to give the final product with an *anti-Markovnikov* orientation (Sec. 15.B.i).<sup>160</sup> It must be emphasized that this is true *only* for HBr. of HF and HI has never been observed, even in the presence of peroxides; free-radical addition of HCl has been observed only rarely. In the rare cases where free-radical addition of HCl was noted, the orientation was still Markovnikov, presumably because the more stable product was formed.<sup>161</sup> Free-radical addition of HF, HI, and HCl is energetically unfavorable (Sec. 14.B.i and Sec. 14.C.i).

It is known that under some conditions anti-Markovnikov addition of HBr takes place even when peroxides have not been added. This reaction happens because the substrate alkenes absorb oxygen from the air, forming small amounts of peroxides (14-6). Markovnikov addition can be ensured by rigorous purification of the substrate, but in practice this is not easy to achieve, and it is more common to add inhibitors, for example phenols or quinones, which suppress the free-radical pathway. The presence of free-radical precursors such as peroxides in the reaction of HBr does not inhibit the ionic mechanism. Markovnikov addition of HBr, HCl, and HI has also been accomplished, in high yields, by the use of phase-transfer catalysis.<sup>162</sup> Anti-Markovnikov bromides were prepared by the reaction of alkenes and HBr in acetic acid.<sup>163</sup>

Fluorination of alkenes is possible. Alkenes reacted with  $\text{KHSO}_4 \cdot 13\text{HF}$  to give the corresponding Markovnikov alkyl fluoride.<sup>164</sup> The reaction of alkenes with Selectfluor, mediated by  $\text{Fe(III)/NaBH}_4$ , led to free-radical hydrofluorination of unactivated alkenes with exclusive Markovnikov addition.<sup>165</sup> The Co-catalyzed hydrofluorination of alkenes using  $(\text{Me}_2\text{SiH})_2\text{O}$  and *N*-fluoropyridinium salts gave the alkyl fluoride with Markovnikov selectivity.<sup>166</sup> Aryl alkenes reacted with 2 equivalents of Selectfluor in the presence of a Pd catalyst to give the  $\alpha$ -fluoro arene.<sup>167</sup> Treatment of an alkene with  $\text{KHF}_2$  and  $\text{SiF}_4$  leads to the alkyl fluoride.<sup>168</sup>

Alkynes also react as bases with acids such as HX. It is possible to add 1<sup>169</sup> or 2 equivalents of any of the four hydrogen halides to triple bonds:

Markovnikov's rule ensures that *gem*-dihalides and not *vic*-dihalides are the products of the addition of 2 equivalents. Alkynes were converted to vinyl bromides with anti-Markovnikov regioselectivity using  $(\text{CCl}_2\text{B})_2$ , with both *i*-PrCuCl and 2-*tert*-butyl potassium phenoxide in catalytic amounts, in the presence of  $\text{Ph}_2\text{SiH}_2$ . A halosilane was formed and generated HX *in situ*.<sup>170</sup> Heating alkynes with dibromomethane in the presence of *N,N*-dimethylaniline and air gave the corresponding vinyl bromide.<sup>171</sup> Alkynes reacted with

phosphorus reagents and iodine to give the corresponding vinyl iodide.<sup>172</sup> Terminal alkynes reacted with excess LiCl in the presence of a Pd catalyst and a catalytic amount of CuCl<sub>2</sub> to give the vinyl chloride.<sup>173</sup> Phenylacetylene reacted with HCl in the presence of a Ru catalyst to give the 1-chloro-1-phenylethene.<sup>174</sup> 2-Bromo-1-alkenes were prepared from 1-alkynes using a microwave-assisted reaction with LiBr, TMSCl, and tetraethylammonium bromide in acetonitrile.<sup>175</sup> Bromotrimethylsilane adds to alkynes to give the vinyl bromide.<sup>176</sup>

Brønsted-Lowry acids such as HX are electrophilic reagents, and many polyhalo or polycyano alkenes do not react with them in the absence of free-radical conditions. A nucleophilic addition mechanism is possible, and occurs with *Michael-type substrates* C=C-Z,<sup>177</sup> where the nucleophile adds to the β carbon, even in the presence of free-radical initiators. Vinylcyclopropanes, however, react with opening of the cyclopropane ring to give a homoallylic chloride.<sup>178</sup>

The reaction with HX has been carried out with conjugated dienes, where both 1,2- and 1,4-addition are possible. Hydrogen iodide adds 1,4 to conjugated dienes in the gas phase by a pericyclic mechanism.<sup>179</sup> Ketenes reacted with HX to give acyl halides.<sup>180</sup>

## B. Oxygen on the Other Side

### 15-3 Hydration of Double Bonds

Double bonds can be hydrated by treatment with water and an acid catalyst. Sulfuric acid is a common catalyst, but other acids that have relatively nonnucleophilic counterions, such as nitric, perchloric, or, more commonly, sulfonic acids (*p*-toluenesulfonic acid, methanesulfonic acid, etc.) can also be used. The mechanism is electrophilic and begins with attack of the π bond on an acidic proton (Sec. 15.A.i). The resulting carbocation is then attacked by negative species, such as HSO<sub>4</sub><sup>-</sup> (or similar counterion in the case of other acids), to give the initial product, an alkyl hydrogensulfate (H-C-C-OSO<sub>2</sub>OH), which can be isolated in some cases. However, such compounds are rather unstable, and under the reaction conditions are usually hydrolyzed to the alcohol (**10-4**).

Other nucleophiles are present in the reaction under some reaction conditions, either from the solvent or from added compounds. In an aqueous medium, water is a competitive nucleophile, and attack by water forms oxonium ion **14**.

Products such as the alkyl hydrogensulfate are not involved when other nucleophiles react with the carbocation, and the mechanism is exactly (by the principle of microscopic reversibility) the reverse of E1 elimination of alcohols (**17-1**).<sup>181</sup> *The initial carbocation occasionally rearranges to a more stable one.* For example, hydration of  $\text{CH}_2=\text{CHCH}(\text{CH}_3)_2$  gives  $\text{CH}_3\text{CH}_2\text{COH}(\text{CH}_3)_2$ . Hydration of simple alkenes leads to alcohols predicted by *Markovnikov's rule*.

*Oxymercuration*<sup>182</sup> (addition of oxygen and mercury) of alkenes followed by *in situ* treatment with sodium borohydride<sup>183</sup> (**12-24**), gives an alcohol under mild conditions, in high yields, and *without rearrangement products*. In oxymercuration the *mercury stabilizes the initially formed carbocation by back-donation of the mercury d orbitals such that rearrangement does not occur*.<sup>184</sup> For example, treatment of 2-methylbut-1-ene with aqueous mercuric acetate,<sup>185</sup> followed by reaction with  $\text{NaBH}_4$ , gave 2-methylbutan-2-ol. This method, which is applicable to mono-, di-, tri-, and tetraalkyl- as well as phenyl-substituted alkenes, gives almost complete Markovnikov addition. Hydroxy, methoxy, acetoxy, halo, and other groups may be present in the substrate, and generally do not cause difficulties.<sup>186</sup> Oxymercuration of alkenes has been reported in water, using cyclodextrins as phase-transfer catalysts.<sup>187</sup> When two double bonds are present in the same molecule, changing the carboxylic acid ligand of the mercuric salt allows oxymercuration of the less-substituted one without affecting the other, using ultrasound.<sup>188</sup>

Indirect hydration, with anti-Markovnikov orientation, was achieved using hydroboration (**15-11**). Alkenes react with  $\text{PhO}_2\text{BH}$  and a Nb catalyst, followed by oxidation with  $\text{NaOO}^-$ , to give the alcohol,<sup>189</sup> and  $\text{Cp}_2\text{TiCl}_4$  can also be used.<sup>190</sup> Ketenes add water to give carboxylic acids ( $\text{R}_2\text{C}=\text{C}=\text{O} \rightarrow \text{R}_2\text{CO}_2\text{H}$ ) in a reaction catalyzed by acids.<sup>191</sup> The hydration of the allene moiety of electron-deficient allenic esters and ketones, promoted by

### 15-4 Hydration of Triple Bonds

Alkynes react with water and a Brønsted acid catalyst<sup>197</sup> to give an enol, which tautomerizes to the carbonyl. The hydration of terminal alkynes leads to a methyl ketone and internal alkynes can lead to two different ketones. Only acetylene gives an aldehyde. Metal-free reactions are known, often using strong acids. Terminal aryl alkynes reacted with water in the presence of 20% triflic acid, in 2,2,2-trifluoroethanol, to give the acetophenone.<sup>198</sup> Phenyl acetylene was converted to acetophenone, for example, in water at 100 °C with a catalytic amount of  $\text{Tf}_2\text{NH}$  (trifluoromethanesulfonimide), which is a very powerful acid.<sup>199</sup> Simple alkynes can also be converted to ketones by heating with formic acid, without a catalyst.<sup>200</sup> Allenes can be hydrolyzed to ketones using an acid catalyst.<sup>201</sup>

The hydration of triple bonds can be carried out with aqueous mercuric ion salts (often the sulfate or acetate or even mercuric oxide) as catalysts,<sup>202</sup> and always gave the more stable vinyl carbocation, and reaction with water gives the hydroxy/mercury intermediate via a vinyl/mercury complex. In contrast to oxymercuration of alkenes, the hydroxy/organomercury intermediate from this reaction ( $\text{Hg}^+ \text{—C}=\text{C—OH}$ ) is unstable and loss of mercury *in situ* leads to an enol product, which tautomerizes to the ketone. It is noted that a spectrum of the enol was detected by flash photolysis when phenylacetylene was hydrated photolytically.<sup>203</sup> The reaction can be conveniently carried out with a catalyst prepared by impregnating mercuric oxide onto Nafion-H (a superacidic perfluorinated resin/sulfonic acid; Sec. 5.A.ii).<sup>204</sup> Note that another possibility for a vinyl/mercury

complex is a mercury-stabilized carbocation rather than a formal three-membered ring complex.

Other catalysts used to convert alkynes to the ketone include Cu,<sup>205</sup> Fe,<sup>206</sup> Pd,<sup>207</sup> Ru,<sup>208</sup> Rh,<sup>209</sup> In,<sup>210</sup> Mn,<sup>211</sup> Co,<sup>212</sup> Ag,<sup>213</sup> or Au.<sup>214</sup> Gold(I) catalysts have also been used in the hydration of allenes.<sup>215</sup> The aerobic hydration of aryl acetylenes gave acetophenone derivatives in the presence of an Fe catalyst in acetic acid.<sup>216</sup> The microwave-assisted, Cu-catalyzed hydration of aryl acetylenes has been reported.<sup>217</sup> The Pd-catalyzed reaction of aryl terminal alkynes with aqueous HCl gave the acetophenone derivative.<sup>218</sup> Alkynes were converted to methyl ketones by reaction with cobaloxime with methanol in air.<sup>219</sup> The reaction of alkynes and water in the presence of an In catalyst and PTSA gave the corresponding ketone.<sup>220</sup>

Terminal alkynes reacted with water, in the presence of a Au/Ru catalyst, to give the Markovnikov alcohol, whereas reaction with water in the presence of a diruthenium catalyst gave the anti-Markovnikov alcohol, both in isopropanol.<sup>221</sup> Catalysts have been developed for the *anti-Markovnikov* hydration of alkynes.<sup>222</sup> When oct-1-yne was heated with water, isopropyl alcohol, and a Ru catalyst, for example, the product was octanal.<sup>223</sup> The presence of certain functionality can influence the regioselectivity of hydration. Terminal alkynes reacted with aqueous THF and a Ru catalyst, and with a bipyridyl ligand, to give the corresponding aldehyde.<sup>224</sup> An Fe catalyst has been used to convert terminal alkynes to aldehydes.<sup>225</sup>

When a carboxylic acid that contains a double bond in the chain is treated with a strong acid, the intramolecular hydration reaction gives a  $\gamma$ - and/or a  $\delta$ -lactone, regardless of the original position of the double bond in the chain, since strong acids catalyze double bond

shifts (**15-1**; and see **12-2**).<sup>226</sup> The double bond always migrates to a position favorable for the reaction, whether this has to be toward or away from the carboxyl group. The use of a chiral *Cinchonidine* alkaloid additive leads to lactone formation with modest enantioselectivity.<sup>227</sup>

Carboxylic esters, thiol esters, and amides can be made, respectively, by acid-catalyzed hydration of acetylenic ethers, thioethers,<sup>228</sup> and ynamines, without a mercuric catalyst.<sup>229</sup> This reaction is ordinary electrophilic addition, with rate-determining protonation as the first step.<sup>230</sup> The trifluoroacetic acid (TFA)-mediated hydration of ynamides to give amides was reported.<sup>231</sup> Certain other alkynes have also been hydrated to ketones with strong acids in the absence of mercuric salts.<sup>232</sup>

OS III, 22; IV, 13; V, 1024.

### 15-5 Addition of Alcohols and Phenols to Give Ethers

Just as water adds to an alkene via hydration to form an alcohol, alcohols can also add to form an ether.<sup>233</sup> The addition of alcohols and phenols to double bonds is catalyzed by acids or bases. When the reactions are acid catalyzed, the mechanism is electrophilic, where H<sup>+</sup> from the acid catalyst is attacked by the π bond. The more stable carbocation is formed and subsequently attacked by a molecule of alcohol to give an oxonium ion, **15**.

The addition, therefore, follows *Markovnikov's rule*. Primary alcohols give better results than secondary, and tertiary alcohols are relatively inactive. Addition of alcohols to allylic systems can proceed with rearrangement, and the use of chiral additive can lead to asymmetric induction.<sup>234</sup> The uncatalyzed addition of alcohols occurs in supercritical alcohols.<sup>235</sup>

Metal-catalyzed addition to alkenes is a useful variation. The Au(III)/CuCl<sub>2</sub>-catalyzed reaction of alcohols and alkenes gave the ether.<sup>236</sup> The Pd-catalyzed addition of alcohols to aryl alkenes gives the ether,<sup>237</sup> and the Au-catalyzed intermolecular addition of phenols

leads to aryl ethers.<sup>238</sup> Aryl ethers were prepared by the Ir-<sup>239</sup> or Pd-catalyzed<sup>240</sup> reaction of terminal alkenes with phenols. 2-Alkenyl cyclic ethers were prepared from dienes that have a distal hydroxyl group when heated with catalytic Au and catalytic Ag compounds.<sup>241</sup>

The oxymercuration-demercuration procedure mentioned in **15-3** can be adapted to the preparation of ethers in what is known as *alkoxymercuration-demercuration* (with Markovnikov orientation), if the reaction is carried out in an alcohol (ROH) solvent.<sup>242</sup> Primary alcohols give good yields when mercuric acetate is used, but for secondary and tertiary alcohols it is necessary to use mercuric trifluoroacetate.<sup>243</sup> However, even this reagent fails where the product would be a ditertiary ether. It is possible to combine the alcohol reactant with another reagent. If the oxymercuration is carried out in the presence of a hydroperoxide instead of an alcohol, the product (after demercuration with NaBH<sub>4</sub>) is an alkyl peroxide (*peroxy-mercuration*).<sup>244</sup> This reaction can be done intramolecularly.<sup>245</sup>

Alcohols add intramolecularly to alkenes to generate cyclic ethers, and the product often bears a hydroxyl unit,<sup>246</sup> but not always.<sup>247</sup> A transition metal-free synthesis of tetrahydrofurans from alkene alcohols used a catalytic amount of iodine and a catalytic amount of PhSiH<sub>3</sub>.<sup>248</sup> Cyclization is facilitated by Re,<sup>249</sup> Ti,<sup>250</sup> or Pt compounds,<sup>251</sup> leading to functionalized tetrahydrofurans<sup>252</sup> or tetrahydropyans. Furan derivatives are available from alkene ketones using CuCl<sub>2</sub> and a Pd catalyst<sup>253</sup> or a Cr,<sup>254</sup> Ag(I),<sup>255</sup> or lanthanide catalyst.<sup>256</sup> A Au catalyst was used with conjugated ketones bearing an alkyne substituent to give fused-ring furans.<sup>257</sup> Intramolecular addition of alcohols to alkenes can be promoted by a Pd catalyst, but migration of the double bond in the final product can be a problem.<sup>258</sup> Tetrahydrofurans were prepared from alkene alcohols by using a Cu,<sup>259</sup> No,<sup>260</sup>

or an Fe catalyst.<sup>261</sup> Substituted tetrahydropyrans were prepared from allylic alcohols that have a distal hydroxyl group using an Fe catalyst.<sup>262</sup> Tetrahydropyrans or tetrahydrofurans were prepared from alkenes that have a distal hydroxyl group by treatment with  $\text{Ca}(\text{NTf}_2)_2/\text{Bu}_4\text{NPF}_6$ .<sup>263</sup> The intramolecular reaction of unsaturated alcohols to form cyclic ethers was catalyzed by self-assembled resorcin[4]arene hexamer.<sup>264</sup> The asymmetric synthesis of THF derivatives from  $\epsilon$ -hydroxy- $\alpha,\beta$ -unsaturated ketones was mediated by cinchona/alkaloid/thiourea-based bifunctional organocatalysts.<sup>265</sup>

Alcohols add to alkynes under certain conditions to give vinyl ethers. In an excess of alcohol, and in the presence of a Pt<sup>266</sup> or a Au catalyst,<sup>267</sup> internal alkynes are converted to ketals. The alcohol to alkyne addition reaction is quite useful for the preparation of heterocycles, and dihydrofurans,<sup>268</sup> furans,<sup>269</sup> benzofurans,<sup>270</sup> and pyran derivatives<sup>271</sup> have been prepared using this approach. The alkoxymercuration of alkynes generally gives an acetal. Allenes or alkynes react to form a Rh complex, generated by a Rh compound and HX, and subsequent reaction with an alcohol gives a chiral allylic ether.<sup>272</sup> Allenes reacted with alcohols in the presence of a Au catalyst and MS 3Å to give allylic ethers.<sup>273</sup> The reaction of ethanol with 1,1-diphenylethene and a Co catalyst and a photocatalyst gave the vinyl ether.<sup>274</sup> The Au-catalyzed reaction of alcohols and alkynes to give vinyl ethers has been reported with good regioselectivity.<sup>275</sup> The Rh-catalyzed anti-Markovnikov hydroalkoxylation of terminal alkynes gave the vinyl ether.<sup>276</sup>

Enol ethers are more susceptible than triple bonds to electrophilic attack, and the addition of alcohols to enol ethers can also be catalyzed by acids.<sup>277</sup> One utilization of this is the reaction of dihydropyran (a vinyl ether) with an alcohol to give the 2-alkoxytetrahydropyran, which is often used to protect the OH groups of primary and secondary alcohols<sup>278</sup> and phenols.<sup>279</sup> For deprotection, the 2-alkoxytetrahydropyran is easily cleaved back to the alcohol and dihydropyran by treatment with dilute acids (10-6).

Allenenes react with alcohols and so allenic alcohols have been converted to tetrahydrofuran derivatives bearing a vinyl group at the  $\alpha$  position, using diphenyliodonium salts.<sup>280</sup> In

the presence of allylic bromide and a Pd catalyst, allenic alcohols lead to allylically substituted dihydrofurans.<sup>281</sup> The intramolecular Au-catalyzed reaction of alcohols and allenes has been reported.<sup>282</sup> Intramolecular addition of alcohols to allenes leads to cyclic vinyl ethers.<sup>283</sup>

Base-catalyzed reactions are known. For those substrates more susceptible to nucleophilic attack, for example, polyhalo alkenes and alkenes of the type C=C–Z (Z is an electron-withdrawing group), it is better to carry out the reaction in basic solution, where the attacking species is RO<sup>–</sup>.<sup>284</sup> Since triple bonds are more susceptible to nucleophilic attack than double bonds, it might be expected that bases would catalyze addition to triple bonds particularly well. This is the case, and enol ethers and acetals can be produced by this reaction.<sup>285</sup> In base-catalyzed addition to triple bonds, the rate falls in going from a primary to a tertiary alcohol, and phenols require more severe conditions. Phenyl acetylenes were converted to the corresponding methoxy alkene (vinyl ether) by treatment with KOMe in DMF, with improved yields by the addition of DMEDA (*N,N'*-dimethylethylenediamine).<sup>286</sup>

Photochemical addition of alcohols to certain double bond compounds (cyclohexenes, cycloheptenes) is possible<sup>287</sup> in the presence of a photosensitizer such as benzene. The mechanism is electrophilic and *Markovnikov* orientation is found. The alkenes react in their first excited triplet states.<sup>288</sup>

Both alcohols and phenols add to ketenes to give carboxylic esters:<sup>289</sup>

This reaction has been done intramolecularly (with the ketene end of the molecule generated and used *in situ*) to form medium- and large-ring lactones.<sup>290</sup> In the presence of a strong acid, ketene reacts with aldehydes or ketones (in their enol forms) to give enol acetates. 1,4-Asymmetric induction is possible when chiral alcohols add to ketenes.<sup>291</sup>

In the presence of other reagents, functionalized ethers can be formed. In methanol with an R–Se–Br reagent, alkenes are converted to selenoalkyl ethers (MeO–C–C–SeR).<sup>292</sup>

Carboxylic esters are produced by the addition of carboxylic acids to alkenes, a reaction that is usually acid catalyzed (by Brønsted-Lowry or Lewis acids<sup>293</sup>) and similar in mechanism to **15-5**. Since *Markovnikov's rule* is followed, hard-to-get esters of tertiary alcohols can be prepared from alkenes of the form  $R_2C=CHR$ .<sup>294</sup> The reaction of alkenes and carboxylic acids in the presence of an acridinium photooxidant and 20% of thiophenol gave the anti-Markovnikov ester addition product.<sup>295</sup> An alkene reacted with carboxylic acids using a disilane catalyst with a photosensitizer to give the allylic ester.<sup>296</sup> Alkenoic acids were cyclized to  $\gamma$ -lactones using an Ir catalyst.<sup>297</sup>

Carboxylic esters have also been prepared by the acyloxymercuration-demercuration of alkenes (similar to the procedures mentioned in **15-3** and **15-4**).<sup>298</sup> Addition of carboxylic acids to alkenes to form esters or lactones is catalyzed by Pd compounds.<sup>299</sup> Thallium acetate also promotes this cyclization reaction.<sup>300</sup> Diene carboxylic acids have been cyclized using acetic acid and a Pd catalyst to form lactones that have an allylic acetate moiety elsewhere in the molecule.<sup>301</sup>

Imidazole derivatives proved to be effective ligands in the Ru-catalyzed reaction of alkenes and formates to give one-carbon-elongated esters.<sup>302</sup> Terminal alkenes reacted with carboxylic acids using Pd catalyst, in the presence of benzoquinone, to give an allylic ester.<sup>303</sup> Styrene derivatives reacted with formic acid and a Pd catalyst to give the carboxylic acid product, and the regiochemical selectivity was controlled by the choice of phosphine ligand.<sup>304</sup> Carboxylic acids with a distal allene moiety cyclized in the presence of a Rh catalyst to give the corresponding lactone that has an alkenyl unit.<sup>305</sup> Lactones were formed by the intramolecular reaction of acid and an alkene moiety, catalyzed by a Au compound<sup>306</sup> or an Ir catalyst.<sup>307</sup>

Triple bonds can give enol esters<sup>308</sup> or acylals when treated with carboxylic acids. Mercuric salts are typical catalysts<sup>309</sup> and vinylmercury compounds ( $RO_2C-C=C-HgX$ ) are intermediates,<sup>310</sup> but Ru complexes have also been used.<sup>311</sup> Terminal alkynes ( $RC\equiv CH$ )

react with CO<sub>2</sub>, a secondary amine R'<sub>2</sub>NH, and a Ru complex catalyst to give enol carbamates RCH=CHOC(=O)NR.<sup>312</sup> This reaction has also been performed intramolecularly, to produce unsaturated lactones.<sup>313</sup> Cyclic unsaturated lactones (internal vinyl esters) have been generated from alkyne carboxylic acids using a Pd<sup>314</sup> or a Ru catalyst.<sup>315</sup>

Enol esters were generated by the reaction of alkynes and carboxylic acids using a Ru catalyst<sup>316</sup> or a Pd catalyst with silver carbonate.<sup>317</sup> Aryl 1-alkynyl-2-aldehyde dimethylacetals gave enantioselective carboalkoxylation to the optically active β-alkoxyindanone derivatives. This was catalyzed by cationic Au complexes and the methodology was extended to the enantioselective synthesis of 3-methoxycyclopentenones.<sup>318</sup> Ynol ethers reacted with carboxylic acids and silver oxide to give the *trans* addition product, a (*Z*)-α-alkoxy enol ester. Subsequent Ni-catalyzed reaction with arylboronic acids (**13-13**) gave the 1-aryl vinyl ether.<sup>319</sup> Carboxylic acids reacted with alkynes to give the vinyl ester with a dinuclear Pd catalyst, with a catalytic amount of tributylborane.<sup>320</sup> A computational study for the mechanism of coinage metal-catalyzed reactions of carboxylic acids with alkynes has been reported.<sup>321</sup> Enynes reacted with carboxylic acids at the alkyne moiety, in the presence of trialkylphosphines, to give the dienyl ester.<sup>322</sup>

Allene carboxylic acids have been cyclized to butenolides with copper(II) chloride.<sup>323</sup> Allene esters were converted to butenolides by treatment with acetic acid and LiBr.<sup>324</sup> Cyclic carbonates can be prepared from allene alcohols using carbon dioxide and a Pd catalyst.<sup>325</sup> A carboxylic acid with a distal alkene unit was cyclized and gave a selenomethyl ester by treatment with (DHQD)<sub>2</sub>PHAL and *N*-phenylselenophthalimide.<sup>326</sup>

Sulfonic acids add to alkenes and alkynes. The reaction of an alkyne with *para*-toluenesulfonic acid and treatment with silica gives the vinyl sulfonate (C=C—OSO<sub>2</sub>Tol).<sup>327</sup> Cyclic sulfonates can be generated by the reaction of an allylic sulfonate salt (C=C—C—OSO<sub>3</sub><sup>-</sup>) with silver nitrate in acetonitrile containing an excess of bromine and a catalytic amount of water.<sup>328</sup> Sultones are formed when alkenes react with PhIO and 2 equivalents of Me<sub>2</sub>SiSO<sub>3</sub>Cl.<sup>329</sup>

## C. Sulfur on the Other Side

15-7 Addition of H<sub>2</sub>S and Thiols to Give Thiols or Thioethers

Hydrogen sulfide (H<sub>2</sub>S) and thiols add to alkenes to give alkyl thiols or sulfides by electrophilic, nucleophilic, or free-radical mechanisms.<sup>330</sup> In the absence of initiators, the addition to simple alkenes is by an electrophilic mechanism, similar to that in **15-5**, and *Markovnikov's rule* is followed. However, this reaction is usually very slow and often cannot be done, or it requires very severe conditions unless a Brønsted-Lowry or Lewis acid catalyst is used. For example, the reaction can be performed in concentrated H<sub>2</sub>SO<sub>4</sub><sup>331</sup> or with the addition of AlCl<sub>3</sub>.<sup>332</sup> In the presence of free-radical initiators, H<sub>2</sub>S and thiols add to double and triple bonds by a free-radical mechanism and the orientation is *anti-Markovnikov*.<sup>333</sup> Anti-Markovnikov addition of thiols to vinyl ethers occurs under solvent-free and catalyst-free conditions,<sup>334</sup> and is promoted by water.<sup>335</sup>

Additives can influence the regioselectivity. Styrene reacts with thiophenol to give primarily the anti-Markovnikov product, but addition of thiophenol in the presence of Montmorillonite K-10 clay gives primarily the Markovnikov addition product.<sup>336</sup> The addition of thiophenol to an alkene with a zeolite, however, leads to the anti-Markovnikov sulfide.<sup>337</sup> In fact, the orientation can be used as a diagnostic tool to indicate which mechanism is operating. Free-radical addition can be done with H<sub>2</sub>S, RSH (R may be primary, secondary, or tertiary), ArSH, or RCOSH.<sup>338</sup> The alkenes may be terminal, internal, contain branching, be cyclic, and have various functional groups including OH, CO<sub>2</sub>H, CO<sub>2</sub>R, NO<sub>2</sub>, RSO<sub>2</sub>, and so on. Addition of Ph<sub>3</sub>SiSH to terminal alkenes under radical conditions also leads to the primary thiol.<sup>339</sup> Lewis acids have been used for the hydrothiolation of alkenes.<sup>340</sup> Thiols add to alkenes under photochemical conditions to form thioethers, and the reaction can be done intramolecularly to give cyclic thioethers.<sup>341</sup> Diaryl sulfides were added to multiple bond compounds via an electrogenerated acid catalyst.<sup>342</sup> The reaction of aryl alkynoates

with thiols gave the vinyl sulfide via decarboxylative coupling when treated with dicumyl peroxide.<sup>343</sup>

Transition metal catalysts have been used for hydrothiolation reactions. A Cu catalyst has been used with alkenes that bear a heteroatom.<sup>344</sup> Vinyl halides reacted with thiols when heated with KOH in the presence of a catalytic amount of Cu<sub>2</sub>O and 1,10-phenanthroline.<sup>345</sup> The Au-catalyzed hydrothiolation of unactivated alkenes with thiols gave vinyl sulfides, with *anti*-Markovnikov selectivity.<sup>346</sup>

Alkynes react with thiols to give vinyl sulfides. With alkynes it is possible to add 1 or 2 molar equivalents of RSH, giving a vinyl sulfide<sup>347</sup> or a dithioketal, respectively. Thiols also add to alkynes with a Pd catalyst to give vinyl sulfides.<sup>348</sup> Sulfonic acids add to alkynes to give vinyl sulfonates in the presence of a Au catalyst.<sup>349</sup> The Rh,<sup>350</sup> In,<sup>351</sup> organoactinide,<sup>352</sup> organozirconium,<sup>353</sup> or Pt-catalyzed<sup>354</sup> reaction of alkynes with thiols gives the corresponding vinyl sulfide. The intramolecular addition of a thiol to an ene-yne, with a Pd catalyst, leads to substituted thiophene derivatives.<sup>355</sup> The reaction of an alkyne with diphenyl disulfide and a Pd catalyst leads to the bis(vinyl)sulfide, PhS-C=C-SPh.<sup>356</sup> Ketenes add thiols to give thiol esters.<sup>357</sup>

(*Z*)-Organothioenynes were prepared by hydrothiolation of buta-1,3-ynes.<sup>358</sup> The Pd and Cu co-catalyzed Markovnikov addition of thiols to alkenes or alkynes gave alkyl sulfides or vinyl sulfides.<sup>359</sup> A Ru complex allowed hydrothiolation of alkynes.<sup>360</sup> 1-Alkenyl sulfides were prepared from alkynes and organic disulfides using organoaluminum reagents.<sup>361</sup> Terminal alkynes reacted with thiols to give the (*E*)-vinyl sulfide in the presence of a Cu catalyst, but gave the *Z* isomer with the Cu catalyst and CO<sub>2</sub>.<sup>362</sup> Arylthiols reacted with alkynes to give vinyl sulfides in the presence of potassium phosphate to give (*Z*)-vinyl sulfides, whereas (*E*)-vinyl sulfides were formed under solvent- and base-free conditions.<sup>363</sup> Thiols reacted with alleneols in the presence of an In catalyst to give a

## D. Nitrogen or Phosphorus on the Other Side

### 15-8 Addition of Ammonia and Amines, Phosphines, and Related Compounds<sup>370</sup>

Ammonia and primary and secondary amines add to alkenes *in some cases*.<sup>371</sup> Ammonia and amines are much weaker acids than water, alcohols, and thiols (see 15-3, 15-5, 15-7) and since acids turn NH<sub>3</sub> into the weak acid, the ammonium ion NH<sub>4</sub><sup>+</sup>, this reaction does not occur by an electrophilic mechanism. The reaction tends to give very low yields, if any, with ordinary alkenes, unless extreme conditions are used (e.g., 178–200 °C, 800–1000 atm, and the presence of metallic Na, for the reaction between NH<sub>3</sub> and ethylene<sup>372</sup>). There is, however, a proton-catalyzed hydroamination reaction in which aniline derivatives add to alkenes in the presence of anilinium salts, in 20–90% yield depending on the alkene.<sup>373</sup> The hydroamination of terminal alkenes via reaction of *N*-alkylhydroxylamines with allylic amines gave 3-amino-2-*N*-hydroxylamino compounds.<sup>374</sup>

There are many examples of transition metal-catalyzed<sup>375</sup> addition of nitrogen compounds to alkenes, alkynes,<sup>376</sup> and so on. Amines can be added to many alkenes using

Y reagent.<sup>423</sup> A Zn/Zr bimetallic catalyst has been used with high enantioselectivity.<sup>424</sup> A Pd/Ir tandem catalyst was reported for the two-step hydroamination of alkenes with an ammonia source that gave branched primary amines.<sup>425</sup> Other nitrogen compounds, among them hydroxylamine and hydroxylamines,<sup>426</sup> *O*-benzoylhydroxylamines with a Cu catalyst,<sup>427</sup> hydrazines,<sup>428</sup> and amides (**15-9**), also add to alkenes.

Amines add to triple bonds<sup>429</sup> to give enamines that have a hydrogen on the nitrogen and (analogously to enols) tautomerize (Sec. 2.N.ii, category 4) to the more stable imine.<sup>430</sup>

When ammonia is used instead of a primary amine, the corresponding  $\text{R}_2\text{C}=\text{NH}$  imine product is not stable enough for isolation, but polymerizes. The frustrated Lewis acid-catalyzed hydroamination of terminal alkynes has been reported.<sup>431</sup>

Transition metal catalysis for reaction with alkynes is an important area of research, and catalysts include Pd,<sup>432</sup> Rh,<sup>433</sup> Ti,<sup>434</sup> Ta,<sup>435</sup> Ni,<sup>436</sup> Cu,<sup>437</sup> Ag,<sup>438</sup> Ta,<sup>439</sup> Ga,<sup>440</sup> Zr,<sup>441</sup> or Au.<sup>442</sup> Anti-Markovnikov addition of alkynes is possible using a Cu catalyst.<sup>443</sup> The intramolecular addition of amines to alkynes has been reported using a Pd catalyst.<sup>444</sup> When benzylamines with a chloroacetylene moiety<sup>445</sup> were heated with a Rh catalyst, an intramolecular debenzylative cyclization gave butyrolactams.

Many heterocycles have been prepared by this methodology. An intramolecular addition of amines to an alkyne unit in the presence of a Pd catalyst generated heterocyclic<sup>446</sup> or cyclic amine compounds.<sup>447</sup> A variation treats an alkynyl imine with CuI to form pyrroles.<sup>448</sup> *N,N*-Diphenylhydrazine reacts with diphenyl acetylene and a Ti catalyst to give indole derivatives.<sup>449</sup> Treatment of an imine of 2-alkynyl benzaldehyde with iodide gave a functionalized isoquinoline.<sup>450</sup> Ammonia and primary amines (aliphatic and aromatic) add to conjugated diynes to give pyrroles.<sup>451</sup>

The enantioselective, Au-catalyzed hydroamination of dienes has been reported.<sup>452</sup> Conjugated dienes reacted with amines in the presence of a Ti catalyst to give homoallylic amines.<sup>453</sup> 1,3-Dienes<sup>454</sup> and also allenes<sup>455</sup> undergo hydroamination in the presence of an Au catalyst. Allenes are reaction partners,<sup>456</sup> and amines add to allenes in the presence of a catalytic amount of Cu,<sup>457</sup> Au,<sup>458</sup> or Pd compounds.<sup>459</sup> The Rh-catalyzed hydroamination of terminal allenes gave branched allylic amines.<sup>460</sup> Asymmetric Brønsted acids have been used to catalyze the hydroamination of dienes and allenes.<sup>461</sup> Hypervalent iodine has been used for the amination of allenes.<sup>462</sup> Intramolecular reaction of allene amines leads to dihydropyrroles, using a Au catalyst.<sup>463</sup>

A NH<sub>2</sub> or NR<sub>2</sub> unit can be added to double bonds (even ordinary double bonds) in an indirect manner by the use of hydroboration (**15-11**) followed by treatment with NH<sub>2</sub>Cl or NH<sub>2</sub>OSO<sub>2</sub>OH (**12-31**). This produces a primary amine with *anti*-Markovnikov orientation. An indirect way of adding a primary or secondary amine to a double bond consists of aminomercuration to give an amino mercuric acetate, followed by reduction with NaBH<sub>4</sub> to give the amine.<sup>464</sup> The addition of a secondary amine produces a tertiary amine, while addition of a primary amine gives a secondary amine. The overall orientation follows *Markovnikov's rule*.

Phosphines add to alkenes to give alkylphosphines (C–PR<sub>2</sub>) and to alkynes<sup>465</sup> to give vinylphosphines. Alkenes reacted with triphenylphosphonium tetrafluoroborate under

radical initiation conditions, or under photochemical conditions, to give phosphonium salts.<sup>466</sup> Alkenes reacted with  $\text{Ph}_2\text{P}(\text{O})\text{PPh}_2$ , with a radical initiator, to give radical addition that led to 1-phosphinyl-2-phosphinoalkanes regioselectively.<sup>467</sup> The microwave-assisted hydrophosphinylation of alkenes at 180 °C, using aqueous H-phosphoric acids, did not require added metal or a radical initiator.<sup>468</sup> The transition metal-catalyzed addition reaction is known, using Ni<sup>469</sup> or Pd<sup>470</sup> catalysts. The hydrophosphinylation of ynamides has been reported using a Cu catalyst.<sup>471</sup> A Pd-catalyzed reaction of alkenes and triarylphosphines gives alkyltriarylphosphonium salts.<sup>472</sup> Alkenes also react with diarylphosphines and a Ni catalyst to give the alkylphosphine.<sup>473</sup> Silylphosphines ( $\text{R}_3\text{Si}-\text{PAR}_2$ ) react with alkenes and  $\text{Bu}_4\text{NF}$  to give the anti-Markovnikov allylphosphine.<sup>474</sup>

Chiral  $\alpha$ -amino phosphonates were prepared by the enantioselective phosphorylation of allylamine with phosphites in the presence of a chiral Brønsted acid catalyst and silver carbonate.<sup>475</sup>

Phosphonate esters were similarly prepared from alkenes, diethyl phosphite [ $(\text{EtO})_2\text{P}(\text{=O})\text{H}$ ], and a Mn catalyst in a reaction exposed to oxygen.<sup>476</sup> Similar addition was observed in the reaction of an alkene with  $\text{NaH}_2\text{PO}_2$  to give the phosphinate:<sup>477</sup>

The reaction of terminal alkynes with dimethyl phosphite and a Ni catalyst gave the *Markovnikov* vinyl phosphonate ester.<sup>478</sup> Phosphine oxides can be prepared by the reaction of an aryl-substituted alkene and diphenylphosphine oxide,  $\text{Ph}_2\text{P}(\text{=O})\text{H}$ .<sup>479</sup>

In the presence of an Yb catalyst, diphenylphosphine added to diphenyl acetylene to give the corresponding vinylphosphine.<sup>480</sup> A Pd catalyst was used for the addition of diphenylphosphine to terminal alkynes, giving the anti-Markovnikov vinylphosphine, but a Ni catalyst led to the *Markovnikov* vinylphosphine.<sup>481</sup> A Co catalyst has also been used.<sup>482</sup> Diphenylphosphine oxide also reacted with terminal alkynes to give the anti-Markovnikov vinylphosphine oxide using a Rh catalyst.<sup>483</sup> Other phosphites were added to dienes to give an allylic phosphonate ester using a Pd catalyst.<sup>484</sup>

### 15-9 Addition of Amides

Under certain conditions, primary and secondary amides can add directly to alkenes to form *N*-alkylated amides. Sulfonamides react in a similar manner. Styrene derivatives reacted with a hypervalent iodine(III) reagent as an oxidant and bis-tosylimide as a nitrogen source to give the tosylamide addition product.<sup>485</sup> Treatment of triflamide alkenes with triflic acid gives the corresponding *N*-triflyl cyclic amine.<sup>486</sup>

Alkenes react with amides and related compounds in the presence of certain transition metals.<sup>487</sup> The Pd-catalyzed amidation of alkenes gives the corresponding amides with good enantioselectivity.<sup>488</sup> The Cu-catalyzed amidation and imidation of alkenes has been reported.<sup>489</sup> The reaction of amines and conjugated dienes using a Co/Ir-co-catalyzed, photoredox-generated  $\alpha$ -amino radical species gave homoallylic amines.<sup>490</sup> Conjugated dienes reacted with aniline and CO with a Pd catalyst to give an amide.<sup>491</sup> A Rh catalyst was used with alkenes.<sup>492</sup>

The amidation of alkenes can be done intramolecularly.<sup>493</sup> 3-Pentenamide cyclized to 5-methyl-2-pyrrolidinone by treatment with trifluorosulfonic acid.<sup>494</sup> *N*-Benzyl pent-4-ynamide reacted with tetrabutylammonium fluoride to form an alkylidene lactam.<sup>495</sup> Chiral 2-piperidinone compounds were prepared via a Pd-catalyzed asymmetric 6-*endo* cyclization of dienamides.<sup>496</sup> The Ti-catalyzed reaction of alkenyl *N*-tosylamines gave *N*-tosyl cyclic amines. Homopropargylic *N*-tosylamides gave pyrrolidinone derivatives upon treatment with a Au catalyst and mcpba in the presence of mesitoic acid.<sup>497</sup> Lactams were prepared by the intramolecular hydroamidation of benzamide derivatives that bear an *ortho* alkenyl unit, by using a Ru catalyst and a base.<sup>498</sup>

Alkynes and allenes also react with amides. The Ru/In-,<sup>499</sup> Pd-,<sup>500</sup> Bi-, or Hf-catalyzed<sup>501</sup> reaction of sulfonamides with alkynes gave cyclic *N*-sulfonyl derivatives.

Phenylthiomethyl alkynes were converted to *N*-Boc-*N*-phenylthio allenes with Boc azide and an iron catalyst.<sup>502</sup> Enamides were prepared by the Pd-,<sup>503</sup> Re-,<sup>504</sup> or Ru-catalyzed<sup>505</sup> hydroamidation of terminal alkynes with amides. The Pd-catalyzed reaction of an allene amide with iodobenzene leads to *N*-sulfonyl aziridines having an allylic group at C-1.<sup>506</sup> Other allene *N*-tosylamines similarly give *N*-tosyl tetrahydropyridines.<sup>507</sup> The reaction of amines and alkynes in supercritical carbon dioxide gave amides.<sup>508</sup> The reaction of alkynes with TMSN<sub>3</sub> using a Au/Ag co-catalyst gave the amide.<sup>509</sup>

When a carbamate was treated with Bu<sub>3</sub>SnH and AIBN, addition to an alkene led to a bicyclic lactam.<sup>510</sup> Alkenyl amides and carbamates react with transition metal catalysts to form lactams or cyclic carbamates. Both Pd-<sup>511</sup> and Au-catalyzed<sup>512</sup> cyclization reactions of carbamates are known, and Os compounds have also been used.<sup>513</sup> Ionic liquids have been used to catalyze these reactions.<sup>514</sup> Imides can also add to alkenes or alkynes. Phthalimide reacts with an alkene in the presence of a Pd catalyst.<sup>515</sup>

Ni-catalyzed hydrophosphinylation, such as the reaction of an alkyne with an alkyl phosphinate, gave a vinyl phosphinate ester.<sup>516</sup> Both H-phosphinates and secondary phosphine oxides add to alkenes in an anti-Markovnikov manner, induced by air, in what is likely a radical reaction.<sup>517</sup>

### 15-10 Addition of Hydrazoic Acid and Alkyl Azides

Hydrazoic acid (HN<sub>3</sub>) can be added to certain Michael-type substrates (Z is an electron-withdrawing group) to give β-azido compounds.<sup>518</sup> The reaction apparently fails if R is phenyl. HN<sub>3</sub> also adds to enol ethers CH<sub>2</sub>=CHOR to give CH<sub>3</sub>-CH(OR)N<sub>3</sub>, and to silyl

enol ethers.<sup>519</sup> However,  $\text{HN}_3$  does not add to ordinary alkenes unless a Lewis acid catalyst, such as  $\text{TiCl}_4$ , is used, in which case good yields of azide can be obtained.<sup>519</sup> Hydrazoic acid can also be added indirectly to ordinary alkenes by azidomercuration, followed by demercuration,<sup>520</sup> analogous to the similar procedures mentioned in **15-3**, **15-5**, **15-6**, and **15-8**. The method can be applied to terminal alkenes or strained cycloalkenes (e.g., norbornene) but fails for unstrained internal alkenes. A variation is the hydroazidation reaction of alkenes using a Co catalyst and *tert*-BuOOH to give the alkyl azide.<sup>521</sup>

The reaction of alkenes with  $\text{NaIO}_4$  and 3 equivalents of  $\text{NaN}_3$  in DMSO/AcOH gave the diazide.<sup>522</sup> Diazides were also prepared using an Fe catalyst.<sup>523</sup> The Au-catalyzed reaction of azides and allenes has been reported.<sup>524</sup> 1,6-Dienes that were reacted first with CatBH and then with  $\text{PhSO}_2\text{N}_3$  and an initiator gave a six-membered ring with a pendant azide moiety.<sup>525</sup> Terminal alkynes reacted with trimethylsilyl azide (in the presence of  $\text{H}_2\text{O}$  and a silver catalyst to give the corresponding vinyl azides.<sup>526</sup>

## E. A Metal on the Other Side

### 15-11 Hydroboration

Alkenes react with borane,<sup>527</sup> in ether solvents, such that B and H add across the double bond to form an organoborane.<sup>528</sup> The boron reacts as a Lewis acid with the alkene. Since  $\text{BH}_3$  dimerizes to diborane  $\text{B}_2\text{H}_6$ , it cannot be prepared as a stable pure compound,<sup>529</sup> but it is commercially available in the form of “ate” complexes with THF,  $\text{Me}_2\text{S}$ ,<sup>530</sup> phosphines, or tertiary amines. Pyridine/borane can be used for the hydroboration of alkenes at room temperature.<sup>531</sup>

In all cases the boron goes to the side of the double bond that is less substituted, whether the substituents are aryl or alkyl.<sup>532</sup> This regioselectivity is due mostly to steric factors,

although electronic factors also play a part. For most substrates, the addition in hydroboration is highly regioselective and *syn*, with delivery of B and H<sup>533</sup> occurring from the less-hindered side.<sup>534</sup> The mechanism<sup>535</sup> probably involves a *four-center transition state rather than a formal intermediate*.<sup>536</sup> When both sides of the double bond are monosubstituted or both disubstituted, about equal amounts of each regioisomer are obtained. However, it is possible in such cases to make the addition regioselective by the use of a large borane molecule.<sup>537</sup> When the substrate is an allylic alcohol or amine, the addition is generally *anti*,<sup>538</sup> although the stereoselectivity can be changed to *syn* by the use of catecholborane and Rh complexes.<sup>539</sup> Organoboranes are useful intermediates for the preparation of a wide variety of compounds. The organoborane product is oxidized to an alcohol with hydrogen peroxide and NaOH (see **18-23**), with *anti-Markovnikov regioselectivity* in what is probably the most-used application. The hydroboration-oxidation of alkenes has been done using flow conditions (Sec. 7.D).<sup>540</sup> Note that organoboranes can be analyzed using <sup>11</sup>B NMR.<sup>541</sup>

With relatively unhindered alkenes, the process cannot be stopped with the addition of one molecule of BH<sub>3</sub> because the resulting RBH<sub>2</sub> adds to another molecule of alkene to give R<sub>2</sub>BH, which in turn adds to a third alkene molecule, so that the isolated product is a trialkylborane R<sub>3</sub>B. When the alkene is moderately hindered, *the product is the dialkylborane R<sub>2</sub>BH or even the monoalkylborane RBH<sub>2</sub>*.<sup>542</sup> For example, 2-methylbut-2-ene and borane gives *disiamylborane* and 2,3-dimethylbut-2-ene and borane gives *thexylborane*.<sup>543</sup> Surprisingly, when methylborane MeBH<sub>2</sub>,<sup>544</sup> which is not a bulky molecule, adds to alkenes in the solvent THF, the reaction can be stopped with one addition to give the dialkylboranes RMeBH.<sup>545</sup> Monochloroborane<sup>546</sup> BH<sub>2</sub>Cl coordinated with dimethyl sulfide shows greater regioselectivity than BH<sub>3</sub> for terminal alkenes or those of the form R<sub>2</sub>C=CHR, and the hydroboration product is a dialkylchloroborane R<sub>2</sub>BCl.<sup>547</sup> Treatment of alkenes with dichloroborane/dimethyl sulfide BHCl<sub>2</sub>/SMe<sub>2</sub> in the presence of BF<sub>3</sub><sup>548</sup> or with BCl<sub>3</sub> and Me<sub>3</sub>SiH<sup>549</sup> gives alkylchloroboranes RBCl<sub>2</sub>. A useful reagent is

bis(pinacolato)diboron,  $B_2pin_2$ , which contains two boron atoms and two pinacolato ligands.<sup>550</sup>

Intramolecular hydroboration reactions are possible.<sup>551</sup> When cycloocta-1,5-diene reacts with borane, one C=C reacts and a remaining B-H unit reacts intramolecularly to give 9-borabicyclo[3.3.1]nonane (9-BBN)<sup>552</sup> which has the advantage that it is stable in air. Disiamylborane, 9-BBN, and similar molecules are far more selective than  $BH_3$ , and preferentially react at the less-hindered bonds, so it is often possible to hydroborate one double bond in a molecule and leave others unaffected or to hydroborate one alkene in the presence of a less reactive alkene.<sup>553</sup>

Thexylborane<sup>543</sup> is particularly useful for achieving the cyclic hydroboration of dienes, conjugated or nonconjugated, as in the formation of **23**.<sup>554</sup>

Rings of five, six, or seven members can be formed in this way. Similar cyclization can also be accomplished with other monoalkylboranes and, in some instances, with  $BH_3$  itself.<sup>555</sup> One example is the formation of 9-BBN, and another is conversion of 1,5,9-cyclododecatriene to perhydro-9*b*-boraphenalene.<sup>556</sup>

Asymmetric hydroboration has been developed as a very useful extension of the basic methodology. The reagent diisopinocampheylborane **24** was prepared by treating optically active  $\alpha$ -pinene with  $BH_3$ .<sup>557</sup> The reagent is used in a hydroboration-oxidation to give enantioselective formation of alcohols.<sup>558</sup> Since both (+)- and (-)- $\alpha$ -pinene are readily available, both enantiomers can be prepared.

For a study of electronic effects, see Garner, C.M.; Chiang, S.; Nething, M.; Monestel, R. *Tetrahedron Lett.* **2002**, 43, 8339.

However, **24** does not give good results with even moderately hindered alkenes; a better reagent for these compounds is isopinocampheylborane,<sup>559</sup> although optical yields are lower. Limonylborane,<sup>560</sup> 2- and 4-dicaranylboranes,<sup>561</sup> a myrtanylborane,<sup>562</sup> and dilongifolylborane<sup>563</sup> have also been used.

Other new asymmetric boranes have also been developed. The chiral cyclic boranes, *trans*-2,15-dimethylborolanes, add enantioselectively to alkenes (except alkenes of the form  $\text{RR}'\text{C}=\text{CH}_2$ ) to give organoboranes of high optical purity.<sup>564</sup> When chiral boranes are added to trisubstituted alkenes of the form  $\text{RR}'\text{C}=\text{CHR}''$ , two new stereogenic centers are created, and, with some reagents, only one of the four possible diastereomers is predominantly produced, in yields greater than 90%.<sup>564</sup> This approach has been called *double-asymmetric synthesis*. 1,1-Dialkylalkenes reacted with HBPIn in the presence of a chiral Co catalyst to give the corresponding borane, with excellent enantioselectivity.<sup>565</sup> A supramolecular catalyst has been used for catalytic asymmetric hydroboration.<sup>566</sup>

The hydroboration of triple bonds<sup>567</sup> gives vinylic boranes. Subsequent oxidation of vinylboranes derived from terminal alkynes give aldehydes whereas internal alkynes give vinylboranes that are oxidized to ketones. However, terminal alkynes give vinylic boranes<sup>568</sup> (and hence aldehydes) *only* when treated with a hindered borane<sup>569</sup> or with  $\text{BHBr}_2/\text{SMe}_2$ .<sup>570</sup> The reaction between terminal alkynes and  $\text{BH}_3$  produces 1,1-dibora compounds, which can be oxidized either to primary alcohols or to carboxylic acids (with mcpba).<sup>571</sup> Double bonds can be hydroborated in the presence of triple bonds if the reagent is 9-BBN.<sup>572</sup> On the other hand, dimesitylborane selectively hydroborates triple bonds in

the presence of double bonds.<sup>573</sup> Terminal alkynes reacted with  $B_2(\text{Pin})_2$  with 0.5 equivalents of  $\text{LiOt-Bu}$  to give a metal-free hydroboration reaction and formation of the alkyl boronate.<sup>574</sup> Alkynes reacted with pinacolborane using a carboxylic acid catalyst to give the vinyl boronate.<sup>575</sup>

Transition metal-catalyzed reactions are known for the hydroboration of alkenes or alkynes, including Co-,<sup>576</sup> Cu-,<sup>577</sup> and Rh-catalyzed<sup>578</sup> reactions. When the reagent is catecholborane, hydroboration is catalyzed by Rh complexes,<sup>579</sup> such as *Wilkinson's catalyst* [chloridotrisrhodium(I);  $\text{RhCl}(\text{PPh}_3)_3$ ], and<sup>580</sup>  $\text{SmI}_2$ ,<sup>581</sup> Fe,<sup>582</sup> Ag,<sup>583</sup> or lanthanide<sup>584</sup> reagents. The Fe-catalyzed addition of pinacolborane to alkenes was reported, with selectivity for terminal alkenes.<sup>585</sup> The hydroboration of allyl or vinyl arenes reacted with  $B_2(\text{Pin})_2$  gave the corresponding alkylboranes by use of a Cu catalyst.<sup>586</sup> The Cu-catalyzed alkene hydroboration gave the alkylated organoborane.<sup>587</sup> Alkenes reacted with aryl halides and  $B_2(\text{pin})_2$ , in the presence of a Pd catalyst, to give the 2-aryl alkyl boronate.<sup>588</sup>

The reaction of alkynes and pinacolborane gave the vinyl boronate with a dialkylaluminum hydride catalyst.<sup>589</sup> Alkynes reacted with  $B_2(\text{pin})_2$  in the presence of a Cu catalyst and alkyl halides to give the corresponding alkylated vinyl boronate.<sup>590</sup> *N*-Boc-propargylamines reacted with  $B_2(\text{pin})_2$  with a catalytic amount of a *N*-heterocyclic carbene (NHC)/Cu complex to give the vinyl boronate.<sup>591</sup> Either the  $\alpha$ - or the  $\beta$ -boryl isomer was prepared by the choice of ligand with an NHC/Cu catalyst, in which propargylic alcohols and ethers were converted to the appropriate vinyl boronate by reaction with  $B_2(\text{Pin})_2$ .<sup>592</sup> The reaction of terminal alkynes with  $B_2(\text{pin})_2$  and a Ag *N*-heterocyclic carbene complex as catalyst gave the vinyl boronate.<sup>593</sup> Terminal alkynes reacted with  $B_2(\text{pin})_2$  in aqueous

methanol with NaOH, CuBr<sub>2</sub>, and cyclodextrin/bis(pyridine) to give the vinyl boronate.<sup>594</sup> The Rh-catalyzed hydroboration of terminal alkynes with pinacolborane was reported.<sup>595</sup> *o*-Bromostyrene derivatives reacted with B<sub>2</sub>(Pin)<sub>2</sub> and a Pd catalyst to give β,β-disubstituted vinyl boronates via an aryl to vinyl Pd 1,4-migration and trapping of the Pd complex with the diboron compound.<sup>596</sup> Vinylarenes and methyl crotonate reacted with aryl halides and B<sub>2</sub>(Pin)<sub>2</sub> catalyzed by Pd/Cu to give 2-boryl-1,1-diarylethanes and an α-aryl-β-boryl ester.<sup>597</sup> The Fe-,<sup>598</sup> Rh-,<sup>599</sup> or Cu<sup>600</sup>-catalyzed reactions have been reported.

The double bonds in a conjugated diene are hydroborated separately, that is, there is no 1,4-addition. However, it is difficult to hydroborate just one double bond in a conjugated system, since conjugated double bonds are less reactive than isolated ones. With Cu catalysis, the asymmetric conjugate addition (**15-24**) of organoboron reagents to conjugated enones has been reported.<sup>601</sup> Conjugated ketones reacted with B<sub>2</sub>(Pin)<sub>2</sub> in the presence of a *N*-heterocyclic carbene/Cu complex to give β-boration of acyclic enones, producing β-boryl ketones with high enantioselectivity.<sup>602</sup>

The presence of certain functional groups has directing effects on hydroboration reactions. Amides direct hydroboration reactions in alkenyl amides, for example.<sup>603</sup> Intramolecular hydroboration is directed by amine groups in alkenyl amines.<sup>604</sup> Alkenyl alcohols or ethers also undergo hydroboration, where delivery of boron is directed by the oxygen.<sup>605</sup> Functional groups such as OR, OH, NH<sub>2</sub>, SMe, halogen, and CO<sub>2</sub>R may be present in the molecule,<sup>606</sup> but not groups that are reducible by borane, such as COOH.

Boronate esters are prepared from alkenes. The reaction of an alkene with pyridine iodoborane, followed by treatment with pinacol and NaOH, for example, leads to the pinacol boronate ester.<sup>607</sup> Various cyclopropane derivatives were converted to the cyclopropyl boronate, catalyzed by the combination of (η<sup>6</sup>-mes)IrBpin<sub>3</sub> and a phenanthroline to give selective reaction at the methylene C–H bonds rather than methine or methyl C–H bonds.<sup>608</sup>

organometallic compounds.<sup>609</sup> The hydroboration reaction (**15-11**) is the most important example but, as mentioned, other important metals in this reaction are Al,<sup>610</sup> Sn,<sup>611</sup> and Zr<sup>612</sup> (which is a Group 4 metal). Some of these reactions are uncatalyzed, but in other cases various types of catalyst have been used.<sup>613</sup> The mechanism with Group 13 hydrides seems to be electrophilic (or four-centered pericyclic with some electrophilic characteristics) while with Group 14 hydrides a mechanism involving free radicals seems more likely.

Other metals add to  $\pi$  bonds. Hydrozirconation of alkenes or alkynes is the addition of Zr-H across a  $\pi$  bond.<sup>614</sup> Hydrozirconation is most commonly carried out with Cp<sub>2</sub>ZrHCl (Cp = cyclopentadienyl; zirconocene hydrochloride or zirconocene chloride hydride), known as *Schwartz's reagent*.<sup>615</sup> The Co-catalyzed alkenylzincation of alkynes has been reported.<sup>616</sup> The Fe-catalyzed hydromagnesiation<sup>617</sup> is known, and dialkylmagnesium reagents have been obtained by adding MgH<sub>2</sub> to double bonds.<sup>618</sup> Some reagents can add 1 or 2 equivalents<sup>619</sup> to triple bonds.<sup>620</sup> When 2 molar equivalents are added, electrophilic addition generally gives 1,1-dimetallic products (as with hydroboration), while free-radical addition usually gives the 1,2-dimetallic products. Hydronicellation of allenes<sup>621</sup> and the metal-catalyzed hydrostannation of alkenes<sup>622</sup> and alkynes<sup>623</sup> are known. The *trans*-selective hydrogermylation of alkynes was reported, by reaction with methyliron and a bis(germyl)hydroiron catalyst.<sup>624</sup> The hydroalumination of alkynes has been reported.<sup>625</sup> The hydromagnesiation of alkynes is also known.<sup>626</sup> The magnesiation or zincation of acrylonitriles, acrylates, and nitroalkenes has been reported using

## F. Carbon or Silicon on the Other Side

### 15-13 Addition of Alkanes

There are two important ways of adding alkanes to alkenes: (i) direct heating and (ii) acid catalysis.<sup>629</sup> Both give mixtures, and neither is useful for the preparation of relatively pure compounds in reasonable yields. However, both are useful industrially. In the thermal method, the reactants are heated to high temperatures (~500 °C) at high pressures (150–300 atm) without a catalyst. As an example, propane and ethylene gave 55.5% isopentane, 7.3% hexanes, 10.1% heptanes, and 7.4% alkenes.<sup>630</sup> There is kinetic evidence that the initiation takes place primarily by steps that are called *symproportionation* steps<sup>631</sup> (the opposite of disproportionation, Sec. 5.C.ii).

In the acid-catalysis method, a protonic or Lewis acid is used as the catalyst and the reaction is carried out at temperatures between –30 and 100 °C. This is a *Friedel-Crafts* process that proceeds via a carbocation mechanism.<sup>632</sup> An alkene reacts with H<sup>+</sup> to give a carbocation, which abstracts hydride (H<sup>–</sup>) from R–H to give an alkane and R<sup>+</sup>, which reacts with more alkene to give a new carbocation. The initially formed carbocation often rearranges before a hydride is transferred, explaining, for example, why the principal product from the reaction between isobutane and ethylene is 2,3-dimethylbutane. Instead of abstracting a hydride, it is also possible for either of the carbocation intermediates to add to another molar equivalent of alkene, so that not only rearrangement products but also dimeric and polymeric products are frequent. If the tri- or tetrasubstituted alkenes are treated with Me<sub>4</sub>Si, HCl, and AlCl<sub>3</sub>, protonation gives a tertiary carbocation, which reacts with the Me<sub>4</sub>Si to give a product that is the result of addition of H and Me to the original alkene.<sup>633</sup> An intramolecular cyclization of dodec-1-ene to cyclododecane was reported using aluminum chloride in an ionic liquid.<sup>634</sup>

Alkanes add to alkynes under photolysis conditions to give an alkene.<sup>635</sup> The reaction can also be base catalyzed, in which case there is nucleophilic addition and a carbanion mechanism.<sup>636</sup> The carbanions that are most often used are those stabilized by one or more

$\alpha$ -aryl groups. For example, toluene adds to styrene in the presence of sodium to give 1,3-diphenylpropane.<sup>637</sup> Conjugated dienes give 1,4-addition.<sup>638</sup>

There are transition metal-catalyzed addition reactions of alkyl units to alkenes,<sup>639</sup> often proceeding with metal hydride elimination to form an alkene. An intramolecular cyclization reaction of an *N*-pyrrolidino amide alkene was reported, using an iridium catalyst for addition of the carbon  $\alpha$  to nitrogen at the alkene unit.<sup>640</sup>

OS I, 229; IV, 665; VII, 479.

## 15-14 Addition of Silanes (Hydrosilation)

Silanes bearing at least one Si–H unit do not generally react with alkenes or alkynes, but transition metals catalyze the addition to give the corresponding alkylsilane or vinylsilane.<sup>641</sup> This reaction is known as hydrosilation. Transition metals used to catalyze the reaction of an alkylsilane and an alkene include Ru,<sup>642</sup> Rh,<sup>643</sup> Pd,<sup>644</sup> Re,<sup>645</sup> La,<sup>646</sup> Y,<sup>647</sup> Pt,<sup>648</sup> Co,<sup>649</sup> Fe,<sup>650</sup> Cu,<sup>651</sup> or Sm,<sup>652</sup> giving the alkylsilane with high anti-Markovnikov selectivity. In the presence of  $\text{BET}_3$ , silanes add to alkenes to give the alkylsilane with anti-Markovnikov selectivity,<sup>653</sup> or add to alkynes to give the corresponding vinylsilane.<sup>654</sup> Silanes add to alkenes under radical conditions (using AIBN) with high anti-Markovnikov selectivity.<sup>655</sup> Silanes also add to alkenes to form the anti-Markovnikov alkylsilane ( $\text{R}_3\text{Si}-\text{C}-\text{C}-\text{R}'$ ) in the presence of a hyponitrite.<sup>656</sup> Transfer hydrosilation is known.<sup>657</sup>

Silanes add to dienes with a Pd catalyst, and asymmetric induction is achieved by using a chiral additive.<sup>658</sup> Enantioselective hydrosilation has been reported using frustrated Lewis pairs.<sup>659</sup> Dienes reacted with Zr,<sup>660</sup> Ru,<sup>661</sup> or Pt<sup>662</sup> compounds and silanes to produce cyclic compounds in which the silyl group has also added to one C=C unit. Rhodium compounds allow silanes to add to enamides to give the  $\alpha$ -silyl amide.<sup>663</sup> Formation of silanes via reaction with alkenes can be followed by reaction with fluoride ion and then oxidation to give an alcohol<sup>664</sup> (see **10-16**; *Tamao-Fleming oxidation*). A variation of this reaction generated allylic silanes from terminal alkenes and a dianion-type zincate using a Ti catalyst.<sup>665</sup>

The reaction of enynes with Me<sub>2</sub>SHCl, using a Pd catalyst, showed selectivity for hydrosilation of the triple bond rather than the alkene moiety.<sup>666</sup> The use of an Ir catalyst allowed selectivity for the alkene unit rather than the alkyne.<sup>667</sup> Hydrosilation of alkynes is accomplished using transition metal catalysts<sup>668</sup> such as Ru,<sup>669</sup> Pt,<sup>670</sup> Ti,<sup>671</sup> Pd,<sup>672</sup> Cu,<sup>673</sup> Co,<sup>674</sup> or Ir.<sup>675</sup> Organocatalysts have been used as well.<sup>676</sup> Siloxanes such as (RO)<sub>3</sub>SiH add to alkynes with a Ru catalyst to give the corresponding vinylsilane.<sup>677</sup> The reaction of Cl<sub>2</sub>MeSiH and terminal alkynes, in ethanol/triethylamine with a Ru catalyst, give primarily the Markovnikov vinylsilane.<sup>678</sup> However, Et<sub>3</sub>SiH adds to terminal alkynes with a Rh<sup>679</sup> or a Pt<sup>680</sup> catalyst to give the anti-Markovnikov vinylsilane. Intramolecular reactions are possible, such as the reaction of but-3-yn-1-yldimethyl(phenyl)silane with HfClO<sub>4</sub> to give the cyclized vinylsilane, 1,1-dimethyl-4-phenyl-2,3-dihydro-1*H*-silole. The addition of PhMe<sub>2</sub>SiB(Pin) to terminal alkynes using a Cu catalyst gave primarily Markovnikov

addition and the vinylsilane.<sup>681</sup> The hydrosilation of alkynes with trialkylsilanes gave the vinylsilane when treated with Lewis acids such as organofluorophosphonium salts.<sup>682</sup>

Allenes reacted with trialkylsilanes with a Ni catalyst to give the vinylsilane, whereas using a Pd catalyst gave the allylic silane.<sup>683</sup> Transition metal catalysts such as Au,<sup>684</sup> Pd,<sup>685</sup> or Cu<sup>686</sup> have been used for the regioselective hydrosilation of allenes.

### 15-15 Addition of Alkenes and/or Alkynes to Alkenes and/or Alkynes

Alkenes can be coupled by acid catalysts in the presence of certain substrates, to give an alkene.<sup>687</sup> Transition metal catalysts can also be used.<sup>688</sup> Metal catalysts include alkylaluminum compounds (known as *Ziegler catalysts*)<sup>689</sup> and Rh,<sup>690</sup> Fe,<sup>691</sup> or Ni<sup>692</sup> catalysts.  $\alpha$ -Alkenes add to dienes in a 1,4-manner in the presence of an Fe catalyst.<sup>693</sup> The 1,4-addition of alkenes to conjugated dienes to give nonconjugated dienes<sup>694</sup> occurs with various catalysts, as does the dimerization of buta-1,3-dienes to octatrienes.<sup>695</sup> Ethylene adds to alkenes to form a new alkene in the presence of a Ni<sup>696</sup> or a Zr catalyst,<sup>697</sup> and to alkynes in the presence of a Ru catalyst<sup>698</sup> to form a diene. The addition of alkenes to alkenes<sup>699</sup> can also be mediated by bases.<sup>700</sup> Vinyl halides added to conjugated dienes in the presence of a Pd catalyst to give the nonconjugated diene.<sup>701</sup> Alkenes with an electron-withdrawing group added to bicyclic alkenes in the present of a Ru catalyst.<sup>702</sup> The Ti-catalyzed coupling of vinyl sulfones and allenes gave 1,4-dienes.<sup>703</sup> The Pd-catalyzed cyclization reactions of allenes with alkenes or alkynes has been reviewed.<sup>704</sup> The Cu-catalyzed hydroallylation of

allenes using allylic chlorides and hydrosilanes has been reported.<sup>705</sup> With an Fe catalyst and PhSiH<sub>3</sub>, unactivated alkenes were coupled to electron-deficient alkenes to give the saturated linkage.<sup>706</sup> When the reaction is applied to enynes, compounds are formed using various catalysts, but with only one double bond.<sup>707</sup>

This reaction can also be done intramolecularly, as in the formation of **25** by treatment with an acid catalyst. Transition metal catalysts can be used for cyclization of diynes to (*E,E*)-exocyclic dienes, including a Zr,<sup>708</sup> Rh,<sup>709</sup> Ru,<sup>710</sup> Au,<sup>711</sup> or Pt<sup>712</sup> complexes. Carbocyclization was reported using Pd,<sup>713</sup> Rh,<sup>714</sup> Ru,<sup>715</sup> Ir,<sup>716</sup> Y,<sup>717</sup> Ti,<sup>718</sup> or a Zr<sup>719</sup> catalyst. In some cases, internal coupling of two alkenes can form larger rings.<sup>720</sup> A Pd-catalyzed cyclization is known in which dienes are converted to cyclopentene derivatives such as **26**.<sup>721</sup>

A molecule containing two distal conjugated diene units was cyclized to give a bicyclic molecule with an exocyclic double bond using a Pd catalyst.<sup>722</sup> A Ni catalyst converted a similar system to a saturated five-membered ring containing an allylic group and a vinyl group.<sup>723</sup> Spirocyclic compounds can be prepared from enynes in this manner using formic acid and a Pd catalyst.<sup>724</sup>

The Pd-catalyzed cyclization of enynes in the presence of ArB(OH)<sub>2</sub> gave the arylated cyclized product.<sup>725</sup> The intramolecular cyclization reaction of one alkyne to an alkyne

unit within the same molecule, catalyzed by a Pd complex, gave the enyne product with an exocyclic methylene unit.<sup>726</sup> The cycloisomerization of an alkyne with a distal vinyl group, using a gold catalyst, gave the cyclized product.<sup>727</sup> The Au-catalyzed cycloisomerization of 1,5-enynes gave the cyclic alkene.<sup>728</sup>

Processes of this kind are important in the biosynthesis of steroids and tetra- and pentacyclic terpenes, illustrated by the conversion of squalene 2,3-oxide to dammaradienol by enzymatic catalysis. The squalene → lanosterol biosynthesis (which is a key step in the biosynthesis of cholesterol) is similar. The idea that the biosynthesis of such compounds involves this type of multiple ring closing was proposed in 1955 and is known as the *Stork-Eschenmoser hypothesis*.<sup>729</sup> Such reactions can also be carried out in the laboratory, without enzymes.<sup>730</sup> Cation-stabilizing groups were incorporated at positions at which positive charges develop by Johnson and co-workers, and as many as four rings could be closed stereoselectively in high yield, in one operation.<sup>731</sup> An example is formation of **27**,<sup>732</sup> by what is known as the *Johnson polyene cyclization*.<sup>733</sup> Lewis acids can be used to initiate this cyclization.<sup>734</sup>

A radical cyclization approach (**15-26**) to polyene cyclization using a seleno ester anchor gave a tetracyclic system.<sup>735</sup> Both  $\text{InI}_3$  and  $\text{InBr}_3$  catalyzed the  $\pi$  activation of  $\text{C}\equiv\text{C}$  bonds to initiate the conversion of polyene molecules that contain a chiral propargylic alcohol unit to the corresponding polycyclic compound.<sup>736</sup> A Bi-catalyzed cyclization of trienes to bicyclic hydrocarbons was reported.<sup>737</sup> A hypervalent iodine polycyclization process of an aryl derivative with a pendant enyne moiety has been reported.<sup>738</sup> An alkene-terminated cation-alkene cascade reaction was initiated by a dicationic Pt complex and gave a polycyclic compound.<sup>739</sup>

In the presence of cuprous chloride and ammonium chloride, acetylene undergoes self-coupling to give vinylacetylene. Alkynes are coupled to dienes to give enynes in the presence of a Ni catalyst.<sup>740</sup> Nonconjugated enynes were prepared by the Cu-catalyzed coupling of propargyl alcohols and alkenes.<sup>741</sup> Conjugated enynes were prepared by the Co-catalyzed, Zn-mediated, coupling of terminal alkenes and allenes.<sup>742</sup> A Rh-catalyzed coupling reaction of alkenes and electron-deficient internal alkynes leads to 1,3-dienes.<sup>743</sup> Alkynes can also be coupled to allylic silyl ethers with a Ru catalyst to give dienes.<sup>744</sup> Other alkyne-allylic coupling reactions are known to give dienes.<sup>745</sup> The reaction of an alkyne with a *Grignard reagent*, followed by an Fe complex and then an alkene, leads to enynes.<sup>746</sup> Alkynes are coupled to give enynes using Ni,<sup>747</sup> Pd,<sup>748</sup> Lu,<sup>749</sup> and Ru<sup>750</sup> catalysts. Alkynes added to allylic *N*-tosylamines using a Ru catalyst to give the alkenyl enamide.<sup>751</sup> Alkynes with a distal vinyl group were cyclized to a ring compound with an exo-methylene group using a Ru catalyst and a catalytic amount of Ag in ethanol.<sup>752</sup> *trans*-Disubstituted alkenes were prepared by the Co-catalyzed coupling of alkynes and activated alkenes.<sup>753</sup> Alkynes were coupled to conjugated esters using a Ru catalyst to give the conjugated dienyl ester.<sup>754</sup> The Ni-catalyzed, three-component cross-trimerization reaction between triisopropylsilylacetylene, diarylacetylene, and a terminal alkyne gave the diene-yne product via oxidative addition of the terminal silylacetylene.<sup>755</sup> The Cu-catalyzed coupling of potassium alkynyl carboxylates with 1,1-dibromo-1-alkenes gave unsymmetrical 1,3-diyne and 1,3,5-triyne derivatives.<sup>756</sup>

Enynes gave cyclic compounds with an endocyclic double bond conjugated to another alkene unit (a conjugated diene) when treated with GaCl<sub>3</sub><sup>757</sup> or a Pt catalyst in an ionic liquid.<sup>758</sup> Enynes can also be converted to cyclic and bicyclic compounds using Au,<sup>759</sup> Rh,<sup>760</sup> Fe,<sup>761</sup> or Pd<sup>762</sup> catalysts. The Rh-catalyzed cyclization of 1,6-enynes, triggered by

arylboronic acids, leads to rings with an exocyclic alkylidene group.<sup>763</sup> The reaction has been carried out internally to convert diynes to large-ring cycloalkynes with an exocyclic double bond.<sup>764</sup> Enynes having a conjugated alkene unit also undergo this reaction in the presence of ZnBr<sub>2</sub>.<sup>765</sup> Using mercury(II) triflate in water, cyclization leads to five-membered rings having an exocyclic double bond and a pendant alcohol group.<sup>766</sup>

OS VIII, 190, 381, 505; IX, 310.

### 15-16 Metallo-Alkylation of Non-Conjugated Double and Triple Bonds

In the absence of a transition metal catalyst, neither *Grignard reagents* nor lithium dialkyl-copper reagents generally add to ordinary C=C double bonds to form a new organometallic.<sup>767</sup> Cyclopropenes are an exception, and an excess of a Grignard reagent will add at low temperatures.<sup>768</sup> However, active Grignard reagents (benzylic, allylic) also add to the double bonds of allylic amines,<sup>769</sup> and of allylic and homoallylic alcohols,<sup>770</sup> as well as to the triple bonds of propargyl alcohols and certain other alkynols.<sup>771</sup> Grignard reagents can add to double bonds that are susceptible to nucleophilic attack (e.g., fluoroalkenes and tetracyanoethylene).<sup>772</sup> Transition metal complexes facilitate the addition of Grignard reagents to alkenes, and typical metals include Ti,<sup>773</sup> Mn,<sup>774</sup> Zr,<sup>775</sup> Ni,<sup>776</sup> Fe,<sup>777</sup> and Cu<sup>778</sup> compounds. Cyclopropene derivatives also react with CuI and then allyl bromide.<sup>779</sup>

The Fe/Cu-catalyzed coupling of alkynes and alkyl Grignard reagents (RMgX) led to addition of the addition of “R” and “MgX” to the  $\pi$  bond (carbomagnesiation) and formation of a vinyl Grignard reagent.<sup>780</sup> The Ag-catalyzed carbomagnesiation of alkynes with alkyl halides and Grignard reagents has been reported.<sup>781</sup> The Pd<sup>782</sup> and also the

Cu<sup>783</sup>-catalyzed carbozincation of cyclopropanes has been reported as has the Co-catalyzed carbozincation of ynamides.<sup>784</sup> The hydroalumination and carbocupration of alkynes has been reported.<sup>785</sup> The Ta-catalyzed carboalumination of alkenes has been reported.<sup>786</sup> An arylmagnesium of alkynes has been reported.<sup>787</sup> The Cu-catalyzed carbomagnesium of cyclopropanes has been reported.<sup>788</sup>

The intramolecular addition of RMgX to completely unactivated double and triple bonds has been demonstrated.<sup>789</sup> The reaction of tosylates bearing a remote alkene unit and a Grignard reagent leads to cyclization when a Zr catalyst is used.<sup>790</sup> The intramolecular addition of a CH<sub>2</sub>Br unit to the C=C unit of an allylic ether was accomplished using PhMgBr and a Co catalyst, giving a functionalized tetrahydrofuran and incorporation of the phenyl group on the C=C unit as well.<sup>791</sup>

Conjugated dienes react with arylmagnesium halides, Ph<sub>3</sub>SiCl, and a Pd catalyst to give a coupling product involving the reaction of 2 equivalents of the diene and incorporation of two SiPh<sub>3</sub> units.<sup>792</sup> The Cr-catalyzed formation of arylmagnesium compounds<sup>793</sup> and the Rh-catalyzed hydroarylation<sup>794</sup> of alkynes are also known. The Pd-catalyzed hydroarylation<sup>795</sup> of alkynes is possible using arenediazonium salts as substrates<sup>796</sup> or hydroarylation of 1,3-dienes with boronic acids.<sup>797</sup>

## 15-17 Addition of Alkyls or Aryls to Alkenes (Hydroalkylation; Hydroarylation)

The addition of alkyl groups to alkenes or alkynes<sup>798</sup> leads to saturated hydrocarbon fragments, or alkylated alkenes.<sup>799</sup> Such a reaction is known as hydroalkylation, in which an alkyl group, R, and a hydrogen atom add across the  $\pi$  bond.<sup>800</sup> Such a reaction usually involves an organometallic reagent, and often the formation of a new organometallic that reacts with a proton source.

Organolithium reagents add to the double and triple bonds of allylic and propargylic alcohols<sup>801</sup> (tetramethylethylenediamine is a catalyst) and also to certain other alkenes containing hetero groups, such as OR, NR<sub>2</sub>, or SR. Mixing an organolithium reagent with

transition metal compounds, such as  $\text{CeCl}_3$ <sup>802</sup> or  $\text{Fe}(\text{acac})_3$ ,<sup>803</sup> leads to addition of the alkyl group. Organolithium reagents add to the less substituted  $\text{C}=\text{C}$  unit of conjugated dienes.<sup>804</sup> Addition of butyllithium to alkenes has been observed with good enantioselectivity when sparteine was added.<sup>805</sup>

The intramolecular addition of  $\text{RLi}$  and  $\text{R}_2\text{CuLi}$  has been reported.<sup>806</sup> Cyclization<sup>807</sup> can occur at low temperatures when an organolithium reagent contains an alkene<sup>808</sup> or alkyne<sup>809</sup> unit. Tandem cyclization is possible with dienes and enynes to form more than one ring,<sup>810</sup> including bicyclic compounds.<sup>811</sup> Alkyl iodides add intramolecularly to alkenes with a Ti catalyst<sup>812</sup> or add to alkynes using In metal and additives.<sup>813</sup> The intramolecular hydroalkylation gave the cyclic alkene using an organocatalyst, a chiral organophosphine.<sup>814</sup> Alkenes reacted with 5-(trifluoromethyl)dibenzothiophenium trifluoromethanesulfonate (*Utemoto's reagent*) in the presence of a Rh catalyst, exposure to visible light, and methanol as a proton source to give the anti-Markovnikov trifluoromethyl hydroalkylation product.<sup>815</sup> The Fe-catalyzed hydromethylation reaction of alkenes used formaldehyde,  $\text{PhSiH}_3$ , and octanesulfonyl hydrazine.<sup>816</sup> The Cu-catalyzed hydromethylation of alkenes used  $\text{Cp}_2\text{ZrMeCl}$ .<sup>817</sup> Silyl enol ethers with a distal vinyl group reacted via a Pd catalyst to give the cyclic ketone with a  $\beta$ -exo methylene compound.<sup>818</sup> Trimethylaluminum reacts with alkynes.<sup>819</sup> Ruthenium catalysts have been used to mediate the addition of allylic alcohols to alkynes.<sup>820</sup> Allyl manganese compounds add to allenes to give nonconjugated dienes.<sup>821</sup>

The stereochemistry of the metal-catalyzed, intramolecular carboalkylation of 1,6-dienes to give cyclic compounds has been discussed.<sup>822</sup> The metal-catalyzed cyclization of alkynes and their adherence to Baldwin's rules has been reviewed.<sup>823</sup> Cyclobutanes

Aryl iodides add to alkynes using a Pt complex in conjunction with a Pd catalyst.<sup>847</sup> A Pd catalyst has been used alone for the same purpose,<sup>848</sup> and the intramolecular addition of an arene to an alkene was accomplished with a Pd,<sup>849</sup> Ga,<sup>850</sup> or a Ru<sup>851</sup> catalyst. The Mn-catalyzed hydroarylation of alkynes has been done using continuous flow techniques (Sec. 7.D).<sup>852</sup> The Ir-catalyzed, asymmetric hydroheteroarylation of bicyclic alkenes has been reported,<sup>853</sup> and a Rh-catalyzed heteroarylation has been reported.<sup>854</sup> The hydroarylation of conjugated alkynyl ketones with aryl iodides used a Ni catalyst and a Mn reductant.<sup>855</sup>

Phenylboronic acids add to alkynes in the presence of a Co<sup>856</sup> or a Pd<sup>857</sup> catalyst. Arylboronic acids (see **13-13**) add to alkynes to give the substituted alkene using a Rh catalyst.<sup>858</sup> Allenes react with phenylboronic acid and an aryl iodide, in the presence of a Pd catalyst, to give a substituted alkene.<sup>859</sup>

Ketones with an  $\alpha$ -hydrogen can add to alkenes intramolecularly when heated in a sealed tube with CuCl<sub>2</sub> and a Pd catalyst.<sup>860</sup> A similar reaction was reported using Yb(OTf)<sub>3</sub> and a Pd,<sup>861</sup> In,<sup>862</sup> or an Au<sup>863</sup> catalyst. 1,3-Diketones add to dienes (1,4-addition) using a Pd,<sup>864</sup> Rh,<sup>865</sup> Au/Ag,<sup>866</sup> or Au/Ga<sup>867</sup> catalyst. This addition has been done intramolecularly using 2.4 molar equivalents of CuCl<sub>2</sub> and a Pd catalyst.<sup>868</sup> The intermolecular addition of diesters, such as malonates, to alkynes was accomplished in acetic acid and using a Pd catalyst under microwave irradiation.<sup>869</sup> Silyl enol ethers add to alkynes using a W catalyst.<sup>870</sup>

## 15-18 The Addition of Two Alkyl Groups to an Alkyne

Two different alkyl groups can be added to a terminal alkyne<sup>871</sup> in one laboratory step by treatment with an alkylcopper/magnesium bromide reagent (called *Normant reagents*)<sup>872</sup> and an alkyl iodide in ether/HMPA containing triethyl phosphite.<sup>873</sup> The groups add stereoselectively *syn*. The reaction, which has been applied to primary<sup>874</sup> R<sup>1</sup> and to primary, allylic, benzylic, vinylic, and  $\alpha$ -alkoxyalkyl R<sup>1</sup>, involves initial addition of an intermediate alkylcopper reagent,<sup>875</sup> followed by a coupling reaction (**10-57**). Acetylene itself (R = H) undergoes the reaction with R<sub>2</sub>CuLi instead of the Normant reagent.<sup>876</sup> If the alkyl iodide is omitted, the vinylic copper intermediate can be converted to a carboxylic acid by the addition of CO<sub>2</sub> and P(OEt)<sub>2</sub> in HMPA (see **16-30**) or to an amide by the addition of an isocyanate, and P(OEt)<sub>2</sub> and HMPA and a catalytic amount of triethyl phosphite.<sup>877</sup> The use of I<sub>2</sub> results in a vinylic iodide.<sup>878</sup>

Similar reactions, in which two alkyl groups are added to a triple bond, have been carried out with trialkylalanes (R<sub>3</sub>Al), with zirconium complexes as catalysts.<sup>879</sup> Internal alkynes undergo bis(allylation) using a Ni catalysts and triallylindium.<sup>880</sup> Allyl ethers and iodobenzene have also been added using a Zr complex.<sup>881</sup>

The Re-catalyzed reaction of  $\beta$ -keto sulfones with terminal alkynes gave unsaturated  $\delta$ -keto sulfones in good to excellent yields.<sup>882</sup> The Mn-catalyzed carboacylation of alkenes with alkyl iodides has been reported.<sup>883</sup> The  $\beta$ -selective hydrocarboxylation of styrenes has been done under flow conditions (Sec. 7.D).<sup>884</sup> Arylboronic acids (see **13-14**) react with alkynes and 1 equivalent of an aryl iodide, with a Pd catalyst, to add two aryl groups across the triple bond.<sup>885</sup>

15-19 The Ene Reaction<sup>886</sup>

An interesting addition of R–H to a double bond involves the reaction of alkenes with an alkene having an allylic hydrogen (C=C–CH), and is called the *ene reaction*, the *Alder ene reaction*, or the *ene synthesis*.<sup>887</sup> The reaction can proceed thermally without a catalyst, but one of the components must be a reactive dienophile (reacts with a diene; see 15-56), such as maleic anhydride, but the other (which supplies the hydrogen) may be a simple alkene such as propene *as long as there is an allylic hydrogen atom*. Rather high reaction temperatures (250–450 °C) are common unless the substrates are very activated, but steric acceleration of the uncatalyzed ene reaction is known.<sup>888</sup> The reaction is compatible with a variety of functional groups that can be appended to the ene and the dienophile. A retro-ene reaction is known with allylic dithiocarbonate.<sup>889</sup> The reaction can be extended to less-reactive enophiles by the use of Lewis acid catalysts, especially alkylaluminum halides.<sup>890</sup> Titanium,<sup>891</sup> Sc,<sup>892</sup> LiClO<sub>4</sub>,<sup>893</sup> Y,<sup>894</sup> In,<sup>895</sup> Pd,<sup>896</sup> Co,<sup>897</sup> Ni,<sup>898</sup> as well as a combination of Ag and Au have been used as catalysts.<sup>899</sup> An Ir-catalyzed ene reaction has been done in an ionic liquid.<sup>900</sup>

There has been much discussion of the mechanism of this reaction,<sup>901</sup> and both concerted pericyclic (as shown in the generic reaction) and stepwise mechanisms have been suggested. Mechanistic studies have been reported for the intramolecular aryne ene reaction.<sup>902</sup> The mechanism of the ene reaction of singlet (<sup>1</sup>Δ<sub>g</sub>) oxygen with simple alkenes was found to involve two steps, with no intermediate.<sup>903</sup> The Lewis acid-catalyzed

reaction probably has a stepwise mechanism.<sup>904</sup> The reaction between maleic anhydride and optically active PhCHMeCH=CH<sub>2</sub> gave an optically active product,<sup>905</sup> which is strong evidence for a concerted rather than a stepwise mechanism.<sup>906</sup> Arynes reacted with alkenes via the ene reaction.<sup>907</sup> An ene reaction of arynes with alkynes gave aryl allenes.<sup>908</sup>

Intramolecular ene reactions are known,<sup>909</sup> including those catalyzed by transition metals such as Cu.<sup>910</sup> An example is the intramolecular ene reaction of **28**, catalyzed by BF<sub>3</sub>, which gave **29** in a synthesis of hippolachnin A.<sup>911</sup> The reaction can be highly stereoselective.<sup>912</sup>

Ene reactions with imines<sup>913</sup> and nitrile oxides,<sup>914</sup> as well as nitroso ene reactions,<sup>915</sup> are known. Vinyl boronates have been prepared via a Ru-catalyzed ene reaction.<sup>916</sup> Tetrahydrothiopyrans were formed via a (3,5)-thionium ene cyclization,<sup>917</sup> and a transition metal photoredox thiol-ene reaction is known.<sup>918</sup>

Ene reactions of imines are sometimes called *imino-ene reactions*.<sup>919</sup> An *aza-ene reaction*<sup>920</sup> has been used in a synthesis of enantioenriched piperidines, using two different imines as starting materials.<sup>921</sup> An enantioselective aza-ene reaction in the presence of an organocatalyst led to 1,4-dihydropyridines.<sup>922</sup> A Au carbene-catalyzed reaction is known.<sup>923</sup>

## 15-20 The Michael Reaction

The reaction of carbanion nucleophiles, including enolate anions, with  $\alpha,\beta$ -unsaturated compounds that contain an electron-withdrawing group gives the conjugate (1,4) addition product. This reaction is called the *Michael reaction*.<sup>939</sup> The product formed,  $RCH_2Z$  or  $RCHZZ'$ , where Z, an electron-withdrawing group, can include aldehydes,<sup>940</sup> ketones,<sup>941</sup> esters,<sup>942</sup> diesters,<sup>943</sup> diketones,<sup>944</sup> keto esters,<sup>945</sup> carboxylic acids, dicarboxylic

acids,<sup>946</sup> nitriles,<sup>947</sup> vinyl sulfones,<sup>948</sup> nitro compounds,<sup>949</sup> and others of the form  $ZCH_3$ ,  $ZCH_2R$ ,  $ZCHR_2$ , and  $ZCHRZ'$ .<sup>950</sup> Malonate derivatives also add to conjugated ketones,<sup>951</sup> and keto esters add to conjugated esters.<sup>952</sup> Ultrasound has been used to promote asymmetric Michael reactions.<sup>953</sup> In reactions of enolate anions, both the enolate anion and substrate can exist as *Z* or *E* isomers. With enolates derived from ketones or carboxylic esters, the (*E*)-enolates gave the *syn* pair of enantiomers (Sec. 4.G), while (*Z*)-enolates gave the *anti* pair.<sup>954</sup> When the substrate contains *gem-Z* groups, e.g.,  $C=C(CN)CO_2Et$ , bulky groups can be added if the reaction is carried out under aprotic conditions.<sup>955</sup>

Transition metal compounds,<sup>956</sup> such as Ce,<sup>957</sup> Yb,<sup>958</sup> Bi,<sup>959</sup> Fe,<sup>960</sup> Ni,<sup>961</sup> Cu,<sup>962</sup> La,<sup>963</sup> Ru,<sup>964</sup> Rh,<sup>965</sup> Pd,<sup>966</sup> or Sc,<sup>967</sup> also induce the reaction. Conjugate addition has also been promoted by Y zeolite,<sup>968</sup> and water-promoted Michael additions have also been reported.<sup>969</sup> Malonate derivatives give conjugate addition using a Ni catalyst,<sup>970</sup> organocatalysts,<sup>971</sup> or genomic salmon testes DNA for reactions in water.<sup>972</sup> Michael addition is known to be

catalyzed by phosphines<sup>973</sup> and other organocatalysts,<sup>974</sup> and catalysts are known that are compatible with an aqueous medium.<sup>975</sup> An organocatalyst has been used for the conjugate addition of malonates to enones,<sup>976</sup> and solvent-free conditions with an organocatalyst have been reported.<sup>977</sup> A chiral phase-transfer catalyst was used for the conjugate addition of malonate derivatives to enones, with an unusual inversion of enantioselectivity that is solvent and substitution dependent.<sup>978</sup>

The 1,2-addition to a C=O or C≡N group often competes and sometimes predominates (16-38).<sup>979</sup> Note that  $\alpha,\beta$ -unsaturated aldehydes seldom give 1,4-addition.<sup>980</sup> Better yields with fewer side reactions are realized by conversion of the nucleophile to a *preformed enolate*.<sup>981</sup> Phase-transfer catalysts have been used,<sup>982</sup> and ionic liquids have been used in conjunction with phase-transfer catalysis.<sup>983</sup> The kinetics of conjugate addition of  $\beta$ -keto esters to acrylates in ionic liquids has been discussed.<sup>984</sup> The mechanism of the iodine-catalyzed conjugate addition has been discussed.<sup>985</sup> In certain cases, Michael reactions can take place under acidic conditions.<sup>986</sup> Michael-type addition of radicals to conjugated carbonyl compounds is also known.<sup>987</sup> Radical addition can be catalyzed by Yb(OTf)<sub>3</sub>,<sup>988</sup> but radicals add under standard conditions as well, even intramolecularly.<sup>989</sup> Electrochemical-initiated Michael additions are known.

Silyl enol ethers such as **30** add to  $\alpha,\beta$ -unsaturated ketones and esters when catalyzed<sup>990</sup> by TiCl<sub>4</sub><sup>991</sup> or InCl<sub>3</sub>.<sup>992</sup> A solid-state version of the reaction used alumina•ZnCl<sub>2</sub>.<sup>993</sup> This reaction has been performed with good diastereoselectivity,<sup>994</sup> and silyl enol ethers have been used in conjunction with chiral additives.<sup>995</sup>

<sup>995</sup> Harada, T.; Adachi, S.; Wang, X. *Org. Lett.* **2004**, *6*, 4877.

Vinylogous Michael reactions are well known, using a variety of nucleophilic species<sup>996</sup> (Sec. 6.B for vinylogy). 1,6-Additions are also known.<sup>997</sup> The *N*-heterocyclic carbene-catalyzed umpolung of Michael acceptors has been reported.<sup>998</sup> The Co-catalyzed 1,6-addition of trialkylsilylacetylene derivatives has been reported.<sup>999</sup> The conjugated addition of triallyl(aryl)silanes to conjugated carbonyl compounds used a Rh catalyst.<sup>1000</sup>

Intramolecular versions of Michael addition are known.<sup>1001</sup> The stereochemical course of the intramolecular reaction has been discussed.<sup>1002</sup> The intramolecular Michael addition of an  $\alpha$ -chloro ketone enolate anion, formed *in situ* using DABCO, leads to formation of a bicyclo[4.1.0] diketone.<sup>1003</sup> A double Michael process is possible, where conjugate addition to an alkynyl ketone is followed by an intramolecular Michael reaction to form a functionalized ring.<sup>1004</sup> The Co-catalyzed, intramolecular conjugate addition of alkene moieties gave cyclic compounds with a  $\gamma,\delta$ -alkene unit.<sup>1005</sup> Alkenyl aldehydes cyclized via an intramolecular conjugate addition when treated with KO*t*-Bu and imidazolium carbenes to give cyclic compounds with a pendant aldehyde<sup>1006</sup> or ketone moiety.<sup>1007</sup> The intramolecular reaction of alkenes to conjugated carbonyl compounds used a Cu catalyst to give the cyclic alkene.<sup>1008</sup> Alkynes with an electron-withdrawing group such as CO<sub>2</sub>R or CN reacted intramolecular with a distal alkene unit in the presence of TMSiCN and a trialkylphosphine to give the cyclic alkene nitrile.<sup>1009</sup>

Alkynes are reactive, and Michael reactions are sometimes applied to substrates of the type C=C–Z, where Z is an electron-withdrawing group; the co-products are conjugated systems of the type C=C–Z.<sup>1010</sup> Terminal alkynes add to conjugated systems.<sup>1011</sup> Due to the greater susceptibility of triple bonds to nucleophilic attack, it is even possible for non-activated alkynes, e.g., acetylene, to be substrates in this reaction.<sup>1012</sup> The Pd-catalyzed conjugate addition of terminal alkynes to enones has been reported.<sup>1013</sup>

An important cyclization procedure involves the acid-catalyzed addition of diene ketones such as **31**, where one conjugated alkene adds to the other conjugated

alkene to form cyclopentenones (**32**). This transformation is called the *Nazarov cyclization*.<sup>1014</sup>

The addition is formally a *Michael addition*, and structural variations are possible that prepare a variety of cyclopentenones. Substituents on the C=C units lead to cyclopentenones that bear those substituents. The steric influence of substituents<sup>1015</sup> and also the effects of torquoselectivity<sup>1016</sup> have been discussed. The rate-accelerating influence observed in *N*- and *S*-heterocycles has been noted.<sup>1017</sup> Fully substituted dienones have been used.<sup>1018</sup> It is noted that the iso-Nazarov reaction has been reviewed.<sup>1019</sup> The Nazarov reaction of aryl vinyl  $\beta$ -keto esters gave indanone derivatives.<sup>1020</sup> Note that a *retro*-Nazarov is possible with  $\alpha$ -bromocyclopentanones.<sup>1021</sup> There is a so-called interrupted Nazarov, in which an amine is trapped after cyclization to give an  $\alpha$ -amino conjugated cyclopentenone.<sup>1022</sup> Treatment of a Nazarov diene with  $\text{BF}_3 \cdot \text{OEt}_2$  and then treatment with  $\text{Br}_2$  gave the Nazarov product dibromide in an interrupted Nazarov cyclization process.<sup>1023</sup> A decarboxylative Nazarov cyclization, mediated by carbon dioxide, has been reported.<sup>1024</sup> Spirocycles have been prepared via a tandem *Nazarov-Wagner-Meerwein* sequence.<sup>1025</sup> An aza-Nazarov-type reaction is known.<sup>1026</sup> A vinylogous Nazarov reaction is involved in the cyclization of cross-conjugated trienes<sup>1027</sup> (Sec. 6.B for vinylogy). The use of a chiral ligand gave the cyclopentenone with modest enantioselectivity,<sup>1028</sup> although asymmetric Nazarov

The conjugate addition reaction of organometallic reagents to conjugated compounds generates an enolate anion as the product, which can be hydrolyzed to the carbonyl derivatives.<sup>1071</sup> One of the better known variations reacts lithium dialkylcopper reagents ( $R_2CuLi$  reagents,<sup>1072</sup> also known as *Gilman reagents*, see **10-57**) with  $\alpha,\beta$ -unsaturated aldehydes<sup>1073</sup> and ketones ( $R' = H, R, Ar$ ) and other systems of the form  $C\equiv C-C=O$ <sup>1074</sup> to give conjugate addition products.<sup>1075</sup>  $\alpha,\beta$ -Unsaturated esters are less reactive,<sup>1076</sup> and the corresponding acids do not react at all. If  $Me_3SiCl$  is present, the enolate anion product is trapped as the silyl enol ether and the reaction takes place much faster, and in higher yield.<sup>1077</sup> Solvent effects are important for the reactivity of organocuprates,<sup>1078</sup> which influence aggregation and aggregation state of the dialkyl cuprate.<sup>1079</sup>

Conjugate addition of the cuprate to the  $\alpha,\beta$ -unsaturated ketone leads to substitution at the  $\beta$  position and formation an enolate ion, as noted above. It is possible for this enolate anion to react with an electrophilic species such as an alkyl halide (*tandem vicinal difunctionalization*), in some cases at the O and in most cases at the C.<sup>1080</sup> For example, if an alkyl halide  $R^2X$  is present ( $R^2 =$  primary alkyl or allylic), the enolate anion can be alkylated directly to give an  $\alpha$ -substituted carbonyl compound.<sup>1081</sup>

An excess of the cuprate reagent relative to the conjugated substrate is often required. In general, only one of the R groups of  $R_2CuLi$  adds to the substrate; the other is wasted with respect to the conjugated substrate. The difficulty of group transfer can be overcome by using one of the mixed reagents  $R(R'C\equiv C)CuLi$ ,<sup>1082</sup>  $R(O-t-Bu)CuLi$ ,<sup>1083</sup> or  $R(PhS)CuLi$ ,<sup>1084</sup> each of which transfers only the R group. Mixed reagents are easily prepared by the reaction of  $RLi$  with  $R'C\equiv CCu$  ( $R' = n-Pr$  or  $t-Bu$ ),  $t-BuOCu$ , or  $PhSCu$ , respectively. The mixed reagents  $R(CN)CuLi$ <sup>1085</sup> (prepared from  $RLi$  and  $CuCN$ ) and

$R_2Cu(CN)Li_2$ <sup>1086</sup> also selectively transfer the R group.<sup>1087</sup> With mixed cuprates, one of the ligands may be less prone to transfer than the other, as  $R(R'Se)Cu(CN)Li_2$ , leading to selective transfer of the R group.<sup>1088</sup> This less transferable ligand is sometimes referred to as a “dummy ligand.” The selectivity of ligand transfer depends on two factors, (i) thermodynamics of groups such as alkyl or thioalkyl and (ii) kinetic reactivity of groups such as silylalkyl or vinyl.<sup>1089</sup> A Cu(III) complex has been detected using rapid injection NMR.<sup>1090</sup>

The 1,4-addition of organometallic compounds has been performed diastereoselectively<sup>1091</sup> and enantioselectively.<sup>1092</sup> The influence of solvent and additives on yield and selectivity has been examined.<sup>1093</sup> Addition of chiral ligands to the organocuprate conjugate addition reaction leads to alkylation with good to excellent enantioselectivity.<sup>1094</sup> The conjugate addition of dimethyl cuprate in the presence of a chiral ligand, such as **33**, is an example.<sup>1095</sup>

Chiral bis(oxazoline) copper catalysts have been used for the conjugate addition of indoles to  $\alpha,\beta$ -unsaturated esters.<sup>1096</sup> Enantioselectivity is effectively controlled by the choice of ligand and its interaction with a Cu compound, where different ligands on the metal may lead to differences in selectivity.<sup>1097</sup>

Conjugated alkynyl ketones also react via 1,4-addition to give substituted alkenyl ketones.<sup>1098</sup> Organocopper reagents  $RCu$  as well as certain  $R_2CuLi$  reagents add to  $\alpha,\beta$ -unsaturated and acetylenic sulfoxides.<sup>1099</sup> The reaction has been carried out<sup>1100</sup> with  $\alpha,\beta$ -acetylenic ketones,<sup>1101</sup> esters, and nitriles. Conjugate addition to  $\alpha,\beta$ -unsaturated and acetylenic acids and esters, as well as ketones, can be achieved by the use of the coordinated reagents  $RCu \cdot BF_3$  ( $R$  = primary).<sup>1102</sup> The silylcupration of conjugated alkynes in water has been reported.<sup>1103</sup>

Various functional groups may be present in the substrate when organocuprates are employed.<sup>1104</sup> There is generally little or no competition from 1,2-addition (to the C=O). However, when R is allylic, 1,4-addition is observed with some substrates and 1,2-addition with others.<sup>1105</sup> The diastereoselectivity for the conjugate addition of cuprate to unsaturated lactams was shown to be reversed.<sup>1106</sup> Amine units have been transferred using  $\alpha$ -lithio amides, CuCN, and various additives, which gave conjugate addition of an amidomethyl unit,  $-\text{CH}_2\text{N}(\text{Me})\text{Boc}$ .<sup>1107</sup>

Other organometallic compounds add to conjugated systems. Grignard reagents add to conjugated substrates such as  $\alpha,\beta$ -unsaturated ketones, cyano ketones,<sup>1108</sup> and alkenitriles,<sup>1109</sup> but 1,2-addition may seriously compete:<sup>1110</sup> In general, substitution at the carbonyl group increases 1,4-addition, while substitution at the double bond increases 1,2-addition. In most cases both products are obtained, but  $\alpha,\beta$ -unsaturated *aldehydes* nearly always give exclusive 1,2-addition when treated with Grignard reagents. Grignard reagents mixed with  $\text{CeCl}_3$  generate a reactive species that gives primarily 1,4-addition.<sup>1111</sup> The extent of 1,4-addition of Grignard reagents can be increased by the use of a Cu catalyst such as  $\text{CuCl}$  or  $\text{Cu}(\text{OAc})_2$ ,<sup>1112</sup> forming a magnesium cuprate *in situ*. The Cu-catalyzed conjugate addition of Grignard reagents to enones has been done using flow techniques (Sec. 7.D).<sup>1113</sup> Catalytic enantioselective conjugate addition has been reported with Grignard reagents.<sup>1114</sup> Formation of the conjugate addition product is often controlled by steric factors. It is likely that alkylcopper reagents, formed from  $\text{RMgX}$  and  $\text{Cu}^+$  (cupric acetate is reduced to cuprous ion by excess  $\text{RMgX}$ ), are the actual reactive species in these cases.<sup>1073</sup> Grignard reagents add to cyclic enones in the presence of a Cu catalyst.<sup>1115</sup> Chiral templates have also been used with Grignard reagents, both directly<sup>1116</sup> and in the presence of  $\text{AlMe}_2\text{Cl}$ .<sup>1117</sup> The enantioselective Grignard addition to nitroalkenes has been discussed.<sup>1118</sup>

The mechanisms of most of these reactions have been studied. The 1,4-uncatalyzed Grignard reaction has been postulated to proceed by a cyclic mechanism, but there is evidence

against it.<sup>1119</sup> The  $R_2CuLi$ -<sup>1120</sup> and Cu-catalyzed Grignard additions may involve a number of mechanisms, since the actual attacking species and substrates are so diverse.<sup>1121</sup> A free-radical mechanism of some type (perhaps SET) has been suggested<sup>1122</sup> although the fact that retention of configuration at R has been demonstrated in several cases rules out a completely free  $R\cdot$  radical.<sup>1123</sup> For simple  $\alpha,\beta$ -unsaturated ketones, such as 2-cyclohexenone, and  $Me_2CuLi$ , there is evidence<sup>1124</sup> for a  $d,\pi^*$  complex, with bonding between copper, as a base supplying a pair of  $d$  electrons, and the enone, as a Lewis acid using the  $\pi^*$  orbital of the allylic system.<sup>1122</sup> The  $^{13}C$  NMR spectrum of an intermediate similar to an enolate/Cu complex has been reported.<sup>1125</sup>

Organolithium reagents<sup>1126</sup> generally react with conjugated aldehydes, ketones, and esters by 1,2-addition,<sup>1127</sup> but can be made to give 1,4-addition with  $\alpha,\beta$ -unsaturated ketones<sup>1128</sup> and aldehydes<sup>1129</sup> if the reactions are conducted in the presence of HMPA.<sup>1130</sup> Among organolithium reagents that have been found to add 1,4 in this manner are 2-lithio-1,3-dithianes (see **10-71**)<sup>1131</sup> and vinyl lithium reagents.<sup>1132</sup> A reagent based on  $RMgX/3 MeLi$  gave conjugate addition with  $\alpha,\beta$ -unsaturated amides and carboxylic acid derivatives.<sup>1133</sup> If the organolithium reagent is complexed, 1,4-addition is more successful. The reaction of an aryllithium reagent with  $B(OMe)_3$ , for example, led to a Rh-catalyzed conjugate addition with excellent enantioselectivity when a chiral ligand was employed.<sup>1134</sup>

Organozinc compounds add to conjugated systems, especially dialkyl zinc compounds,  $R_2Zn$ . Many dialkylzinc compounds can be used, including vinylzinc compounds.<sup>1135</sup> The use of chiral ligands is effective for conjugate addition of dialkylzinc compounds to  $\alpha,\beta$ -unsaturated ketones, esters, and so on,<sup>1136</sup> including conjugated lactones.<sup>1137</sup> The addition of a chiral complex to dialkylzinc compounds leads to enantioselective conjugate addition in conjunction with  $Cu(OTf)_2$ ,<sup>1138</sup>  $CuCN$ ,<sup>1139</sup> or other Cu

## 15-22 The Sakurai Reaction

Allylic silanes (R<sub>2</sub>C=CHCH<sub>2</sub>SiMe<sub>3</sub>) rather than silyl enol ethers can be added to conjugated systems in what is known as the *Sakurai reaction*.<sup>1174</sup> For example, an allyl group can be added to  $\alpha,\beta$ -unsaturated carboxylic esters, amides, and nitriles, with CH<sub>2</sub>=CHCH<sub>2</sub>SiMe<sub>3</sub> and F<sup>-</sup> ion (see **15-43**).<sup>1175</sup> This reagent gave better results than lithium diallylcuprate (**15-21**). Catalytic Sakurai reactions are known.<sup>1176</sup> The Pd-catalyzed reaction of conjugated ketones with PhSi(OEt)<sub>3</sub> with SbCl<sub>3</sub> and Bu<sub>4</sub>NF in acetic acid gave the 1,4-addition product.<sup>1177</sup> Silicomolybdic acid supported on silica gel has been used to catalyze the reaction.<sup>1178</sup> A similar reaction was reported using PhSi(OMe)<sub>3</sub> with a Rh catalyst.<sup>1179</sup> Silver fluoride was used to catalyze the reaction with allyl(trimethoxy)silane.<sup>1180</sup> The Sakurai reaction has been used in multi-component reactions.<sup>1181</sup>

An enantioselective aza-Sakurai cyclization has been reported.<sup>1182</sup> The Ce-catalyzed enantioselective Sakurai reaction of aldehydes and allyltrimethylsilane has been reported.<sup>1183</sup> A counteranion-controlled disulfonimide organocatalyst allowed an enantioselective *Hosomi-Sakurai reaction* of (hetero)aromatic aldehydes and allylsilanes.<sup>1184</sup>

### 15-23 Conjugate Addition of Boranes to Activated Double Bonds

Just as trialkylboranes add to simple alkenes (**15-11**), they rapidly add to the double bonds of conjugated alkenes such as acrolein or methyl vinyl ketone in THF to give enol borinates (also see **10-68**), which can be hydrolyzed to aldehydes or ketones.<sup>1185</sup> If water is present in the reaction medium from the beginning, the reaction can be run in one laboratory step. Since the boranes can be prepared from alkenes (**15-11**), this reaction provides a means of lengthening a carbon chain by three or four carbons, respectively. Compounds containing a terminal alkyl group, such as crotonaldehyde ( $\text{CH}_3\text{CH}=\text{CHCHO}$ ) and 3-penten-2-one, fail to react under these conditions, as does acrylonitrile, but slow and controlled addition of  $\text{O}_2$  or by initiation with peroxides or UV light allows these compounds to react.<sup>1186</sup> A disadvantage is that only one of the three R groups of  $\text{R}_3\text{B}$  adds to the substrate, so that the other two are wasted. This difficulty is overcome by the use of a  $\beta$ -alkyl borinate,<sup>1187</sup> which permits *tert*-butyl groups to be added. Transition metals catalyze the addition of trialkylboranes to conjugated systems, and enantioselective reactions are known.<sup>1188</sup> The addition of allylboranes in the presence of a Ni catalyst is known,<sup>1189</sup> and this reaction was enhanced by the addition of methanol.<sup>1190</sup>

The conjugate addition of  $\text{B}_2(\text{Pin})_2$  to conjugated carbonyl compounds was catalyzed by Cu in a reaction that was done in water and open to the air.<sup>1191</sup> The mechanism of the *N*-heterocyclic carbene-catalyzed conjugated addition of  $\text{B}_2(\text{Pin})_2$  and borosilanes to conjugated carbonyl compounds has been probed.<sup>1192</sup> The asymmetric conjugate arylation of enones was catalyzed by a binaphthol derivative.<sup>1193</sup> The corresponding  $\beta$ -1-alkynyl-9-BBN compounds also give the reaction.<sup>1194</sup> Vinyl boranes add to conjugated ketones in the

acids to conjugated systems.<sup>1220</sup> Potassium vinyltrifluoroborates (see **10-59**, **13-13**, **13-14**) give 1,4-addition with a Rh catalyst,<sup>1221</sup> as do aryltrifluoroborates.<sup>1222</sup> The Cu-catalyzed reaction of conjugated compounds with  $B_2(OH)_4$  gave  $\beta$ -borylation.<sup>1223</sup> The Pd-catalyzed addition of boronic acids to ynamides gave (*Z*)- $\alpha,\beta$ -disubstituted enamides.<sup>1224</sup>

### 15-24 Radical Addition to Activated Double Bonds

In a reaction similar to **15-21**, alkyl groups can be added to alkenes activated by such groups as  $COR'$ ,  $CO_2R'$ ,  $CN$ , and even  $Ph$ .<sup>1225</sup> This is a radical addition reaction.<sup>1226</sup> In the method illustrated above, the  $R^1$  group comes from an alkyl halide ( $R^1$  = primary, secondary, or tertiary alkyl;  $X = Br$  or  $I$ ) and the hydrogen from the tin hydride (H atom transfer agents). The reaction of *tert*-butyl bromide,  $Bu_3SnH$ , and AIBN (Sec. 14.A.i), for example, adds a *tert*-butyl group to a conjugated ester via 1,4-addition.<sup>1227</sup> The  $Bu_3SnH$  can also be generated *in situ*, from  $R_3SnX$  and  $NaBH_4$ . Like **15-23**, these additions have free-radical mechanisms.

A  $BEt_3$ -initiated reaction of conjugated amides with an alkyl iodide, in the presence of  $Bu_3SnH$  and  $O_2$ , leads to conjugate addition of the alkyl group.<sup>1228</sup> Enantioselective radical addition has been reported.<sup>1229</sup> Conjugate addition is possible using photolysis. The photoinduced 1,4-addition of indoles to enones proceeds when irradiated at 350 nm.<sup>1230</sup>

In the presence of a Rh catalyst,  $LiBPh(OMe)_3$  gave conjugate addition of the phenyl group to  $\alpha,\beta$ -unsaturated esters.<sup>1231</sup> The fact that these reactions are catalyzed by free-radical initiators and inhibited by galvinoxyl<sup>1232</sup> (a free-radical inhibitor) indicates that free-radical mechanisms are involved (**15-24**). The Ru-catalyzed reaction of enones with photogenerated  $\alpha$ -amino radicals in the presence of TFA gave the  $\gamma$ -amino ketone.<sup>1233</sup>

15-25 Radical Addition to Unactivated Double Bonds<sup>1234</sup>

Radical addition to alkenes is usually difficult, except when addition occurs to conjugated carbonyl compounds (**15-20**). An important exception involves radicals bearing a heteroatom  $\alpha$  to the carbon bearing the radical center. Such radicals are much more stable and can add to alkenes, usually with *anti-Markovnikov* orientation, as in the radical-induced addition of HBr to alkenes (**15-2**).<sup>1235</sup> The Fe-catalyzed conversion of alkenes to radicals allows their use in the construction of C–C bonds.<sup>1236</sup>

Other radicals can add to alkenes, and the rate constant for the addition of methyl radicals to alkenes has been studied,<sup>1237</sup> and the rate of radical additions to alkenes in general has also been studied.<sup>1238</sup> The kinetic and thermodynamic control of radical addition regiochemistry has also been studied.<sup>1239</sup> Alkynes are generally less reactive than alkenes in radical coupling reactions.<sup>1240</sup> Nonradical nucleophiles usually react faster with alkynes than with alkenes, however.<sup>1241</sup> Radicals generated from a photoorganocatalyst added to alkenes in the presence of *p*-anisaldehyde.<sup>1242</sup>

The Rh-catalyzed addition of alkyl radicals, oxidatively generated from organotrifluoroborates, to alkenes was reported under photoredox conditions.<sup>1243</sup> In the presence of a Co catalyst, THF reacted with alkenes via radical addition.<sup>1244</sup> The photoredox-catalyzed radical addition of  $\alpha$ -halo amides to alkenes has been reported.<sup>1245</sup> Alkenes reacted with the alkyl radical generated from hydrazines via treatment with potassium ferrocyanide trihydrate ( $\text{K}_4[\text{Fe}(\text{CN})_6] \cdot 3\text{H}_2\text{O}$ ), which promoted aryl radical addition in the presence of oxygen.<sup>1246</sup>

Examples of this type of reaction include the use of alcohol, ester,<sup>1247</sup> amino, and aldehyde-stabilized radicals.<sup>1248</sup> The alkyl group of alkyl iodides adds to alkenes with  $\text{BET}_3/\text{O}_2$  as the initiator and in the presence of a tetraalkylammonium hypophosphite.<sup>1249</sup>  $\alpha$ -Iodo amides add to alkenes using a water-soluble *azobis* initiator (Sec. 14.A.i) to give the iodo

ester, which cyclizes under the reaction conditions to give a lactone.<sup>1250</sup> 2-Fluoropyridyl derivatives of allylic alcohols react with xanthates in the presence of lauroyl peroxide to give alkenes.<sup>1251</sup>

The Cu-catalyzed radical addition alkenylation reaction of alkyl bromides has been reported.<sup>1252</sup> Arylalkynes reacted with alkyl diacyl peroxides, catalyzed by Ni and Ru compounds under photolytic conditions, to give the hydralkylation product, the alkene, with *Z* selectivity.<sup>1253</sup> Thiols were converted to thiyl radicals that added to alkenes to give the corresponding sulfide.<sup>1254</sup>

### 15-26 Radical Cyclization<sup>1255</sup>

$\omega$ -Haloalkenes generate radicals upon treatment with radical initiator reagents such as AIBN, or under photolysis conditions,<sup>1256</sup> and the radical carbon adds to the alkene to form cyclic compounds.<sup>1257</sup> This intramolecular addition of a radical to an alkene is called *radical cyclization*. In a typical example, haloalkene **35** reacts with the radical produced by AIBN to give radical **34**. The radical can add to the more-substituted carbon to give **36** via a 5-*exo-trig* reaction (see *Baldwin rules*, Sec. 6.E).<sup>1258</sup> If the radical adds to the less-substituted carbon, **37** is formed via a 6-*endo-trig* reaction.<sup>1259</sup> In both cases, the product is another radical, which must be converted to an unreactive product.

A 4-*exo-trig* radical cyclization has been studied,<sup>1260</sup> as has selectivity in a 7-*endo* versus 6-*exo* cyclization,<sup>1261</sup> and also an 8-*endo-trig* reaction.<sup>1262</sup>

The mechanism of this reaction has been discussed.<sup>1263</sup> Cyclization via 5-*endo-dig* transition states require reorientation of the radical orbital needed to reach the in-plane acetylene  $\pi$  orbital in the bond-forming step, with accompanying loss of conjugative stabilization and an increase in the activation energy. Therefore, many 5-*endo* cyclizations undergo H abstraction or equilibration with an isomeric radical.<sup>1264</sup> The issue of dissociation vs. cyclization has been discussed.<sup>1265</sup> Such cyclizations normally give predominant formation of five-membered rings, but large rings (11–20 members) have also been synthesized by this reaction.<sup>1266</sup>

This reaction is generally accomplished by adding a hydrogen-transfer agent<sup>1267</sup> such as tributyltin hydride ( $\text{Bu}_3\text{SnH}$ ), which reacts with **36** to form methylcyclopentane and  $\text{Bu}_3\text{Sn}\cdot$ , or reacts with **37** to give cyclohexane. The  $\text{Bu}_3\text{Sn}\cdot$  formed in both cases usually dimerizes to form  $\text{Bu}_3\text{SnSnBu}_3$ . Cyclization can compete with hydrogen transfer<sup>1268</sup> from  $\text{Bu}_3\text{SnH}$  to **34** to give the reduction product. Atom-transfer cyclization is possible with other atoms, such as halogen, catalyzed by  $\text{InCl}_3$ <sup>1269</sup> or  $\text{CuBr}$ .<sup>1270</sup> Tin-free radical cyclizations are known using  $\text{CpCr}(\text{CO}_3\text{H})$ .<sup>1271</sup>

In general, formation of the five-membered ring dominates the cyclization,<sup>1272</sup> but if addition to the  $\text{C}=\text{C}$  unit is relatively slow, the reduction product is formed preferentially. This preference may be caused by more favorable entropy factors leading to a five-membered ring, as well as by stereoelectronic factors, but other explanations have also been offered.<sup>1273</sup> In each case, the smaller ring (*exo-trig* addition) is preferred to the larger (*endo-trig* addition).<sup>1274</sup> However, when a radical that is unsaturated in the 5,6 position contains an alkyl group in the 5 position, formation of the six-membered ring is generally favored, presumably due to unfavorable steric interactions.<sup>1275</sup>

Radical rearrangements can diminish the yield of the desired product.<sup>1276</sup> Given a choice between a larger ring and a smaller ring, radical cyclization generally gives the smaller ring,<sup>1277</sup> but not always.<sup>1278</sup> Formation of other size rings is possible of course. In radical

cyclization to form large rings, 1,5- and 1,9-hydrogen atom abstractions can pose a problem<sup>1279</sup> The former abstraction proceeds via a six-center transition state. Ring expansion during radical cyclization is possible when the terminal intermediate is a cyclobutylcarbonyl radical.<sup>1280</sup>

In cases where hydrogen atom transfer gives primarily reduced products, one solution to promote cyclization generates the radical by photochemical cleavage of  $\text{Bu}_3\text{Sn}-\text{SnBu}_3$  and the resulting carbon radical can cyclize (see **15-42**).<sup>1281</sup> A halogen atom transfer agent, such as iodoethane, is used rather than a hydrogen transfer agent, so the final product is an alkyl iodide. Samarium(II) has been used to initiate 5-*exo-trig* ketyl-alkene coupling, and the mechanism of the reaction has been examined.<sup>1282</sup> Radical cyclization has also been terminated by Ir-catalyzed hydrogen atom transfer.<sup>1283</sup>

Radical cyclization reactions often proceed with high diastereoselectivity<sup>1284</sup> and high asymmetric induction when chiral precursors are used. Internal alkynes are good substrates for radical cyclization,<sup>1285</sup> but terminal alkynes tend to give mixtures of *exo/endo-dig* products (Sec. 6.E).<sup>1286</sup> Radical cyclization has been used to transfer asymmetry from transient atropisomers to form lactams.<sup>1287</sup>

Radical cyclization is compatible with the presence of other functional groups, and heterocyclic rings may be formed via radical cyclization.<sup>1288</sup> Aryl radicals participate in radical cyclization reactions when the aromatic ring has an alkene or alkyne substituent. *o*-Iodo aryl allyl ethers cyclize to benzofuran derivatives, for example, when treated with AIBN, aqueous  $\text{H}_3\text{PO}_2$ , and  $\text{NaHCO}_3$  in ethanol.<sup>1289</sup> Cyclizations of vinyl radicals<sup>1290</sup> and allenyl radicals<sup>1291</sup> are also well known. Cyclization of *N*-iodoethyl-5-vinyl-2-pyrrolidinone led to the corresponding bicyclic lactam,<sup>1292</sup> and there are other examples of radical cyclization with molecules containing a lactam unit<sup>1293</sup> or an amide unit.<sup>1294</sup>  $\beta$ -Lactams can be produced by radical cyclization, using  $\text{Mn}(\text{OAc})_3$ .<sup>1295</sup> Primary amides with a distal (*Z*)-iodoalkene moiety cyclized to a piperidone derivative via a 6-*exo* reaction of an amidyl radical when treated with lead tetraacetate and iodine under photolytic conditions.<sup>1296</sup>

Radical cyclization occurs with oximes to form the corresponding heterocyclic ring.<sup>1297</sup>  $\omega$ -Iodo acrylate esters cyclize to form lactones,<sup>1298</sup> and allylic acetoxy compounds of the type  $C=C-C-O_2C-CH_2I$  cyclize in a similar manner to give lactones.<sup>1299</sup> Iodolactonization (see **15-37**) occurs under standard radical cyclization conditions using allylic acetoxy compounds<sup>1300</sup> and  $HGaCl_2/BET_3$  has been used to initiate the radical process.<sup>1301</sup> Organoborane-mediated radical cyclizations are known (Sec. 14.A.i).<sup>1302</sup>

A mixture of a *Grignard reagent* and  $CoCl_2$  has been used to initiate aryl radical cyclizations.<sup>1303</sup> Transition metal catalysis is known.<sup>1304</sup> The influence of the halogen atom on radical cyclization has been studied.<sup>1305</sup>

Both phenylthio<sup>1306</sup> and phenylseleno groups<sup>1307</sup> can be used as “leaving groups” for radical cyclization, where S or Se atom transfer leads to formation of the radical. A seleno ester,  $R_2N-CH_2C(-O)SeMe$ , has also been used with  $(Me_3Si)_3SiH$  [tris(trimethylsilyl)silane], TTMSS) and AIBN to generate  $R_2NCH_2\cdot$ .<sup>1308</sup> *O*-Phosphonate esters have also served as the leaving group.<sup>1309</sup>

Radical cyclization of iodo aldehydes or ketones, at the carbon of the carbonyl, is effectively an acyl addition reaction (**16-22**, **16-23**). This cyclization is often reversible, and there are many fewer examples of addition to an alkene or alkyne. In one example, a  $\delta$ -iodo aldehyde was treated with  $BET_3/O_2$  to initiate formation of the radical, and, in the presence of  $Bu_3SnH$ , cyclization gave a cyclopentanol.<sup>1310</sup> The reaction of an aldehyde alkene with AIBN, 0.5  $PhSiH_3$  and 0.1  $Bu_3SnH$  generated a radical from the alkene, which cyclized at the aldehyde to give cyclopentanol derivatives.<sup>1311</sup> Acyl radicals can be generated and they cyclize in the usual manner.<sup>1312</sup>

Molecular orbital calculations have shown that acyl radicals, as well as silyl radicals, simultaneously use SOMO–LUMO (Singly Occupied Molecular Orbital) and LUMO–HOMO interactions in reactions with alkenes.<sup>1313</sup> A polyene-cyclization reaction generated four rings, initiating the sequence by treatment of a phenylseleno ester with  $Bu_3SnH/AIBN$  to form the acyl radical, which added to the first alkene unit,<sup>1314</sup> and the

of carbamates.<sup>1357</sup> Indoles add to nitro alkenes in the presence of an organocatalyst.<sup>1358</sup> Indoline derivatives have been reported via aza-Michael addition, prepared with good enantioselectivity.<sup>1359</sup> The conjugate addition of pyrroles to enones was catalyzed by *Cinchona* alkaloid-derived primary amines.<sup>1360</sup>

Lactams have been shown to add to conjugated esters in the presence of Si(OEt)<sub>4</sub> and CsF.<sup>1361</sup> Amines also add in a conjugate manner to alkynyl phosphonate esters, C≡C–PO(OEt)<sub>2</sub>, using a CuI catalyst.<sup>1362</sup> Trimethylsilyl azide with acetic acid reacts with conjugated ketones to give the β-azido ketone.<sup>1363</sup> Sodium azide adds to conjugated ketones in aqueous acetic acid and 20% PBU<sub>3</sub>.<sup>1364</sup> An interesting variation involves a double Michael addition of amido amines, amido alcohols, or amido thiols to conjugated alkynes, forming pyrrolidine, oxazolidine, or thiazolidine derivatives.<sup>1365</sup>

The nitrogen of carbamates adds to conjugated ketones with Pt,<sup>1366</sup> Pd,<sup>1367</sup> Cu,<sup>1368</sup> or a bis(triflamide) organocatalyst.<sup>1369</sup> The amine moiety of a carbamate adds to conjugated ketones with a polymer-supported acid catalyst,<sup>1370</sup> or with BF<sub>3</sub>•OEt<sub>2</sub>.<sup>1371</sup>

Phosphines react similarly to the reactions of amines under certain conditions. The steric and electronic effects that affect the phospho-Michael addition to activated internal alkenes have been discussed.<sup>1372</sup> Conjugate addition of R<sub>2</sub>PH and a Ni catalyst give conjugate addition to α,β-unsaturated nitriles.<sup>1373</sup> A Pd-catalyzed addition of diarylphosphines proceeds with good enantioselectivity to give chiral phosphines.<sup>1374</sup> The phospho-Michael reaction with nitroalkenes has been reported.<sup>1375</sup> An enantioselective phospho-Michael addition of diarylphosphines to β,γ-unsaturated-α-keto esters and amides has been reported.<sup>1376</sup> Asymmetric phospho-Michael reactions were catalyzed by bicyclic guanidines.<sup>1377</sup>

Alcohols add to conjugated ketones with a PMe<sub>3</sub> catalyst to give the β-alkoxy ketone<sup>1378</sup> in what is called an *oxy-Michael reaction*.<sup>1379</sup> An intramolecular variation is known that

promotes the conjugate addition of thiols.<sup>1404</sup> Addition to conjugated lactones is possible to produce  $\beta$ -aryl thiolated lactones.<sup>1405</sup>

The reaction of dialkyl diselenides with conjugated carbonyl compounds in the presence of  $\text{NaBH}_4$  gave the  $\beta$ -selenide product.<sup>1406</sup>

### 15-28 Acylation of Activated Double Bonds and of Triple Bonds

Under some conditions, acid derivatives add directly to activated double bonds to give the hydroacylation product. Acetic anhydride, Mg metal, and  $\text{Me}_3\text{SiCl}$  react with conjugated esters to give a  $\gamma$ -keto ester.<sup>1407</sup> Similar reaction with vinyl phosphonate esters leads to a  $\gamma$ -keto phosphonate ester.<sup>1408</sup> Thioesters undergo conjugate addition to  $\alpha,\beta$ -unsaturated ketones in the presence of  $\text{SmI}_2$ .<sup>1409</sup> Under microwave irradiation, aldehydes add to conjugated ketones using  $\text{DBU}/\text{Al}_2\text{O}_3$  and a thiazolium salt.<sup>1410</sup> The conjugate addition of acyl zirconium complexes in the presence of  $\text{BF}_3 \cdot \text{OEt}_2$  is catalyzed by palladium acetate.<sup>1411</sup>

An acyl group can be introduced into the 4 position of an  $\alpha,\beta$ -unsaturated ketone by treatment with an organolithium compound and nickel carbonyl<sup>1412</sup> to give a 1,4-diketone. The R group may be aryl or primary alkyl. The reaction can also be applied to alkynes (which need not be activated), in which case 2 molar equivalents add and the product is also a 1,4-diketone, e.g.,  $\text{R}'\text{C}\equiv\text{CH} \rightarrow \text{RCOCHR}'\text{CH}_2\text{COR}$ .<sup>1413</sup> In a different procedure,  $\alpha,\beta$ -unsaturated ketones and aldehydes are acylated by treatment at  $-110^\circ\text{C}$  with  $\text{R}_2(\text{CN})\text{CuLi}_2$  and CO. This method is successful for R = primary, secondary, and tertiary alkyl.<sup>1414</sup> For secondary and tertiary groups,  $\text{R}(\text{CN})\text{CuLi}$  (which does not waste an R group) can be used instead.<sup>1415</sup>

The hydroacylation of cyclic ketene silyl acetals with acyl fluorides, catalyzed by a functionalized thiourea and 4-pyrrolidinopyridine, gave the 2-acyl butyrolactone.<sup>1416</sup> The hydroacylation of cyclopropane was catalyzed by *N*-heterocyclic carbenes.<sup>1417</sup> The Rh-catalyzed hydroformylation of alkenes has been reported.<sup>1418</sup> Aldehydes reacted with 1,3-dienes with a Co catalyst, and aryl aldehydes gave primarily the 1,4-alkenyl ketone

(the  $\beta,\gamma$ -derivative), whereas aliphatic aldehydes gave primarily the 1,2-alkenyl ketone (the  $\gamma,\delta$ -derivative).<sup>1419</sup> The Pd-catalyzed hydroacylation of allenes uses acid chlorides and hydrosilanes.<sup>1420</sup>

The reaction of acyl chlorides with alkynes, with an Ir catalyst, gave the  $\beta$ -chloro- $\alpha,\beta$ -unsaturated ketone.<sup>1421</sup> The hydroacylation of alkynes gave the conjugated carbonyl, and choice of the Ru catalyst allowed switching the regioselectivity.<sup>1422</sup> Allenes reacted with acyl chlorides in the presence of  $\text{HSi}(\text{O}i\text{-Pr})_3$  and with a Pd catalyst to give conjugated ketones.<sup>1423</sup>

The reaction of an aldehyde and cyanide ion (see **16-51**) in a polar aprotic solvent (e.g., DMF or DMSO) leads to a cyanohydrin, which generates a diketone via loss of HCN.<sup>1424</sup> This method has been applied to  $\alpha,\beta$ -unsaturated ketones, esters, and nitriles to give the corresponding 1,4-diketones,  $\gamma$ -keto esters, and  $\gamma$ -keto nitriles, respectively (see also, **16-54**).

OS VI, 866; VIII, 620.

### 15-29 Addition of Alcohols, Amines, Carboxylic Esters, Aldehydes, and so on

Formates, primary and secondary alcohols, amines, ethers, alkyl halides, compounds of the type  $Z\text{--CH}_2\text{--Z}'$ , and a few other compounds add to double bonds in the presence of free-radical initiators.<sup>1425</sup> Alcohols, ethers, amines, and alkyl halides add via the OH-bearing carbon. Compounds with an active hydrogen such as  $Z\text{CH}_2\text{Z}'$  react with alkenes.<sup>1426</sup> Similar additions have been successfully carried out with carboxylic acids, anhydrides,<sup>1427</sup> acyl halides, carboxylic esters, nitriles, and other types of compounds.<sup>1428</sup>

Similar reactions have been carried out on acetylene.<sup>1429</sup> Aldehydes add to alkynes in the presence of a Rh catalyst to give conjugated ketones.<sup>1430</sup> In a cyclic version of the addition of aldehydes, penten-4-al was converted to cyclopentanone with a Rh complex catalyst.<sup>1431</sup> An intramolecular acyl addition to an alkyne was reported using silyl ketones, acetic acid, and a Rh catalyst.<sup>1432</sup> Formamides add to alkynes in the presence of a Pd catalyst to form conjugated amides.<sup>1433</sup>

## 15-30 Addition of Aldehydes

In the presence of metal catalysts such as Rh<sup>1434</sup> or Yb<sup>1435</sup>, aldehydes can add directly to alkenes to form ketones. Additives play an important role in such reactions.<sup>1436</sup> The reaction of  $\omega$ -alkenyl aldehydes with a Rh catalyst leads to cyclic ketones,<sup>1437</sup> with high enantioselectivity if chiral ligands are employed. A carbene organocatalyst was used for an enantioselective intramolecular reaction.<sup>1438</sup>  $\beta,\gamma$ -Unsaturated ketones are prepared by the Rh-catalyzed addition of aldehydes to dienes.<sup>1439</sup> The addition of aldehydes to activated double bonds, mediated by a catalytic amount of thiazolium salt in the presence of a weak base, is called the *Stetter reaction*.<sup>1440</sup> An internal addition of an alkynyl aldehyde, catalyzed by a Rh complex, led to a cyclopentenone derivative.<sup>1441</sup> These reactions are not successful when the alkene contains electron-withdrawing groups, such as halo or carbonyl groups. A free-radical initiator is required,<sup>1442</sup> usually peroxides or UV light. The aldehyde is first converted to an acyl radical, which adds to an alkene to give a new radical. This radical deprotonates another molecule of the aldehyde in a chain-carrying step to give the acylated product and another acyl radical. In the presence of BF<sub>3</sub> and a Ag salt, aldehydes add to alkynes to give the corresponding conjugated ketone,<sup>1443</sup> but polymers are often side products. Photochemical addition of aldehydes to conjugated C=C units can be efficient when a triplet sensitizer (Sec. 7.A.vi, category 5) such as benzophenone is used.<sup>1444</sup>

*N*-Heterocyclic carbene-catalyzed C–C bond cleavage of carbohydrates via a retro-benzoin-type reaction generated the acyl anion intermediates that were formaldehyde equivalents for a *Stetter reaction* with conjugated ketones, and the product was a  $\beta$ -formyl ketone.<sup>1445</sup> The *Stetter reaction* is the 1,4-addition of a nucleophile.<sup>1446</sup> Other organocatalysts have been used for an intermolecular and enantioselective *Stetter reaction*.<sup>1447</sup> Apart

from the formation of keto esters,<sup>1448</sup> the Stetter reaction has been applied to conjugated sulfones<sup>1449</sup> and nitrostyrenes.<sup>1450</sup>

### 15-31 Hydrocarboxylation

The acid-catalyzed hydrocarboxylation of alkenes (the *Koch reaction*) can be performed in a number of ways.<sup>1451</sup> In one method, the alkene is treated with carbon monoxide and water at 100–350 °C and 500–1000 atm pressure with a mineral acid catalyst. However, the reaction can also be performed under milder conditions. If the alkene is first treated with CO and catalyst and then water added, the reaction can be accomplished at 0–50 °C and 1–100 atm. If formic acid is used as the source of both the CO and the water, the reaction can be carried out at room temperature and atmospheric pressure.<sup>1452</sup> The formic acid procedure is called the *Koch-Haaf reaction* (the Koch-Haaf reaction can also be applied to alcohols, see **10-78**). Nearly all alkenes can be hydrocarboxylated by one of these procedures. However, conjugated dienes are polymerized under these conditions. Hydrocarboxylation can also be accomplished under mild conditions (160 °C and 50 atm) by the use of Ni(CO)<sub>4</sub> as catalyst. Acid catalysts are used along with the Ni(CO)<sub>4</sub>, but basic catalysts can also be employed.<sup>1453</sup> The Ni(CO)<sub>4</sub>-catalyzed oxidative carbonylation with CO and water as a nucleophile is often called *Reppe carbonylation*.<sup>1454</sup> The toxic nature of Ni(CO)<sub>4</sub> has led to development of other catalysts.<sup>1455</sup> Indeed, variations in the reaction procedure include the use of Pd,<sup>1456</sup> Pt,<sup>1457</sup> and Rh<sup>1458</sup> catalysts. This reaction carboxylates alkenes, alkynes, and dienes and is tolerant of a wide variety of functional groups. When the additive is alcohol or acid, the products are saturated or unsaturated acids, esters, or anhydrides (see **15-32**). The transition metal-catalyzed carbonylation has been done enantioselectively, with moderate to high optical yields, by the use of an optically active Pd complex catalyst.<sup>1459</sup>

Alkenes also react with  $\text{Fe}(\text{CO})_5$  and CO to give carboxylic acids.<sup>1460</sup> Electrochemical carboxylation procedures have been developed, including the conversion of alkenes to 1,4-butanedicarboxylic acids.<sup>1461</sup> A reductive carboxylation of alkenes with CO and cesium carbonate has been reported.<sup>1462</sup>

When applied to triple bonds, hydrocarboxylation gives  $\alpha,\beta$ -unsaturated acids under very mild conditions. Triple bonds give unsaturated acids and saturated dicarboxylic acids when treated with carbon dioxide and an electrically reduced nickel complex catalyst.<sup>1463</sup> A related reaction with CO and Pd catalysts in the presence of  $\text{SnCl}_2$  leads to conjugated acid derivatives.<sup>1464</sup> Terminal alkynes react with  $\text{CO}_2$  and  $\text{Ni}(\text{cod})_2$ , and subsequent treatment with DBU gives the  $\alpha,\beta$ -unsaturated carboxylic acid.<sup>1465</sup>

When acid catalysts are employed, in the absence of nickel carbonyl, the mechanism<sup>1466</sup> involves (i) initial attack on a proton to give a carbocation, followed by (ii) attack by carbon monoxide on the resulting carbocation on to give an acyl cation, and (iii) subsequent reaction with water gives the product, the carboxylic acid. *Markovnikov's rule* is followed, and carbon skeleton rearrangements and double bond isomerizations (prior to attack by CO) are frequent.

For the transition metal-catalyzed reactions, the nickel carbonyl reaction has been well studied and the addition is *syn* for both alkenes and alkynes.<sup>1467</sup> The accepted mechanism<sup>1467</sup> involves formation of  $\text{Ni}(\text{CO})_3$  from  $\text{Ni}(\text{CO})_4$ , which reacts with the alkene to give a bridged Ni complex. Subsequent treatment with  $\text{H}^+$  opens the three-membered ring and a rearrangement gives the acyl Ni complex, which leads to the carboxylic acid.

Hydrocarboxylation was reported via the Fe-catalyzed reaction of aryl alkenes with  $\text{CO}_2$  and methylmagnesium bromide to give  $\alpha$ -aryl carboxylic acids.<sup>1468</sup> Vinyl triflates or aryl triflates were converted to the corresponding carboxylic acids via reaction with  $\text{CO}_2$ , mediated by Mn, catalyzed by a Co or a Ni catalyst.<sup>1469</sup> The Co-catalyzed allylic carboxylation with  $\text{CO}_2$  was reported.<sup>1470</sup> The reaction of  $\text{CO}_2$  with 1,3-dienes via Pd-catalyzed

hydrocarboxylation, mediated by  $\text{AlEt}_n(\text{OEt})_{3-n}$ , gave the  $\beta,\gamma$ -unsaturated carboxylic acid.<sup>1471</sup> The hydrocarboxylation of styrenes with  $\text{CO}_2$  was accomplished using continuous flow techniques (Sec. 7.D).<sup>1472</sup>

The alkoxy carbonylation of 1-alkenes used a Lewis acid and a Pd catalyst to give the carboxylic ester.<sup>1473</sup> The Ni-catalyzed double carboxylation of alkynes with  $\text{CO}_2$  and 3 equivalents of Zn powder and 2 equivalents of  $\text{MgBr}_2$  gave the maleic anhydride derivative.<sup>1474</sup> The Pd-catalyzed hydrocarboxylation of alkenes with phenyl formate and formic acid gave the carboxylic acid.<sup>1475</sup>

### 15-32 Carbonylation, Alkoxy carbonylation, and Aminocarbonylation Of Double And Triple Bonds

In the presence of certain metal catalysts, alkenes and alkynes can be carbonylated or converted to give an amide or an ester.<sup>1476</sup> There are several variations.<sup>1477</sup> The reaction of an alkyl iodide and a conjugated ester with CO,  $(\text{Me}_3\text{Si})_3\text{SiH}$ , and AIBN in supercritical  $\text{CO}_2$  (Sec. 9.D.ii) gave a  $\gamma$ -keto ester.<sup>1478</sup> Conjugated dienes react with thiophenol, CO, and  $\text{Pd}(\text{OAc})_2$  to give the  $\beta,\gamma$ -unsaturated thioester.<sup>1479</sup> Alkynes react with thiophenol and CO with a Pd<sup>1480</sup> or Pt<sup>1481</sup> catalyst to give a conjugated thioester. Terminal alkynes react with CO and methanol, using a combination of a Pd and a Cu catalyst, to give a conjugated diester,  $\text{MeO}_2\text{C}-\text{C}=\text{C}-\text{CO}_2\text{Me}$ .<sup>1482</sup> A similar reaction with alkenes using a combination of a Pd and a Mo catalyst led to a saturated diester,  $\text{MeO}_2\text{C}-\text{C}-\text{C}-\text{CO}_2\text{Me}$ .<sup>1483</sup> Note that alkenes are converted to primarily the *anti-Markovnikov* ester upon treatment with aryl-methyl formate esters ( $\text{ArCH}_2\text{OCHO}$ ) and a Ru catalyst.<sup>1484</sup>

A bicyclic ketone was generated when 1,2-diphenylethyne was heated with CO, methanol, and a dirhodium catalyst.<sup>1485</sup> Another variation reacted a conjugated allene alkene with 5 atmospheres of CO and a Rh catalyst to give a bicyclic ketone.<sup>1486</sup> An intermolecular version of this reaction is known using a Co catalyst, giving a cyclopentenone<sup>1487</sup> in a reaction related to the *Pauson-Khand reaction* (see below). The reaction of a conjugated diene having a distal alkene unit and CO with a Rh catalyst led to a bicyclic conjugated ketone.<sup>1488</sup> Alkynes were converted to cyclobutenones using  $\text{Fe}_3(\text{CO})_{12}$  to form an initial complex, followed by reaction with copper(II) chloride.<sup>1489</sup> Bicyclic fused cyclopentenones were prepared from *Baylis-Hillman* acetates (**16-27**) of acetylenic aldehydes.<sup>1490</sup> Aliphatic alkynes are also substrates.<sup>1491</sup> The reaction of allylic alcohols used a Rh catalyst with CO/ $\text{H}_2$ , followed by  $\text{NaClO}_2$ ,  $\text{NaH}_2\text{PO}_4$ , and 2-methylbut-2-ene to give the carboxylic acid.<sup>1492</sup> The reaction of alkenes with aniline derivatives, in the presence of Pd catalyst and CO/ $\text{H}_2$ , gave hydroaminocarbonylation and the corresponding amide.<sup>1493</sup> Heating alkenes with benzylamine•HCl, CO, and a Pd catalyst gave the amide.<sup>1494</sup>

The reactions of dienes, diynes, or enynes with transition metals<sup>1495</sup> (usually Co)<sup>1496</sup> form organometallic coordination complexes. Rhodium,<sup>1497</sup> Ti,<sup>1498</sup> Mo,<sup>1499</sup> and W<sup>1500</sup> complexes have been used for this reaction. In the presence of CO, the metal complexes derived primarily from enynes (alkene alkynes) generate cyclopentenone derivatives in what is known as the *Pauson-Khand reaction*.<sup>1501</sup> This reaction involves formation of a hexacarbonyldicobalt alkyne complex and subsequent decomposition of the complex in the presence of an alkene.<sup>1502</sup> A typical example is the preparation of **38**.<sup>1503</sup> An yne diene can also be used for the Pauson-Khand reaction.<sup>1504</sup> A pseudo-Pauson-Khand reaction has been reported that gave cyclopentenones.<sup>1505</sup>

using this reaction.<sup>1528</sup> Heating an alkenyl aldehyde with a Rh catalyst gave cyclopentanone derivatives.<sup>1529</sup>

The accepted mechanism was proposed by Magnus,<sup>1530</sup> and is shown for the formation of **39**.<sup>1531</sup> This is supported by Krafft's work.<sup>1532</sup> Mechanistic work continues.<sup>1533</sup> It has been shown that CO is lost from the Pauson-Khand complex prior to alkene coordination and insertion.<sup>1534</sup> Calculations led to the conclusion that the LUMO of the coordinated alkene plays a crucial role in alkene reactivity by determining the degree of back donation in the complex.<sup>1535</sup>

The Pd-catalyzed alkoxy carbonylation of allenes with aliphatic alcohols and CO gave  $\alpha,\beta$ - and  $\beta,\gamma$ -unsaturated esters.<sup>1536</sup> Alkenes reacted with CO<sub>2</sub> with a Ti catalyst; alkyl alkenes gave the terminal carboxylic acid whereas aryl alkenes gave the benzylic carboxylic acid.<sup>1537</sup> The hydroesterification reaction of alkenes was reported by heating sodium formate and alcohols with a Ru catalyst and a catalytic amount of 2-pyridinemethanol to 170 °C.<sup>1538</sup> The Pd-catalyzed, photolytic reaction of alkenes, CO, alcohols, and alkyl iodides gave the corresponding ester.<sup>1539</sup> The reaction of alkenyl amines with benzylic formates and a Ru catalyst gave the corresponding  $\delta$ -amino ester.<sup>1540</sup>

The reaction of cyclic alkenes with an *O*-carbamate unit gave the oxazolidone compound upon photolysis with an Ir catalyst and a phosphate base.<sup>1541</sup> The intramolecular oxidative carbonylation of enamides with CO used a Pd and photoredox catalysis, with oxygen as the oxidant, to give 1,3-oxazin-6-ones.<sup>1542</sup> The reaction of an alkene with an alcohol, 20% of

PTSA, and a dipalladium catalyst gave the corresponding ester, with high regioselectivity and good enantioselectivity.<sup>1543</sup>

The reaction of terminal alkynes with CO<sub>2</sub>, AgI, and Cs<sub>2</sub>CO<sub>3</sub> gave the propiolic acid derivative.<sup>1544</sup> The reaction of diynes with CO<sub>2</sub>, 3 equivalents of Et<sub>2</sub>Zn, and a Ni catalyst gave 2,4-alkadienoic acids,<sup>1545</sup> and a similar reaction with alkynes gave the conjugated carboxylic acid.<sup>1546</sup> The Cu-catalyzed hydrocarboxylation of alkynes using carbon dioxide gave conjugated carboxylic acids in the presence of a hydrosilane.<sup>1547</sup>

Other carbonylation methods are available. Carbonylation occurs with conjugated ketones to give 1,4-diketones, using phenylboronic acid (see **13-11**), CO, and a Rh catalyst.<sup>1548</sup> A noncarbonylation route treated a conjugated diene with an excess of *tert*-butyllithium, and quenching with carbon dioxide led to a cyclopentadienone.<sup>1549</sup> When quenched with CO rather than CO<sub>2</sub>, a nonconjugated cyclopentenone was formed.<sup>1550</sup> It is noted that a carbonylation reaction with CO, a diyne, and an Ir catalyst<sup>1551</sup> or a Co catalyst<sup>1552</sup> provided similar molecules.

With any method, if the alkene contains a functional group such as OH, NH<sub>2</sub>, or CONH<sub>2</sub>, the corresponding lactone (**16-62**),<sup>1553</sup> lactam (**16-73**), or cyclic imide may be the product.<sup>1554</sup> Titanium,<sup>1555</sup> Pd,<sup>1556</sup> Ru,<sup>1557</sup> and Rh<sup>1558</sup> catalysts have been used to generate lactones. Larger-ring conjugated lactones can also be formed by this route using the appropriate allenic alcohol.<sup>1559</sup> Propargylic alcohols lead to β-lactones<sup>1560</sup> or to butenolides with CO/H<sub>2</sub>O and a Rh catalyst.<sup>1561</sup> Conjugated imines are converted to similar products with CO, ethylene, and a Ru catalyst.<sup>1562</sup> Amines add to allenes, in the presence of CO and a Pd catalyst, to form conjugated amides.<sup>1563</sup>

Alkenes can be hydroformylated<sup>1564</sup> by treatment with CO and hydrogen over a catalyst. The catalyst is usually a Co carbonyl or a Rh complex,<sup>1565</sup> but other transition metal compounds have also been used,<sup>1566</sup> including Ir<sup>1567</sup> and Os.<sup>1568</sup> Cobalt catalysts<sup>1569</sup> are less active than the Rh type, and catalysts of other metals are generally less active.<sup>1570</sup> Commercially, this is called the *oxo process*, but it can be carried out in the laboratory in an ordinary hydrogenation apparatus. The order of reactivity is straight-chain terminal alkenes > straight-chain internal alkenes > branched-chain alkenes. With terminal alkenes, for example, the aldehyde unit is formed on both the primary and secondary carbon, but proper choice of catalyst and additive leads to selectivity for the secondary product<sup>1571</sup> or primary product.<sup>1572</sup> Alkylidene cyclopropane derivatives undergo hydroformylation to give aldehydes with a quaternary center.<sup>1573</sup> A retro-hydroformylation reaction has been reported.<sup>1574</sup> Hydroformylation has been done using flow conditions (Sec. 7.D).<sup>1575</sup>

Good yields for hydroformylation have been reported using Rh catalysts in the presence of certain other additives.<sup>1576</sup> Among the side reactions are the *aldol reaction* (**16-34**), acetal formation, the *Tishchenko reaction* (**19-86**), and polymerization. Conjugated dienes give dialdehydes when rhodium catalysts are used<sup>1577</sup> but saturated monoaldehydes with cobalt carbonyls (the second double bond is reduced). Both 1,4- and 1,5-dienes may give cyclic ketones.<sup>1578</sup>

The Pd-catalyzed hydroformylation of alkenes used formic acid.<sup>1579</sup> Hydroformylation using a Rh catalyst has been reported in supercritical CO<sub>2</sub>.<sup>1580</sup> Formaldehyde has been used for hydroformylation, using a Rh catalyst. The Rh-catalyzed hydroformylation of 1,3-dienes with chiral ligands gave  $\beta,\gamma$ -unsaturated aldehydes.<sup>1581</sup> The hydroformylation of styrenes with diethoxyacetic acid as the formylation reagent and a photocatalytic dye to give

the aldehyde was shown to follow a radical pathway.<sup>1582</sup> Hydroformylation of heterocyclic alkenes is known, using a Rh catalyst.<sup>1583</sup>

Hydroformylation of triple bonds proceeds very slowly,<sup>1584</sup> but the Rh-<sup>1585</sup> or Pd-catalyzed<sup>1586</sup> reaction gave conjugated aldehydes. In the presence of a Rh catalyst, the triple bond of a conjugated enyne is formylated.<sup>1587</sup> The Rh-catalyzed reaction can be regioselective.<sup>1588</sup> Many functional groups, such as OH, CHO, CO<sub>2</sub>R,<sup>1589</sup> and CN, can be present in the molecule, although halogens usually interfere. Stereoselective *syn* addition has been reported,<sup>1590</sup> and also stereoselective *anti* addition.<sup>1591</sup>

Asymmetric hydroformylation of alkenes has been accomplished with a chiral catalyst.<sup>1592</sup> The choice of ligand is important in such reactions.<sup>1593</sup> Cyclization to prolinal derivatives has been reported with allylic amines.<sup>1594</sup>

When dicobalt octacarbonyl, [Co(CO)<sub>4</sub>]<sub>2</sub>, is the catalyst, the species that actually adds to the double bond is tricarbonylhydrocobalt HCo(CO)<sub>3</sub>.<sup>1595</sup> Carbonylation RCo(CO)<sub>3</sub> + CO → RCo(CO)<sub>4</sub> takes place, followed by a rearrangement and a reduction of the C–Co bond. The reducing agent in the reduction step is tetracarbonylhydrocobalt HCo(CO)<sub>4</sub>,<sup>1596</sup> or, under some conditions, H<sub>2</sub>.<sup>1597</sup> When HCo(CO)<sub>4</sub> was the agent used to hydroformylate styrene, the observation of CIDNP (Sec. 5.C.i) indicated that the mechanism is different, and involves free radicals.<sup>1598</sup> Key intermediates have been detected in the Co-catalyzed hydroformylation reaction.<sup>1599</sup> Alcohols can be obtained by allowing the reduction to continue after all the carbon monoxide is used up.

## 15-34 Hydrocyanation of Alkenes or Alkynes

Ordinary alkenes do not react with HCN, but polyhalo alkenes and alkenes of the form  $\text{C}=\text{C}-\text{Z}$  add HCN to give nitriles, where Z is an electron-withdrawing group.<sup>1600</sup> The reaction is therefore a nucleophilic addition and is base catalyzed. Hydrogen cyanide can be added to ordinary alkenes in the presence of dicobalt octacarbonyl<sup>1601</sup> or certain other transition metal compounds.<sup>1602</sup> When Z is COR or, more especially, CHO, 1,2-addition (**16-52**) is an important competing reaction and may be the only reaction. An acid-catalyzed hydrocyanation is also known.<sup>1603</sup> Triple bonds react very well when catalyzed by an aqueous solution of CuCl, NH<sub>4</sub>Cl, and HCl or by Ni or Pd compounds.<sup>1604</sup> The HCN can be generated *in situ* from acetone cyanohydrin (**16-51**), avoiding the use of the poisonous HCN.<sup>1605</sup> Alkenes react with HCN via this procedure to give a nitrile in the presence of a Ni complex.<sup>1606</sup>

$\alpha,\beta$ -Unsaturated sulfones undergo conjugate addition of a cyano group using Et<sub>2</sub>AlCN.<sup>1607</sup> Trimethylsilyl enol ethers reacted with 3 equivalents of TMS-CN in the presence of PhIO and BF<sub>3</sub>·OEt<sub>2</sub> to give the  $\alpha$ -cyano ketone.<sup>1608</sup> Conjugated *N*-acylpyrroles reacted with HCN in the presence of ruthenium catalyst to give the  $\beta$ -cyano ketone.<sup>1609</sup>

The reaction of alkenes with cyanohydrins gave the corresponding nitrile using a Ni catalyst and 10–30% Zn.<sup>1610</sup> Conjugate addition of the cyano group gave the  $\beta$ -cyano ketone, using cyanohydrins and a phase-transfer catalyst.<sup>1611</sup> Magnesium complexes have been used to catalyze the conjugate cyanation of conjugate amides and ketones.<sup>1612</sup>

Alkylaluminum cyanides (Et<sub>2</sub>AlCN), or mixtures of HCN and trialkylalanes R<sub>3</sub>Al, are especially good reagents for conjugate addition of HCN<sup>1613</sup> to  $\alpha,\beta$ -unsaturated ketones and  $\alpha,\beta$ -unsaturated acyl halides. *tert*-Butyl isocyanide and TiCl<sub>4</sub> have been used to add HCN to  $\text{C}=\text{C}-\text{Z}$  alkenes.<sup>1614</sup> Pretreatment with NaI/Me<sub>3</sub>SiCl followed by CuCN converts alkynes

### 15.C.iii. Reactions in Which Hydrogen Adds to Neither Side

Some of these reactions are *cycloadditions* (reactions 15-46, 15-58, 15-50, and 15-53 to 15-62). In such cases, addition to the multiple bond closes a ring.

#### A. Halogen on One or Both Sides

##### 15-35 Halogenation of Double and Triple Bonds (Addition of Halogen, Halogen)

Most double bonds are easily halogenated<sup>1617</sup> with bromine, chlorine, or inter-halogen compounds.<sup>1618</sup> Substitution can compete with addition in some cases.<sup>1619</sup> Iodination has also been accomplished, but the reaction is slower.<sup>1620</sup> Under free-radical conditions, iodination proceeds more easily.<sup>1621</sup> However, *vic*-diiodides are generally unstable and tend to revert to iodine and the alkene.

The mechanism is usually electrophilic and involves formation of an halonium ion (**40**),<sup>1622</sup> followed by nucleophilic ring opening to give the *vic*-dihalide. When an alkene attacks (donates two electrons to)  $\text{Br}^+$  (or  $\text{Br}_2$ ) to give **40**, the addition is *anti*, so the reaction is diastereospecific.

Nucleophilic attack occurs with selectivity for the less-substituted carbon. Similar results are found when the reaction is carried out in the presence of water<sup>1623</sup> (15-36) or in the presence of other nucleophiles.<sup>1624</sup> *Ab initio* molecular orbital studies show that **40** is more

stable than its open isomer **1** ( $Y = \text{Br}$ ),<sup>1625</sup> and there is evidence that the formation of **40** is reversible.<sup>1626</sup> It is noted that theoretical and experimental studies have shown that in nonpolar solvents the bromination of acetylene via a covalent tribromide adduct is strongly favored over the textbook mechanism via a bridged bromonium ion.

Where electrophilic addition involves bridged-ion intermediates, those arising from triple bonds (**41**) are more strained than the corresponding **42**. This fact may be a reason why electrophilic addition by such electrophiles as Br, I, SR, and so on, is slower for triple bonds than for double bonds.<sup>1627</sup> As might be expected, triple bonds connected to a Z group ( $\text{C}=\text{C}-\text{Z}$ ) undergo nucleophilic addition especially well.<sup>73</sup> Markovnikov's rule is also followed where bromonium ions or other three-membered rings intermediates are formed in protic solvents such as methanol.<sup>1628</sup>

A number of examples have been found where addition of bromine is not stereospecifically *anti*. For example, the addition of  $\text{Br}_2$  to *cis*- and *trans*-1-phenylpropenes in  $\text{CCl}_4$  was not stereospecific.<sup>1629</sup> Furthermore, the stereospecificity of bromine addition to stilbene depends on the dielectric constant of the solvent.<sup>1630</sup> Likewise in the case of triple bonds, stereoselective *anti* addition was found in bromination of hex-3-yne, but both *cis* and *trans* products were obtained in bromination of phenylacetylene.<sup>1631</sup> These results indicate that a bromonium ion is not formed when the open cation can be stabilized in other ways.<sup>1632</sup> Previously seen cases (Sec. 10.C.i, category 4) showed that cations require more stabilization from outside sources as they become intrinsically less stable themselves.<sup>1633</sup>

When the  $\pi$  bond of an alkene attacks  $\text{Cl}^+$ ,<sup>1634</sup>  $\text{I}^+$ ,<sup>1635</sup> or  $\text{RS}^+$ ,<sup>1636</sup> the result is similar to that when the electrophile is  $\text{Br}^+$ ; there is a spectrum of mechanisms between cyclic intermediates and open cations. As might be expected from the discussion in Sec. 10.C, iodonium ions compete with open carbocations more effectively than bromonium ions, while chloronium ions compete less effectively. There is kinetic and spectral evidence that at least in some cases, the electrophile forms a  $\pi$  complex with the alkene before a covalent bond

is formed.<sup>1637</sup> There is evidence for  $\beta$ -chloro- and  $\beta$ -bromocarbenium ions in some reactions.<sup>1638</sup> Iodine monochloride cyclization reactions are known.<sup>1639</sup>

Under ordinary conditions, fluorine itself is too reactive to give simple addition and mixtures are obtained.<sup>1640</sup> However,  $F_2$  has been successfully added to certain double bonds in an inert solvent at low temperatures ( $-78^\circ C$ ), usually by diluting the  $F_2$  gas with Ar or  $N_2$ .<sup>1641</sup> The Au-catalyzed reaction of  $Et_3N/HF$  with alkynes gives vinyl fluorides.<sup>1642</sup>

The reaction with bromine is very rapid and is easily carried out at room temperature,<sup>1643</sup> although the reaction is reversible under some conditions.<sup>1644</sup> In the case of bromine, an alkene $\cdot Br_2$  complex has been detected in at least one case.<sup>1645</sup> Bromine is often used as a qualitative or quantitative test for unsaturation<sup>1646</sup> because the vast majority of double bonds can be successfully brominated. Bromination has been carried out in an ionic liquid.<sup>1647</sup> Alkenes were converted to vicinal dichlorides by reaction with  $NH_4Cl$  and Oxone<sup>®</sup>.<sup>1648</sup> The dichlorination of alkenes was reported using NCS and  $PPh_3$ .<sup>1649</sup>

Several reagents other than chlorine gas add  $Cl_2$  to double bonds, among them  $Me_3SiCl/MnO_2$ ,<sup>1650</sup>  $BnNEt_3MnO_4/Me_3SiCl$ ,<sup>1651</sup> and  $KMnO_4$ -oxalyl chloride.<sup>1652</sup> A convenient reagent for the addition of  $Br_2$  to a double bond on a small scale is the commercially available pyridinium bromide perbromide  $C_5H_5NH^+Br_3^-$ .<sup>1653</sup> Potassium bromide with ceric ammonium nitrate, in water/dichloromethane, gives the dibromide.<sup>1654</sup> A combination of  $KBr$  and Selectfluor also gives the dibromide.<sup>1655</sup> A combination of  $CuBr_2$  in aq. THF and a chiral ligand led to the dibromide with good enantioselectivity.<sup>1656</sup>

Catalytic, enantioselective halogenation of alkenes has been reviewed.<sup>1657</sup> Allylic alcohols are dichlorinated with good enantioselectivity using aryl iododichlorides, catalyzed by dimeric *Cinchona* alkaloid derivatives.<sup>1658</sup> The enantioselective dibromination of allylic alcohols was reported using dibromomalonate as the bromine source and a Ti catalyst.<sup>1659</sup>

Alkenes reacted with Selectfluor and  $\text{Pyr}\cdot(\text{HF})_x$  in the presence of  $\text{ArIF}_2$  to give the vicinal difluoride.<sup>1660</sup>

Mixed halogenations have also been achieved, and the order of activity for some of the reagents is  $\text{BrCl} > \text{ICl}^{1661} > \text{Br}_2 > \text{IBr} > \text{I}_2$ .<sup>1662</sup> Mixtures of  $\text{Br}_2$  and  $\text{Cl}_2$  have been used to give bromochlorination,<sup>1663</sup> as has tetrabutylammonium dichlorobromate,  $\text{Bu}_4\text{NBrCl}_2$ .<sup>1664</sup> Iodochlorination has been achieved with  $\text{KICl}_2$ ,<sup>1665</sup>  $\text{CuCl}_2$ , and one of  $\text{I}_2$ ,  $\text{HI}$ , or  $\text{CdI}_2$ ; iodofluorination<sup>1666</sup> has been achieved with mixtures of  $\text{AgF}$  and  $\text{I}_2$ ;<sup>1667</sup> and mixtures of *N*-bromo amides in anhydrous  $\text{HF}$  give bromofluorination.<sup>1668</sup> Bromo-, iodo-, and chlorofluorination have also been achieved by treatment of the substrate with a solution of  $\text{Br}_2$ ,  $\text{I}_2$ , or an *N*-halo amide in polyhydrogen fluoride/pyridine,<sup>1669</sup> while addition of  $\text{I}$  along with  $\text{Br}$ ,  $\text{Cl}$ , or  $\text{F}$  has been accomplished with the reagent bis(pyridine)iodo(I) tetrafluoroborate [ $(\text{Py})_2\text{BF}_4$ ] and  $\text{Br}^-$ ,  $\text{Cl}^-$ , or  $\text{F}^-$ , respectively.<sup>1670</sup> This reaction (which is also successful for triple bonds<sup>1671</sup>) can be extended to the addition of  $\text{I}^-$  and other nucleophiles.<sup>1671</sup>

The addition of  $\text{Br}$  and  $\text{Cl}$  across an alkene  $\pi$  bond was promoted by a Schiff base catalyst in the presence of  $\text{NBS}$  and  $\text{ClTi}(\text{O}i\text{-Pr})_3$ .<sup>1672</sup> The reaction of 1-trimethylsilylalkynes and  $\text{ICl}^{1673}$  gave the (*Z*)-1-iodo-2-chloroalkene.<sup>1674</sup> Iodofluorination of alkynes gave the iodofluoroalkene using  $\text{IF}_5\cdot\text{pyridine}\cdot\text{HF}$ .<sup>1675</sup> The reaction of alkynes with  $\text{IBr}$ , generated by sequential reaction with  $\text{TMSBr}$  and then  $\text{NIS}$ , gave the (*E*)-bromiodoalkene.<sup>1676</sup>

When free-radical initiators (or UV light) are present, addition can occur by a free-radical mechanism.<sup>1677</sup> Once  $\text{Br}\cdot$  or  $\text{Cl}\cdot$  radicals are formed, however, substitution may compete (**14-1** and **14-3**). This competition is especially important when the alkene has allylic or benzylic hydrogen atoms. Under free-radical conditions (UV light), bromine or chlorine adds to a benzene substituent to give, respectively, hexabromo- or hexachlorocyclohexane. These are mixtures of stereoisomers (Sec. 4.K.ii).<sup>1678</sup>

Triple bonds add bromine, although generally more slowly than double bonds (Sec. 15.B.i). Molecules that contain both double and triple bonds are preferentially

### 15-36 Addition of Hypohalous Acids and Hypohalites (Addition of Halogen, Oxygen)<sup>1685</sup>

Hypohalous acids ( $\text{HOCl}$ ,  $\text{HOBr}$ , and  $\text{HOI}$ ) react with alkenes<sup>1686</sup> to produce halohydrins.<sup>1687</sup> Both  $\text{HOBr}$  and  $\text{HOCl}$  can be generated *in situ* by the reaction between water and  $\text{Br}_2$  or  $\text{Cl}_2$ , respectively.  $\text{HOI}$ , generated from  $\text{I}_2$  and  $\text{H}_2\text{O}$ , also adds to double bonds, if the reaction is carried out in tetramethylene sulfone/ $\text{CHCl}_3$ <sup>1688</sup> or if an oxidizing agent, such as  $\text{HIO}_3$ , is present.<sup>1689</sup> Iodine and cerium sulfate in aqueous acetonitrile generates iodohydrins,<sup>1690</sup> as do iodine and ammonium acetate in acetic acid,<sup>1691</sup> or  $\text{NaIO}_4$  with sodium bisulfite.<sup>1692</sup> The impact of water on the reaction has been studied, and “the reaction between  $\text{ClOH}$  and the  $\text{H}_2\text{O}\cdots\text{HO}$  complex is slower, but it is up to 2.2 times faster than the reaction without water.”<sup>1693</sup> In addition, “a three-body interchange reaction that can occur,”<sup>1693</sup> is

Alkenes reacted with Chloramine-T trihydrate, 1,3-dichloro-5,5-dimethylhydantoin, or *N*-bromoacetamide and *N*-tosyl-L-threonine to give the chlorohydrin.<sup>1694</sup> The ring openings of *meso*-epoxides, catalyzed by chiral phosphine oxides, gave chiral 1,2-chlorohydrins.<sup>1695</sup>

The HOBr can be conveniently used in a reaction using a *N*-bromo amide (e.g., NBS or *N*-bromoacetamide) and a small amount of water in a solvent such as DMSO or dioxane.<sup>1696</sup> *N*-Iodosuccinimide (NIS) in aqueous dimethoxyethane leads to the iodohydrin.<sup>1697</sup> An especially powerful reagent for HOCl addition is *tert*-butyl hydroperoxide (or di-*tert*-butyl peroxide) along with TiCl<sub>4</sub>.<sup>1698</sup> Chlorohydrins were formed by the reaction of alkenes with ClCH<sub>n</sub>MgCl•LiCl.<sup>1699</sup> The compound HOI can be added by treatment of alkenes with periodic acid and NaHSO<sub>3</sub>.<sup>1700</sup> There are Se-catalyzed iodohydrin-forming reactions.<sup>1701</sup> Hypervalent iodine compounds react with an alkene and iodine in aqueous media to give the iodohydrin.<sup>1702</sup> Halohydrins are produced in ionic liquids.<sup>1703</sup> *N*-Bromo and *N*-iodosaccharin have been used to prepare the corresponding halohydrins.<sup>1704</sup> Alkenes were converted to chlorohydrins by a Ru-based artificial enzyme.<sup>1705</sup> The compound HOF has also been used, but this reagent is difficult to prepare in a pure state and *explosions have occurred*.<sup>1706</sup> Fluorohydrins have been prepared by the fluorination of allylsilanes by reaction with Selectfluor.<sup>1707</sup>

The mechanism of HOX addition is electrophilic, with initial attack by the alkene on the positive halogen end of the HOX dipole. Following *Markovnikov's rule*, the positive halogen goes to the side of the double bond that has more hydrogen atoms (forming a more stable carbocation). This carbocation (or bromonium or iodonium ion in the absence of an aqueous solvent) reacts with <sup>-</sup>OH or H<sub>2</sub>O to give the product. If the substrate is treated with Br<sub>2</sub> or Cl<sub>2</sub> (or another source of positive halogen such as NBS) in an alcohol or a carboxylic acid solvent, it is possible to obtain C—C—OR or X—C—C—OCOR, respectively, directly (see also, **15-44**).<sup>1708</sup> There is evidence that the mechanism with Cl<sub>2</sub> and H<sub>2</sub>O is different from that with HOCl.<sup>1709</sup> HOCl and HOBr can be added to triple bonds to give dihalo carbonyl compounds —CX<sub>2</sub>—CO—.

Alcohols and halogens react with alkenes to form halo ethers.<sup>1710</sup> When a homoallylic alcohol is treated with bromine, cyclization occurs to give a 3-bromotetrahydrofuran

### 15-37 Halolactonization

Halo esters can be formed by addition of halogen atoms and ester groups to an alkene. Alkene carboxylic acids give a tandem reaction of formation of a halonium ion followed by intramolecular displacement of the carboxylic group to give a halo lactone. This tandem addition of X and OCOR to form a lactone is called *halolactonization*.<sup>1720</sup>

The most common version of this reaction is known as *iodolactonization*,<sup>1721</sup> and an enantioselective example is the conversion of **43** to **44** in Martin and Klosowski's synthesis of (+)-disparlure.<sup>1722</sup>

Bromo lactones and, to a lesser extent, chloro lactones have also been prepared. In general, addition of the halogen to an alkenyl acid, as shown, leads to the halo lactone. Other reagents include  $\text{I}^+(\text{collidine})_2 \text{PF}_6^-$ ,<sup>1723</sup> NIS,<sup>1724</sup> KI/sodium persulfate,<sup>1725</sup> and

a CO<sub>2</sub>-promoted reaction with Chloramine-T (TolSO<sub>2</sub>N<sup>-</sup>-Cl).<sup>1758</sup> These are free-radical additions, with initial attack by the R<sub>2</sub>NH<sup>•+</sup> radical ion.<sup>1759</sup> Amines add to allenes in the presence of a Pd catalyst.<sup>1760</sup> Iodoamination of alkenes has been reviewed.<sup>1761</sup>

Bromoamidation of alkenes was accomplished using a NBS/sulfonamide protocol.<sup>1762</sup> The chloroamidation (the acetamide derivative) of alkenes occurs by reaction with NCS with 20% of Ph<sub>2</sub>Se in aqueous acetonitrile.<sup>1763</sup> The Ag or Ag/In-catalyzed haloamidation of alkenes was accomplished using *N*-halophthalimides as both the source of nitrogen and the halogen. The iodoamidation of alkenes in aqueous media used chloramine salts and iodine.<sup>1764</sup> The intramolecular iodoamination of alkenes used MnI<sub>2</sub> as a catalyst.<sup>1765</sup>

The intramolecular aminobromination of alkenes was Fe catalyzed.<sup>1766</sup> The enantioselective bromination of allylic alcohols used *Cinchona*-derived thiourea as the catalyst and *N,N*-dibromo-4-nitrobenzenesulfonamide as a bromine and amine source.<sup>1767</sup> The chloroamination of alkenes used *N*-chlorosulfonamide as the source of both N and Cl, and was promoted by visible light.<sup>1768</sup>

Formation of halo lactams by a procedure similar to halolactonization is difficult, but the problems have been overcome. Formation of a triflate from pent-4-enamide followed by treatment with iodine leads to the iodolactam, **45**.<sup>1769</sup>

A related cyclization of *N*-sulfonyl amino alkenes and NBS gave the bromolactam,<sup>1770</sup> and a dichloro-*N,N*-bis(allyl amide) was converted to a dichlorolactam with FeCl<sub>2</sub>.<sup>1771</sup> It is noted that lactone formation is possible from unsaturated amides.

### 15-40 Addition of NOX and NO<sub>2</sub>X (Addition of Halogen, Nitrogen)

There are three possible products when NOCl is added to alkenes: (i) a β-halo nitroso compound, (ii) an oxime, or (iii) a β-halo nitro compound.<sup>1772</sup> The initial product is always the

$\beta$ -halo nitroso compound,<sup>1773</sup> but these are stable only if the carbon bearing the nitrogen has no hydrogen. If it has, the nitroso compound tautomerizes to the oxime:

With some alkenes, the initial  $\beta$ -halo nitroso compound is oxidized by the NOCl to a  $\beta$ -halo nitro compound.<sup>1774</sup> The mechanism in most cases is probably simple electrophilic addition, and the addition is usually *anti*, although *syn* addition has been reported in some cases.<sup>1775</sup> *Markovnikov's rule* is followed, the positive NO going to the carbon that has more hydrogen atoms. The nitration of alkenes was reported using silver nitrate and TEMPO.<sup>1776</sup> Nitroalkenes were formed by the reaction of *t*-BuONO and TEMPO.<sup>1777</sup>

Nitryl chloride (NO<sub>2</sub>Cl) also adds to alkenes, to give  $\beta$ -halo nitro compounds, but this is a free-radical process. The NO<sub>2</sub> goes to the less-substituted carbon.<sup>1778</sup> Nitryl chloride also adds to triple bonds to give the expected 1-nitro-2-chloro alkenes.<sup>1779</sup> The compound FNO<sub>2</sub> can be added to alkenes<sup>1780</sup> by treatment with HF in HNO<sub>3</sub>.<sup>1781</sup>

OS IV, 711; V, 266, 863.

#### 15-41 Addition of XN<sub>3</sub> (Addition of Halogen, Nitrogen)

The addition of iodine azide to double bonds gives  $\beta$ -iodo azides.<sup>1782</sup> The reagent can be prepared *in situ* from KI/NaN<sub>3</sub> in the presence of Oxone/wet alumina.<sup>1783</sup> The addition is stereospecific and *anti*, suggesting that the mechanism involves a cyclic iodonium ion intermediate.<sup>1784</sup> The reaction has been performed on many double bond compounds, including allenes<sup>1785</sup> and  $\alpha,\beta$ -unsaturated ketones. Similar reactions can be performed with BrN<sub>3</sub><sup>1786</sup> and ClN<sub>3</sub>. 1,4-addition has been found with acyclic conjugated dienes.<sup>1787</sup> In the case of BrN<sub>3</sub>, both electrophilic and free-radical mechanisms are important,<sup>1788</sup> while with ClN<sub>3</sub>

the additions are chiefly free radical.<sup>1789</sup> Iodine azide (IN<sub>3</sub>) also adds to triple bonds to give β-iodo-α,β-unsaturated azides.<sup>1790</sup>

β-Iodo azides can be reduced to aziridines with LiAlH<sub>4</sub><sup>1791</sup> or converted to *N*-alkyl- or *N*-aryl aziridines by treatment with an alkyl- or aryl dichloroborane followed by a base.<sup>1792</sup> In both cases the azide is first reduced to the corresponding amine (primary or secondary, respectively) and ring closure (**10-30**) follows. With Chloramine T (TsNCl<sup>-</sup> Na<sup>+</sup>) and 10% of pyridinium bromide perbromide, however, the reaction with alkenes give an *N*-tosyl aziridine directly.<sup>1793</sup>

OS VI, 893.

### 15-42 Addition of Alkyl Halides (Addition of Halogen, Carbon)<sup>1074</sup>

The difunctionalization of compounds with multiple bonds is known.<sup>1794</sup> Alkyl halides can be added to alkenes in the presence of a *Friedel-Crafts catalyst*, most often AlCl<sub>3</sub>.<sup>1795</sup> The yields are best for tertiary R. Secondary R can also be used, but primary R give rearrangement products (as with **11-11**). The reactive species is the carbocation formed from the alkyl halide and the catalyst.<sup>1796</sup> The reaction with an alkene follows *Markovnikov's rule*, and generates the more stable carbocation from the alkene after reaction with the carbocation. Methyl and ethyl halides, which cannot rearrange to a more stable secondary or tertiary carbocation, give no reaction at all. When R<sup>+</sup> reacts with an alkene, a new carbocation is the product. Subsequent reaction with a nucleophile gives the substitution product whereas loss of a proton leads to the alkene. Triple bonds also undergo the reaction, to give vinylic halides.<sup>1797</sup> Conjugated dienes give 1,4-addition.<sup>1798</sup>

The Pd-catalyzed intramolecular carbiodination reaction was reported by heating *ortho*-iodoarenes that have an alkenyl unit to give the iodomethylbenzofuran or indoline derivative.<sup>1799</sup> The Pd-catalyzed reaction of styrenes with Selectfluor and an arylboronic acid added fluorine and the aryl group across the C=C unit.<sup>1800</sup> The Ir-photocatalyzed reaction of alkynes with CF<sub>3</sub>SO<sub>2</sub>Cl gave the chloro trifluoromethyl alkene.<sup>1801</sup> Alkynes reacted with allylic alcohols with an In catalyst to give halogen-substituted 1,4-dienes.<sup>1802</sup> The

Pd-catalyzed reaction of an alkyne with  $\text{CuBr}_2$  and an allylic alcohol gave  $\delta$ -bromo- $\gamma,\delta$ -unsaturated carbonyls in the presence of oxygen.<sup>1803</sup>

The cyclization reaction of  $(\text{NH}_4)_2\text{S}_2\text{O}_8$  and *N*-aryl acrylamides proceeded by halocarbocyclization to the alkene moiety to give the oxindole.<sup>1804</sup> 1-Halo-1,4-dienes are prepared by the Pd-catalyzed reaction of alkynes and allylic alcohols in the presence of  $\text{CuX}_2$ .<sup>1805</sup> The Fe-catalyzed reaction of terminal alkynes and benzylic hydrocarbons with NCS and DDQ gave chlorobenylation and formation of the vicinal chloro benzylic alkenes.<sup>1806</sup> Allenes reacted with allyl bromides and AIBN via bromoallylation to give the 2-bromo-1,5-diene.<sup>1807</sup>

Simple polyhalo alkanes, such as  $\text{CCl}_4$ ,  $\text{BrCCl}_3$ ,  $\text{ICF}_3$ , and related molecules, add to alkenes in good yield.<sup>1808</sup> These are free-radical additions and require initiation, for example,<sup>1809</sup> by peroxides, metal halides (e.g.,  $\text{FeCl}_2$ ,  $\text{CuCl}$ ),<sup>1810</sup> Ru catalysts,<sup>1811</sup> or UV light. The initial reaction generates the more stable radical intermediate, as in most free-radical reactions with alkenes. Polyhalo alkanes add to halogenated alkenes in the presence of  $\text{AlCl}_3$  by an electrophilic mechanism. This has been called the *Prins reaction* (not to be confused with the reaction most identified as the *Prins reaction*, **16-53**).<sup>1812</sup>  $\alpha$ -Iodo lactones add to alkenes in the presence of  $\text{BEt}_3/\text{O}_2$  to give the addition product.<sup>1813</sup> Other  $\alpha$ -iodo esters add under similar conditions to give the lactone.<sup>1814</sup> Iodo esters also add to alkenes in the presence of  $\text{BEt}_3$  to give iodo esters that have not cyclized.<sup>1815</sup>

OS II, 312; IV, 727; V, 1076; VI, 21; VII, 290.

### 15-43 Addition of Acyl Halides (Addition of Halogen, Carbon)

Acyl halides add to many alkenes using *Friedel-Crafts* catalysts, although polymerization is a problem. The reaction has been applied to straight-chain, branched, and cyclic alkenes, but to very few alkenes that contain functional groups, other than halogens.<sup>1816</sup> The mechanism is similar to that of **15-42**, and, as in that case, substitution competes

## B. Oxygen, Nitrogen, or Sulfur on One or Both Sides

### 15-44 Dihydroxylation and Dialkoxylation (Addition of Oxygen, Oxygen)<sup>1824</sup>

There are many reagents that add two OH groups to a double bond (dihydroxylation).<sup>1825</sup> The most common are OsO<sub>4</sub>,<sup>1826</sup> first used by Criegee in 1936,<sup>1827</sup> and alkaline KMnO<sub>4</sub>.<sup>1828</sup> Less-substituted double bonds are oxidized more rapidly than more-substituted alkenes.<sup>1829</sup> Both give *syn* addition from the less-hindered side of the double bond. Permanganate adds to alkenes to form an intermediate manganate ester (**46**), which is decomposed under alkaline conditions via coordination of the base and **46**.<sup>1830</sup> Transition state structures and the energetics of the permanganate oxidation of alkenes has been studied using molecular mechanics.<sup>1831</sup> Note that there are alternative Mn complexes that may be used for *cis*-dihydroxylation of alkenes.<sup>1832</sup> Osmium tetroxide reacts rather slowly but almost

quantitatively to form a cyclic osmate ester such as **47** as an intermediate,<sup>1833</sup> which may be isolated in some cases, but is usually decomposed in solution with sodium sulfite ( $\text{Na}_2\text{SO}_3$ ) in ethanol or other reagents.<sup>1834</sup>

The chief drawbacks to the use of  $\text{OsO}_4$  are expense and toxicity, but the reaction is made catalytic in  $\text{OsO}_4$  by using *N*-methylmorpholine-*N*-oxide (NMO),<sup>1835</sup> *tert*-butyl hydroperoxide in alkaline solution,<sup>1836</sup>  $\text{H}_2\text{O}_2$ ,<sup>1837</sup> or peroxyacid.<sup>1838</sup> Polymer-bound  $\text{OsO}_4$ <sup>1839</sup> and encapsulated  $\text{OsO}_4$  have been shown to give the diol in the presence of NMO.<sup>1840</sup> Dihydroxylation has also been reported in ionic liquids.<sup>1841</sup> Other metals have been used to catalyze dihydroxylation, including Fe,<sup>1842</sup> Ir,<sup>1843</sup> or Ru<sup>1844</sup> with hydrogen peroxide.

The end product of the reaction is a 1,2-diol, but potassium permanganate is a strong oxidizing agent that can oxidize the glycol product<sup>1845</sup> (see **19-7** and **19-10**). In acidic and neutral solution oxidation almost always occurs so diols must be prepared with alkaline permanganate,<sup>1846</sup> but the conditions must be mild. Even so, yields are seldom  $>50\%$ , although they can be improved with phase-transfer catalysis<sup>1847</sup> or increased stirring.<sup>1848</sup> The use of ultrasound with permanganate has resulted in good yields of the diol.<sup>1849</sup> This reaction is the basis of the *Baeyer test* for the presence of double bonds.

*Anti* hydroxylation can be achieved by treatment with  $\text{H}_2\text{O}_2$  and formic acid. In this case, epoxidation (**15-46**) occurs first, followed by an  $\text{S}_{\text{N}}2$  reaction, which results in overall *anti* addition. The same result can be achieved in one step with *m*-chloroperoxybenzoic acid (mcpba) and water,<sup>1850</sup> and cyclobutane malonoyl peroxide has been used.<sup>1851</sup> Overall *anti* addition can also be achieved by the method of Prévost (the *Prévost reaction*). In this

method, the alkene is treated with iodine and silver benzoate in a 1:2 molar ratio. The initial addition is *anti* and results in a  $\beta$ -halo benzoate, as shown, which can be isolated.

However, under the normal reaction conditions, the iodine is replaced by a second  $PhCOO$  group. This is a nucleophilic substitution reaction via the neighboring-group mechanism (Sec. 10.C), so the groups are still *anti*. Hydrolysis of the ester does not change the configuration. An enantioselective version of these reactions has been developed.<sup>1852</sup>

The Woodward modification of the Prévost reaction is similar, but results in overall *syn* hydroxylation.<sup>1853</sup> In this procedure, the alkene is treated with iodine and silver acetate in a 1:1 molar ratio in acetic acid containing water. Here again, the initial product is a  $\beta$ -halo ester; the addition is *anti* and a nucleophilic replacement of the iodine occurs. However, in the presence of water, neighboring-group participation is prevented or greatly decreased by solvation of the ester function, and the mechanism is the normal  $S_N2$  process,<sup>1854</sup> so the monoacetate is *syn* and hydrolysis gives the diol as the product, with overall *syn* addition. Although the Woodward method results in overall *syn* addition, the product may be different from that with  $OsO_4$  or  $KMnO_4$ , since the overall *syn* process is from the *more-hindered side* of the alkene.<sup>1855</sup> Both the Prévost and the Woodward methods<sup>1856</sup> have been carried out in high yields with thallium(I) acetate and thallium(I) benzoate instead of the silver carboxylates.<sup>1857</sup> Note that cyclic sulfates can be prepared from alkenes by reaction with  $PhIO$  and  $SO_3 \cdot DMF$ .<sup>1858</sup> Diacetates have been prepared from alkenes using a Cu-catalyzed reaction with  $PhI(OAc)_2$  as the oxidizing agent.<sup>1859</sup> A similar Pd/Cu-catalyzed reaction is known using  $O_2$  as the oxidant.<sup>1860</sup> Organocatalysts have been used,<sup>1861</sup> as well as a microchemical system,<sup>1862</sup> and a chiral iodine(III) derivative.<sup>1863</sup>

1,2-Diols are also generated from terminal alkynes by two sequential reactions with a Pt catalyst and then a Pd catalyst, both with  $HSiCl_3$ , and a final oxidation with  $H_2O_2/KF$ .<sup>1864</sup> The dihydroxylation of a vinyl ether, derived from an alkyne, leads to  $\alpha$ -hydroxy aldehydes.<sup>1865</sup> Dihydroxylation of alkenes has been reported using a lipase and hydrogen peroxide, under microwave irradiation.<sup>1866</sup> A Pd-catalyzed diacetoxylation is also known.<sup>1867</sup>

Dihydroxylation to alkenes of the form  $RCH=CH_2$  has been made enantioselective, and addition to  $RCH=CHR'$  both diastereoselective<sup>1868</sup> and enantioselective,<sup>1869</sup> using chiral additives or chiral catalysts<sup>1870</sup> that are derivatives of the naturally occurring quinine and quinuclidine,<sup>1871</sup> along with  $OsO_4$ ,<sup>1872</sup> in what is called *Sharpless asymmetric dihydroxylation*.<sup>1873</sup> Other chiral ligands<sup>1874</sup> have also been used, as well as polymer-bound<sup>1875</sup> and silica-bound<sup>1876</sup> *Cinchona* alkaloids. These amines bind to the  $OsO_4$  *in situ* as chiral ligands, causing it to add asymmetrically.<sup>1877</sup> Osmium tetroxide and Streptavidin has been developed as a tunable catalyst.<sup>1878</sup> Magnetically recoverable osmium catalysts have been developed.<sup>1879</sup> This asymmetric reaction has been done both with the stoichiometric method and with the catalytic method.<sup>1880</sup> The catalytic method has been extended to conjugated ketones<sup>1881</sup> and to conjugated dienes, which give tetrahydroxy products diastereoselectively.<sup>1882</sup> Asymmetric dihydroxylation has also been reported with chiral alkenes.<sup>1883</sup>

Two phthalazine derivatives,<sup>1884</sup> (DHQD)<sub>2</sub>PHAL (**48**) and (DHQ)<sub>2</sub>PHAL (**49**), are used in conjunction with an Os reagent to improve the efficiency and ease of use, and are

commercially available as AD-mix- $\beta$  (using **48**) and AD-mix- $\alpha$  (using **49**).<sup>1885</sup> These catalysts lead to diol formation with the opposite enantioselectivity. Styrene, for example, gave the (*R*)-diol with **48**, and the (*S*)-diol with **49**.<sup>1886</sup> Catalyst **48** is prepared from dihydroquinidine (DHQD) and 1,4-dichlorophthalazine (PHAL), and **49** is prepared from dihydroquinine (DHQ) and PHAL. The actual oxidation using AD-mix- $\alpha$  or AD-mix- $\beta$  uses **49** or **48**, respectively, mixed with potassium osmate [K<sub>2</sub>OsO<sub>2</sub>(OH)<sub>6</sub>], powdered K<sub>3</sub>Fe(CN)<sub>6</sub>, and powdered K<sub>2</sub>CO<sub>3</sub> in an aqueous solvent mixture.<sup>1884</sup> One study showed that osmylation does not always occur preferentially on the most electron-rich double bond,<sup>1887</sup> and there are examples of the less-rich double bond reacting preferentially, and such preferences may be amplified using AD-type reagents, as they add significant steric hindrance to the overall system.<sup>1888</sup> Note that ionic liquids have been used in asymmetric dihydroxylation.<sup>1889</sup>

These additives have been used in conjunction with microencapsulated OsO<sub>4</sub>,<sup>1890</sup> and polymer bound **48** has been used.<sup>1891</sup> An asymmetric dihydroxylation was reported catalyzed by ionic polymer-supported OsO<sub>4</sub>.<sup>1892</sup> Both **48**<sup>1893</sup> and **49**<sup>1894</sup> have been used to generate diols with high enantioselectivity. Oxidation of a terminal alkene with AD-mix and then oxidation with TEMPO/NaOCl/NaOCl<sub>2</sub> leads to  $\alpha$ -hydroxyl carboxylic acids with high enantioselectivity.<sup>1895</sup>

Enantioselective addition and diastereoselective addition have also been achieved by using preformed derivatives of OsO<sub>4</sub> already containing chiral ligands<sup>1896</sup> and by the use of OsO<sub>4</sub> on alkenes that have a chiral group elsewhere in the molecule.<sup>1897</sup> A Rh-catalyzed dimerization of alkenes in the presence of a chiral ligand, leads to the corresponding diol with good enantioselectivity after oxidation.<sup>1898</sup>

Dialkoxylation reactions are possible. The reaction of an aryl alkene with methanol, O<sub>2</sub>, and a Pd catalyst leads to the dimethoxy compound with moderate enantioselectivity if a chiral ligand is used.<sup>1899</sup> 3-Methoxy tetrahydrofuran derivatives were prepared from 1-allylcyclopentan-1-ol derivatives by reaction with iodine and [hydroxy(tosyloxy)iodo]benzene (HTIB).<sup>1900</sup> A BF<sub>3</sub>•OEt<sub>2</sub>-promoted diacetoxylation of alkenes used PhI(OAc)<sub>2</sub>.<sup>1901</sup> Oxidizing agents, such as benzoquinone, MnO<sub>2</sub>, or O<sub>2</sub>, along

### 15-45 Dihydroxylation of Aromatic Rings

One  $\pi$  bond of an aromatic ring can be selectively oxidized to give a cyclohexadiene 1,2-diol<sup>1903</sup> by reaction with enzymes associated with *Pseudomonas putida*.<sup>1904</sup> *para*-Substituted arenes were dihydroxylated using *Escherichia coli* JM109 (pDTG601), an organism expressing toluene dioxygenase.<sup>1905</sup> A variety of substituted aromatic compounds can be oxidized, including bromobenzene, chlorobenzene,<sup>1906</sup> and toluene.<sup>1907</sup> In these latter cases, introduction of the hydroxyl groups generates a chiral molecule that can be used as a template for asymmetric syntheses.<sup>1908</sup>

OS X, 217.

### 15-46 Epoxidation (Addition of Oxygen, Oxygen)<sup>1909</sup>

Alkenes are converted to epoxides (oxiranes) by reaction with many peroxyacids.<sup>1910</sup> The reaction, called the *Prilezhaev reaction*, has wide utility.<sup>1911</sup> The limiting factor concerning choice of the peroxyacid is usually whether or not it is commercially available because an in-lab preparation is potentially rather dangerous. The peroxyacid used most often is probably *m*-chloroperoxybenzoic acid (mcpba). However, peroxyacetic acid and peroxybenzoic

acid are available, and trifluoroperoxyacetic acid<sup>1912</sup> and 3,5-dinitroperoxybenzoic acid<sup>1913</sup> are particularly reactive. Magnesium monoperoxyphthalate (MMPP)<sup>1914</sup> is commercially available, and has been shown to be a good substitute for mcpba in a number of reactions.

Alkyl, aryl, hydroxyl, ester, and other groups may be present in the alkene, but not amino groups since they are oxidized by the reagent. The presence of electron-donating groups increases the rate, and the reaction is particularly rapid with tetraalkyl alkenes. Epoxidation has been carried out in ionic liquids using 10% H<sub>2</sub>O<sub>2</sub> with MnSO<sub>4</sub><sup>1915</sup> or an Fe catalyst.<sup>1916</sup> Epoxidations with peroxyacids have been reported in supercritical CO<sub>2</sub> and using flow conditions (Sec. 7.D).<sup>1917</sup> Epoxidations using silica-supported peroxyacids have been reported.<sup>1918</sup> Hypervalent iodine compounds, such as PhI(OAc)<sub>2</sub>, in conjunction with a Ru catalyst in aqueous media,<sup>1919</sup> or in an ionic liquid with a Mn catalyst,<sup>1920</sup> converted alkenes to epoxides. Microwave-assisted epoxidations are known using H<sub>2</sub>O<sub>2</sub>.<sup>1921</sup> Epoxidation of vinyl ethers has been studied.<sup>1922</sup> The conformation of cyclic alkenes can affect the epoxidation reaction.<sup>1923</sup> Transition metal catalysts can facilitate epoxidation of alkenes at low temperatures or with alkenes that may otherwise react sluggishly.<sup>1924</sup>

The one-step mechanism involving a transition state such as **50**<sup>1925</sup> was proposed by Bartlett.<sup>1926</sup>

Evidence for this concerted mechanism is as follows:<sup>1927</sup>

1. The reaction is second order. If ionization were the rate-determining step, it would be first order in peroxyacid.
2. The reaction readily takes place in nonpolar solvents, where formation of ions is inhibited.<sup>1928</sup>

3. Measurements of the effect on the reaction rate of changes in the substrate structure show that there is no carbocation character in the transition state.<sup>1929</sup>
4. The addition is stereospecific (i.e., a *trans* alkene gives a *trans* epoxide and a *cis* alkene gives a *cis* epoxide) even in cases where electron-donating substituents would stabilize a hypothetical carbocation intermediate.<sup>1930</sup> However, where there is an OH group in the allylic or homoallylic position, the stereospecificity diminishes or disappears, with both *cis* and *trans* isomers giving predominantly and exclusively the product where the incoming oxygen is *syn* to the OH group. This probably indicates a transition state in which there is hydrogen bonding between the OH group and the peroxyacid.<sup>1931</sup>

Although *cis-trans* isomerization of epoxides is not formally associated with this section, it is a potential issue in the conversion of an alkene to an epoxide.

In general, in the absence of transition metal catalysts, peroxides (HOOH<sup>1932</sup> and ROOH) are poor reagents for epoxidation of simple alkenes since OH and OR are poor leaving groups in the concerted mechanism shown above.<sup>1933</sup> Epoxidation occurs with Fe,<sup>1934</sup> Re,<sup>1935</sup> Mn,<sup>1936</sup> Co,<sup>1937</sup> Ti,<sup>1938</sup> W/V,<sup>1939</sup> or V catalysts.<sup>1940</sup> Transition metal catalysts<sup>1941</sup> have been used with alkyl hydroperoxides.<sup>1942</sup> Epoxides can also be prepared by treating alkenes with oxygen or with an alkyl peroxide<sup>1943</sup> catalyzed by a complex of transition metals such as V, Mo, Ti, La,<sup>1944</sup> Y,<sup>1945</sup> or Co.<sup>1946</sup> In the presence of some other

reagents,<sup>1947</sup> peroxides give good yields of the epoxide; such reagents include DCC,<sup>1948</sup> metalloporphyrins,<sup>1949</sup> and arsines in fluoruous solvents.<sup>1950</sup> The Ti-catalyzed epoxidation of primary allylic alcohols using *gem*-dihydroperoxides proceeded with good enantioselectivity.<sup>1951</sup> The reaction of alkenes with 2,6-dichloropyridine-*N*-oxide and a Ru catalyst in the presence of HCl gave the epoxide.<sup>1952</sup> The Ru-catalyzed reaction of O<sub>2</sub> with conjugated alkenes gave the epoxide.<sup>1953</sup>

Several homogeneous and heterogeneous asymmetric epoxidation protocols have been developed.<sup>1954</sup> Enzymatic epoxidation<sup>1955</sup> and epoxidation with catalytic antibodies<sup>1956</sup> have been reported. Biomimetic epoxidation in aqueous media was catalyzed by cyclic dipeptides.<sup>1957</sup> The use of chiral additives leads to enantioselective epoxidation,<sup>1958</sup> and organocatalysts have been used as well.<sup>1959</sup> *Cinchona*-derived phase-transfer catalysts, initially used by Wynberg, are now common.<sup>1960</sup> Chiral hydroperoxides have been used for enantioselective epoxidation.<sup>1961</sup> Enantioselectivities can be significantly improved by changes of the catalyst structure as well as the type of oxidant.<sup>1962</sup> A biomimetic Fe catalyst has been used for the epoxidation of alkenes using molecular oxygen.<sup>1963</sup> The Fe-catalyzed asymmetric epoxidation of trisubstituted conjugated esters is known.<sup>1964</sup>

Other epoxidation methods are available. Dioxiranes,<sup>1965</sup> such as dimethyldioxirane (**51**, R = Me),<sup>1966</sup> either isolated or generated *in situ*,<sup>1967</sup> are important epoxidation reagents.

With dimethyldioxirane, C–H insertion reactions can occur preferentially.<sup>1968</sup> The reaction with alkenes is rapid, mild, and safe, and a variety of methods have been developed using an oxidant as a co-reagent.<sup>1969</sup> Substituent effects in such reactions have been studied<sup>1970</sup> and also substrate variations.<sup>1971</sup>

The most commonly used co-reagent is probably potassium peroxomonosulfate (KHSO<sub>5</sub>). Oxone (2KHSO<sub>5</sub>•KHSO<sub>4</sub>•K<sub>2</sub>SO<sub>4</sub>) is a common source of KHSO<sub>5</sub>. Oxone reacts with ketones<sup>1972</sup> and sodium bicarbonate to convert an alkene to an epoxide. Oxone, with hydrogen peroxide or a similar oxidant, can be used with chiral ketones<sup>1973</sup> or chiral aldehydes to convert alkenes to chiral, nonracemic epoxides.<sup>1974</sup> This reaction probably converts alkenes to epoxides with good enantioselectivity by *in situ* generation of a dioxirane.<sup>1975</sup> This transformation with chiral carbohydrates is sometimes called *Shi epoxidation*.<sup>1976</sup> Chiral dioxiranes have reportedly given nonracemic epoxides.<sup>1977</sup>

Oxone oxidizes iminium salts to an oxaziridinium intermediate **52**, which can transfer oxygen to an alkene to form an epoxide and regenerate the iminium salt.<sup>1978</sup> Epoxidation does not occur in good yields with these reagents in most other solvents, and it is suggested that the active agent that generates dioxirane is peroxyimideic acid MeC(=NH)OOH.<sup>1979</sup> This variation has been applied to asymmetric<sup>1980</sup> epoxidations using chiral iminium salt precursors.<sup>1981</sup> Other asymmetric epoxidation reactions of alkenes use chiral ketones and

iminium salts with an organocatalyst.<sup>1982</sup> Direct epoxidation of alkenes has been done using oxaziridinium salts.<sup>1983</sup>

It would be useful if triple bonds could be similarly epoxidized to give oxirenes, but they are not stable compounds.<sup>1984</sup>

Two oxirenes have been trapped in solid argon matrices at very low temperatures, but they decayed upon warming to 35 K.<sup>1985</sup> Oxirenes probably form in the reaction,<sup>1986</sup> but react quickly before they can be isolated. Note that oxirenes are expected to be antiaromatic (Sec. 2.B and 2.K.ii).

Conjugated dienes can be epoxidized (1,2-addition), although the reaction is slower than for corresponding alkenes, but  $\alpha,\beta$ -unsaturated ketones do not generally give epoxides when treated with peroxyacids.<sup>1987</sup>  $\alpha,\beta$ -Unsaturated compounds can be epoxidized by alkyl hydroperoxides and a base,<sup>1988</sup> or with  $\text{H}_2\text{O}_2$  and a base,<sup>1989</sup> or heteropoly acids.<sup>1990</sup> The epoxidation of  $\alpha,\beta$ -unsaturated ketones with hydrogen peroxide under basic conditions, which involves attack by  $\text{HO}_2^-$ ,<sup>1991</sup> is known as the *Waits-Scheffer epoxidation* and was discovered in 1921.<sup>1992</sup> This reaction has been extended to  $\alpha,\beta$ -unsaturated ketones, aldehydes, and sulfones.<sup>1993</sup>

The reaction has been carried out with LiOH and polymer-bound quaternary ammonium salts.<sup>1994</sup> A Yb/BINOL complex with *t*-BuOOH led to epoxidation of conjugated ketones with high asymmetric induction,<sup>1995</sup> as did a mixture of NaOCl and a *Cinchona*

alkaloid.<sup>1996</sup> The asymmetric epoxidation of conjugated carbonyl compounds used a *Cinchona* primary amine catalyst with H<sub>2</sub>O<sub>2</sub>.<sup>1997</sup> The asymmetric bio-epoxidation of enones has been reported,<sup>1998</sup> and the asymmetric epoxidation of alkenes has been achieved using flow conditions (Sec. 7.D).<sup>1999</sup> β,β-Disubstituted enones have been epoxidized with good enantioselectivity using an Fe catalyst.<sup>2000</sup>

Another important asymmetric epoxidation of a conjugated system is the reaction of alkenes with poly(leucine),<sup>2001</sup> DBU, and urea/H<sub>2</sub>O<sub>2</sub>, giving an epoxy carbonyl compound with good enantioselectivity.<sup>2002</sup> The hydroperoxide anion epoxidation of conjugated carbonyl compounds with a polyamino acid such as poly-L-alanine or poly-L-leucine is known as the *Juliá-Colonna epoxidation*.<sup>2003</sup> Epoxidation of conjugated ketones to give non-racemic epoxy ketones was done with aq. NaOCl and a *Cinchona* alkaloid derivative as catalyst.<sup>2004</sup> β-Peptides have been used as catalysts in this reaction.<sup>2005</sup>

When a carbonyl group is elsewhere in the molecule but not conjugated with the double bond, the *Baeyer-Villiger reaction* (18-19) may compete. Allenes<sup>2006</sup> are converted by peroxyacids to allene oxides<sup>2007</sup> or spiro dioxides, both of which species can in certain cases be isolated<sup>2008</sup> but more often are unstable under the reaction conditions and react further to give other products.<sup>2009</sup>

Allylic alcohols can be converted to epoxy alcohols with *tert*-butylhydroperoxide on molecular sieves,<sup>2010</sup> or with peroxyacids.<sup>2011</sup> Asymmetric epoxidation using a Ti catalyst has been reported.<sup>2012</sup> The addition of an appropriate chiral ligand to the metal-catalyzed hydroperoxide epoxidation of allylic alcohols leads to high enantioselectivity. This important modification is known as the *Sharpless asymmetric epoxidation*,<sup>2013</sup> where *allylic alcohols are converted to optically active epoxides* with excellent enantioselectivity by treatment with *t*-BuOOH, titanium tetrakisopropoxide, and optically active diethyl

tartrate.<sup>2014</sup> Since the allylic alcohol moiety is necessary for binding to the catalyst, asymmetric induction with nonallylic alcohols is poor to nonexistent. The  $\text{Ti}(\text{O}i\text{-Pr})_4$  and diethyl tartrate can be present in catalytic amounts (15–10 mol %) if molecular sieves are present.<sup>2015</sup> The use of a tartrate-PEG reagent (PEG<sub>350</sub> or PEG<sub>750</sub>) allows generation of both enantiomers.<sup>2016</sup> Both (+)- and (–)-diethyl tartrate are readily available, so either enantiomer of the product can be prepared.

Epoxidation has been successful for a wide range of primary allylic alcohols, including substrates where the double bond is mono-, di-, tri-, and tetrasubstituted,<sup>2017</sup> and is highly useful in natural product synthesis. The mechanism of the Sharpless epoxidation is believed to involve reaction of the substrate with a complex<sup>2018</sup> formed from titanium alkoxide and diethyl tartrate that also contains the substrate and the *t*-BuOOH.<sup>2019</sup>

Homoallylic alcohols have been converted to the epoxide, however, using a V catalyst in the presence of a chiral bis(hydroxyamide).<sup>2020</sup> Simple alkenes can be epoxidized enantioselectively with sodium hypochlorite (NaOCl, commercial bleach) and an optically active manganese complex catalyst.<sup>2021</sup> Apart from the commonly used NaOCl, urea/ $\text{H}_2\text{O}_2$  has been used.<sup>2022</sup>

The use of a manganese/salen complex<sup>2023</sup> with various oxidizing agents, in what is called the *Jacobsen-Katsuki reaction*,<sup>2024</sup> converts simple alkenes to the corresponding epoxide with high enantioselectivity.<sup>2025</sup> In addition to Mn, Cr/salen complexes,<sup>2026</sup> Ti/salen complexes,<sup>2027</sup> and Ru/salen complexes<sup>2028</sup> have been used for epoxidation.<sup>2029</sup> Note that salen ligands are based on salen, which is 2,2'-ethylenebis(nitriolomethylidene) diphenol. The mechanism of this reaction has been examined.<sup>2030</sup> Radical intermediates

<sup>2062</sup> Xie, J.; Wang, Y.-W.; Qi, L.-W.; Zhang, B. *Org. Lett.* **2017**, *19*, 1148.

The reaction of a carbamate with (DHQ)<sub>2</sub>PHAL (**49**) and the osmium compound, with NaOH and *tert*-butyl hypochlorite, leads to a diastereomeric mixture of amido alcohols **53** and **54**, each formed with high enantioselectivity.<sup>2063</sup>

The aminohydroxylation of trisubstituted and 1,1-disubstituted alkenes with benzoyloxycarbamate and a OsO<sub>4</sub> catalyst gave the more-substituted alcohol isomer.<sup>2064</sup> An organocatalytic reaction has been reported.<sup>2065</sup> An enantioselective aminohydroxylation of acrylamides has been reported.<sup>2066</sup> The Cu-catalyzed reaction of protected β-aryl enamines with PhI=NNs and an alcohol gave the *syn* β-alkoxydiamine.<sup>2067</sup> The Mn reaction is also known.<sup>2068</sup>

In general, the nitrogen adds to the less sterically hindered carbon of the alkene to give the major product. *N*-Bromo amides, in the presence of a catalytic amount of (DHQ)<sub>2</sub>PHAL and LiOH, converts conjugated esters to β-amido-α-hydroxy esters with good enantioselectivity.<sup>2069</sup> Another oxyamination reaction involves treatment of a Pd complex of the alkene with a secondary or primary amine, followed by lead tetraacetate or another oxidant.<sup>2070</sup>

An organolanthanide-catalyzed alkene hydroamination has been reported.<sup>2071</sup> With this approach, amino alkenes (not enamines) can be cyclized to form cyclic amines,<sup>2072</sup> and amino alkynes lead to cyclic imines.<sup>2073</sup> The use of synthesized C-1<sup>2074</sup> and C-2 symmetric<sup>2075</sup> chiral organolanthanide complexes give the amino alcohol with good enantioselectivity. β-Amino alcohols can be prepared by treatment of an alkene with a reagent prepared from HgO and HBF<sub>4</sub> along with aniline to give an aminomercurial compound PhHN–C–C–HgBF<sub>4</sub> (aminomercuration; see **15-7**), which is hydrolyzed to PhHN–C–C–OH.<sup>2076</sup> The use of an alcohol instead of water gives the corresponding amino ether. β-Azido alcohols are prepared by the reaction of an alkene with Me<sub>3</sub>SiOOSiMe<sub>3</sub>, Me<sub>3</sub>SiN<sub>3</sub>, and 20% (Cl<sub>2</sub>SnO)<sub>n</sub>, followed by treatment with aqueous acetic acid.<sup>2077</sup>

### 15-49 Diamination (Addition of Nitrogen, Nitrogen)

Two amine and/or two amide units can be added to a C=C unit (diamination).<sup>2081</sup> Primary (R = H) and secondary aromatic amines react with alkenes in the presence of thallium(III) acetate to give *vic*-diamines in good yields.<sup>2082</sup> The reaction is not successful for primary aliphatic amines. In another procedure, alkenes can be diaminated by treatment with the Os compounds R<sub>3</sub>NOsO (R = *t*-Bu) and R<sub>2</sub>NOsO<sub>2</sub>,<sup>2083</sup> analogous to the Os compound mentioned at 15-52.<sup>2084</sup> The Pd-promoted method of 15-49 has also been extended to diamination.<sup>2085</sup> The Pd-catalyzed addition of saccharin and H(NTs)<sub>2</sub> with an alkene, in the presence of a hypervalent iodine oxidant, leads to a precursor that can be converted to a 1,2-diamine.<sup>2086</sup> Styrene derivatives reacted with ArI(NTs)<sub>2</sub> reagents to give the vicinal diamide derivative.<sup>2087</sup> The diamination of styrenes used a chiral hypervalent iodine(III) reagent as an oxidant and bis(mesyylimide) as a nitrogen source.<sup>2088</sup> To achieve the diamination of buta-1,3-dienes, they were reacted with amines and a hypervalent iodine reagent to give the diamination product and, depending on the substrate, this reaction proceeds either with 1,2- or 1,4-regioselectivity.<sup>2089</sup>

Two azido groups can be added to double bonds by treatment with sodium azide and iodosobenzene in acetic acid.<sup>2090</sup>

## 15-50 Formation of Aziridines (Addition of Nitrogen, Nitrogen)

Aziridines can be prepared directly from double bond compounds by photolysis or thermolysis of a mixture of the substrate and an azide.<sup>2091</sup> The reaction has been carried out with R = aryl, cyano, EtOOC, and RSO<sub>2</sub>, as well as other groups. The reaction can take place by at least two pathways.

In one pathway, a 1,3-dipolar addition (**15-54**) takes place to give a triazoline (which can be isolated), followed by thermal extrusion of nitrogen (**17-32**). Evidence for the nitrene pathway is most compelling for R = acyl groups. In the other pathway, the azide is converted to a nitrene, which adds to the double bond in a manner analogous to that of carbene addition (**15-60**). Sulfonyloxy amines, such as ArSO<sub>2</sub>ONHCO<sub>2</sub>Et, form an aziridine when treated with CaO in the presence of a conjugated carbonyl compound,<sup>2092</sup> and nitrene precursors that have an attached chiral ester have been prepared.<sup>2093</sup> In the presence of Cu,<sup>2094</sup> Co,<sup>2095</sup> or Rh complexes,<sup>2096</sup> ethyl diazoacetate adds to imines to give aziridines. Diazirenes (Sec. 5.D.ii) with *n*-butyllithium converted conjugated amides to α,β-aziridino amides.<sup>2097</sup> The oxidation of hydrazine derivatives in the presence of alkenes gave the *N*-aminoaziridine derivative.<sup>2098</sup> Alkenes reacted with aryl azides in the presence of an Fe catalyst to give the aziridine.<sup>2099</sup> The reaction of alkenes with TMSN<sub>3</sub> and a Mn catalyst in the presence of air, followed by PPh<sub>3</sub>, gave the corresponding azido alcohol.<sup>2100</sup> The conjugate addition of *N*-chloro-*N*-sodiocarbamates with conjugated carbonyl compounds that have a chiral auxiliary gave the *N*-acyl aziridine in the presence of a chiral ammonium salt.<sup>2101</sup>

Alkyl azides add to conjugated alkenes in the presence of an acid.<sup>2102</sup> Tosylamines react with alkenes in the presence of a Rh catalyst<sup>2103</sup> or with iodine/PhI(OAc)<sub>2</sub>.<sup>2104</sup> Trichloroethylsulfamate esters react with PhI(OAc)<sub>2</sub> and a Rh catalyst to give the

<sup>2104</sup> Fan, R.; Pu, D.; Gan, J.; Wang, B. *Tetrahedron Lett.* **2008**, *49*, 4925.

corresponding *N*-sulfonyl aziridine.<sup>2105</sup> Enantioselective aziridination of enones has been investigated.<sup>2106</sup> The formation of sulfonyl nitrene from *N,N*-dibromo-*p*-toluenesulfonamide (TsNBr<sub>2</sub>) when treated with K<sub>2</sub>CO<sub>3</sub> gave aziridines.<sup>2107</sup>

As discussed in Sec. 5.E, singlet nitrenes add stereospecifically while triplet nitrenes do not. Aminonitrenes (R<sub>2</sub>NN:) have been shown to add to alkenes<sup>2108</sup> to give *N*-substituted aziridines and to triple bonds to give 1-azirines, which arise from rearrangement of the initially formed 2-azirines.<sup>2109</sup>

An electrocatalytic method for the preparation of aziridines has been reported by the reaction of alkenes with *N*-aminophthalimide, a catalytic amount of Bu<sub>4</sub>NI, and LiClO<sub>4</sub> in ethanol.<sup>2110</sup>

1*H*-Azirines are unstable and tend to rearrange to the more stable 2*H*-azirine. 2*H*-Azirines are analogous to strained imines and can be reduced to give chiral aziridines.<sup>2111</sup> 2*H*-Azirines are commonly prepared by thermolysis of vinyl azides via formation of a nitrene.<sup>2112</sup> However, 1*H*-azirines are thought to be short-lived intermediates, and the isoquinoline-catalyzed synthesis of 1*H*-azirines from phenacyl bromides and *N,N'*-dialkylcarbodiimides did not give the antiaromatic 1*H*-azirines, but rather *N*-acyl-*N,N'*-dialkylureas.<sup>2113</sup>

Chloramine-T and NBS also give the *N*-tosyl aziridine,<sup>2114</sup> while Bromamine-T (TsNBr<sup>-</sup> Na<sup>+</sup>)<sup>2115</sup> and TsNIK<sup>2116</sup> have also been used in a similar manner. Other sulfonamide reagents can be used.<sup>2117</sup> The reaction of alkenes and PhI=NTs,<sup>2118</sup> as well as other

nitrene precursors, with a Cu or Co catalyst, gave the aziridine with good enantoselectivity.<sup>2119</sup> Chloramine-T has been used in ionic liquids with a Cu<sup>2120</sup> or Pd<sup>2121</sup> catalyst and methyl trioxorhenium (MeReO<sub>3</sub>) can be used in these reactions.<sup>2122</sup> Arylsulfonamides react with alkenes via the nitrene using an Au catalyst<sup>2123</sup> or a Cu catalyst.<sup>2124</sup> Diazoalkanes react with imines to give aziridines.<sup>2125</sup>

Aziridines were formed by the reaction of amino alcohols and ClSO<sub>3</sub>H followed by reaction with aqueous NaOH.<sup>2126</sup> Alkenes reacted with ArI=NSO<sub>2</sub>R using flow conditions (Sec. 7.D) to generate aziridines *in situ*, which then reacted with nucleophiles to give the sulfonamide derivative.<sup>2127</sup> Cyclic alkenes reacted with Cl<sub>3</sub>CCH<sub>2</sub>OCON<sub>3</sub> with an Ir catalyst and exposure to visible light to give the *N*-Troc aziridine.<sup>2128</sup> The Cu-catalyzed intramolecular hydroamination of hydroxylamine esters gave alkyl-substituted chiral aziridines.<sup>2129</sup> A Rh-catalyzed aziridination of alkenes used hydroxylamine-*O*-sulfonic acids as the nitrogen source.<sup>2130</sup>

The cation radical-induced cycloaddition of aryl imines and ethyl diazoacetate gave the aziridine.<sup>2131</sup> Organocatalysts have been used for the enantioselective aziridination of the C=C unit in conjugated aldehydes.<sup>2132</sup> The hydrozirconation of Boc-protected chiral allylic amines via reaction with Cp<sub>2</sub>Zr(H)Cl and then iodine, followed by reaction with NaHMDS, gave enantiomerically enriched *cis*-2,3-disubstituted azetidines.<sup>2133</sup> Nitrenes can also add to aromatic rings to give ring expansion products analogous to those mentioned in **15-58**.<sup>2134</sup> OS VI, 56.

### 15-51 Aminosulfenylation (Addition of Nitrogen, Sulfur)

An amino group and an aryl thio group can be added to a double bond by treatment with a sulfenamide (PhSNHAr) in the presence of BF<sub>3</sub>-etherate.<sup>2135</sup> The addition is *anti*, and the mechanism probably involves a thiiranium ion. In another aminosulfenylation procedure,

the substrate is treated with dimethyl(methylthio)sulfonium fluoroborate ( $\text{MeS}^+\text{SMe}_2\text{BF}_4^-$ ) and ammonia or an amine,<sup>2136</sup> the latter acting as a nucleophile. This reaction was extended to other nucleophiles:<sup>2137</sup>  $\text{N}_3^-$ ,<sup>2138</sup>  $\text{NO}_2^-$ ,  $\text{CN}^-$ ,  $^-\text{OH}$ , and  $^-\text{OAc}$  to give  $\text{MeS}-\text{C}-\text{C}-\text{A}$ , where  $\text{A} = \text{N}_3$ ,  $\text{NO}_2$ ,  $\text{CN}$ ,  $\text{OH}$ , and  $\text{OAc}$ , respectively. An RS (R = alkyl or aryl) and an NHCOME group have been added in an electrochemical procedure.<sup>2139</sup>

The Lewis basic selenophosphoramidate catalyst and a Brønsted acid co-catalyst gave enantioselective, intramolecular sulfenoamination of anion derivatives with alkene substituents that led to indolines, tetrahydroquinolines, and tetrahydrobenzazepines with good enantioselectivity.<sup>2140</sup> The vicinal sulfonamination of alkynes gave 3-sulfonylindoles by the reaction of 2-alkynyl arylazides with sulfinic acids in the presence of *tert*-butyl hydroperoxide.<sup>2141</sup>

### 15-52 Acyloxylation, Acylthiolation, and Acylamidation (Addition of Oxygen–Carbon, Sulfur–Carbon, or Nitrogen–Carbon)

An acyl group and an acyloxy group can be added to a double bond by treatment with an acyl fluoroborate and acetic anhydride.<sup>2142</sup> As expected, the addition follows Markovnikov's rule, with the electrophile  $\text{Ac}^+$  going to the carbon with more hydrogen atoms.

Mediated by  $\text{Ar}_2\text{I}^+\text{BF}_4^-$  and an Ir catalyst with visible light, styrene derivatives reacted with alcohols to give the diaryl alcohol and reacted with nitriles to give the diaryl amide.<sup>2143</sup> The Cu-catalyzed 1,2-alkyl esterification of 1,3-dienes with diacyl peroxides gave branched allylic esters.<sup>2144</sup> Aryldiazonium salts reacted with styrene derivatives with KOAc in aqueous acetonitrile to give the diaryl alcohol.<sup>2145</sup> The reaction of alkenes with phthalimides and  $\text{O}_2$  gave the *trans*-amido alcohol derivative<sup>2146</sup> whereas oxidation with  $\text{PhI}(\text{OAc})_2$  gave the *cis*-enamine.<sup>2147</sup>

In an analogous reaction, an acyl group and an amido group can be added to give a  $\beta$ -amido ketone, if a nitrile is used in place of the anhydride. Similarly, halo acetoxylation is known.<sup>2148</sup> Allenes reacted with anilines, CO, and methanol using  $\text{Cu}(\text{OCOEt})_2$  and a Pd catalyst to give the  $\alpha$ -arylamino acrylate derivative.<sup>2149</sup> The intramolecular carboamination reaction of tosylamides with a distal alkene with Selectfluor and AgOTf with a Pd

catalyst gave the 3-OCF<sub>3</sub>-substituted piperidine.<sup>2150</sup> The Cu-catalyzed intramolecular reaction of *N*-allyl amidines using PhI(OAc)<sub>2</sub> as an oxygen source gave 4-acetoxymethyl-4,5-dihydroimidazoles.<sup>2151</sup> The Pd-catalyzed reaction of an halomethylamide that has a distal alkene unit gave intramolecular aminoalkylation of unactivated alkenes which led to the pyrrolidinone derivative.<sup>2152</sup>

Both  $\gamma$ -lactams and pyrrolidines were prepared by the irradiation of alkenes and activated unsaturated amides or protected unsaturated amines using a mesityl acridinium single-electron photooxidant and a thiophenol co-catalyst.<sup>2153</sup>

This reaction has also been carried out on triple bonds, via addition.<sup>2154</sup>

### 15-53 The Conversion of Alkenes or Alkynes to Lactones (Addition of Oxygen, Carbon)

This reaction is clearly related to forming esters and lactones<sup>2155</sup> by reaction of carboxylic acids with alkenes (**15-6**), but the Mn reagent leads to differences. Alkenes react with manganese(III) acetate to give  $\gamma$ -lactones.<sup>2156</sup> The mechanism is probably free radical, involving addition of  $\bullet\text{CH}_2\text{COOH}$  to the double bond. Ultrasound improves the efficiency of the reaction.<sup>2157</sup> In a related reaction, cyclohexene reacted with MeO<sub>2</sub>CCH<sub>2</sub>CO<sub>2</sub>K and Mn(OAc)<sub>3</sub> to give an  $\alpha$ -carbomethoxy bicyclic lactone.<sup>2158</sup> The use of dimethyl malonate and ultrasound in this reaction gave the same type of product.<sup>2159</sup> Lactone formation has also been accomplished by treatment of alkenes with  $\alpha$ -bromo carboxylic acids in the presence of benzoyl peroxide as catalyst,<sup>2160</sup> and with alkylidene Cr(CO)<sub>5</sub> complexes.<sup>2161</sup> Cyclic dienes react with  $\beta$ -keto esters, in the presence of a Ga<sup>2162</sup> catalyst and water, to give an  $\alpha$ -acyl bicyclic lactone.

The enantioselective cyclization of carboxylic acids with a distal alkene unit gave the corresponding lactone via radical formation by treatment with 2 equivalents of 2,6-di-*t*-butylpyridine, Cu catalyst, and, in a reaction with various electrophiles (including aryldiazonium salts), gave the aryl derivative.<sup>2163</sup> Xanthates were used in 5-*exo-trig*

radical cyclizations to give lactones.<sup>2164</sup> The cyclization of 4-bromo-3-yn-1-ols to give  $\gamma$ -butyrolactones used a Au catalyst in wet toluene.<sup>2165</sup> The Au-catalyzed cycloisomerization/oxidation of homopropargyl alcohols using mcpba as the oxidant gave  $\gamma$ -lactones.<sup>2166</sup> The Ir-catalyzed reaction under visible light photoredox conditions gave the  $\gamma$ -lactone by reaction of arylalkenes and  $\alpha$ -bromo esters in aqueous acetonitrile and  $\text{LiBF}_4$ .<sup>2167</sup> The reaction of lithium enediolates, generated by reaction of aliphatic carboxylic acids with butyllithium or LDA, followed by reaction with vinylsulfoxonium and  $\alpha,\beta$ -unsaturated sulfoxonium salts gave primarily the *trans*- $\alpha,\beta$ -disubstituted  $\gamma$ -lactones.<sup>2168</sup>  $\gamma$ -Lactones and  $\gamma$ -lactams were prepared by intramolecular Pd-catalyzed reactions.<sup>2169</sup>

Larger ring conjugated lactones were prepared by the reaction of 2-alkoxytetrahydropyrans with 1-trimethylsilyl alkynes with  $\text{BF}_3 \cdot \text{OEt}_2$ .<sup>2170</sup> Homoallylic carboxylic acids such as (*E*)-4-phenylbut-3-enoic acid reacted with *N*-trifluoromethylthiosaccharin as the  $\text{SCF}_3$  reagent and a selenide as the catalyst in the presence of triflic acid and gave the  $\beta$ -trifluoromethylthiolated lactone.<sup>2171</sup>

Alkenyl acids cyclize to the corresponding lactone upon treatment with sodium hypochlorite and a Lewis acid.<sup>2172</sup> Alkynyl acids cyclize upon treatment with PIFA [phenyliodine(III)-bis(trifluoroacetate)] to give  $\omega$ -acyl lactones.<sup>2173</sup> A variation of this reaction also employs a diselenide.<sup>2174</sup> Treatment of alkynyl acids with a Au catalyst<sup>2175</sup> leads to an alkyldiene lactone. An intramolecular variation involving amides is known, and generates a lactam.<sup>2176</sup>

alkynes.<sup>2178</sup> This reaction is quite useful in the synthesis of alkaloids,<sup>2179</sup> including asymmetric syntheses.<sup>2180</sup> These dipolar compounds have a sequence of three atoms  $a-b-c$ , of which  $a$  has a sextet of electrons in the outer shell and  $c$  an octet with at least one unshared pair (see Table 15.3).<sup>2181</sup> The reaction can then be formulated as shown to generate a five-membered ring. Note that the initial reaction of potassium permanganate (**15-44**) occurs by [3 + 2] cycloaddition to give a manganate ester (**47**).<sup>2182</sup>

1,3-Dipoles of the type shown in Table 15.3 have an atom with six electrons in the outer shell, which is usually unstable, and they will delocalize the charge to alleviate this electronic arrangement (i.e., they are *resonance stabilized*). 1,3-Dipolar compounds can be divided into two main types:

1. Those in which the dipolar canonical form has a double bond and the other canonical form has a triple bond on that atom:

If the discussion is limited to the first row of the periodic table,  $b$  can only be nitrogen,  $c$  can be carbon or nitrogen, and  $a$  can be carbon, oxygen, or nitrogen; hence there are six types. Among these are azides ( $a = b = c = \text{N}$ ) and diazoalkanes.

2. Those in which the dipolar canonical form has single bonds and the other form has a double bond:

Here  $b$  can be nitrogen or oxygen, and  $a$  and  $c$  can be nitrogen, oxygen, or carbon, but there are only 12 types, since, for example,  $\text{N}-\text{N}-\text{C}$  is only another form of  $\text{C}-\text{N}-\text{N}$ . Examples are shown in Table 15.3.

<sup>2182</sup> Houk, K.N.; Strassner, T. *J. Org. Chem.* **1999**, *64*, 800.

Of the 18 systems, some of which are unstable and must be generated *in situ*,<sup>2183</sup> the reaction has been accomplished for at least 15, but not in all cases with a carbon–carbon double bond (the reaction also can be carried out with other double bonds<sup>2184</sup>). Not all alkenes undergo 1,3-dipolar addition equally well. The reaction is most successful for those that are good dienophiles in the *Diels-Alder reaction* (15-56).

The addition is stereospecific and *syn*, largely controlled by frontier molecular orbital (FMO) considerations,<sup>2185</sup> and the mechanism is probably a one-step concerted process.<sup>2186</sup> Reactivity has been shown to correlate with the energy required to distort 1,3-dipoles and dipolarophiles to the transition state.<sup>2187</sup> In-plane aromaticity has been invoked for these dipolar cycloadditions.<sup>2188</sup> As expected for this type of mechanism, the rates do not vary much with changes in solvent,<sup>2189</sup> although rate acceleration has been observed in ionic liquids.<sup>2190</sup>

There are no simple rules covering orientation in 1,3-dipolar additions. The regioselectivity has been explained by molecular orbital treatments,<sup>2201</sup> where overlap of the largest orbital coefficients of the atoms forming the new bonds leads to the major regioisomer. In a theoretical study of the 1,3-dipolar cycloadditions (diazomethane and ethene; fulminic acid [H–C≡N–O] and ethyne),<sup>2202</sup> calculations based on valence bond descriptions suggest that many concerted 1,3-dipolar cycloaddition reactions follow an electronic heterolytic mechanism where the movement of well-identifiable orbital pairs is retained along the entire reaction path from reactants to product.<sup>2203</sup> When the 1,3-dipolar compound is a thiocarbonyl ylid ( $R_2C=S^+-CH_2^-$ ), the addition has been shown to be nonstereospecific with certain substrates but stereospecific with others, indicating a nonsynchronous mechanism in these cases. In fact, a diionic intermediate (see mechanism *c* in **15-59**, category 4) has been trapped in one such case.<sup>2204</sup>

Many of the cycloadducts formed from the dipoles in Table 15.3 are unstable, leading to other products. The reaction of alkyl azides with alkenes generates triazolines (**15-50**), which extrude nitrogen (N≡N) upon heating or photolysis to give an aziridine.<sup>2205</sup> With a transition metal catalyst, alkyl azides add to alkynes to give triazoles.<sup>2206</sup> Retro [3 + 2] cycloaddition reactions are also known.<sup>2207</sup> Cycloaddition of azides to allenes leads to pyrrolidines.<sup>2208</sup> The 1,3-dipolar reagent can in some cases be generated by the *in situ* opening of a suitable three-membered ring system. For example, aziridines open to give a zwitterion that can add to activated double bonds to give pyrrolidines.<sup>2209</sup> Conjugated dienes generally give exclusive 1,2-addition, although 1,4-addition (a [3 + 4] cycloaddition) has been reported.<sup>2210</sup>

A lot of research continues in this area. It is noted that diazomethane has been generated using flow conditions (Sec. 7.D).<sup>2211</sup> The reaction of azides and nitriles gave tetrazoles, and has been done using flow conditions.<sup>2212</sup> The chemistry of nitrilium ions has been reviewed.<sup>2213</sup> Diazoketones reacted with ynamides using both batch and flow photochemical conditions.<sup>2214</sup> It is noted that diazoketones have been prepared using flow conditions (Sec. 7.D).<sup>2215</sup>

Nitrile oxide cycloadditions have also been done in supercritical carbon dioxide.<sup>2216</sup> Oximes are precursors to nitrile oxides.<sup>2217</sup> Ionic liquids have been developed for cycloaddition reactions of azides.<sup>2218</sup> Brønsted acid-catalyzed reactions of hydrazones gave hydrazone/ phosphoramidate anion complexes and [3 + 2] cycloadditions with alkenes gave pyrazolidines.<sup>2219</sup> The first 1,3-dipolar cycloaddition of 1,2-cyclohexadiene, generated *in situ*, and trapped with nitrones gave isoxazolidine products.<sup>2220</sup> Oxallyl cations have been used in [3 + 2] cycloaddition reactions,<sup>2221</sup> and the reaction with alkynes leads to cyclopentanone derivatives (**15-55**). Trimethylenemethane reacted with imines using a Pd catalyst to give pyrrolidines.<sup>2222</sup> The Rh-catalyzed [3 + 2] cycloaddition of vinyl diazoacetates with nitrones gave 2,5-dihydroisoxazoles.<sup>2223</sup> The reaction of isocyanides and alkynes gave pyrroles using a Ag catalyst,<sup>2224</sup> and oxazoles were formed by reaction with carboxylic acids and a Zn catalyst.<sup>2225</sup>

When diazoalkanes (including diazo acetates such as ethyl diazoacetate, N<sub>2</sub>CHCO<sub>2</sub>Et) react with an alkene and a Cr catalyst, the initially formed product is a five-membered ring, a pyrazoline.<sup>2226</sup> *Pyrazolines are generally unstable and extrusion of nitrogen leads to a cyclopropane.*<sup>2227</sup> Nitrones react with conjugated carbonyl compounds, with a transition metal catalyst such as a Ti complex, to give an 1,2-oxazoline.<sup>2228</sup> [3 + 2] cycloaddition reactions occur intramolecularly to generate bicyclic and polycyclic compounds.<sup>2229</sup> The intramolecular cycloaddition of azomethine imines give bicyclic pyrazolidines, for example.<sup>2230</sup>

There are many cases where the [3 + 2] cycloaddition leads to cycloadducts with high enantioselectivity.<sup>2231</sup> Cycloaddition of diazo esters with a Co catalyst having a chiral

ligand leads to cyclopropane derivatives with good enantioselectivity.<sup>2232</sup> Cycloaddition of nitrones and pyrazolinones with a Cu catalyst and a chiral ligand leads to pyrrolidine derivatives with good enantioselectivity.<sup>2233</sup> In the presence of a Ni catalyst and a chiral ligand, nitrones react with activated cyclopropanes to give tetrahydro-1,2-oxazines, with high enantioselectivity.<sup>2234</sup>

Carbon–carbon triple bonds can also undergo 1,3-dipolar addition.<sup>2235</sup> For example, azides react with alkynes to give triazoles, **55**. This reaction has been called the *Huisgen cycloaddition*,<sup>2236</sup> and this reaction has been identified by Sharpless as one of the important reactions for “click” chemistry.<sup>2237</sup> It has been shown that cyclohexyne can also be used.<sup>2238</sup>

Enantioselective Ni-catalyzed cycloaddition reactions have been reviewed.<sup>2239</sup> The Ru-catalyzed azide alkyne cycloaddition has been reviewed.<sup>2240</sup> Cyclooctyne derivatives that have a distal azide moiety as well as a distal oxime moiety reacted intramolecularly via the alkyne unit and the azide to give the 1,2,3-triazole in methanol and via the alkene and the nitrile oxide derived from the oxime when treated with [bis(acetoxy)iodo]benzene to give the isoxazole.<sup>2241</sup> Aziridines also add to C≡C triple bonds as well as to other unsaturated linkages, including C=O, C=N, and C≡N.<sup>2242</sup> In some of these reactions it is a C–N bond of the aziridine that opens rather than the C–C bond.

OS V, 957, 1124; VI, 592, 670; VIII, 231. Also see, OS IV, 380.

## A. Carbon on Both Sides<sup>2243</sup>

### 15-55 All-Carbon [3 + 2] Cycloadditions<sup>2244</sup>

Several methods have been reported for the formation of cyclopentanes by [3 + 2] cycloadditions.<sup>2245</sup> Heating conjugated ketones with trialkylphosphines generates an intermediate

that adds to conjugated alkynes.<sup>2246</sup> One method involves reagents that produce intermediates **56** or **57**.<sup>2247</sup> Note that **57** also reacts with *N*-tosyl aziridines, with 20% *n*-butyllithium and 10% of Pd(OAc)<sub>2</sub>, to give a vinylidene piperidine derivative.<sup>2248</sup> Similar or identical intermediates generated from bicyclic azo compounds **58** (see **17-32**) or methylenecyclopropane **59**<sup>2249</sup> also add to activated double bonds. With suitable substrates, the addition can be enantioselective.<sup>2250</sup>

A synthetically useful example<sup>2251</sup> uses 2-[(trimethylsilyl)methyl]-2-propen-1-yl acetate (**60**) (which is commercially available) and a Pd or other transition metal catalyst to generate **56** or **57**, which adds to double bonds to give cyclopentanes with an exocyclic double bond. The reaction occurs with **60** to generate trimethylenemethane *in situ*, which reacts with alkenes to give methylenecyclopentane derivatives.<sup>2252</sup>

A similar reaction occurs with imines to give methylene pyrrolidines.<sup>2253</sup> The Pd-catalyzed reaction with carbon dioxide leads to butenolides.<sup>2254</sup> The Pd-catalyzed reaction of trimethylenemethane with aldehydes gave methylenetetrahydrofurans.<sup>2255</sup> Tetramethylenethane equivalents have been used for cycloaddition reactions.<sup>2256</sup>

The Rh(I)-catalyzed intramolecular [3 + 2] cycloaddition reactions of 1-ene- and 1-ynevinylcyclopropanes gave bicyclic products.<sup>2257</sup> The [3 + 2] reaction of aryl cyclopropyl ketones with alkenes, using a photocatalytic system comprising Ru(bpy)<sub>3</sub><sup>2+</sup>, La(OTf)<sub>3</sub>, and TMEDA, gave cyclopentane rings via an intermediate radical anion.<sup>2258</sup> Cyclopropyl

ketones also reacted with alkynes using a Ni/Al co-catalyst system.<sup>2259</sup> The cycloaddition of allenes to acrylates gave cyclopentenones using a dipeptide-derived phosphine catalyst.<sup>2260</sup>

The phosphine-catalyzed intramolecular [3 + 2] annulation of allenes with alkenes gave cyclopentene derivatives.<sup>2261</sup> The Sc(OTf)<sub>3</sub>-catalyzed [3 + 2] annulation reaction between cyclopropanones and donor–acceptor cyclopropanes gave 4-oxaspiro[2.4]hept-1-ene derivatives.<sup>2262</sup>

An antibody-catalyzed [3 + 2] cycloaddition has been reported.<sup>2263</sup> Metal-assisted dipolar additions are also known.<sup>2264</sup> In a different metal-mediated reaction, alkenyl *Fischer carbene complexes* reaction with alkynes, in the presence of a Ni catalyst, to give cyclopentenones.<sup>2265</sup> Fischer carbene complexes take the form R<sub>2</sub>C=M(CO)<sub>x</sub>,<sup>2266</sup> and the metals include those of low oxidation state, and Fe, Mo, Cr, or W. Ligands include π electron acceptors and π donor substituents on methylene groups, such as alkoxy and amino groups.

In a different type of procedure, [3 + 2] cycloadditions are performed with allylic anions. Such reactions are called 1,3-anionic cycloadditions.<sup>2267</sup> For example, α-methylstyrene adds to stilbene on treatment with the strong base LDA to give 1,3,5-triphenylcyclopentane.<sup>2268</sup> In these cases the reagent is an allylic anion, but similar [3 + 2] cycloadditions involving allylic cations have also been reported.<sup>2269</sup>

OS VIII, 173, 347.

## 15-56 The Diels-Alder Reaction<sup>2270</sup>

In the prototype *Diels-Alder reaction* the double bond of an alkene adds 1,4 to a conjugated diene (a [4 + 2] cycloaddition),<sup>2271</sup> so the product is always a cyclohexene. The cycloaddition is not limited to alkenes or to dienes (see 15-57). The substrate that reacts with the diene is called a *dienophile*. The reaction is of very broad scope<sup>2272</sup> and reactivity of

dienes and dienophiles can be predicted based on analysis of the HOMOs<sup>2273</sup> and LUMOs of these species (using frontier molecular orbital theory, FMO).<sup>2274</sup> Ethylene and simple alkenes make poor dienophiles, unless high temperatures and/or pressures are used.<sup>2275</sup> Most dienophiles are of the form  $-C=C-Z$  or  $Z-C=C-Z'$ , where  $Z$  and  $Z'$  are electron-withdrawing groups.<sup>2276</sup> The industrial applications of the Diels-Alder reaction have been reviewed.<sup>2277</sup>

Electron-withdrawing groups may be incorporated to facilitate the Diels-Alder reaction of simple alkenes and then removed after cycloaddition. An example is phenyl vinyl sulfone  $\text{PhSO}_2\text{CH}=\text{CH}_2$ ,<sup>2278</sup> as the  $\text{PhSO}_2$  group can be easily removed with  $\text{Na/Hg}$  after the ring-closure reaction. Similarly, phenyl vinyl sulfoxide  $\text{PhSOCH}=\text{CH}_2$  can be used as a synthon for acetylene.<sup>2279</sup> In this case  $\text{PhSOH}$  is lost from the sulfoxide product (**17-10**). Dehydrogenation of pericyclic reactions leads to dehydropericyclic processes, and formation of strained or reactive intermediates.<sup>2280</sup>

Electron-donating substituents in the diene accelerate the reaction; electron-withdrawing groups retard it.<sup>2281</sup> For the dienophile it is just the reverse: electron-donating groups decrease the rate, and electron-withdrawing groups increase it. The *s-cis* (cisoid) conformation is required for the cycloaddition,<sup>2282</sup> and acyclic dienes are conformationally mobile so the *s-cis* conformation will be available.<sup>2283</sup> Cyclic dienes, in which the *s-cis* conformation is built in, usually react faster than the corresponding open-chain compounds, which have to achieve the *s-cis* conformation by rotation.<sup>2284</sup> Dienes may not be frozen into a *s-trans* (transoid) conformation (see **64**). Nearly all conjugated dienes undergo the reaction with suitable dienophiles.<sup>2285</sup> Quinones are important dienophiles<sup>2286</sup> and arynes have been used as dienophiles.<sup>2287</sup>

While Diels-Alder reactions generally require no catalyst, they do require heating. Brønsted acids have been used to accelerate the rate of the Diels-Alder reaction.<sup>2288</sup> Diels-Alder reactions have been done in ionic liquids (Sec. 9.D.iii).<sup>2289</sup> Solvent-free Diels-Alder reactions are known.<sup>2290</sup> Lewis acids are effective catalysts,<sup>2291</sup> particularly for those reactions in which Z (an electron-withdrawing group) in the dienophile is a C=O or C=N group.<sup>2292</sup> Chemoselectivity is related to the choice of Lewis acid or Brønsted-Lowry acid catalyst.<sup>2293</sup> A Lewis acid catalyst usually increases both the regioselectivity of the reaction (in the sense given above) and the extent of *endo* addition,<sup>2294</sup> and, in the case of enantioselective reactions, the extent of enantioselectivity. It has been shown that a rigid bicyclo[2.2.2]octene-based diene lowers the Diels-Alder activation energy by 5.4 kcal mol<sup>-1</sup> (22.6 kJ mol<sup>-1</sup>) compared with the acyclic analog in a so-called proximity-induced Diels-Alder reaction.<sup>2295</sup>

A great many catalysts have been developed for aqueous Diels-Alder reactions<sup>2296</sup> including catalysts that can be used for ionic Diels-Alder reactions.<sup>2297</sup> Transition metal-based catalysts have been developed, including those based on Cu<sup>2298</sup> or Fe.<sup>2299</sup> Lanthanum triflate [La(OTf)<sub>3</sub>] has been reported as a reusable catalyst<sup>2300</sup> and Me<sub>3</sub>SiNTf<sub>2</sub> has been used as a green Lewis acid catalyst.<sup>2301</sup> Trimethylaluminum/triflimide complexes have been used to catalyze the Diels-Alder reaction of highly hindered systems.<sup>2302</sup> Certain antibodies have been developed that catalyze Diels-Alder reactions.<sup>2303</sup> Natural Diels-Alderase enzymes have been reported but whether the reactions proceed via the concerted, synchronous pericyclic transition state required is an open question.<sup>2304</sup> Several organocatalysts have been developed, including amino catalysts,<sup>2305</sup> *N*-heterocyclic carbenes,<sup>2306</sup> and organocatalysts that are suitable for ionic liquid/water phases.<sup>2307</sup> An

enantioselective, organocatalyzed Diels–Alder reaction has been reported using flow conditions (Sec. 7.D).<sup>2308</sup>

Cationic Diels–Alder catalysts have been developed, such as oxazaborolidine catalysts.<sup>2309</sup> Zirconocene-catalyzed cationic Diels–Alder reactions are known.<sup>2310</sup> Some Diels–Alder reactions can also be catalyzed by the addition of a stable cation radical.<sup>2311</sup> Radical cation Diels–Alder reactions have been reported using visible light photocatalysis.<sup>2312</sup> Photochemically induced Diels–Alder reactions are also known.<sup>2313</sup>

Apart from addition of Lewis acids, a number of other methods have been reported for the acceleration of Diels–Alder reactions,<sup>2314</sup> including the use of microwave irradiation,<sup>2315</sup> ultrasound,<sup>2316</sup> and the use of an ultracentrifuge<sup>2317</sup> (one of several ways to achieve reaction at high pressures).<sup>2318</sup> Solid state Diels–Alder reactions are known,<sup>2319</sup> reactions on solid supports have also been reported,<sup>2320</sup> and zeolites have been used in conjunction with catalytic agents.<sup>2321</sup> One of the most common methods is to use water as a solvent or a co-solvent (a hydrophobic effect).<sup>2322</sup> There are cases of hydrogen-bonding acceleration.<sup>2323</sup> The influence of hydrophobicity of reactants on the reaction has been examined,<sup>2324</sup> as has micellar effects.<sup>2325</sup> It is noted that Diels–Alder reactions have been done in supercritical CO<sub>2</sub><sup>2326</sup> and in supercritical water.<sup>2327</sup> Diels–Alder reactions can be done in ionic liquids,<sup>2328</sup> including asymmetric Diels–Alder reactions.<sup>2329</sup> It has been pointed out that the rate of Diels–Alder reactions is faster in water than in ionic liquids.<sup>2330</sup> Solvent effects are clearly important in cycloaddition reactions.<sup>2331</sup> Another alternative reaction medium is the

use of 5 M LiClO<sub>4</sub> in Et<sub>2</sub>O as solvent.<sup>2332</sup> An alternative to lithium perchlorate in ether is lithium triflate in acetonitrile.<sup>2333</sup> The addition of HPO<sub>4</sub><sup>-</sup> to an aqueous ethanol solution has also been shown to give a small rate enhancement.<sup>2334</sup>

When an unsymmetrical diene adds to an unsymmetrical dienophile, regioisomeric products (not counting stereoisomers) are possible. Rearrangements have been encountered in some cases.<sup>2335</sup> In simple cases, 1-substituted dienes give cyclohexenes with a 1,2- and a 1,3-substitution pattern. 2-Substituted dienes lead to 1,4- and 1,3-disubstituted products. Although mixtures are often obtained, one usually predominates, the one labeled “major,” but selectivity depends on the nature of the substituents on both diene and alkene.

This regioselectivity, in which the “*ortho*” or “*para*” product is favored over the “*meta*,” has been explained by molecular orbital considerations.<sup>2336</sup> Competing reactions are polymerization of the diene or dienophile, or both, and [1,2] cycloaddition (15-59).

The stereochemistry of the Diels-Alder reaction can be considered from several aspects:<sup>2337</sup>

1. With respect to the dienophile, the addition is stereospecifically *syn*, with very few exceptions.<sup>2338</sup> This means that groups that are *cis* in the alkene will be *cis* in the cyclohexene ring, and groups that are *trans* in the alkene will be *trans* in the cyclohexene ring.
2. With respect to 1,4-disubstituted dienes, fewer cases have been investigated, but here too the reaction is stereospecific and *syn*. Thus, *trans,trans*-1,4-diphenylbuta-1,3-diene gives *cis*-1,4-diphenylcyclohexene derivatives. This selectivity is predicted by disrotatory motion of the substituent in the transition state<sup>2339</sup> of the reaction (see 18-27).
3. The diene must be in the *s-cis* conformation. If it is frozen into the *s-trans* conformation, as in 64 (see above), the reaction does not take place. The diene either must be frozen into the *s-cis* conformation or must be able to achieve it during the reaction.
4. There are two possible ways in which addition can occur to a cyclic diene, if the dienophile is not symmetrical – say a monosubstituted alkene. The substituent on

the dienophile (usually an electron-withdrawing substituent) may approach under the ring (*endo* addition), or away from the ring (*exo* addition), as shown.

Most of the time, the addition is predominantly *endo*; that is, the more bulky side of the alkene is under the ring, and this is probably true for open-chain dienes also.<sup>2340</sup> However, exceptions are known, and in many cases mixtures of *exo* and *endo* addition products are found.<sup>2341</sup> Secondary orbital interactions<sup>2342</sup> have been invoked, but this approach has been called into question.<sup>2343</sup> There has been a direct evaluation of such interactions, however.<sup>2344</sup> It has been argued that facial selectivity is not due to torsional angle decompression.<sup>2345</sup> The *endo/exo* ratio can be influenced by the nature of the solvent.<sup>2346</sup>

- As seen previously, the Diels-Alder reaction can be both stereoselective and regioselective.<sup>2347</sup> In some cases, the Diels-Alder reaction can be made enantioselective,<sup>2348</sup> as described above. Solvent effects are important in such reactions.<sup>2349</sup> The role of reactant polarity on the course of the reaction has been examined.<sup>2350</sup> Most enantioselective Diels-Alder reactions have used a chiral dienophile (e.g., **65**) and an achiral diene,<sup>2351</sup> along with a Lewis acid catalyst.

In such cases, addition of the diene to the two faces<sup>2352</sup> of **65** takes place at different rates, and **66** and **67** are formed in different amounts.<sup>2353</sup> An achiral compound can be converted to a chiral compound by a chemical reaction with a compound that is diastereoselective, but each diastereomer is enantiopure. After the reaction, the resulting diastereomers can be separated, providing enantiopure compounds, each with a bond between the molecule of interest and the chiral compound (a chiral auxiliary). Common chiral auxiliaries include chiral carboxylic acids, alcohols, or sultams. In the case illustrated, hydrolysis of the product removes the chiral R group, making it a chiral auxiliary in this reaction. Asymmetric Diels-Alder reactions have also been carried out with achiral dienes and achiral dienophiles, but with an optically active catalyst.<sup>2354</sup> In many cases, asymmetric Lewis acids form a chiral complex with the dienophile.<sup>2355</sup> Chiral organocatalysts are increasingly important.<sup>2356</sup>

Triple bond compounds ( $-\text{C}\equiv\text{C}-\text{Z}$  or  $\text{Z}-\text{C}\equiv\text{C}-\text{Z}'$ ) may be dienophiles,<sup>2357</sup> generating nonconjugated cyclohexadienes (**68**), and this reaction can be catalyzed by transition metal compounds.<sup>2358</sup>

Aromatic rings can be generated by cycloaddition of aryl alkynes.<sup>2359</sup> Allenes react as dienophiles,<sup>2360</sup> but without activating groups they are very poor dienophiles.<sup>2361</sup> Ketenes, however, do not undergo Diels-Alder reactions.<sup>2362</sup>

Many interesting compounds can be prepared by the Diels-Alder reaction,<sup>2363</sup> some of which would be hard to make in any other way. Benzyne, although not isolable, act as

dienophiles and can be trapped with dienes, as shown for the preparation of **69** from benzyne and cyclopentadiene.<sup>2364</sup>

Naphthalene and phenanthrene are poor reaction partners, although naphthalene has given Diels-Alder addition at high pressures.<sup>2365</sup> Anthracene and other compounds with at least three linear benzene rings give Diels-Alder reactions readily.

For both all-carbon and hetero systems, the “diene” can be a conjugated enyne. If the geometry of the molecule is suitable, the diene can even be nonconjugated, as shown with bicyclo[2.2.1]hepta-2,5-diene.<sup>2366</sup>

The reaction shown above is known as the *homo-Diels-Alder reaction*. A similar reaction has been reported with alkynes, using a mixture of a Co complex, ZnI<sub>2</sub>, and Bu<sub>4</sub>N<sup>+</sup> BH<sub>4</sub><sup>-</sup>.<sup>2367</sup>

Intramolecular versions of the Diels-Alder reaction are well known,<sup>2368</sup> and they are a powerful method for the synthesis of mono- and polycyclic compounds.<sup>2369</sup> The origin of *cis/trans* stereoselectivity has been examined using density functional theory.<sup>2370</sup> Enantioselective organocatalytic intramolecular Diels-Alder reactions are known.<sup>2371</sup>

Internal Diels-Alder reactions can be accomplished by linking the diene and alkene by a tether, usually of carbon atoms. Dienophile twisting and substituent effects influence the rate of cycloaddition.<sup>2372</sup> Replacing the tether with functional groups allow the selectivity inherent to the intramolecular cycloaddition, but the tether can be cleaved to give a functionalized cyclohexene derivative. Such tethered reactions allow enhancement of stereoselectivity,<sup>2373</sup> and sometimes reactivity, relative to an untethered reaction,

giving an indirect method for enhancing those parameters. Tethers or linkages include C—O—SiR<sub>2</sub>—C,<sup>2374</sup> C—O—SiR<sub>2</sub>—O—C,<sup>2375</sup> or hydroxamides.<sup>2376</sup> The nature of the tether plays a role in *cis/trans* selectivity for the intramolecular reaction.<sup>2377</sup>

Aromatic derivatives can be prepared from more saturated precursors via a two-step process defined as a *dehydrogenative Diels-Alder reaction*.<sup>2378</sup> In initial studies, the dehydrogenative cycloaddition of dieneynes possessing a diene in the form of a styrene moiety, such as **70**, gave the cycloadduct, **71**.<sup>2378</sup> A hexadehydro Diels-Alder cycloisomerization has been reported.<sup>2379</sup>

The Diels-Alder reaction is usually reversible, although the retro reaction typically occurs at significantly higher temperatures than the forward reaction. However, the reaction is reversible<sup>2380</sup> and this fact has been used synthetically. The *retro*-Diels-Alder reaction has also been done in water.<sup>2381</sup> A convenient substitute for butadiene in the Diels-Alder reaction is the compound 3-sulfolene since the latter is a solid, which is easy to handle, while butadiene is gas.<sup>2382</sup> Butadiene is generated *in situ*; 3-sulfolene is heated and a reverse Diels-Alder reaction generates SO<sub>2</sub> and buta-1,3-diene, which reacts with a suitable alkene.

There are, broadly speaking, three possible mechanisms that have been considered for the uncatalyzed Diels-Alder reaction.<sup>2383</sup>

1. The bulk of the evidence suggests that most Diels-Alder reactions take place by the one-step cyclic mechanism,<sup>2384</sup> although it is possible that a diradical<sup>2385</sup> or even a diion<sup>2386</sup> mechanism may be taking place in some cases.
2. Electrophilicity/nucleophilicity indices have been analyzed to understand the mechanism of polar Diels-Alder reactions.<sup>2387</sup>
3. Radical cation Diels-Alder reactions have been considered.<sup>2388</sup>

The main evidence in support of the one-step mechanism is as follows:

1. The reaction is stereospecific in both the diene and dienophile. A completely free diradical or diion probably would not be able to retain its configuration.
2. In general, the rates of Diels-Alder reactions depend very little on the nature of the solvent. This observation would rule out a diion intermediate because polar solvents increase the rates of reactions that develop charges in the transition state.
3. It was shown that, in the decomposition of **72**, the isotope effect  $k_I/k_{II}$  was equal to 1.00 within experimental error.<sup>2389</sup>

If bond  $x$  were to break before bond  $y$ , there should surely be a secondary isotope effect. This result strongly indicates that the bond breaking of  $x$  and  $y$  is simultaneous. This is the reverse of a Diels-Alder reaction and, by the principle of microscopic reversibility, the mechanism of the forward reaction should involve simultaneous formation of bonds  $x$  and  $y$ . Subsequently, a similar experiment was carried out on the forward reaction<sup>2390</sup> and the result was the same. There is other evidence for this mechanism.<sup>2391</sup> However, the fact that the mechanism is concerted does not necessarily mean that it is synchronous.<sup>2392</sup> In the transition state of a synchronous reaction both new  $\sigma$  bonds would be formed to the same extent. However, a Diels-Alder reaction with nonsymmetrical components might very well be nonsynchronous;<sup>2393</sup> that is, it could have a transition state in which one bond has been

formed to a greater degree than the other.<sup>2393,2394</sup> A biradical mechanism has been proposed for some Diels-Alder reactions.<sup>2395</sup>

Normally, a reactive alkene has electron-withdrawing groups and is considered to be an electrophile.<sup>2396</sup> If the alkene contains strongly electron-releasing groups and the diene has strongly electron-withdrawing groups, reactivity can be reversed. Perchlorocyclopentadiene reacts better with cyclopentene than with maleic anhydride, for example, and not at all with tetracyanoethylene, although the latter is normally the most reactive dienophile known. Reactions of this type are said to proceed with *inverse electron demand*.<sup>2397</sup> It is known that alkynyl boronates participate in inverse electron demand cyclization.<sup>2398</sup> The Ag-catalyzed inverse demand reaction of 1,2-diazines and siloxyalkynes has been reported.<sup>2399</sup>

The Diels-Alder reaction generally takes place rapidly and conveniently. In sharp contrast, the apparently similar dimerization of alkenes to cyclobutanes (**15-59**) gives very poor results in most cases, except when photochemically induced. Woodward and Hoffmann have shown that these contrasting results can be explained by the *principle of conservation of orbital symmetry*,<sup>2400</sup> which predicts that certain reactions are allowed and others forbidden. The orbital symmetry rules (also called the *Woodward-Hoffmann rules*)<sup>2401</sup> apply *only to concerted reactions*, for example, and are based on the principle that reactions take place in such a way as to maintain maximum bonding throughout the course of the reaction. In separate work, Fukui<sup>2402</sup> used molecular orbital arguments to explain these reactions. There are several ways of applying the orbital symmetry principle to cycloaddition reactions, three of which are used more frequently than others.<sup>2403</sup> Of these three, two will be discussed: the frontier orbital method and the Möbius-Hückel method. The third, called the correlation diagram method,<sup>2404</sup> is less convenient to apply than the other two.

**FIGURE 15.1.** Schematic drawings of the  $\pi$  orbitals of an isolated C=C bond and a conjugated diene.

The Frontier Orbital Method<sup>2405</sup> As applied to cycloaddition reactions, the rule is that reactions are allowed only when all overlaps between the highest occupied molecular orbital (HOMO) of one reactant and the lowest unoccupied molecular orbital (LUMO) of the other are such that a positive lobe overlaps only with another positive lobe and a negative lobe only with another negative lobe.<sup>2406</sup> Recall that monoalkenes have two  $\pi$  molecular orbitals (Sec. 1.D) and that conjugated dienes have four (Sec. 2.C), as shown in Figure 15.1.

A concerted cyclization of two monoalkenes (a [2 + 2] reaction) is not allowed because it would require that a positive lobe overlap with a negative lobe (Figure 15.2).
