Photoremovable protecting groups are enjoying a resurgence of interest since their introduction by Kaplan[1a] and Epstein[1b] in the late 1970s. A review of published work since 1993[2] is timely and will provide information about several new groups that have been recently developed. The scope of this review is, therefore, limited to recent developments in the field and will cover only the applications with major functional groups that have been "protected" by a photoremovable chromophore. The review is not intended to be comprehensive but focuses instead on a series of well-chosen examples of chromophores that were deployed as protecting groups with a select group of representative functional groups. Because the focus of this review is the application of photoremovable protecting groups, emphasis is placed on synthesis of the protected functionality and on the procedures employed for deprotection, including the protection and photodeprotection yields, the deprotection reaction rates, and the quantum efficiencies, when available. An attempt has been made to list the advantages and disadvantages of each photoremovable protecting group as well as a brief discussion of the mechanism for the photodeprotection.

0-8493-1348-1/04/$0.00+$1.50

When the literature is insufficient for providing a comprehensive treatment of applications of a photoprotecting group, then only a brief discussion is provided. An exhaustive list of applications for any of the chromophores is not included; these may be found by consulting other reviews or the original literature on a topic. Several good reviews on photoremovable protecting groups have appeared since this topic was reviewed in 1993 (e.g., Adams and Tsien[3] and Corrie and Trentham[4]). Notable among the more recent reviews are those by Wirz,[5] Bochet,[6] and Givens.[7] A volume of *Methods in Enzymology* devoted entirely to the chemistry and applications of photoremovable protecting groups, also termed "caged" compounds, that are employed in biochemistry and other biological studies has also appeared.

In general, photolysis reactions present a noteworthy and often ideal alternative to all other methods for introducing reagents or substrates into reactions or biological media. The ability to control the spatial, temporal, and concentration variables by using light to photochemically release a substrate provides the researcher with the ability to design more precisely the experimental applications in synthesis, physiology, and molecular biology. Among the many possible examples is the recently reported inhibition–reactivation of protein kinase A by photolysis of the dormant enzyme.[8–10] In this demonstration, it is necessary that the deprotection process be initiated by photolysis of the dominant chromophore of the protecting group. Covalent blocking of the functional groups at the active site of an enzyme essentially suspends its mode of action and virtually shuts down the catalytic cycle. It is this feature that has attracted biochemists to the use of protecting groups for the investigation of biological mechanisms.

In synthesis, the protecting group serves as a mask that renders a functional group inert to subsequent synthetic reaction conditions,[11] except, of course, conditions that are required for the removal of the protecting group. Construction of combinatorial platforms with photoremovable linkers is just one example of the applications in synthesis. Photorelease is sometimes termed a *traceless reagent process* because no reagents other than light are needed. The advantage of a process that requires no further separation of spent reagents is attractive.

There are several limitations to the use of commonly employed protecting groups in synthesis and for mechanistic studies of biological processes. The reactions for incorporating and subsequently removing protecting groups often involve acid or base that may be too harsh and interfere with the normal processes or otherwise be incompatible with the chemistry or biology under investigation. In mechanistic biochemistry, it is often the case that the typical hydrolysis deprotection reaction is far too slow to serve as a means of investigating the initial rates of reaction for rapid biochemical processes.

An ideal remedy to these limitations is a protecting group that could be removed under neutral buffered aqueous conditions, thus avoiding any alterations to the substrate or to the natural biological environment.[12] The release should occur on a time scale fast enough for kinetic analysis of any subsequent rapid biological processes. Such a group may be a photoremovable protecting group.

69.2 Historical Review

In 1962, Barltrop et al.[13] were among the first to report a photochemical deprotection reaction of a biologically significant substrate; here, glycine was released from *N*-benzyloxycarbonyl glycine:

(69.1)

This seminal discovery prompted the development of several additional photoremovable protecting groups. The success of many researchers in biology, particularly Kaplan,[1a] led to the description of the photoactivatable group as a "cage" to describe its deactivating influence on the biological substrate to which it is covalently attached.[14–17] Ideally, the cage detaches only through the action of light.

It is important that the photoremovable protecting group also possess several other desirable properties. The properties were originally compiled by several researchers in the field, including Sheehan and Umezawa[12] and Lester and Nerbonne,[18] who provide a series of benchmarks for evaluating the efficacy of a photoremovable group in a given circumstance or for evaluating the potential of a new cage chromophore. A more useful adaptation of the Lester rules and Sheehan criteria includes the following:

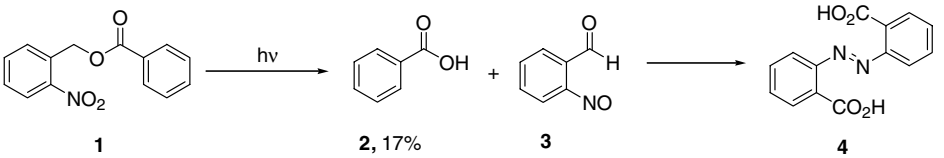
1. The substrate, caged substrate, and photoproducts have good aqueous solubility for biological studies. For synthetic applications, this requirement is relaxed.
2. The photochemical release must be efficient (e.g., $\Phi > 0.10$).
3. The departure of the substrate from the protecting group should be a primary photochemical process (i.e., occurring directly from the excited state of the cage chromophore).
4. All photoproducts should be stable to the photolysis environment.
5. Excitation wavelengths should be longer than 300 nm and must not be absorbed by the media, photoproducts, or substrate.
6. The chromophore should have a reasonable absorptivity (a) to capture the incident light efficiently.
7. The caged compounds, as well as the photoproduct from the cage portion, should be inert or at least benign with respect to the media, other reagents, and products.
8. A general, high-yielding synthetic procedure for attachment of the cage to the substrate must be available.
9. In the synthesis of a caged substrate, the separation of caged and uncaged derivatives must be quantitative. This is also necessary for the deprotection process for synthetic applications.

While these are the desirable guidelines for an ideal photoremovable protecting group, a potential cage that lacks one or two of these properties may still be very useful; however, the absence of several of these features may militate against the use of that group as a photoremovable protecting group for a specific application.

Some representative examples of photoremovable protecting groups that qualify as meeting the Lester and Sheehan criteria include α-substituted acetophenones, benzoins, benzyl groups, cinnamate esters, coumaryl groups, and, the most popular of them all, the *o*-nitrobenzyl esters and their analogs.

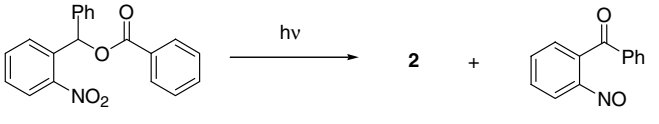
o-Nitrobenzyl

It was also Barltrop et al.[19] who first reported the use of an *o*-nitrobenzyl group to release benzoic acid (see Eq. (69.2)). The poor yield stemmed from the subsequent conversion of 2-nitrosobenzaldehyde (**3**), the initial photoproduct, into azobenzene-2,2′-dicarboxylic acid (**4**),[20] which then competed for the incident light. Yields were dramatically improved with the use of α-substituted nitrobenzyl esters (75 to 95% conversion), as seen from **5** in Eq. (69.3). The resulting photoproduct from *o*-nitrobenzyl ester **5** was a less reactive nitroso benzophenone derivative.



1 **2**, 17% **3** **4**

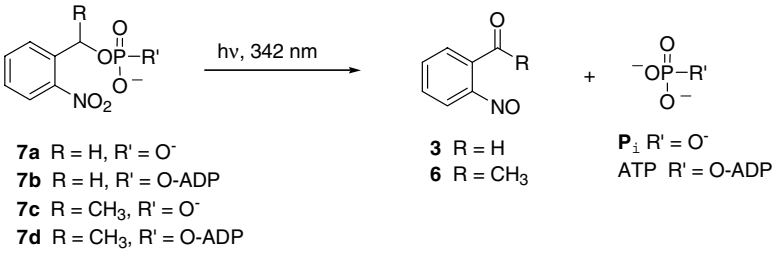
(69.2)



5 **6**

(69.3)

The report of the release of ATP by this method appeared in a 1978 rate study reported by Kaplan and co-workers.[1a] Inorganic phosphate ($\mathbf{P}_i$) and ATP were released from their 1-(2-nitrophenyl)ethyl (NPE) and 2-nitrobenzyl (NB) esters, respectively:



7a R = H, R' = O^-
7b R = H, R' = O-ADP
7c R = CH_3, R' = O^-
7d R = CH_3, R' = O-ADP

3 R = H
6 R = CH_3

$\mathbf{P}_i$ R' = O^-
ATP R' = O-ADP

(69.4)

The results of the release of $\mathbf{P}_i$ from NPE and NB showed very similar quantum efficiencies of 0.58 and 0.50, respectively; however, the release of ATP from the two cages gave very different rates of conversion. NPE released 80% of the caged ATP in less than 60 s compared with 25% for release from the NB caged ATP. These results further indicated that the α-substituted nitrobenzyl esters were better suited as phototriggers.

Kaplan's investigation also explored the potential use of photoprotecting groups in a physiological environment. Na^+,K^+-ATPase, the enzyme responsible for sodium/potassium transport through cell walls, served as the model for exploring the effect of the caged ATP (NPE-ATP) on the Na^+:K^+ transport associated with enzymatic activity. The enzyme acquires ATP as the energy source through hydrolysis of the terminal γ-phosphate. The hydrolytic activity of the enzyme can be monitored by the detection of $\mathbf{P}_i$ generated from the free ATP consumed by the enzyme. In the absence of photolysis, NPE-ATP was shown to be resistant to hydrolysis by the enzyme. Upon photolysis, the liberated ATP triggered the response of the enzyme and $\mathbf{P}_i$ release was observed.

The successful introduction of *o*-nitrobenzyl caged ATP into physiological media instigated interest in expanding the applications of caged release to a wide variety of biochemical systems. The list includes the mechanism of release of $\mathbf{P}_i$ in skeletal muscle,[21] the function of cAMP in the relaxation of distal muscle,[22] the ATP-induced mechanism of actomyosin in muscle contraction,[23] and the activation of antitumor antibiotics to highly reactive pyrrolic-type intermediates responsible for DNA crosslinking reactions.[24]

Benzoin

Sheehan and Wilson[25] were the first to explore the photochemical rearrangement of certain benzoin derivatives to yield 2-phenylbenzofuran (**9**). These rearrangements occurred with concurrent loss of groups attached α to the carbonyl just as in the case of the α-chloroacetophenones. They suggested that benzoins, especially the 3′,5′-dimethoxybenzoin chromophore, could serve as a photoremovable protecting group for carboxylic acids. In 1984, Givens et al.[26] showed that phosphates were quantitatively expelled from the ungarnished benzoin cage, as shown in Eq. (69.5), thus extending the range of applications and the nature of the parent chromophore. The only major product accompanying the released phosphate

TABLE 69.1 Quantum Efficiencies for Benzoin Phosphate Esters **8a–c**

(69.5)

was 2-phenylbenzofuran **9**. These reactions were quenched with naphthalene, piperylene, or, for aqueous studies, sodium 2-naphthalenesulfonate, all well-known triplet quenchers; this established the short-lived triplet (3 to 14 ns) as the reactive excited state for benzoin. Further information was revealed from Stern–Volmer quenching analyses which provided the rate of release of phosphate from the benzoin-caged ester. Extremely fast rates ($k_r > 10^8\ s^{-1}$) were measured along with good efficiencies for the reaction, ranging from 28 to 38% (Table 69.1).[27,28] Phosphorescence spectra supported the multiplicity assignments and also established the triplet energy at 73 ± 1 kcal/mol.

The efficiencies for the disappearance of the caged phosphates (Φ_{dis}), as well as the appearance of 2-phenylbenzofuran (Φ_{furan}) and phosphate ($\Phi_{phosphate}$), were determined to be pH dependent with higher efficiencies reported under acidic conditions. The greater efficiency at lower pH suggests that the protonated phosphate is a more favorable leaving group than its conjugate base. This study was extended to nucleotide release from the benzoin cage through the synthesis and photolysis of benzoin cAMP. The efficient release of cAMP as the exclusive product with quantum efficiencies on the same order of magnitude as the model phosphate esters first demonstrated the application of benzoin as a cage for

TABLE 69.2 Quantum Efficiencies for Photolysis of Benzoin Adenosine Cyclic 3′,5′-Monophosphate[a]

Aqueous Buffer	pH	Φ_{dis}	Φ_{furan}	Φ_{cAMP}
Tris (D_2O)	7.3	0.39	0.19	0.34

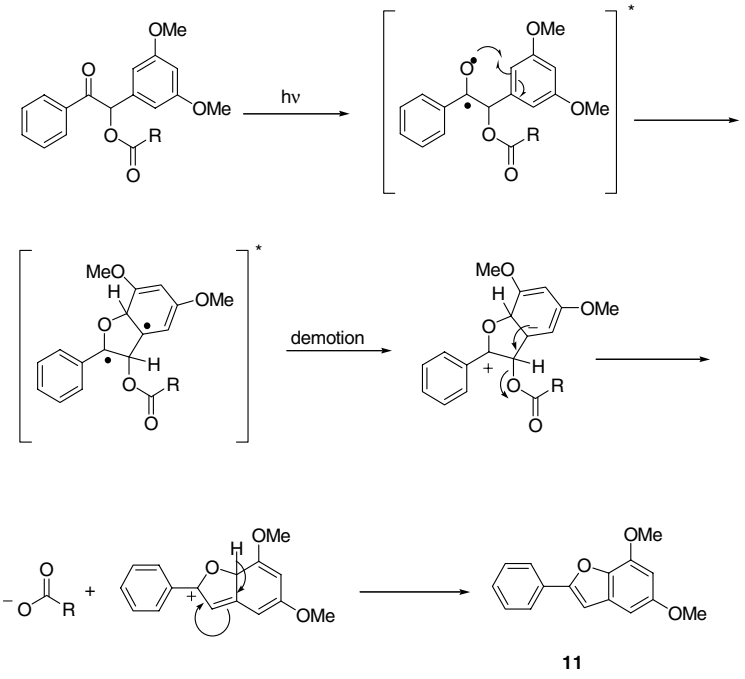


SCHEME 1 Benzoin photorelease mechanism.

nucleotides (Table 69.2). ^{31}P spectra of released cAMP demonstrated that cAMP was the only phosphate present after release. As Table 69.2 indicates, the quantum efficiencies remained relatively constant throughout the pH range examined.

It has been determined that carboxylate derivatives are released more readily when there are electron-donating substituents at the *meta* positions of the benzyl ring.[29] The absorption spectra of the benzoin esters along with the observations that cyclization was enhanced by *meta* electron donating groups led observers to believe that reaction was taking place through an n,π^* singlet state (see Scheme 1). It was suggested that the excitation of the phenacyl group led to a short-lived 1,3-biradical, followed by demotion to the ground state. The zwitterionic intermediate led directly to the loss of the leaving group. Aromatization through loss of a proton gave the benzofuran **11** as the principal photoproduct. The inability to quench the reactions with high concentrations of piperylene suggested that the reaction originated from the singlet excited state or, alternatively, from a very short-lived, unquenchable triplet.

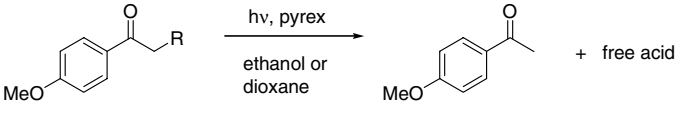
Based on these observations Corrie and Trentham[4] re-examined the photochemistry of several substituted benzoin phosphates. They found that the 3′,5′-dimethoxybenzoin cage was best suited among those investigated for the release of $\mathbf{P}_i$. The formation of 3′,5′-dimethoxy-2-phenylbenzofuran (**11**) occurred at a rate that exceeded 10^5 s^{-1} and a quantum efficiency of 0.78. While the rate of product formation was lower than that reported by Givens and Matuszewski,[26] the efficiency for the substituted benzofuran analog was much higher. For the benzoin series, the primary photoproduct **11** is also a strongly absorbing chromophore and thus competes for incident light and forms photodimers along with several other unidentified products upon further irradiation. Yet another limitation of this system is the presence of a chiral center alpha to the carbonyl, which engenders isolation and purification problems in the synthesis of benzoin-protected chiral substrates.

More recently, Rajesh et al.[30] examined the earliest events in the photolysis of benzoin diethyl phosphate (**8a**). With nanosecond resolution, the LFP excitation of **8a** in trifluoroethanol gave an immediate, permanent 300-nm absorption identified as the benzofuran photoproduct (Eq. (69.5)). A second transient absorption at 570 nm was also observed which decayed with a first-order rate constant of $\sim 2 \times 10^6$ s^{-1} in degassed acetonitrile or trifluoroethanol that was assigned to the triplet α-ketocation **10.** The intermediate could be trapped by trifluoroethanol, yielding trifluoroethyl benzoin ether. Evidence for the intermediacy of the α-ketocation triplet came from experiments with added halide ion or azide in which electron transfer quenching of the transient was observed. Oxygen and naphthalene quenching experiments demonstrated that ^{3}**10** was formed adiabatically on the triplet manifold from ^{3}**8a**. Temperature-dependent studies indicated an activation energy for decay of ^{3}**10** of 8.6 kcal/mol to the singlet, which then reacted with trifluoroethanol to form the trifluoroethyl ether. Stern–Volmer analysis of the naphthalene quenching gave a triplet lifetime for ^{3}**8a** of $\tau^3 = 18$ ns.

The formation of 2-phenylbenzofuran during the nanosecond laser flash experiment was corroborated by a picosecond study of **8a**. A rise time of 2 to 4 ps was determined for the 340 nm transient. A rich fluorescence emission obtained in the nanosecond study was shown to arise from ^{1}**9** generated during the nanosecond laser excitation pulse. Naphthalene also quenched the formation of **9** at the same rate as the formation of ^{3}**10**, establishing that the two primary photoproducts came from the same triplet (i.e., ^{3}**8a**). Thus, for the unsubstituted benzoin phosphates, reaction proceeds exclusively through the triplet manifold

Phenacyl

In a similar study, Sheehan and Umezawa[12] employed a stripped-down version of the benzoin chromophore, the *p*-methoxyphenacyl group, for the release of benzoic acid, several amino acid derivatives, and peptides, as shown in Eq. (69.6) and Table 69.3.



12 **13** (69.6)

In this case, the photoproduct was the *p*-methoxyacetophenone (**13**), a reduction product. The proposed mechanism (Scheme 2) was a simple homolysis of the carbon-oxygen bond. Ethanol serves as a hydrogen atom donor during this process, and in the presence of 1-*M* benzophenone or naphthalene the reaction was completely quenched, indicating a triplet reaction pathway. Benzophenone and naphthalene are known quenchers of acetophenones and have triplet energies of 68 and 62 kcal/mol, respectively.

Epstein and Garrossian[31] reported the release of ethyl and phenyl phosphate esters from the corresponding *p*-methoxyphenacyl phosphates in 1,4-dioxane. The released phosphates were recovered in high yields (Et, 86%; Ph, 74%) along with **13** (91–84%) as the only observed photoproducts. The absence of any rearranged ester products contrasted with reports by Anderson and Reese[34] for substituted α-chloroacetophenones (*vide infra*). The rationale for the discrepancy advanced by Epstein was an altered

TABLE 69.3 Percent Yield for the Release of Various Acids[a] from the Corresponding 4-Methoxyphenacyl Esters (12)

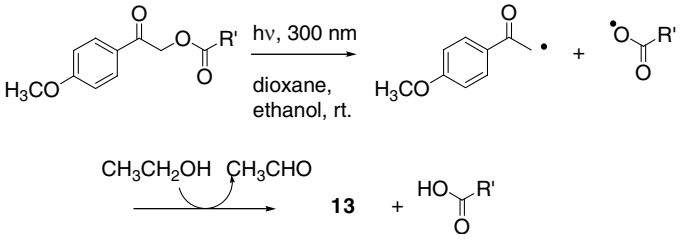
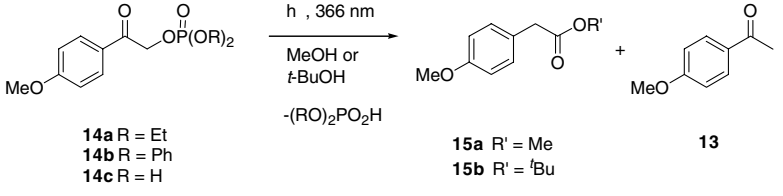


SCHEME 2 Sheehan et al. mechanism

mechanism due to a change in solvent. The solvent 1,4-dioxane may not be sufficiently polar to support the formation of the zwitterionic precursor to the Favorskii-like rearrangement that was proposed by Anderson and Reese. This was required for the rearrangement to the spirodienedione intermediate. Reinvestigation of the photolytic cleavage using polar solvents would have been an interesting test of this hypothesis.



(69.7)

Givens et al.[28] examined the photorelease of phosphate esters using *t*-butyl alcohol and methanol as solvents, the former being a poor hydrogen atom donor and both exhibiting increased polarity compared with 1,4-dioxane. The results correlated well with those of Anderson and Reese in that the major photoproduct was the rearranged ester, not the photoreduction product (Eq. (69.7)). The amount of **13** was decreased to 21% in methanol and 14% in *t*-butyl alcohol. Further investigation of the solvent dependency for the release of phosphates revealed a solvent isotope effect with deuterated vs. protiated methanol as the solvent (Table 69.4). The formation of *p*-methoxyacetophenone was suppressed by a factor of five when

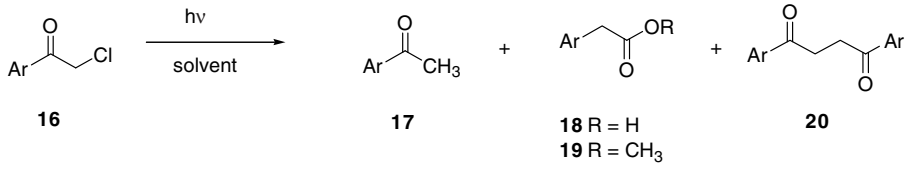
Source: Adapted from Dhavale et al.[32]

photolysis was carried out in CD_3OD compared with either CH_3OD or CH_3OH, suggesting that a rate-determining hydrogen abstraction occurs in the photoreduction process. Sheehan first suggested this mechanistic pathway (*vide supra*).

Indeed, Dhavale et al.[32] have shown that the ratio of rearrangement to reduction for substituted α-chloroacetophenones is solvent dependent [Eq. (69.5) and Table 69.5]. Dhavale's group reported that irradiation of substituted α-choroacetophenones in methanol resulted in more photoreduction, whereas in aqueous acetonitrile rearrangement to the phenylacetate esters became the major pathway. For a given solvent, the ratio of rearrangement to reduction increased with the electron-donating power of the substituent.



(69.8)

Scheme 3 outlines Dhavale's proposed mechanism for the chloride loss and subsequent rearrangement, beginning with carbon–chlorine bond homolysis. An electron transfer from the α-ketoradical to the chlorine atom leads to the ion pair **21**. The ion pair is more susceptible to Favorskii-like rearrangement in polar solvents; therefore, the rearranged phenylacetic acid is favored in polar, protic solvents. Hydrogen abstraction, resulting in the formation of **17**, prevails in those solvents that are good hydrogen atom donors.

Sonawane et al.[33] investigated the photorearrangement of several *para*-substituted propiophenones as a convenient entry for substituted α-arylpropionic acids, as shown in Eq. (69.9):

In almost every case, *para*-substitution promoted rearrangement (Table 69.6). Phenyl- and chloro-substitutions in the *para* position were the only cited examples where rearrangement did not dominate in methanol. These cases also showed significant reduced and hydrolyzed products.

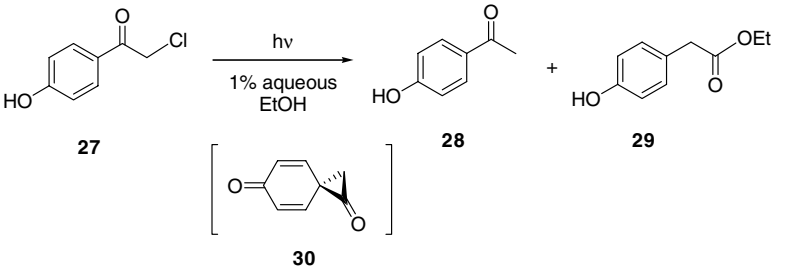
Source: Adapted from Anderson and Reese.[34]

While not purported to be a photoremovable protecting group, the study by Anderson and Reese[34] on substituted phenacyl chlorides did reveal an interesting photochemical rearrangement for certain members of the series, particularly the report that the Favorskii-like rearrangement of *p*-hydroxyphenacyl chloride (**27**) in 1% aqueous ethanol gave two major photoproducts: *p*-hydroxyacetophenone (**28**) and ethyl *p*-hydroxyphenyl acetate (**29**), as shown in Eq. (69.10). The authors proposed a spiro intermediate **30**.



(69.10)

Further examination of the proposed aryl participation hypothesis led to the observation that electron-donating groups in the *ortho* or *para* positions were necessary for the rearrangement to occur (Table 69.7).

The results of Anderson and Reese coupled with the efficacy of the benzoin chromophore for cleavage of α substituents attracted our interest in developing the *p*-hydroxyphenacyl group as a photoremovable protecting group. We further rationalized that the introduction of a phenolic hydroxy group would enhance the aqueous solubility. The absence of the attendant α phenyl substituents on benzoin alleviated the stereogenic center problem present with benzoin derivatives. Furthermore, Anderson and Reese reported a Favorskii-like rearrangement of the chromophore, e.g., *p*-hydroxyphenacyl to *p*-hydroxyphenylacetate for **27** → **29** and for **16b,c**, suggesting a significant hypsochromic shift in the chromophore. Thus the promise of *p*-hydroxyphenacyl as a possible phototrigger was too enticing to pass up.

In 1995, we began a comprehensive exploration of a variety of *p*-substituted phenacyl phosphates for their efficacy toward releasing phosphate.[2,28] Among the substituents examined, the *p*-acetamido, methyl *p*-carbamoyl, and *n*-butyl *p*-carbamoyl groups proved untenable because they gave a plethora of products, most of which resulted from coupling or reduction of an intermediate phenacyl radical [Eq. (69.11)][35,36]

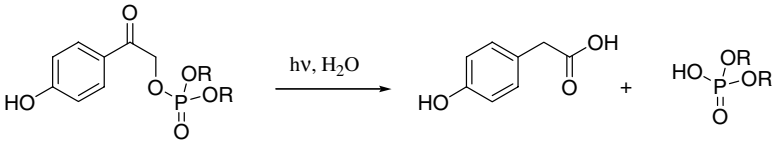
(69.11)

Table 69.8 gives the disappearance efficiencies for several *p*-substituted phenacyl phosphates from which it is evident that release of phosphate does occur very efficiently for the acetamido and carbamoyl derivatives; however, the large array of products of the phototrigger discouraged our further interest in these three electron-donating groups.

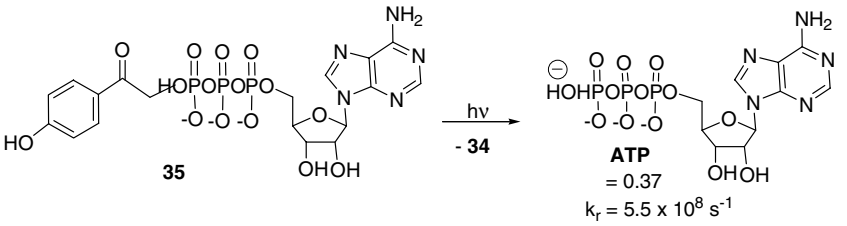
The methoxy substituent (**14c**) showed a much cleaner behavior, yielding only two products from the chromophore, *p*-methoxyacetophenone and the rearrangement product *p*-methoxyphenylacetic acid. The *p*-hydroxyphenacyl phosphate (**33**) gave the rearranged *p*-hydroxyphenylacetic acid when photolyzed in mixed aqueous organic solvents (Eq. (69.12)); in fact, of all of the groups examined, only *p*-hydroxy and *p*-methoxy produced any rearranged phenylacetic acids.



33, R = Et **34**

(69.12)

The initial discovery that diethyl *p*-hydroxyphenacyl phosphate exclusively followed a rearrangement pathway was followed by an extension of our study to *p*-hydroxyphenacyl ATP (**35**). Irradiation of **35** at 350 nm released ATP and *p*-hydroxyphenylacetic acid with a quantum efficiency of 0.37 ± 0.01 and a rate constant for ATP appearance of $5.5 \pm 1.0 \times 10^8$ s^{-1} [Eq. (69.13)].

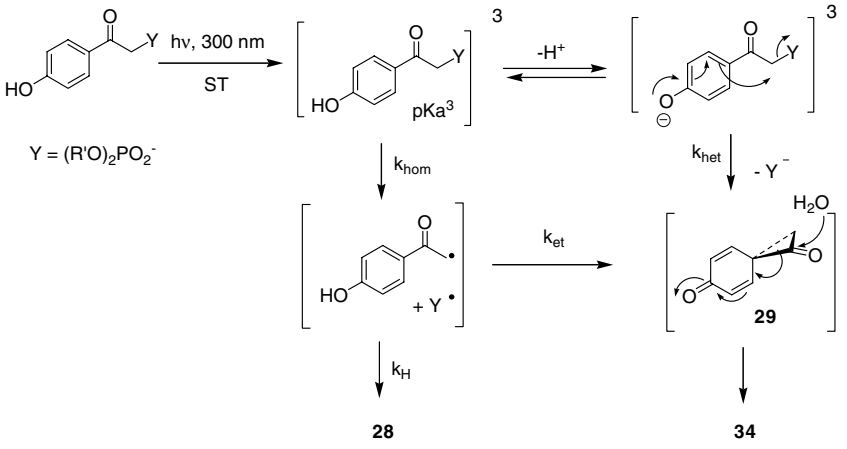


(69.13)

While the mechanism of this process is unknown, the *p*-hydroxyphenacyl photorelease likely involves an initial triplet state deprotonation of the phenolic hydrogen. In one scenario, the initially generated triplet intermediate partitions between loss of a proton and C-O bond cleavage, as pictured in Scheme 4. The exact course of the reaction depends greatly on the leaving group, solvent, and substituents attached to the chromophore. Here, the triplet phenol undergoes the equivalent of a homolytic cleavage of the bond to the substrate. In this scenario, it was envisaged that initial homolysis of the C-Y bond might be followed by a rapid single-electron transfer process; that is, the triplet phenol is essentially converted to its conjugate base (Y^-) before other competing processes for the radical pair can intervene. In this sequence, a spirodienedione is eventually generated by electrocyclic closure of the intermediate zwitterion or possibly the diradical.

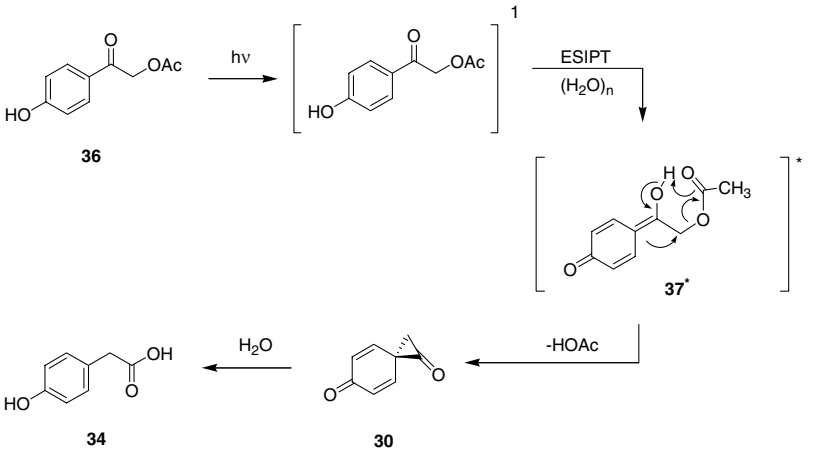
The conjugate base formed by the proton loss undergoes bond reorganization to the putative spirodienedione **30** accompanied by release of ATP. Further hydration of the spirodienedione and bond reorganization lead to the phenylacetic acid that is suggested for both pathways.

A second mechanistic scenario involves proton loss concomitant with direct neighboring group assistance for the release of the substrate and formation of the spirodienedione. The subsequent proposed nucleophilic hydrolysis of the spirodienedione follows as above. Current evidence from subsequent solvent and substituent studies favor the latter mechanism (*vide infra*).



SCHEME 4 Proposed triplet state mechanisms for photorelease of substrates from the *p*-hydroxyphenacyl protecting group.

The onset of the triplet-state phosphorescence emission of several *p*-hydroxyphenacyl esters indicated triplet energies of 68.9 to 70.6 kcal/mol. The phosphorescence emissions were quenched by sodium 2-naphthalenesulfonate or potassium sorbate. Quenching studies confirmed the reactivity of the triplet state and further provided a lifetime of 5.5 ns for the triplet with a release rate of $1.82 \times 10^8\ s^{-1}$ in later studies (*vide infra*).



SCHEME 5 ESIPT singlet state photorelease mechanism of *p*-hydroxyphenacyl acetate.[37]

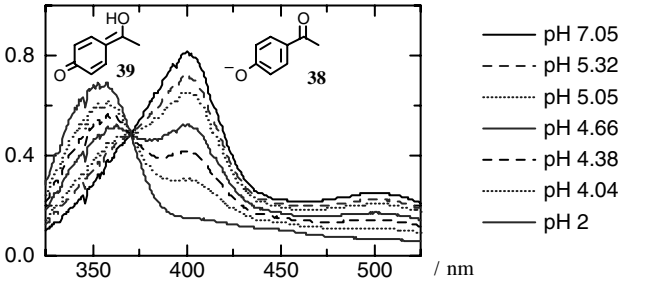


FIGURE 69.1 Transient absorption spectra obtained by LFP of *p*-hydroxyacetophenone in water (10% CH_3CN) with various buffers. (From Conrad II, P. G. et al., *J. Am. Chem. Soc.*, 122, 9346–9347, 2000. With permission.)

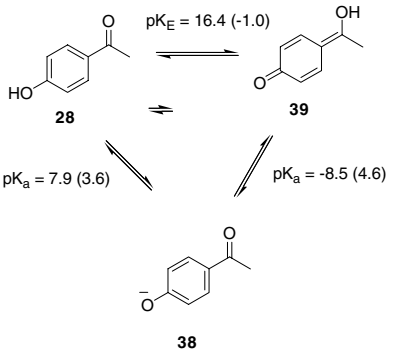
The original proposal that the triplet state was the reactive state was challenged by Zhang et al.[37] An excited singlet state or possibly a tautomeric ground state (e.g., **37***) was proposed as the reaction intermediate. In their studies, quenching by triplet quentchers was not observed during photolysis of *p*-hydroxyphenacylacetate (**36**), suggesting that the release of acetate occurred through an excited singlet state possibly involving an intramolecular proton transfer. They postulated that the excitedsinglet state intramolecular proton transfer (ESIPT) mechanism would form the quinone methide **37*** that could either continue on to the spirodienedione (**30**) or decay to ground state and subsequently undergo release of acetate to form **34**. Such a mechanism has precedence in the earlier work of Wan[37,38a] and Yates.[38b]

Laser flash photolysis (LFP) studies by Givens and Wirz[38] with diethyl pHP phosphate (Eq. (69.12)) confirmed the intermediacy of the phenacyl triplet state. Energy transfer quenching to naphthalene gave a rate of formation of the naphthalene triplet of $7.8 \times 10^9\ M^{-1}\ s^{-1}$. The presence of dioxygen increased the decay rate of the pHP phosphate triplet ($k_q \approx 3 \times 10^9\ M^{-1}\ s^{-1}$). It was estimated from this study that pHP intersystem crosses with a rate constant of $3.1 \times 10^{11}\ s^{-1}$ in aqueous acetonitrile. Quenching studies of the photochemical release of substrates from a series of pHP derivatives employing potassium sorbate gave excellent linear Stern–Volmer quenching results with lifetimes of 10^{-8} to 10^{-9} s for their pHP triplet states. These combined results firmly established the triplet as the reactive excited state.

LFP studies on the parent chromophore proved revealing. The *p*-hydroxyacetophenone triplet undergoes a facile adiabatic proton tautomerization conerting the phenol **28** into its conjugate base **38**. Evidence



SCHEME 6 Tautomerization of *p*-hydroxyacetophenone in the ground state and triplet excited state (in parentheses). (From Conrad II, P.G. et al., *J. Am. Chem. Soc.,* 122, 9346-9347, 2000. With permission.)

for this unusual adiabatic proton transfer to solvent from the triplet *p*-hydroxyacetophenone came from analysis of the transient triplet absorption spectra of **28** as a function of the pH (Figure 69.1).

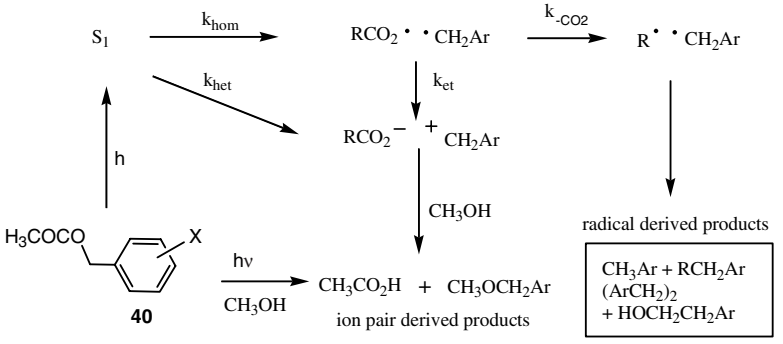
These results were further supported by DFT calculations that provided the tpK$_E$ values for the equilibrium **28** $\rightleftharpoons$ **39** in their ground and triplet excited states. A pK$_a$[3] for **28**[3] of 3.6 was derived from these data and the triplet state pK$_a$[3] of **39** (4.6) and the known ground state pK$_a$ of **28** (7.9) (Scheme 6). These studies revealed an increase in acidity over four pK$_a$ units relative to the ground state. The proton tautomer 39 is a non-productive intermediate because it is thermodynamically incapable of cleaving the ester C–O bond.

Incorporating the rapid deprotonation that results from the large adiabatic decrease in pK$_a$ of **28** as a feature of the *p*-hydroxyphenacyl mechanism suggests that the conjugate base **38** is an attractive precursor to the rate-limiting release of the substrate. Because the triplet is formed with a ST rate constant of 3.1 $\times 10^{11}$ s^{-1}, it is unlikely that there is any singlet state contribution to the deprotonation step. Rather, this appears to be exclusively a triplet process occurring on the excited triplet surface; that is, the two protonated species and the unprotonated ion undergo adiabatic proton tautomerizations (Scheme 6). The electron-rich aromatic ring increases the potential for intramolecular neighboring group attack at the α-carbon, leading to the release of the substrate and rearrangement of the chromophore. Thus, it becomes prudent to carefully explore the change in the pK$_a$ of the phenolic protons transitioning between the ground and excited triplet states as a key element in understanding the role played by aryl participation in the release step.

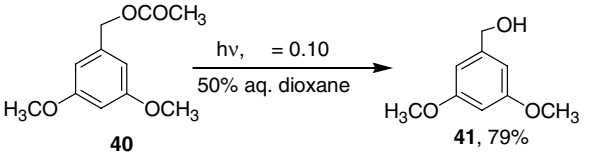
Coumaryl and Arylmethyl

Zimmerman's early studies[40] on the photosolvolysis of benzyl acetates in 50% aqueous dioxane set the stage for a variety of studies that employ *m*,*m*′-dimethoxybenzyl as a photoremovable protecting group. In general, the photofragmentation reactions of benzyl acetates are quite rapid, with rate constants of 10^8 s^{-1} or higher and are primarily singlet-state processes. According to Zimmerman, *meta* activation of the excited singlet state of benzyl acetates occurs through the approach of the excited- and ground-state energy surfaces, funneling the excited state toward heterolysis of the benzyl–ester bond. Substituents, including electron donors, in the *para* position lead primarily to homolytic fission and radical derived products.

Direct heterolytic fission of the substrate-photoprotecting group bond is the required course for photorelease of most biologically important substrates. This process avoids the generation of destructive radicals that could result in reactions such as decarboxylation, radical dimerization, or redox processes. Thus, the effect of *m*-substitution on the photochemistry of benzyl, naphthyl, and other aromatic chromophores has become the object of many studies in search of alternatives to the *o*-nitrobenzyl class of protecting group.



SCHEME 7 Mechanistic scheme for arylmethyl ester photolysis in methanol.[43]

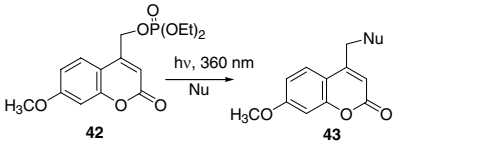


(69.14)

Recent studies by both Zimmerman[41] and DeCosta and Pincock[42,43] on the nature of the *meta* effect have raised concerns about whether heterolytic or homolytic cleavage should be considered the primary photochemical process. According to Pincock, the mechanistic pathway for all substituted arylmethyl substrates begins with homolysis of theC–O ester bond to the substrate followed by a competition between electron transfer to an ion pair or typical ground-state radical reactions (Scheme 7).[43] For those arylmethyl derivatives substituted with a *meta* electron-donating group, such as methoxy, the electron transfer occurs more rapidly than competing radical processes due to favorable redox properties of the radical pair.

Normally, the details of the steps leading to the ion pair would not play a significant role in the outcome of the photorelease process except in those circumstances where the radical pair precursors have rapid, favorable divergent pathways available. Such could be the case for carboxylate esters, such as C-protected amino acid, peptides, and protein derivatives, where decarboxylation of the initially generated carboxy radical may compete with electron transfer to the ion pair. This deleterious process can become significant, leading to destruction of a portion of the released substrate. By either of these mechanisms, however, the product-determining process for *meta*- and especially the di-*meta*-substituted arylmethyl chromophores leads principally to an ion pair, an intermediate arylmethyl carbocation, and the conjugate base of the leaving group.

The coumaryl chromophore is essentially another arylmethyl analog, which has the attractive feature of high yields of fluorescence emission, sometimes a useful property for following the course of substrate-chromophore processes. One of the earliest studies using coumarin as a chromophore was the photorelease of diethyl phosphate from coumarylmethyl diethyl phosphate.[26] The resulting coumarylmethyl cation covalently attaches to a wide variety of nucleophiles, as shown in Eq. (69.15):



(69.15)

Furuta et al.[43] have reported the application of the coumaryl chromophore as a phototrigger for the release of cAMP (Eq. (69.16)); as shown in Table 69.9, the methoxy and hydroxy methylcoumarins gave the best conversions.

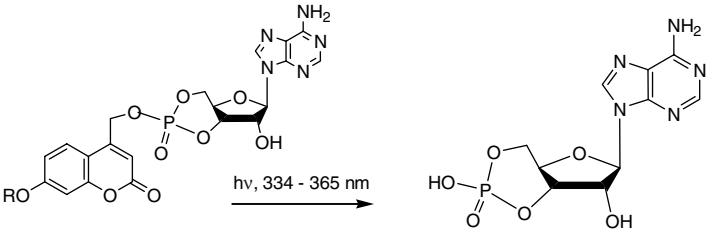
Caged cAMP	R = Acetyl	R = Propionyl	R = Hydroxy	R = Methoxy
Conversion (%)	23	9	64	60



44

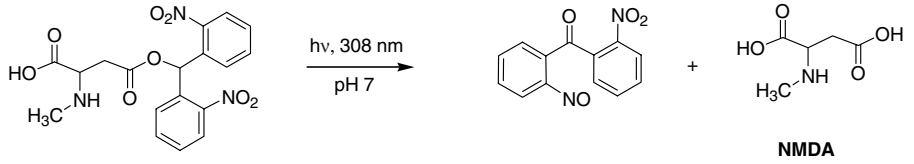
(69.16)

The historical and mechanistic background for the most common photoprotecting groups were presented above. Examples that employ photoremovable protecting groups are given to illustrate the range and variety of the applications in chemistry and biology. As noted earlier, these are a very limited set of examples of the numerous published applications in biology and, to a lesser extent, in chemistry. Further information can be obtained from the reviews listed in References 1 through 7.

69.3 Carboxylic Acids

o-Nitrobenzyl

Because *o*-nitrobenzyl derivatives have been the most widely applied photoremovable protecting groups, modifications of this chromophore have received considerable attention. A recent study[45] employing 2,2′-dinitrobenzhydryl (DNB) for *N*-methyl-D-aspartate (NMDA) probed the NMDA receptor, which is one of the general classes of known glutamate receptors. The carboxyl group of NMDA was esterified with DNB, a stronger UV absorber (λ_{max} 350 nm: $\varepsilon = 1.69 \times 10^4\ M^{-1}\ cm^{-1}$) than typical *o*-nitrobenzyl analogs. The poor aqueous solubility of DNB-NMDA, however, required addition of 20% DMSO to attain complete dissolution. A single 308-nm laser pulse was sufficient to release NMDA within 4.2 μs, with a quantum efficiency of 0.18, as shown in Eq. (69.17).



β-O-DNB-NMDA **NMDA**

(69.17)

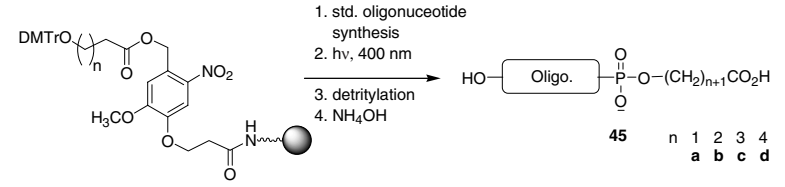
The time constant for the release of NMDA is pH dependent, occurring within 3.8 μs at pH 3.8 and 13.8 μs at pH 10.6, consistent with the rate of decay of the aci-nitro intermediate. The relatively rapid release rate from DNB suggests that this protecting group could be useful for further studies of the NMDA receptor.

The versatility of the *o*-nitrobenzyl group has also been demonstrated in solid-phase synthesis. The phosphate group of the nucleotide tethered to a carboxylic acid through an alkyl chain provides a convenient link to the *o*-nitrobenzyl group, which is attached to a solid support. Synthetic manipulation of the oligonucleotide can be carried out under standard conditions and then release of the synthesized

TABLE 69.10 Isolated Yields of Completely Deprotected Oligonucleotides

	Protection (%)	Deprotection (%) 45	Deprotection (%) 45′
a	96	70	77
b	89	91	80
c	97	92	71
d	90	69	70

oligonucleotide from the support is conducted photochemically.[46] The carboxylate and substituted *o*-nitrobenzyl alcohol were coupled in 89 to 97% yields followed by the controlled pore glass (CPG) loading. Standard oligonucleotide synthesis was then carried out at the 3′-terminus of **45a–d** and **45′a–d** to obtain **45′a-d** (Eq. (69.18).



DMTr = 4,4'-dimethoxytrityl

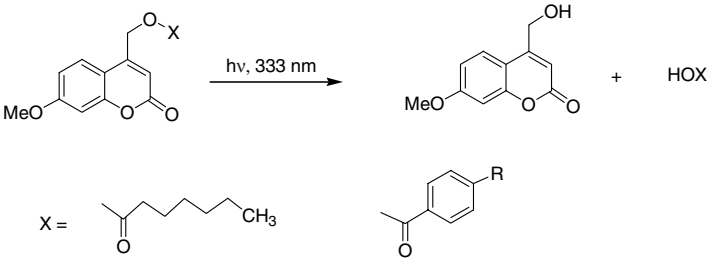
45a-d (n = 1-4) Oligo = T_{20}
45'a-d (n = 1-4) Oligo = TAC GCA ATC CTA GAT CTA AT

(69.18)

Upon completion of the synthesis, the oligonucleotides were severed from the CPG solid support photochemically using a 400-nm light source. The efficiency of the release process was as high as 92%, as shown in Table 69.10. This protocol is useful for elaborating the 3′-terminus of oligopeptides using mild, traceless reagent conditions at room temperature and neutral pH.

Coumaryl

The photochemical and photophysical behavior of 4-(hydroxymethyl)-7-methoxycoumarin (MCM) caged acids was studied under physiological conditions by Bendig et al.[47] (Eq. (69.19)).



46a

46b: R = OCH_3
46c: R = H
46d: R = CN

(69.19)

Photocleavage of the excited singlet state of MCM caged compounds is thought to proceed via a photo-S_N1 mechanism (solvent-assisted photoheterolysis). Evidence favoring this mechanism was found from irradiation of MCM caged derivatives in ^{18}O-labeled water, which exclusively incorporated the ^{18}O-label in the MCM–^{18}OH product (see Scheme 8). The deprotection process of the MCM derivatives was

TABLE 69.11 Data for 4-(Hydroxymethyl)-7-Methoxycoumarin (MCM) Caged Acids

Acid	Protection (% Yield)	Deprotection (Φ)
46a	82.6	0.0043

dependent on the leaving group and the solvent polarity. The quantum efficiencies for the reactions of **46a–d** were low, in the range of 0.0043 to 0.0064 as listed in Table 69.11. MCM–OH is a highly fluorescent product that can be conveniently monitored during the course of the reaction. Furthermore, MCM caged compounds are very stable to the hydrolysis.

Phenacyl

The rapid release (~10^8 s^{-1}) of substrates from the *p*-hydroxyphenacyl (pHP) group enables fast biological processes to be studied. *p*-Hydroxyphenylacetic acid (**34**) is generated with a quantum efficiency (Φ_{rea}) of ~0.18. In contrast, the presence of added electron-donating substituents on the aromatic ring of the pHP group makes the rearrangement a minor pathway for **47′a–b** and completely suppress it for **47″a–b** (Scheme 9).[48] The quantum efficiencies for the disappearance of the various pHP esters, the appearance of (**34**), and corresponding pHP-protected substrates are given in Table 69.12 .

A complication that could arise in such systems is the potential for decarboxylation of the released carboxylate ion. However, no decarboxylation products were observed within the detection limits of ^{1}H-NMR and HPLC.

With the production of a biologically benign photoproduct, the pHP protecting group has proven to be an efficient tool for investigations of fast biological processes. For example, Givens et al.[49] applied the pHP phototrigger to the investigation of the bradykinin BK2 receptor. It is known that bradykinin acts as an active pain-transducer when released during tissue damage. A major difficulty in studying the detailed physiological mechanism of the action of bradykinin is a concomitant rapid enzymatic degradation of the nonapeptide immediately after its release from its precursor protein. Therefore, the photorelease from pHP bradykinin (**48**), which protects bradykinin from degradation of the agonist prior

TABLE 69.12 Quantum Yields of pHP Esters for Irradiation at 300 nm[a]

	Ester	Solvent (Water/AcCN)	Φ_{dis}	Φ_{app}	Φ_{rea}

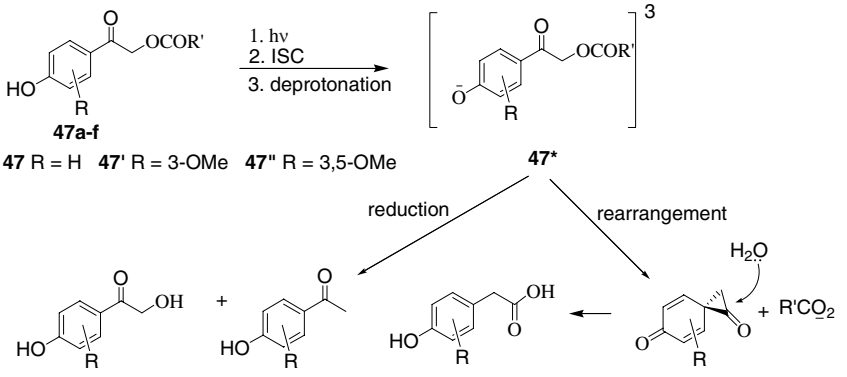
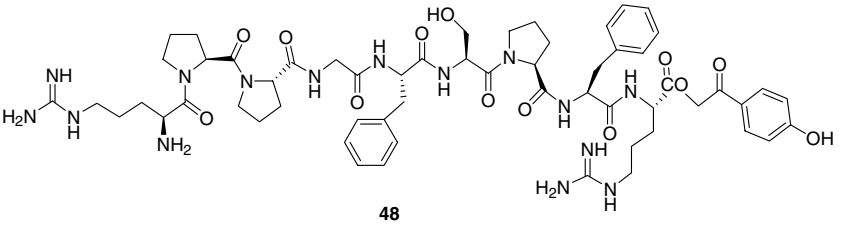


SCHEME 9 Photoreaction for the pHP esters.

to release, facilitates the investigation of its action during the transduction process by allowing precise temporal and spatial release of bradykinin to activate the bradykinin BK2 receptor (Eq. (69.20).



(69.20)

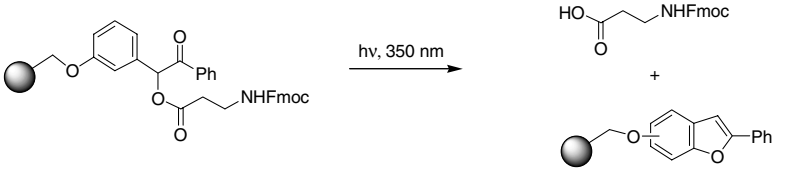
pHP Bradykinin **48** was obtained in an overall yield of 84% by derivatizing the partially protected brdykinin, obtained by cleavage of the C-terminus from the resin after sold-phase Merrifield synthesis.[49]

Reaction of the C-termnus with *p*-hydroxyphenacyl bromide followed by treatment with 1% TFA gave pHP bradykinin 48, free of the other protecting groups employed during the solid phase synthesis.[49]

A single 337-nm flash (<1 ns) released sufficient bradykinin to excite the BK2 receptors on single rat sensory neurons, which dramatically increased the intracellular calcium concentration measured with Indo-1, a Ca^{2+}-chelating fluorescent indicator. The quantum efficiency of bradykinin appearance was idependently determined to be 0.22, as shown in Table 69.12.

Benzoin

There are a number of examples of benzoin and substituted benzoin esters that have been employed as photoremovable protecting groups for carboxylic acids. Among these, the application of benzoin as a traceless linker for solid-phase synthesis of oligopeptides and introduction of Fmoc-protected amino acids by Balasubramanian[50] is instructive. As an example, the release of Fmoc-Ala shown in Eq. 69.21 occurs upon photolysis at 350. Balasubramanian found that the maximum yield was obtained after a 2-h photolysis as determined by HPLC (Eq. (69.21).



(69.21)

In order to avoide premature photolysis of the benzoin linker by adventitious room light during the course of the synthesis, the dithiane-protected 3-alkoxybenzoin (**49a**) has been suggested as a "UV-inactive" linker. The dithiane-protected 3-alkoxybenzoin (**49a**) released less than 3% of the product after irradiation at 350 nm. The photosensitivity is restored by hydrolysis of the dithiane prior to photocleavage, as illustrated in Eq. (69.22). Photolysis of the deprotected linker resulted in a 75% yield of the product.

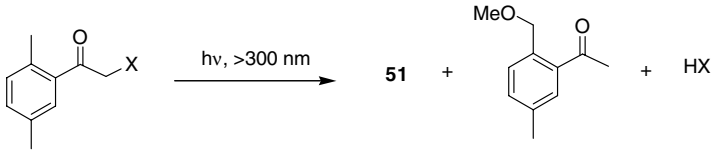
$-OCOCH_3$	84	Benzene	0.25
		Methanol	0.14

[a] Quantum yield for ester release; valerophenone was used as an actinometer; irradiated at λ >300 nm. Error margins are approximately 10%.

The formation of the corresponding carboxylic acids occurred with almost quantitative isolated yields, as shown in Table 69.13.[51] In contrast with the structurally related *p*-hydroxyphenacyl esters, the release mechanism from **50** occurs through an efficient intramolecular γ-hydrogen abstraction via the (n,π^*) excited ketone.

Recently, Wirz's group[51] conducted LFP of 2,5-dimethylphenacyl (DMP) esters in benzene or cyclohexane (Eq. (69.24)).

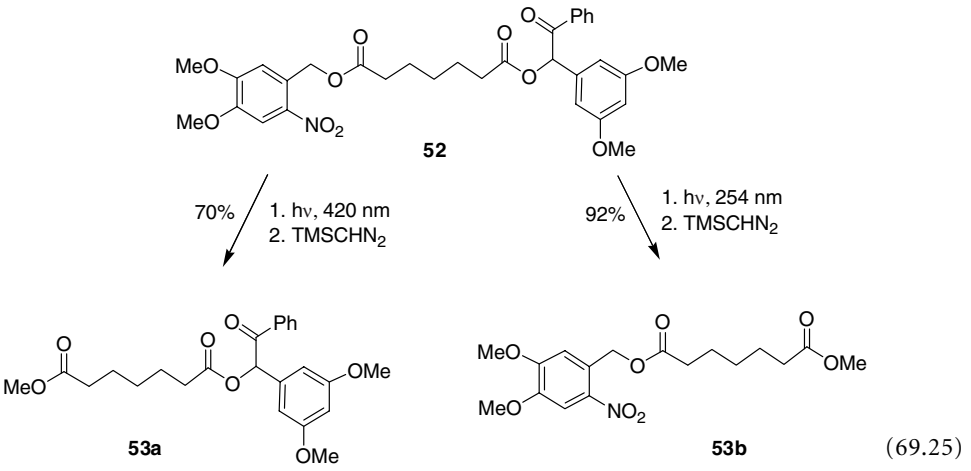


(69.24)

Recently, Wirz and Klan[52] reported LFP studies on several of the DMP esters in benzene and methanol (Eq. (69.24)). Quantum efficiencies (Φ) in benzene are 0.18 to 0.25, while those in methanol fell to 0.09 to 0.14. Thus, this photoprotecting group appears to be better suited to applications in nonpolar media such as benzene rather than methanol (Table 69.14).

A novel design of "orthogonal" protecting groups, i.e., the removal of protecting groups selectively from a multi-protected substrate, has been reported by Bochet[53] in which the irradiation wavelengths

serve as the "orthogonal reagents". A mixed diester of pimelic acid was capped with a dimethoxybenzoin group at one end and an *o*-nitrobenzyl group at the other terminus. Despite the possibility that intramolecular energy transfer or equilibration could occur between the two chromophores, selective photolysis led to the sequential removal of each with high chemical yield, as shown in Eq. (69.25). Upon photolysis of **52** at 254 nm for 5 minutes, 92% of **53b** was released, whereas irradiation at 420 nm for 24 hours released 70% of **53a**, as determined by ^{1}H NMR.

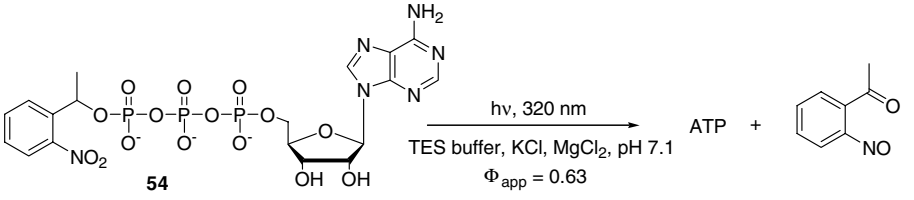


(69.25)

69.4 Phosphates and Phosphites

o-Nitrobenzyl

The most notable example of *o*-nitrobenzyl (ONB) caged phosphates remains that reported by Trentham and co-workers[54] on the synthesis and photochemistry of caged ATP in the late 1980s. Caged ATP, P^3-1-(2-nitrophenyl)ethyladenosine 5′-triphosphate (**54**), was synthesized in nearly quantitative yield in three steps starting with commercially available *o*-nitroacetophenone. Reaction with hydrazine to give the corresponding hydrazone, followed by oxidation with MnO_2 provided the aryldiazoethane precursor that was used to alkylate ATP. The photolysis of caged ATP furnished ATP with an efficiency of 0.63, as illustrated in Eq. (69.26):



(69.26)

The rate of release of ATP was found to be dependent on the pH and the relative concentration of magnesium ion in solution. Pelliccioli and Wirz[5] have shown that the rate-determining step is the decay of the hemiacetal (or hemiketal) intermediate between pH 4 and 8. In this region, the slow hydrolysis of the hemiacetal limits the mechanistic value of the *o*-nitrobenzyl protecting group to studies of relatively slow reactions (e.g., $k_r < 10^3\ s^{-1}$).

The nitroso byproduct has also proved problematic for spectroscopic analyses of ONB reactions due to its reactivity with some substrates and with proteins. This problem was circumvented by conducting the photolysis in the presence of dithiothreitol, a hydrophilic thiol and an excellent nucleophile that readily sequesters the nitroso byproduct.

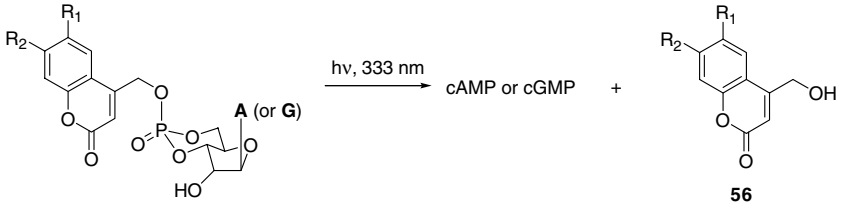
TABLE 69.15 Results of Photolysis of cAMP and cGMP Coumaryl Esters

Coumaryl Derivative	Solvent	Φ_{dis} [a]	λ_{max} (nm)
55a	80:20 HEPES-KCl buffer/MeOH	0.21 (0.25)	402
55b	HEPES-KCl buffer, pH 7.2	0.12 (0.16)	326
55c	HEPES-KCl buffer, pH 7.4	0.10 (0.14)	346

[a] For the cAMP ester; quantum efficiency for the cGMP derivative is in parentheses.

Coumaryl

Coumarylmethyl esters have been used as photoprotecting groups by several groups (e.g., Furuta et al.[55,56] and Hagen et al.[57]) for deprotection of cAMP and cGMP. To overcome the limited aqueous solubility of these derivatives, Hagen has modified the coumaryl chromophore with carboxyl and amino substituents.[57] Three new variants of the coumaryl system were synthesized and their photochemistry explored — (7-diethylaminocoumarin-4-yl)methyl (DEACM), (7-carboxymethoxycoumarin-4-yl)methyl (CMCM), and (6,7-*bis*[carboxymethoxy]coumarin-4-yl)methyl (BCMCM) as esters of cAMP and cGMP. Photolysis resulted in liberation of the free cyclic phosphate along with the hydrolyzed chromophores, i.e., **56a-c** (Eq. (69.27).



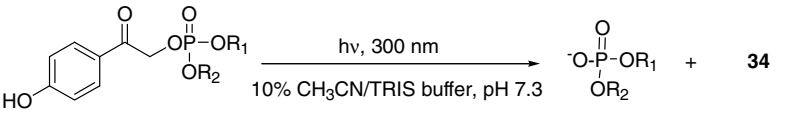
55a R_1 = H, R_2 = Et_2N
55b R_1 = H, R_2 = OCH_2CO_2H
55c R_1 = R_2 = OCH_2CO_2H

(69.27)

The caged coumaryl compounds were synthesized in 11 to 34% yield, clearly a limitation with this photoremovable protecting group. The addition of the carboxymethoxy groups in **55b** and **55c** dramatically enhanced the water solubility of these analogs as compared with the ester **55a**, and their photorelease occurred with good quantum efficiencies as seen in Table 69.15. On the other hand, the less water-soluble **55a** had the best quantum efficiency, and its absorption maximum was the most red shifted in the series.

Phenacyl

In light of its inherent advantages over other chromophores, the *p*-hydroxyphenacyl group has received recent attention as a promising photoprotecting group for phosphates. Recent reports on *p*-hydroxyphenacyl esters of phosphate, diethyl phosphate, and ATP by Givens et al.[36] and on GTP by Du et al.[58] indicate that these phosphate esters undergo efficient photorelease of the phosphoric acid moiety along with the rearranged *p*-hydroxyphenylacetic acid as the sole photoproducts of the reaction (Eq. (69.28).



57a $R_1 = R_2 = Et$
57b $R_1 = R_2 = NH_4^+$
57c $R_1 = GDP$, $R_2 = NH_4^+$
35 $R_1 = ADP$, $R_2 = NH_4^+$

(69.28)

TABLE 69.16 Data for pHP Caged Phosphates

Caged Phosphate[a]	Protection (% Yield)	Deprotection (% Yield)	Φ_{dis}
57a	87	Not determined	0.77
57b	96	Quant	0.38
35	42	Quant	0.37 (0.30)[b]
57c	20	Not determined	Not determined

[a] Results shown for **57c** are from Du et al.;[58] derivative **57c** was photolyzed at 308 nm.
[b] The value in parentheses for **35** is the quantum efficiency for the appearance of ATP.

Derivative **57a** was synthesized by reacting the phosphate directly with *p*-hydroxyacetophenone bromide. Derivative **57b** was synthesized from hydrogenolysis of the pHP dibenzyl phosphate ester. For **35** and **57c**, the pHP monophosphate (**57b**) was first protected as the corresponding ketal that was then coupled with ADP or GDP, respectively. The caged ATP and GTP analogs were then obtained by hydrolysis of the ketal. Yields and quantum efficiencies for the disappearance of the pHP phosphate esters are given in Table 69.16.

pHP caged ATP was recently used as a probe in the study of $Na,^+$ K^+-ATPase, an enzyme involved in the intracellular transport of sodium and potassium ions.[59] Membrane samples possessing the ion-channel proteins were bathed in caged ATP which was activated by UV laser flash photolysis. $Na,^+$ K^+ channel transport was observed as a result of the activation of the enzyme by the released ATP. Direct spectroscopic evidence of the release of ATP was obtained by time-resolved Fourier transform infrared (FTIR) spectroscopy (Figure 69.2). The changes in the characteristic absorptions of the prominent functional groups of the reactant and product include the disappearance of the γ-PO_2^- ester band of the caged ATP at 1270 cm^{-1} and the appearance of the free γ-PO_3^{-2} band of the released ATP at 1129 cm^{-1}.

Benzoin

In 1994, Pirrung and Shuey[60] reported the protection of phosphates using the dimethoxybenzoin. Resolved *(R)*3′,5′-dimethoxybenzoin (optically active) was converted to the phosphoramidite by treatment with diisopropylaminocyanoethoxychlorophosphine. Subsequent reaction with the appropriate primary or secondary alcohol followed by oxidation led to the series of phosphate esters **58a-e** in moderate to high yields:

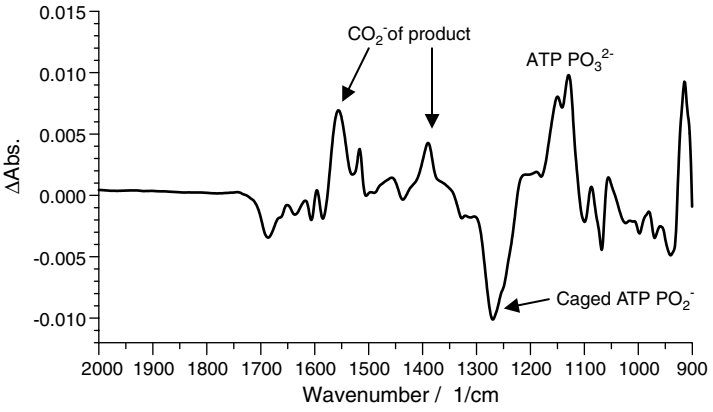


FIGURE 69.2 Time-resolved FTIR difference spectrum for the photolysis of pHP caged ATP. The absorbance was measured 10 ms to 11 s after the photolysis flash and subtracted from the absorbance prior to photolysis. (We thank Professors Klaus Fendler and Andreas Barth for the TR-FTIR results with pHP ATP.)

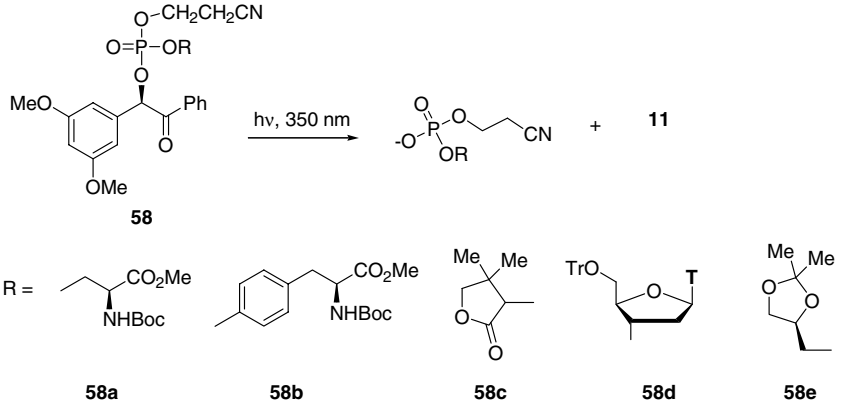

(69.29)

Photolysis of **58a-e** shown in Eq. (69.29) led to release of the phosphate derivative along with the benzofuran byproduct **11**. The overall sequence from the phosphoramidites to phosphate esters **58a–e** was accomplished in moderate yields, and the unprotected phosphates were obtained in good yields upon photolysis, as seen from Table 69.17.

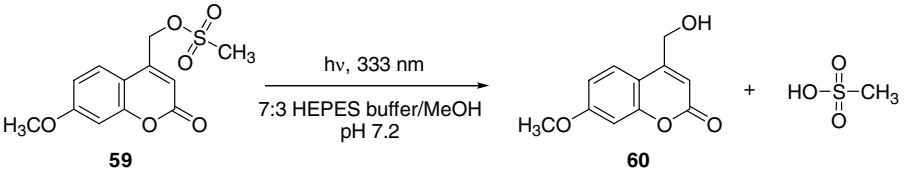
69.5 Sulfates and Other Acids

Sulfonic acids have largely remained unexplored in terms of a functional group that is released from a photoremovable protecting group. One recent example has been reported by Bendig et al.,[46] in which methanesulfonic acid was protected as the corresponding methoxycoumarin derivative. (7-Methoxycoumarin-4-yl)methylmethanesulfonate **59** was synthesized from reaction of methanesulfonic acid with 4-(diazomethyl)-7-methoxycoumarin in refluxing chloroform. Photolysis at 333 nm resulted in the release of methanesulfonic acid, as shown in Eq. (69.30).



59 **60**

HEPES = *N*-(2-hydroxyethyl)piperazine-*N*'-(2-ethanesulfonic acid)

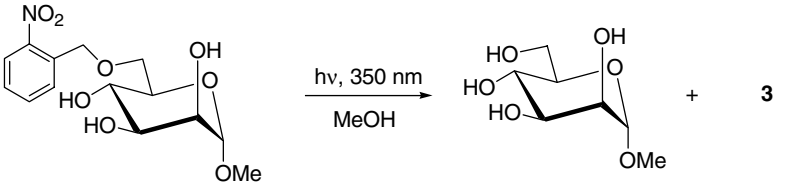
(69.30)

While the protection yield for **59** was low (26%), the quantum efficiency of 0.081 is reasonable when compared with other leaving groups that were reported in this study. The chemical yield of the deprotection was not provided; however, the photoproduct **60** was recovered in ≥95% yield, suggesting a high yield of the released sulfonic acid.

69.6 Alcohols, Thiols, and *N*-Oxides

o-Nitrobenzyl

Among the most common photoprotecting groups used for alcohols are the *o*-nitrobenzyl derivatives. Recently, Iwamura[61] reported the synthesis and photochemistry of caged carbohydrates protected with an *o*-nitrobenzyl group at one or more positions within the molecule. Equation (69.31) illustrates a typical example in which photolysis of the caged glucopyranoside **61** at 350 nm in methanol led to the release of the free methylglycoside **62** in 60% yield, along with the nitroso byproduct **3**.

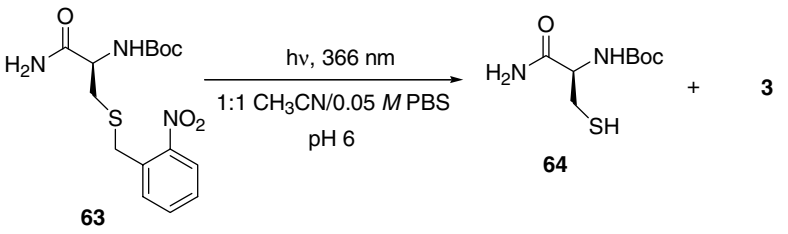


61 **62** **3**

(69.31)

Derivative **61** was synthesized in 71% yield by reductive bond cleavage of the corresponding 4,6-*O*-*o*-nitrobenzylidene acetal of methyl 3,4-acetyl-β-glucoside with triethylsilane and boron trifluoride etherate, followed by deacetylation of the 3,4-diacetates with sodium methoxide in methanol.

o-Nitrobenzyl chemistry was also extended to the release of thiols as demonstrated by Smith et al.,[62] who demonstrated that a cysteine congener was protected as the corresponding thioether **63** in 89% yield. Photocleavage occurred at 366 nm to give the liberated Boc-protected thiol **64** in 44% yield in the presence of semicarbazide hydrochloride, a carbonyl scavenger (Eq. 69.32).



(69.32)

Finally, the addition of ascorbic acid as an antioxidant to the reaction mixture gave a quantitative yield of **64**. No thiol was recovered when the photolysis was carried out in the absence of ascorbic acid, despite experimental evidence of the disappearance of **63**.

While the *o*-nitrobenzyl system is well accepted as a photoremovable protecting group, it nevertheless suffers the limitation of toxicity to the biological entity and a highly reactive nitroso functional group formed as the byproduct. As was seen in the case of the cysteine cogener **63**, the photodeprotection may require a scavenging or reducing agent if thiols are to be generated in such a strategy.

In the late 1990s, Pfleiderer and co-workers[63] developed a new, β-substituted variant of the *o*-nitrobenzyl chromophore, 2-(*o*-nitrophenyl)ethoxycarbonate. The 5′-*O*-2-(*o*-nitrophenyl)ethoxycarbonyl thymidines were obtained from 2-(*o*-nitrophenyl)ethanol carbonates by reaction with diphosgene under basic conditions, followed by treatment with thymidine in anhydrous methylene chloride at reduced temperature. The synthetic yields ranged from 41 to 81%.

Photolysis of a 0.1-m*M* solution of the photoprotected thymidine **65** in a 1:1 methanol/water mixture at 365 nm resulted in the release of thymidine (**66**), carbon dioxide, and the photolabile *o*-nitrostyrene derivative **67** (Eq. (69.33).The photorelease is believed to occur through a β-elimination mechanism[64,65] from the aci-nitro intermediate **67′** shown in Scheme 10.

nd = not determined

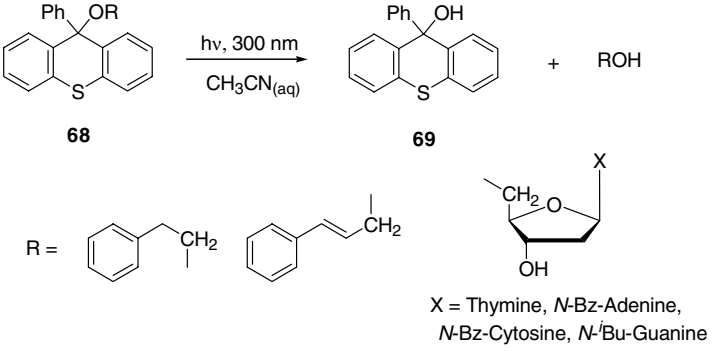
Some advantages of this nitrobenzyl variant include the lack of the nitroso byproduct and release rates that are relatively fast compared with the parent *o*-nitrobenzyloxycarbonyl derivative. For example, the release of thymidine from **65b** is reported to be twice as fast as that for the α-substituted derivative; however, the nitrostyrenes (i.e., **67**) are photolabile and thus can compete with the starting material for incident light.

The quantum efficiencies for the release of thymidine varied depending on the substituents on **65**. Substitutions at the benzylic carbon appeared to give the highest release efficiencies, whereas the chloro derivatives gave slightly better conversions, as seen in Table 69.18.

The high quantum efficiency and respectable protection and deprotection yields obtained for the methyl-substituted 2-(*o*-nitrophenyl)ethoxycarbonyl photoprotecting group prompted Pirrung et al.[66] to use this protecting group for the solid-phase synthesis of oligodeoxynucleotides.

Thiopixyl and Coumaryl

Coleman and Boyd[67] introduced the 9-phenylthioxanthyl or S-pixyl photoprotecting group for the fourt principal nucleosides, thymidine and three other benzoyl protected nucleoside bases. The chromophore was synthesized in three steps, starting with thioxanthone, through Grignard addition of phenylmagnesium bromide, followed by dehydration with trimethylsilyl chloride and dimethylsulfoxide to give the 9-chloro-9-phenylthioxanthene. Treatment with the corresponding alcohol in a dry solution of pyridine and dimethylaminopyridine (DMAP) afforded the photoremovable protected hydroxy derivatives **68** in good yields (Table 69.19). Irradiation of **68** in aqueous acetonitrile resulted in the release of the nucleoside or alcohol along with **69** (Eq. (69.34)).



(69.34)

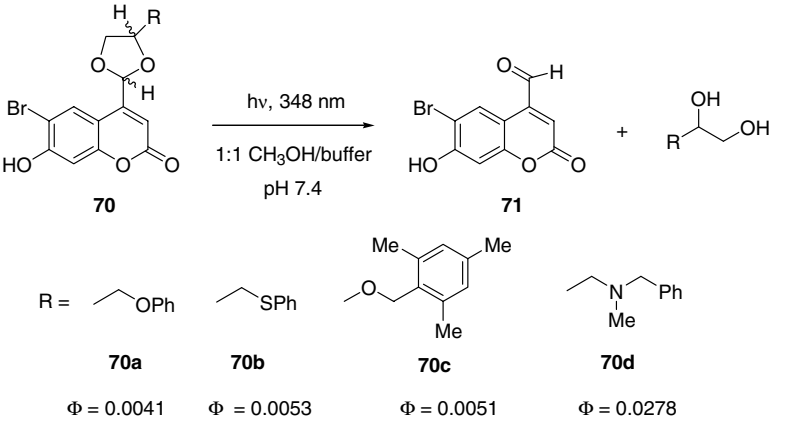
N-^{i}Bu-guanosine	92	89

[a] Based on isolated yields after column chromatography.
[b] Substrate concentrations were approximately 0.1 m*M*; yields were determined by HPLC.

Mechanistically, this photorelease reaction occurs via photosolvolysis of the aryl ether carbon–oxygen bond. The resulting resonance stabilized S-pixyl carbocation reacts with water to form **69**. Control experiments showed that the photoprotected alcohols are stable under thermal conditions; that is, refluxing in aqueous acetonitrile resulted in no detectable decomposition. Each of the caged products was obtained as a solid, a convenience for laboratory purification and manipulation. The best deprotection yields were obtained with solvent mixtures containing the maximum concentration of water permissible, limited only by the solubility of the protected alcohol. Concentrations of water ranged from 40 to 60%, depending on the type of alcohol used. In most cases, excellent deprotection yields were obtained.

A factor that limits the versatility of the S-pixyl group is the wavelength range required for photolysis. The range of excitation wavelengths from 200 to 300 nm overlaps with a number of functional groups that could compete with the incident light. For example, the pyrimidine base cytosine has substantial absorptivity at 300 nm. As a result, extended irradiation times were required to effect deprotection of the *N*-Bz-cytidine analog and a lower yield was obtained, as seen from Table 69.19.

Coumaryl photoprotecting groups have also been used for the protection of alcohols. A recent study by Lin and Lawrence[69] described the synthesis and photorelease of caged diols using a coumaryl acetal derivative **70** (Eq. (69.35)).

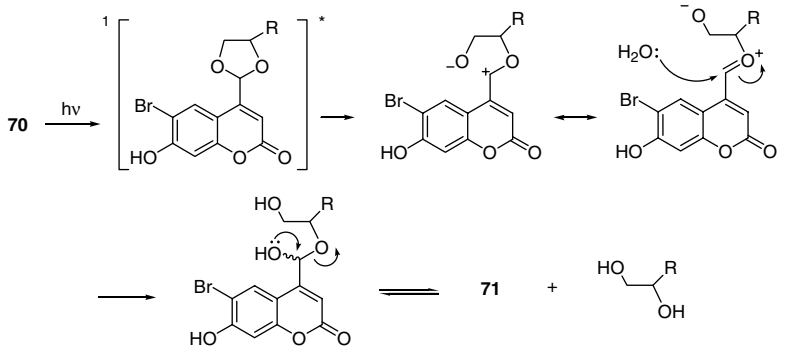


(69.35)

Acetal **70** was prepared in a two-step sequence starting with oxidation of 6-bromo-7-hydroxy-4-hydroxymethylcoumarin with manganese dioxide, followed by addition of the corresponding diol in

anhydrous toluene. Protection yields ranged from 94% for **70a** to 15% for **70d**. Photolysis of **70** at 348 nm in a methanol/aqueous buffer solution afforded the free diol accompanied by the aldehyde photoproduct **71**. The specific deprotection yields were not provided but in all cases were reported to exceed 75%.

The photorelease mechanism is not well understood but is speculated to proceed through an intramolecular ion pair[69] generated from photoheterolysis of the carbon oxygen bond, as shown in Scheme 11. Attack of a water molecule at the electrophilic carbon generates a hemiacetal that eliminates the alkoxy group to afford the diol and byproduct **71**.



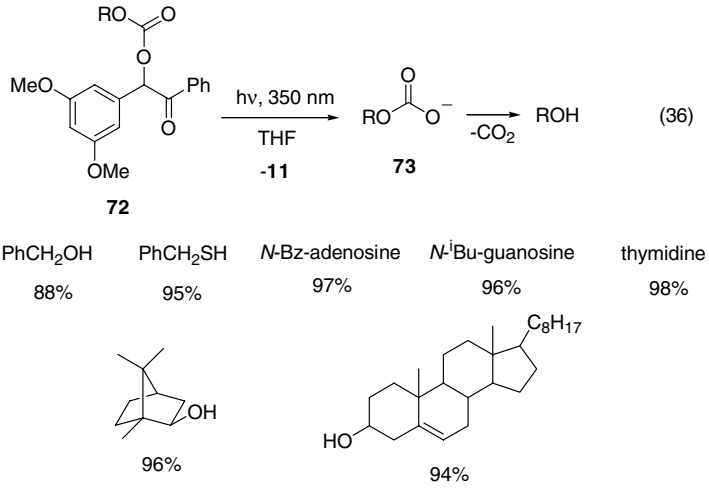
SCHEME 11 Mechanism proposed for the photorelease of caged diols from **70**.

This particular coumaryl variant offers a unique advantage in essentially being able to protect both hydroxyl groups of a diol using only one equivalent of the protecting group. In addition, the derivatives in this study were shown to be stable to hydrolysis in aqueous solvents at neutral or basic pH. For example, incubation of compounds **70a–d** in a 1:1 methanol/buffer solution (pH 7.4) resulted in no detectable degradation after a period of two weeks. Despite these advantages, the range of applications of the coumarin group is limited thus far to 1,2- and 1,4-diols (1,3-diols were found to be inert to photolysis). Like the *o*-nitrobenzyl group, the coumaryl group also has the disadvantage of producing a highly absorbing photoproduct. In addition, further studies need to be carried out in order to elucidate the mechanism of the photocleavage.

Benzoin

In 1995, Pirrung and Bradley[70] reported the use of dimethoxybenzoin (DMB) carbonate to protect various alcohols, including the 5′-hydroxyl group of nucleosides. The DMB carbonate was synthesized in three steps, starting with methylation of carbonyldiimidazole with methyl triflate followed by addition of 2-(3,5-dimethoxyphenyl)-2-hydroxy-1-phenylethanone to form a relatively stable activated acylating agent. Treatment with an alcohol under basic conditions in nitromethane furnished the protected alcohol **72** in yields that ranged from 42 to 95%.

Irradiation of **72** at 350 nm resulted in release of the alcohol and formation of dimethoxybenzofuran **11** (Eq. (69.36)). A wide variety of alcohols, including a thiol, were explored in this protection/deprotection scheme. Excellent deprotection yields were obtained, as high as 98% for the protected thymidine derivative. The mechanism as discussed earlier is postulated to proceed through intramolecular cyclization followed by demotion to form a zwitterionic intermediate. Expulsion of the alcohol occurs either concomitantly with the release of carbon dioxide or by a stepwise decarboxylation of the initially released carbonate **73**. In most cases, excellent deprotection yields were obtained.



(69.36)

Attractive features of the DMB photoprotecting group are that the benzofuran photoproduct **11** is inert and exhibits strong fluorescence at 396 nm, allowing the deprotection conversions to be monitored spectroscopically. In the same study, the DMB group was successfully used to synthesize two trinucleotides bearing adjacent thymidine residues, demonstrating its potential in solid-phase DNA synthesis. Compared with nitrobenzyl photoprotecting groups, the rate of release of substrate is much faster for the DMB group[70] ($k_{release} \sim 10^8$–10^9 s^{-1}). The main disadvantages of the DMB group are the competition for incident light by the photoproducts and poor solubility in aqueous media.

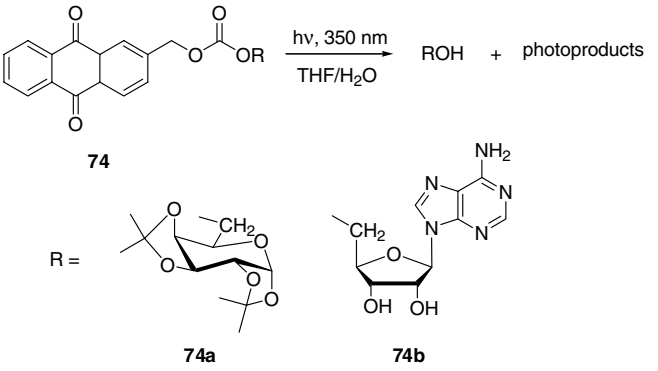
Other

The anthraquinon-2-ylmethoxycarbonyl (Aqmoc) photoprotecting group is a relatively recent addition to the chromophores used as photoremovable groups. In a recent application for alcohols, Furuta et al.[71] reported that the caged derivative could be synthesized in two steps from anthraquinonylmethanol by treatment with 4-nitrophenylchloroformate in DMAP followed by coupling to the desired alcohol with DMAP to provide **74** in good yields (Table 69.20). Photolysis of **74** in 50% aqueous tetrahydrofurane (THF) at 350 nm resulted in the release of the alcohol (Eq. (69.37)).

TABLE 69.20 Yields and Quantum Efficiencies[a] for Aqmoc Derivatives

Aqmoc Derivative	Protection (% Yield)	Φ	Deprotection (% Yield)
74a	76	0.1	68
74b	86	Not determined	91[b]

[a] For the disappearance of starting material.
[b] Determined by HPLC.



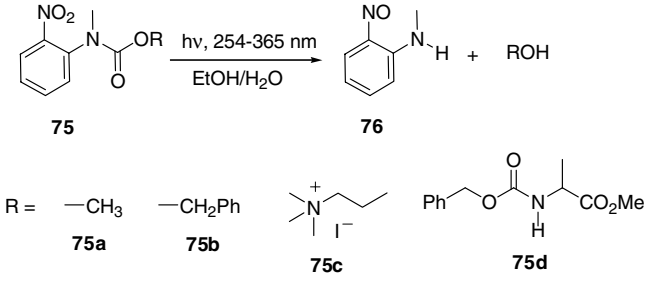
(69.37)

The photoproducts from the anthraquinone moiety were not fully characterized; however, in the case of **74a**, an anthraquinon-2-ylmethanol tetrahydrofuranyl ether was isolated, probably the result of hydrogen atom abstraction from the solvent. Also, a small amount of *bis*(1,2,3,4-di-*O*-isopropylidene-D-galacto-pyranosyl) carbonate was obtained after photolysis of **74a**, likely the result of attack of the released alcohol on the starting material.

Little is known about the photorelease mechanism of the Aqmoc group. Stern–Volmer analysis showed that the triplet excited state is the reactive excited state that leads to release of the alcohol. The rate constant determined for **74a** (4.6×10^6 s^{-1}) is consistent with rapid release of the carbonate followed by a slower, rate-limiting loss of carbon dioxide to give the free alcohol. Additional studies are needed to confirm this mechanism.

Recently, it was shown that nitro-substituted aryl carbamates could be used as photolabile protecting groups for alcohols.[72] *N*-Methyl-*N*-(*o*-nitrophenyl)carbamate **75** (Eq. (69.38)) was synthesized in two steps, beginning with acylation of *N*-methyl-2-nitroaniline with phosgene followed by nucleophilic addition of the alcohol, either as an alkoxide or in the presence of DMAP and triethylamine. An alternative synthetic route involved the generation of the corresponding chloroformate from the alcohol and phosgene followed by nucleophilic addition of the nitroaniline. The carbamate derivatives **75a-d** were synthesized in yields ranging from 58 to 94%.

Photolysis of carbamate **75** at various wavelengths led to deprotection of the alcohol, which was accompanied by formation of nitrosoaniline **76** as a byproduct. Deprotection yields for all derivatives were not provided; however, the reported yields for **75c** and **75d** were 100% and 91%, respectively. Such high yields are a definite advantage in terms of both synthetic and biological applications. Another attractive feature is the solubility in ethanol and water, solvents suitable for biological studies. Despite these advantages, two main limitations are worthy of note. First, the carbamate cages are susceptible to hydrolysis, particularly in basic media,[73] thus limiting their use to aqueous solvents with relatively neutral pH. Second, longer irradiation wavelengths were found to result in decreased deprotection yields; for example, when **75c** was irradiated at 312 nm, a quantitative deprotection yield was obtained. The yield dropped to 76% when the photolysis was carried out at 365 nm.



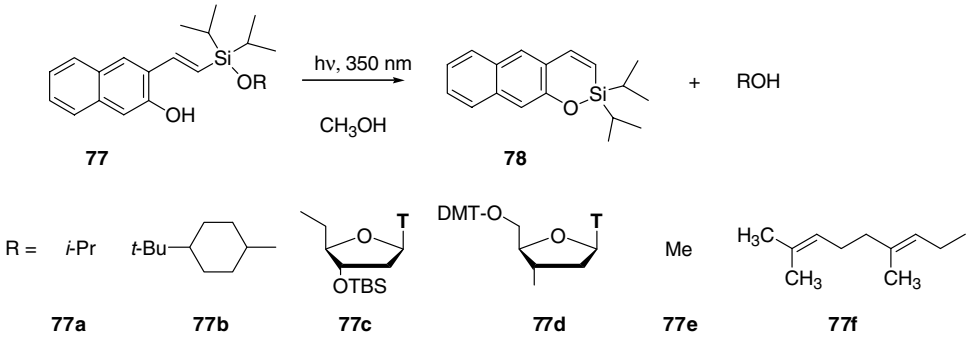
(69.38)

TABLE 69.21 Caged Silyl Derivatives and Their Corresponding Deprotection Yields in Methanol

Silyl Ether	Protection (% Yield)	Deprotection (% Yield)
77a	82	94[a]
77b	80	89
77c	77	90
77d	79	92
77e	81	86[a]
77f	85	90

[a] Based on the yield of the byproduct **78**.

Silyl photoprotecting groups have recently been developed for primary and secondary alcohols.[74] The silyl cage, (2-hydroxy-3-naphthylvinyl)-diisopropylsilyl ether **77,** was synthesized in nine steps starting with the commercially available naphthalene-2,3-diol. Irradiation at 350 nm in methanol triggered the release of the alcohol, accompanied by the formation of a cyclic silyl byproduct **78** (Eq. (69.39). This byproduct is likely formed via intramolecular attack of the naphthol oxygen at silicon following a trans,cis-isomerization of the starting material. Synthetic and photochemical yields are listed in Table 69.21.



(69.39)

Byproduct **78** exhibits its strongest absorption in the region below 310 nm and, therefore, does not significantly compete with **77** for incident light. The yields from Table 69.21 are sufficiently high to enable the practical use of the silyl photoprotecting group in synthetic applications; however, the silyl cages lack the water solubility necessary for application in aqueous media. Like triisopropylsilyl ethers, the cages are also susceptible to cleavage in the presence of acidic media or solutions containing fluoride such as 1-*N* HCl or TBAF.[75]

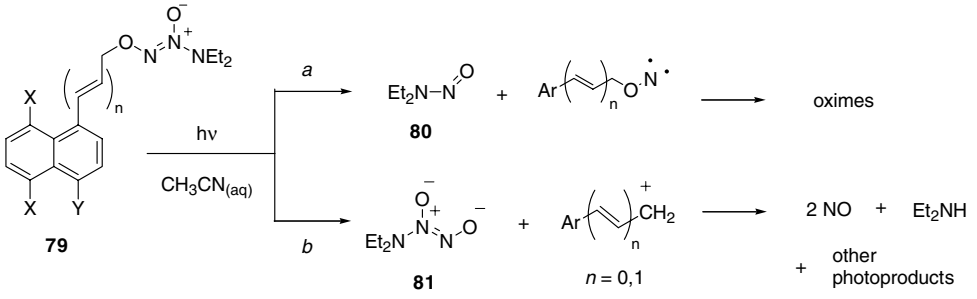
The importance of nitric oxide (NO) in bioregulatory processes and other physiological functions prompted the development of photoprotecting groups specifically designed for its release. A most recent example is the synthesis and photochemistry of a series of naphthylmethyl and naphthylallyl diazeniumdiolates.[76] These derivatives, represented by **79** in Eq. (69.40), were prepared from reaction of 1-(*N*,*N*-diethylamino)-diazen-1-ium-1,3-diolate (**81**) with the corresponding alkyl bromide. Photolysis produced a mixture of products that resulted from two different reaction pathways. Path *a* is a nonproductive pathway that leads to the formation of nitrosamine **80** and oxime byproducts. Path *b* leads to diazeniumdiolate **81,** which collapses to give free NO, along with diethylamine and other photoproducts. The extent to which the reaction follows one pathway over another is dependent on the substituents present on the naphthyl ring. As Table 69.22 shows, the best deprotection yields were obtained with a methoxy group at the 5 and 8 positions of the ring.

TABLE 69.22 NO Cages and Their Corresponding Deprotection Yields and Quantum Efficiencies

NO cage	Protection (% Yield)	Φ	Deprotection[a,b] (% Yield)
79a	90	0.007	1
79b	25	Not determined	1
79c	30	0.12	25
79d	36	0.12	40
79e	5	0.66	95

[a] Based on the disappearance of starting material (using HPLC) and the amount of NO measured; thermal decomposition of **81** was found to produce 1.5 equivalents of NO.

[b] For **79a–c**, a wavelength of 300 nm was used; for **79d,e**, the wavelength was 350 nm.

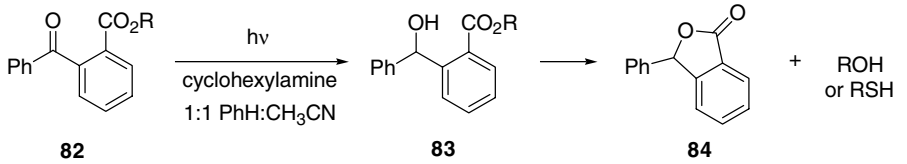


79a *n* = 0, X = Y = H
79b *n* = 0, X = H, Y = Me
79c *n* = 1, X = Y = H
79d *n* = 0, X = OMe, Y = H
79e *n* = 1, X = OMe, Y = H

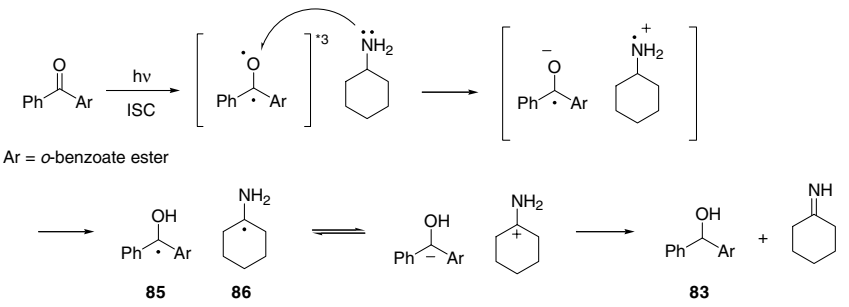
(69.40)

The likely mechanism proceeds through photosolvolysis of the carbon–oxygen bond, resulting in a resonance-stabilized carbocation. Subsequent release of NO occurs from the diazeniumdiolate **81**. Acidic conditions that protonated the amine greatly enhanced the rate of NO release. Derivative **79e** undergoes clean deprotection and exhibits an excellent quantum efficiency, making it the most attractive of the NO cages studied thus far. Some additional advantages are its absorption beyond 300 nm (λ_{max} = 336 nm) and its stability in acidic and basic solutions at room temperature for up to 24 hr. Unfortunately, it suffers from a low protection yield of only 5%, and its solubility is limited to 20 μ*M* in 95% aqueous acetonitrile. Despite these shortcomings, its development may pave the way for similar methoxy-substituted naphthylallyl derivatives with increased solubility in aqueous media and higher protection yields.

A unique photoprotecting group for alcohols and thiols was reported in the mid 1990s.[77] Benzoylbenzoate ester **82** (Eq. (69.41)) was synthesized in one step from DCC coupling of the corresponding alcohol or thiol to 2-benzoylbenzoic acid. Photolysis at ~300 nm in the presence of cyclohexylamine, an electron donor, afforded 3-phenylphthalide **84** along with the free alcohol or thiol.



R = n-$C_{12}H_{25}$-, c-$C_{12}H_{23}$-, cholesteryl-, geranyl-, 2',3'-isopropylidene uridinyl-, n-$C_{12}H_{25}$ (thioester) (69.41)



SCHEME 12 Proposed photoreduction mechanism of benzoylbenzoate esters.[65]

TABLE 69.23 Data for Benzoylbenzoate Esters

R	Protection (% Yield)	Deprotection[a] (% Yield)
n-$C_{12}H_{25}$-	76	95
c-$C_{12}H_{23}$-	50	85
Cholesteryl-	67	100
Geranyl-	63	90[b]
2′,3′-isopropylidene uridinyl	79	90[c]
n-$C_{12}H_{25}$ (thioester)	76	60

[a] Yield of the recovered alcohol (thiol) was determined with NMR.
[b] *sec*-Butylamine was used as the electron donor; the solvent was 1:1 benzene/isopropanol.
[c] *sec*-Butylamine was the electron donor; photolysis was carried out with a uranium filter.

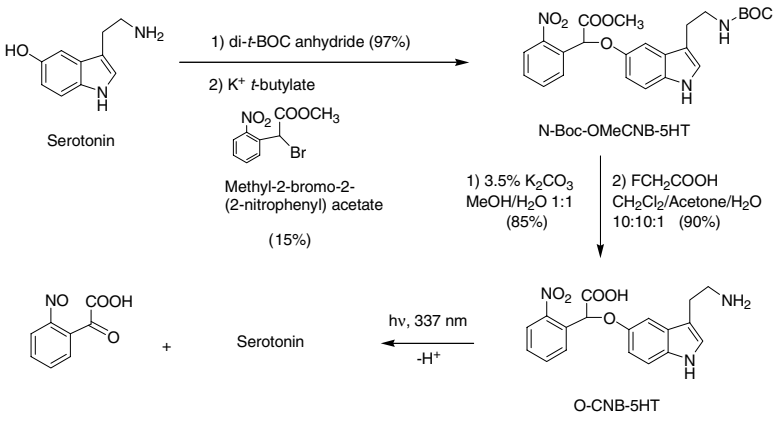
The mechanism outlined in Scheme 12[78] involves electron transfer from the amine to the ketone in the excited state followed by intermolecular proton transfer to generate radical pair **85**–**86**; a second electron transfer and proton exchange lead to the reduced alcohol **83**, which lactonizes to form **84** concurrently with release of the alcohol. In general, the benzoylbenzoate photoprotecting group worked well for the particular substrates studied. Synthesis yields for the benzoylbenzoate cages were respectable, and the deprotection occurred in most cases with good recoveries of the alcohol (Table 69.23). Problems were encountered in the photolysis of the caged thiol that led to the formation of side products and thus a lower overall deprotection yield.

While the benzoylbenzoate cages exhibit good deprotection yields for alcohols, their application is limited to organic solvents. The presence of an electron donor (i.e., aliphatic amine) is also required, a necessity that may complicate the reaction mixture in the presence of other sensitive functional groups. Finally, the release process must be inherently a slow one due to the ground state lactonization process involved.

69.7 Phenols and Other Weak Acids

o-Nitrobenzyl

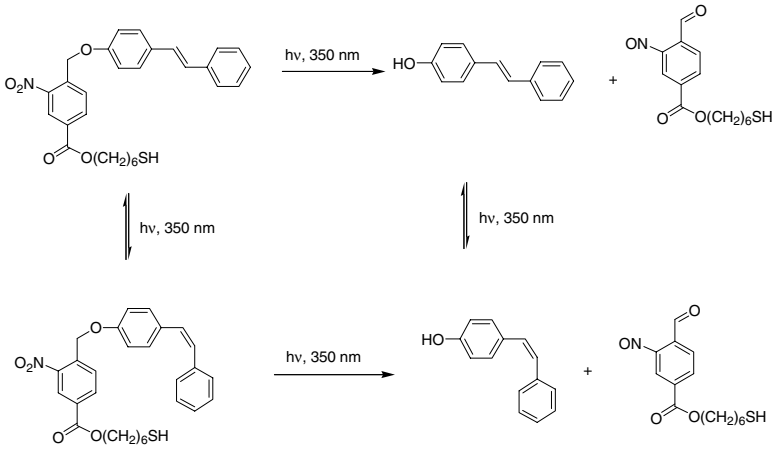
The photolabile *o*-nitrobenzyl derivative was utilized to protect the phenolic OH group of serotonin.[79] The serotonin type-3 receptor is the only ligand-gated ion channel in the 5-HT receptor family.[80,81] The protection of the phenolic hydroxy group of serotonin required four steps, as shown in Scheme 13. The substrate was released upon excitation with 337-nm laser pulses. The signal decay from pulsed laser



SCHEME 13 Protection and photochemical deprotection of serotonin.

studies gave a time constant of 16 μs, and the quantum yield was determined to be 0.03. The rate of decay of the intermediate was observed to be pH dependent. The caged serotonin showed good solubility in buffered aqueous media (in excess of 2 m*M*); however, the authors suggested that the caged compound was subject to hydrolysis in the dark on standing.

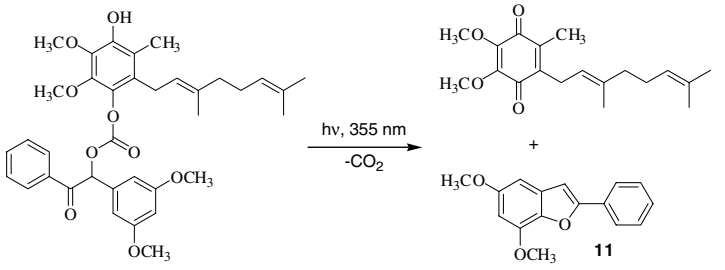
This photoremovable protecting group has been employed as a photocleavable linker to reagents bound to Au surfaces.[82] 4-Hydroxy-stilbene was linked to 6-bromohexyl-3-nitro-4-bromomethylbenzoate in 51% yield, then thiolated by trimethylsilylthioxy dehalogenation in THF, followed by desilylation *in situ*. The self-assembled monolayers of long-chain alkyl thiolate on bulk polycrystalline gold were constructed. Upon irradiation at 350 nm, the *Z,E*-photoisomerization attained a photostationary state within 25 min, while the dissociation took about 60 min; however, sensitization with 1,4-dibromonaphthalene (E_T = 58.1 kcal/mol) produced a cleaner photoisomerization. The unidirectional isomerization, from cis to trans, by both direct irradiation and sensitization was followed by the release of a bound chain from the metal surface.



SCHEME 14

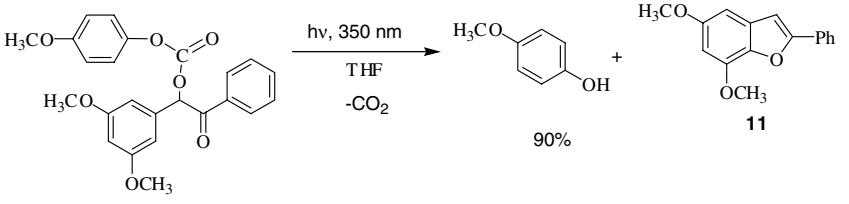
Benzoin

The ubiquinol oxidizing enzyme is a redox active enzyme that requires a fast two-electron reduction of ubiquinone. 3′,5′-Dimethoxybenzoin (DMB) caged ubiquinol[83] was synthesized to study the detailed enzymatic mechanism of the fast electron-transfer process in redox active enzymes. The monosilylated ubiquinol was coupled to the protecting group to form the *o*-nitrophenylcarbonate ester of 3′,5′-dimethoxyphenyl(phenyldithiane) in 55% yield. Upon photolysis, DMB caged ubiquinol generated ubiquinone with a rate greater than 10^6 s^{-1}(Eq. (69.42)).



(69.42)

Pirrung and Bradley[70] also applied DMB (3′,5′-dimethoxybenzoin) to protect the phenolic group, demonstrating that 4-methoxyphenol was released upon irradiation at 350 nm in 90% yield (Eq. (69.43)).

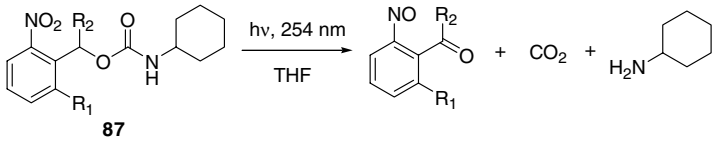


(69.43)

69.8 Amines

o-Nitrobenzyl

There are few variations for effective amine photoremovable protecting groups. The *o*-nitrobenzyl group remains the most popular group and among the many examples the studies by Cameron and Frechet are noteworthy.[84] In general, *o*-Nitrobenzylcarbamates of aliphatic amines upon photolysis release the amine in good yield. For example, cyclohexyl amine is released from its *o*-nitrobenzyl carbamate **87** as the corresponding free carbamate upon irradiation in THF at 254 nm (Eq. (69.44)).



(69.44)

Subsequent loss of carbon dioxide frees the amine. Quantum efficiencies varied depending on the substituents present at the ortho and benzylic positions (Table 69.24). The best efficiencies were obtained with two *o*-nitro groups on the aryl ring, likely increasing the probability for the hydrogen atom abstraction by one of the nitro groups.

TABLE 69.24 Protection Yields[a] and Quantum Efficiencies for Various Substituted *o*-Nitrobenzyl Carbamates

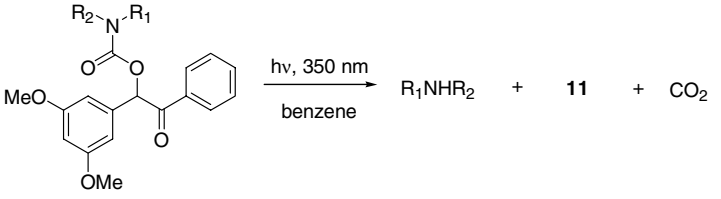
R_1	R_2	Protection (% Yield)	Φ
H	H	71	0.13
NO_2	H	78	0.62
H	Me	71	0.11
NO_2	Me	71	0.35
H	*o*-Nitrophenyl	79	0.26
NO_2	2,6-Dinitrophenyl	52	0.28

[a] Deprotection yields were not provided.

A problem that is not entirely avoidable is the formation of imine byproducts via reaction of the released amine with the aldehydic group in the photoproduct. This occurrence could be suppressed with alkyl or aryl substitution at the benzylic position, leading to the formation of a less reactive ketone in comparison with the nitroso aldehyde formed with no substitution at the benzylic position. Imine byproduct formation is also less likely to occur in relatively nonpolar solvent systems, such as THF, which ultimately limits the application of the *o*-nitrobenzyl carbamate photoprotecting group to nonaqueous systems in this regard.

Benzoin Derivatives

In the mid-1990s, Pirrung and Huang[85] extended the use of the benzoin photoprotecting group to the release of amines by synthesizing *m*,*m*′-dimethoxybenzoin (DMB) carbamates. The DMB derivatives were synthesized by coupling the corresponding amine with benzoin carbonyl chloride that had been elaborated by reaction of carbonyldiimidazole with the methyl triflate of **88** followed by nucleophilic addition of DMB. Irradiation in benzene or THF at 350 nm produced the free amine, carbon dioxide, and the benzofuran byproduct (Eq. (69.45)).



88

(69.45)

Five different amines were protected and recovered in moderate to good yields as shown in Table 69.25. The DMB carbamates appeared to work well for a variety of amines in the presence of other functional groups, such as alcohols or esters; however, the reaction is limited to secondary amines, as primary amines were found to undergo intramolecular cyclization leading to byproducts that are inert to photolysis.

Arylsulfonamides

Corrie and Papageorgious[86] have reported the synthesis and photochemistry of various methoxy-substituted arylsulfonamides. Similar derivatives had been previously found to undergo single electron transfer reactions in the excited state, leading to cleavage of the sulfur–nitrogen bond.[87,88] It was reasoned that such a process could be used for the rapid release of neurologically active amines.

The arylsulfonamide derivatives were synthesized in several steps, starting from 1,5-dimethoxynaphthalene. Photolysis of **89** in phosphate buffer (pH 7.0) in the presence of ascorbate resulted in release of

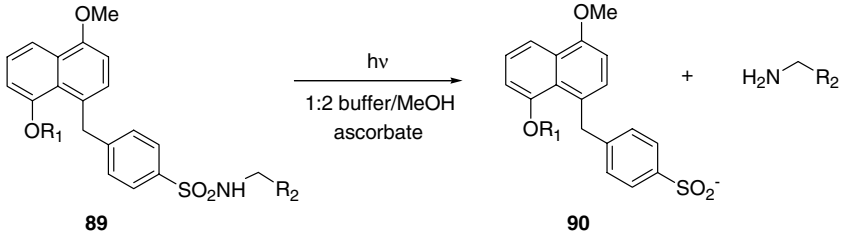
[a] The amine was recovered as the corresponding hydrochloride salt.

TABLE 69.26 Synthesis and Photochemistry Yields of Arylsulfonamides

R_1	R_2	Protection (% Yield)	Deprotection[a] (% Yield)
$(CH_2)_3OPO_3^{-2}$	CO_2^-	71	35
$(CH_2)_3OPO_3^{-3}$	$CH_2CO_2^-$	61	22[b]
Me	CO_2Me	59	53

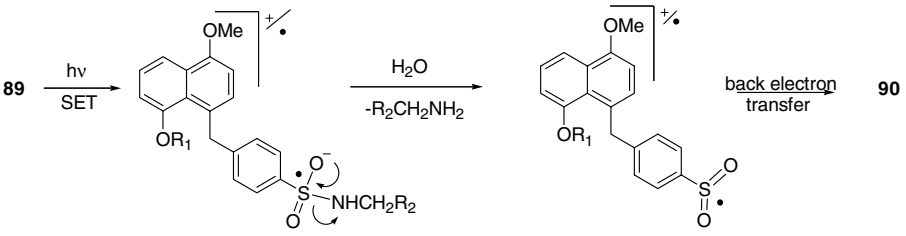
[a] Yields were determined using quantitative amino acid analysis; irradiations were only carried out to approximately 50% conversion of the starting material in the presence of 10-m*M* ascorbate.
[b] Photolyzed in buffer solution only.

the free amine in low to moderate yields, accompanied by the reduced arylsulfonyl byproduct **90** (Eq. (69.46) and Table 69.26).



89 **90**

(69.46)



SCHEME 15 Proposed mechanism for amino acid release from arylsulfonamides.

The mechanism is thought to involve an excited state intramolecular single eletron trnasfer from the electron-rich naphthalene sulfur (Scheme 15); release of the amine then occurs via assistance from the neighboring oxygen, leading to a radical cation that is subsequently reduced to **90** by ascorbate.

It was speculated that, in the case of the glycine and β-alanine substrates, a competitive electron transfer was occurring from the carboxylate group to the radical cation of **90**. Such a process would yield a carboxyl radical that would undergo subsequent decarboxylation, leading to a mixture of side products and thus a lower yield of the free amino acid. Spectroscopic evidence using LFP combined with FTIR spectroscopy supported this hypothesis. Low yields were still encountered even in the presence of increased amounts of ascorbate, suggesting that the electron transfer was taking place within a solvent cage.

Despite this shortcoming, the arylsulfonamide group may still hold promise as a photoremovable protecting group for amines lacking a carboxylate moiety. Further studies would need to be carried out to fully establish its capabilities in this regard.

69.9 Conclusion

A wide variety of photoremovable protecting groups have been added to the veteran *o*-nitrobenzyl series. Each new group has been developed to address the shortcomings of the *o*-nitrobenzyl group or to add features such as faster rates for release, extension of the absorption range into the near UV-visible region, improved solubility, higher efficiencies, improved conversions and yields, and more benign photoproducts from the protecting group. Extensions and applications of this chemistry to two photon excitation processes, to traceless reagents in the combinatorial and photolithography, as orthogonal reagents in synthesis, and to time-resolved spectroscopic techniques wil make even more demands on the design, synthesis, and development of new photoremovable protecting groups.

Even now, however, no single photoremovable protecting group fulfills all nine criteria Sheehan and Lester had suggested (outlined at the beginning of this chapter). Nevertheless, important progress has been achieved as evidenced by the growing number of applications reported for many of these photoremovable groups, especially in biological studies. Applications in synthesis, combinatorial chemistry, micro arrays, and photolithography are also forthcoming. These fields have benefited and will continue to draw the interest of science community as improvements of existing systems and discovery of new photoactive protecting groups are developed. This field of photoremovable protecting groups is still in its infancy.

Photodeconjugation of Enones and Carboxylic Acid Derivatives

Olivier Piva
Centre National de la Recherche Scientifique–Université Claude Bernard Lyon I

70.1 Introduction

Photodeconjugation of carboxylic acid derivatives **1** (Scheme 1) and α,β-unsaturated carbonyl compounds (enones or alkenals **2**) is a general process that has been studied for a long time[1–3] and reviewed.[4–6] Since the first reports devoted to mechanistic studies[7–17] and the observation of photodienol species, reports on synthetic developments have appeared more recently. In this context, β,γ-unsaturated carboxylic acid derivatives represent the starting materials of choice for the synthesis of butyrolactones and other five-membered-ring frameworks of numerous natural products. Their synthesis has attracted the attention of a growing number of chemists, and photoirradiation of α,β-unsaturated carboxylic acid derivatives is nowadays a very convenient method that excludes the use of strong bases required for similar isomerizations performed in the ground state.[18] Finally, an asymmetric version has also been successfully designed, in particular from α,β-unsaturated esters under either enantioselective or diastereoselective approaches, and has been applied to the synthesis of natural products.

70.2 Photophysical Properties of Enones and α,β-Unsaturated Carboxylic Derivatives

Enones and α,β-unsaturated acid derivatives possess two absorption bands in the ultraviolet (UV) spectrum corresponding to n,π^* and π,π^* transitions. For enones, two distinct absorptions can be observed: typically a very strong band around 210 to 240 nm, corresponding to the π,π^* absorption, and a weaker band at 300 to 320 nm, corresponding to the n,π^* transition. For acid derivatives (esters and lactones), a very strong band has been attributed to the π,π^* absorption, which usually masks the n,π^* absorption band.

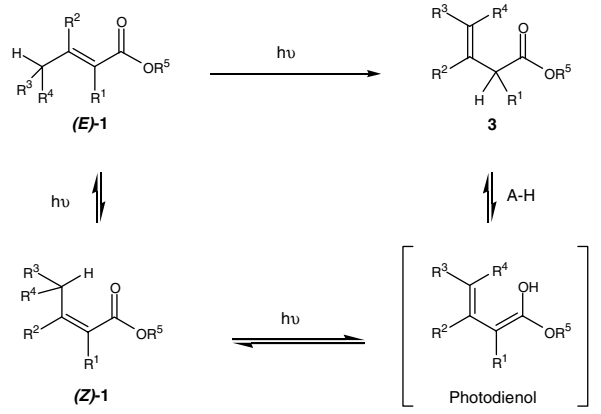
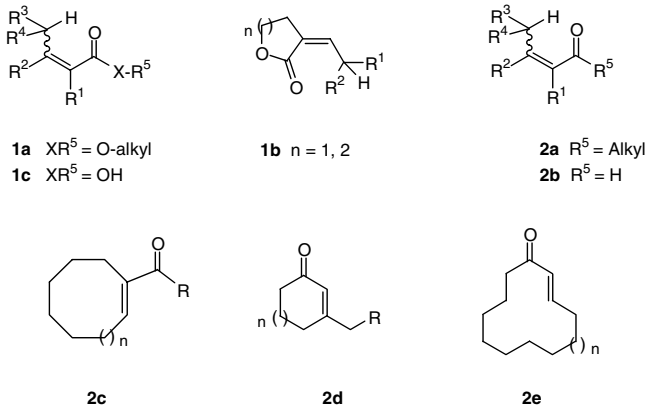


SCHEME 2

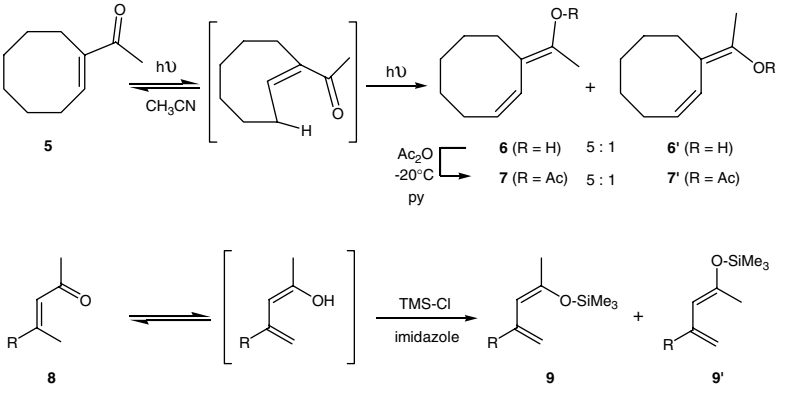
70.3 General Mechanism of Deconjugation

Under irradiation, aliphatic and medium ring size enones or acid derivatives undergo a rapid *E/Z* isomerization of the CC double bond leading to a photostationary mixture of geometric isomers. This process can be performed in the presence of triplet sensitizers such as acetone. With longer irradiation times, new compounds have appeared that have been identified as β,γ-unsaturated isomers. The position of the maximum absorption of these new structures is typically at a shorter wavelength compared to the starting molecules; therefore, the reaction can be carried out to complete conversion without significant chemical alteration. The representative mechanism of deconjugation is depicted for esters (X = O) in Scheme 2.

The formation of deconjugated isomers **3** results from a two-step procedure starting from the unsaturated isomer (*Z*)-**1**. This isomer is the only one capable, for steric reasons, of undergoing a concerted and antarafacial [1,5]-sigmatropic hydrogen migration following the Woodward–Hoffman rules. This affords a photodienol intermediate, via the singlet-excited state. The six-membered cyclic transition state imposes, at least for low conversions, a unique stereochemistry to the newly formed 1,2-double bond. This photodienol can finally revert to the starting material according to a thermal suprafacial [1,5]-sigmatropic migration or can furnish after tautomerism the β,γ-unsaturated isomer. The process has been applied to a wide range of α,β-unsaturated substrates such as aliphatic enones **2a**,[19–34] medium ring size unsaturated ketones **2c–d**,[35–37] alkenals **2b**,[38–40] conjugated esters **1a**,[7,9–15,41–49] alkylidene lactones **1b**,[51–52] and acids **1c** [1,10,53–54] (Scheme 3).



SCHEME 3



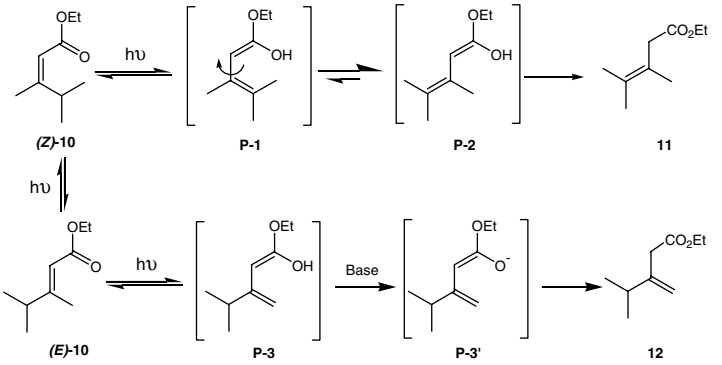
SCHEME 4

Evidence of a dienolic intermediate has been confirmed by infrared (IR) spectroscopy during the irradiation of acetyl cyclooctene in acetonitrile.[55,56] Irradiation of crotonal in the gas phase (either at 254 and 313 nm) also allows the detection of a dienol intermediate.[39] Nuclear magnetic resonance (NMR) spectroscopy can also be a useful method to characterize these species formed from acetyl cyclooctene[55] or also from mesityl oxide.[57–58] Similarly, UV spectroscopy can also be of interest for this purpose.[58]

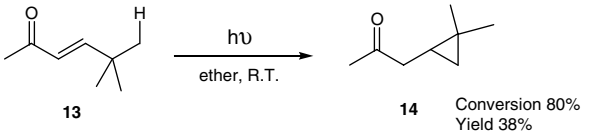
Moreover, dienols derived from enones have been trapped by acetic anhydride as enol acetates **7**[55] or as dienol silyl ethers **9**[59] (Scheme 4). Noteworthy, a careful NMR study shows the unique stereochemistry of C1C2 double bond, at least for low conversion, which confirms that a cyclic transition state is involved. At higher conversion, the *E*-siloxydiene **9′** can finally be detected, resulting from a triplet-sensitized isomerization of the CC double bond.

Lifetimes of dienols depend strongly on their substitution pattern. For enones, this value has been estimated to be in the order of 1 s at room temperature.[5] Usually, the lifetime is longer for enones than for those obtained from carboxylic acid derivatives.

The formation of β,γ-unsaturated isomers from photodienols is also strongly dependent on the nature of the solvent and/or the presence of additives, which could catalyze the phototropic step. By using nonpolar solvents, such as methylene chloride or hexane, irradiation is usually unsuccessful. By contrast, introduction to the medium of a small amount of an acid[60–61] or a base such as imidazole and dimethylimidazole[45–46,48] or diethylamine[62] greatly enhances the rate of the reaction and also the yields



SCHEME 5



SCHEME 6

of products. In polar solvents such as methanol, the reaction is also efficient; however, exchange of the dienolic proton can occur and can affect the rate of the process. For example, when O-deuterated methanol is used, irradiation of substrates yields products with incorporation of deuterium at the α or γ-position, while the starting material was only partly deuterated at the γ position.[12,21,25]

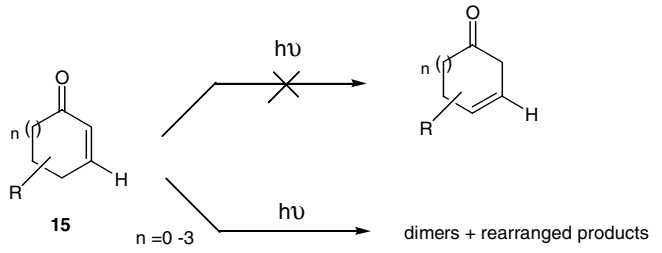
Obviously, the reaction of deconjugation is also highly sensitive to the substitution of the substrates, especially on the γ-position. With substrates without substituents at this site, the reaction is not synthetically efficient, and starting materials are recovered almost quantitatively even after prolonged irradiation.[23]

If different alkyl substituents are present on the γ-position, two regioisomers are usually obtained after irradiation. The regioselectivity depends strongly on the presence of additives which could favor the re-ketonization of one of the two dienol species.[45–46] Thus, in methanol, irradiation of ester **10** gives predominantly deconjugated ester **11** via the formation of photodienol that can exist in two conformations **P-1** and **P-2**. The latter is far less favorable for a reverse thermal [1,5]-hydrogen shift and can rapidly undergo re-ketonization to **11**. In contrast, when the reaction is performed in the presence of *N*-methylimidazole, the regioselectivity is totally reversed, and compound **12** is isolated in good yield. The base can interact with the less hindered photoenol **P-3** to afford the dienolate **P-3′**, thus preventing the much easier reverse [1,5]-hydrogen shift (Scheme 5).

With substrates (esters or ketones) without hydrogen on the γ-position, the expected isomerization is not possible, and a rearrangement can take place to give cyclopropane derivatives (Scheme 6).[12,20]

Another limitation for the deconjugation process is linked to the size of the cycloalkenones and 1-acylcycloalkenes.[63] For example, unsubstituted 2-cyclopentenone ($n = 1$) and 2-cyclohexenone ($n = 2$) affords cyclobutane dimers or rearranged products on irradiation. The homologous substrates ($n = 3$, 4) undergo isomerization to the highly strained *trans*-2-cycloheptenone and cyclooctanone (Scheme 7).

With 3-alkyl-2-cyclohexenones[64–67] and related fused ring systems,[68–79] the irradiation affords deconjugated compounds only when the reaction is performed in the presence of small amounts of a weak acid like acetic acid. This occurs irrespective of the solvent. The course of the process is depicted in Scheme 8. The isomerization is not a concerted process but occurs by a fast protonation of the highly



15

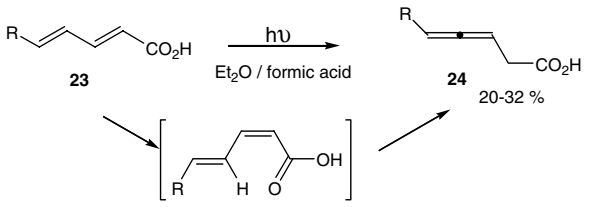
SCHEME 9

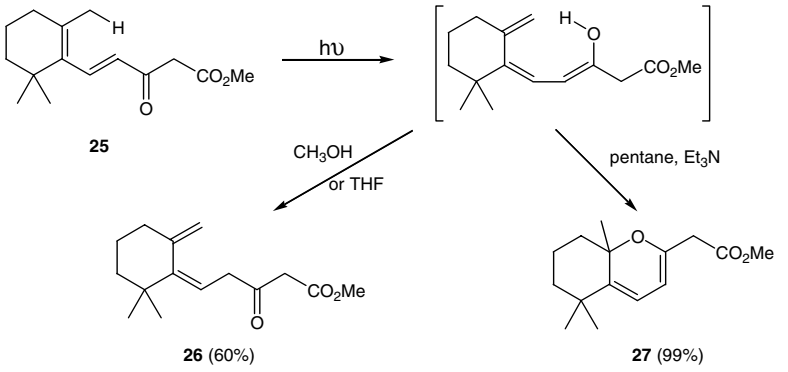
strained twisted enone in the triplet excited state.[80–84] The tertiary carbocation can then eliminate a proton to reform the starting enone or to yield the deconjugated isomer **17**.[67]

Instead of the deconjugated product, acetylcyclopentenes lead, under photochemical activation, to spiranic ketones.[85] In this case, the γ-abstraction is not effective for steric reasons. Instead, a competitive intramolecular hydrogen abstraction gives a new biradical, which collapses to the spiranic cyclobutanone **19** (Scheme 9). With larger membered ring alkenones, the isomerization proceeds like the acyclic substrates.[35–37,86] Interestingly, when the reaction is carried out for a longer time, a rearrangement of the deconjugated isomers by α-cleavage can be observed.[36] Thus starting from (*Z*)-2-cyclodecenone **20**, *E* and *Z* isomers **21** are isolated in 50% yield along with 2-vinylcyclooctane **22** in moderate yield (Scheme 9).

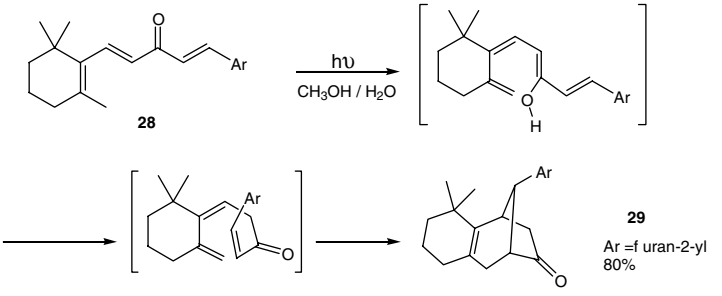
The reaction can also be carried out in conjugated dienoic acids and esters or dienones. For example, after irradiation in ether, sorbic acid leads to 3,4-hexadienoic acid.[60] The process is much more efficient if the reaction is performed in the presence of formic acid (Scheme 10). Similar substrates have been irradiated in the presence of hindered amines such as tetramethylpiperidine or Bronsted acids to give, quantitatively, the corresponding allenic derivatives **24**.[87]



SCHEME 10



SCHEME 11

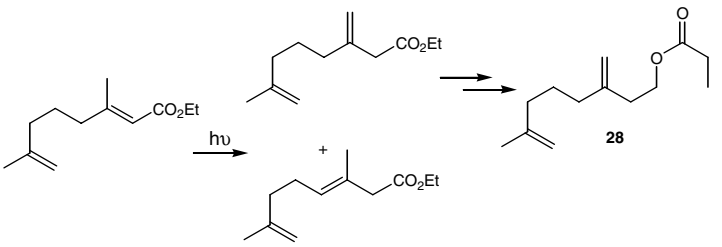


SCHEME 12

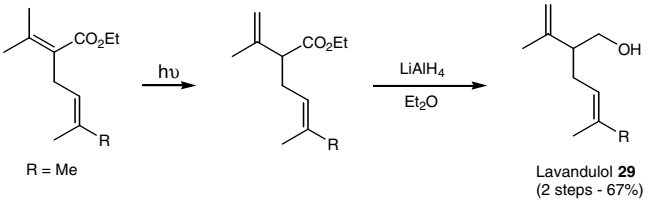
With nonlinear substrates such as β-ketoester **25**, the deconjugation can take place according to a [1,7]-hydrogen shift and formation of a putative phototrienol. Depending on the nature of the medium, this intermediate gives the 3-keto-5,6,7,8-dienoate **26** in methanol or a pyran derivative **27** by thermal cyclization initiated by the presence of a tertiary amine[88–89] (Scheme 11). α- and β-ionones derivatives and α-damascone have been converted advantageously by irradiation in acetonitrile into the deconjugated isomers.[3,90–94] With more functionalized substrates such as **28**, the deconjugation[95] performed in aqueous methanol can also be combined with a Diels–Alder reaction to yield tricyclic adducts **29** (Scheme 12).

70.4 Synthetic Applications

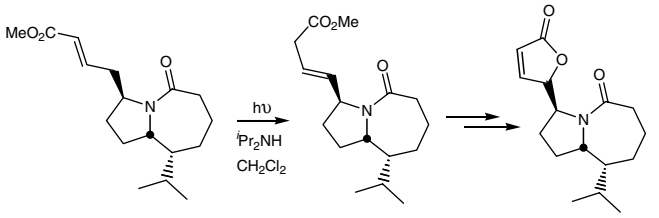
The photodeconjugation process has been successfully applied to the synthesis of various natural or bioactive compounds.[96–104] In only a few steps, the aggregation pheromone of San Jose scale (**28**, a pest in North American orchards) has been prepared. This reaction also yields regio- and stereoisomers[99]



SCHEME 13



SCHEME 14



SCHEME 15

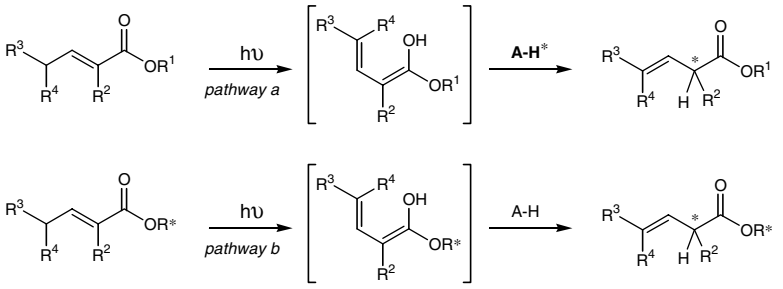
(Scheme 13). Recently, a similar process was used to prepare *rac*-lavandulol **29**[101] (Scheme 14) and also to confirm the structure of bisanhydrofarnesol (named also peplusol), a terpene isolated from *Euphorbia* sp.[102]

As already pointed out in the introduction, β,γ-unsaturated esters are suitable substrates to prepare related butyrolactones. For example, irradiation of ethyl esters followed by treatment with TMS-I allows a short access to this class of compounds.[62] Hydroxybutyrolactones can also be synthesized by osmylation of deconjugated esters. This strategy has been developed to prepare α-fluorobutyrolactones[103] or to achieve a synthetic approach to *Stemona* alkaloids[104] (Scheme 15).

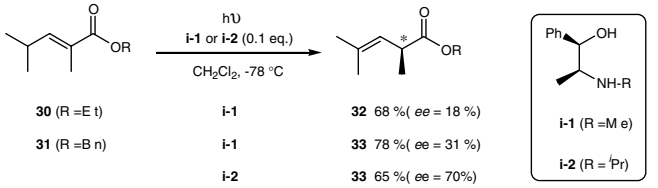
70.5 Asymmetric Photodeconjugation

Principle

When the starting ester is substituted by a R^2 group different from a hydrogen atom, the photodienol produced can be considered as a prochiral species. The selective protonation[105] of one of the two *Si* or *Re* faces can then be expected under appropriate conditions to furnish a mixture enriched in one of the two stereoisomers. Two approaches toward this goal have been considered for esters, as depicted on Scheme 16:



SCHEME 16



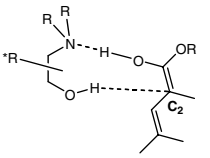
SCHEME 17

- Enantioselective protonation of the prochiral photodienol performed by use of an external chiral source of protons AH* (pathway a)
- A diastereoselective reaction for which the asymmetric information is already present on the substrate (e.g., R*O) and which can direct the formation of the new CH bond during the protonation step (pathway b)

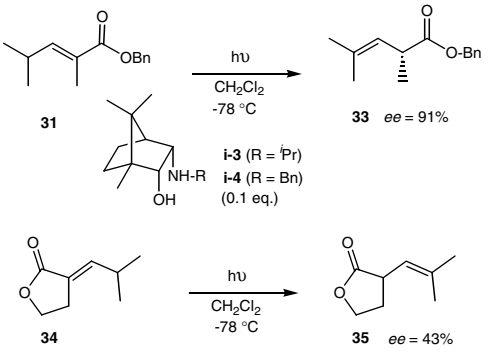
Enantioselective Photodeconjugation of α,β-Unsaturated Esters and Lactones

The primary results in this field have been obtained starting from achiral ethyl and benzyl unsaturated esters **30** and **31**. When irradiation of these substrates is performed at low temperature in the presence of (–)-ephedrine **i-1**, a common amino-alcohol, the deconjugated isomers **32** and **33** are isolated in good yields and with enantioselectivities up to 31% (Scheme 17).[106–109] These selectivities, although low, have demonstrated the potential of this strategy. Furthermore, only catalytic amounts (10%) of the protonating agent AH* are sufficient to deliver the highest value of enantioselectivity for a given inductor. A general study of the enantioselective reaction has been undertaken first to improve the selectivities but also to try to understand the recognition step. The nature of the solvent, the effect of the temperature and the substitution of the amino-alcohol on the efficiency of the process have been investigated in detail.[110–111] The nature of the solvent is crucial. When the irradiation of ester **31** (R = benzyl) is performed in the presence of ephedrine and in a solvent with donor groups (Et_2O or CH_3CN), the selectivities are either considerably reduced or nil, probably due to competition in the protonation step between the chiral inductor, present only in catalytic amounts (0.1 equivalent) and the solvent itself which can also promote the ketoenolization step without chiral induction. Thus, the media of choice for asymmetric photodeconjugation are alkanes (*n*-pentane, *n*-hexane), arenes (benzene, toluene), or chlorinated solvents (CH_2Cl_2). As with many procedures, the temperature effect is also of considerable interest. While the enantiomeric excess (EE) for **33** reaches only less than 10% at 25°C, a decrease in the temperature to –40°C results in an increase in the enantioselectivities of up to 37%.

Photodeconjugations of **31** performed in the presence of a chiral alcohol or a chiral amine or a 1:1 mixture of both these protonating agents in methylene chloride are successful but afford the isomer **33**



SCHEME 18



SCHEME 19

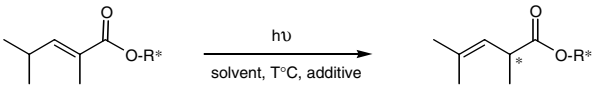
in miserable EE, in comparison with the previous result obtained with ephedrine. The hypothesis in which both the amino and the hydroxy groups are essential for a convenient level of induction has been assumed and a very simple model has been designed (Scheme 18). The amino group is considered to abstract the most acidic hydrogen atom (in other words, the hydrogen of the OH group of the photodienolic intermediate), whereas the hydroxy group of the amino-alcohol allows the protonation of carbon C2. In order to improve the selectivities, new aminoalcohols have been synthesized. Among them, the *N*-isopropylephedrine derivative **i-2** furnishes **33** with EEs up to 70% (Scheme 17).[112]

According to the hypothesis on the synergism of both hydroxy and amino group for the enantioselective protonation, the use of more rigid cyclic aminoalcohols has been also investigated. Results observed with endo,endo-aminobornanols **i-3** and **i-4** are really impressive for **33** with EEs up to 91%[113] (Scheme 19). Using these aminoalcohols as chiral protonating agents, the enantioselective photodeconjugation of other substrates has been undertaken (e.g., enones[114] and α-alkylidene lactones[113]). In these cases, the selectivities are much lower: 52 and 43%, respectively.

Diastereoselective Photodeconjugations

While the concept of enantioselective photodeconjugation is of great interest, the process is efficient in relatively few cases and cannot be applied to the total synthesis of natural products. The diastereoselective reaction has been also examined in parallel to the enantioselective one. High levels of induction (up to 88%) were first achieved using Helmchen's derivatives as chiral alkoxy moieties (Scheme 20, entry a);[115,116] unfortunately, these chiral alcohols are expensive or require numerous steps to be prepared.

Two other less expensive and commercially available compounds were then considered for this diastereoselective process. L-Lactic acid and its ethyl ester have been successfully tested, giving diastereoselective excesses of up to 86% at room temperature (Scheme 20, entries b and c).[117] Sugars also represent a valuable source of chiral inductors. Among them, D-glucose, one of the most abundant carbohydrates, has been chosen. Its diacetonide derivative (DAG) has been attached to various α,β-unsaturated acid chains, and irradiation of the corresponding esters has been performed in the presence of different protonating agents. The most efficient is *N*,*N*-dimethylaminoethanol **38**, introduced in stoichiometric



36 **37**

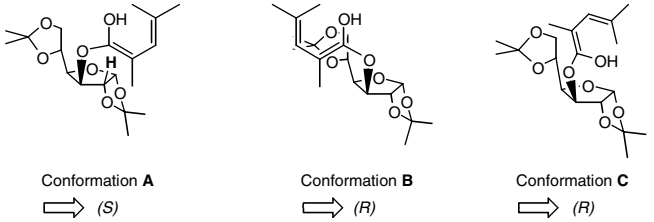
SCHEME 20

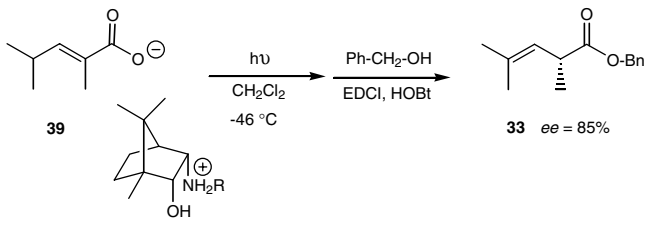


SCHEME 21

or in catalytic amounts. At low temperature (–50°C), selectivities higher than 97% have been obtained regardless of the nature of R^1 or R^2 (Scheme 20, entry d).[118]

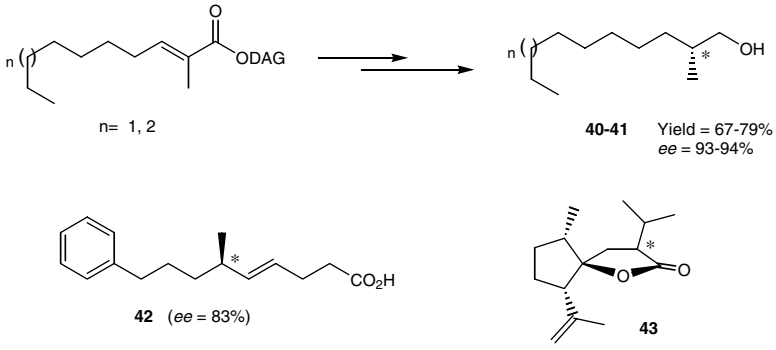
An empirical model to link the shape of the chiral moiety to the configuration of the new chiral center (on C2) has been proposed. The 5,6-isopropylidene group of the sugar moiety could have a shielding effect towards the approach of the bidentate protonating agent (Scheme 21). In conformation **A,** leading to the minor diastereoisomer, steric hindrance could occur between the hydrogen on C2 of the sugar and the α-substituent of the dienol. In contrast, no interactions between the acid chain and the rest of the sugar group are present in conformation **B**. Furthermore, a hydrogen bond between the hydrogen of the dienol and one oxygen of the sugar moiety could stabilize and even block this conformation. Due to the shielding effect of the 5,6-isopropylidene group, the bidentate molecule **38** could protonate the less hindered face, giving selectively the deconjugated ester with the (R)-configuration. Conformation **C**, recently proposed, can be of equal importance.[119]

This effect was demonstrated by considering the irradiation of an epimeric ester bearing the diacetonide allo-furanose group.[120] In this case, the selectivity decreased to 52%, which can be attributed to the absence of the shielding effect described above.



39 **33** *ee* = 85%

SCHEME 22



n= 1, 2 **40-41** Yield = 67-79%, *ee* = 93-94%

42 (*ee* = 83%) **43**

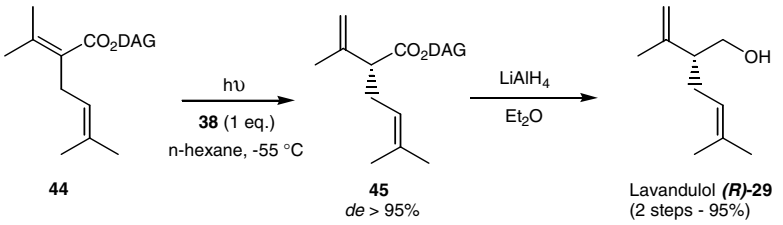
SCHEME 23

A major drawback of the use of the chiral pool in asymmetric synthesis is the difficulty and the cost of having to handle the chiral auxiliary in both enantiomeric forms. By this method, the configuration of the new chiral center created during the process could be controlled and chosen, but L-glucose is not readily available; therefore, a search for new chiral entities has been carried out. For example, diacetone L-fructopyranose, prepared in few steps from L-sorbose, can be advantageously used for this purpose, and selectivities are of the same level (Scheme 20, entry e) as those measured with DAG derivatives.[119] Similarly, (R)-pantolactone, which possesses only one stereogenic center, has been attached to various unsaturated acid chains according to two different activation procedures: DCC activation delivers the expected substrates with the same configuration, while the enantiomer can be prepared by condensation under Mitsunobu conditions. Irradiation affords in this case selectivities up to 88% (Scheme 20, entry f).[121]

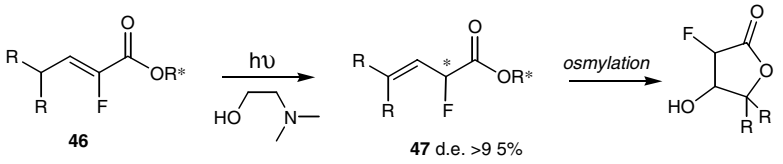
Finally, it should be pointed out that enantiopure ammonium ene carboxylates derived from aminobornanol **i-4** have been subjected to irradiation in dichloromethane to furnish, after acidification and esterification, the deconjugated ester **33** with EEs up to 85%.[122] Obviously, in that case, aminobornanol **i-4** was used in stoichiometric amounts (Scheme 22).

70.6 Recent Applications to the Synthesis of Natural Products

Finally, this new asymmetric reaction (and more particularly the diastereoselective version) has been applied to the synthesis of natural products. First, rapid access to 2-methyldecanol and undecanol **40** and **41**, two insect pheromones, has been performed. The β,γ-unsaturated esters have been hydrogenated over catalytic amounts of PtO_2 and then reduced without epimerization to the chiral 2-methylalkanols.[123] According to a similar approach, the side chain of Zaragozic acid C **42** has been prepared in high EE,[124] while access to curcumanolide A **43** and its analogs has been developed (Scheme 23).[125]



SCHEME 24



SCHEME 25

The diastereoselective synthesis of (R)-(–)-lavandulol **29**, a constituent of lavender oil, has been also accomplished.[101] The crucial step is the photoisomerization of **44** to **45** that allows both the creation of the chiral center and the generation of the double bond in the required position (Scheme 24).

Because the synthesis of chiral fluoro compounds is of great interest, due to their biological properties, the asymmetric photodeconjugation of α-fluoro-α,β-unsaturated esters **46** has been explored.[126] Despite the high acidity of the hydrogen on the C2 atom, the diastereoselective isomerization to the β,γ-unsaturated isomers is effective with levels of induction for **47** similar to those for non-fluorinated substrates (Scheme 25).

In conclusion, photodeconjugation of enones or carboxylic acid derivatives is a mild process by which to prepare β,γ-unsaturated carbonyl and carboxylic derivatives in good yields. These substrates represent interesting frameworks useful for the synthesis of natural products. The asymmetric version of the process also allows the formation of new chiral centers under very mild conditions and with high selectivities.

[2+2]-Photocycloaddition Reactions of Cyclopentenones with Alkenes

Jean-Pierre Pete
Université de Reims Champagne Ardenne

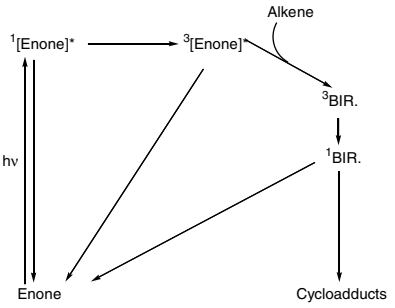
71.1 Introduction

The photocycloaddition reaction of cyclic enones with alkenes has previously been reviewed,[1,2] especially in the preceding edition of this Handbook.[3] The multistep mechanism of the reaction was established on the basis of spectroscopic and kinetic data and from the selective intermediate trapping. However, new experiments were needed not only to extend the value of the mechanistic conclusions to a larger variety of substituted cyclopentenones but also to give a better understanding of intramolecular photocycloaddition processes. These new investigations, using the selective trapping of intermediates, have allowed determination of the relative deactivation rates for 1,4-biradical intermediates. Furthermore, a verification of the validity of the "rule of five" in intramolecular processes has been possible. Simultaneously, attempts to develop asymmetric [2+2]-photocycloadditions have been described in connection with synthetic applications. The high efficiency and high selectivity usually observed in the [2+2]-photocycloaddition of cyclopentenone derivatives with alkenes have led synthetic chemists to use this reaction for the building of complex structures and polyfunctional molecules. Thus, the purpose of this chapter is to summarize the recent findings on the chemo- or stereoselectivity of the cycloaddition process of cyclopentenones and related systems (furanones, maleic anhydrides, and maleimides) with alkenes or alkynes. A review of some recent synthetic applications of the reaction is also presented.

71.2 Mechanistic Aspects

As previously established, the mechanism of the [2+2]-photocycloaddition of cyclopentenones with alkenes can be summarized as shown in Scheme 1. The interaction of the alkene with the enone, excited

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1

in its triplet state, is believed to form one or more of the possible 1,4-biradical intermediates. These biradicals can either cyclize and lead to the final cyclobutane products or revert to the ground-state starting materials.[4] The composition of the final reaction mixture reflects the respective rates of cleavage and cyclization of the 1,4-biradical intermediates.

In order to gain better knowledge of the influence of substituents on these respective rates and the regioselectivity of the reaction, new experiments involving selective chemical trapping of the 1,4-biradicals by hydrogen selenide have been carried out. Previous studies have now been extended to the cycloaddition of 2-cyclopentenones to polar alkenes and of substituted cyclopentenones with 2-methylpropene. The results confirm that the regiochemistry of the cycloaddition process is dominated by the relative rates of closure to the cycloadducts or reversion to the starting materials of the 1,4-biradical intermediates.[5,6] Furthermore, a detailed analysis of the photocycloaddition of 3-phenylcyclopentenone with 1-phenylpropene indicated that only 5% of the 1,4-biradicals convert to adducts.[7]

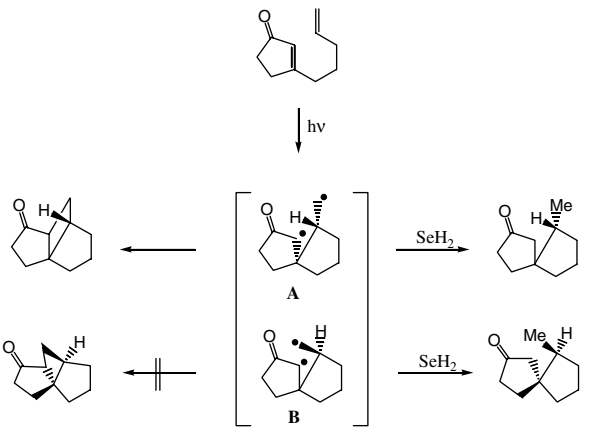
In contrast to intermolecular processes, intramolecular photocycloadditions are usually highly regio- and stereoselective. To explain this selectivity in the case of ω-heptadienic systems (according to the "rule of five"), 1,4-biradicals in which a cyclopentane ring has been formed are believed to be produced preferentially. In order to test the validity of this rule in the case of intramolecular [2+2]-photocycloaddition of 3-(ω-pentenyl)cyclopent-2-enone, a selective trapping of the 1,4-biradical intermediates was attempted. When the irradiation was performed in toluene using a Pyrex-filtered light with a medium-pressure mercury lamp, a single cycloadduct was isolated. When the same irradiation was carried out in the presence of SeH_2, the cycloadduct could not be observed, and a mixture of two diastereoisomeric spiroketones was isolated in a ratio that did not depend on the concentration of hydrogen selenide. These results were considered as proof that only two biradical intermediates (resulting from a 5-exotrig addition of the enone in its triplet state) were produced during the reaction. As shown in Scheme 2 and for steric reasons, only biradical **A** could cyclize to the corresponding cyclobutane.[8]

If the "rule of five" applies to the intramolecular photocycloaddition of β-substituted cyclic enones having a ω-pentenyl residue, the question of which bond is formed first and the problem of the efficiency of the cyclization step remains open as soon as the tether between the ethylenic bonds becomes longer.[9,10] As already determined for cyclohexenone derivatives, the efficiency of the cycloaddition of cyclopentenones drops rapidly with the length of the tether, except if some steric restrictions can favor the reactive conformation (Scheme 3);[11] similar results were obtained for the intramolecular [2+2]-photocycloaddition of furanones.

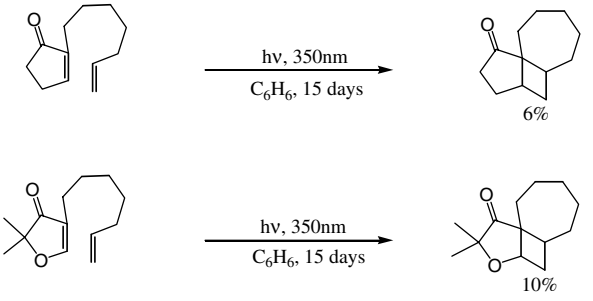
The fate of the reaction can also depend on the nature and the position of the substituents on the cyclopentenone unit. Furthermore, the efficiency of the cycloaddition process is usually very similar for cyclopentenone and the corresponding cyclohexenone derivatives (Scheme 4).[12]

When polar substituents are introduced on the linker, intramolecular hydrogen abstraction processes can be competitive and rearranged products can be obtained, as illustrated in Scheme 5.[13,14]

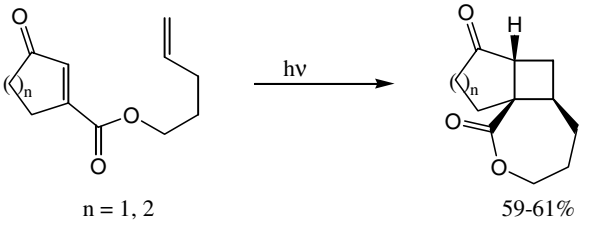
When the unsaturated side chain is located on the β-carbon of the enone, the diastereoisomeric ratio of the adducts does not depend on the stereochemistry of the alkene if a cyclopentane ring has been



SCHEME 2



SCHEME 3

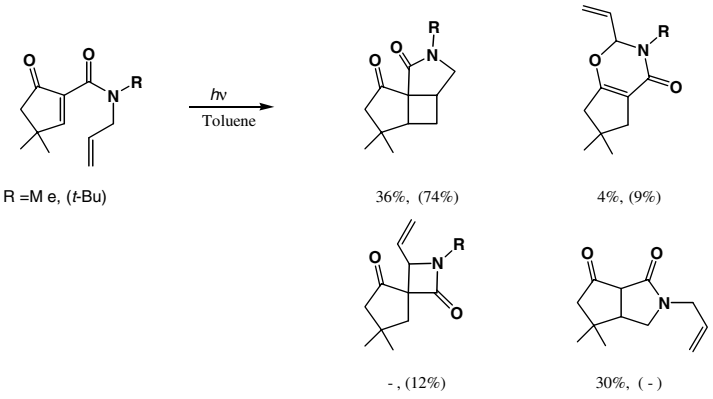


SCHEME 4

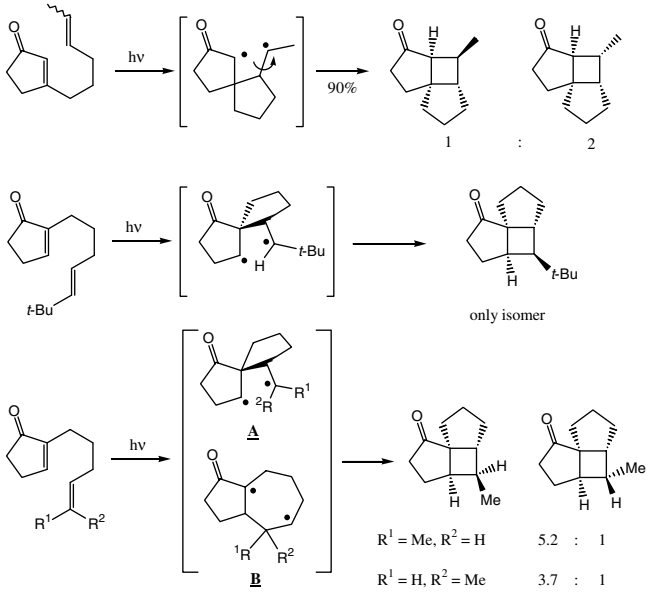
formed in the intermediate; however, as shown in Scheme 6, more complex results can be observed from α-substituted enones.[15]

When *cis*- and *trans*-2-(hex-4-enyl)cyclopent-2-enones were irradiated separately, a different ratio between the stereoisomeric adducts was obtained. This observation was taken as evidence that biradicals **A** and **B**, resulting from the initial formation of either a cyclopentane or a cycloheptane ring on the alkene unit, respectively, were required to explain the results. When a large *t*-butyl substituent was present, only the less hindered stereoisomer could be observed.

The stereoselectivity of intramolecular cycloadditions is due primarily to the steric restrictions appearing during the cyclization step. In the presence of stereogenic centers in the starting molecules, the stereochemistry of the newly created asymmetric carbons can be influenced and the reaction can even



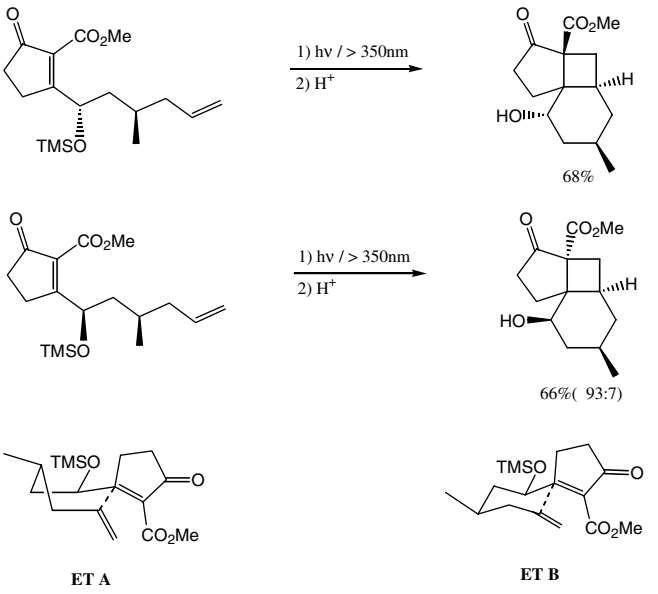
SCHEME 5



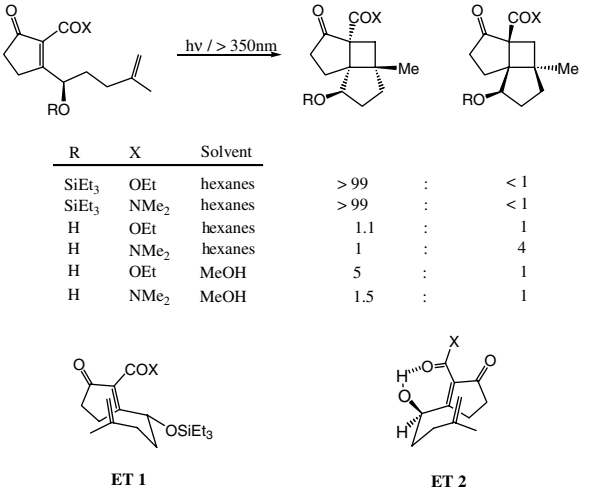
SCHEME 6

become highly stereoselective when several stereogenic centers are present on the tether. Interestingly, the stereochemistry of the major adduct can be explained on the basis of transition states having the tether either in a chair or a boat conformation and the substituents in an equatorial position. When the relative configurations of 1,3-stereogenic centers on the tether are either *anti* or *syn*, transition states **ET-A** or **ET-B** involving the formation of a six-membered ring are preferred (Scheme 7).[16]

Although steric hindrance is usually the determining factor that controls the stereoselectivity, hydrogen bonding can also be important. Among large substituents that prefer to occupy an equatorial position in the chair transition state, **ET-1** trialkylsilyl ethers can induce a high selectivity. Interestingly, when hydroxyl groups rather than their corresponding silyl ethers are present on the tether, a reversal of the diastereoselectivity can be observed in nonpolar solvents. This effect could be explained by an inversion of the chair conformation of the linker in transition state **ET-2** due to an intramolecular hydrogen bond (Scheme 8).[17] In alcohol, intermolecular hydrogen bonding can become competitive, and hydroxyl groups again behave as large substituents favoring transition state **ET-1**.



SCHEME 7



R	X	Solvent

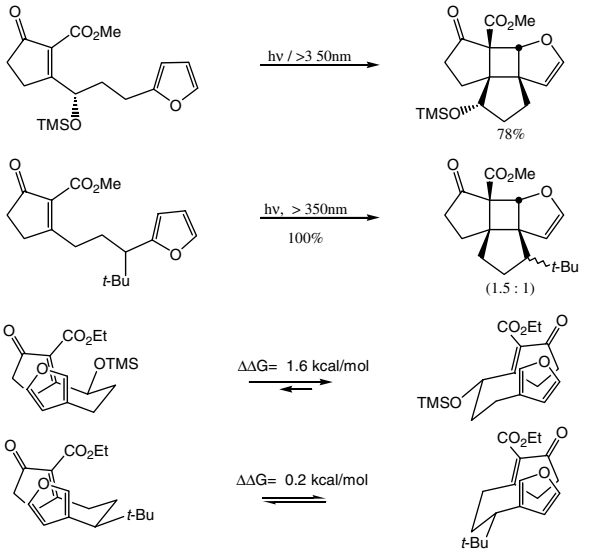
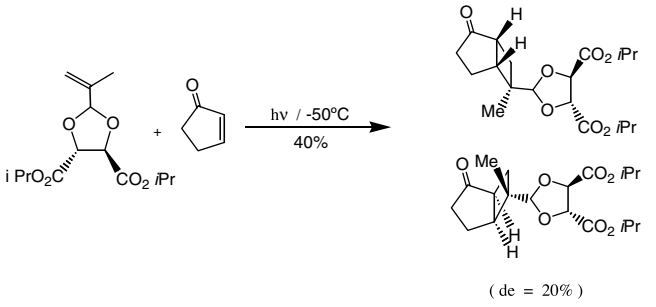
H	NMe_2	hexanes	1	:	4
H	OEt	MeOH	5	:	1
H	NMe_2	MeOH	1.5	:	1

SCHEME 8

In order to support this rationalization, a computation of the possible transition states by molecular mechanics was carried out. The low deformation of a cyclopentenone unit in its $^3(\pi,\pi^*)$ excited state[18] allows an approach of the reacting double bonds in almost parallel planes. Among the possible conformations available in the transition states, six-membered chair and boat conformations placing the substituents in equatorial position were favored. The calculated energy difference between the competitive transition states was found to be close to the experimental value derived from the observed product ratio.[19,20] Similar conclusions, based on MM2 calculations, were obtained with cyclopentenones linked to a 3-furylpropanyl substituent (Scheme 9).[21]



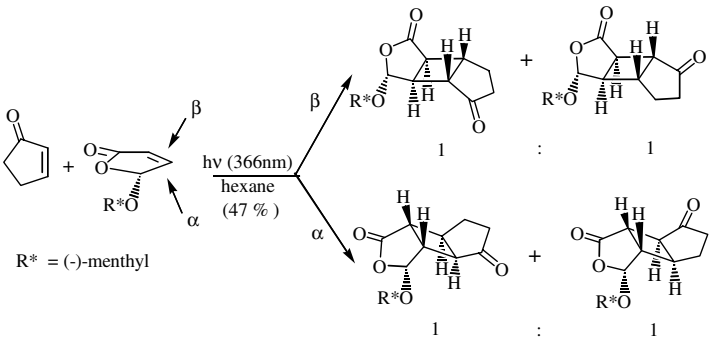
SCHEME 9



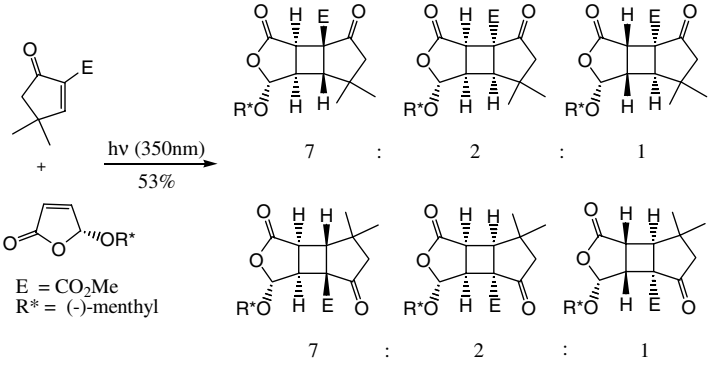
SCHEME 10

From the high diastereoselectivities usually observed in the [2+2]-photocycloaddition of chiral cyclopentenones, it was tempting to examine the effect of removable chiral auxiliaries. The development of enantioselective synthetic schemes requires chiral auxiliaries that can be easily introduced and easily removed. Among the possible functional groups that could be envisaged, ketals and esters were particularly attractive. By utilizing chiral ketals derived from cyclopentenone and a tartaric ester having a C2 axis of symmetry, an important asymmetric induction could be observed.[22] With aliphatic enones ketals, the stereoselectivity dropped considerably, and mixtures of regioisomers were observed (Scheme 10).[23]

5-Menthyloxy-2[5*H*]-furanone, with one face of the ethylenic bond selectively hindered by the alkoxy group, is another interesting chiral unsaturated ketal known to allow ground-state additions of nucleophiles or radicals with a total facial selectivity.[24] Excited cyclopentenones and cyclohexenones, which can relax to a low and twisted π,π^* triplet state, possess a biradical character. They should behave as radicals and add stereospecifically from the less hindered side of 5-menthyloxyfuranone. However, no regioselectivity and no stereoselectivity could be detected when cyclopentenone was selectively excited in the presence of 5-menthyloxyfuranone (Scheme 11). An initial energy transfer followed by cycloaddition of the triplet-excited furanone to cyclopentenone in its ground state accounted for these disappointing results.[25]



SCHEME 11



SCHEME 12

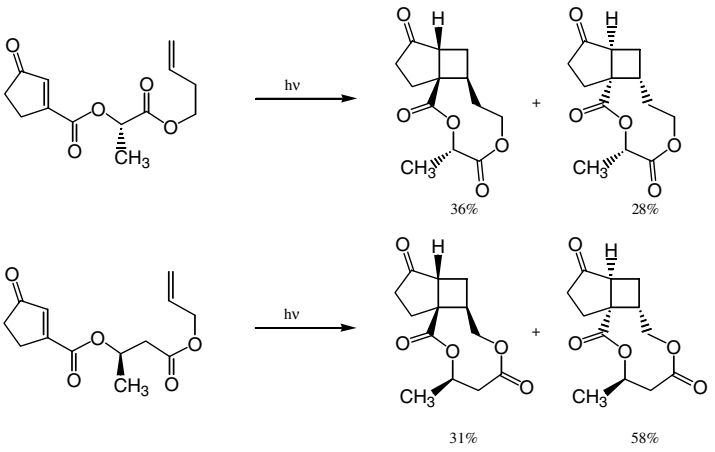
Although the facial selectivity increased with more flexible or more electron-deficient cyclic enones, a mixture of regioisomers and *syn*/*anti* stereoisomers was obtained that precluded synthetic applications (Scheme 12).

The use of removable chiral tethers between the reacting double bonds could be an interesting solution for the synthesis of enantiomerically pure cycloadducts. Derivatives of inexpensive chiral hydroxy acids such as lactic and β-hydroxy acids allow high asymmetric inductions with cyclohexenone derivatives.[26] Unfortunately, the diastereoselectivities obtained during the photochemical step with the corresponding cyclopentenones were considerably lower (Scheme 13).[27]

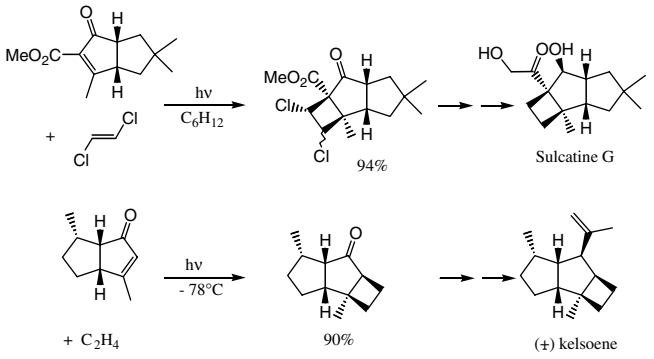
71.3 Synthetic Applications

All of these photoadducts obtained are polycyclic, and even polyfunctional molecules that have an α-cyclobutyl keto group. They can be used as very versatile starting materials for the synthesis of complex molecules. The [2+2]-photocycloaddition reaction constitutes a method of choice for creating a four-membered ring in polycyclic molecules. The photoreaction of a cyclopentenone unit with an alkene has recently been used in the synthesis of two natural products containing a cyclobutane unit — namely, sulcatine G[28] and (±)-kelsoene (Scheme 14).[29]

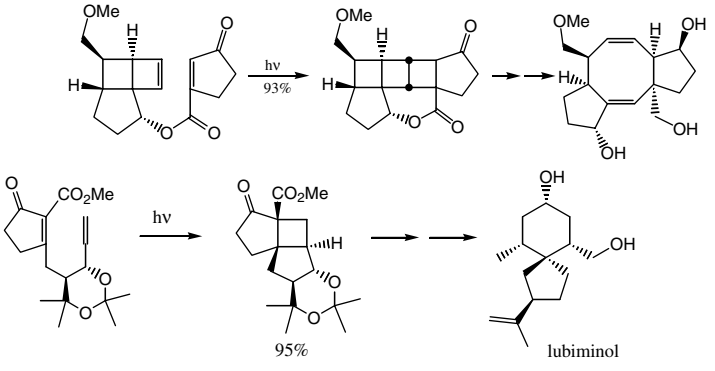
Ring opening or rearrangement with ring expansion of the cyclobutanes, present in the primary photoadducts, is still very attractive for organic chemists. For example, the intramolecular [2+2]-photocycloaddition of a cyclopentenone with a cyclobutene unit can be followed by consecutive thermal rearrangements to lead stereoselectively to 5–8–5 ring systems (Scheme 15).[30]



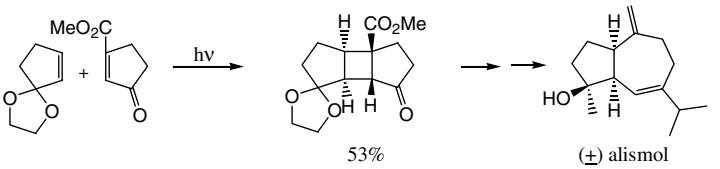
SCHEME 13



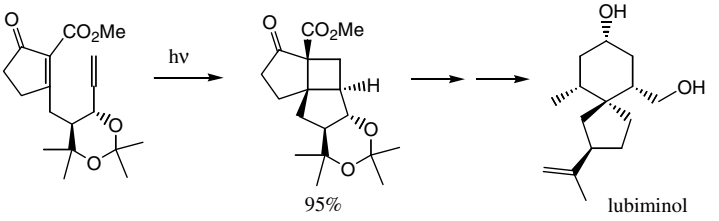
SCHEME 14



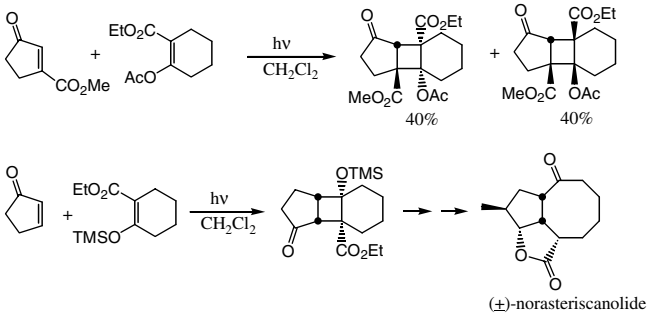
SCHEME 15



SCHEME 16



SCHEME 17



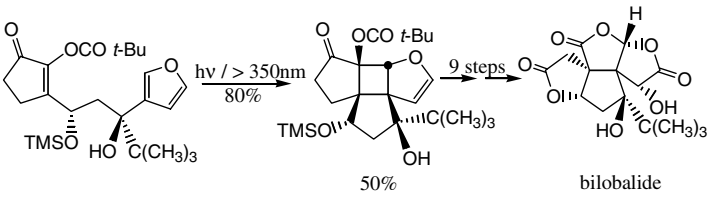
SCHEME 18

By using a free-radical fragmentation of α-cyclobutylmethyl radicals, a variety of polycyclic structures can be obtained. When applied to the initial photocycloadduct of a 3-cyclopentenone carboxylic acid with a substituted cyclopentene, a 5–7 ring system can be obtained. This approach was used for a total synthesis of (±)-alismol (Scheme 16).[31]

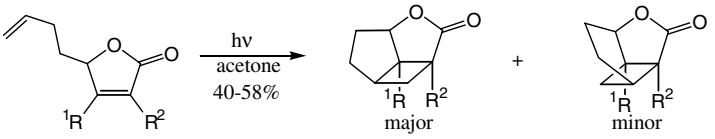
Similarly, radical opening of an α-cyclobutylmethyl radical can be followed by an efficient rearrangement involving a carbonyl group. This technique was used to transform the tetracyclic adduct obtained through an intramolecular photocycloaddition into a spiranic skeleton and to (±)-lubiminol (Scheme 17).[19]

When enol esters derived from β-diketones are used in the photocycloaddition reaction with an alkene (de Mayo's reaction), a hydrolysis of the ester group of the cyclobutyl intermediate allows opening of the cyclobutane ring by a retro-Aldolization process and the formation of medium-ring cyclic compounds. Similarly, hydrolysis of the cycloadduct obtained by irradiation of 3-carbomethoxycyclopentenone in the presence of a β-ketoester allowed facile access to (±)-norasteriscanolide (Scheme 18).[32]

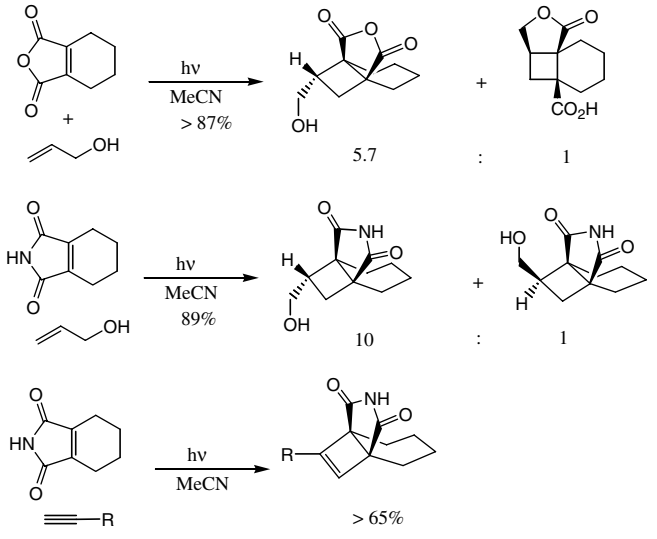
The creation of up to four new asymmetric centers during the photochemical addition step allows very fast access to complex structures. This is illustrated by the synthesis of bilobalide (Scheme 19).[21]



SCHEME 19



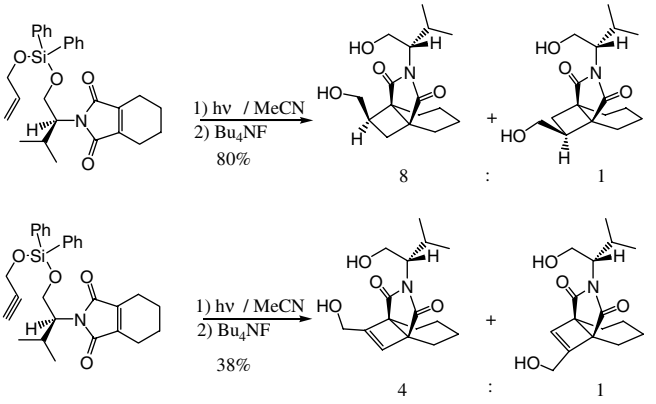
SCHEME 20



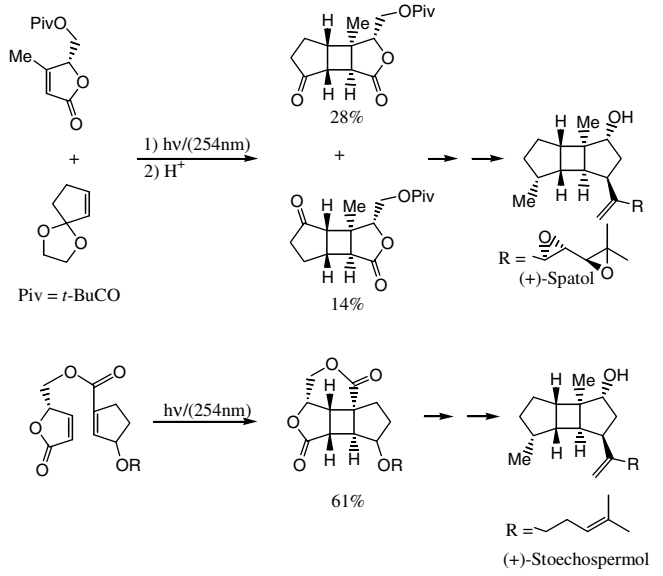
SCHEME 21

71.4 Related Photocycloadditions: Furanones, Maleic Anhydride, and Maleimides

Furanones, maleic anhydride, maleimides, and cyclopentenones behave similarly when irradiated in the presence of alkenes. [2+2]-Photocycloaddition reactions of furanones, especially γ-substituted furanones with alkenes, can be highly diastereoselective. A detailed analysis of the cycloaddition of ethylene with substituted furanones gave a deep insight into the origin of the diastereoselectivity. Based on product ratio dependence on temperature and the substituents, it was proposed that a pyramidalization of the β-carbon of furanones in their relaxed $^3(\pi,\pi^*)$ excited state and a homo-anomeric effect determined the observed selectivity.[33] Cycloadducts can also be obtained in good yields from furanones by intermolecular or intramolecular processes (Scheme 20).[34]



SCHEME 22



SCHEME 23

Recently, it was reported that the [2+2]-photocycloaddition of 3,4,5,6-tetrahydrophthalic anhydride and the related imide occurred efficiently and stereoselectively with a variety of alkenes and alkyn-3-ols (Scheme 21).[35,36]

Furthermore, the method was extended to an intramolecular [2+2]-photocycloaddition of imides linked to an allylic alcohol or a propargyl alcohol by a chiral tether (Scheme 22).[37] Interestingly, when L-valinol was used as a chiral auxiliary, a high diastereoselectivity was also observed for the cycloaddition of the unsaturated anhydride with an alkenyl or an alkynyl unit.

The high facial stereoselectivity observed for the [2+2]-photocycloadditions of alkenes with chiral butenolides and the polyfunctional nature of the cycloadducts have led to interesting new applications in the field of natural products. The total synthesis of (+)-stoechospermol[38] and (+)-spatol (Scheme 23),[39] as well as new syntheses of (+)-grandisol,[40,41] including photochemical cycloaddition as a key step, have been recently reported (Scheme 23).

71.5 Conclusion

The mechanism of the [2+2]-photocycloaddition of cyclopentenones with alkenes is now well established. A similar mechanism seems to be involved in the corresponding photocycloaddition of maleic anhydrides, maleimides, and furanones; therefore, interest in this reaction resides primarily in the formation of strained and polyfunctional cycloadducts. The high versatility of the cyclobutanes can be used for access to a great variety of polycyclic structures and to the skeleton of many natural products. Some progress remains to be made to improve the diastereoselectivity, especially in the presence of a removable chiral auxiliary. The search for new chiral auxiliaries has to deal with creation of polyfunctional starting materials. Unfortunately, and despite the generality of the photocycloaddition reaction, hydrogen abstraction or electron transfer processes and other rearrangements might become competitive.

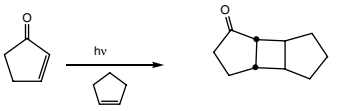
Mechanistic Issues in [2+2]-Photocycloadditions of Cyclic Enones to Alkenes

David I. Schuster
New York University

72.1 Introduction

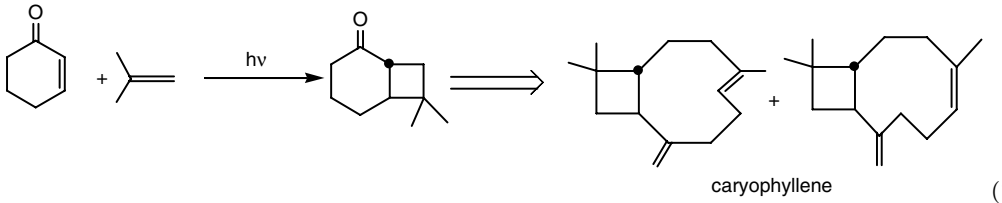
Following Eaton's original discovery of the photocyclodimerization of 2-cyclopentenone (CP)[1] and of photocycloaddition of this enone to cyclopentene (Eq. (72.1)),[2] Corey and co-workers reported [2+2]-photocycloadditions of 2-cyclohexenone (CH) to a variety of alkenes,[3] and established many of the characteristic features of this reaction.

0-8493-1348-1/04/$0.00+$1.50



(72.1)

The potential of this type of reaction, as a key step in the synthesis of natural products, was first shown by Corey in his landmark synthesis of caryophyllene (Eq. (72.2)).[4]



(72.2)

Subsequently, inter- as well as intramolecular [2+2]-photocycloadditions have become part of the standard repertoire of synthetic organic chemists, and this process is now probably the most widely used photochemical reaction in synthetic organic chemistry.[5] Numerous reviews on the synthetic utility[5] and mechanism of this reaction[6] have been published. The salient features of this process, as well as new theoretical calculations that bear directly on the mechanism, are presented in this chapter.

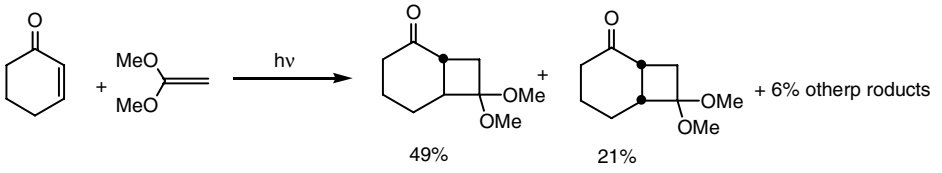
Photodimerization of cyclic enones in solution to give mixtures of *cis-anti* head-to-head (HH) and head-to-tail (HT) [2+2]-photodimers occurs via the lowest energy enone triplet excited state, as established using triplet sensitization and quenching techniques.[7–11] In 1969, Wagner and Bucheck[10,11] suggested that the inefficiency in photodimerization of CP and CH was principally associated with reversion of initially formed dimeric intermediates, possibly 1,4-biradicals, to two enone ground-state molecules and that the extent of this biradical reversion was probably different for the biradicals leading to HH as opposed to HT dimers. If this were the case, there would be no direct relationship between quantum efficiencies of dimer formation and triplet state reactivities (i.e., the rate of attack of the triplet enone on a corresponding ground-state molecule). Even at this early date, the lack of a correlation between quantum yields and excited-state reactivity in nonconcerted reactions involving triplet-excited states was well established.[10] de Mayo came to similar conclusions at the same time regarding photoaddition of CP to alkenes where CP triplet states were postulated to be reaction intermediates.[12]

Based upon earlier spectroscopic studies of steroid enones[13] and calculations of energies of relaxed n,π^* and π,π^* states,[14] de Mayo concluded that the lowest energy enone triplet state of cyclic enones and the one responsible for photoaddition reactions, was probably the $^3(\pi,\pi^*)$ state.[15] This conclusion was later confirmed by studies using transient absorption spectroscopy and time-resolved photoacoustic calorimetry carried out by Schuster and co-workers.[16,17] However, in the case of very rigid cyclic enones, where conformational relaxation is difficult or impossible, the lowest n,π^* and π,π^* triplet states are very close in energy.[5a,16,18] Estimates by de Mayo[12,15] of the rate constants k_d and k_r, corresponding to radiationless decay of the enone triplet and triplet reaction with alkenes, respectively, were made on the basis of quenching kinetics. As in Wagner's photodimerization study,[11] piperylene and acenaphthylene were used as triplet quenchers, and it was assumed that quenching of enone triplets occurred at the diffusion-controlled rate. Schuster and co-workers[16] later measured triplet lifetimes of a number of cyclic enones in solution using flash photolysis and demonstrated that alkenes directly quench these triplets, allowing direct determination of the reaction rate constants.[19,20] Trends in these values will be discussed later, but it should be noted that these rate constants are about an order of magnitude smaller than de Mayo's estimates[12,15] because of the overly generous value assumed by de Mayo for the rate constant for triplet–triplet energy transfer.

72.2 General Characteristics of [2+2]-Photocycloadditions of Cyclic Enones to Alkenes

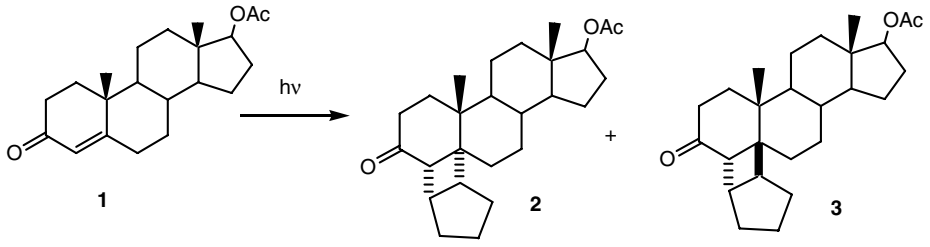
Stereochemistry of Ring Fusion of Cycloadducts

Corey established in 1964 that *trans*- as well as *cis*-fused cycloadducts are formed on photoaddition of CH to simple alkenes, the former often being the major products.[3] This is illustrated in Eq. (72.3) for photoaddition of CH to 1,1-dimethoxyethene.



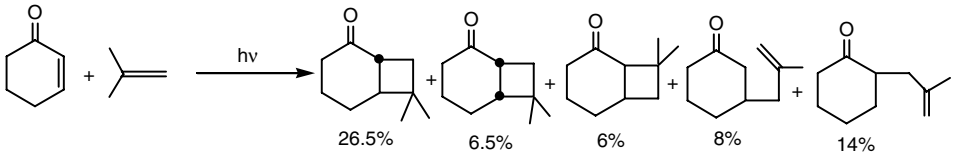
(72.3)

This observation is not confined to simple monocyclic systems. Thus, photoaddition of testosterone acetate **1** to cyclopentene gives both *cis*- and *trans*-fused photoadducts (**2** and **3**) in an initial ratio of 2:1 (Eq. (72.4)).[21]



(72.4)

A gradual change in favor of the *cis*-adduct **2** as the reaction proceeds is due to secondary phototransformations that preferentially consume **3**.[22] This stereoselectivity in the [2+2]-addition must have a kinetic rather than thermodynamic basis, as x-ray crystal structures show that the cyclohexanone in the *cis*-fused adduct **2** is in a boat conformation and the cyclobutane ring is relatively flat, while in *trans*-fused structure **3** a relatively undistorted half-chair cyclohexanone ring is linked diequatorially to a severely twisted cyclobutane.[21] Thus, there is no question that *cis*-fused adduct **2** is thermodynamically much more stable than the *trans*-fused adduct **3**. The difference in energies of the stereoisomeric adducts derived from CH and 2,3-dimethyl-2-butene, according to MM2 calculations, is ~3.0 kcal/mol in favor of the *cis*-adduct but increases to 7.4 kcal/mol for CH–cyclopentene adducts analogous to **2** and **3**.[21] In some cases (e.g., photoaddition of CH to 2-methylpropene), formation of [2+2]-cycloaddition products is accompanied by products attributable to disproportionation of 1,4-biradical intermediates:[3]



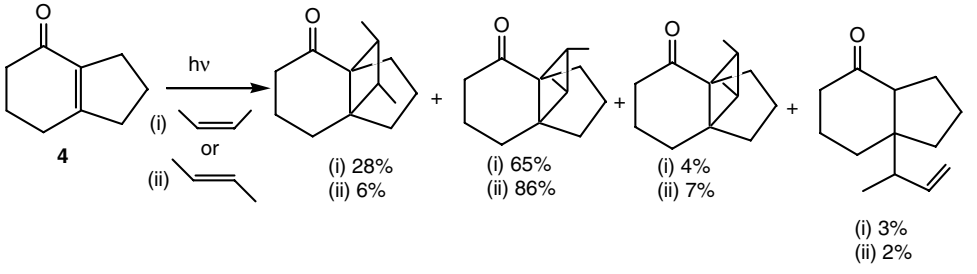
(72.5)

Stereochemistry of the Alkene Component in Enone Photocycloadditions

Intermolecular Photocycloadditions

Corey[3] reported that an identical mixture of cycloadducts was obtained from photoaddition of CH to either *Z*- or *E*-2-butene, indicating that the stereochemistry of the alkene component is lost in the course of the reaction. Recovery of the alkene component at various reaction times indicated that <1% isomerization of the starting material had occurred. Thus, stereomutation must occur at some intermediate reaction stage, indicating that the two new sigma bonds in the cycloadduct must be formed sequentially. The generally accepted mechanistic interpretation, which has received ample experimental and theoretical validation, is that the addition process involves rotationally equilibrated triplet 1,4-biradicals as precyclization intermediates. It was not clear in Corey's study whether initial bonding occurred at the α- or β-carbon of the enone, or both, a question that was unresolved for some time. The reported lack of isomerization of the starting alkene indicated that reversion of the 1,4-biradicals to starting materials by fragmentation is not competitive with cyclization, which is surprising in light of more recent findings (see below).

Cargill and co-workers[23] found that bicyclo[4.3.0]non-1(6)-en-2-one (BNEN, **4**) gives the same four products on photoaddition to either *Z*- or *E*-2-butene, again indicating that the stereochemical integrity of the alkene component is lost during the reaction:



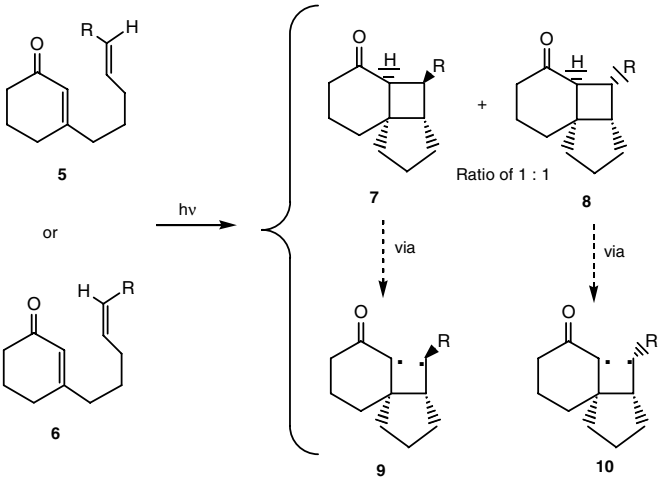
(72.6)

A similar study involving photoaddition of CP to *Z*- and *E*-1,2-dichloroethene was reported by Dilling et al.[24] In both of these cases, the possibility of biradical reversion to starting materials resulting in *Z,E*-isomerization of the alkene was not explicitly considered or investigated. McCullough et al.[25] found that, at 2% conversion in the photoaddition of 3-phenyl-CH to *Z*-2-butene, recovered alkene contained 9% of the *E* alkene, consistent with biradical reversion to ground-state starting materials and demonstrating that this process is in most cases a major source of inefficiency in these photoreactions.

Biradical reversion appears to be a much more important process in enone additions to electron-deficient alkenes. Thus, Schuster and co-workers[26] found that, in the reaction of 3-methylcyclohexenone (3-MCH) with *Z*- and *E*-1,2-dicyanoethene (maleo- and fumaronitrile), isomerization of the alkenes accompanies formation of cycloadducts. Based upon quantum yields for all processes and the rate constants for quenching of the enone triplet by these alkenes, Schuster et al.[26] concluded that alkene isomerization occurred by reversion of 1,4-biradical intermediates (i.e., a Schenck-type mechanism)[27] rather than by triplet–triplet energy transfer from the enone to the alkenes, although the latter was a distinct possibility due to the relatively low triplet energies of these particular alkenes.[28] The full significance of biradical reversion as a critical factor in affecting the course of enone photocycloadditions is discussed below.

Intramolecular Photocycloadditions

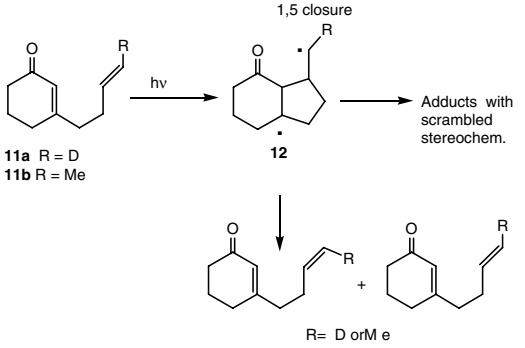
Stereochemical scrambling in intramolecular photocycloadditions of cyclohexenones with tethered alkene moieties has also been extensively investigated. Becker and Haddad[29] found that the isomeric β-linked 1-acyl-1,6-heptadienes **5** and **6** (R = CH_3) give a 1:1 mixture of stereoisomeric cycloadducts **7** and **8,** but the dienes do not isomerize during the irradiation process:[29]



(72.7)

Similar results were also obtained with **5** (R = isopropyl) and with a *cis*-dideuterio analog, demonstrating that steric effects did not play an important role. The results indicate that initial bonding occurs between C2 (the β-carbon of the enone) and C6 of the heptadiene moiety in accord with the notorious "rule of five"[30] to give triplet 1,4-biradicals **9** and **10**, whose lifetimes are sufficiently long to allow complete rotational equilibration prior to ring closure. Curiously, 1,4-biradicals **9** and **10** do not appear to revert to starting materials accompanied by isomerization (see Eq. (72.5)).

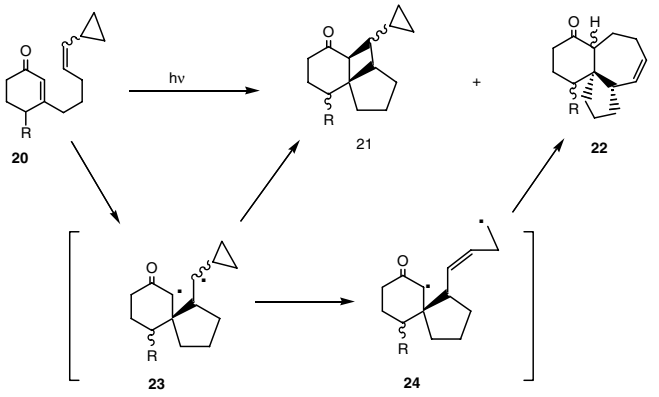
In contrast, Agosta found that the acylhexadienes **11** undergo scrambling of the label (D or CH_3) on the CC double bond in the side chain competitive with formation of photoproducts:[31]



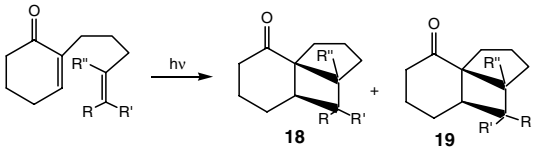
(72.8)

Similar results were found for an acyclic analog. For **11**, reaction almost surely occurs via 1,4-biradicals **12** formed by initial 1,5-bonding to the α-carbon of the enone. Inversion and rotation at the radical center then occurs prior to fragmentation or cyclization. Based upon quantum yields, the ratios of the rate of biradical reversion to product formation (k_r/k_p) are 0.75 for **11a** and 1.81 for **11b**. It is obvious that the competition between the various pathways for biradical formation and decay depends critically on the substitution pattern in these systems.

Becker and Haddad[29] later investigated the photoreactions of the α-linked cyclohexenones **13** to **17**, where once again *Z,E*-isomerization of the starting materials was not observed:



SCHEME 1



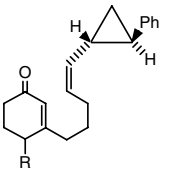
13 R = Me, R' = R'' = H
14 R' = Me, R = R'' = H
15 R = *i*-Pr, R = R''= H
16 R' = *i*-Pr, R= R''= H
17 R = R'' = D, R' = H

Ratio of **18 : 19** = 35 : 1 for **13**
Ratio of **18 : 19** = 5.8 : 1 for **14**
Ratio of **18 : 19** = 3.8 : 1 for **15**
Ratio of **18 : 19** = 1.4 : 1 for **16**
Ratioo f **18 : 19** = 2 : 1 for **17**

(72.9)

While mixtures of stereoisomeric cycloadducts were formed in each case, no simple pattern of reactivity emerges. Both **13** and **14** preferentially afford diastereomer **18**, but the ratio of **18** to **19** is quite different in each case, indicating that the reaction is more complicated than with the analogous β-linked dienones. With the isomeric *n*-propyl-substituted dienones **15** and **16**, cycloaddition again gave **18** in preference to **19**, but to different extents than above. Even with the dideuteriodienone **17**, diastereoselectivity is observed on ring closure. These results clearly require the participation of several competing reaction pathways.

To further probe the nature and properties of the biradicals generated on photoexcitation of **13** to **17**, Becker et al.[32] studied the analogous dienones **20** (as a *Z/E* mixture) with a cyclopropyl substituent on the CC double bond in the β-linked side chain. The ring opening of cyclopropylcarbinyl to 3-butenyl radicals, for which a rate constant of 1×10^8 s^{-1} has been determined,[33] is considered to be a reliable radical clock for estimation of biradical lifetimes. Photoexcitation of **20** gave rearranged products **22** in competition with normal intramolecular [2+2]- cycloadducts **21** in a ratio of 45:55, as shown in Scheme 1, indicating that (1) bonding in this system occurs exclusively between the β-carbon of the enone and the alkene carbon β to cyclopropyl to give **23**, and (2) ring opening of **23** to give biradical **24** (which closes to **22**) occurs at about the same rate as ring closure of **23** to **21**. From this, the lifetime of biradical **23** can be estimated to be on the order of 10 ns. In a related study, photoaddition of CP to vinylcyclopropane gave HH and HT cycloadducts, as well as products derived from ring opening of the intermediate biradicals, whose lifetimes were estimated to be ~50 ns.[34] Because ring opening of phenyl-substituted cyclopropylcarbinyl radicals is estimated to be much faster than the parent system by about three orders of magnitude, the analogous phenyl-substituted compound **25** was prepared and irradiated.[35]



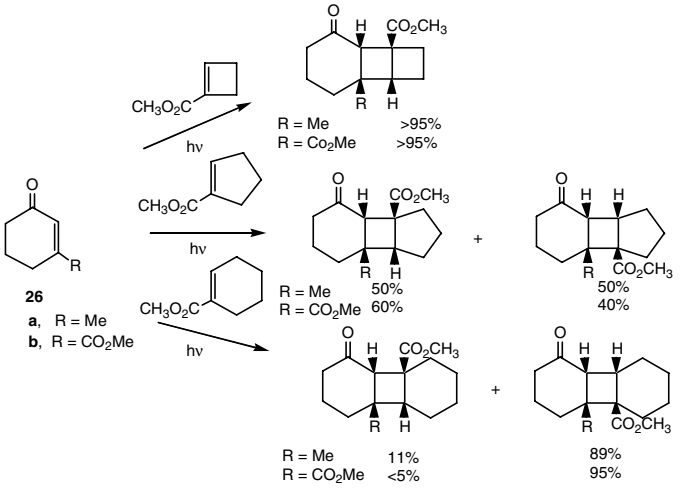
25 *Z,E*

Indeed, as anticipated, only rearrangement products analogous to **22** were isolated, with no detectable amounts of the [2+2]-adducts analogous to **21**.[35] Similar studies of the α-linked compounds analogous to **20** and **25** showed that in this case the first bond forms at both the α (major) and β (minor) carbons of the enone, followed by competitive cyclization and ring-opening reactions.[35]

Regiochemistry in Enone-Alkene [2+2]-Photocycloadditions

One of the most significant findings in Corey's pioneering study[3] was that photocycloadditions of cyclohexenones to unsymmetrical alkenes were invariably regioselective. Thus, the reaction of CH and 2-methylpropene (Eq. (72.3)) and 1,1-dimethoxyethene (Eq. (72.1)) showed a clear preference for formation of HT vs. HH adducts. Corey[3] observed similar selectivity for photoaddition of CH to allene, vinyl acetate, methyl vinyl ether, and benzyl vinyl ether, as was found also by Cantrell et al.[36] for the reaction of 3-MCH with 1,1-dimethoxyethene (DME) and by Lenz[37] for photoaddition of a steroid enone to 1,1-dialkoxyethene and 2-methylpropene. In contrast, HH adducts were preferentially formed between CH and acrylonitrile, although the structures of the adducts (including stereochemistry) were not firmly established.[3] Although photoaddition of 3-MCH to acrylonitrile also gave mainly two HH adducts[36] (the structure of a third adduct was not firmly established), Rao et al.[38] found that the major photoadduct from 4,4-dimethylcyclohexenone (DMCH) and acrylonitrile had a HT structure, while Weedon and coworkers[39] established that the ratio of HH to HT adducts formed from 2-cyclopentenone and acrylonitrile was 40:60. Thus, the original suggestion[3] that the regioselectivity in [2+2]-photocycloadditions of cyclic enone and alkenes is generally reversed using electron-deficient in place of electron-rich alkenes appears is clearly incorrect.

Strong evidence that regioselectivity in [2+2]-photocycloadditions does not follow a simple pattern comes from a study by Lange et al.[40] on addition of enones **26a** and **26b** to a series of methyl 1-cycloalkene-1-carboxylates:



(72.10)

While additions to the cyclobutenyl ester gave exclusively HH adducts in line with Corey's generalization, increasing proportions of HT adducts were obtained as the ring size of the alkene was increased, resulting eventually in a reversal of regioselectivity. Thus, the HH to HT adduct ratio was 1:1 for **26a** and 60:40 for **26b** with the cyclopentenyl ester, but turned around to 1:9 and <1:20 for reactions of **26a** and **26b**, respectively, with the analogous cyclohexenyl ester. It is obvious that the regiochemistry associated with enone–alkene photocycloadditions is clearly much more complex than originally envisioned.[3] The mechanistic rationalization of these findings is deferred until Section 72.3.

Reactivity of Alkenes Toward Photoexcited Enones

In 1964, Corey and co-workers[3] determined "relative reactivities" for competitive additions of photoexcited CH to alkenes by measuring the ratio of adducts derived from 1:1 alkene mixtures. The so-called "relative rate factors," correcting for statistical factors, were 4.66 for 1,1-dimethxyethene, 1.57 for methoxyethene, 1.00 for cyclopentene (reference compound), 0.40 for isobutene, and 0.234 for allene; acrylonitrile was much less reactive than any of the other alkenes listed. Based upon these data, Corey concluded that photoexcited CH was a moderately electrophilic species toward alkenes.

These data were accepted for a long time as proper measures of alkene reactivity in photocycloadditions and were critical elements in the formulation of Corey's famous "exciplex mechanism" to explain enone photocycloadditions.[5b–d] However, as is now well known, product ratios in photochemical processes reflect relative quantum efficiencies for disappearance of starting materials and/or formation of products and rarely reflect relative rates of reaction of the photoexcited state, particularly when it is a triplet state.[6,10–12,41,42]

The lack of a relationship between product quantum yields and the rate constants of a single reaction step in a multistep reaction pathway was demonstrated dramatically many years ago by Wagner[42] for Norrish type II reactions of aromatic ketones. In this reaction, quantum efficiencies are determined by the competition between reversion of 1,4-biradical intermediates to starting material and product formation and do not correlate at all with the rate constants for formation of the biradicals from ketone triplet states.[42] Because 1,4-biradicals clearly play a crucial role in enone photocycloaddition to alkenes, it would be surprising if relative yields of enone–alkene photoadducts directly reflect the rates of the initial interaction of alkenes with enone triplet excited states.[5a,6,15,19,20,43] In fact, such a correlation does not exist.

Rate constants for interaction of triplet excited states of cyclic enones with alkenes were first reported by Schuster et al.[16,19,20] using transient absorption spectroscopy (nanosecond flash photolysis). The rate constants k_q were obtained from the relationship $(\tau_T)^{-1} = (\tau_0)^{-1} + k_q$ (alkene), where τ_0 is the limiting triplet lifetime of the enone at a given concentration in the absence of alkene. The decay of enone triplet absorption at 280 nm could be conveniently followed upon excitation of the enones (cyclopentenone [CP], 3-methylcyclohexenone [3-MCH], testosterone acetate [TA], and BNEN [**4**] were all studied]) in acetonitrile and cyclohexane at 355 nm using the third harmonic of a Nd:YAG laser. In all cases, triplet decays were clearly first order. Quantum efficiencies for capture of enone triplets by alkenes (Φ_{tc}) are given by $k_q\tau_T$ (alkene) using the experimentally determined values of k_q and τ_T.

No correlation exists between the rate constants k_q for interaction of the enone triplets with the alkenes and the overall quantum efficiency for formation of products.[16,19,20] In general, electron-rich alkenes give higher quantum yields for adduct formation, while the highest rate constants for triplet quenching are found with electron-deficient alkenes, such as acrylonitrile and fumaronitrile. Efficiencies of triplet capture (Φ_{tc}) at the alkene concentrations (typically 0. 5 *M*) at which quantum yields for product formation (Φ_{add}) were measured are invariably higher than Φ_{add}. This is definitive evidence for formation of intermediates that revert to starting materials in competition with progress to adducts. Furthermore, no correlation exists between k_q and the ionization potentials of the alkenes, as would be expected if quenching involved formation of a donor–acceptor complex, with the alkene as electron donor and the electronically excited enone as electron acceptor. Also, no significant difference has been observed between

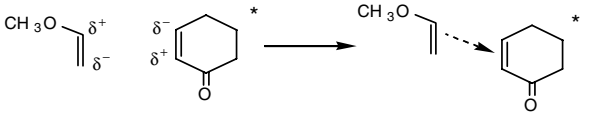
rate constants measured in polar (acetonitrile) and nonpolar (cyclohexane) solvents, arguing against charge polarization in the transition state for the initial electronic interaction between enone triplets and alkenes.

Two different mechanisms for quenching of enone triplets could be operating with electron-deficient alkenes, triplet energy transfer, and a Schenck-like addition mechanism involving intermediate 1,4-biradicals.[26] It was shown that quenching of 3-MCH by 1,2-dicyanoethenes involves a Schenck mechanism,[27] while interaction of higher energy triplets of the rigid enone BNEN with the same alkenes involves triplet–triplet energy transfer.[18] Inhibition of triplet energy transfer from 3-MCH and similar conformationally flexible enones by the Dexter exchange mechanism can be attributed to poor π overlap between the twisted chromophore of the enone triplets and the alkenes.[44] No such inhibition would occur with conformationally constrained enones such as BNEN.

72.3 Mechanistic Proposals

The Corey–de Mayo Exciplex Mechanism

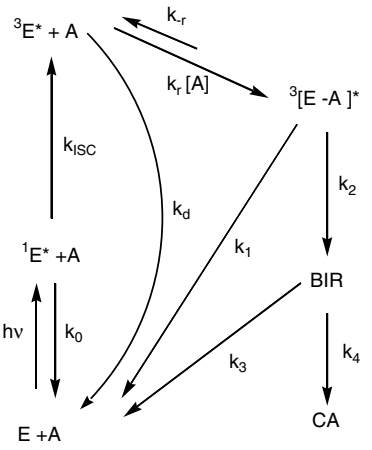
On the basis of the regiochemistry and the relative rate factors observed in his studies of alkene additions to photoexcited CH (see above), Corey[3] proposed in 1964 that the first step of the [2+2]- photocycloaddition of enones to alkenes involved interaction of a polarized enone triplet excited state with the ground-state alkene to give an "oriented π-complex" (illustrated in structure **27**) for the case of addition of CH to methoxyethene.



27

Assuming (incorrectly as it subsequently turned out) that the reactive excited state of the enone was an $^3(n,\pi^*)$ state, the electron polarization from extended Huckel calculations was predicted to be as shown, with higher electron density at C_β than at C_α.[45] In this donor–acceptor π-complex, the alkene ground state was proposed to act as the electron donor and the enone-excited state as the electron acceptor, the two moieties being held together by coulombic attraction. Corey noted[3] that it was likely that the π-complex model could not be extended to enone photodimerization or to reactions of enones with alkenes possessing strong electron-withdrawing substituents such as CN or COOR. Steric factors remained to be assessed. The alternative hypothesis (namely, that the regiospecificity in these reactions might be governed by preferences in formation of 1,4-biradicals) was rejected, because it did not explain the observed selectivity in photoaddition of CH to DME nor the relative rate factors. However, biradical intermediates on the reaction pathway were invoked to rationalize the occasional formation of disproportionation products (see Eq. (72.3)), as well as the loss of stereochemistry observed on photoaddition of CH to the isomeric 2-butenes.

de Mayo later suggested that Corey's proposed π-complexes might decay to ground-state reactants competitive with formation of products.[9,12,42] He noted that quantum yields for adduct formation from CP and a variety of alkenes were never greater than 0.50, even in neat alkene. de Mayo initially concluded that the intermediate undergoing reversion to ground-state reactants was the exciplex, rather than a biradical derived from the exciplex, because little if any alkene isomerization occurred ($\Phi < 0.033$) on irradiation of CP in the presence of 3-hexene.[46] He also suggested that adducts might arise, at least in part, directly from the exciplex, bypassing the biradical; however, de Mayo recognized that variations with temperature of the quantum yield for photoadditions could most easily be explained in terms of changes in the partitioning of the 1,4-biradical intermediate.[47]



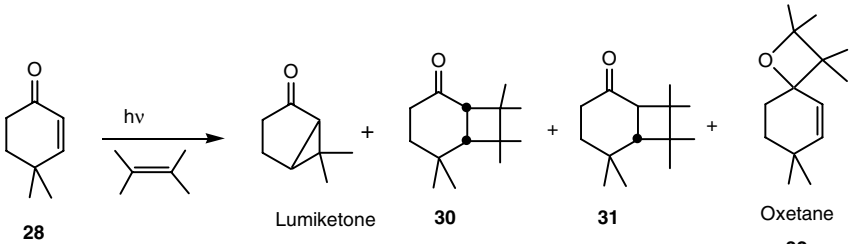
E= enone, A = alkene, BIR = 1,4-biradical, CA = cycloadducts

SCHEME 2

Loutfy and de Mayo[48] maintained that a triplet exciplex is formed first, and irreversibly, from the enone triplet and the alkene ground state and that the exciplex collapses to one or more triplet 1,4-biradicals, which either cyclize or revert to ground-state starting materials. Insufficient evidence was available to indicate whether the first bond in the adduct is formed α or β to the carbonyl group on the enone. However, their kinetic data[48] in no way *requires* formation of an exciplex precursor to biradicals in these reactions. For the analogous process of oxetane formation from benzophenone and alkenes, Caldwell et al.[49] concluded that some kind of complex, most likely a π-complex, was an *obligatory* precursor to triplet 1,4-biradicals, based on secondary kinetic isotope effects associated with initial quenching of the ketone triplet, formation of oxetanes, and *cis-trans* isomerization of the alkenes. The Corey-de Mayo exciplex mechanism is shown in Scheme 2.[48]

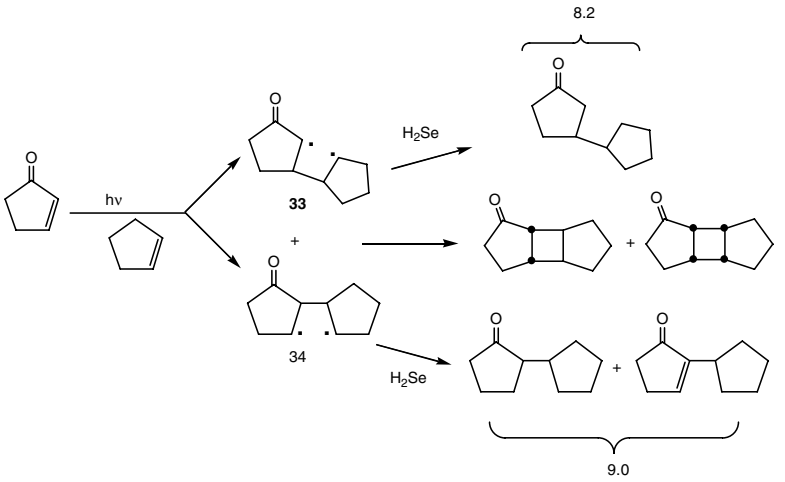
Identification of the Reactive Enone Intermediate

As noted previously, it was concluded earlier from spectroscopic data that the lowest energy triplet state of cyclic enones and cyclohexenones, in particular, is a $^3(\pi,\pi^*)$ state, not a $^3(n,\pi^*)$ state.[13] Evidence that the $^3(\pi,\pi^*)$ state is the reactive excited state in [2+2]-photocycloadditions derives from the nanosecond flash photolysis studies of Schuster and co-workers referred to earlier,[16,19,20] as well as studies on 4,4-dimethylcyclohexenone (DMCH) **28**. The latter gives the rearranged lumiketone **29** and cycloadducts **30** and **31** upon irradiation in the presence of 2,3-dimethyl-2-butene:[37,50,51]



(72.11)

Kinetic studies demonstrated that adducts **30** and **31** and lumiketone **29** arise from the same enone excited state. Abundant data indicates that the photorearrangement arises from the enone $^3(\pi,\pi^*)$ state.[52] When DMCH is irradiated in neat alkene, oxetane **32** is formed in addition to the other products. The



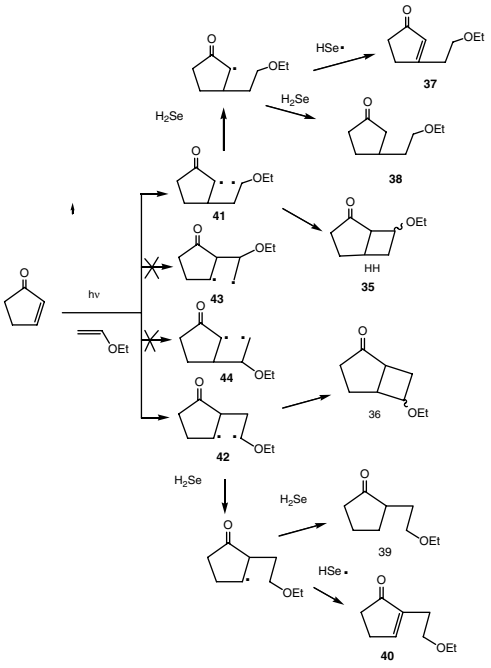
SCHEME 3

Stern–Volmer slope for quenching by naphthalene of oxetane formation, a reaction attributed to $^3(n,\pi^*)$ states,[41] is indeed different from that for quenching **29**, **30**, and **31**. This leaves no doubt that in this system and, by extension, in other cyclohexenones the reactive excited state is the enone $^3(\pi,\pi^*)$ state. There is convincing evidence from transient absorption spectroscopy[16] and photoacoustic calorimetry[17] that relaxed $^3(\pi,\pi^*)$ states of simple cyclohexenones are highly twisted. This twisting is indeed crucial in the photorearrangement pathway[52] and may well be an important factor in formation of both *cis*- and *trans*-fused products in the cycloaddition pathway. The suggestion that ground-state *trans*-cyclohexenones might be on the pathway for formation of [2+2]-cycloadducts as well as rearrangement products has been frequently considered[52–59] but remains controversial to this day. In any event, these experimental studies establish that at least for conformationally flexible cyclic enones, the reactive excited state in [2+2]-cycloaddition to alkenes is definitely a $^3(\pi,\pi^*)$ state. Theoretical studies to be described later strongly support this conclusion.

Bauslaugh's Biradical Proposal: Trapping and Detection of Biradical Intermediates in Enone [2+2]-Photocycloadditions

In 1970, Bauslaugh[60] proposed that the regiochemistry in [2+2]-photocycloadditions of enones could be explained without invoking exciplexes, by considering the most likely conformations of various possible HH and HT 1,4-biradicals and whether they were more likely to either cyclize or to undergo fragmentation to regenerate starting materials.. This proposal received strong experimental support from studies by Weedon and co-workers,[39,61] who succeeded in trapping intermediate 1,4-biradicals in [2+2]-photocycloaddition reactions using hydrogen selenide. Thus, while photocycloaddition of CP to cyclopentene in benzene gives a mixture of *cis-syn-cis* and *cis-anti-cis* adducts (Eq. (72.1)), no cycloadducts were formed in the presence of 0.3-*M* H_2Se (see Scheme 3). Rather, a series of new products were observed, attributable to H-transfer from H_2Se to the putative 1,4-biradical intermediates, followed by reduction and disproportionation of the resulting monoradicals. From the product ratio, it was concluded that the HH and HT 1,4- biradicals **33** and **34** are formed in a 1:1 ratio; that is, there is no significant difference in reactivity of the α and β carbons of the CP triplet toward cyclopentene.

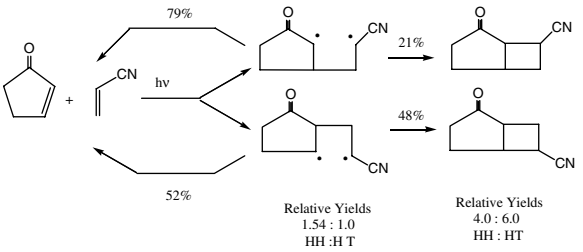
An even more revealing finding involves [2+2]-photoaddition of CP to ethyl vinyl ether (EVE),[39,61] which gives a 3:1 mixture of HT and HH cycloadducts **35** and **36**, in accord with Corey's original findings.[3] Adduct formation is again totally suppressed by H_2Se, yielding instead a mixture of four new products **37** to **40** directly attributable to trapping of the HT and HH 1,4-biradicals **41** and **42** (see Scheme 4). From the product yields, it can be concluded that HH and HT biradicals **41** are again formed in a 1:1



SCHEME 4

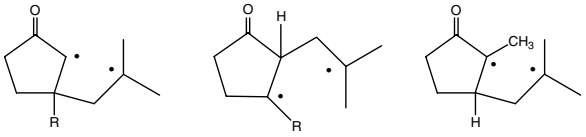
ratio. Furthermore, only the more substituted biradicals are formed (i.e., no products derived from biradicals **43** and **44** containing a primary radical center were observed). The observed 3:1 HT/HH regioselectivity in adduct formation, therefore, must originate from differences in cyclization vs. fragmentation to starting materials of the HH and HT 1,4-biradicals. It was suggested that the fact that the HT biradical shows a much greater preference to undergo cyclization vs. scission, while the HH biradical shows a greater tendency for scission as opposed to cyclization, may relate to differing populations of extended vs. closed conformations of these isomeric biradicals. Recent theoretical studies that validate this hypothesis are discussed later.

Further biradical trapping studies using H_2Se demonstrate the generality of the conclusion that the regiochemistry of enone photocycloaddition reactions is entirely determined by the fates of the various 1,4-biradical intermediates (i.e., fragmentation to regenerate ground-state enone and alkene *vs.* cyclization to cyclobutane adducts) and not by the relative rates of formation of these biradicals. For CP, such studies have been successively carried out for photoadditions to allene, 2-methylpropene, 1,1-difluoroethene, and methyl acrylate.[62] In general, comparable amounts of HH and HT biradicals are formed (see Scheme 4) by bonding between the α and β carbons of the enone and the less substituted alkene carbon, generating the more stable biradical intermediate. Thus, for photoaddition of CP and 3-methyl-CP to 2-methylpropene,[62a] the biradicals of type **45**, which are precursors to HH cycloadducts and arise from reaction at the β position of the enone, are formed in 64.5 and 70.5% relative yields. However, they overwhelmingly undergo fragmentation to enone and alkene (95.5 and 88%, respectively) as opposed to cyclization. The corresponding 1,4-biradicals **46** which are precursors to the HT adducts are formed to a much lesser extent by reaction at the α position of the enone, but fragment to a significantly lesser extent (79 and 68%, respectively). The overall result is that more of the HT than the HH product is formed, even though the rate of formation of the biradical precursors is precisely the reverse; that is, HH (**45**) > HT (**46**). Perhaps the most extreme illustration of this curious phenomenon is the photoaddition of 2-methyl-CP to 2-methylpropene,[62a] in which biradical **47** is formed in 90.4% yield but undergoes fragmentation to starting materials to the extent of 97%! As a consequence, only 3% of the isolated products in this reaction are derived from **47**. Furthermore, the presence of the methyl group at C3 (β)



SCHEME 5

on CP has little affect on either the formation of the biradicals or on their tendency to undergo ring closure, while a methyl group at C2 (α) clearly inhibits ring closure. Weedon[62a] interprets these findings to mean that the radical center at C3 in the 1,4-biradical adopts a pyramidalized sp^3 configuration, directing the methyl group on the ring away from the side-chain isobutyl radical in the ring closure step, while the radical center at C2 remains sp^2, so that the methyl is now in the way of the approaching isobutyl radical.



45 R = H, CH_3 **46** R = H, CH_3 **47**

For photoaddition of CP to acrylonitrile (AN), Weedon[62d] found that the ratio of HT to HH diastereomeric cycloadducts was 60:40, reversed from the ratio of 24:76 for addition of AN to 2-cyclohexenone. The latter is in agreement with Corey's original finding.[3] Thus, as in Lange's study discussed earlier,[40] enone ring size clearly affects overall regioselectivity, which directly conflicts with the exciplex hypothesis. While biradical trapping experiments were not successful in the first of these reactions, it was possible to generate the intermediate HH and HT CP/AN biradicals by an alternative route from diketone precursors and determine the cyclization/fragmentation ratio for each of them. From these data, it was possible to construct the reaction scheme shown in Scheme 5,* in which it can be seen that the HH biradical is preferentially formed, but that this biradical again shows a greater propensity to undergo fragmentation than the HT biradical, accounting for the higher yields of HT than of HH adducts.

Finally, analogous radical trapping studies were reported on photoaddition of CH to cyclopentene and ethoxyethene.[63] Once again, a discrepancy is observed between the rates of formation of the various biradical intermediates and the relative yields of the adducts. For CH and cyclopentene, HH and HT biradicals were formed to similar extents, just as was found for CP. For the CH and ethoxyethene reaction, the ratio of HH to HT adducts was 19:81, while the yields of the biradical precursors was 55:45, again demonstrating that overall regiochemistry is determined by the differing extent to which the precursor biradicals undergo cyclization vs. fragmentation. The fact that the reaction pattern is the same as with the CP photoaddition reactions[39,61,62] indicates that the factors operating in both systems are similar.

Weedon's data clearly demonstrate that not only is it not necessary to invoke exciplexes or oriented π-complexes in order to explain the regioselectivity in [2+2]-photocycloaddition of cyclopentenones and cyclohexenones to alkenes, but also that expectations based on the exciplex mechanism are contrary to experimental observations. It is clear that regioselectivity is entirely due to differences in behavior of the intermediate triplet 1,4-biradicals, not to their rates of formation, as was originally hypothesized.[3]

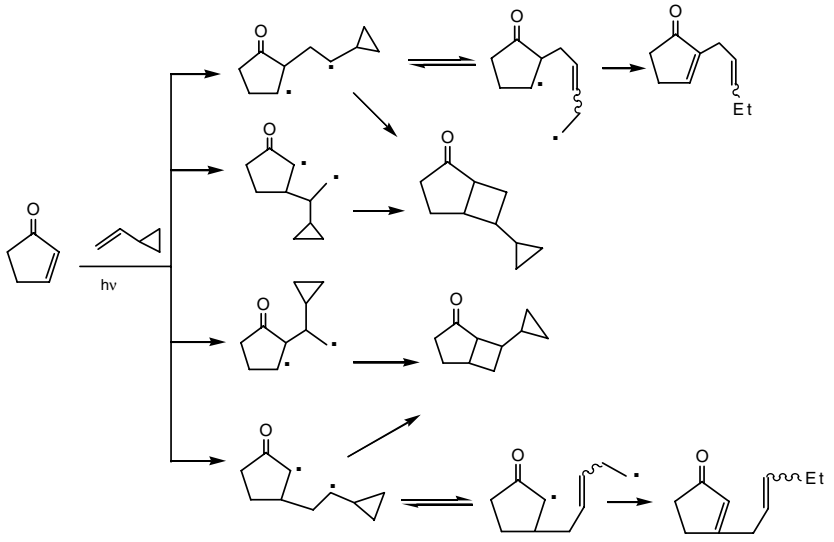
Lifetimes and Energies of 1,4-Biradical Intermediates in Enone–Alkene Photocycloadditions

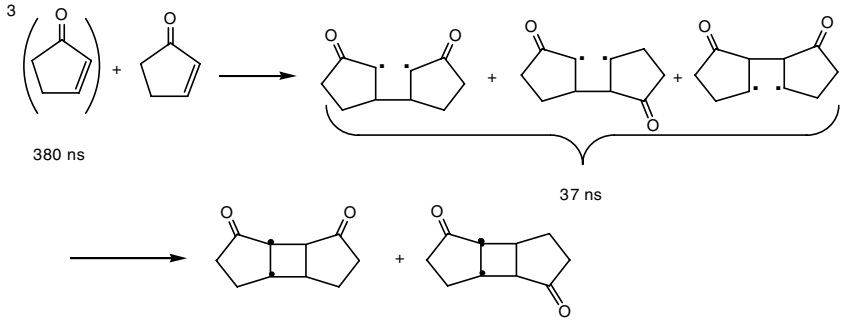
As already discussed, one approach to determination of lifetimes of triplet 1,4-biradicals is by using a radical clock, most commonly the ring opening of cyclopropylcarbinyl to 3-butenyl radicals.[33] Thus, in the work of Becker and co-workers[32] on dienones analogous to **5** with a cyclopropyl substituent on the CC double bond in the side chain, the biradical lifetimes were estimated to be on the order of 50 ns. Photoaddition of CP to vinylcyclopropane (see Eq. (72.12)) gave cycloadducts as well as products derived from the ring opening of the intermediate HH and HT biradicals, whose average lifetimes were also estimated to be ~50 ns.[34]



(72.12)

However, in the photoaddition of cyclopentenone to 1,6-heptadiene, the initial 1,4-biradicals were observed, consistent with the lower rate of rearrangement of 1-hexenyl to cyclopentylmethyl radicals, $<10^5$ s^{-1}.[64] The initially formed triplet 1,4-biradicals in the cycloaddition reactions must therefore have lifetimes substantially less than 10 μs, consistent with the results on the cyclopropyl-substituted systems. A similar observation was made in intramolecular photoadditions of cyclohexenones possessing a tethered diene moiety.[29]

Caldwell et al.[65] succeeded in directly detecting triplet 1,4-biradicals in enone cycloadditions using nanosecond flash photolysis. Excitation of CP in acetonitrile gives complex transient decay profiles at 280 nm that can be resolved into two first-order decays, one dependent on the concentration of the enone and a second that is not. The former is concluded to be the CP triplet,[6,11,12,53,65] whose limiting lifetime in acetonitrile is 380 ± 75 ns. The much smaller CP triplet lifetime of 30 ns reported earlier by Bonneau[55] is consistent with the concentration-independent lifetime of 37 ns for the second transient in the laser flash studies,[65] which is now attributed to the (weighted) average lifetime of the HH and HT triplet 1,4-biradicals formed by CP self-quenching:



(72.13)

Note that two stereogenic centers are generated on formation of the first CC bond, so that each of the three 1,4-biradicals in Eq. (72.9) is actually a mixture of two diastereomers; thus, as many as six 1,4-biradicals can be formed in this reaction. Using time-resolved photoacoustic calorimetry (PAC) at moderate CP concentrations, a short-lived transient species was detected whose lifetime was in perfect agreement with that derived from the flash photolysis study and is identified with the dimeric biradicals shown in equation 9.[65] From the PAC data the energy of the biradicals (relative to a pair of ground-state CP molecules) was determined to be 47.4 ± 1.7 kcal/mol, in excellent agreement with values of 44 and 51 kcal/mol for the HH and HT biradicals estimated using the Benson group additivity technique.[66] These are the only such data reported for enone-derived triplet 1,4-biradicals.

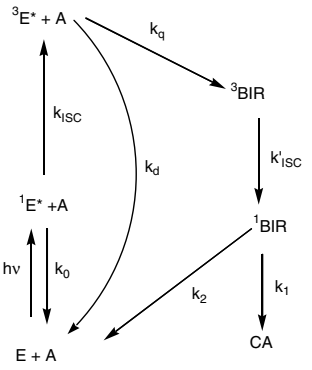
More recently, the PAC technique has been used to measure lifetimes and energies of triplet 1,4-biradicals derived from a number of model enones and alkenes.[67] The biradical lifetimes vary from 20 to 600 ns. The shortest lifetimes are for biradicals derived from 3-MCH and cyanoalkenes, while the longest is for 3-MCH and 2,3-dimethyl-2-butene. A typical value is 59 ± 5 ns for the biradical(s) derived from testosterone acetate and cyclopentene. Again, these represent average lifetimes of the biradicals formed in the reaction, some of which may not even yield products to a significant extent, as discussed above. The average energies of these biradicals range from 36 to 60 kcal/mol, relative to the ground states of the reactants. These values are again in good agreement with estimates based upon Benson's additivity rules.[66] It is clear that the triplet 1,4-biradicals derived from enone triplets and alkenes have lifetimes allowing for complete conformational equilibration. On this basis, it is not at all obvious why certain cyclohexenone photoadditions (e.g., to *Z*- and *E*-2-butene) are apparently not accompanied by at least partial isomerization of the recovered alkene[3] and why there is no loss of alkene stereochemistry in recovered starting material in the intramolecular photocycloadditions reported by Becker.[29]

The Bauslaugh–Schuster–Weedon Mechanism for Enone–Alkene Photocycloadditions

The Corey–de Mayo exciplex mechanism[3,15,48] for photocycloaddition of enones to alkenes has provided a stimulus for workers in this field and undoubtedly has had heuristic value in accounting for experimental observations in a vast number of reactions.[5] Nonetheless, the experimental findings discussed above make it clear that this mechanism for enone [2+2]-photocycloadditions has been discredited and should be abandoned.

There is a single isolated case in which spectroscopic evidence for formation of a triplet exciplex in an enone photocycloaddition has been reported, involving the photoreaction between 4,4-dimethyl-2-cyclohexenone (DMCH, **28**) and 1,1-diphenylethene (DPE).[68a] Laser flash photolysis (LFP) of DMCH in cyclohexane yields the expected enone triplet (λ_{max} = 280 nm), with a lifetime of 24 ns, as previously reported,[16] and the DPE triplet was similarly characterized (λ_{max} = 335 nm, τ = 34 ns). Photolysis of DMCH in the presence of DPE leads to quenching of DMCH triplets at a rate constant in line with those previously reported and formation of a new transient whose spectrum is essentially identical to that of ^{3}DPE*, but which decays with a lifetime of 50 ns. Oxygen quenching studies indicate that the 50-ns transient is a source of the $^1O_2$ formed in this reaction, which is greater than if the enone triplet was the only sensitizer of $^1O_2$ formation. Azulene quenching studies show that the yield of azulene triplets in the presence of DPE is also considerably higher than that attributable to DMCH triplets under these conditions, as DPE triplets are themselves not quenched by azulene. On the basis of these findings, Caldwell et al.[68a] originally argued that the 50 ns transient is a triplet exciplex resulting from interaction of DPE with ^{3}DMCH*, and that it is formed prior to or in competition with triplet 1,4-biradicals. Based upon new laser flash photolysis experiments, Caldwell now concludes[68b] that the temporal data and quenching studies are best fit by a composite of triplet state transients including the triplet state of DPE and a triplet 1,4-biradical and perhaps other species. The earlier interpretation[68a] that the transient was a ^{3}DMCH*-DPE exciplex is now concluded to be "unnecessary and unlikely".

Thus, the role of exciplexes as intermediates in [2+2]-photocycloadditions of enones to alkenes in general remains highly doubtful. The mechanism for [2+2]-photocycloaddition shown in Scheme 6,[6a]



E = enone, A= alkene,B IR = 1,4-biradical, CA = cycloadducts

SCHEME 6

essentially an elaboration of that postulated by Bauslaugh,[60] is sufficient to rationalize all the data obtained to date concerning this process. In this mechanism, the only intermediates invoked in the addition process are the enone triplet excited states and triplet and singlet adduct 1,4-biradicals. Further specification of the nature and behavior of the intermediate biradicals comes from the theoretical studies discussed in the next section.

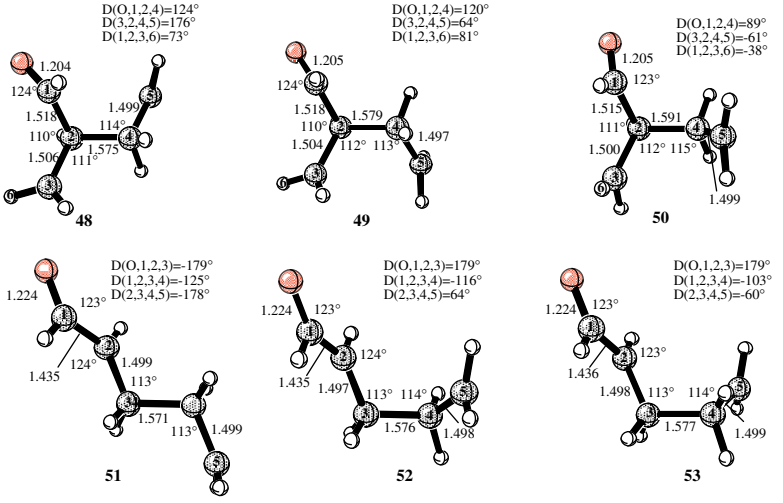
72.4 Theoretical Studies of [2+2]-Photocycloadditions of Enones to Alkenes

Several theoretical descriptions of this reaction have appeared in the past few years.[69,70] The following discussion is based on the very thorough treatment published by Wilsey et al.[70] in which the potential energy surfaces of the ground-state (S_0), triplet excited state (both $^3[\pi,\pi^*]$ and $^3[n,\pi^*]$), and singlet excited state ($^1[n,\pi^*]$) potential surfaces for the addition of acrolein (CH_2=CH–CH=O) to ethene to give formylcyclobutane were calculated by *ab initio* techniques. Calculations were performed using CASSCF (complete active space SCF) procedures and the standard 6–31G* basis set available in Gaussian 94. This approach was used specifically because it allows for balanced representation of several electronic states simultaneously. Dynamic correlation effects, which should not affect arguments regarding biradicaloid structures, were neglected in these calculations. The geometry and energy of the optimized 1,4-biradical intermediates formed on attack at the α- and β-carbons of acrolein and transition structures leading to these biradicals on each of the potential surfaces, as well as transition structures for reaction of each of these biradicals, were determined. The transition structures on the excited-state surface determine the nature of the initially formed biradical intermediate, while those on the ground-state surface control the competition between cyclization (i.e., product formation) and cleavage (reversion to starting materials).

A number of general observations were made.[70] The initial part of the reaction involves attack by the alkene on the triplet state of *s-cis*- or *s-trans*-acrolein at either the α- or β- carbon, leading to a large set of *anti* and *gauche* conformations of the triplet biradical intermediate, which then undergo intersystem crossing to the ground-state potential surface. The second part of the reaction is controlled by the topology on the ground-state surface. Not unexpectedly and in accord with Bauslaugh's original hypothesis,[60] the *anti* biradicals have a tendency to dissociate to regenerate starting materials, whereas the *gauche* biradicals favor cyclobutane formation. At the geometry of the ground-state reactants, the lowest energy excited state is the $^3(n,\pi^*)$ state, with both $^3(\pi,\pi^*)$ and $^1(n,\pi^*)$ lying 4 to 5 kcal/mol higher in energy. As soon as the geometries are allowed to relax, the $^3(\pi,\pi^*)$ state becomes the lowest energy excited state, and the reaction with the alkene follows from this state. Specifically, the $^3(\pi,\pi^*)$ minimum is 60 kcal/mol above the minimum on the ground-state surface and is 9.2 kcal/mol below the planar $^3(n,\pi^*)$ state. Furthermore, the barriers for addition of the $^3(n,\pi^*)$ state to ethylene at both the α- and β-carbons are significantly

higher than found for the $^3(\pi,\pi^*)$ state, α-attack being particularly disfavored as it involves decoupling of electrons. Therefore, reaction from the $^3(n,\pi^*)$ surface, if it occurs at all, should occur only by β-attack. This is expected only in rigid enone systems that cannot undergo conformational relaxation. Thus, as already concluded on the basis of experimental data,[50–53] we need only be concerned with reaction via the $^3(\pi,\pi^*)$ state for enones with some degree of conformational flexibility, such as cyclohexenones and probably also cyclopentenones.

The lowest energy *anti* and *gauche* transition structures for α-attack on the $^3(\pi,\pi^*)$ state both lie about 20 kcal/mol above the reactant minimum, with no preference between them. The three most stable biradicals that result after conformational relaxation are shown in structures **48**, **49**, and **50**.* The energies of the transition structures for β-attack on the $^3(\pi,\pi^*)$ state are 3 to 4 kcal/mol lower than for α-attack, leading to biradicals **51**, **52** and **53**,* which themselves are some 10 kcal/mol than the biradicals formed by α-attack. Interestingly, these biradical minima are almost degenerate with the corresponding minima on the ground-state surface, but spin-orbit coupling at these topologies is negligible. Nonetheless, the fact that the excited- and ground-state surfaces are parallel to each other over a wide range of geometries provides a high probability of intersystem crossing to the ground-state surface.



The barriers for dissociation (cleavage) on the ground-state surface are only 0.3 and 0.7 kcal/mol for the α-biradicals in the two *gauche* conformations **49** and **50** and disappear entirely for the corresponding *anti* biradical **48**. The barriers for ring closure of **48** and **49** are comparable (0.3 and 0.8 kcal/mol), suggesting a slight preference for ring closure from **48** over **49**. The barrier for interconversion of the *anti* and *gauche* biradicals on the ground-state surface is approximately 3.4 kcal/mol and is slightly higher on the excited-state surface. Nonetheless, the barrier is such that *anti/gauche* interconversion could occur before intersystem crossing to the ground-state surface. For the β-biradicals, the energies of the transition structures for dissociation on the ground-state surface are slightly higher (1.8 to 2.7 kcal/mol), while the competing barriers for ring closure (from **52** and **53**) are only 0.1 and 0.7 kcal/mol. The barriers for conformational equilibration are similar to those for the α-biradicals. Thus, once again, the *gauche* β-biradicals prefer to cyclize, while the *anti* biradicals prefer to fragment. It is noted that the barriers for dissociation of the α-biradicals are about 1 kcal/mol lower than for the analogous tetramethylene biradical,[71] indicating that fragmentation competes more effectively with ring closure for the α–biradicals even in the *gauche* minima; however, for the corresponding β-biradicals, the dissociation transition structures are higher in energy than for tetramethylene biradicals,[71] indicating a higher tendency of the former to undergo cyclization.

In summary, the calculations indicate that for ethylene the *anti* biradical formed by β-attack on the enone $^3(\pi,\pi^*)$ state should form most rapidly but will mainly undergo dissociation. The *gauche* biradicals will form more slowly but have a better chance of undergoing ring closure. Similar behavior is expected with electron-deficient alkenes. For electron-rich alkenes, Houk and co-workers[69a,70] propose that attack occurs preferentially at the more electrophilic α-carbon of the enone $^3(\pi,\pi^*)$ state, affording both *anti* and *gauche* biradicals to a similar extent, but that these α-biradicals will mainly dissociate. In this scenario, cyclobutane formation will occur slowly from the gauche α-biradicals, leading to HT products. However, Weedon's studies[39,61–63] indicate that even with electron-rich alkenes, such as ethoxyethene, reaction at the β-carbon of the enone competes effectively with reaction at the α–carbon, for both CP and CH, demonstrating that both β- and α-biradicals play a significant role in these systems. That is, the difference in electrophilicity at the two carbons of the enone $^3(\pi,\pi^*)$ state appears in reality to be quite small.

In most significant respects, these calculations provide a very strong theoretical framework for the mechanism presented in Scheme 3, providing values for the energies of the transition structures for formation of the biradicals on the excited-state surface and for the competitive dissociation/cyclization pathways of the various biradicals on the ground-state surface, data that would be difficult to obtain experimentally. They also clearly demonstrate the great importance of molecular topology on both the ground state and excited-state surfaces in determining the course of these reactions.

72.5 Conclusions and Future Directions in Research on Enone Photocycloadditions

The mechanistic questions regarding this reaction, after intensive research for almost 40 years, are essentially resolved in favor of the triplet biradical mechanism shown in Scheme 3. It is unlikely that further research on the reaction mechanism will be profitable, although further insight into the properties (energies, lifetimes, and geometry) of the intermediate biradicals may yet evolve. One possible benefit of this revised mechanism is that more attention may be paid to photoadditions of cyclohexenones to electron-deficient alkenes, now that the mechanistic bias against such reactions has been removed. While these are sometimes accompanied by unwanted side reactions, such as polymer formation in the case of AN,[19,32] such reactions oftentimes proceed quite cleanly.[36] Just as [2+2]-photoaddition of enones to electron-rich alkenes have been profitably used by synthetic chemists,[5] there is no reason why analogous reactions using electron-poor alkenes should not also find synthetic utility.

One example of this is the photochemical [2+2]-addition of cyclic enones to C_{60}, which in many ways behaves as an electron deficient alkene. Thus, C_{60} is readily attacked by nucleophiles and free radicals but not by electrophiles.[72] Schuster and co-workers[73] have shown that ultraviolet irradiation of a large variety of cyclic enones in the presence of C_{60} leads to both *cis*- and *trans*-fused [2+2]-cycloadducts in good yields by a reaction that involves attack of enone triplet excited states on ground-state fullerene. Photoaddition does not occur if the fullerene is selectively excited at longer wavelengths (532 nm). The reaction, which is an effective route for functionalisation of fullerenes, appears to occur by the general triplet biradical mechanism outlined in Scheme 6. More recently, Vassilikogiannakis and Orfanopoulos[74] reported that acyclic enones also undergo reversible [2+2]-photoaddition to C_{60} upon ultraviolet irradiation. This reaction is unusual in that acyclic enones rarely undergo photoaddition to alkenes, because *Z,E*-isomerization of the enone excited state is typically the dominant process upon photoexcitation of the enone.[6] The observed regio- and stereoselectivity of the addition reaction[74] could be explained in terms of the relative stability of the 1,4-biradical intermediates that are presumably involved. It is additionally interesting to note that these photocycloadditions occur despite the fact that the triplet excited state of C_{60} is of much lower energy than that of the enones. Thus, addition of the enone triplet to the fullerene is faster than intermolecular triplet–triplet energy transfer. Possible explanations for this observation have been discussed by Schuster et al.[73]

The possibility of altering the course of enone [2+2]-photocycloadditions by modification of reaction conditions needs to be investigated. One approach would be to carry out such reactions in nonhomog-

enous media.[75] For example, photodimerization of coumarin in cyclodextrins[76] as well as of CP and CH in dry zeolites[77] give product distributions that are quite different from those in fluid solution. The factors that control the stereochemistry of the 6/4-ring fusion in [2+2]-photoadditions of CH systems still remain to be completely elucidated. Nonetheless, approaches to achieving stereochemical control in enone-alkene [2+2]-photocycloadditions have been reported[78] that will further enhance the synthetic utility of these reactions.

[2+2]-Photocycloadditions in the Solid State

Yoriko Sonoda
National Institute of Advanced Industrial Science and Technology

73.1 Introduction[1,2]

[2+2]-Photocycloaddition is one of the best known reactions in solid-state organic photochemistry. The reactions, in general, occur more selectively and efficiently than in homogeneous solution due to tight and regular molecular arrangements in crystals. It is often observed that the photoproducts in the solid state are entirely different from those in solution.

During the 1960s and 1970s, Schmidt and co-workers studied the solid-state [2+2]-cycloadditions of cinnamic acids thoroughly and systematically.[1–4] From the crystallographic investigations, topochemical rules, which connect the configuration of the product and crystal structure of the reactant, were revealed. It is well known that for topochemical [2+2]-photocycloaddition, the distances between the potentially reactive double bonds should be less than ~4.2 Å.[3,4] Following the pioneering work of Schmidt et al., several groups have investigated structure–reactivity correlations in the solid state, and the main factors required for the cycloaddition to occur in the solid state are now understood fairly well. However, the principal problem — namely, complete control of molecular arrangements in the crystal lattice— has not been overcome fully. Although several kinds of steering groups are known to make olefinic compounds photoreactive in the solid state, our understanding of the various forces that control the crystal packing is highly fragmentary. One of the major problems is lack of complete understanding of the intra- and intermolecular interactions leading to the observed crystal packing.

For aligning the reactive double bonds, three distinct strategies have been employed and are discussed in this chapter: intramolecular substitution, formation of mixed crystal using donor–acceptor charge transfer (CT) type of intermolecular interactions, and, more recently, inclusion within host structures. Recent developments in this field are mainly concerned with absolute asymmetric synthesis of organic compounds using [2+2]-photocycloaddition in the solid state. Optically active products can be obtained in the absence of any external chiral source using chiral crystals of achiral molecules, mixed crystals of two different kinds of achiral molecules, and inclusion crystals of achiral guest molecules in chiral host crystals.

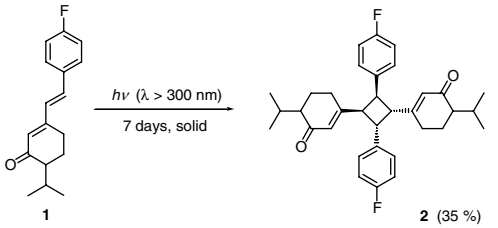
73.2 Crystal Photolysis

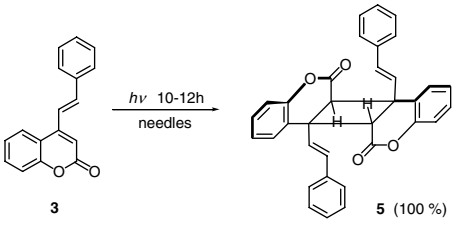
One-Component Crystals[3–5]

It is known that chlorine substitution is very effective in inducing photoreactivity in the solid state.[3,4] Recently, fluorine substitution, as well, has been proven to be useful for constructing photoreactive crystals. The effect of fluorine substitution on the crystal structure and the solid-state photochemical behavior of benzylidenepiperitone has been examined.[6] No F···F contacts are less than the sum of the van der Waals radii (2.94 Å); however, C–H···F interactions are observed in the crystal structure of **1.** The fact that the unsubstituted parent compound does not photodimerize in the crystalline state whereas the fluorine-substituted **1** does illustrates the importance of fluorine substitution.

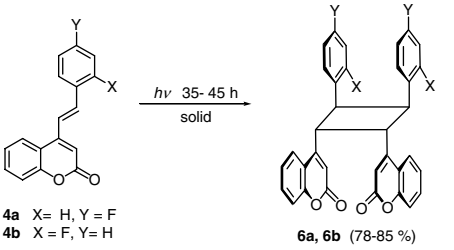


1 **2** (35 %)

The effects of fluorine substitution on crystal packing and topological photodimerization have also been investigated for styrylcoumarins.[7,8] Styrylcoumarin **3** yields the centrosymmetric (α-mode, *anti*-head-to-tail [HT]) photodimer **5** when irradiated in the solid state; however, the inclusion of a fluorine substituent dramatically alters the packing mode and steers molecules **4a** and **4b** to form stereospecific photodimers **6a** and **6b** (β-mode, *syn*-head-to-head [HH]) by reaction at the styrenic double bonds.



3 **5** (100 %)



4a X= H, Y = F
4b X = F, Y= H

6a, 6b (78-85 %)

The face-to-face stacking interaction between the phenyl and the perfluorophenyl groups is shown to be a general supramolecular synthon. The solid-state packing structure and reactivity of several monoolefins and diolefins substituted with phenyl and perfluorophenyl groups has been investigated.[9] Compounds **7** and **9** undergo photoinduced [2+2]-cycloaddition reactions in the solid state to give dimer **8** and polymer **10**, respectively. Although compound **11** is completely photostable, the co-crystal of **9** and **11** is photoreactive to give a cyclobutane-containing polymer. The stereochemistry of the photoproduct and/or x-ray structural analysis of the olefinic precursors reveals the stacked interaction between phenyl and perfluorophenyl groups in the photoactive crystals.

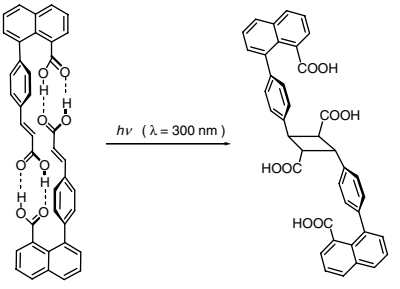
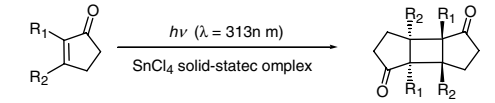
11

The strong hydrogen bonds of C=O···H–O in carboxylic acids are often used to control molecular arrangements in the solid state.[10,11] For the U-shaped diacid **12**, efficient stereo- and regiocontrolled photodimerization through preorganization enforced by C=O···H–O hydrogen bonds in the solid state has been reported.[12] Irradiation of **12** gives dimer **13** quantitatively. Thus, it is demonstrated that hydrogen bonding can be used to enforce a particular and desirable stereo- and regiochemical outcome in a solid-state transformation that otherwise might not follow this reaction course. The parallel alignment of the acid groups on a single molecule ensures that proximity between the alkene moieties of different acids can be achieved.



12 **13** (~100 %)

The relative orientation of olefins within metal complexes provides an alternative approach to induce stereoselectivity in the cycloadditions of olefins in the solid state. Irradiation of $SnCl_4$ complexes of cyclopentenones **14a–c** in the solid state leads to stereoselective photodimerization to give *anti*-HT cyclodimers **15a–c** in high yields.[13]



14a $R_1 = H$, $R_2 = H$

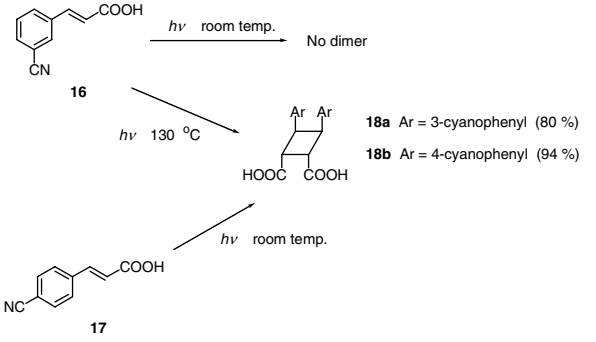
$SnCl_4$ Solid-State Complex of **14a**

The photodimerizatiom of 3-cyanocinnamic acid **16** is temperature dependent.[14] The crystals of **16** and **17** are isostructural, both being β-structures with the short axes ~4 Å. In spite of the close similarity in the crystal structures, however, only **17** undergoes a topochemical [2+2]-photodimerization at ambient temperature to give dimer **18b**. Compound **16** is found to be photostable; however, while **16** is unreactive at room temperature, it becomes photoreactive when heated at 130°C and forms dimer **18a**. The seeming difference in the topochemical [2+2]-photoreactivity of **16** and **17** is explained by differing degrees of molecular motion in the crystals.

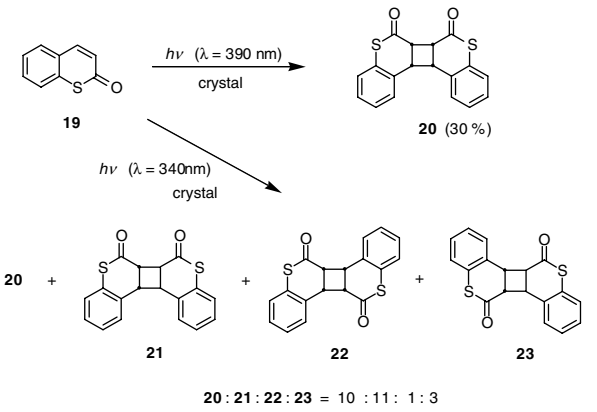


16

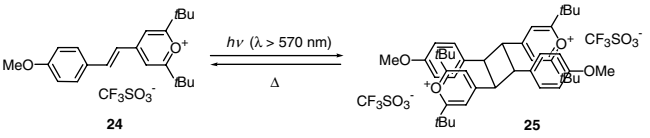
17

18a Ar = 3-cyanophenyl (80 %)
18b Ar = 4-cyanophenyl (94 %)

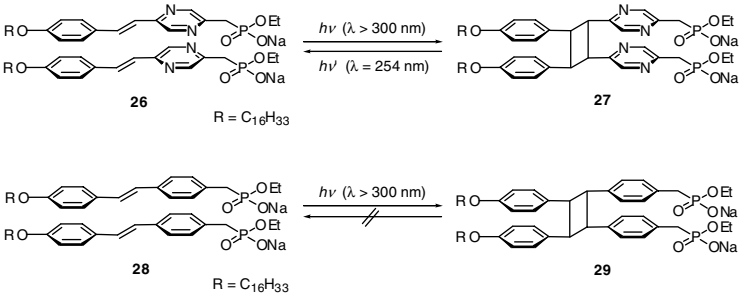
The solid-state photodimerization of 1-thiocoumarin **19**, on the other hand, is shown to be wavelength dependent.[15] Irradiation of **19** with λ > 390-nm light leads to the exclusive formation of HH *cis-syn-cis* dimer **20**, whereas irradiation with shorter wavelengths (λ > 340 nm) results in the formation of a mixture of all four *cis*-fused tricyclic dimers **20** to **23**. The selective formation of HH-*cis-cisoid-cis* dimer in the solid-state irradiation of substituted coumarins occurs quite frequently. The topochemical reactions occur within minimum atomic movements if the reactive double bonds are within the correct distance and aligned in a parallel fashion. The conversion of **19** to **20** on irradiation with λ > 390-nm light proceeds accordingly, the prealignment favoring dimer **20** to the exclusion of others. In contrast, the wavelength dependence observed during irradiation with λ > 340-nm light is most unusual. The novel wavelength effect in the solid-state photochemistry is explained by assuming that the excitation at 340 nm populates two excited states. If one of them has a much longer lifetime, this would allow exciton migration to defect sites, leading to the non-topochemical behavior.



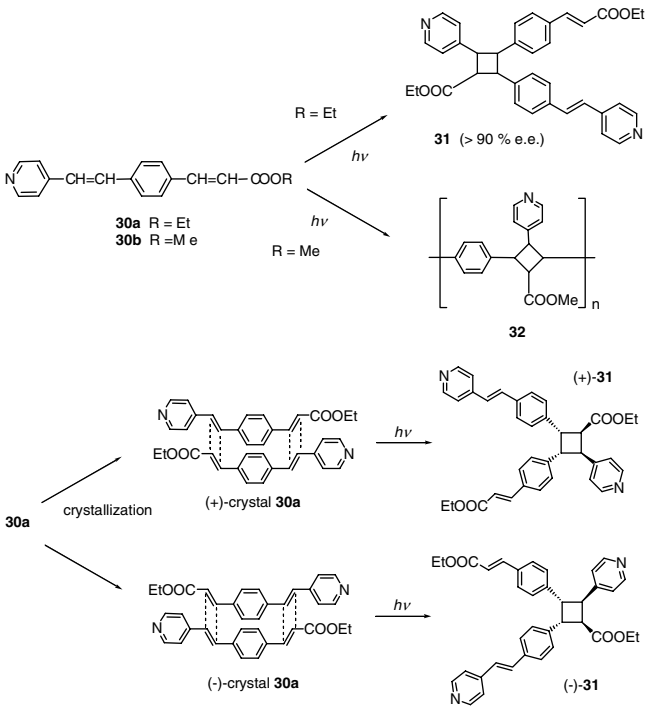
Styrylpyrilium salt **24** shows reversible [2+2]-photodimerization in the solid state when irradiated with λ > 570-nm light.[16] The system of **24** and its dimer **25** not only undergoes single-crystal-to-single-crystal photodimerization but also returns thermally to pure crystals of the monomer. With light of wavelengths around its absorption maximum (λ = 420 nm), a heterogeneous reaction is observed and the original monomer crystals break up completely on further irradiation.



Styrylpyrazine amphiphile **26** shows reversible photodimerization in aqueous dispersion.[17] Compound **26** undergoes quantitative photodimerization with λ > 300-nm light, and the reverse reaction from **27** occurs with 254-nm light. The corresponding stilbene analog **28** undergoes similar photodimerization to give **29**, but the reaction is not photochemically reversible.



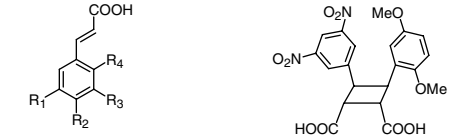
Asymmetric [2+2]-cycloadditions for one-component crystals have been reported. Ethyl ester **30a** forms chiral crystals of β-type packing. Irradiation of the single crystals of **30a** affords the optically active dimer **31** with an enantiomeric excess (EE) of >90%.[18,19] In contrast, methyl ester **30b** yields the highly crystalline polymer **32** through a typical [2+2]-topochemical photopolymerization.



The signs of optical rotations are arbitrary.

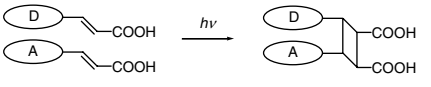
Mixed Crystals[4,5,20]

The 1:1 molecular CT complex of 3,5-dinitrocinnamic acid **33a** with 2,5-dimethoxycinnamic acid **33d** is irradiated for 5 days in the solid state to give the unsymmetrical dimer **34** in 60% yield.[21] Similarly, the 1:1 mixed crystals of **33a** and **33c** yields the corresponding truxinic acid. The complex of **33b** and **33c** and that of **33b** and **33d** are completely photostable.

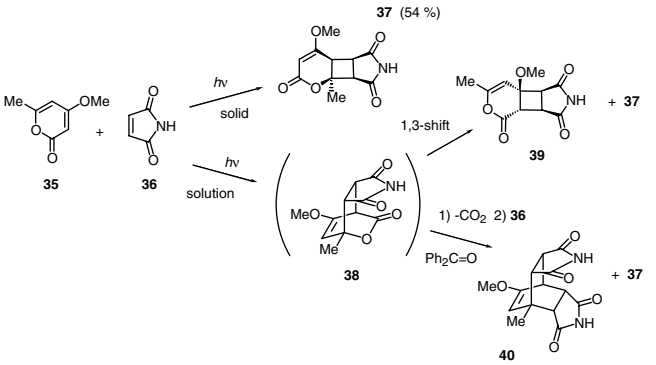


33a $R_1 = R_3 = NO_2$, $R_2 = R_4 = H$
33b $R_2 = R_4 = NO_2$, $R_1 = R_3 = H$
33c $R_2 = R_3 = OMe$, $R_1 = R_4 = H$
33d $R_1 = R_4 = OMe$, $R_2 = R_3 = H$

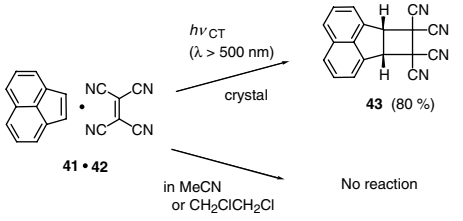
34



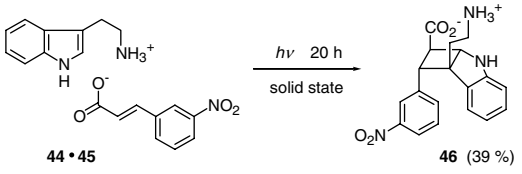
Irradiation of the 1:1 complex crystals of 4-methoxy-6-methyl-2-pyrone **35** and maleimide **36** gives **37** in 54% yield as a sole product, which is entirely different from the solution products **39** and **40**.[22] The peri-, site-, and stereospecific photoreaction in the solid state is considered to be brought about by two sets of the hydrogen bonding and CT stacking between **35** and **36** in the complex.



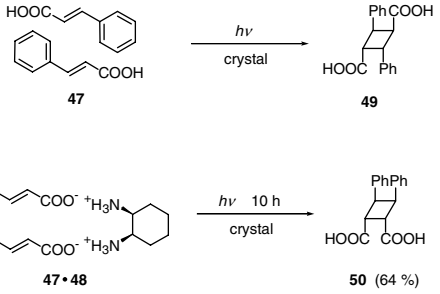
Selective excitation of the CT complex between acenaphthylene **41** and tetracyanoethylene **42** in the crystalline state exclusively affords the 1:1 [2+2]-cycloadduct **43**, in contrast to the excitation in solution.[23,24] On irradiation of the complex of **41** and **42** with light of wavelength $\lambda > 500$ nm, where neither **41** nor **42** is excited, **43** is obtained in 80% yield. Irradiation of an equimolar mixture of **41** and **42** in solution with $\lambda > 500$ nm light induces no reaction.



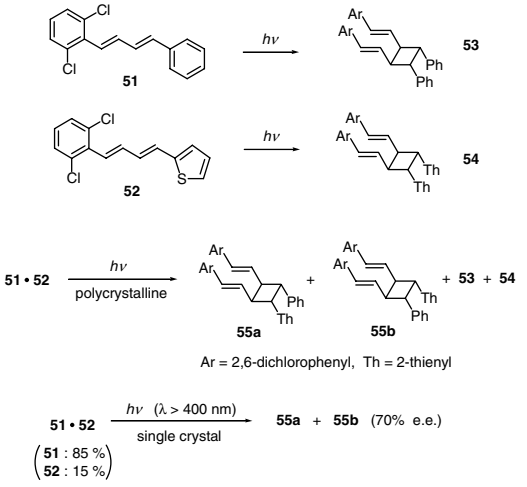
A crystalline salt of tryptamine **44** and *trans*-3-nitrocinnamic acid **45** undergoes cross photocycloaddition to give **46** in 39% yield.[25] In contrast, irradiation of the solid mixture of **44** and **45** fails to give the product.



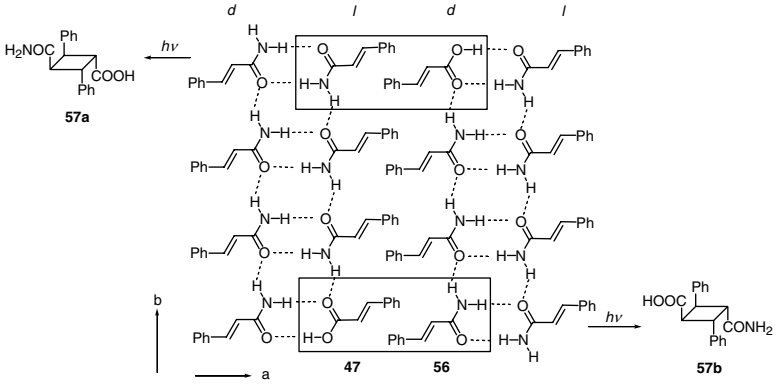
Photodimerization of *trans*-cinnamic acid **47** is controlled by the formation of a double salt with diamines.[26,27] It is known that **47** gives α-truxillic acid **49** efficiently on irradiation. The double salt crystals of **47** and *cis*-1,2-cyclohexanediamine **48**, on the other hand, yield β-truxinic acid **50** predominantly.



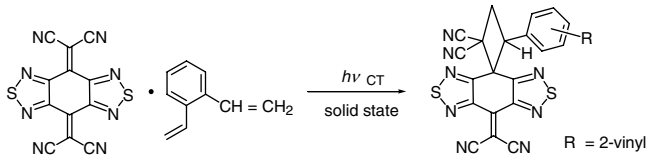
One of the earliest examples for the formation of an optically active heterophotodimer from mixed crystals of achiral molecules is the photoreaction of the single crystals of *trans, trans*-1-(2,6-dichlorophenyl)-4-phenyl-1,3-butadiene **51**, and its thiophene analog **52**.[28,29] Irradiation of crystalline samples of **51** or of **52** yield achiral cyclobutane dimers **53** and **54**, respectively. When a (polycrystalline) sample of mixed crystals of **51** and **52** is irradiated, the reaction affords the enantiomeric heterodimers **55a** and **55b** in addition to the homodimers **53** and **54**. The formation of **53** and **54** can be minimized by using small amounts of the thiophene monomer **52**, which absorbs at slightly longer wavelengths than does the phenyl monomer **51** and by irradiating through appropriate cutoff filters so that only **52** absorbs light. The dilution of **52** in a large excess of **51** minimizes the formation of **54**, and the lack of excitation of **51** prevents the formation of **53**. With the use of a 400-nm cutoff filter, irradiation of large, single, mixed crystals containing 15% **52** and 85% **51** leads to high yields of the optically active heterodimers. The optical yield of the reaction is reported to be ~70%.[29]



Absolute asymmetric synthesis has been performed by controlled reduction in crystal symmetry.[30] The principle is based on selective induction of a guest molecule into a centrosymmetric host structure, thus reducing the symmetry of the mixed crystals. Crystallization of the *trans*-cinnamamide host **56** in the presence of the *trans*-cinnamic acid guest **47** results in the formation of mixed crystals composed of two enantiomorphous halves each containing 0.5 to 1.0% of the acid. Irradiation of each half separately yields the optically active dimers **57a** and **57b** in excess with an enantiomeric yield in the range of 40 to 60%. This varies from one single crystal to another.



Charge transfer excitation of the solid-state molecular complex of **58** with *o*-divinylbenzene **59** yields [2+2]-cycloadducts **60** via single-crystal-to-single-crystal transformation.[31] The apparent reactivity of the complex crystals is much higher than that in solution. Due to the asymmetric structure of the complex crystals of **58** and **59**, the optically active product (71% EE at 15°C and 95% EE at –70°C) is obtained from the achiral components without any external chiral source.



58 **59** **60**

Inclusion (Host–Guest) Crystals[5,32–35]

The [2+2]-cycloaddition reactions in inclusion crystals, or host–guest crystals, have been thoroughly reviewed.[5] Coumarin **61a**, thiocoumarin **61b**, and cyclohex-2-enone **62** efficiently undergo single-crystal-to-single-crystal enantioselective photodimerization in inclusion complexes with chiral host compounds (R,R)-(–)-*trans* **63a**, (R,R)-(–)-*trans* **63b**, and (–)-**64**, respectively.[36] The products are (–)-*anti*-HH **65a** (100% EE), (+)-*anti*-HH **65b** (100% EE), and (–)-*syn-trans* **66** (48% EE) dimers. An example for enantioselective intramolecular [2+2]-photocycloadditions in inclusion crystals is the reaction of guest **67** in chiral host **68**.[37] Irradiation of the powdered inclusion crystals in water suspension affords the optically active photocyclization product **69** with 100% EE in 90% yield.

73.3 Inclusion Complexes in the Solid State

Host compounds such as cyclodextrins (CDs) and zeolites have attracted considerable attention recently because they are expected to be useful as artificial reaction cavities to control photoreactions in the solid state. In spite of many examples of the photoreactions in these media being identified, however, much chemistry still remains to be done.

Cyclodextrin Hosts[35,38]

The [2+2]-photodimerizations of coumarin and its derivatives proceed selectively in solid inclusion complexes with CDs.[39] The yield and distribution of the photodimers are very different from those in the neat coumarin solids. For the 4,7-dimethyl (**70a**) and the 4,6-dimethyl (**70b**) derivatives, for example, photodimers are obtained by irradiation of the CD complexes as shown in Table 73.1, whereas no dimer is formed from neat solid coumarins. Depending on the substitution pattern of the coumarin molecules and the type of CD employed, complexes whose host/guest ratios are 1:1, 1:2, and 2:2 are identified. The stereochemistry of the dimers depends on the cavity size of the CD and the relative orientations of coumarins within a complex. The photodimerization of acenaphthylene **41** is accelerated by the formation of 1:2 inclusion compound between γ-CD and **41** to give *cis* (**71a**) and *trans* (**71b**) dimers (*cis* : *trans* = 99:1).[40] In contrast, the dimerization is inhibited by β-CD due to the formation of 1:1 inclusion complex.

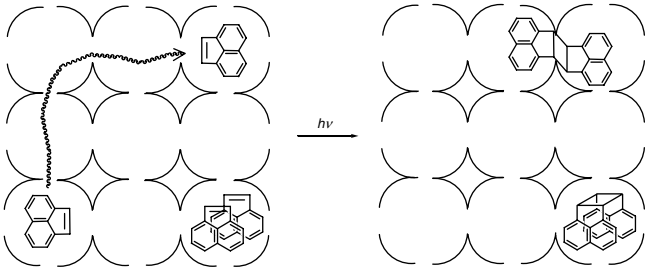
CsX	0.50	CsY	0.79 ± 0.02		

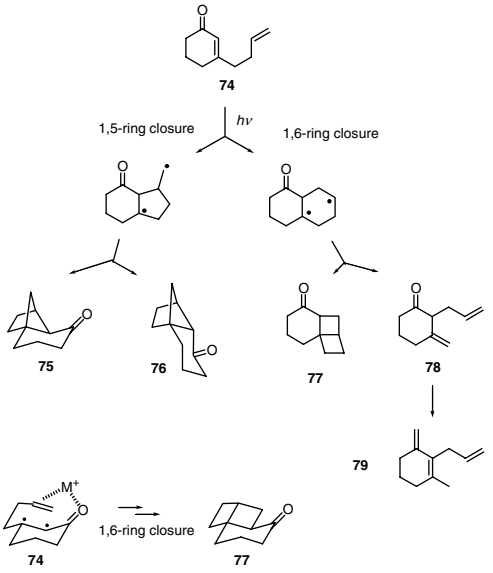
Zeolites[41–43]

One of the most well-known examples of controlled photoreactions in zeolites may be the cation-controlled photodimerization of acenaphthylene **41** in faujasites reported by Ramamurthy and co-workers.[44,45] Irradiation of **41** in organic solvents yields both *cis* (**71a**) and *trans* (**71b**) dimers. It is believed that the singlet excited state gives predominantly the *cis* dimer, whereas the triplet excited state gives the *cis* and *trans* dimers in comparable amounts. Irradiation of dry solid inclusion complexes of **41** in various cation (Li, Na, K, Rb, Cs, and Tl) exchanged Y zeolites gives the *cis* and *trans* dimers. The ratio of *cis* to *trans* dimer depends on the types of cation present in the zeolite supercage (and the number of guest molecules per supercage). In the case of lower atomic weight cations such as Li and Na, the dimerization occurs via the singlet excited state resulting in the preferential formation of the *cis* dimer. For higher atomic weight cations, on the other hand, the reaction occurs via the triplet state, which is in agreement with the formation of the *trans* and *cis* dimers in the cages of K, Rb, and CsY. In the dry RbY zeolite solid, the major part of the dimer is rationalized to come from the reaction between acenaphthylene molecules in different cages.[45] On irradiation of **41** in the zeolite (RbY)–solvent (hexane) slurry, on the other hand, the dimerization is expected to occur preferentially from doubly occupied cages, leading to a higher yield of the *cis* dimer with respect to that in dry RbY.



The effects of zeolites on photodimerization of cyclopentenone **14a** and cyclohexenone have been investigated (Table 73.2).[46] Little control over the regiochemistry of such reactions is attainable when they are carried out in isotropic solvents. A relatively high degree of regioselectivity in the dimerization can be achieved in zeolites due to cavity-size effects in the supercages of X- and Y-type faujasites as well as the complexing ability of the cation within the zeolite with included guests. An increase in the formation of the HH (**73**) relative to the HT (**72**) dimer occurs in both X- and Y-type faujasites, as the size of the cation increases and the available space in the zeolite cavity decreases.

Intramolecular [2+2]-photocycloaddition of enone **74** is affected by zeolites.[47,48] On irradiation of **74** adsorbed in cation-exchanged X and Y zeolites, the products from closure of the 1,6-biradical, **77** to **79**, are more efficiently formed when compared to the results in solution. The regio- and stereochemical outcomes of the photocycloadditions in zeolites are interpreted by the binding of the guest molecules with the cations in the zeolite supercages. It is possible that the carbonyl group and the olefinic bond of the guest molecules electronically interact with the cation within the cages, resulting in a configuration favoring the formation of **77** to **79**.



73.4 Industrial Applicability[49]

The most industrial applications of solid-state [2+2]-photocycloadditions are in the field of polymer layers via crosslinking (photoresists) or by photopolymerization of doubly unsaturated crystalline alkenes. One of the recent examples for such a polymerization is the photoreaction of cyano-substituted diphenylhexatriene **80** in the solid state.[50] Compound **80** undergoes intermolecular photocycloaddition at the 1,2-positions of the trienes to give oligomers **82** in addition to the *syn*-HH dimer **81**.

The photochemical reversible reaction ([2+2]-photocycloaddition and the reverse reaction) of oriented chromophores in aggregates with alternate irradiation at two independent wavelengths has attracted much attention due to the potential application to photomemory, to on–off photoswitching systems, and to its availability in controlling the release of entrapped reagents in vesicles.[16,17] If the reacting monomers are colored their photochromism may be used technically in various ways.

Photochemical valence isomerization between norbornadiene **83** and quadricyclane **84**, which includes [2+2]-cycloaddition, has long been of interest because of its potential use in solar energy conversion and storage. Photoenergy can be stored as strain energy (~20 kcal/mol) in a molecule of **84**; however, the problem is that the photoreaction of **83** does not ordinarily occur on irradiation with sunlight due to

inefficient absorption of visible light by the compound. To extend the absorption to longer wavelengths, suitable chromophores are often introduced into **83**. It has recently been reported, for example, that trifluoromethyl-substituted derivatives **85a–c** not only absorb visible light efficiently but also produce stable derivatives of **84**.[51] The key to this behavior may lie in the CT character of **85a–c**. Solar energy storage has been realized in several cases; however, no large-scale applications have yet been reported.

Photochemistry of Homoquinones

Ken Kokubo
Osaka University

Takumi Oshima
Osaka University

74.1 Introduction

Homoquinone is a compound that is formally constructed by the fusion of a cyclopropane ring to the electron-deficient CC double bond of a quinone. The methylene homologation certainly exerts significant electronic and structural effects on the highly conjugated planar quinone. The two carbonyl groups are slightly warped toward opposite sides of the fused cyclopropane ring.[1] Such modification results in a considerable hypsochromic (or blue) shift of the longest wavelength absorption compared to the parent quinone (Figure 74.1).[2]

Due to the conjunction of a functional quinone and the cyclopropane ring, homoquinones attract much attention from the synthetic, mechanistic, and theoretical points of view; however, only a few scattered studies have addressed the photochemical and thermal reactions of these quinone derivatives mainly because of somewhat restricted synthetic methods (*vide infra*). Therefore, the photochemical behavior of these fascinating compounds has been studied to gain further insight into quinone photochemistry.[3]

In this chapter, we focus on the photoreactions of homoquinones. First, the [2+2]-photoaddition of the enedione linkage with alkenes and alkynes is described in order to elucidate the factors controlling the regio- and stereochemistry of the photoadducts. The next topic is the photoinduced hydrogen abstraction of the carbonyl function and/or the cleavage of the incorporated cyclopropane ring. Finally, the photoinduced electron transfer (PET) reactions with typical donor components such as amines and arene derivatives are discussed. This is of importance because the attachment of two carbonyl groups on the central π-bond bestows greater ability to accept electrons on these species as compared with the α,β-unsaturated ketones.

74.2 Synthesis of Homoquinones

The classical synthetic method for homoquinones is based on the 1,3-dipolar cycloaddition of diazoalkanes to 1,4-quinones.[4] This reaction consists of the addition of diazoalkanes to the quinonoid CC double

0-8493-1348-1/04/$0.00+$1.50

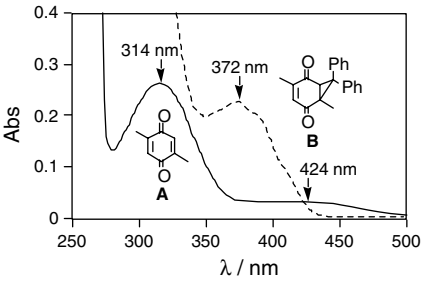

FIGURE 74.1 Absorption spectra of 2,5-dimethyl-1,4-benzoquinone **A** (solid line) and the corresponding diphenylhomoquinone **B** (dotted line) in acetonitrile (1 mM).

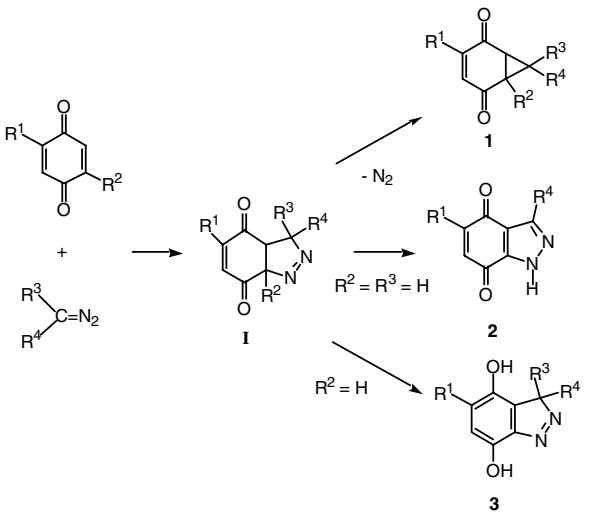
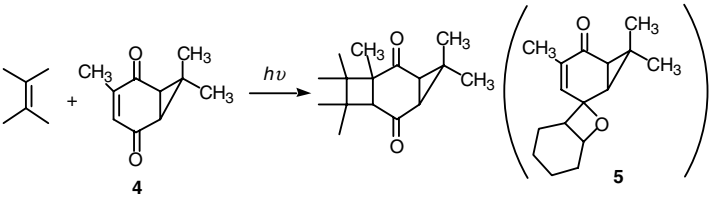


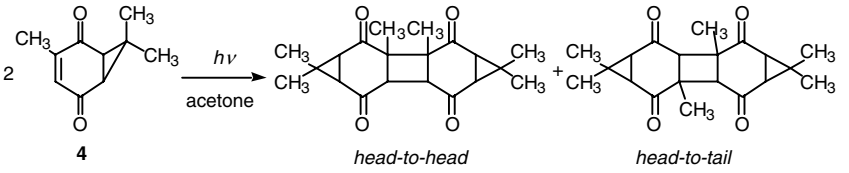
SCHEME 1

bond to give primarily the pyrazolines **I** (Scheme 1). Depending on the substitution pattern of the quinone and the diazoalkane used, the pyrazolines can undergo several transformations, such as loss of nitrogen, isomerization of the azo-containing ring, and *bis*-enolization of the fused quinone function. Homoquinones **1** are usually formed by loss of nitrogen from the pyrazolines when secondary diazoalkanes, bearing no mobile hydrogen on the diazo-carbon atom, are added to the substituted quinonoid ethylene linkage.[5] Otherwise, the pyrazolines derived from diazoalkanes, such as diazomethane, are transformed into pyrazoles **2** *via* isomerization as well as oxidation in preference to the nitrogen release.[6] Moreover, the pyrazolines from such quinones as 1,4-benzoquinone and 1,4-naphthoquinone tend to preferentially suffer the *bis*-enolization to 3*H*-indazole **3**.[5a,7] Another limitation of this method is deactivation of the quinonoid CC double bond by the steric or the electronic factors of the substituents as well as the bulk of the diazoalkanes. These factors change the site of reaction to the less hindered quinonoid CO double bond to afford oxiranes or poly(hydroquinone benzhydryl ether)s as found in the reactions of diazomethane with chloranil[8] and of diphenyldiazomethane with 2,3-dichloro-5,6-dicyanobenzoquinone (DDQ).[9]

Homoquinones are also prepared by a variety of methods that involve the free-radical reactions of propellanes with benzoquinones,[10] the Michael addition of sulfoxonium methylide[11] and ethyl cyanoacetate anion[12] to naphthoquinone and of sulfonium methylides to benzoquinones,[13] the photooxygenation of norcaradienes,[14] the reaction of diethoxyphthalans with quinones,[15] and the Diels–Alder reactions of siloxy- and alkoxy-substituted furans with cyclopropenes.[16]



SCHEME 2



SCHEME 3

74.3 [2+2]-Photocycloaddition Reaction

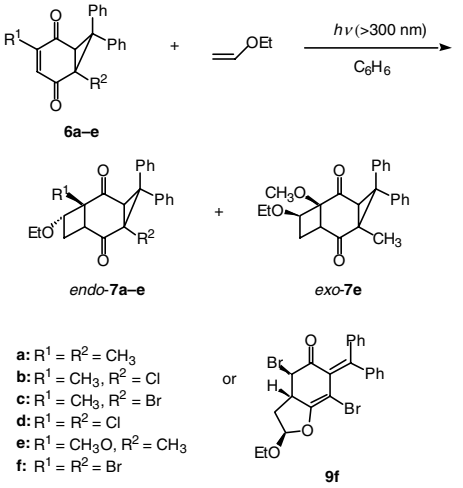
Intermolecular Reaction

Some homoquinones are known to have a biological activity[17] and are exemplified by the terpenoid Eucarvone[18] and 3-carene-2,5-dione[19] which were isolated from natural resources.[20] In 1968, Still et al.[21] reported the first [2+2]-photocycloaddition of the homoquinone, 3-carene-2,5-dione **4**, with various alkenes and alkynes. They obtained the cyclobutane (and cyclobutene) adducts exclusively in moderate to excellent yields. Low yields of the spirooxetane **5** were obtained with cyclohexene resulting from addition to the carbonyl group (Scheme 2).[21] However, the regio- and stereochemical assignment was not established in great detail, and some products were obtained as a mixture of stereoisomers. Furthermore, using acetone as a photosensitizer, the [2+2]-photodimerization of **4** could be brought about to yield two major stereoisomers of the *head-to-head* (HH) adduct and one minor isomer of *head-to-tail* (HT) orientation (Scheme 3).[22]

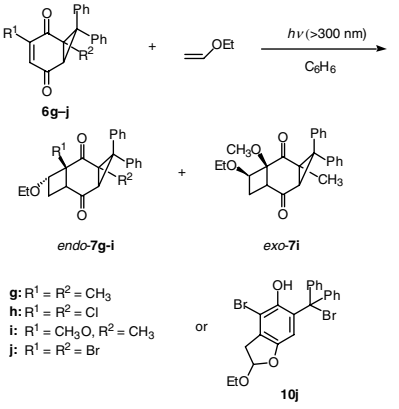
About 30 years later, the Kokubo et al.[23] conducted the [2+2]-photocycloadditions of variously *p*-substituted (R,[1] R[2]) diphenylhomoquinones **6a–f** with various alkenes or alkynes. Detailed assignment of the structures for all the regio- and stereoisomers obtained allowed detailed considerations of the stereochemical features of the photoadditions. Irradiation of the homoquinones **6a–e** with ethyl vinyl ether proceeded regio- and stereoselectively to give the *endo*-**7a–e** in preference to the *exo*-isomer **7e** in good total yields (Scheme 4).[23a]

In case of *p*-dibromo-substituted **6f**, the dihydro-*o*-benzoquinone monomethide **9f**, involving ring opening of the cyclopropane moiety, was only obtained as a secondary product by way of a subsequent acid-catalyzed skeletal rearrangement. (Initially, formed (but not detected) **7f** gave **9f** during the irradiation time; the acid-catalyzed rearrangement was confirmed by the independent experiment of the conversion of **7c** to **9c**). Similar products were formed on irradiation of *m*-substituted homoquinones **6g–i** which gave, preferentially, the *endo*-**7g–i** analogous to the reaction of *p*-substituted **6a–e**, although the primary adduct from **6j** underwent the skeletal transformation to **10j** (Scheme 5).

The regiochemistry of the [2+2]-additions of *p*- and *m*-substituted **6** was only affected by the substituents at the CC double bond of homobenzoquinones and not by the cyclopropane substituents, although the *endo* selectivity was appreciably reduced by the methoxy substituent. As a result, it is concluded that the spin density and the steric nature of the excited triplet state as well as the relative stability of the HH 1,4-biradical play a crucial role in the stereochemical course of these reactions.



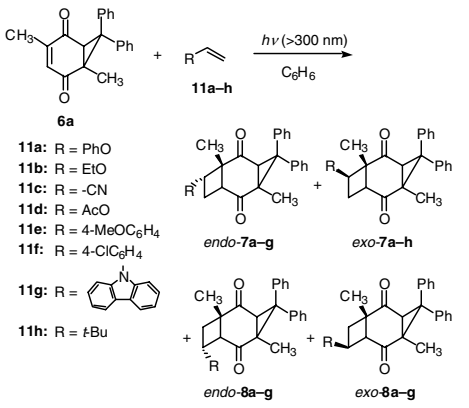
SCHEME 4



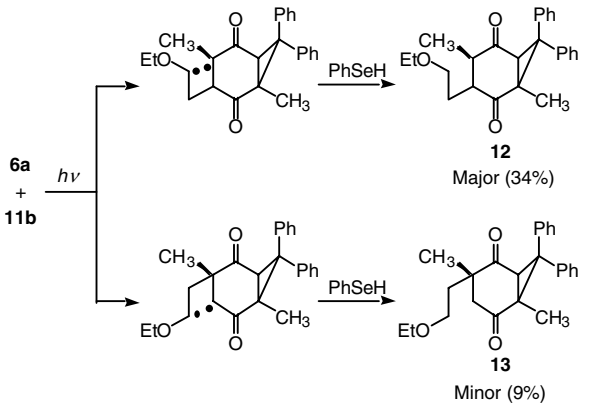
SCHEME 5

In the next study, further details of these [2+2]-photoreactions were investigated for *p*-dimethyl-substituted **6a** as a common substrate with various alkenes **11a–h** in order to explore the factors that control the regiochemistry and the *exo*/*endo*-selectivity (Scheme 6).[23b] The relative configuration of all the tricyclic-ring skeletons was identified as *cis-transoid-cis*, showing the exclusive *anti* approach of the alkenes with respect to the cyclopropane ring of homoquinone **6a**. This is probably the result of steric hindrance of the *endo* phenyl group. The sum of the yields of *endo*- and *exo*-**7** exceeded that of the regioisomeric *endo*- and *exo*-**8**. It is also noted that the major HH addition mode preferentially provides *endo*-**7** for the alkenes **11a–d** with smaller substituents but *exo*-**7** for alkenes **11e–h** with aromatic and/or bulky substituents. Similar substituent effects on the *exo*/*endo* selectivity were also observed for the minor HT addition mode giving **8**, although the effects were not so appreciable. The preferred regiochemistry was rationalized in terms of the more stable 1,4-biradical intermediates as described above. In fact, a trapping experiment using PhSeH in the reaction of **6a** with ethyl vinyl ether **11b** proved the involvement of the two regioisomeric triplet 1,4-biradical intermediates as indicated by the isolation of **12** (34%) and **13** (9%) (Scheme 7).

The observed reversal of *exo*/*endo* selectivity on changing alkene substituents was interpreted as follows. According to Griesbeck's concept proposed for the Paternò–Büchi reaction, it is necessary to orient the



SCHEME 6

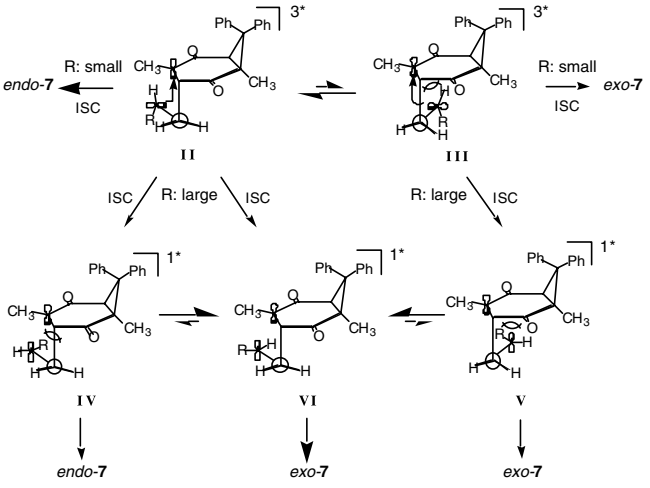


SCHEME 7

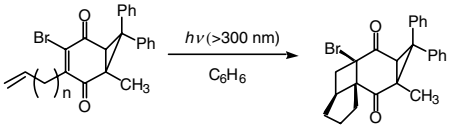
two singly occupied orbitals of the triplet 1,4-biradicals perpendicular to each other in order to maximize spin-orbit coupling (SOC), as represented for the conformers **II** and **III** responsible for the major HH addition (Scheme 8). Thus, in the case of the smaller substituent R, the fast cyclization in the spin-inverted singlet 1,4-biradical affords *endo* adducts preferentially. The stereochemical *exo*/*endo* reversal for the bulky **11e–h** can be rationalized by the occurrence of some CC bond rotation around the substituted radical chain of the singlet 1,4-biradical prior to the ring-closure. As a result of the increased population of the sterically less hindered conformer **VI**, the larger substituent R prefers the formation of the *exo* adducts.

Intramolecular Reaction

Intramolecular photocycloaddition of alkenes to α,β-conjugated enones was first reported by Ciamician and Silber.[24] Since then, the reaction has received much attention in view of its utility for the synthesis of polycyclic systems incorporating a cyclobutane ring.[25] The intramolecular [2+2]-photocycloaddition has been examined for homobenzoquinones bearing alkenyl side chains. Although 3-butenyl-substituted homobenzoquinone **6k** (n = 2) was quantitatively recovered even when irradiated for 1 hr, chain-elongated 4-pentenyl-substituted **6l** (n = 3) successfully achieved an intramolecular reaction to give tetracyclic dione **14l** in good yield, obeying the "rule of five" (Scheme 9).[26] This compound has a unique tetracyclic dione structure containing three-, four-, five-, and six-membered rings. All the rings are *cis*-fused, and the three- and four-membered rings adopt the *anti* structure.



SCHEME 8



SCHEME 9

74.4 Hydrogen Abstraction Reaction

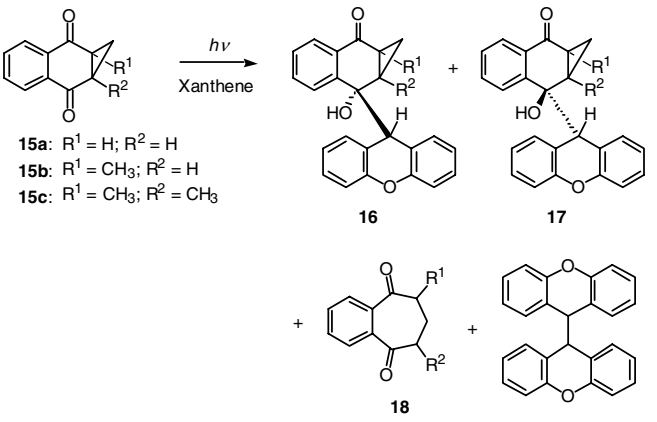
Intermolecular Reaction

The photoinduced inter- and intramolecular hydrogen abstraction is a matter of interest in the field of ketone photochemistry from both synthetic and mechanistic points of view.[27] In general, the radical species generated by hydrogen abstraction lead to recombination, rearrangement, or disproportionation. Thus, the hydrogen abstraction of homoquinones is of interest in regard to the site selectivity of carbonyl functions as well as possible cleavage of the cyclopropane ring.

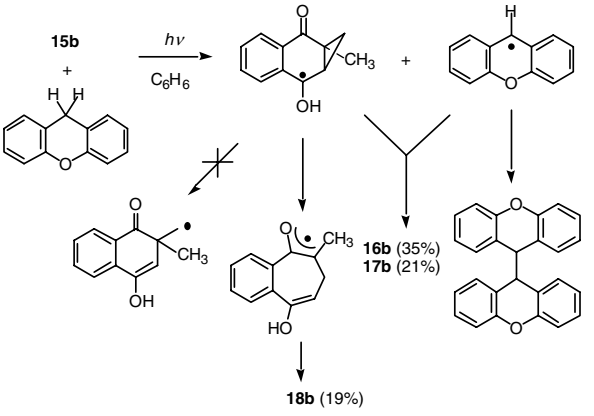
Maruyama and Tanioka[28] found that the photoreaction of homonaphthoquinones **15**, in the presence of xanthene as a hydrogen donor, gave the stereoisomeric 1:1 adducts (**16** and **17**) and ring-expanded cycloheptadione **18** together with 9,9′-bixanthenyl (Scheme 10).

The exclusive addition of the xanthene moiety to the sterically less hindered carbonyl group was observed in **15b**, in accordance with the lower reactivity of dimethyl-substituted **15c**. The CIDNP experiment revealed that **16** and **17** are recombination products via an initially formed triplet radical pair. The proposed mechanism is shown in Scheme 11. The hydrogen abstraction of the excited triplet state of **15** from xanthene generates ketyl and xanthenyl radicals. A possible product derived from outer cyclopropane bond cleavage was not obtained because of the lower stability of a primary radical compared with the conjugated radical formed by inner cyclopropane bond cleavage.

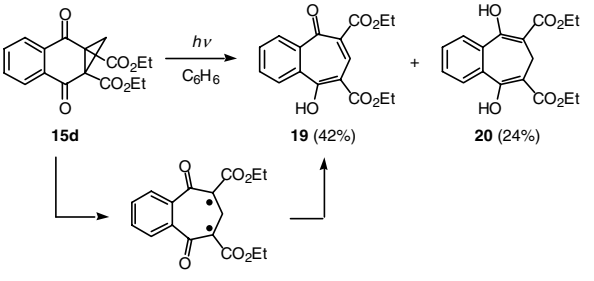
In contrast, irradiation of diethoxycarbonyl-substituted **15d** afforded the cyclopropane bond-cleaved **19** and **20** even in the absence of xanthene (Scheme 12). The photoisomerized **19** may be formed through subsequent 1,4-hydrogen atom migration. The presence of xanthene resulted in a higher yield (45%) of **20** but no appreciable change in the yield of **19**. The results indicate that compound **20** is a reduction



SCHEME 10



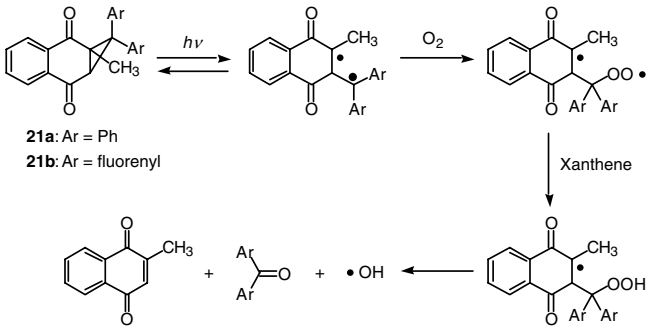
SCHEME 11



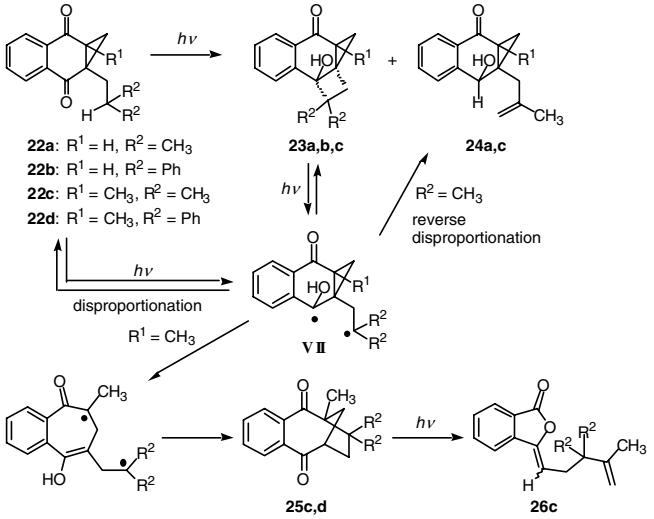
SCHEME 12

product arising from the intermolecular hydrogen abstraction by the photoexcited **15d** from another molecule of **15d** or xanthene. The preferred rupture of the inner bond of **15d** is probably due to the spin delocalization over the ethoxycarbonyl functions within the 1,3-biradical.

Contrary to the reaction of **15a–d**, diaryl-substituted **21a** and **21b** showed no reaction in the presence of xanthene even under completely deaerated conditions; however, oxygen introduction brought about a drastic change in the photochemical behavior to give 2-methylnaphthoquinone and the corresponding



SCHEME 13



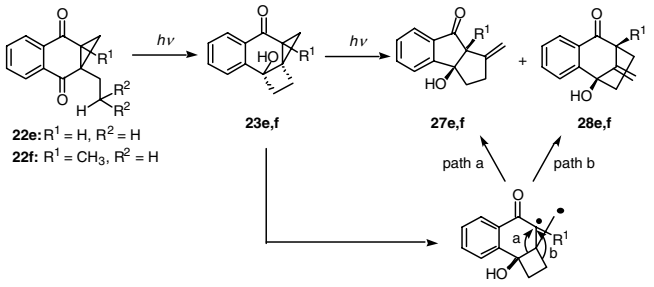
SCHEME 14

diaryl ketones together with 9,9′-bixanthenyl (Scheme 13). The mechanism involving a carbene intermediate was ruled out because the absence of xanthene afforded no photoproduct and the reaction in benzene/methanol solution gave no methanol adduct attributable to carbene insertion. As a result, the diaryl-substituted biradicals can add an oxygen molecule but cannot abstract a hydrogen atom from xanthene.

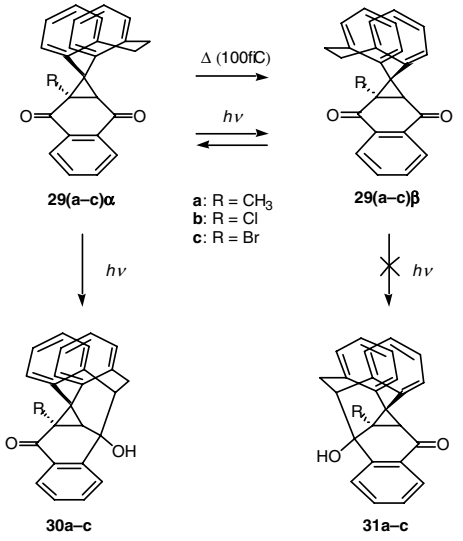
Intramolecular Reaction

The intramolecular photoinduced hydrogen abstraction of carbonyl compounds, known as the Norrish type II reaction, is one of the most important primary photochemical processes, usually giving the corresponding cyclic alcohols via hydrogen abstraction of the excited triplet carbonyl oxygen followed by radical recombination.

Osuka et al.[29] described the type II photoreaction of various homonaphthoquinones **22a–d** with abstractable γ-hydrogens. The photochemical behavior of these substrates is very dependent on the cyclopropane substituents (R^1 and R^2). Irradiation of **22a** (R^1 = H, R^2 = CH_3) gave the usual cyclobutanol **23a** along with the unsubstituted alcohol **24a** (Scheme 14). The compound **24** may be derived by hydrogen transfer from a δ-carbon to the less reactive ketyl radical center of the primary biradical **VII**. It was confirmed that a photoequilibrium takes place between **22** and **23** via **VII** as a common intermediate.



SCHEME 15



SCHEME 16

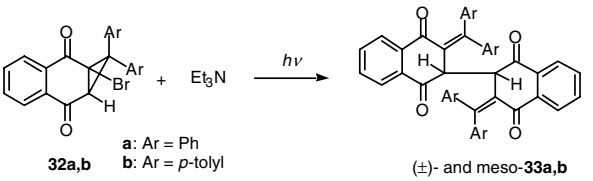
This allows slow leakage to **24** via a very rare reverse disproportionation. Replacement of the CH_3 on R^2 by Ph also attained photoequilibration, as indicated by the constant ratio of **22b** to cyclobutanol **23b** on extended irradiation.

In contrast, irradiation of **22c** ($R^1 = CH_3$, $R^2 = CH_3$) produced bicyclic diketone **25c** and alkylidene phthalide **26c** together with cyclobutanol **23c** and the unsaturated alcohol **24c**. Compound **26** is the result of secondary photoisomerization of **25**. The formation of **25** can be explained by a cyclopropylcarbinyl rearrangement of ketyl radical **VII** followed by 1,5-biradical-recombination. Such an inner cyclopropane bond fission may be favored by the better stabilization by R^1 (= CH_3) of the new radical center. As found in **22d**, replacement of $R^2 = CH_3$ by a Ph group simplified the reaction outcome to provide only **25**.

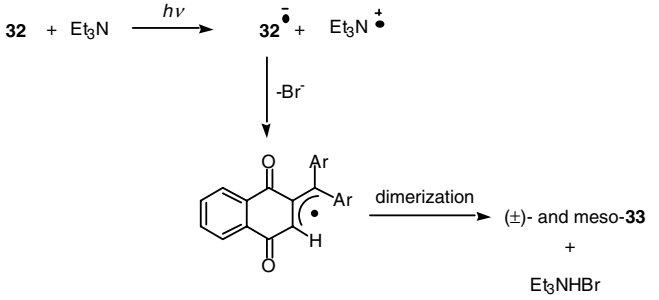
Interestingly, in the case of R^2 = H, further irradiation of the cyclobutanol products **23e** and **23f** led to β,γ-unsaturated bicyclic ketones **27** and **28** via cleavage of an outer cyclopropane ring bond followed by a dual 1,2-alkyl migration (Scheme 15).

The conformationally restricted 1,7-hydrogen abstraction was observed for homonaphthoquinones **29a–c** with a spiro-linked dibenzocycloheptene[30] (Scheme 16). This homoquinones have two isolable conformational isomers **29α** and **29β** at room temperature, and when heated the less stable **29α** isomerizes almost completely to 29**β** via a conformational inversion of the twist-boat cycloheptene ring.

The irradiation of the less stable isomer **29α** brought about a conformationally specific 1,7-hydrogen abstraction to give the tetracyclic alcohol **30**; the stable **29β** did not lead to the corresponding **31** but did



SCHEME 17



SCHEME 18

yield identical **30** via a reversible photoisomerization between **29α** and **29β**. Thus, the hydrogen abstraction in this system requires proper spatial orientation of the relevant hydrogen atom toward the excited carbonyl oxygen as proposed by Scheffer et al.[31]

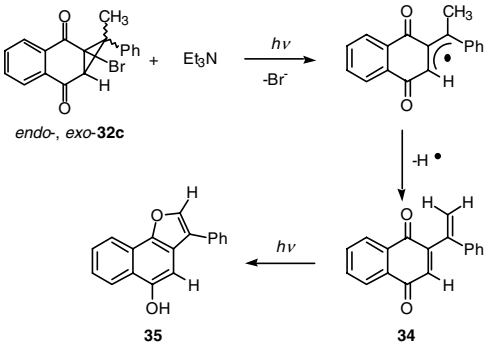
74.5 Photoinduced Electron Transfer Reaction

Intermolecular Reaction

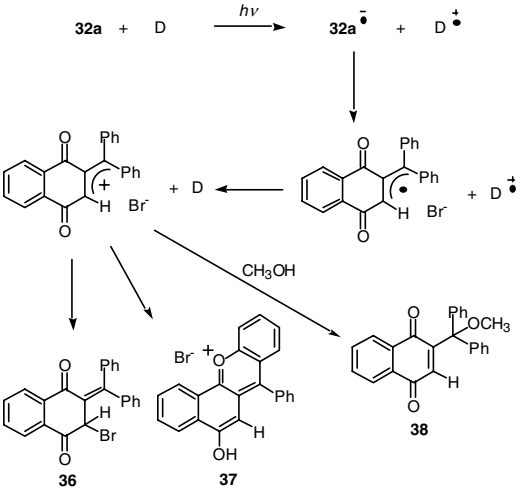
Because of the fusion of the quinone function, homoquinone is expected still to be capable of behaving as an electron acceptor; however, the electron-accepting capabilities of homoquinone are considerably reduced as compared with the parent quinone. The photoirradiation of bromo-substituted diarylhomonaphthoquinones **32a,b** in the presence of triethylamine (Et_3N) in acetonitrile gave dimeric products **33a,b** as a mixture of (±)- and *meso*-isomers (1:1) (Scheme 17);[32] the reaction did not occur when the labile bromine was substituted by chlorine or methyl groups.

The fluorescence of compound **32** was quenched by Et_3N. Stern–Volmer plots of the fluorescence quenching in acetonitrile were linear with amine concentration, suggesting electron transfer to the excited singlet state of **32**. The value of the quenching rate constant k_q obtained was 2.90×10^9 dm^3/mol/s. The free-energy changes (ΔG), calculated according to the Rehm–Weller equation for the system of **32a** and various amines used, are all negative.[33] This means electron transfer from amines to excited **32a** should be spontaneous. No new emission attributable to exciplex fluorescence was observed in the quenching experiments. No essential differences in the absorption spectra were found in a mixture of **32** and amines at various concentrations. From these results, it is proposed that the photoreaction proceeds through the mechanism outlined in Scheme 18.

The first step is photoexcitation of **32** followed by a single electron transfer (SET) from the amine to the excited **32**. The generated radical anion then undergoes ring opening with loss of bromide to generate the allyl radical. In contrast, the possible radical anions with poor or less labile chloro or methyl substituents would undergo back-electron transfer to the amine radical cation. The allyl radical collapses to give the dimer **33**. The hydrogen bromide salt of the Et_3N was quantitatively obtained as a byproduct.



SCHEME 19



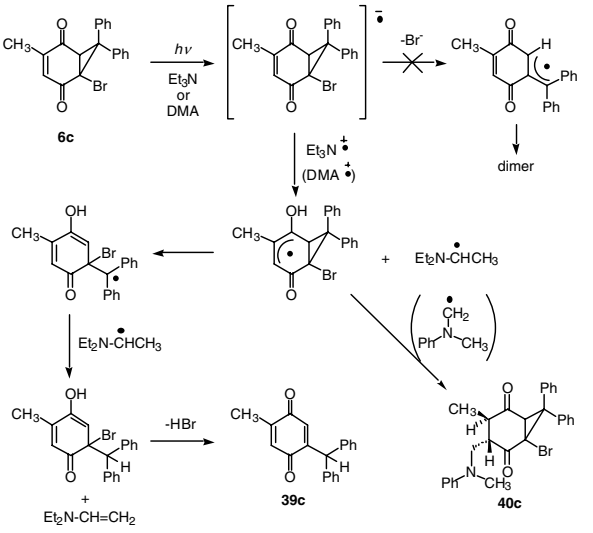
SCHEME 20

A similar irradiation of methylphenylhomonaphthoquinone (*endo*- and *exo*-**32c**) afforded the naphthofuran derivative **35** instead of the expected dimer (Scheme 19). It was reported that the direct irradiation of the analogous 2-(α-phenylvinyl)-1,4-benzoquinone **34** resulted in the quantitative formation of the corresponding benzofuran derivative.[34]

On the other hand, irradiation of **32a** with an equimolar amount of arene donors, such as naphthalene, dimethoxybenzene, or triphenylamine, afforded 2-bromo-3-diphenylmethylene-2,3-dihydronaphthoquinone **36** and xanthylium salt **37** instead of the corresponding dimer (Scheme 20).

The photoreaction in methanol gave the methanol adduct **38** along with **37**. The path involving back-electron transfer from the allyl radical intermediate to the radical cation of the arene donor rationalized the major change in product distribution. For the amine donors, proton abstraction by a second molecule of amine occurred exclusively rather than the back-electron transfer, and the formed radical collapsed to the dimer. It is of interest that the similar photoreaction of **32a** in the presence of xanthene as the donor gave both the dimer **33** and the ring-opened **36** together with xanthylium salt **37** and 9,9′-bixanthenyl. This result indicates that xanthene occupies a borderline position in this photoreaction due to its increased proton-donating ability relative to other arene donors.

The reactivity of homobenzoquinones was quite different from that of homonaphthoquinones. The irradiation of bromo-substituted homobenzoquinone **6c** in the presence of Et_3N as an electron donor



SCHEME 21

resulted in debromination and cyclopropane ring cleavage to give **39c** instead of the corresponding dimer (Scheme 21).[35]

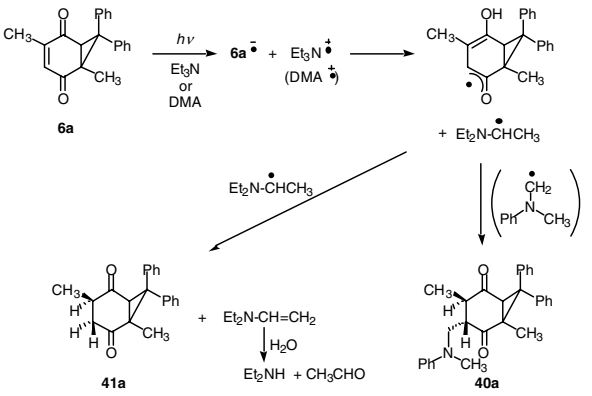
Other secondary and tertiary amines or diethylaniline could be used in place of Et_3N; however, in the case of dimethylaniline (DMA) as an electron donor, the aniline adduct **40c** was obtained as a major product along with **39c**. These reactions failed to occur in the absence of amine or in the dark. Replacement of amine by 2-propanol as the hydrogen donor also resulted in the quantitative recovery of **6c**. Stern–Volmer plots of the fluorescence quenching of **6c** by Et_3N were linear with amine concentration, indicating electron transfer to the excited singlet state of **6c**. Free-energy changes (ΔG) calculated according to the Rehm–Weller equation for the system of **6c** and various amines used are all negative.

These observations indicate that the radical anion of homobenzoquinone arising from the photoinduced electron transfer from the amine to the excited **6c** afforded the allyl radical intermediate via fast proton transfer from the radical cation of the amine (Scheme 21). The successive cleavage of cyclopropane ring and elimination of hydrogen bromide gave diphenylmethyl-substituted quinone **39c**, while the fast radical coupling gave **40c** in the case of DMA. This different mode of reaction can be attributed to the bulkiness and hydrogen-donating ability of the respective amino radicals. Further interest lies in the marked difference in the products between the photoreaction of the homobenzoquinone and that of the homonaphthoquinone described above. The radical anion derived from homobenzoquinone exhibits preferred proton acceptability. The fused-benzene nuclei of the radical anion of homonaphthoquinone may allow the accumulation of spin density on the adjacent ketyl carbon atom, just as in a π-conjugative benzyl radical, by which the outer cyclopropane ring opening is favored to give rise to the corresponding allyl radical.

Irradiation of dimethyl-substituted homobenzoquinone **6a** in the presence of Et_3N or diethylamine gave dihydrogenated **41a** without cyclopropane ring cleavage (Scheme 22). In the case of DMA, only the aniline adduct **40a** was produced as well as in the reaction of **6c**. The stereoselective formation of **40** and **41** is rationalized by the stability of their half-chair conformations.[36] In conclusion, irradiation of homoquinones in the presence of donors resulted in a photoinduced electron transfer that is responsible for the subsequent dimerization, donor amine addition, and hydrogenation, depending on the nature of the homoquinone and the donor.

Intramolecular Reaction

Homoquinones also undergo intramolecular photoinduced electron transfer reactions when the electron-donating substituent is attached to the geminal diaryl group. Semiempirical calculations revealed that



SCHEME 22

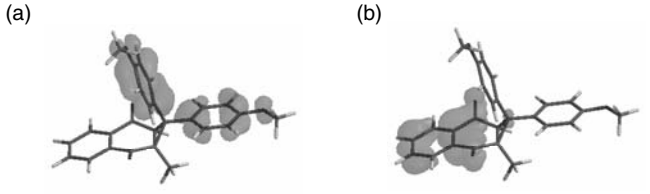


FIGURE 74.2 HOMO (a) and LUMO (b) of Dianisylhomonaphthoquinone **42a** calculated at MOPAC PM3 level.

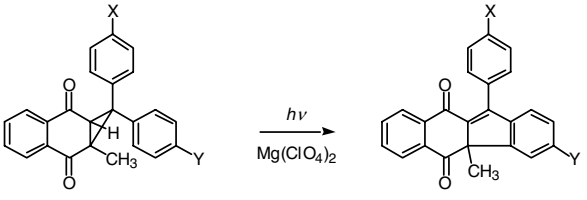


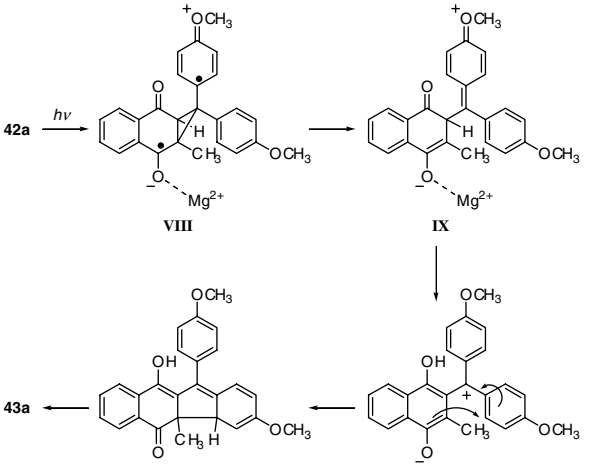
42a: X = Y = OCH_3
endo-**42b:** X = OCH_3, Y = H
exo-**42b:** X = H, Y = OCH_3
42c: X = Y = CH_3
42d: X = Y = H

43a: X = Y = OCH_3
43b: X = OCH_3, Y = H

SCHEME 23

the HOMO of *bis*(*p*-anisyl)homonaphthoquinone **42a** is located on the diaryl ring and the LUMO is on the quinone moiety (Figure 74.2). Indeed, the irradiation of **42a** gave the cyclopropane ring-expanded indenonaphthoquinone derivative **43a** quantitatively under the influence of $Mg(ClO_4)_2$ (Scheme 23).[37]

Similar treatment of *p*-anisylphenylhomonaphthoquinones (*endo*- and *exo*-**42b**) provided the identical **43b** accompanied by the *endo-exo* photoisomerization of the starting homoquinone **42b**; however, these reactions did not occur in the absence of $Mg(ClO_4)_2$. Due to the poor donor ability of aryl groups, *bis*(*p*-tolyl)- and diphenyl-homonaphthoquinones **42c** and **42d** remained intact on such irradiation. It was proposed that these photoreactions proceed by way of the mechanism outlined for **42a** in Scheme 24. The photoinduced intramolecular electron transfer furnishes the radical ion **VIII** capable of undergoing ring opening into the zwitterion **IX**; the zwitterion **IX** degrades to **43a** via cyclization involving the loss of two hydrogen atoms (Scheme 24).



SCHEME 24

The role of added magnesium perchlorate is probably suppression of the intramolecular back-electron transfer as well as stabilization of **VIII** and **IX**. Such effects of metal ions added to enhance PET reactions are well known.[38]

74.6 Conclusions

A survey of the literature reveals some characteristic photochemical features of homoquinones: (1) [2+2]-photocycloaddition with alkenes and alkynes, (2) hydrogen abstraction and/or ring opening of incorporated cyclopropane, and (3) photoinduced electron transfer reactions, as described below. The photocycloaddition with alkenes and alkynes took place exclusively at the ethylene linkage of homobenzoquinones to afford cyclobutanes (or cyclobutene derivatives) regio- and *exo*/*endo* stereoselectively, depending on the identity of both the homobenzoquinones as well as the alkenes.

Photoinduced intermolecular hydrogen abstraction of homonaphthoquinone occurred in the presence of hydrogen sources such as xanthene to furnish dimerization of initially formed ketyl radicals as well as the ring opening of an inner cyclopropane bond. However, diaryl-substituted homologs did not show such a hydrogen abstraction but instead showed oxygen uptake at the biradical formed by cleavage of an outer bond of the cyclopropane moiety. Contrary to the foregoing, homonaphthoquinones bearing γ-hydrogens afforded cyclobutanols and unsaturated keto alcohols via Norrish type II biradicals. Further reactivity of these occurred when the substrates have additional spin-stabilizing alkyl substituents that can influence the inner cyclopropane ring-cleavage process. The conformationally specific 1,7-hydrogen abstraction was observed for the homonaphthoquinones with spatially restricted orientation of relevant hydrogen toward the carbonyl group.

Irradiation of bromo-substituted homonaphthoquinone with donor amines and arene compounds resulted in photoinduced electron transfer to bring about dimerization of the intermediate allyl radical or intramolecular cyclization to xanthylium salt via cyclopropane ring-opening associated with bromide release or bromide recombination, respectively. However, similar reactions of homobenzoquinone brought about hydrogenated cyclopropane ring opening and amination of the homoquinone CC double bond. Moreover, intramolecular electron transfer was found for homonaphthoquinones with anisyl substituents to yield indenonaphthoquinone derivatives.

The Quantitative Cavity Concept in Crystal Lattice Organic Photochemistry: Mechanistic and Exploratory Organic Photochemistry

Howard E. Zimmerman
University of Wisconsin

75.1 Introduction

Solid-state organic photochemistry had its beginnings over a century ago. For the most part, it has been an empirical science. Where theory has been applied, the tendency has been to apply a method either to a single reaction or to a type of reaction, such as a [2+2]-cycloaddition involving little molecular motion. In view of the present author's interest in molecular rearrangements and reactions involving considerable molecular reorganization, the approach taken in our group has been to search for methodology that is quantitative and also can be tested on a variety reactions.

One of the most important beginnings in the field of solid-state photochemistry was the concept of the reaction cavity proposed by Cohen and Schmidt.[1] Another suggestion by the same authors was that reactions take place with least motion. Both suggestions were qualitative. The first is quite valid, while the least motion idea has proven not to be general. This chapter aims at presenting the methods of most use in our research on solid-state photochemistry.

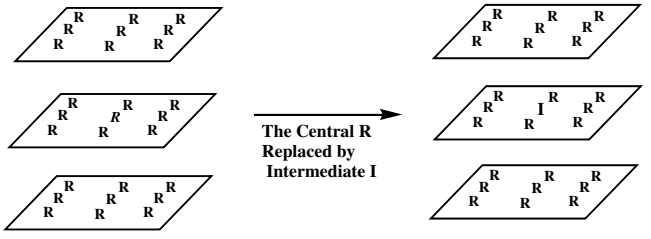
75.2 Methodology and Examples

There are a number of approaches to understanding the course of solid-state reactions which are reasonably complex. Thus, the treatment of molecular rearrangements poses more difficulty than other types (e.g., [2+2]-cycloadditions). Most of the methods require having x-ray structures of the reactant. A simple approach involves inspection of the x-ray coordinates of the reactant and determining if some functional group is hindered by the surrounding shell of neighbors.

A second approach[2] (note Scheme 1) relies on a "mini-crystal lattice" composed of the reactant molecule and the nearest layers of neighboring molecules. If one envisions the central molecule being absent, one has a cavity. The atoms nearest the center of the cavity and their x-ray coordinates then define a quantitative cavity of the type suggested qualitatively by Schmidt and Cohen. One then can consider all the reasonable reaction mechanisms leading to the experimentally observed photoproducts and the first intermediates in each of the mechanisms can be generated theoretically using quantum mechanics. Then, one needs to see how well each intermediate fits into the cavity. In effect, one replaces the originally extracted reactant molecule with a molecule of the first intermediate. In doing this, one keeps corresponding atoms of reactant and first intermediate as geometrically close as possible. The "fit" of each intermediate in the cavity is then determined by the amount of van der Waals overlap with the surrounding neighbors or by using molecular mechanics to obtain the energy of the aggregate.



SCHEME 1 The mini-crystal lattice and injection of a reaction intermediate I replacing the central reactant molecule.

A third approach[3] is aimed at avoiding use of molecular mechanics to treat reaction intermediates, which are triplets or other open shell species. The method takes the mini-crystal lattice consisting of the reacting species surrounded by a shell of neighbors. The atoms of this shell that are closest to the imbedded central molecule are retained, while all remaining atoms of the surrounding molecules are computationally annihilated. To circumvent the problem of having "dangling" free valences at the residual atoms of the neighbors, the hydrogen atoms are computationally converted to heliums, and the carbons, oxygens, and nitrogens are converted to neons. This then provides an "inert gas shell" that defines the reaction cavity. While the inert gas atoms of this shell are kept fixed, the entirety is geometry optimized using quantum mechanics, which may range from AM1 to Hartree-Fock to CASSCF. The inert gas atoms take virtually no computation time and thus one can quite easily determine the energies of a variety of alternative reacting species in the shell. The method then circumvents the matter of treating an open shell species with a molecular mechanics calculation. After all, molecular mechanics completely ignores the electronic contributions to the total energy.

A fourth approach[4] utilizes ONIOM, a computational method devised by Morokuma.[5] The method was intended to dissect a large molecule into portions. One portion is subject to quantum mechanical computation. Further portions are treated by molecular mechanics. In dissecting a molecule by breaking bonds, the Morokuma method "caps" the dangling valences with light atoms as hydrogens.

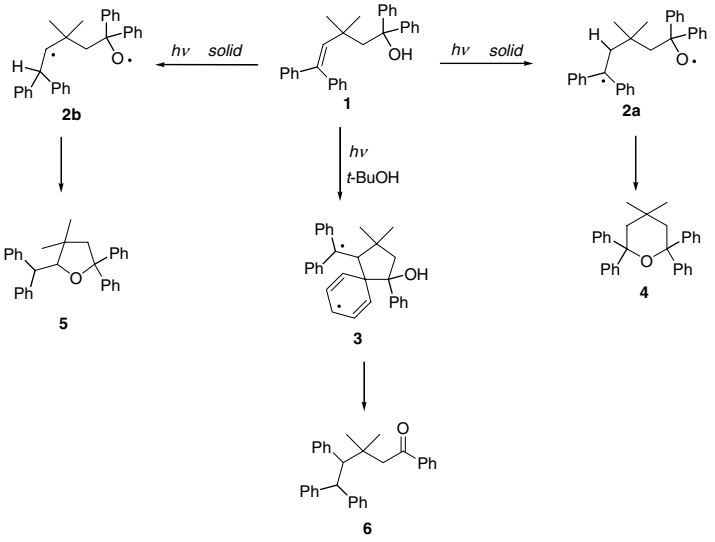
In applying ONIOM to a mini-crystal lattice consisting of a reacting molecule imbedded in an aggregate of reactant neighbors, it is not necessary to break bonds. The reacting molecule can be treated with *ab initio* quantum mechanics. Then, a next layer of neighbors can be treated by molecular mechanics with geometry optimization. Our treatment, however, adds an outer layer of reactant molecules that is held rigid. The aim is to permit and simulate relaxation of the first layer of molecules while keeping the outer layer fixed.

75.3 Some Examples

In one study we compared solution and solid-state photochemistry for a series of reactions.[2,6] Scheme 2 outlines the solution photochemistry of pentenol **1,** which underwent a long-range phenyl migration giving ketone **6.** In contrast, in a crystal lattice, the same reactant cyclized to tetrahydropyran (**4**) and tetrahydrofuran derivatives (**5**), respectively. In this study we considered three reactivity factors as possibly involved:

1. Least motion had been considered as an important controlling factor
2. Overlap of the reacting species with the neighboring molecules (i.e., the cavity)
3. The energy of the imbedded species in the surrounding cavity.

We note in Scheme 2 that the formation of the ketone **6** involves more molecular reorganization, considerably more motion, more of an increase in molecular volume, and more overlap with the neighboring crystal lattice than the formation of products **4** and **5**. In considering these reactions, we focus on the requirements in the molecule reaching the first intermediates — **2a** affording product **4**, **2b** affording **5**, and **3** leading to product **6**.



SCHEME 2 Contrasting solution and solid-state reactivity.

Reference to Table 75.1 confirms the intuitive conclusions above. Thus, for this case, each of the three factors considered seems to play a role. However, this turns out not to be generally the case for all of these factors.

One of the most reliable parameters in this early study was overlap of the reacting species with the neighbors. For example, in the rearrangement depicted in Equation 75.1, the overlap with the surrounding neighbors of the cavity of the *cis*-cyanophenyl enone **7** was 27.8 Å^3 while the overlap for migration of the C-4 phenyl group was 5.6 Å^3.[7,8]

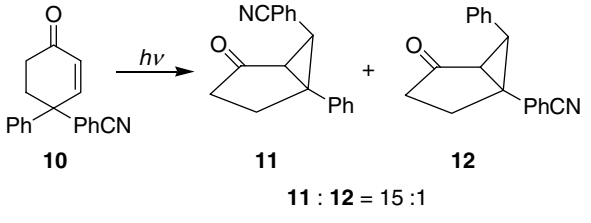
[b] Relative decrease in lattice volume due to van der Waals overlap.

A particularly intriguing example was found when crystallization of 4-phenyl-4-*p*-cyanophenyl **10** was found to afford two different modifications (i.e., dimorphs). These gave differing reactivity, as might have been anticipated from the differing crystal lattices. But more interesting results ensued.

Thus, a series of critical results arose from this observation.[9] The solution photolysis of this reactant (i.e., **10**) is an example of the well-known Type B Rearrangement[10] and affords a preferential cyanophenyl migration in a 15:1 ratio as depicted in Equation 75.2.[10c]



(75.2)

This result is not surprising in view of the greater electron delocalization[11] (2.5 kcal/mole) in the initial triplet bridged diradical **13,** which has the *p*-cyano group on the migrating aryl group, compared with species **14,** which has only a migrating phenyl group (see Figure 75.1).

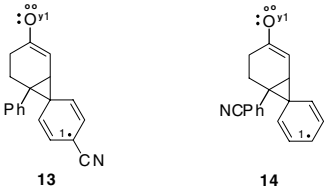


FIGURE 75.1 Alternative Triplet Biradical Intermediates. Solid dots represent π-system electrons, *y*s are p_y-orbital electrons, and circles are the collinear sp-hybrid electrons.

What was intriguing was the observation that one of the two dimorphs (termed "Crystal B"), in the crystalline state, underwent a preferential phenyl migration, in complete contrast with the solution preference for cyanophenyl migration. A second remarkable observation was that this regioselectivity was constant to 16% conversion, at which point the regioselectivity switched to a constant 1:1 ratio of phenyl vs. cyanophenyl migration. This result proved especially important and is considered below in the context of reactions proceeding in stages.

The usual treatment of imbedding each of the two alternative half-migrated triplet biradicals in the mini-crystal lattice of reactant — afforded only a prediction of a preferred cyanophenyl migration. However, careful study of the x-ray structure of the reactant provided a clue. The crystal had *C*2/*c* symmetry; being centrosymmetric, the enone molecules were ordered in pairs of enantiomers. However, the crystal that initially was thought to be slightly disordered, actually had each molecule surrounded by five neighbors, and one neighbor was the "wrong" enantiomer. This occurred systematically throughout the crystal. This might be termed "orderly disorder."

We developed a computer program called "Pairs."[3b] This considered each atom of a single molecule and its distance to all other atoms of surrounding molecules. The sorted pairs of atoms thus indicated which neighboring atoms were closest to a given reactant molecule. Interestingly, it was the nearest molecule of the five neighbors that was the "wrong" enantiomer. When our treatment replaced this nearest reactant molecule with its enantiomer, then a mini-crystal was produced in which the phenyl-half-migrated species was lower in energy despite the extra delocalization with *p*-cyanophenyl migrating and in contrast to the solution regioselectivity.

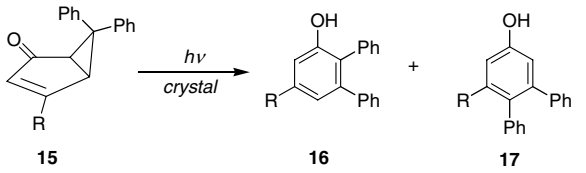
75.4 The Inert Gas Model

Up to this point we had been using molecular mechanics to assess energy effects. While this is quite reasonable for estimating reactant/neighbor van der Waals interactions, and while our molecular mechanics assessment of the relative energies of a variety of reaction intermediates were successful in predicting the lowest energy reaction path, nevertheless, there was an inherent problem. Many of these reaction intermediates were excited-state species and thus had electronic features not accounted for by molecular mechanics. For example, there is no account taken of the species' multiplicities. This fact was noted by one referee of one our manuscripts. The point was that, while one cannot argue with success, nevertheless one ideally should be using quantum mechanical and not molecular mechanical treatments to deal with excited states.

This led the present author to consider ways of dealing quantum mechanically with very large aggregates of molecules. The main impediment to a quantum mechanical computation is the size of a typical mini-crystal lattice. Even with AM1, such a large molecular system cannot be handled practically.

Our approach was to use Pairs,[3b] the program we had developed and which is described above, to determine which atoms of the neighbors were reasonably close to the reaction intermediate in the mini-crystal lattice. Then, all of the more distant atoms were computationally annihilated. However, this step leaves "dangling" free valencies originating from the remaining atoms not annihilated and yet surrounding the reacting species. The next step was to computationally convert each of the residual atoms to inert gas atoms, thus limiting the dangling free valence problem. Hydrogens are converted to heliums, and carbons, oxygens, and nitrogens are converted to argons. This does make these surrounding atoms somewhat larger than the originals, and a method was developed to expand this shell of inert gas atoms from the center (i.e., where the reacting species resides) to compensate for the slightly greater proximity before expansion. However, this gave only minor differences in the final computations. The final step of the procedure involved keeping the inert gas shell rigid and carrying out a quantum mechanical computation on the entirety, with the reacting species being permitted to undergo geometry optimization. While this could involve using just a semi-empirical computation such as AM1, it proved quite efficient to use Gaussian 98.[11] Thus, the presence of the inert gas atoms did not appreciably increase the computation times. This approach then provides an irregularly shaped, yet rigid cavity of the type considered qualitatively by Cohen and Schmidt. Thus, in a number of our publications we have termed this approach as the "quantitative cavity."

We found that this method properly predicts the reactivity of a number of solid-state reactions.[3] For example, note Equation 75.3 and the reactivity of the bicyclo[3.1.0]hexenones **15a** and **15b,** which were in agreement with the Inert Gas model.



15 **16** **17**

Reactant	*Product Ratios*	
15a R = H	*3.0*	*2.0*
15b R = Me	*0.0*	*1.0*

(75.3)

23

FIGURE 75.2 The Type A Zwitterion (i.e., **18S$_o$** with the aryl groups shown as different due to substitution or to cavity asymmetry).

Scheme 3 shows both possible pathways available to zwitterion **18S$_o$**, migration to C2 and to C4. In solution photochemistry, migration to C2 is preferred. However, this is seen not to be the case in the solid-state photochemistry.

Furthermore, there is one additional item of particular interest. While Equation 75.3 and Scheme 3 describe the photochemistry of the 5,5-diphenyl reactant **15a**, the photochemistry of counterparts in which one of the two phenyl groups bears a *p*-cyano or *p*-methoxy substituent was also studied. In the solution photochemistry, it is seen that the two faces of zwitterion **18S$_o$** are equivalent. This is not the

case in the crystal lattice photochemistry (see Figure 75.2) where the cavity makes the two faces of the zwitterion **23** non-equivalent.

Most interestingly, it is the *endo* aryl group in the substituted **15** that undergoes the migration. Indeed, the computations confirm that this is the energetically preferred reaction course in the cavity. In the case of the unsubstituted reactant **15** itself, without labeling, there is no way to tell which of the two phenyl groups does the migration. But here, the computational results agree that it is the *endo* group that, again, does the migration.

75.5 The ONIOM QM/MM Approach

Despite the success of the inert gas cavity method, it seemed important to see if computations could include the neighboring molecules more realistically and yet still use quantum mechanics for the reacting species. The ONIOM-QM/MM method of Morokuma[5] provided a practical method. The method permits quantum mechanical computations on part of a large molecular system, along with molecular mechanical computations on the rest of the molecule. Our aim was to use *ab initio* quantum mechanics for the reacting species and molecular mechanics on the rest of the mini-crystal lattice. This proved highly successful.[4] Thus, Gaussian 98[11] was reserved for the reacting species. The results, as in the Inert Gas model, were usefully predictive for the reaction course in general. However, they proved most useful in the case of host–guest reactivity (*vide infra*). One further result derived from this study, namely the finding that least motion, often termed the "topochemical principle," does not correlate well with the molecular rearrangements studied.

75.6 Host–Guest Reactivity

In the case of the two dimorphs with differing reactivity[9] (*vida supra*) we had the interesting possibility that, in general, one might obtain varying reactivity by just looking at the chemistry of dimorphs. However, these are rather difficult to obtain. The requirement is that the thermodynamic stability of the two modifications does not differ very appreciably and that the modifications do not interconvert so rapidly that the individual isomeric crystals cannot be studied.

However, host–guest complexes are known, and each such inclusion compound will have a different crystal morphology. Thus, with an infinite number of host–guest complexes possible for a given reactant, one can anticipate each host–guest pair to exhibitits own unique reactivity. Some hosts, which have proven useful to us, are given in Figure 75.3.[4] The chiral host **A** is Taddol,[12a,b] also termed the Seebach-Toda host. Each host has a differing shaped cavity and leads to differing reactivity. Thus, Taddol forms both1:1 and 2:1 inclusion compounds with 4-phenyl-4-*p*-cyanophenylcyclohexenone. The 1:1 inclusion compound (**10R+A,** 1:1) is seen in Scheme 4 to afford **11a**, one enantiomer of the cyanophenyl migrated Type-B enone rearrangement product. With host B, the otherenantiomer, **11b**, of the *p*-cyanophenyl migration product results. The 2:1 inclusion compound of reactant with Taddol (**10S+A**, 1:2) leads to both phenyl and *p*-cyanophenyl migration (i.e., products **10b** and **12a**), but with only one enantiomer of each being formed. With the chiral hosts, formation of chiral product is not unexpected. Most remarkably, with host **C**, phenyl migration results and the product is racemic.

[a] Energies in Hartrees (627.5 kcal/mole).

[b] kcal/mole.

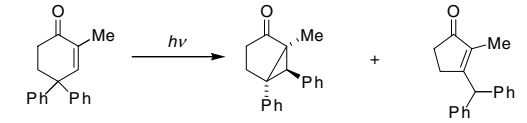
Treatment of the host–cavity energetics in these cases required some new software programming. For conversion of x-ray coordinates to our mini-crystal lattices having single molecules imbedded, we wrote a program termed Smartpack. For cases of the host–guest type, modification was required and we called this program Icepack. With this programming we could again use ONIOM Gaussian 98 *ab initio* computations. The results for some of the photochemistry described above is summarized in Table 75.2. For the two cases cited in Table 75.2, as well as the other examples studied, the energetics proved in agreement with experiment. Some further interesting results were uncovered in this study of inclusion compounds. One was that in using ONIOM, the boundary between the outer layer of molecules and the intermediate layer just outside the reactant could be adjusted to afford fewer or more molecules in the layer immediately surrounding the reactant. The intermediate layer was permitted to geometry optimize while the outermost layer was kept fixed and rigid. This is equivalent to permitting a varied number of molecules immediately surrounding the reactant to be susceptible to relaxation. Interestingly, beyond one layer of surrounding neighbors there is very little effect on the energy of a reacting species. Thus, long-range stress effects seem minor.

75.7 The General Concept of Stages

It has often been erroneously assumed that solid-state photochemistry cannot be taken to high conversion because as product is formed, the crystal is pictured as disintegrating. However, in many solid-state photolyses, the crystal maintains its integrity.

Nevertheless, for a number of reactions, a rather interesting and important phenomenon was uncovered. The first case was that of the dimorphs of 4-phenyl-4-*p*-cyanophenylcyclohexenone **10**. In the case of "Crystal B," which initially exhibited only phenyl migration, sharply at 16% conversion, the regioselectivity changed to a 1:1 ratio of phenyl to cyanophenyl migration. Thus, there were two "stages," one up to 16% conversion and the other beyond that point.[7]

This result led us to consider whether more generally there were succeeding stages of reactions of crystal lattices. Indeed, this turned out to be a general phenomenon.[13,14] Thus, material that in the past had been discarded (i.e., material formed in Stage 2), often provides photoproducts not otherwise obtainable. One example is given in Scheme 5, which describes the photochemistry of 2-methyl-4,4-diphenylcyclohex-2-enone **27** in solution and in two stages of crystal-lattice reactivity. In solution, only the typical Type B enone photoproduct **28** is formed. In Stage 1 of the reaction, two photoproducts,(**28** and **29**) result. In contrast, in Stage 2 of the reaction, only photoproduct **28** is formed. Thus, the use of crystal-lattice photochemistry permits one to obtain a photoproduct (i.e., **29**) not otherwise accessible. Additionally, if one wishes to obtain photoproduct **29** in solid-state photochemistry, one needs to not permit the reaction to proceed to Stage 2.



27 **28** **29**

Solution:	1.0	0
Solid-state stage 1 (to10%):	1.0	1.0
Solid-state stage 2 (above 10%):	1.0	0

SCHEME 5 Photochemistry of 2-methyl-4,4-diphenylcyclohex-2-enone **27.**

75.8 Solid-State Kinetics

Curiously, despite the fact that crystal-lattice photochemistry has a long history, the matter of a kinetic treatment had not been investigated. Our treatment of the photochemistry of "Crystal B" of the dimorphs of 4-phenyl-4-*p*-cyanophenylcyclohexenone **10** provides one example.[9] In Equation 75.4 we take ***C*** to represent the extent of conversion of the photolysis. ***Ph*1** represents the amount of phenyl migration product in Stage 1; ***Ph*2**, the amount of phenyl migration in Stage 2; and ***CN*2,** the amount of cyanophenyl migration in Stage 2. The sum of ***Ph*1, *Ph*2,** and ***CN*2** (note: no cyano product ***CN1*** is formed in Stage 1) gives the total conversion ***C*** as indicated in this equation. The ratio of the two photoproducts, from phenyl migration and from cyanophenyl migration, is then given by **R** in Equation 75.5. Properly combining Equations 75.4 and 75.5 obtains Equation 75.6, which indicates a linearity between the ratio of photoproducts and the ratio plus unity divided by the conversion. Thus, the plot of ***R*** versus (***R***+1)/***C*** in Figure 75.4 is linear. In plotting data points after the end of Stage 1, the slope gives *Ph*1, the amount

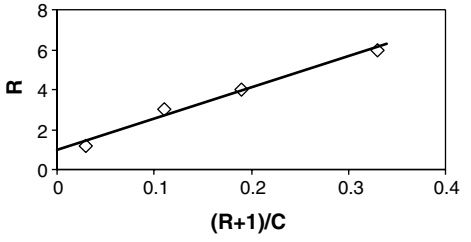


FIGURE 75.4 Plot of phenyl to cyanophenyl migration ratio *R* vs, (*R*+1)/*C*.

of phenyl migration in Stage 1 (i.e., 0.16), and the intercept affords the ratio of the two regioisomers in Stage 2 (i.e., unity). The actual slope and intercept as measured are close to these expected values.

$$\boldsymbol{C} = \boldsymbol{Ph1} + \boldsymbol{Ph2} + \boldsymbol{CN2} \text{ [Three product components giving conversion]} \tag{75.4}$$

$$\boldsymbol{R} = (\boldsymbol{Ph1} + \boldsymbol{Ph2})/\boldsymbol{CN2} \text{ [Ratio of phenyl to cyanophenyl products]} \tag{75.5}$$

$$R = Ph1(R + 1)/C + (Ph2/CN2) \tag{75.6}$$

75.9 Conclusion

Crystal lattice photochemistry, a field with a very long history, has proven to be of practical value in affording photoproducts not obtainable otherwise. However, a comprehensive quantitative treatment had been lacking. This chapter outlined some of our attempts to put this chemistry on a more quantitative basis.

Acknowledgment

Our research in crystal lattice photochemistry has been supported by the National Science Foundation. This support is gratefully acknowledged, in particular because of NSF's interest in supporting basic science.

76.1 Introduction

Despite the fact that synthetically relevant reactions of cyclohex-2-enones are more often bimolecular ones, for example, wherein the excited enone undergoes cycloaddition to an alkene, (monomolecular) photorearrangements of cyclohex-2-enones have been extensively investigated in recent decades and appropriately reviewed ten years ago.[1] This chapter presents and discusses both novel preparative results as well as alternative mechanistic interpretations to apparently well-known reactions.

76.2 Photorearrangement of 4,4-Dialkylcyclohex-2-enones

The light-induced rearrangement of 4,4-dialkylcyclohex-2-enones **1** with concommitant formation of 6,6-dialkylbicyclo[3.1.0]hexan-2-ones ("lumiketones" **2**) and cyclopent-2-enones **3** has been quite thoroughly investigated by the author of this corresponding review in 1995.[1] Nevertheless, the question of the mechanism (Scheme 1) of this rearrangement remained unanswered as both a concerted as well as a stepwise mechanism had been proposed. In any event, the lifetime of the eventual propane-1,3-diyl-biradical **4** has to be short, as (1) in some cases the reaction proceeds with retention of configuration at the dialkyl-substituted C-atom, and (2) no products derived from a cyclopropylcarbinyl-radical-ring opening were detected in the corresponding photorearrangement of 4,4-dicyclopropylcyclohex-2-enone (**5**).[2]

Detailed investigations of a series of 4,4-dimethylcyclohex-2-enones bearing further substituents on C(5) or C(6) were undertaken.[3] It was found that on irradiation with light of $\lambda = 350$ nm in acetonitrile, cyclohexenones **6** rearranged to mixtures of bicyclohexanones **7** and cyclopentenones **8** with similar quantum yields ($\Phi_{\text{-}\mathbf{6}} \cong 0.004$–$0.024$) as well as product ratios (**7**/**8** = 2:1–1:2), indicating the rearrangement to be relatively insensitive to these additional substituents. The cyclohexenones with just one alkyl group

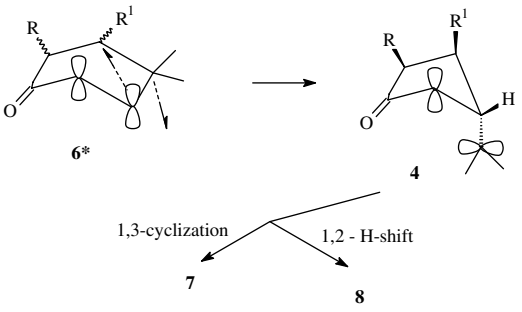
SCHEME 2

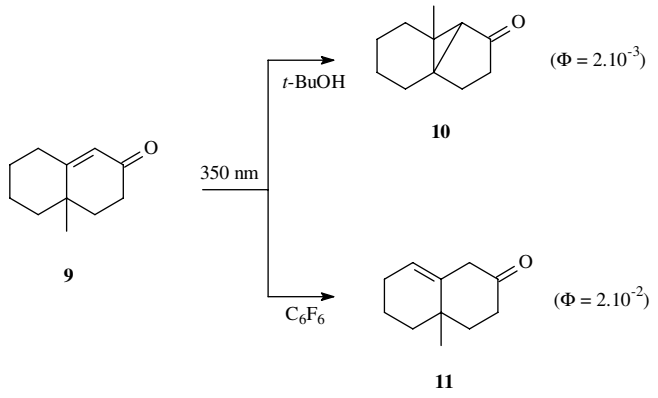
at either C(5) or C(6) (i.e., **6a**, **6b,** and **6c**) rearrange selectively to the diastereoisomer **7** with the alkyl group and the three-membered ring in *trans*-configuration (Scheme 2), while the 6-fluorocyclohexenones **6d** and **6e** afford mixtures of diastereomeric bicyclohexanones.

According to the authors,[3] the conversion of triplet cyclohexenone is best described as an intramolecular homolytic substitution (S_H2 reaction) with attack of the radical center C(3) on C(5), the leaving group (i.e., the dialkyl-substituted C(4)) then being *trans* to the alkyl group at C(5) or C(6) (Scheme 3). The propane-1,3-diyl triplet intermediate **4** is then expected not to relax thermally on the triplet surface, but rather undergo very rapid intersystem crossing.

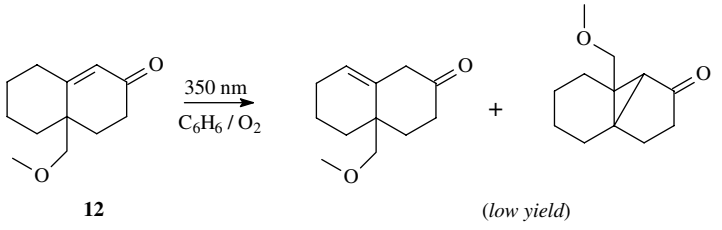
A somewhat different situation arises for 4,4-dialkylcyclohex-2-enones bearing an additional CH-substituent on C(3). Thus, 4a-methyl-4,4a,5,6,7,8-hexahydro-2(3*H*)-naphthalenone (**9**) affords selectively the



SCHEME 3



SCHEME 4



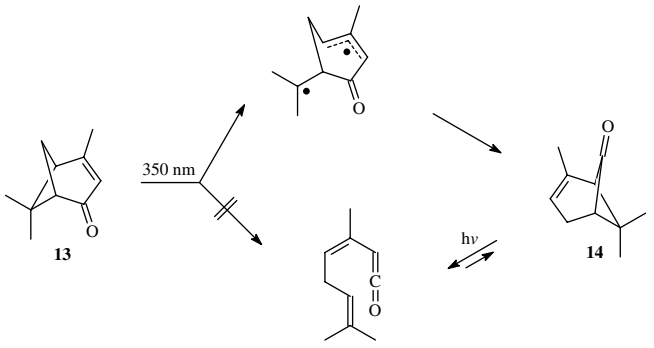
SCHEME 5

"lumiketone" **10** on irradiation in *t*-butanol; while in hydrocarbon solvents (C_6H_6, C_6F_6), deconjugation to the β,γ-unsaturated ketone **11** becomes the predominant process (Scheme 4).[4]

Interestingly, the corresponding 4a-methoxymethylnaphthalenone **12** only undergoes very slow rearrangement and deconjugation (Scheme 5) in deaerated hydrocarbon solutions, but both processes are accelerated by the presence of air. An explanation for this peculiar finding was not given.[5]

76.3 Photorearrangement of 4,6-Methano-Bridged Cyclohex-2-enones

It has already been reported more than 40 years ago that verbenone (**13**) undergoes isomerization to chrysanthenone (**14**) on irradiation in cyclohexane.6 More detailed studies revealed that (1) the reaction



13 **14**

SCHEME 6

17	all R = OAc	**20**

SCHEME 7

proceeds with a reasonable degree of stereoselectivity, (i.e.,with only a small degree of racemization, and (2) (−)-chrysanthenone obtained from (−)-verbenone (Scheme 6) on irradiation ($\lambda = 350$ nm) undergoes subsequent photoreactions when using light of shorter wavelength.[7] It was therefore assumed that this rearrangement occurs via a formal 1,3-shift of the dialkylated C-atom rather than via α-cleavage to an (achiral) ketene intermediate followed by electrocyclic ring closure, albeit this latter intermediate might be of importance in the consecutive photoreactions of **14**.

This same type of rearrangement has also been observed for a series of tricyclic sesquiterpenes. Thus, in the field of longipin-2-en-1-ones, both the parent vulgarone B (**15**) as well as the acetoxy derivatives **16** and **17** photorearrange (Scheme 7) to vulgarone A (**18**) and the corresponding acetoxy derivatives **19** and **20**, respectively.[8,9]

76.4 Photorearrangement of 4,4-Diarylcyclohex-2-enones

Cyclohex-2-enones bearing at least one aryl group (in addition to an alkyl group) on C(4) undergo photorearrangements different from that presented in Section 76.1. The so-called "di-π-methane rearrangement" mode — typical of molecules containing a 3-phenylprop-1-ene substructure which isomerizes to a phenylcyclopropane moiety — now becomes predominant, as illustrated for the photoisomerization of 4,4-diphenylcyclohex-2-enone (**21**) to a mixture of diastereomeric 5,6-diphenylbicyclo[3.1.0]hexan-2-ones **22** (Scheme 8).[10]

Further investigations were run on the chiral cyclohexenone **23** showing that the formal 1,2-phenyl migration to **24** occurred without any loss of optical purity.[11] A bridged intermediate was proposed to explain the selective formation of the *endo*-bicyclic derivative **24** to the exclusion of any *exo*-derivative (Scheme 9).

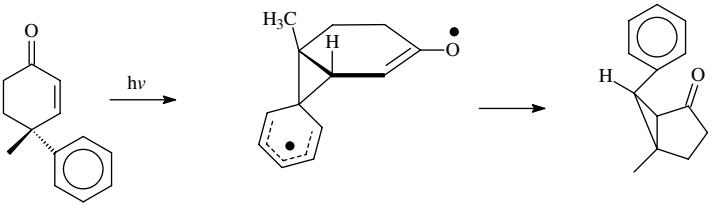
SCHEME 8



23 **24**

SCHEME 9

Zimmerman has recently reviewed his research work of the past two decades focusing on the photorearrangement of 4,4-diarylcyclohex-2-enones in the crystalline state.[12] A comparison of the different criteria of crystal lattice reactivity was provided in a study of 5-substituted 4,4-diarylcyclohex-2-enones.[13] As shown for **25** and **26**, the product distributions in the crystal lattice chemistry differ from those in solution photochemistry (Scheme 10). It becomes evident from the synthetic viewpoint that one can obtain, using solid-state irradiation, photoproducts that are unobtainable as appreciable products in solution. A highly interesting result started with the observation that 4-phenyl-4-cyanophenylcyclohexenone **27** crystallizes in two modifications. The first of the two dimorphs, the one with $P2_1/c$ symmetry, afforded only the cyanophenyl-migrated bicyclic ketone **28**, while the other one, with *C2/c* symmetry, underwent only phenyl migration to give product **29** (Scheme 11). In this latter example, the preference for phenyl migration was observed only during the first 16% conversion ("Stage 1"). Beyond this point ("Stage 2"), a consistent 1:1 regioselectivity resulted.[14]

76.5 Photorearrangement of 2*H*,6*H*-Thiin-3-ones to Thietan-3-ones

In contrast to the rather inefficient triplet state photorearrangement of (4,4-dialkyl)-cyclohex-2-enones to bicyclo[3.1.0]hexan-2-ones, 5-thiacyclohex-2-enones **30, 31,** and **32** undergo a highly efficient (Φ = 0.8) ring contraction from the first excited singlet state, affording 2-alkenylthietan-3-ones **33, 34**, and **35,** respectively (Scheme 12).[15] This rearrangement also seems to be typical for bicyclic compounds **36** through **39** containing this same ring system. Depending on the substitution pattern and on the wavelength chosen, the bicyclic thietanones (**40, 41**) are stable,[16] or (**42, 43**) undergo further light-induced conversions (e.g., a 1,3-acyl shift) to the final products (**44, 45**) as shown in Scheme 13.[17,18] The proposed mechanism for these ring contractions involves a sulfuranyl-alkyl biradical **46** as intermediate.[15,19] Evidence for such an intermediate (Scheme 14) comes from the fact that the efficiency of ring contraction

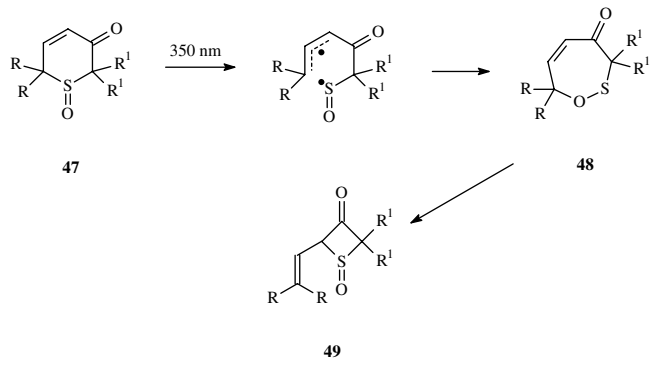
SCHEME 14

for compounds **33, 34,** and **35** is not sensitive to the stability of the — formally — displaced radical group (H_2C vs. $(CH_3)_2C$), which excludes a possible C–S bond cleavage step as the rate-determining one.

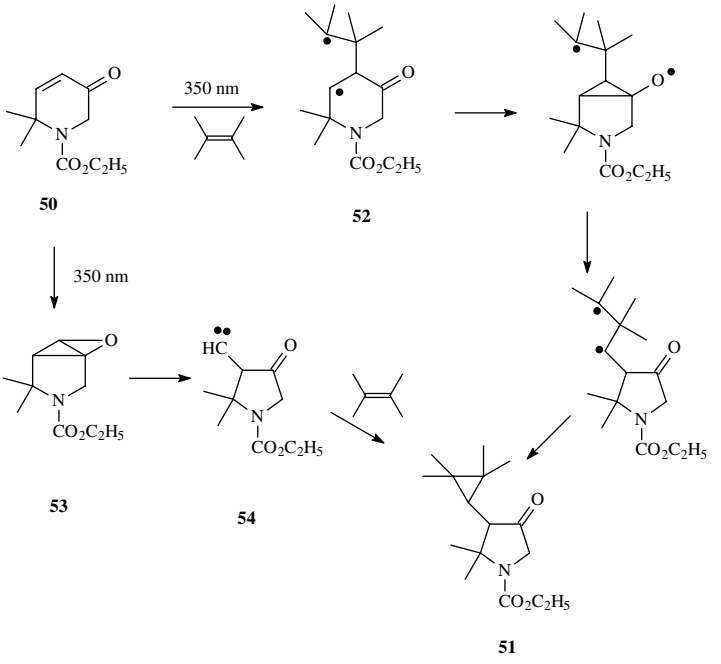
In contrast, the corresponding sulfoxides do undergo such a bond rupture between the *allylic C*-atom and the neighboring S-atom as a first chemical step after photoexcitation.[20] As shown in Scheme 15, 2*H*,6*H*-thiin-3-one-1-oxides **47** photoisomerize to 3*H*,7*H*-1,2-oxathiepin-4-ones **48**, which undergo a further thermal ring contraction to thietanone-1-oxides **49** via a 2,3-sigmatropic rearrangement.

Interestingly, ethyl 2,2-dimethyl-5-oxo-5,6-dihydro-2*H*-pyridine-1-carboxylate (**50**), an aza-derivative of thiinone **34**, behaves in a totally different way.[21] On irradiation in benzene, it undergoes slow photodecomposition, while in the same solvent in the presence of 2,3-dimethylbut-2-ene, pyrrolidinone **51** is formed as the major (50%) photocycloadduct. Although the authors[21] proposed a rearrangement sequence of the intermediate biradical **52** formed by addition of the alkene to triplet excited **50**, an alternative path (Scheme 16), including first photoisomerization of **50** to oxabicyclobutane **53** and then to the ring-contracted carbene **54**, which then would be trapped by the alkene, cannot be excluded.

It is unfortunate that no irradiations of **50** were run in methanol, as this would have allowed trapping of the postulated carbene intermediate **54**. The photoisomerization of *s-trans*-1,3-dienes to bicyclobutanes in general and that of 3-methylenecyclohexene to tricyclo[3.2.0.$0^{1,6}$]heptane (the all-carbon analogue of **53**) in particular are well-established reactions.[22]



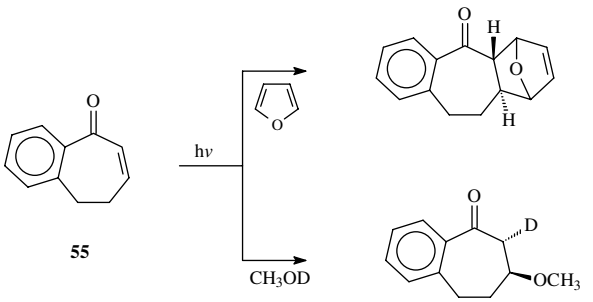
SCHEME 15



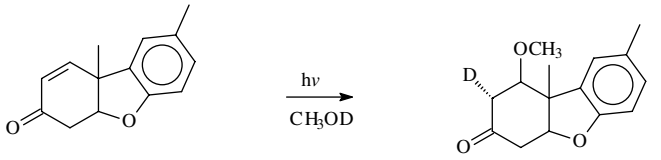
SCHEME 16

76.6 *Z-E*-Photoisomerization of Cyclohexenones

Cyclooct-2-enone and cyclohept-2-enone undergo $Z \rightarrow E$ isomerization on irradiation. While *E*-cycloocten-2-one can be characterized spectroscopically at room temperature, *E*-cyclohep-2-enone is stable only at temperatures around –180°C, but can be trapped with dienes in a dark reaction at –78°C.[23–26] The photoisomerization of these medium-ring cycloalkenones appears to occur much faster than intermolecular processes, e.g., cycloaddition to alkenes or energy transfer to triplet quenchers. Another seven-membered ring enone, 2,3-benzocyclohepta-2,6-dienone (**55**) was found to afford *trans*-fused [4+2]



SCHEME 17



SCHEME 18

cycloadducts on irradiation in furan, and, on irradiation in methanol, a 6-MeO adduct wherein the MeO group and the (new) H-atom are *trans* to each other (Scheme 17). The authors[27, 28] inferred from these results that the primary process was *Z-E* isomerization of the C–C double bond in the seven-membered ring, and that the *E*-enone was then trapped by either furan or MeOH.[27,28]

As for six-membered enones, cyclohex-2-enone on irradiation in furan afforded both [4+2] and [2+2] cycloadducts.[29] Although the configuration of these products is unknown, a mechanism involving attack of an enone triplet on a ground-state diene molecule was proposed. Triplet biradicals have also been proposed as intermediates in the photocycloaddition of *Pummerer*'s ketone (**56**) with furan. [30,31] This dihydrodibenzofuranone also gives a methanol adduct (Scheme 18), wherein the MeO group and the new H-atom are again *trans* to each other. The authors proposed a reactive excited molecule or an intermediate in which the C–C double bond is twisted by nearly 90 on which then MeOH undergoes a regio- and stereospecific *cis*-addition.[32]

Irradiation of 2,2-dimethyl-2,3-dihydro-4*H*-thiin-4-one (**57**) — a "4-thiacyclohex-2-enone" — in neat furan afforded three cycloadducts **58**, **59**, and **60**, in a 5:4:1 ratio, whose formation is quenched by appropriate triplet quenchers. Irradiation of **57** in methanol afforded a 3:2 mixture of adducts **61** and **62**; and in CD_3OD, a similar mixture of $\mathbf{D_4}$**–61** and $\mathbf{D_4}$**–62**. Finally, irradiation of **57** in furan:MeOH (1:1) gives only cycloadducts **58**, **59**, and **60** to the exclusion of adducts **61** and **62** (Scheme 19). Compound **57** was chosen for these studies because the longer C–S bonds (as compared to C–C bonds) should make such dihydrothiinones ideal model compounds for the investigation of photochemically generated, highly twisted monocyclic cyclohexenones.[33]

These latter results, combined with the older ones reported, were interpreted as follows.[33] Excitation of **57,** followed by intersystem crossing, gives triplet enone **63**, which reacts with furan to give two diastereomeric biradicals, **64** and **65**, the precursors of **58** and **60**, and **59**, respectively. In the absence of furan, **63** affords *E*-enone **64,** which either re-isomerizes to **57** or is trapped by methanol to give **61** and **62.** In contrast to (carbocyclic) cyclohexenones, two regioisomers are formed from **57** as both the carbonyl group and the S-atom stabilize an adjacent carbanionic center (Scheme 20).

New Results on the Triplet Reactivity of β,γ-Unsaturated Carbonyl Compounds

Diego Armesto

Universidad Complutense of Madrid

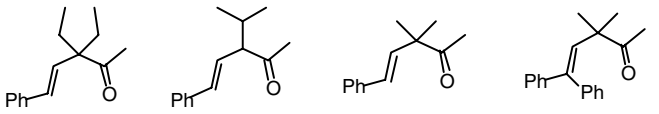
77.1 Introduction

The photochemistry of carbonyl compounds has been one of the main areas of research in organic photochemistry for many years.[1] Among all the different types of carbonyl compounds, β,γ-unsaturated ketones have been the subject of extensive studies.[2] The results obtained from these efforts, conducted over a 30-year period, show that, in general, direct irradiation of β,γ-unsaturated ketones yields products resulting from 1,3-acyl migration, while triplet-sensitized reactions of these compounds affords cyclopropyl ketones by oxa-di-π-methane (ODPM) rearrangement pathways.[2] Alternative reaction routes, such as decarbonylation, ketene formation, epimerization, [2+2]-intramolecular cycloadditions, Norrish Type I and Norrish Type II reactions, *cis-trans* isomerizations, and reductions of the C–C double bond, have also been described in some instances, depending on some particular structural features present in the β,γ-unsaturated ketone.[2a] However, the photoreactivity of these compounds is dominated by the two main processes mentioned above.

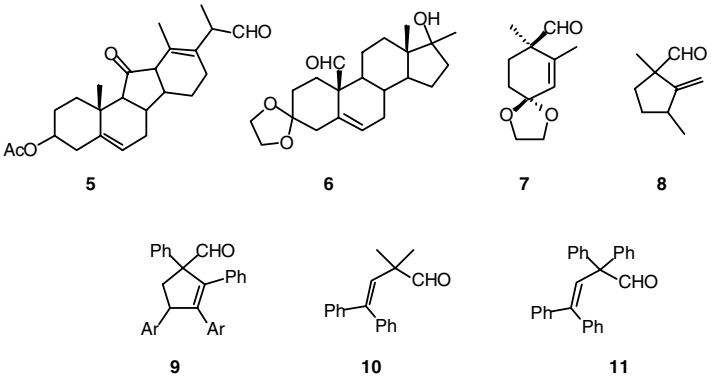
The ODPM rearrangement has proven to have important synthetic applications.[2e-g] This is due to the fact that most of these reactions are very general; they usually take place with high chemical and quantum yields and also, in many instances, a high degree of stereoselectivity or even enantioselectivity has been observed. As a result, this rearrangement has been used as the key step in the synthesis of natural products and complicated molecules that are difficult to obtain by alternative reaction paths.[2e-g] Despite the large number of examples reported in the literature of cyclic and polycyclic β,γ-unsaturated ketones that undergo the ODPM reaction, there are only a few examples of acyclic ketones that undergo this reaction.[2g] The reasons for the lack of ODPM reactivity in some acyclic compounds are difficult to understand. For example it is surprising that ketones **1** and **2** have been reported to be reactive in the ODPM mode by Cerfontain et al.,[3] whereas the closely related compounds **3**[3] and **4**[4] do not undergo the rearrangement.

0-8493-1348-1/04/$0.00+$1.50



1 **2** **3** **4**

β,γ-Unsaturated aldehydes are a family of carbonyl compounds that have been considered ODPM unreactive for many years. This conclusion was based on literature precedents that indicated that the normal photochemical reactivity of such compounds, both on direct and sensitized irradiation, was decarbonylation to the corresponding alkene.[2c,2f,5] Thus, compounds **5**,[6] **6**,[7] **7**,[8] and **8**[8] are representative examples of a series of steroidal and cyclic β,γ-unsaturated aldehydes, studied by Schaffner et al. about 20 years ago, that undergo decarbonylation on irradiation. Dürr et al.[9] have studied the photochemistry of some aryl-substituted-2-cyclopentene-1-carbaldehydes **9**. In this instance, *cis*-stilbene-type electrocyclic cyclization and decarbonylation were the only reactions observed. Other authors have also reported the decarbonylation of the acyclic β,γ-unsaturated aldehydes **10**[4] and **11**[10] on direct irradiation.



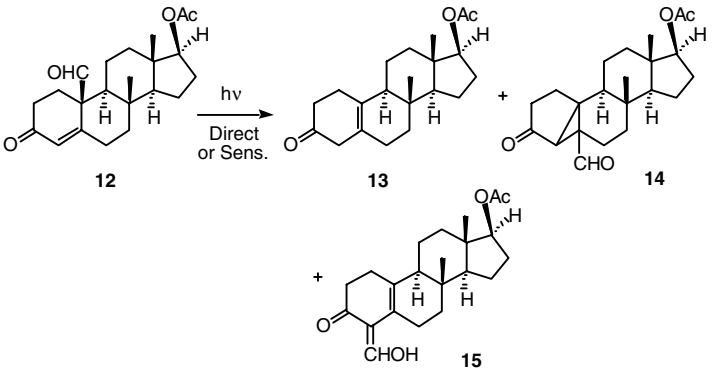
5 **6** **7** **8**

9 **10** **11**

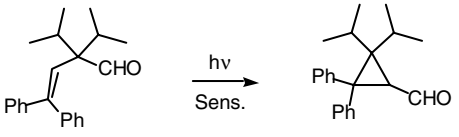
However, two examples of aldehydes that did not follow this general rule were described in the early studies. The first example of an ODPM reaction in a β,γ-unsaturated aldehyde was observed by Schaffner et al.[11] in the direct and triplet-sensitized irradiation of the steroidal aldehyde **12** that gives the alkene **13** resulting from decarbonylation, and two other compounds, **14** and **15**, derived from the ODPM rearrangement and the 1,3-formyl migration, respectively (Scheme 1).

Many years later, Zimmerman and Cassel[12] reported the ODPM triplet reactivity of the aldehyde **16**, which contains two isopropyl groups at C2 and quantitatively yields the cyclopropyl aldehyde **17** (Scheme 2). Therefore, β,γ-unsaturated aldehydes were considered to be unreactive in the ODPM mode, apart from the two exceptions mentioned above.[2c,2f,5]

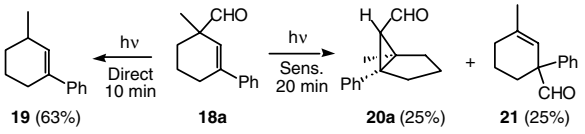
These ideas on the photo-behavior of β,γ-unsaturated aldehydes have changed due to the results emanating from recent studies carried out in our laboratory demonstrating that suitably substituted aldehydes do undergo the ODPM reaction with high chemical efficiency and a high degree of diastereoselectivity, in some cases. Furthermore, a comparative study on the photoreactivity of β,γ-unsaturated aldehydes and the corresponding methyl ketones show that aldehydes undergo the ODPM rearrangement even more efficiently than the corresponding methyl ketones, contrary to common belief. Finally, alternative reaction modes, such as 1,3-formyl migration and decarbonylation, that take place via the T_1 ($\pi\pi^*$) excited state and are, therefore, not typical Norrish Type I processes, have also been uncovered in some cases. The following sections summarize these novel results.



SCHEME 1



SCHEME 2



SCHEME 3

77.2 The Oxa-di-π-methane Rearrangement of β,γ-Unsaturated Aldehydes

Our interest in the photochemistry of β,γ-unsaturated aldehydes was serendipitous. At one point in our studies on the 1-aza-di-π-methane (1-ADPM) rearrangement, we were interested in its application to the synthesis of bicyclo[n.1.0]alkanes.[13] An extension of such a study was aimed at identifying ring contraction processes. To this end, the aldehyde **18a** that could be transformed into different imine derivatives, was selected as the target molecule. Because the photochemistry of the aldehyde **18a** was not described, it was of importance to establish the photochemical behavior of this compound to compare its reactivity with that of the corresponding nitrogen derivatives. Thus, direct irradiation of **18a**, for 10 min, afforded a mixture of starting material (20%) and the alkene **19** (63%), resulting from decarbonylation of aldehyde **18a** (Scheme 3).[14] This result was not a surprise because, as mentioned, it has been established that decarbonylation is the main photochemical reactivity of β,γ-unsaturated aldehydes. However, acetophenone-sensitized irradiation of **18a**, for 20 min, brought about different reactions, affording starting material (11%), the ODPM product **20a** (25%), and the 1,3-migration product **21** (25%) (Scheme 3). The ODPM rearrangement of **18a** is diastereoselective, affording the bicyclic aldehyde **20a** as the *endo*-isomer exclusively.[14]

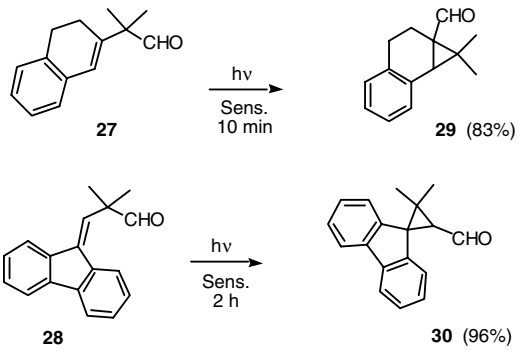
SCHEME 5

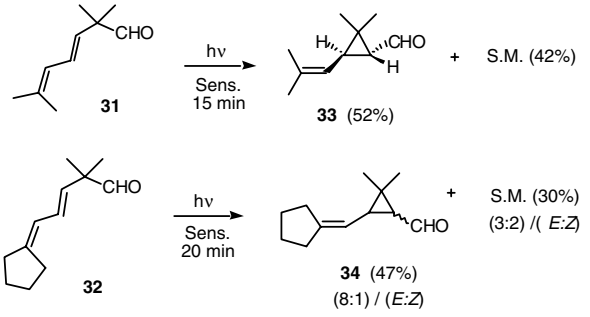
The formation of 1,3-migration products under sensitized conditions involving the T_2 excited state has been reported for several β,γ-unsaturated ketones.[15] However, it is extremely rare to observe such a reaction with analogous aldehydes, and the formation of the ODPM product **20a** is even more surprising. At this point it was difficult to explain the photoreactivity observed in the irradiation of **18a**, although it was thought to be due to the influence of some unknown structural factors present in this aldehyde. Therefore, the study was extended to aldehydes **18b** and **18c** to determine whether this unexpected reactivity could also occur in other related aldehydes. Acetophenone-sensitized irradiation of **18b** afforded the ODPM product **20b** in 90% isolated yield. Similarly, irradiation of **18c** under the same conditions gave the cyclopropyl aldehyde **20c** in 25% yield. In these two instances, the corresponding 1,3-formyl migration products were not formed (Scheme 4).[14b]

To clarify whether or not the unexpected ODPM reactivity of aldehydes **18** was due to some structural factors present in these compounds, we decided to study the photoreactivity the β,γ-unsaturated aldehyde **22**, which presents a substitution pattern that promotes the 1-ADPM rearrangement very efficiently.[16] Triplet-sensitized irradiation of **22**, for 15 min, afforded the cyclopropyl aldehyde **23**, resulting from an ODPM rearrangement, as the *trans*-diastereoisomer, in 90% isolated yield (Scheme 5). This result clearly demonstrated that the ODPM reactivity of β,γ-unsaturated aldehydes is not restricted to cyclic derivatives, such as **18**, or to molecules with special structural features as in the two cases previously reported, but can be extended to acyclic compounds. Furthermore, the efficient ODPM rearrangement of compounds **18a–c** and **22** suggested that the main factor that controls the ODPM reactivity of these aldehydes is the stabilizing influence of phenyl groups on the bridging 1,4-biradical reaction intermediates. To test this hypothesis, the study was extended to aldehydes **10** and **11**. As mentioned, previous reports demonstrate that these two compounds undergo decarbonylation on direct irradiation.[4,10] However, triplet-sensitized irradiation of **10**, for 2 h, afforded the cyclopropyl aldehyde **24** in 57% yield. Similarly, irradiation of **11**, for 10 min, under the same conditions yielded the ODPM product **25** in 82% yield and the alkene **26** (8%), resulting from decarbonylation (Scheme 5).[14b]

These results demonstrate that β,γ-unsaturated aldehydes with phenyl substitution at the γ-position of the β,γ-unsaturated aldehyde skeleton do undergo efficient ODPM rearrangement, according to our postulates. This influence of substitution was further demonstrated in the irradiation of aldehydes **27** and **28**, in which the biradical intermediates are also stabilized by conjugation with phenyl rings. These compounds undergo the ODPM rearrangement, yielding the corresponding cyclopropyl aldehydes **29** (83%) and **30** (96%), respectively, after short irradiation times (Scheme 6).[14b]



SCHEME 6

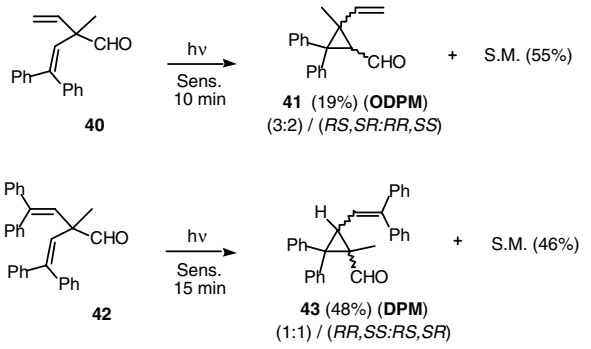


SCHEME 7

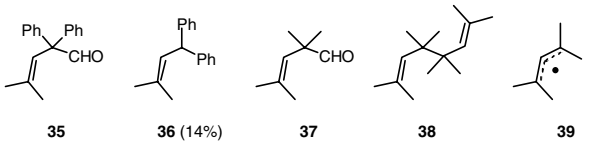
The next question to be answered was whether or not substituents other than phenyl at that position could also promote the reaction. Therefore, the study was extended to aldehydes **31** and **32**, with differently substituted vinyl units at the γ-position. Previously we have observed efficient 1-ADPM rearrangement of the corresponding oxime acetates, showing that the substitution pattern present in **31** and **32** was suitable for promoting DPM reactivity.[17] Triplet-sensitized irradiation of **31**, for 15 min, afforded the ODPM product **33** (52%) as the *trans*-isomer exclusively and starting material (42%), as shown in Scheme 7. Similarly, irradiation of **32**, for 20 min, under the same conditions used for **31**, yielded starting material (30%) as a 3:2 mixture of *E,Z*-isomers and the cyclopropane derivative **34** (47%) as a 8:1 mixture of *E,Z*-isomers (Scheme 7).[14b]

The rearrangements of aldehydes **31** and **32** demonstrated that the ODPM reactivity of β,γ-unsaturated aldehydes is not restricted to phenyl-substituted compounds, but can also be extended to systems in which the intermediate biradicals are stabilized by conjugation with a vinyl group. Furthermore, the efficient synthesis of compounds **33** and **34** is of importance because it opens a novel photochemical route to chrysanthemic acid and other cyclopropyl components present in pyrethrins and pyrethroids.[18] In fact, aldehyde **33** can be transformed to *trans*-chrysanthemic acid by simple oxidation. This new synthetic route to ecologically benign insecticides competes with the one previously described by us using the 1-ADPM rearrangement of β,γ-unsaturated oxime acetates.[17]

In the absence of phenyl or vinyl substituents at the γ-position of the β,γ-unsaturated aldehyde, the rearrangement can also take place, although very inefficiently. Thus, acetone-sensitized irradiation of aldehyde **35**, with diphenyl substitution at C2, for 30 min, gives the ODPM aldehyde **24** in 8% yield, the corresponding alkene **36** (14%) resulting from decarbonylation, and starting material (70%). However, irradiation of aldehyde **37**, in which there are no phenyl or vinyl groups to stabilize the biradical intermediates, under the same conditions used for **35** yielded the diene **38,** resulting from the dimerization of the radical **39** formed by decarbonylation of **37**.[14b]



SCHEME 8



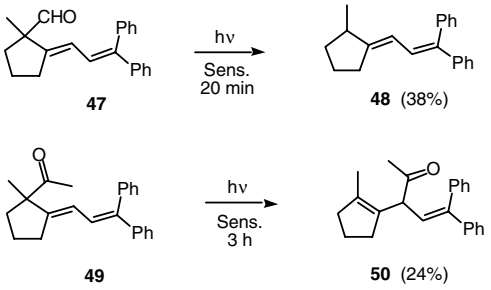
The possible competition between the ODPM and the DPM processes was also studied. Triplet-sensitized irradiation of **40**, for 10 min, afforded recovered starting material (55%) and the cyclopropyl aldehyde **41** (19%), as a 3:2 mixture of *RS,SR:RR,SS* isomers, resulting from an ODPM rearrangement, exclusively, showing that in this instance the ODPM rearrangement dominates over the DPM process (Scheme 8). However, irradiation of aldehyde **42** under the same conditions used for **40**, for 15 min, yielded starting material (46%) and the cyclopropane **43** (48%), resulting from a DPM rearrangement, as a 1:1 mixture of *RR,SS:RS,SR* isomers (Scheme 8). The regioselectivity observed in the rearrangements of **40** and **42** can be justified by taking into account the relative stabilities of the 1,4-bridged biradicals for the two possible rearrangement paths.[14b]

The above results have changed the ideas that most photochemists had for many years about the photoreactivity of β,γ-unsaturated aldehydes. From the previous work on the study of a series of compounds of this type, a general consensus surrounding their lack of ODPM reactivity was originated. Most of the compounds studied previously undergo decarbonylation, with only two exceptions. The decarbonylation takes place via either the S_1 ($n\pi^*$) or T_2 ($n\pi^*$) excited states. However, based on studies with analogous ketones, the ODPM rearrangement of β,γ-unsaturated aldehydes almost surely occurs via the T_1 ($\pi\pi^*$) excited state. The lack of ODPM reactivity of the aldehydes previously studied is probably due to the absence of the adequate substitution pattern that would allow efficient transfer of the triplet energy from the sensitizer to the alkene moiety. Therefore, the T_1 ($\pi\pi^*$) excited state, necessary for the ODPM rearrangement, would not be generated.

Based on our results, we proposed that β,γ-unsaturated aldehydes do indeed undergo efficient triplet ODPM rearrangement when the following criteria are met. First, the triplet energy of the sensitizer must be efficiently transferred to the C–C double bond in order to generate a T_1 ($\pi\pi^*$) excited state of the substrate. Second, the biradical intermediates in the non-concerted ODPM pathway must be stabilized by conjugation with phenyl or vinyl groups. β,γ-Unsaturated aldehydes that do not meet these two requirements, as in most of the cases previously probed, undergo exclusive photodecarbonylation.[14b]

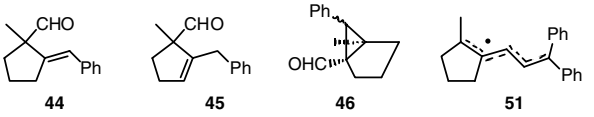
77.3 Reactions of β,γ-Unsaturated Carbonyl Compounds Reminiscent of Norrish Type I Processes

Trying to confirm the above postulates, we have recently investigated the photoreactivity of aldehyde **44** that presents a substitution pattern that should favor the ODPM rearrangement, according to our



SCHEME 9

hypothesis. Compound **44** was selected because the related aldehyde **8**, previously studied by Schaffner et al., undergoes decarbonylation on irradiation, exclusively.[8] If our postulates on the ODPM rearrangement of aldehydes are correct, it would be possible to overcome the lack of ODPM reactivity by modifying the substitution in **8** in such a way to ensure efficient triplet energy transfer to the C-C double bond and stabilization of the biradical intermediates. The conjugation of the C-C double bond with a phenyl ring and the replacement of the methyl at C3 present in **8** by a hydrogen, should favor the ODPM rearrangement of **44**. Unfortunately, all synthetic attempts yielded an inseparable mixture of **44** and its endocyclic double bond isomer **45**. Nevertheless, a 1:1 mixture of **44** and **45** was irradiated using acetophenone as sensitizer. Despite the complexity of the photomixture, ^{1}H NMR analysis suggested that the bicyclic aldehyde **46**, the product of ODPM rearrangement of the aldehyde **44**, was present in the crude photolysate.[19]

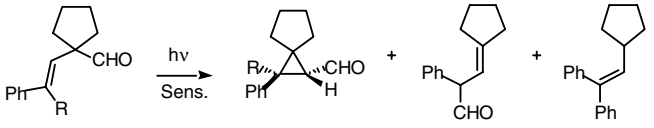


44 **45** **46** **51**

To avoid synthetic problems, we prepared aldehyde **47**, a substrate in which isomerization of the C-C double bond to the endocyclic position is less likely due to the extended conjugation of the alkene moiety. Compound **47** was obtained as a pure substance and also presents a substitution pattern that, according to the above postulates, should favor the ODPM rearrangement. However, irradiation of **47**, using *m*-methoxyacetophenone as sensitizer, led to formation of the diene **48** (38%), as a result of photodecarbonylation (Scheme 9). No ODPM product was formed in this process.[19] Irradiation of the corresponding methyl ketone **49**, under the same conditions as used for **47**, afforded the product of 1,3-acyl migration **50** in 24% yield (Scheme 9). Again, no ODPM product was formed in this instance.[19] The formation of **48** and **50** is reminiscent of Norrish Type I processes. However, in these cases, homolytic bond fission does not occur in the carbonyl nπ^* excited state, as is the case in normal Norrish Type I reactions.[20]

As far as we are aware, these observations show for the first time that the well-known Norrish Type I reactions of β,γ-unsaturated carbonyl compounds can take place by excitation of the alkene moiety rather than the carbonyl group. The reason for this unusual reactivity may be that the T_1 ($\pi\pi^*$) excited states of **47** and **49** have sufficient energy to promote the homolytic bond fission between the carbonyl and the α-carbon due to the stability of the resulting pentadienyl radical **51**. As a consequence, the photodecarbonylation path competes favorably with the ODPM rearrangement.

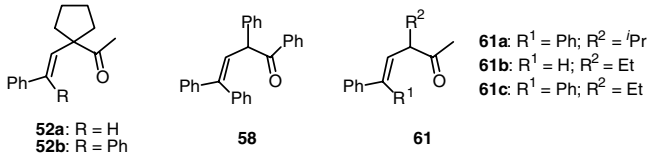
These observations have forced us to modify some of the conclusions of our previous studies. Specifically, the results indicate that, although substituents should be present to stabilize the intermediate biradicals in order to detect ODPM photoreactivity in β,γ-unsaturated aldehydes, they should not enhance alternative reactions, such as allylic homolytic cleavage. Additional examples of this unusual reactivity are collected in the following section. However, further studies will be necessary to confirm this hypothesis and to determine the scope of these new reactions.



SCHEME 10

77.4 A Comparative Study on the ODPM Rearrangements of β,γ-Unsaturated Aldehydes and Methyl Ketones

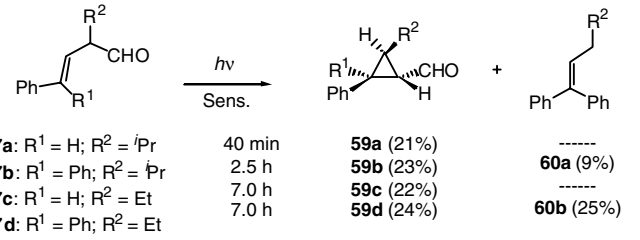
An interesting observation made in our preliminary study is that β,γ-unsaturated aldehyde **10** undergoes photoinduced ODPM rearrangement while the analogous methyl ketone **4** does not react in this manner.[14b] This result suggests that other aldehydes with substitution patterns similar to those found in ODPM unreactive ketones might participate in this photorearrangement process. Previous studies have shown that methyl ketone **52a** is not reactive in the ODPM mode.[3a] The corresponding aldehyde **53a**, which has the same substitution pattern as **52a**, according to our postulates should undergo the ODPM rearrangement. To test this proposal, we have carried out a study on the photoreactivity of aldehydes **53a** and **53b**. Triplet-sensitized irradiation of **53a**, for 1 h, leads to generation of the spirocyclic derivative **54a** (36%), as the *trans*-diastereoisomer, and the aldehyde **55** (13%), resulting from 1,3-formyl migration (Scheme 10). Irradiation of the diphenyl analog **53b**, for 2 h, under the same conditions used for **53a**, gives rise to the ODPM product **54b** (24%), the alkene **56** (5%), and recovered starting material (53%) (Scheme 10).[19]



The formation of **56** is a further example of the novel reaction similar to a Norrish Type I process that takes place via the T_1 ($\pi\pi^*$) excited state. This decarbonylation reaction might be due to the stabilization of the radical resulting from homolytic fission of the bond between the formyl group and the α-carbon, similar to the reaction observed for compound **47**. In contrast, the methyl ketone derivative **52b** does not undergo the ODPM rearrangement on triplet-sensitized irradiation for 17 h; rather it yields recovered starting material (71%) and a complex mixture of products.[19] These additional examples add further support to the proposal that β,γ-unsaturated aldehydes are more prone to undergo the ODPM rearrangement than the corresponding methyl ketones.

In an attempt to establish the limits for ODPM reactivity of β,γ-unsaturated aldehydes, we have extended our studies to aldehydes **57a,b,c,d**, which are monosubstituted at C2. The large number of studies carried out in the di-π-methane area have established that disubstitution at the central carbon of acyclic 1,4-unsaturated substrates is an important structural requirement for efficient rearrangement. In fact, compounds **2**[3] and **58**[21] are the only acyclic β,γ-unsaturated ketones monosubstituted at C2 that undergo the ODPM rearrangement.

Triplet-sensitized irradiation of **57a,b,c,d** leads to formation of the corresponding cyclopropanecarbaldehydes **59ab,c,d** in *ca.* 20% yield (Scheme 11). The ODPM rearrangement of aldehydes **57** is stereoselective, yielding only one diastereoisomer of **59**. The diphenyl-substituted aldehydes **57b** and **57d** yielded, in addition to the ODPM products, the corresponding alkenes **60a** and **60b**, resulting from photodecarbonylation. The formation of these alkenes is probably due to stabilization of the radical, formed by allylic cleavage, by diphenyl-conjugation, as in the cases of aldehydes **47** and **53b**.[19]



SCHEME 11

The ODPM reactivity of aldehydes **57** is surprising because, as mentioned before, the only two ODPM reactive acyclic β,γ-unsaturated mono-C2 substituted ketones are compounds **2**[3] and **58**,[21] each containing bulky substituents at C2. However, the observations made with **57c** and **57d**, each having ethyl groups at C2, clearly demonstrates that the bulk of the C2 substituent is not an important feature in determining the ODPM reactivity of β,γ-unsaturated aldehydes. However, it should be noted that, the isopropyl-substituted aldehydes **57a** and **57b** do react more efficiently, in qualitative terms, than **57c** and **57d**.

Compounds **61a,b,c** were synthesized in an effort to determine if the aldehydes **57** are more reactive toward the ODPM than the corresponding methyl ketones. Prolonged irradiation of **61a** and **61c**, under the same conditions used for **57**, afforded a complex mixture of highly polar materials (*ca.* 20%) along with recovered starting material (*ca.* 80%). Compound (*E*)-**61b** does not undergo the ODPM rearrangement. Irradiation of this ketone affords the corresponding diastereoisomer (*Z*)-**61b** in 50% yield and 25% of recovered starting material, exclusively.[19] These results confirm the postulate that β,γ-unsaturated aldehydes are better substrates for ODPM rearrangement. In this regard, there are questions that still remain to be answered. For example, it is surprising that ketone **2** has been reported to be ODPM reactive[3] while ketones **61a,b,c** do not undergo this rearrangement reaction.

In summary, the results of our current studies contrast with firmly established, but apparently incorrect, ideas about the photochemical reactivity of β,γ-unsaturated aldehydes and corresponding methyl ketones. Thus, from previous studies on photoreactivity of β,γ-unsaturated aldehydes a general consensus surrounding their lack of ODPM reactivity was originated. Most of the compounds studied previously underwent decarbonylation, with only two exceptions. The decarbonylation takes place via either the S_1 ($n\pi^*$) or T_2 ($n\pi^*$) excited states. The lack of ODPM reactivity of the aldehydes previously studied is probably due to the absence of the adequate substitution pattern that would allow efficient transfer of the triplet energy from the sensitizer to the alkene moiety. Therefore, the T_1 ($\pi\pi^*$) excited state, necessary for the ODPM rearrangement, would not be generated. However, our studies show that suitably substituted β,γ-unsaturated aldehydes do undergo the ODPM rearrangement with high chemical efficiency. The results obtained by us indicate that the ODPM rearrangement of β,γ-unsaturated aldehydes occurs when the triplet energy from the sensitizer is efficiently transferred to the alkene moiety generating a T_1 ($\pi\pi^*$) excited state and, furthermore, when the biradical intermediates are stabilized by phenyl or vinyl substitution. However, we have observed the first examples of reactions, similar to the well-known Norrish Type I process, which take place in the triplet excited state of β,γ-unsaturated carbonyl compounds by excitation of the C-C double bond instead of the carbonyl group. This situation occurs when the radical resulting from allylic homolytic bond cleavage is highly stabilized. In addition, a comparison of the photochemical reactivity of β,γ-unsaturated aldehydes and corresponding methyl ketones has shown that the ketones do not undergo the ODPM rearrangement while the corresponding aldehydes are reactive by this pathway. Finally, ODPM rearrangement of aldehydes monosubstituted at C2 is surprising because there are only two precedents of acyclic ketones with this type of substitution that undergo this photoreaction. Furthermore, the photoreactions of these substances are stereoselective, yielding only one of the possible diastereoisomeric cyclopropanecarbaldehyde products. When combined, the results of our studies broaden the synthetic potential of the ODPM rearrangement.

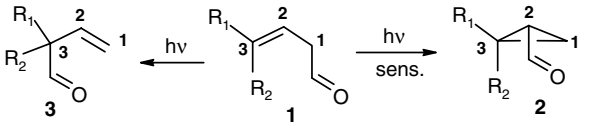
Photochemical Rearrangements in β,γ-Unsaturated Enones: The Oxa-di-π-methane Rearrangement

Vishwakarma Singh
Indian Institute of Technology, Bombay

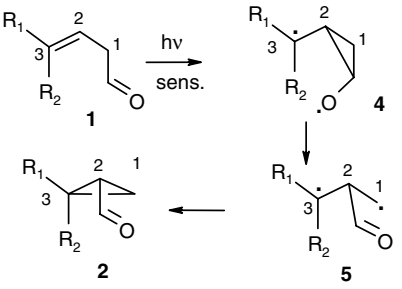
78.1 Introduction and Background

Photochemical reactions of compounds containing a β,γ-enone chromophore have generated intense interest for more than two decades[1–4] and even more so in recent years.[5–7] Several excellent reviews dealing with various aspects of β,γ-enone photochemistry have appeared.[1–7] A good historical background on the photoreactions of β,γ-enones is described by Schuster.[4] In principle, β,γ-enones can undergo photoreactions that are characteristic of carbonyl and olefinic chromophores, such as photoreduction, epimerization and *cis,trans*-isomerization, [2+2]-cycloaddition, etc. They also undergo two unique reactions as

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1



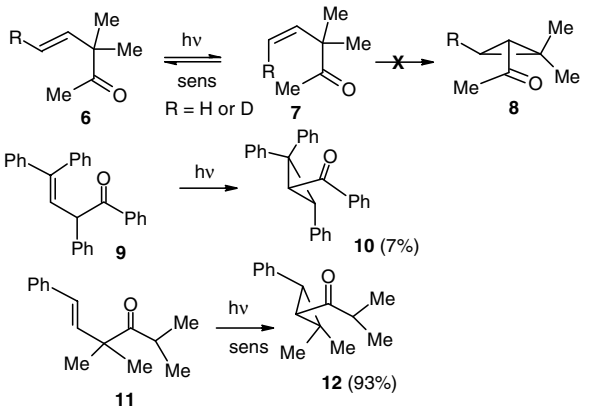
SCHEME 2

a result of interaction between the alkene and carbonyl chromophore. In general, it has been observed that sensitized irradiation of β,γ-enones induces a 1,2-acyl migration that results in the formation of cyclopropyl conjugated ketones of type **2**, a reaction also known as oxa-di-π-methane rearrangement because of its analogy to the di-π-methane (Zimmerman) rearrangement. The direct irradiation of β,γ-enones leads to formation of enones of type **3** as a result of 1,3-acyl migration (Scheme 1).[4]

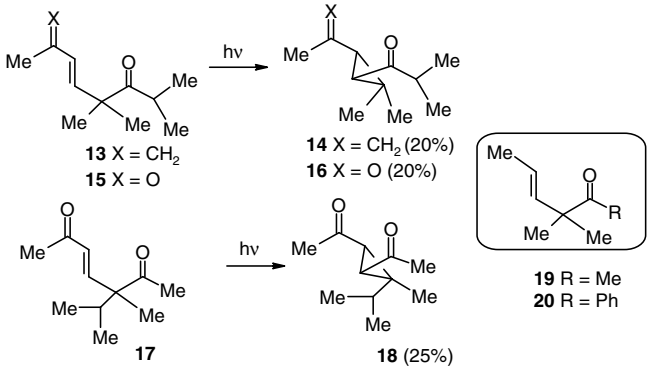
Of these photochemical reactions, the oxa-di-π-methane rearrangement (**1** → **2**) has been extensively studied from both mechanistic and synthetic perspectives. This reaction is highly general for constrained β,γ-enones and proved to be an excellent tool for organic synthesis.

78.2 Mechanism and Correlation of Excited State and Reactivity

The mechanism of the oxa-di-π-methane reaction and 1,3-acyl shift has been studied in great detail, and the correlation of excited-state reactivity has been established.[4–7] In general, the oxa-di-π-methane reaction occurs from the lowest triplet excited state (T_1, ππ*), while 1,3-acyl shift occurs either from the excited singlet (S_1, nπ*) state or the higher triplet (T_2, nπ*) state.[4,7–10] To induce the oxa-di-π-methane reaction (or 1,2-acyl shift) in β,γ-enones, direct excitation to a singlet state should be avoided and a careful choice of sensitizer having an E_T value close to the E_T of the enone should be made so as to selectively populate the lowest triplet excited state. The oxa-di-π-methane reaction path involves two biradical intermediates of type **4** and **5,** as first suggested by Givens and Oettle.[8] The biradical **4** is formed as a result of initial bonding between the carbonyl carbon and β-carbon of the C–C double bond, which undergoes cleavage of the cyclopropane ring to regenerate the CO group and gives the short-lived biradical **5** that rapidly closes to give the cyclopropyl ketone **2** (Scheme 2).[8–13] Although the existence of the biradicals **4** and **5** and the multiplicity of the surfaces on which these are formed have not been demonstrated directly, experimental results [stereochemistry of the reaction CIDNP (chemically induced dynamic nuclear polarization), radical trapping experiments, and quantum yield measurements] support their existence.[4–7] The detailed mechanism of these reactions, however, depends on the structure of the chromophore and the presence of other functionalities in a subtle fashion.[4,5] Recently, the mechanism of ODPM and 1,3-acyl shift based on theoretical calculation and other studies, in terms of potential energy surface and decay funnels, has been described.[14]



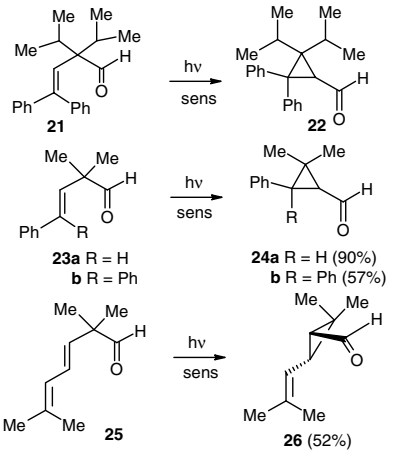
SCHEME 3



SCHEME 4

78.3 Oxa-di-π-methane Reactions in Acyclic β,γ-Enones

Acyclic compounds having a β,γ-enone chromophore do not undergo oxa-di-π-methane rearrangement efficiently, except in those cases where the C–C double bond is further conjugated to a phenyl or vinyl group and with a substituted central carbon. This is mainly because other channels of deactivation of the triplet excited state, such as *cis,trans-* isomerization, become more important than the oxa-di-π-methane pathway. This type of energy dissipation is also known as the free rotor effect in β,γ-enones, which is analogous to similar formulations for the lack of di-π-methane reactivity in acyclic 1,4-dienes in unconstrained systems.[1] Thus, the simple β,γ-enones with an unsubstituted C–C double bond such as **6** undergo *cis,trans*-isomerization without formation of ODPM product **8**.[15] The ketone **9,** having phenyl substituents on the central, γ-, and carbonyl carbons, gave the ODPM product **10** in low yield upon direct irradiation,[16] and the ketone **11** was found to give the cyclopropyl ketone **12** efficiently (93%) (Scheme 3) as a result of ODPM reaction.[17] Moreover, the ketone **13**, in which the β,γ-ene moiety is conjugated with a vinyl group, underwent smooth ODPM reaction upon sensitized irradiation to give **14**.[18] Interestingly, the direct irradiation of **15** and **17** led to ODPM reaction (albeit in low yield) to furnish the cyclopropyl compounds **16** and **18,** respectively (Scheme 4).[18] From these results and photochemical reactions of other acyclic β,γ-enones,[19–23] it appears that the conjugation of the alkene moiety with vinyl, phenyl, or oxo groups and disubstitution or substitution by bulky groups are important



SCHEME 5

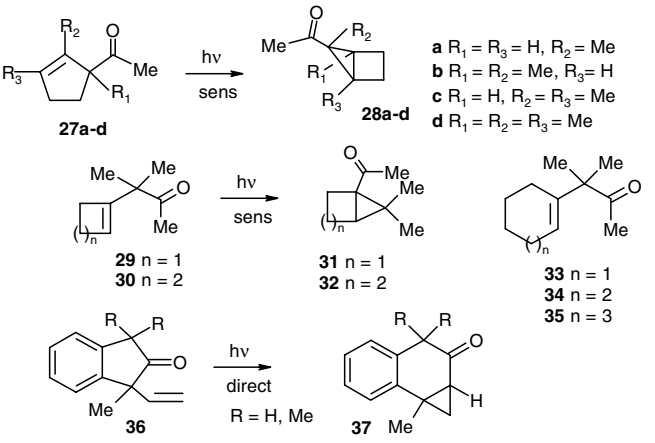
structural features that control ODPM reaction in acyclic β,γ-enones. However, the ketones **19** and **20** did not undergo oxa-di-π-methane reaction.[23]

Earlier attempts to bring about an oxa-di-π-methane reaction of β,γ-unsaturated aldehydes were unsuccessful.[24–26] Zimmerman and Cassel reported ODPM reaction of the aldehyde **21** (Scheme 5) to give the highly crowded cyclopropyl compound **22** in moderate yield.[27] Recently, Armesto and co-workers[28,29] reported efficient oxa-di-π-methane reactivity in the aldehydes **23** on sensitized irradiation to give the corresponding products **24**. Interestingly, the diene-aldehyde **25** undergoes a stereoselective oxa-di-π-methane reaction to give the *trans*-cyclopropane aldehyde **26** upon *m*-methoxyacetophenone-sensitized irradiation, in reasonably good yield (Scheme 5).[29]

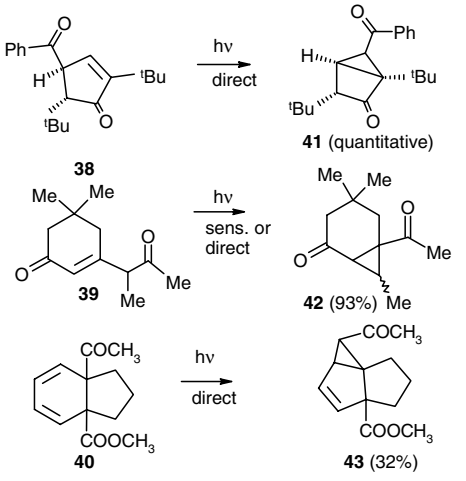
78.4 Oxa-di-π-methane Reaction in Semicyclic β,γ-Enones

β,γ-Enones in which one (or both) of the chromophores form part of a ring, undergo oxa-di-π-methane reactions with better efficiency compared to their acyclic counterparts and are less dependent on substitution pattern. Excitation of a series of ketones of type **27,** in which the double bond is present in a five-membered ring, led to the oxa-di-π-methane products **28**.[29,30] It has been shown that the degree of flexibility of the C–C double bond (effect of ring size) affects the efficiency of the oxa-di-π-methane reaction. Thus, the ketones **29** and **30,** having a C–C double bond in the four- and five-membered rings, respectively, gave ODPM products upon sensitized irradiation in acetone, but the ketones **33**, **34**, and **35** were unreactive (Scheme 6).[31] Interestingly, the enone **36** underwent ODPM reaction to give **37** upon direct irradiation, apparently via $S_2(\pi\pi^*)$.[32] Further, ketones of type **38,**[33] **39,**[18] and **40,**[34] wherein the β,γ C–C double bond is further conjugated, also gave ODPM products **41**, **42**, and **43**, respectively (Scheme 7). The efficiency and yield of the ODPM product in photoreaction of **39** and **40** are wavelength dependent.

Studies on photochemical reaction of β,γ-enones in which both the chromophores are present in different rings provided an in-depth understanding of the stereochemical and mechanistic features of oxa-di-π-methane rearrangements.[9,10] Sensitized irradiation of the optically active enone **44** gave ODPM product **47** in optically pure form.[9] Irradiation of **45** also gave the ODPM product **48** (Scheme 8).[10] Similarly, sensitized photoreaction of the enone **46,** in which five-membered ring is part of the indane ring system, also gave the corresponding ODPM product **49**.[32] Recently, an interesting ionic heavy-atom effect on the photochemical reaction of **44** was observed by Scheffer and co-workers.[35] While the direct irradiation of **44** primarily affords the 1,3-acyl shift product, irradiation of the heavy-atom salts of **44** in the crystalline state gives the ODPM product.[35]



SCHEME 6

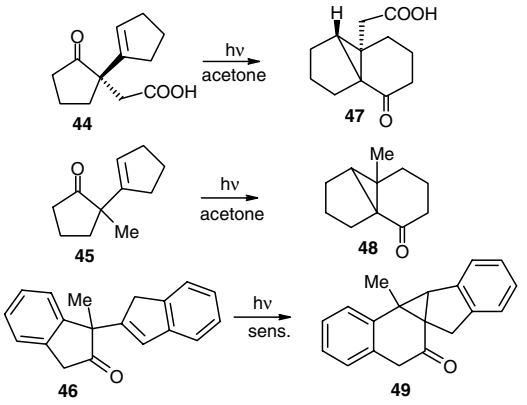


SCHEME 7

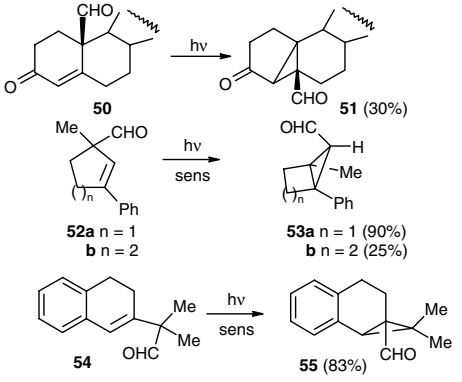
Some of the aldehydes that were reactive toward oxa-di-π-methane reaction are given in Scheme 9. Direct irradiation of the steroidal aldehyde **50** was reported to give the ODPM product **51** in 30% yield, along with two other products.[36] Armesto recently reported the photoreaction of a number of aldehydes, including **52** and **54** that rearranged to the corresponding ODPM products **53** and **55**, respectively, on sensitized irradiation.[28,29]

78.5 Oxa-di-π-methane Reactions in Monocyclic and Ring-Fused Bicyclic β,γ-Enones

The ketones **56**, **57**, and **58** are some of the monocyclic β,γ-enones whose photochemical reactions upon sensitized irradiation have been examined. Irradiation of the dienone **56** in ether is reported to give the bicyclic ketone **59** via oxa-di-π-methane reaction.[37] Recently, the photoreaction of cyclohexadienone **56** and its derivatives having chiral auxiliaries was examined in alkali ion exchanged Y zeolites.[38] Thus, irradiation of **56** in dry (−)-ephedrine-modified zeolite gave the ODPM product in 30% *ee*. Significant



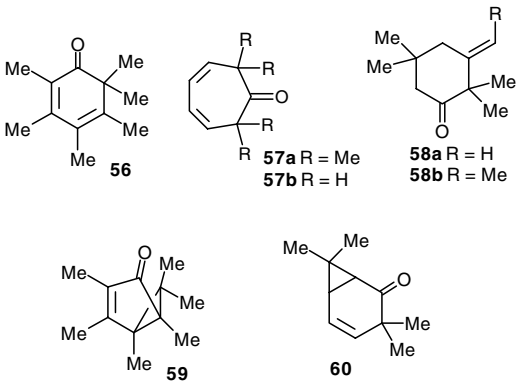
SCHEME 8



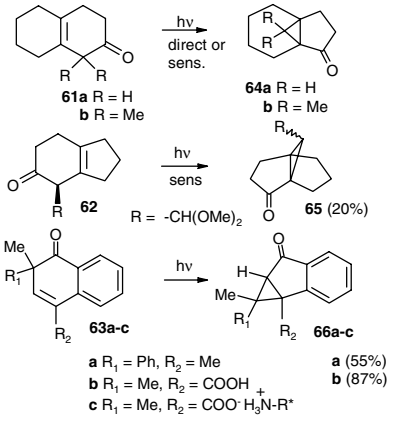
SCHEME 9

enantioselectivity (in the case of achiral) and diastereoselectivity (in the case of chiral) in cyclohexadienones was observed.[38] These studies indicated that photoreaction in modified zeolites may induce asymmetric induction. The cycloheptadienone **57a**, having methyl groups, also gives the ODPM product **60** upon sensitized irradiation, but the unsubstituted analogue **57b** undergoes conrotatory pericyclic reaction and does not give the ODPM product.[39] The enones **58a** and**58b**, in which the β,γ-C=C double bond is exocyclic, also do not undergo oxa-di-π-methane reaction; instead *cis*,*trans*-isomerization is observed (Scheme 10).[40]

A variety of fused bicyclic compounds having a β,γ-enone chromophore have been reported to undergo oxa-di-π-methane reaction upon irradiation.[41–44] Interestingly, both the direct as well as sensitized irradiation of enone **61a** gives the oxa-di-π-methane reaction product **64a**, while the dimethyl analogue **61b** gives ODPM product **64b** only upon sensitized irradiation.[41] It appears that **61a** undergoes efficient intersystem crossing to produce the triplet state, which is responsible for the oxa-di-π-methane reaction.[41] The presence of methyl groups in **61b** induces α-cleavage upon direct irradiation and hence leads to a 1,3-acyl shift. Similarly, the enone **63a** gives the ODPM product **66a** as a major product upon direct irradiation,[44] while the optically pure ketones **62** undergo the oxa-di-π-methane reaction upon sensitized irradiation to give **65** as a mixture of diastereomers.[42] Photochemical reaction of **63b** and **63c** were examined in solution and solid state, respectively.[45] Irradiation of **63b** in solution at 350 nm gave the ODPM product **66b** in excellent yield (87%). Irradiation of the quaternary ammonium salts of type **63c**



SCHEME 10



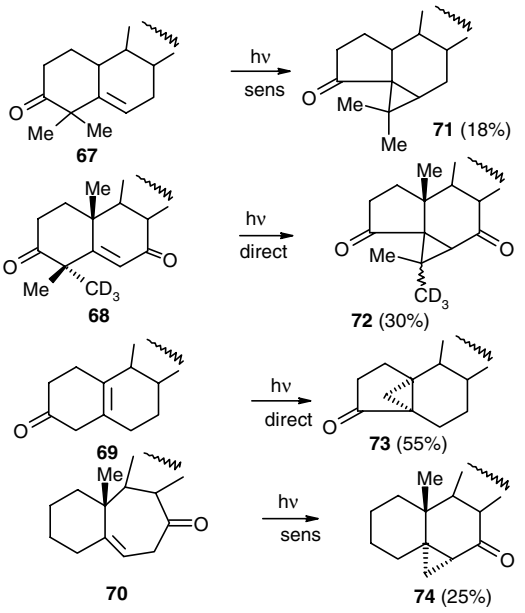
SCHEME 11

containing chirality furnished ODPM products in an enantioselective manner. The best ee (81%) was obtained with the salt derived from α-methylbenzylamine (Scheme 11).[45] These studies may form a basis for developing methods for asymmetric induction in photoreaction of β,γ-enones.

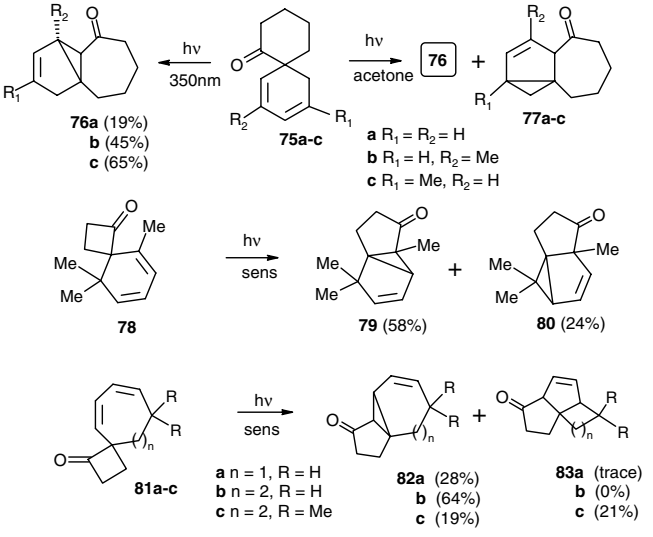
Photochemical reaction of several steroidal β,γ-enones have been examined.[46–49] Thus, the ketones **67** and **70** underwent oxa-di-π-methane reaction on sensitized irradiation,[46,49] while **68** and **69** gave ODPM products upon direct irradiation (Scheme 12).[47,48] The modified steroidal ketone **70** gave the ODPM product **74** on direct irradiation as well.[49] It appears that the dihedral angle between the carbonyl and vinyl groups in the enones controls the efficiency of population of the triplet excited state on direct irradiation and, hence 1,3-acyl shift vs. 1,2-acyl shift (oxa-di-π-methane) selectivity.[50]

78.6 Oxa-di-π-methane Reactions in Spirocyclic β,γ-Enones

Photoreaction of a series of spirocyclic compounds having β,γ,δ,ε-unsaturated carbonyl groups have been studied (Scheme 13).[51–53] The spirodienones of type **75** exhibited interesting photochemical reactions depending on the wavelength of irradiation. While direct irradiation at 350nm gave the oxa-di-π-methane product **76** in a regio- and stereoselective fashion, sensitized irradiation in acetone gave **77** due to vinylogous ODPM reaction, in addition to **76**.[51,52] The ratios of various products formed in acetone-sensitized irradiation was found to be dependent on substitution. It is suggested that the compound **76**



SCHEME 12



SCHEME 13

arises during direct irradiation from $T_2(\pi\pi^*)$, which is populated via intersystem crossing, while the vinylogous ODPM product **77** formed from $T_1(\pi\pi^*)$.[52] Enantioselective oxa-di-π-methane reaction in compounds of type **75** (R_1 = H, R_2 = COOMe) has also been observed.[51] Sensitized irradiation of the spiro dienone **78** gave significant amounts of **80** as a result of vinylogous ODPM reaction, in addition to **79**. Similarly, irradiation of the compound **81c** also gave **82** and **83**. The enones **81a** and **81b** without methyl groups gave primarily the ODPM products **82a** and **82b** (Scheme 13), respectively.[53] Here also, the effect of substitution on the formation of vinylogous ODPM products was noted.[53]

SCHEME 15

78.7 Oxa-di-π-methane Reactions in Cyclic Bridged β,γ-Enones

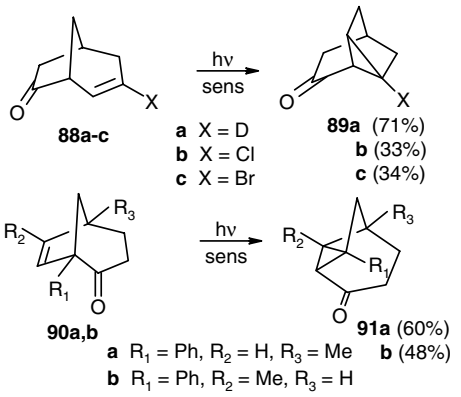
Compounds containing a β,γ-enone chromophore in a conformationally rigid carbocyclic framework undergo oxa-di-π-methane rearrangement more efficiently than other structural types. Bridged compounds in which both the alkene and the carbonyl chromophores are part of constrained ring systems constitute the largest class of β,γ-enones that have been studied and found to undergo oxa-di-π-methane reaction and constitute a very important synthetic methodology. Oxa-di-π-methane reactions in bridged cyclic systems generally give very good yields of the rearranged products in a highly regio- and stereoselective fashion, and also efficiently generate novel carbocyclic structures that are otherwise not readily accessible through ground-state chemical reactions. Photochemical studies on bridged ketones, especially the oxa-di-π-methane reaction, have been most fruitful in terms of the theoretical and mechanistic understanding of this rearrangement and have also provided a unique methodology for organic synthesis. There are a number of examples wherein oxa-di-π-methane reaction in a bridged cyclic system has been employed as a key step in the total synthesis of natural products (*vide infra*).

Bicyclo[2.2.1]heptenones

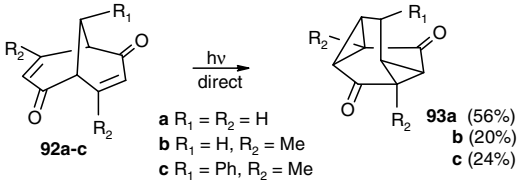
Among bridged bicyclic β,γ-enones, photoreactions of only a few systems with a bicyclo[2.2.1]heptane framework have been studied.[54–56] Thus, sensitized irradiation of **84a** and **84b** gave the corresponding ODPM products **85a** and **85b** in major amounts, respectively (Scheme 14).[54] Recently, ODPM reaction in **84a** induced by an external heavy cationic effect in zeolite was also observed.[56] Acetone-sensitized irradiation of the tricyclic system **86** was reported to give 2,8-didehydro-9-noradamantanone **87** in moderate yield (Scheme 15).[57]

Bicyclo[3.2.1]octenones and Congeners

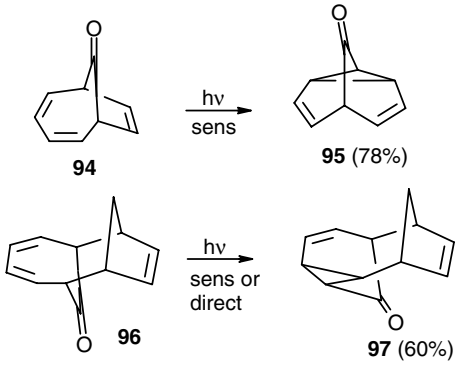
In context with mechanistic studies on the photoreaction of β,γ-enones, especially to resolve the singlet–triplet dichotomy, Givens and co-workers examined the photoreaction of **88a,b,c** upon sensitized and direct irradiations.[58] While direct irradiation led to the characteristic 1,3-acyl shift, acetone-sensitized irradiation of **88a,b,c** gave ODPM products **89a,b,c** (Scheme 16) along with 1,3-acyl shift products. The formation of the 1,3-shift product during sensitized irradiation presumably results either from direct absorption of light or singlet sensitization.[58] The chromophoric systems **90a** and **90b**, in which the CO group is present in the longer bridge, also gave ODPM products **91a** and **90b**, respectively, upon sensitized irradiation in acetone.[59] However, many systems closely related to **90** gave 1,3-acyl shift products during irradiation in acetone.



SCHEME 16

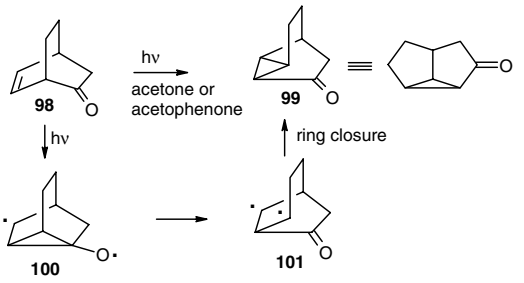


SCHEME 17

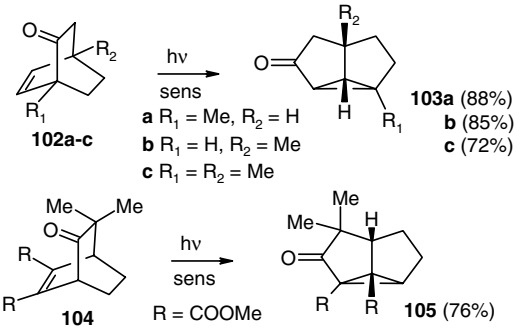


SCHEME 18

Interestingly, the dienediones **92** underwent double oxa-di-π-methane rearrangements upon direct irradiation to give triasteranedione **93** in moderate yields (Scheme 17).[60] The trienone **94** with a bicyclo[4.2.1]nonane ring system gave **95,** wherein the β,γ-C–C double bond of the diene moiety participated in the oxa-di-π-methane reaction.[61] Similarly, the trienone **96** also furnished the oxa-di-π-methane product **97** (Scheme 18).[62]



SCHEME 19

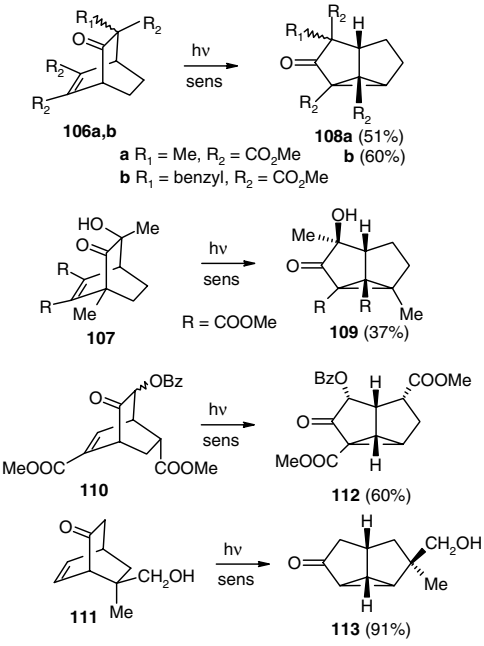


SCHEME 20

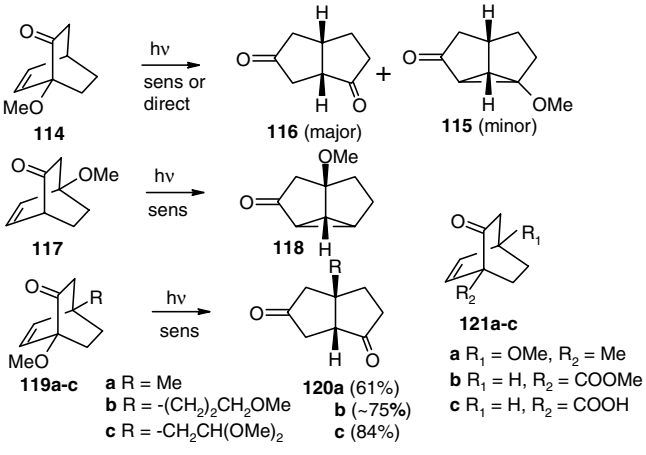
Bicyclo[2.2.2]octenones

Photochemical reactions of this class of compounds have been extensively studied. Bicyclo[2.2.2]octenones constitute an important class of β,γ-enones that stimulated intense interest in their photochemical reactions and a large amount of work has been reported. The oxa-di-π-methane rearrangement is one of the most general and versatile reactions of this class of β,γ-enones. Givens and co-workers reported the transformation of bicyclo[2.2.2]oct-5-en-2-one **98** into tricyclo[3.3.0^{2,8}]octan-3-one **99** upon sensitized irradiation in acetone.[63] Demuth and co-workers later examined the photoreaction of (+)- and (−)-**98** on sensitized irradiation in acetophenone, which gave the corresponding ODPM products in excellent yield (~85%) and demonstrated the stereoselectivity in the oxa-di-π-methane reaction.[64] The reaction proceeds through biradicals **100** and **101** (Scheme 19).[63,64] Photochemical reactions of a variety of bicyclo[2.2.2]octenones were studied and found to undergo efficient oxa-di-π-methane reaction. Thus, acetophenone-sensitized irradiation of **102**[64,65] and **104**[66] gave the tricyclooctanones **103** and **105**, respectively (Scheme 20). Other functionalized analogues of **104** have also been shown to undergo oxa-di-π-methane reaction upon sensitized irradiation.[67] Furthermore, the photoreaction of **106** and **107**, which contain ester and hydroxyl groups at the α′ position, also gave ODPM products **108** and **109,** respectively, upon acetophenone-sensitized irradiation (Scheme 21).[68,69] Liao[70] and Paquette[71] reported oxa-di-π-methane rearrangement of bicyclo[2.2.2]octenones **110** and **111,** leading to the tricyclic compounds **112** and **113,** respectively, upon acetone-sensitized irradiation (Scheme 21).

Bicyclo[2.2.2]octenones with α-methoxy groups undergo a remarkable photoreaction. Rogers and Parker investigated the photochemistry of **114** and its isomer **117,** and other related ketones, upon sensitized as well as direct irradiation.[72–74] Sensitized (acetone or acetophenone in benzene) irradiation of the enone **114**, with a methoxy group at the α-position, was found to give the dione **116** in major quantity; the expected ODPM product was obtained only in minor amounts (Scheme 22).[72] It was

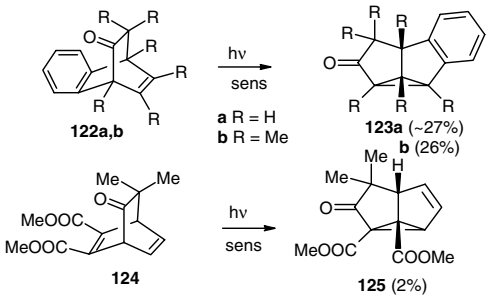


SCHEME 21

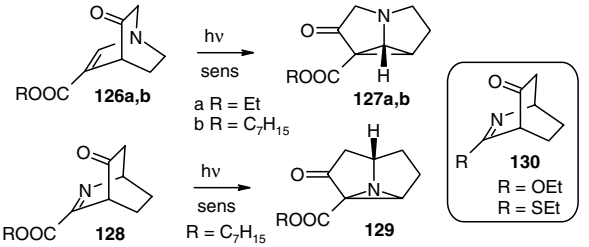


SCHEME 22

suggested that the final product **116** is formed via oxa-di-π-methane reaction followed by cleavage of the cyclopropane ring, loss of a methyl radical, and capture of a hydrogen radical.[72] Sensitized irradiation of **117**, on the other hand, gave the ODPM product **118,** accompanied by a small amount of the 1,3-shift product. It was suggested that the ODPM reaction in **117** originates from the excited singlet state.[74] The photochemical transformation of **114** provided a unique methodology for the synthesis of bicyclo[3.3.0]oct-2,5-dione of type **116** that are not readily available, and also enhanced the synthetic potential of the oxa-di-π-methane reaction. Demuth and co-workers also studied the photoreaction of more elaborate bicyclooctenones with α-methoxy groups and reported transformation of **119a,b,c** into **120a,b,c,** respectively, upon acetophenone-sensitized irradiation.[65,75] While a large number of substrates



SCHEME 23



SCHEME 24

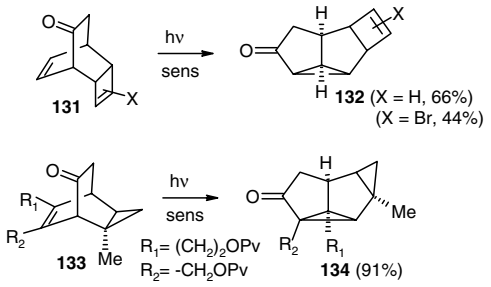
containing a β,γ-enone group in a bicyclo[2.2.2]octane system underwent oxa-di-π-methane rearrangement upon sensitized irradiation, it seems that minor structural changes in the chromophoric system affects this photorearrangement in a very subtle fashion because the compounds of type **121** did not undergo the ODPM reaction (Scheme 22).[65]

The photoreaction of other bicyclo[2.2.2]octenones, and their congeners with more than one β,γ-C–C double bond, have the possibility of dual deactivation pathways; for example, ODPM and di-π-methane reaction upon excitation have been examined.[8,68,76–79] The benzobicyclo[2.2.2]octenones **122a**[8] and **122b**[76] are some of the earlier examples that were found to follow the ODPM reaction pathway upon acetone-sensitized irradiation that involved the non-benzenoid C–C double bond to give the products **123a** and **123b**, respectively, albeit in low yield (Scheme 23). The bicyclo[2.2.2]octadienone **124,** however, yielded a very small amount of ODPM product. The major product was due to di-π-methane reaction.[77]

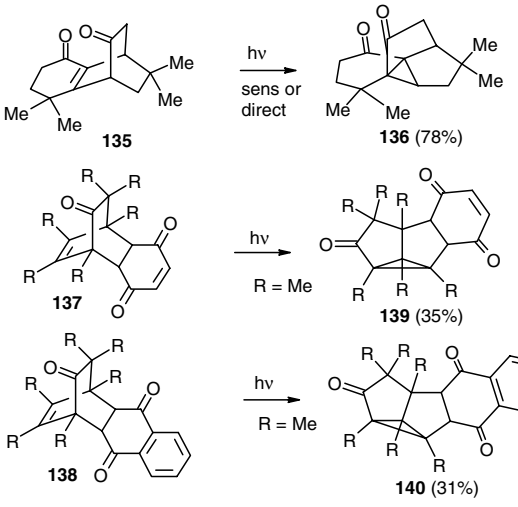
Most recently, oxa-di-π-methane rearrangement in aza-bicyclo[2.2.2]oct-2-en-5-one was explored; this provides a novel route to pyrrozolidine alkaloids.[78] Thus, sensitized irradiation of **126** and **128** furnished azabicyclo[3.3.0]octanones **127** and **129,** respectively (Scheme 24). However, the derivatives **130** did not undergo the oxa-di-π-methane reaction.[78]

Oxa-di-π-methane Rearrangements in Polycyclic-Bridged β,γ-Enones

A variety of compounds containing a β,γ-enone chromophore in a complex molecular framework have been synthesized and their photochemical reactions have been examined. In the majority of the chromophoric systems, the β,γ-enone group is part of a bicyclo[2.2.2]octane framework in which the oxa-di-π-methane reaction is most general and efficient. Mehta and Srikrishna[79] reported an oxa-di-π-methane reaction in the tricyclic compound **131** and its halo analogue that, upon sensitized irradiation, gave **132**. It is interesting to note that $[\pi^{2s}+\pi^{2s}]$-cycloaddition was not observed. Similarly, the β,γ-enone **133** underwent the ODPM reaction to give the compound **134** with a cyclopropane annulated bicyclo[3.3.0]octane framework, in excellent yield (Scheme 25).[80]



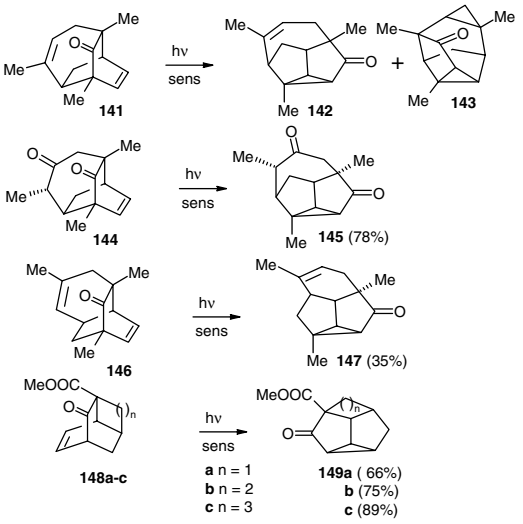
SCHEME 25



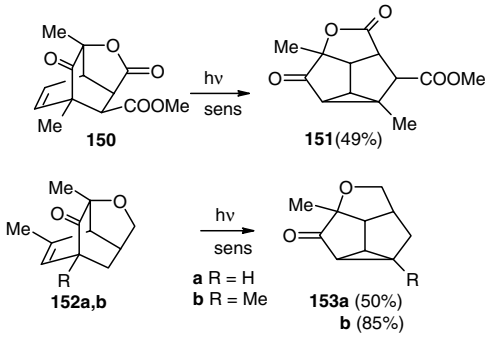
SCHEME 26

The functionally more complex ene-dione **135** also gave an oxa-di-π-methane reaction product **136** upon direct as well as sensitized irradiation. It is suggested that the ODPM occurs from the lowest triplet state (T_1) during direct irradiation.[81] Hart and co-workers[82] examined the photoreaction of the tri- and tetracyclic compounds **137** and **138** in various solvents. Irradiation of **137** in acetone, as well as in acetonitrile, dichloromethane, and cyclohexane, gave the ODPM product **139** in addition to a cage compound as a result of intramolecular [$\pi^{2s}+\pi^{2s}$]-addition. Irradiation of **138** gave the ODPM product exclusively (Scheme 26).

Schmid and Kanagawa reported the photoreaction of the β,γ, γ′, δ′unsaturated ketone **141** and analogues.[83] Thus, the dienone **141** was found to undergo the oxa-di-π-methane (1,2-shift) reaction upon sensitized irradiation in acetone to give **142,** in addition to **143** arising as a result of 1,4-shift. The ratio of **142**:**143** depends on irradiation time. Interestingly, the enedione **144** underwent a very efficient ODPM reaction to yield the tetracyclic product **145** in excellent yield (Scheme 27).[83] Apparently, the photochemistry of the β,γ-enone takes preference over the reaction of the carbonyl group. Schultz and co-workers reported the oxa-di-π-methane rearrangement of ketoesters **148** and their analogues. The ketoesters **148a** and **148c** underwent acetophenone-sensitized irradiation to give **149a** and **149c,** while **148b** gave the corresponding ODPM product upon acetone sensitization, in high yields.[84]



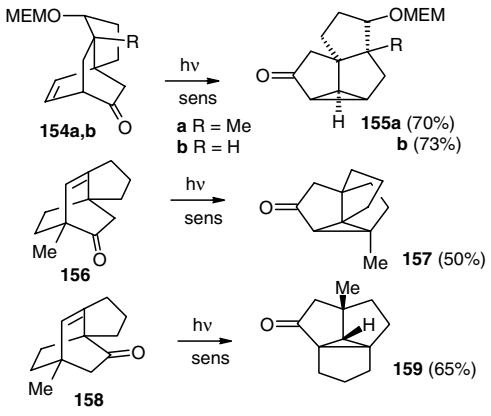
SCHEME 27



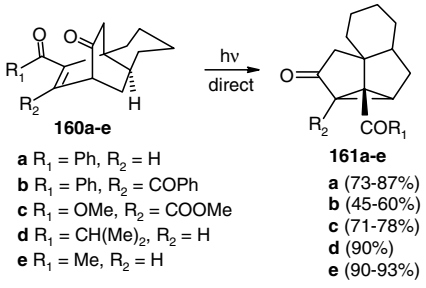
SCHEME 28

Bicyclic[2.2.2]octenones annellated with an oxygen heterocyclic ring also underwent the oxa-di-π-methane reaction upon sensitized irradiation. The tricyclic compounds **150**[66] and **152**[85] gave oxa-di-π-methane products **151** and **153,** respectively, upon sensitized irradiation in acetone (Scheme 28).

Another class of bicyclooctenones whose photoreaction was examined is shown in Scheme 29. Acetone-sensitized irradiation of the tricyclic enones **154a**[86] and **154b**[87] furnished the tetracyclic products **155a** and **155b** in excellent yield and provide a novel method for the synthesis of angular triquinanes. Similarly, the tricyclic compounds **156** and **158** underwent the oxa-di-π-methane reaction upon irradiation in acetone to give the tetracyclic compound **157** containing the [3.3.3]propellane framework and the compound **159,** respectively (Scheme 29).[88,89] The compounds of type **160a–e** containing the δ-keto-β,γ-enone chromophore were also reported to give ODPM products upon direct as well as sensitized irradiation, and the products arise through excited states other than the lowest triplet (Scheme 30).[90,91] It may be noted that the oxa-di-π-methane reaction of these and the other compounds described above provide an efficient preparative route to a variety of carbocyclic systems that are not readily accessible otherwise.



SCHEME 29

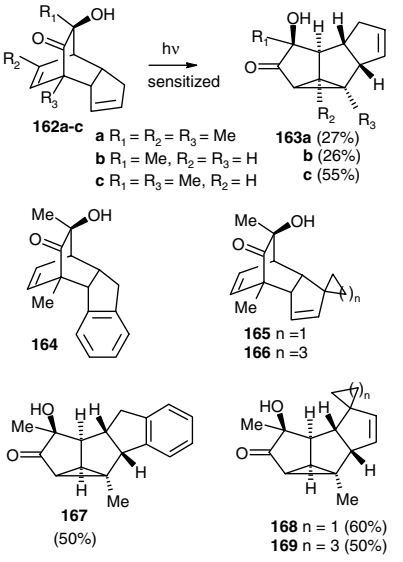


SCHEME 30

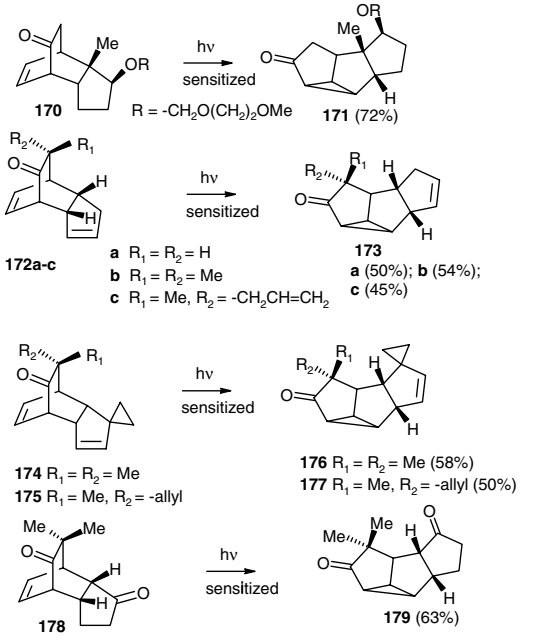
Oxa-di-π-methane Reactions in Polycyclic-Bridged β,γ-Enones Leading to the Linear Triquinane Framework

The recent interest in the chemistry of polyquinane natural products[92,93] has stimulated intense activity in the development of novel, efficient, and stereoselective methodologies for the construction of triquinanes, and the oxa-di-π-methane reaction has played a very important role in this endeavor. A number of tricyclic systems containing a β,γ-enone chromophore were designed, and their photochemical reactions upon triplet-sensitized irradiation were investigated and provided excellent routes to triquinanes. The tricyclo[5.2.2.0.^{2,6}]undecanes of type **162**, incorporating an α′–hydroxy-β,γ-enone, are transformed to the tetracyclic compounds **163** on sensitized irradiation[94,95] and are some of the earlier examples of oxa-di-π-methane reaction in such compounds. Other interesting examples include ODPM reactivity in compounds **164**, **165**, and **166,** which gave the tetracyclic compounds **167**, **168**, and **169**, respectively, in good yields (Scheme 31).[95–97] It is interesting to note that no intramolecular cycloaddition was observed during the irradiation of compounds **162**, **165**, and **166**.

Other examples of oxa-di-π-methane rearrangements of the tricyclo[5.2.2.0^{2,6}]undecane framework containing various substituents and functional groups are presented in the Scheme 32. The tricyclic compound **170** underwent an efficient ODPM reaction to give **171** upon acetone-sensitized irradiation (300 nm).[86] A number of other chromophoric systems having substituents and functional groups were prepared and their oxa-di-π-methane reaction was examined. Thus, compounds **172a,b,c**, **174**, **175**, and **178** all underwent oxa-di-π-methane reaction upon sensitized irradiation in acetone to give the corresponding photoproducts (Scheme 32).[98] It is interesting to note that the tricyclic ene-dione **178** gave the



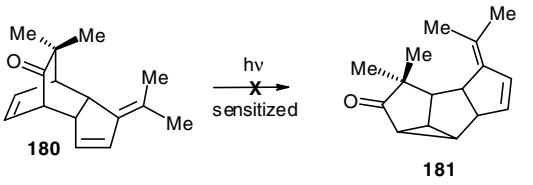
SCHEME 31



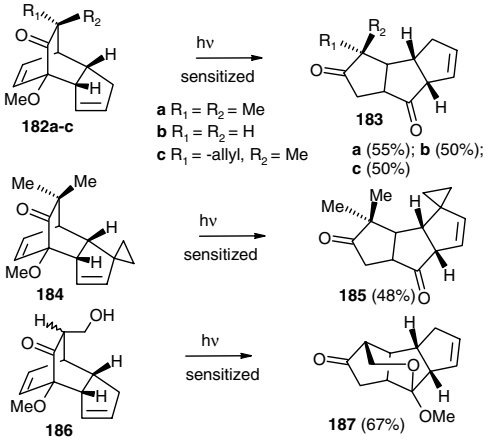
SCHEME 32

ODPM product selectively, even in the presence of the highly reactive carbonyl chromophore present in the five-membered ring.

The *cis:anti:cis*-orientation of the tricyclic framework in the ODPM products depicted above is obviously a result of the *endo*-stereochemistry of the ring annulated to the bicyclo[2.2.2]octenone framework. It should be mentioned that the generation of *cis:anti:cis*-tricyclic framework in a single stereoselective



SCHEME 33

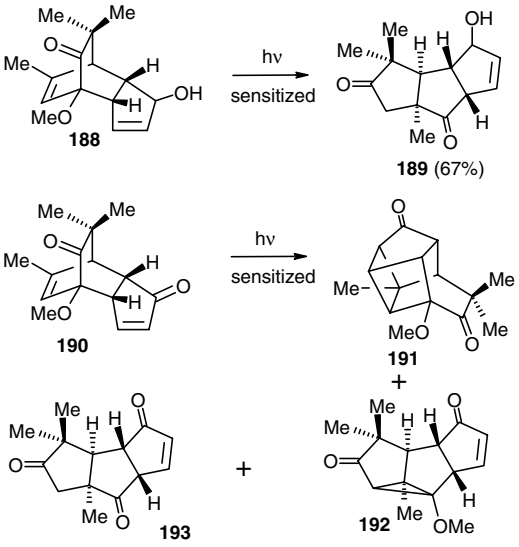


SCHEME 34

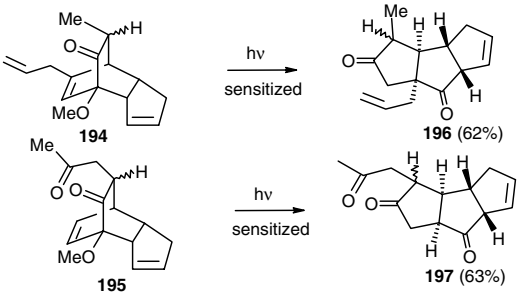
photochemical step has made oxa-di-π-methane reactions a potentially useful tool in the synthesis of polyquinane natural products.

Although a number of tricyclic compounds of the type mentioned above were ODPM reactive, sensitized irradiation of the trienone **180** did not give the ODPM product **181** (Scheme 33).[98] This is presumably due to the quenching effect of the *exo*-cyclic-1,3-diene moiety present in the annulated five-membered ring. The trienone **180**, however, undergoes a 1,3-acyl shift on direct irradiation.[98] These observations further confirm the general understanding regarding reactivity vs. excited states of β,γ-enones.

It is evident that the oxa-di-π-methane reaction of the *endo*-tricyclo[5.2.2.0^{2,6}]undecanes depicted above provides tetracyclic compounds containing a linearly fused *cis:anti:cis*-triquinane framework present in many natural products. However, the transformation of ODPM products to the tricyclopentanoid ring requires selective cleavage of the peripheral cyclopropane bond and thus poses various problems of regioselectivity.[97,98] To circumvent this difficulty, another class of *endo*-tricyclo[5.2.2.0^{2,6}]undecanes, with an α-methoxy group in addition to the β,γ-enone chromophore, was synthesized and their photochemical reactions investigated.[99–103] Sensitized irradiation of **182**, **184,** and their congeners were found to furnish the triquinane diones **183** and **185,** respectively, in reasonably good yields, thus providing a direct route to functionalized linear *cis:anti:cis* triquinanes (Scheme 34).[99,100] The photoreaction proceeds through initial oxa-di-π-methane rearrangement, followed by cleavage of the cyclopropane ring, loss of a methyl radical, and hydrogen abstraction.[74,100] Interestingly, tricyclic compounds **186** having hydroxyl methyl group at the α′ position gave the tetracyclic product **187** after sensitized irradiation in acetone (Scheme 34).[100] While the alcohol **188** underwent ODPM reaction to give the highly functionalized tricyclopentanoid **189**, the dienedione **190** gave a complex mixture of products, including the cage compound **191**, arising through intramolecular [$\pi^{2s}+\pi^{2s}$]-cycloaddition, the usual ODPM product **192,** and tricyclic enetrione **193** (Scheme 35).[101]



SCHEME 35



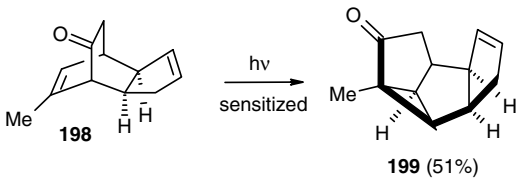
SCHEME 36

In addition to the above examples, more heavily substituted *endo*-tricyclic compounds **194** and **195** also underwent oxa-di-π-methane reaction to give **196** and **197**, respectively, on sensitized irradiation in acetone (Scheme 36).[102] These intermediates were converted into higher polyquinanes.[102] The dominance of the oxa-di-π–methane reaction in **195,** even in the presence of the additional carbonyl chromophore, is noteworthy. Bicyclo[2.2.2]octenones annulated with other higher rings have also been reported to show oxa-di-π-methane reactivity.[98,104]

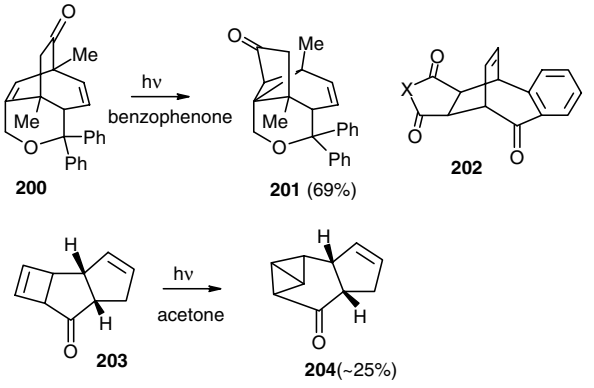
The aforementioned examples of *endo*-annulated bicyclo[2.2.2]octenones led to photoproducts containing a linear *cis:anti:cis*-triquinane framework. The stereochemical feature of the photoproducts in these examples is a direct consequence of stereoselectivity in the ODPM reaction and the orientation of the annulated ring. It is interesting to note that the sensitized irradiation of compound **198** with an *exo*-annulated five-membered ring gave the tetracyclic compound **199** containing a folded *cis:syn:cis*-triquinane ring system (Scheme 37).[105]

Oxa-di-π-methane Reactions in Miscellaneous Carbocyclic β,γ-Enones

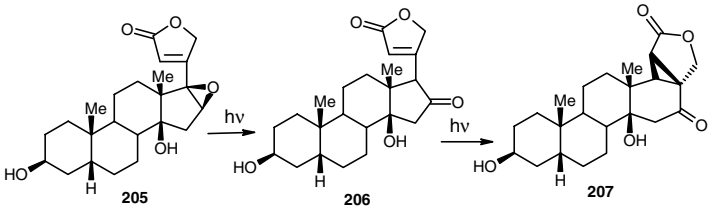
The compound **200** with a bicyclo[3.2.2]nonadienone ring system underwent oxa-di-π-methane reaction involving the C–C double bond in the ethano-bridge. This gives the product **201** selectively upon



SCHEME 37



SCHEME 38

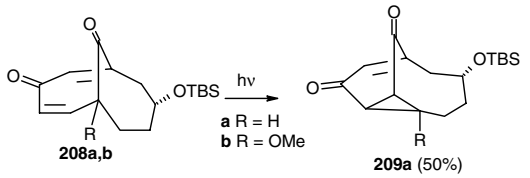


SCHEME 39

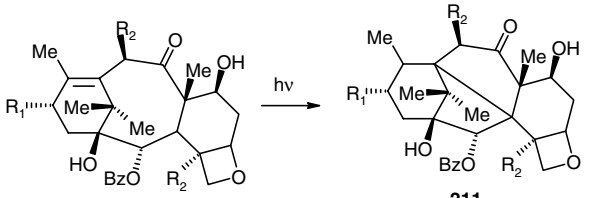
benzophenone-sensitized irradiation.[106] Other closely related compounds did not give ODPM products. Other benzo annulated compounds of type **202** did not undergo the ODPM reaction; instead, a di-π-methane reaction was observed upon sensitized irradiation.[107] Murata and co-workers reported oxa-di-π-methane reactions in the tricyclic compound **203** that gave the highly strained ring system **204** (Scheme 38).[108]

The steroidal epoxy compound **205** was reported to undergo rearrangement to the ketone **206,** which subsequently underwent an oxa-di-π-methane reaction to give the cyclopropyl compound **207** along with its stereoisomer and other compounds (Scheme 39).[109]

Recently, Sulikowski reported the oxa-di-π-methane rearrangement of **208a** with a bicyclo[4.4.1]undecane framework and a cross-conjugated dienone moiety in one of the bridges. This rearranges to **209a** upon direct irradiation in benzene. This reaction provides an interesting avenue to convert the bicyclo[4.4.1]undecane ring into a bicyclo[5.3.1]undecane ring system of taxanes. However, the analogue with a methoxy group at the bridgehead did not react by this path and instead undergoes a 1,3-acyl shift (Scheme 40).[110]



SCHEME 40



R_1 = -COCH(OH)CH(Ph)NHCOC$_6$H$_5$
R_2 = OCOCH$_3$

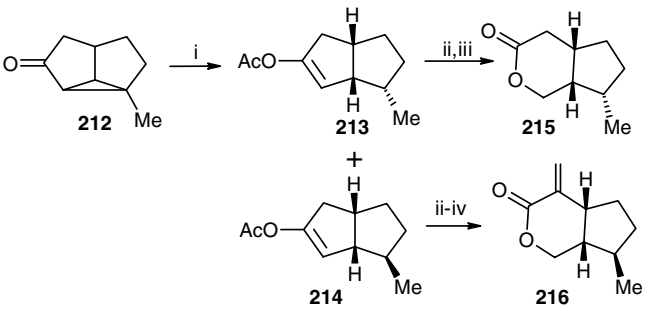
SCHEME 41

Taxol has been reported to undergo a highly interesting photochemical reaction that is dependent on the irradiation wavelength, the solvent, and also remote functional groups. Irradiation of taxol **210** at 280 nm in CCl_4 gave a pentacyclic isomer **211** in 55% yield (Scheme 41).[111] Similar results were also obtained in solvents such benzene and toluene, although the yield of the photoproduct was low. However, irradiation in acetone did not yield the pentacyclic isomer **211**. Remarkably, this photoreaction involves intramolecular energy transfer. The photoreaction proceeds through initial oxa-di-π-methane reaction via excitation of CO [$T_1(\pi\pi^*)$] group at C9, followed by migration of a hydrogen atom from C3 and subsequent bond formation between C3 and C11.[111]

Oxa-di-π-methane Reactions in the Synthesis of Natural Products

It may be evident from the foregoing examples that the oxa-di-π-methane rearrangement is a highly general reaction of β,γ-enones. A variety of substrates, especially those with constrained ring systems, undergo efficient ODPM reactions leading to different molecular frameworks in a stereo- and regioselective fashion. These systems are not readily accessible otherwise. However, its true synthetic potential was realized only recently. As a consequence, many types of chromophoric systems containing a β,γ-enone chromophore were synthesized and the oxa-di-π-methane reaction was employed in the synthesis of compounds of both natural and unnatural origin.[92,93,112] Some examples of the synthesis of natural products in which the ODPM reaction was employed as a key element are presented below. In such synthetic approaches, the assembly of the appropriate chromophoric system is also one of the important aspects and in many cases new methods were developed.

Demuth and co-workers reported the synthesis of a number of natural products containing a cyclopentane ring, such as boschnialactone, allodolicholactone, iridomyrmecin, and isoiridomyrmecin, employing a common intermediate **212** obtained by the oxa-di-π-methane rearrangement. Thus, cleavage of the cyclopropane ring with sodium–ammonia gave the diastereomers **213** and **214**. The intermediate **213** was converted to boschnialactone **215,** and the diastereomer **214** was elaborated to the allodolicholactone **216**. This latter compound was converted into iridomyrmecin and isoiridomyrmecin (Scheme 42).[65] The authors have also employed the ODPM reaction in an enantiospecific synthesis of loganin aglucone



Reagents/conditions: (i) Na, NH_3, ^{t}BuOH, Ac_2O, 60%; (ii) OsO_4, $NaIO_4$; (iii) $NaBH_4$, H_3O^+, 84%; (iv) $CH_2{=}N(Me)_2I$, LDA, MeI, DBN

SCHEME 43

acetate **218,** as shown in Scheme 43. Kon and Isoe have developed an alternate strategy for the synthesis of loganin from the same precursor **212**. [113]

Liao and co-workers carried out the synthesis of (±)-forsythide aglucone dimethyl ester **220** (Scheme 44). Cycloaddition of masked *o*-benzoquinone with DMAD was used to prepare the desired bicyclo[2.2.2]octenone **110**, which upon sensitized irradiation gave the diquinane intermediate **112**. Cleavage of the cyclopropane ring and functional group manipulation led to the dihydroxydiester **219,** which upon oxidative cleavage gave **220.**[70] In another synthesis of forsythide, the diquinane intermediate **98** was employed as a precursor.[114]

Studies on the synthesis of cedranoids, a class of sesquiterpenes that contains a bicyclo[3.2.1]octane ring system as well as diquinane ring, by Yates et al. constitute some of the earlier examples of the use of the oxa-di-π-methane reaction as a key step in this synthetic strategy.[66,67,115,116] Thus, the bicyclic compound **221** was prepared from 2,6,6-trimethylcyclohex-2-en-1,4-dione. Treatment with sodium methoxide furnished the bicyclic chromophoric system **222**, which contains the 12 carbons of a sesquiterpene and the diquinane framework in latent form. Sensitized irradiation of **222** in acetophenone provided the compound **223** in excellent yield. Cleavage of the cyclopropane ring and selective functional group manipulation, followed by the introduction of a two-carbon unit, gave the intermediate **224**. Cyclization gave the compound **225** containing the tricyclic framework of cedranoids. This was elaborated to cedranoid sesquiterpenes, biotols **226** (Scheme 45).[67,115]

Demuth and Hinsken reported the first synthesis of enantiomerically pure (−)-silphiperfol-6-en-5-one **228** from the optically pure tricyclic compound (+)-**154a** whose irradiation in acetone at 300 nm gave the ODPM product (−)-**155a**. This product contains most of the structural and functional features of **228**. Cleavage of the cyclopropane ring, introduction of a methyl group, and deoxygenation of the CO group furnished the triquinane intermediate **227** that was elaborated into the natural product **228** (Scheme 46).[117]

Uyehara and co-workers also employed the oxa-di-π-methane rearrangement to develop a common strategy for the formal syntheses of (±)-isocomene and (±)-modhephene.[118] The required bicycloocten-ones **229** and **232** were prepared from a common bicyclo[3.2.1]octenone precursor in several steps. The oxa-di-π-methane reaction of **229** gave the diquinane **230** in excellent yield. Cleavage of the cyclopropane ring and further manipulation led to the triquinane **231** containing the framework of isocomene. The keto-alcohol **231** was then elaborated to a known intermediate for isocomene. Similarly, photoreaction of the bicyclic octenone **232** gave the ODPM product **233** that was manipulated to give the intermediate **234** for modhephene (Scheme 47).[118]

SCHEME 48

Mehta's approach to modhephene also relied on the oxa-di-π-methane reaction. In this approach, the tricyclic compound **157** with the propellane framework of modhephene was directly generated by the ODPM reaction of the tricyclic system **156** (*vide supra*). The intermediate **157** was then elaborated into (±)-modhephene **236** (Scheme 48).[89] Thus, alkylation, reductive cleavage of the cyclopropane ring, followed by oxidation, gave the intermediate **235.** Alkylation followed by reduction of the carbonyl group gave a mixture of alcohols that was separated and the desired stereoisomer was treated with $POCl_3$ to give the natural product modhephene **236.**

Paquette and co-workers employed the oxa-di-π-methane product **134** for the synthesis of the antibiotic pentalenolactone P methyl ester, a highly functionalized sesquiterpene lactone. The oxa-di-π-methane reaction of **133** into **134** sets most of the stereochemical requirements of the target in a highly

Reagents/conditions: (i) hν, acetone, 74%; (ii) methylallyl chloride, KBr, ^{t}BuOH, ^{t}BuOK, toluene, 95%; (iii) Li, NH_3; (iv) OsO_4, $NaIO_4$, 43% yield for steps (iii and iv); (v) ^{t}BuOK, ^{t}BuOH, toluene, p-TsOH, reflux, ozone, 36%

SCHEME 50

selective fashion. Thus, **134** was converted to the enone aldehyde **237**. Reaction of **237** with methanolic sodium methoxide furnished the intermediate **238** having the tricyclic framework of pentalenolactone. Further manipulation gave the *dl*-pentalenolactone P methyl ester **239** (Scheme 49).[119]

Synthesis of (−)-coriolin **245**, a triquinane antibiotic, by Demuth and co-workers is one of the earliest examples wherein the oxa-di-π-methane reaction of the optically pure bicyclo[2.2.2]octenone **240** was a key step.[120] The requisite chromophoric system (−)-**240** was synthesized from hydroquinone and maleic anhydride in several steps, including resolution. Sensitized irradiation of **240** gave the diquinane intermediate **241** containing 11 of the carbons of coriolin. Introduction of an allyl chain, followed by reductive cleavage of the cyclopropane ring and oxidative degradation, furnished the intermediate **243** that was ready for annelation to create the third cyclopentane ring. Aldol condensation in **243** gave the tricyclic compound **244,** which was elaborated to coriolin (Scheme 50).[120]

It can be seen from the above examples that most of the syntheses involve diquinane intermediates that are generated by the oxa-di-π-methane reaction. The third ring is usually created through annelation. *endo*-Tricyclo[5.2.2.$0^{2,6}$]undecane skeleta of the type represented by **172** and **182** (*vide supra*) have been used as an approach to the synthesis of tricyclopentanoid natural products. It was envisaged that the oxa-di-π-methane reaction of such systems would lead directly to carbocyclic frameworks containing a *cis:anti:cis*-fused triquinane ring system in a single step. It was further postulated that such a methodology would provide an efficient and stereoselective route to polyquinane natural products. Syntheses of

SCHEME 51

capnellene, coriolin, and hirsutene were achieved employing the oxa-di-π-methane reaction of strategically designed tricyclic chromophoric systems.

Capnellene **252**, a sesquiterpene isolated from marine soft coral *Capnella imbricata*, has been a popular target for synthesis due to its role in biosynthesis and defense mechanisms. It also served as a test case for cyclopentane construction.[92,93] Photochemical oxa-di-π-methane reaction provided a novel, stereoselective, and efficient route to (±)-capnellene, as shown in Scheme 51. The *endo*-tricyclic chromophoric system **249** was synthesized from *p*-cresol. Controlled hydroxymethylation of *p*-cresol gave **246**, which upon oxidation with sodium metaperiodate generated the spiroepoxycyclohexa-2,4-dienone **247** that was intercepted with cyclopentadiene to give the *endo*-adduct **248**. Manipulation of the oxirane ring and the annulated five-membered ring furnished the intermediate **249** containing 14 carbons, including the angular and geminal methyl groups and the tricyclic framework of capnellene in latent fashion. Sensitized irradiation of **249** provided the tetracyclic compound **250** in a stereoselective fashion and in very good yield. Cleavage of the peripheral cyclopropane bond, Barton deoxygenation of the carbonyl group, followed by hydrolysis of the ketal group, yielded the ketone **251**. Methylenation by a Wittig reagent furnished (±)-capnellene (Scheme 51).[121,122]

A synthesis of coriolin was devised starting from the aromatic precursor **253**. This was readily transformed into epoxyketone **254** containing a β,γ-enone chromophore. Deoxygenation of the oxirane ring and functionalization of the five-membered ring furnished the crucial tricyclic compound **255** with the major structural and functional features of coriolin. Sensitized irradiation gave the intermediate **256** in good yield. This was then elaborated to the triquinane **257**, a known precursor to coriolin (Scheme 52).[123,124] In yet another formal synthesis of coriolin, the triquinane intermediate **263** was synthesized in a stereoselective fashion via oxa-di-π-methane reaction of the unusual chromophoric system **261** with a five-membered ring attached to one of the bridgeheads. The required chromophoric system was obtained via *in situ* generation of **259** and intramolecular Diels-Alder reaction, followed by manipulation of the resulting adduct (Scheme 53).[125] More recently, a synthesis of hirsutene was also developed as shown in Scheme 54. The tricyclic chromophoric system **265** was prepared by oxidation of salicyl alcohol, followed by manipulation of the resulting adduct and introduction of a methyl group at the ring junction. Oxa-di-π-methane reaction of **265** occurred efficiently and led to the key intermediate **266** that can be readily elaborated to (±)-hirsutene. [126]

78.8 Conclusions

The photochemical reactions of β,γ-enones, especially the oxa-di-π-methane rearrangement or 1,2-acyl shift that began with curiosity about the spectroscopic properties, has evolved into a sub-area of organic photochemistry. Studies on β,γ-enones led to an enhanced understanding of interactions between the alkene and carbonyl chromophores and provided a sound mechanistic picture of the photochemical processes and relationship between excited states and reactivity (despite the debate on singlet–triplet dichotomy). It may be seen from the foregoing discussion that a vast number of compounds with varying structural and functional features undergo the oxa-di-π-methane reaction. Further, oxa-di-π-methane rearrangements appear to be highly general and versatile reactions, especially in rigid systems wherein there exists the possibility of homoconjugation or interaction between the two chromophores. The oxa-di-π-methane reaction has far-reaching significance from a synthetic viewpoint because it provides reaction paths to numerous structural types in a highly stereo- and regioselective manner. The ODPM reaction has been extremely rewarding for the synthesis of cyclopentanoidal natural products. It appears that the design and availability of the requisite chromophoric system may prove to be a limitation — and not the oxa-di-π-methane reaction itself. In the future, it is likely that the oxa-di-π-methane reaction will play a much greater role in organic synthesis.

1,3-Acyl Migrations in β,γ-Unsaturated Ketones

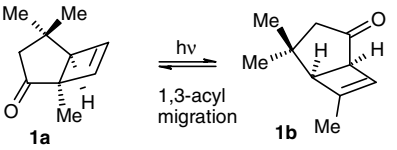
Vishwakarma Singh
Indian Institute of Technology Bombay

79.1 Introduction and Background

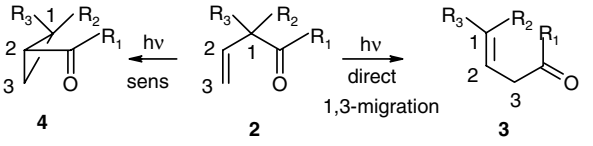
The photochemical reactions of β,γ-unsaturated enones have stimulated intense interest due to their spectroscopic properties, interesting mechanistic implications,[1–4] and application in organic synthesis.[5–7] The interest in β,γ-enone photochemistry was initiated due to the spectroscopic properties of these enones, which indicated interaction between the two chromophores,[1–4] which was further enhanced significantly after a novel observation by Buchi and Burgess,[8] who noted that irradiation of the bicyclic compound **1a** leads to the formation of **1b** (Scheme 1).

Subsequent to the aforementioned photoisomerization, which was later rationalized as a 1,3-acyl sigmatropic shift,[9] photochemical reactions of various types of β,γ-enones were examined. It was observed that β,γ-unsaturated enones undergo two unique reactions (*viz.* 1,3-acyl sigmatropic shift and oxa-di-π-methane (ODPM) reaction or 1,2-acyl shift), which are characteristic of their excited states. The direct irradiation of β,γ-enones such as **2**, in general leads to the formation of another enone **3** as a result of migration of the carbonyl group to the γ-carbon and formation of a new π-bond between the α– and β–carbons (Scheme 2). Sensitized irradiation, on the other hand, causes a 1,2-acyl shift (or oxa-di-π-methane reaction), leading to a cyclopropyl ketone of type **4**.

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1



SCHEME 2

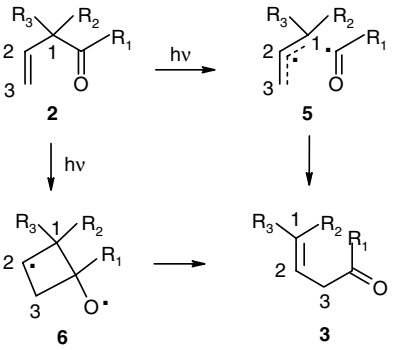
1,3-Migration of the carbonyl group appears to be a characteristic reaction of β,γ-unsaturated ketones upon direct excitation, although it may be accompanied by photoreactions of ketones such as Norrish Type I and Type II, and other photoreactions such as oxetane formation, *cis,trans*-isomerizations, etc., depending on the structure of the chromophoric system.[3,4]

79.2 Mechanism and the Correlation between Excited State and Reactivity

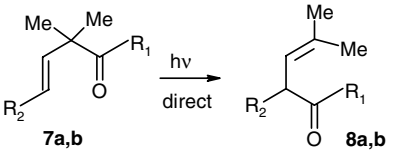
The mechanism of photoreactions has been studied in great detail and the correlation between excited state and reactivity has been established.[3–5] Excellent discussions on the mechanism of both the 1,3-migration and the oxa-di-π-methane reaction have been presented by Schuster and co-workers[4] and by Houk.[3] In general, it is agreed that the 1,3-migration can occur either from the lowest excited singlet (S_1, $n\pi^*$) state or the higher triplet (T_2, $n\pi^*$) state, whereas the lowest triplet excited state (T_1, $\pi\pi^*$) is responsible for the oxa-di-π-methane reaction in β,γ-unsaturated ketones.[3,4,10–12] The 1,3-migration in β,γ-enones can occur competitively from both the S_1 ($n\pi^*$) and T_2($n\pi^*$) states; the latter may be generated from S_1 via intersystem crossing, albeit inefficiently. 1,3-Acyl shifts can be induced via α-cleavage (Norrish Type I reaction) and lead to the formation of biradicaloids of type **5** that gives the final product via radical combination or may proceed via a quasi-concerted pathway through biradicals of type **6** (Scheme 3). In general, acyclic ketones follow the dissociation-recombination pathway,[13–15] while cyclic ketones follow the quasi-concerted pathway.[4,16–18]

The existence of the biradicals and the multiplicity of the surfaces on which these are formed have not been demonstrated directly; however, experimental results (stereochemistry of the reaction, CIDNP [chemically induced dynamic nuclear polarization], radical trapping experiments, and quantum yield measurements) support their existence.[4,10,15–18] Recently, the mechanism of 1,3-migration and oxa-di-π-methane reactions in terms of potential energy surface and decay funnels has been described; this also supports the aforementioned mechanistic implications.[18] The detailed mechanism, however, depends, in a very subtle way, on the structure of the chromophoric system and the presence of the functional groups.

1,3-Migration and oxa-di-π-methane rearrangements are the two fascinating aspects of β,γ-enone photochemistry and studies on both were done in parallel. Oxa-di-π-methane reactions, however, received somewhat more attention, perhaps due to their synthetic applications and, as such, have been discussed in several reviews.[1–6] Most of the studies on 1,3-shifts were made in conjunction with the ODPM reaction with a view to resolve the singlet—triplet dichotomy. Nevertheless, the literature on the 1,3-migration is fairly vast and only some representative examples from various classes of β,γ-enones and the emerging synthetic applications are presented here.



SCHEME 3



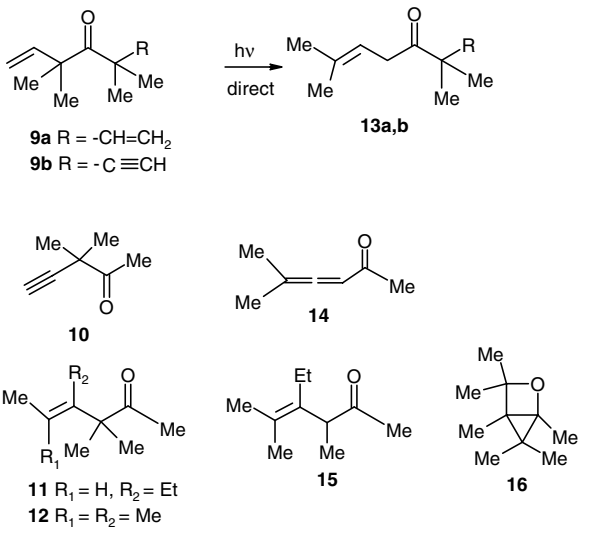
SCHEME 4

79.3 1,3-Acyl Migrations in Acyclic β,γ-Unsaturated Ketones

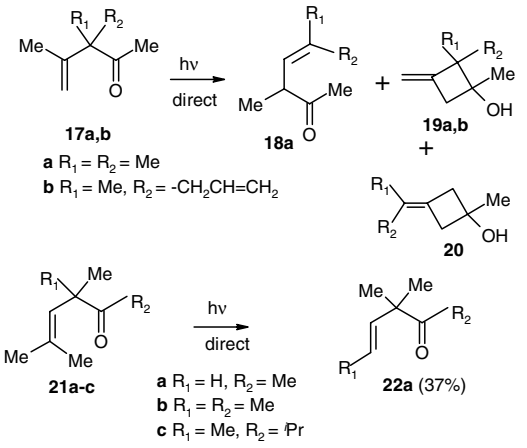
The direct irradiation of acyclic ketones can, in principle, lead to a number of photoreactions, such as *cis,trans*-isomerization, Norrish Type II and Type I reactions, oxetane formation, and 1,3-shifts. The deactivation pathway is dependant on the substituents in the chromophoric systems. Substitution at the α-carbon exerts a fair amount of control on the occurrence of 1,3-migration. Simple acyclic β,γ-enones with mono-substitution at the β-carbon undergo *cis,trans*-isomerization, α-cleavage, and decarbonylation to give radical combination products.[3,4,13,17,19] Similarly, sensitized irradiation of phenyl allyl ketone with a phenyl group at the γ-carbon also led to *cis,trans*-isomerization.[20] In their pioneering studies on photochemistry of β,γ-enones, Dauben and co-workers reported that the ketone **7a** with a gem dimethyl group and a phenyl group at the α- and γ-carbons, respectively, undergoes a 1,3-acyl shift on direct irradiation to give the product **8a**. It was observed that further irradiation of **8a** gives products as a result of decarbonylation and radical combination.[21] Similarly, the direct irradiation of the ketone **7b** containing an α,α-dimethyl group also led to the formation of 1,3-acyl shift product **8b** (Scheme 4) in addition to other products.[13] Other related ketones with substitutents at the α–carbon were also found to undergo a 1,3-acyl shift upon direct irradiation.[22,23]

Engel and Schexnayder examined the photoreaction of a highly interesting set of acyclic β,γ-enones **9** through **12** upon direct and sensitized irradiation.[13] While the direct irradiation of dienone **9a** and acetylenic enone **9b** gave 1,3-shift products **13a** and **13b**, respectively, along with C_{10} hydrocarbons, the acetylenic ketone **10** gave the allenic ketone **14** in addition to biacetyl and hydrocarbons. The photoreaction of the ketone **11** gave a mixture of products containing **15** and products due to γ-hydrogen abstraction, oxetane formation, and biacetyl and hydrocarbons. Interestingly, the direct irradiation of ketone **12** gave only oxetane **16** as a result of intramolecular photocycloaddition (Scheme 5). It was suggested that at least some of the 1,3-shift products arise from the combination of free radicals.[13]

Photochemical reactions of β,γ-enones of type **17** with α,α-disubstitution and a substituent at the β-carbon were examined. While the irradiation of **17a** in solution gave the isomerized enone **18a** and

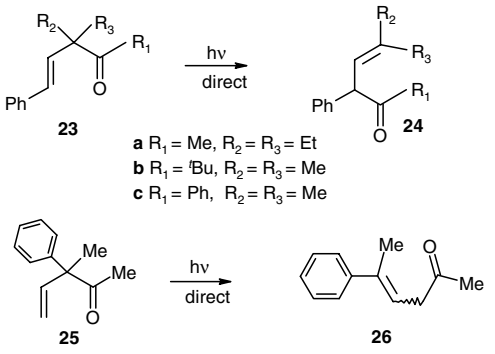


SCHEME 5

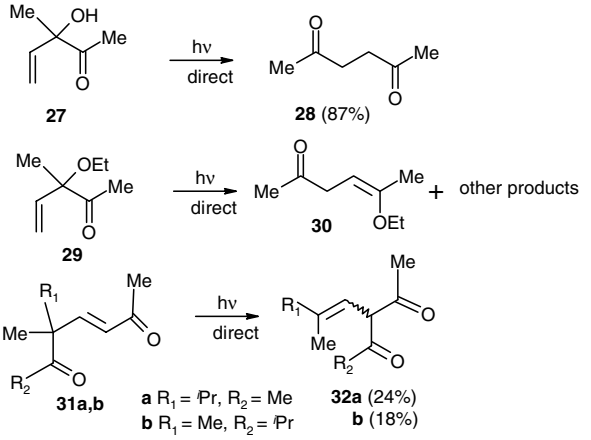


SCHEME 6

cyclobutanols **19a**, **20** arising from a 1,3-acyl shift and hydrogen abstraction, respectively,[24] photoreaction of **17b** gave only cyclobutanols **19b**.[22] Cerfontain and co-workers[25–27] examined the photoreactions of a series of β,γ-enones having various substituents at the α-, β-, and γ-carbons. Direct irradiation of **21a** gave 1,3-acyl shift product **22a** in addition to other products arising via α-cleavage, decarbonylation, and radical combination. However, the ketones **21b,c** did not give products due to a 1,3-acyl shift; instead, decarbonylation occurred and hydrocarbons were obtained via radical combination (Scheme 6).[25] Photoreaction of β,γ-enones containing a phenyl group at γ-carbon and alkyl groups at the α-carbon, such as **23,** were also investigated. The direct irradiation of ketone **23a** underwent a 1,3-acyl shift to give products of type **24a** (Scheme 7) as well as products due to *cis,trans*-isomerization. Irradiation of the enones **23b** gave products as a result of *cis,trans*-isomersization, decarbonylation, and radical combination, in addition to the 1,3-shift product.[26] The enone **23c,** on the other hand, underwent *cis,trans*-isomerization and gave some benzaldehyde.[26] The direct irradiation of ketone **25** gave a complex mixture of products, including the 1,3-acyl shift product **26**.[27]



SCHEME 7

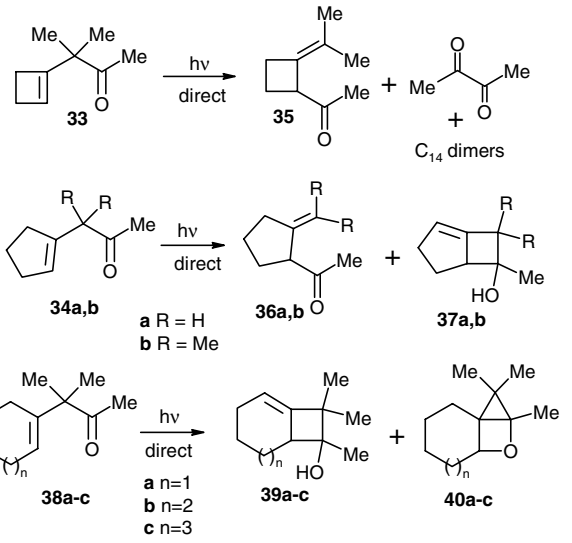


SCHEME 8

Hancock and co-workers investigated the photoreaction of β,γ-enones with α-hydroxy and alkoxy substituents.[28,29] While the direct irradiation of α-hydroxyenone **27** led to the formation of 1,4-dione **28** via an efficient 1,3-acyl shift followed by tautomerization,[28] photoreaction of **29** gave a complex mixture of products arising from various other reactions in addition to the 1,3-acyl shift product **30** (Scheme 8).[29] Eichenberger and co-workers reported 1,3-acyl shift in ketones **31a** and **31b** on photoreaction from a ($^1\pi\pi^*$) state to give **32a** and **32b**, respectively, in addition to an oxa-di-π-methane rearrangement.[30]

79.4 1,3-Acyl Migration in Semicyclic β,γ-Unsaurated Ketones

It is evident from the foregoing examples that photoreaction of acyclic β,γ-enones is quite diverse and highly dependent on the structure of the chromophoric system and substituents present. However, this is not surprising because the remarkable reactions of β,γ-enones (*viz.* 1,3-acyl migration and oxa-di-π-methane reactions) are presumably due to the interaction between the alkene and carbonyl chromophores. The interaction between the chromophores will depend on the structure and conformation of the molecule. To gain a better understanding, the photoreaction of a number of β,γ-enones containing the chromophores in various structural surroundings were examined. Photoreactions of those β,γ-enones in which one of the chromophores is present in a cyclic ring and the other in an acyclic chain, and the enones with the alkene and carbonyl chromophores in two different cycles, are presented below.

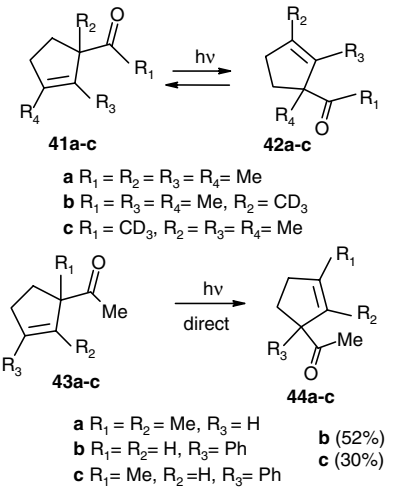


SCHEME 9

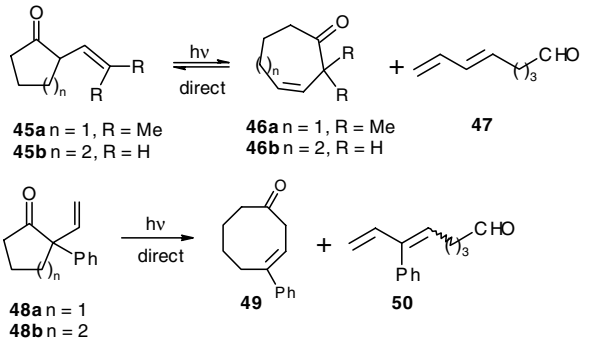
Engel and Schexnayder studied the photoreaction of β,γ-enones in which the alkene chromophore is present in rings of various sizes, and observed very interesting behavior on direct as well as sensitized irradiation.[31] Thus, direct irradiation of the enone **33,** having alkene chromophore in a four-membered ring, gave the 1,3-acyl shift product **35** along with biacetyl and hydrocarbons. The formation of biacetyl and other hydrocarbons in this photoreaction parallels that of acyclic β,γ-enones. The irradiation of **34a** and **34b** yielded the 1,3-acyl shift products **36a** and **36b**, along with the cyclobutanols **37a** and **37b** as a result of γ-hydrogen abstraction (Scheme 9). On the other hand, direct photolysis of the enones **38a,b,c**, in which the alkene chromophore is present in six-, seven-, and eight-membered rings, does not lead to a 1,3-acyl shift; instead, products due to γ-hydrogen abstraction and intramolecular cycloaddition are obtained (Scheme 9). Formation of the products and the different behaviors of these ketones on excitation has been explained in terms of the ionization potential and electron richness of the alkenes.[31]

Schaffner and co-workers examined the photoreactions of several cyclopentenyl methyl ketones of type **41** and **43,** and suggested the intramolecular nature of the 1,3-acyl shift.[16,32–34] The direct irradiation ($n\pi^*$) of optically active ketone (*R*)-**41a** at >300 nm led to the 1,3-acyl shift product (*S*)-**42a** in addition to other products.[32] Photolysis of a mixture of ketones **41b** and **41c** with CD_3 groups did not give hexadeuterated compounds, which indicated the intramolecular nature of the 1,3-acyl migration. These mechanistic implications were further supported by subsequent studies on the photoreaction of ketones **43** and their labeled analogues.[33] While the direct irradiation of **43a** gave a photostationary mixture of **44a** and **43a**, the phenyl ketones **43b** and **43c** disappeared to give the corresponding 1,3-shift products **44b** and **44c**, respectively (Scheme 10). These and other studies on the photoreaction of enantiomerically enriched cyclopent-2-enyl methyl ketones, measurements of quantum yields, fluorescence lifetimes, and kinetic studies suggested the concerted nature of the 1,3-acyl shift.[16,33,34]

Cerfontain and co-workers have examined the photoreaction of ketones **45** and **48** upon direct and sensitized irradiation. The enones **45a** and **45b** were found to undergo a reversible 1,3-shift on direct irradiation. A photostationary state is reached in the case of **45a** (45a:46a = 1:4). The dienal **47** was detected during the irradiation of the cyclohexenyl ketone **45b** in addition to the 1,3-acyl shift product **46b**. Interestingly, the ketone **48a** with a phenyl group at the α-carbon did not undergo any photoreaction, while its higher analogue **48b** gave the 1,3-acyl shift product **49** and the dienal **50** (Scheme 11).[35] Cerfontain and Koppes[36] have examined the photochemical reactivity of a number of ketones of type **51** and **56**. Interestingly, the direct irradiation of indanone **51a** gives products due to decarbonylation, the



SCHEME 10



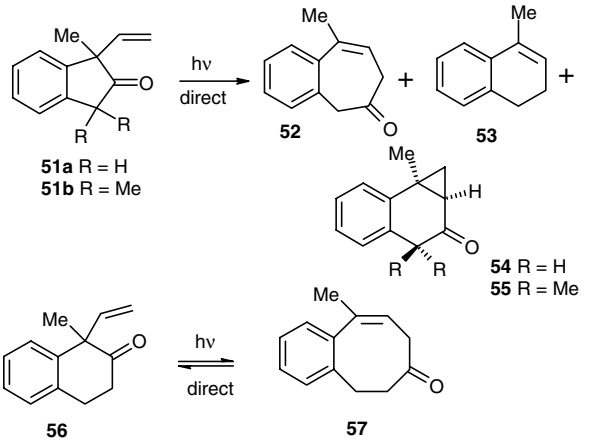
SCHEME 11

1,3-acyl shift product, as well as a product from an oxa-di-π-methane reaction, while the analogue **51b** with a gem-dimethyl group at the α′–position affords only the oxa-di-π-methane product **55** (Scheme 12). On the other hand, the homologous ketone **56** underwent a reversible 1,3-acyl shift to yield **57,** along with products due to ketene elimination.[36]

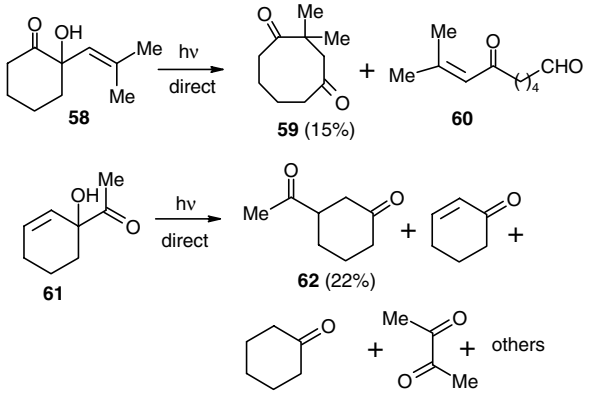
The direct irradiation of ketone **58** containing an α-hydroxy group also gave similar results and produced the ring-expanded ketone **59** and the aldehyde **60**.[37] In view of these results, it is of interest to note that irradiation of ketone **61,** in which the positions of the carbonyl group and the β,γ–olefinic group are exchanged, gives a complex mixture of products containing cyclohexenone, biacetyl, cyclohexanone, and acetaldehyde in addition to the 1,3-acyl shift product **62**.[38] The cyclooctanedione **59** and the 1,4-dione **62** are formed via 1,3-acyl migration followed by tautomerization (Scheme 13).

(+)-4-Acetyl-2-carene **63** was shown to undergo a 1,3-acyl migration on direct irradiation to give the product **64** along with the cyclobutanol **65** arising from Norrish Type II cyclization of **64**. Longer irradiation led to the formation of cyclobutanol **66** derived from **63** (Scheme 14). The reaction occurred from the excited singlet state because the presence of piperylene had no effect on the product distribution.[39]

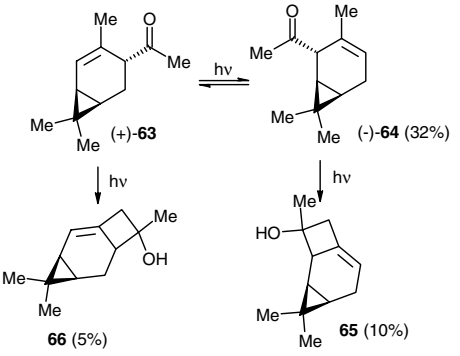
Chae and co-workers studied the photoreaction of optically active ketones **67a,b,c,d** under both direct as well as sensitized conditions. Only the naphthylketone **67a** underwent a 1,3-acyl shift upon direct



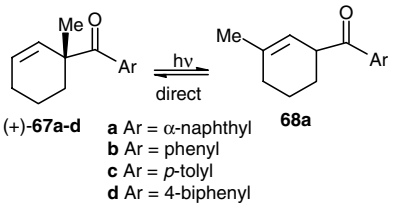
SCHEME 12



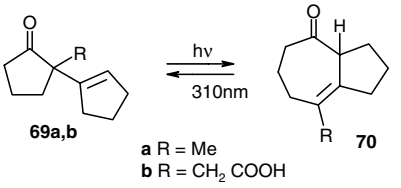
SCHEME 13



SCHEME 14



SCHEME 15



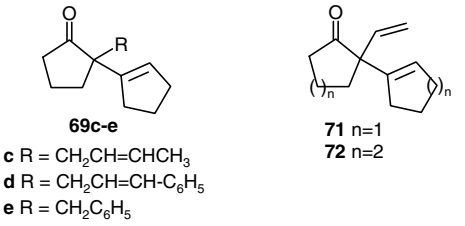
SCHEME 16

irradiation, whereas the other ketones **67b,c,d** underwent racemization with good quantum efficiency (>0.75) and no 1,3-acyl shift product was obtained. It was noted that the formation of the 1,3-acyl shift product **68a** was not quenched by *trans*-piperylene, while racemization was quenched. Sensitized irradiation of **67a,b,c,d** showed racemization, but neither 1,3-migration nor oxa-di-π-methane reactions were observed. It was concluded that the 1,3-acyl shift in **67a** arises from the excited singlet state and that intersystem crossing is very efficient for **67b,c,d** (Scheme 15).[40]

Studies on β,γ-unsaturated ketones of type **69,** in which both the chromophores are present in different rings that are connected through a single bond, played a key role in understanding the mechanism and stereochemistry of both the 1,3-acyl migration and the oxa-di-π-methane reaction. Direct irradiation of **69a** and **69b** gave a single product **70,** and a photostationary state was reached after 33 h. Irradiation of (*R*)-(−)-**69b** gave the (*S*)-(+)-**70b** with the same optical purity as **69b** at low conversions. At higher photochemical conversion, the optical purity of both **69b** and **70b** decreased, which indicated stereochemical equilbration. To probe the origin of this reaction, direct irradiation of **70b** was also studied. Thus, irradiation of **70b** proceeded with loss of stereochemical integrity, even at low photochemical conversion, and gave **69b**. However, **70b** was not racemized to a large extent, suggesting that the transformation **70b** → **69b** occurs with racemization. On the basis of these and other results, it was concluded that the ring-expansion reaction **69** to **70** may be described as [1,3]-suprafacial migration whereas the reverse reaction **70** to **69** is a biradical process with equilibration (Scheme 16).[41] Cerfontain and coworkers have studied the photoreaction of a number of similar ketones **69c,d,e,** which were also found to undergo a 1,3-acyl shift upon direct irradiation; however, the ketones **71** and **72** (Scheme 17) with a vinyl substituent at the α-carbon were unreactive, presumably because of rapid radiationless decay from the excited singlet state.[42]

79.5 1,3-Acyl Migration in Monocyclic and Ring-Fused Bicyclic β,γ-Ketones

Paquette and co-workers examined the photoreactions of cycloheptenones **73** and **74,** and cycloheptadienone **77b** (Scheme 18). The direct irradiation of **73** and **74** gave the corresponding 1,3-acyl shift products **75** and **76,** respectively.[43] In the case of **73**, a photostationary state was reached after 4 h (**75**:**73** = 4). Interestingly, tetramethyl cycloheptadiene **77a** did not undergo a 1,3-acyl shift on direct irradiation;



69c-e

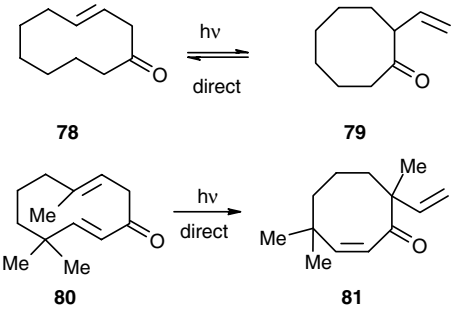
74 **76**

SCHEME 18



78 **79**

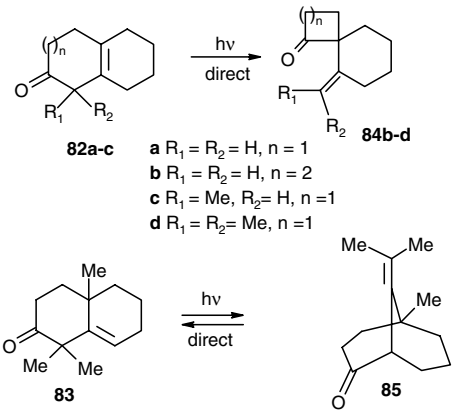
80 **81**

SCHEME 19

instead, an oxa-di-π-methane rearrangement was observed.[43] The parent cycloheptadienone **77b**, however, underwent decarbonylation.[44] Similar behavior is also exhibited by 3-cyclooctenone on direct irradiation, which gives products due to 1,3-acyl shifts and intramolecular disproportionation.[45]

The behavior of cyclodecenones is slightly different, as compound **78** was found to undergo a reversible 1,3-migration on direct irradiation to give **79**.[46] The cyclodecenone derivative **80,** with an additional double bond, undergoes a 1,3-acyl shift to give **81**, in addition to products due to *cis,trans*-isomerization (Scheme 19).[47]

Studies of the photoreactions of bicyclic ketones **82** and **83** provided interesting results. While the six-membered ketone **82a** did not undergo a 1,3-migration on direct irradiation but instead underwent an oxa-di-π-methane process, the homologous ketone **82b** underwent 1,3-migration on direct irradiation and gave **84b**.[48] The ketone **82c,** with a methyl substituent at the α-carbon, undergoes a 1,3-acyl shift to give **84c** in addition to oxa-di-π-methane reaction products upon direct irradiation. Whereas, **82d** with a gem-dimethyl group undergoes a selective 1,3-acyl migration to give **84d**.[49] The ketone **83** also underwent



SCHEME 20

1,3-acyl migration to give **85** (Scheme 20).[50] Other related ketones exhibited similar behavior upon direct irradiation.[51]

Photochemical reactions of several steroids containing β,γ-enone chromophores have been investigated and found to undergo 1,3-acyl migration on direct irradiation.[51–57] The direct irradiation of **86** has been reported to give the compound **87** as the major product, along with a samll amount of the decarbonylated product **88**.[52] Similar results were obtained on direct irradiation of **89**.[53] The direct irradiation of homologated stereoid **91** led to 1,3-acyl migration and gave two products, **92** and **93**.[54] Suginome and co-workers have examined the photoreaction of several modified steroids.[55,56] Thus direct irradiation of **94** in *t*-butanol gave the ring-contracted products **95** as a result of a 1,3-acyl shift, along with an oxa-di-π-methane product.[55] The stereochemistry of the products was found to be conformation dependent (Scheme 21).[55,56] Other steroids, such as 3,19-dioxo-17β-acetoxy-Δ^4-androstene and its derivative, have also been reported to undergo 1,3-migration in addition to other photoreactions.[57]

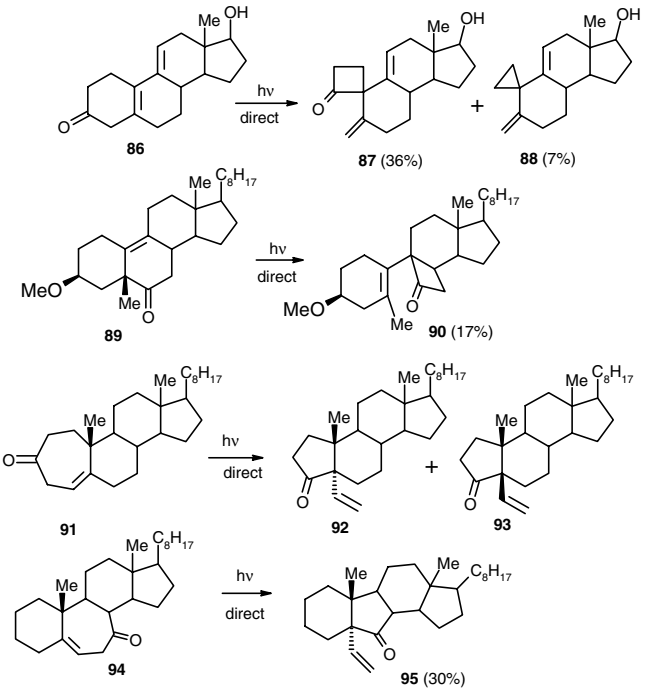
79.6 1,3-Acyl Migrations in Spirocyclic β,γ-Unsaturated Ketones

Photochemical reactions of a number of spirocylic compounds, such as **96**, **97**, and **98** (Scheme 22), upon triplet excitation have been investigated.[58,59] The direct excitation of ketones of type **96** led to an electrocyclic reaction and α-cleavage instead of 1,3-acyl migration.[58]

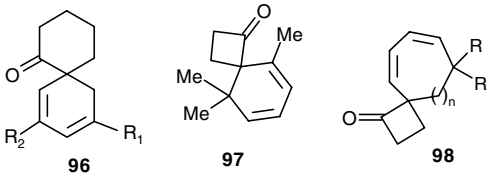
79.7 1,3-Acyl Migrations in Bridged β,γ-Unsaturated Ketones

Bicyclo[2.2.1]heptenones and Bicyclo[3.2.1]octenones

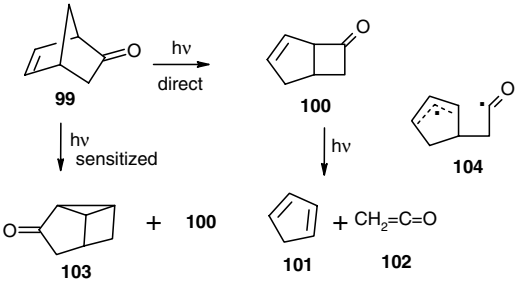
The photochemistry of bridged carbocyclic systems containing a β,γ-unsaturated carbonyl group has stimulated great interest and provided a good probe to unravel various aspects of the photochemical reactions of β,γ-enones. This is presumably due to enhanced interaction between the carbonyl and alkene chromophores, and also to molecular rigidity. The photochemical reaction of bicyclo[2.2.1]heptenone **99** was examined in great detail by several groups (Scheme 23).[60–63] Schenk and co-workers[60] observed photofragmentation to ketene and cyclopentadiene in a variety of solvents, while Schuster[61] found that **99** undergoes a 1,3-acyl migration faster than ketene elimination. Cyclopentadiene and ketene are formed to a large extent from the 1,3-acyl shift product **100**, and that reaction proceeds through the biradical **104**. Ipakscthi reported that the 1,3-acyl shift product **100** is also formed in addition to the oxa-di-π-methane reaction product **103** during sensitized irradiation of **99**.[62] Schexnayder and co-workers also noted the formation of **100** during sensitized irradiation of **99** and that the former is converted into the



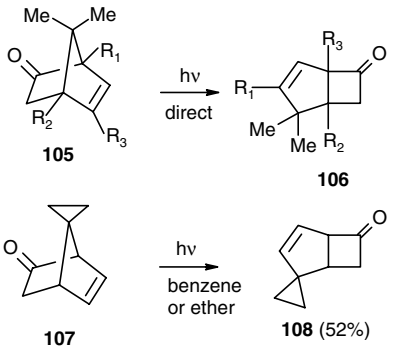
SCHEME 21



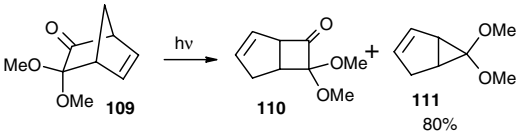
SCHEME 22



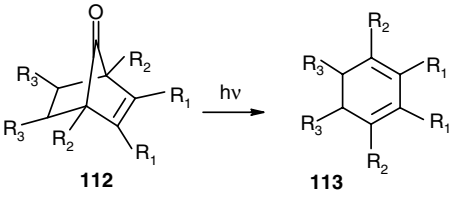
SCHEME 23



SCHEME 24



SCHEME 25

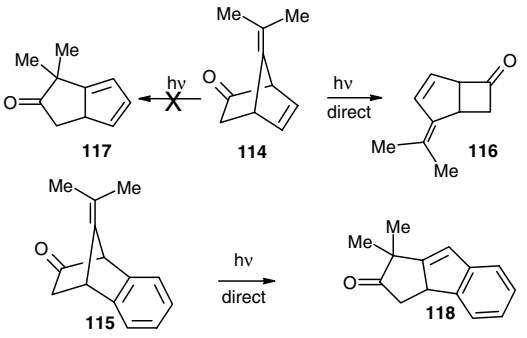


SCHEME 26

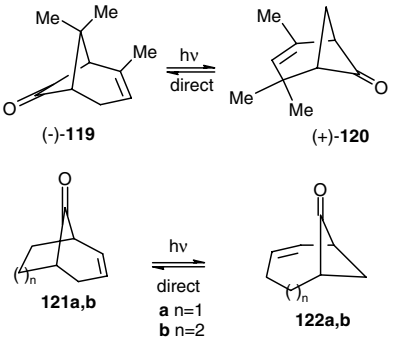
ODPM product on sensitized irradiation in acetone.[63] Similar results were obtained on direct irradiation of bicyclo[2.2.1]heptenones **105** and **107**, which gave the 1,3-acyl migration products **106** and **108**, respectively, in addition to the corresponding cyclopentadienes (Scheme 24).[64,65] Direct irradiation of ketone **107** in methanol, however, gave a complex mixture of products.[65]

Similarly, photolysis of 3,3-dimethoxy-5-norbornen-2-one **109** in various solvents (dioxane, acetonitrile, and acetone) gave the 1,3-acyl shift product **110** in minor amounts and the decarbonylated product **111** as the major product (Scheme 25). Irradiation of **109** in methanol gave a complex mixture of products arising through an oxa-carbene formed from the biradical generated after initial α-cleavage.[66] It was also observed that the decarbonylated product **111** was obtained at the expense of the initially formed 1,3-acyl shift product **110**.

Irradiation of 7-norbornenones of type **112**, wherein the carbonyl group is sited at the methano bridge, does not lead to a 1,3-acyl shift; instead, they undergo decarbonylation to give the corresponding cyclohexadienes (Scheme 26) in addition to 1,3,5-hexatrienes that arise as a result of photochemical electrocyclic ring opening of the initial product.[67] Other compounds of type **112**, readily available by Diels-Alder reaction of cyclopentadienone with dienophiles, undergo a facile decarbonylation upon irradiation.[68]



SCHEME 27



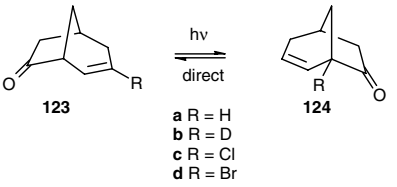
SCHEME 28

The photochemistry of the bis-(β,γ-unsaturated) ketone **114** and the benzo analogue **115** is interesting. The direct irradiation of **114** leads to the formation of a 1,3-acyl shift product **116** selectively. The alternative possibility, **117**, which could arise via participation of the alkene moiety in the methano bridge was not formed. However, irradiation of **115** gave the product **118** (Scheme 27).[65]

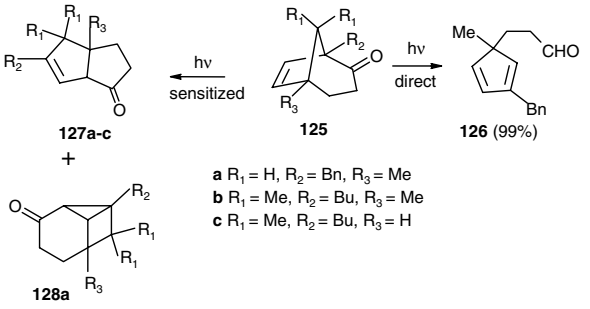
Photochemical reaction of chrysanthenone **119**, a photoisomer of verbenone, has been examined in detail.[69,70] Irradiation of (−)-**119** in cyclohexane led to a reversible 1,3-acyl migration to give (+)-**120** in addition to other products formed as a result of decarbonylation. Other higher homologues such as **121a** and **121b** were also found to undergo reversible 1,3-acyl migration to give **122a** and **122b**, respectively (Scheme 28), in addition to other products.[69,70]

In pioneering studies, Givens and co-workers examined the photochemical reactions of optically active bicyclo[3.2.1]oct-2-en-7-one **123a** and deuterated and halogenated analogues in order to resolve the singlet–triplet reactivity of β,γ-unsaturated ketones and the mechanism of the 1,3-acyl migration and oxa-di-π–methane reaction.[71] The direct irradiation of all the enones led to 1,3-acyl shifts, while the sensitized irradiation gave products due to both the oxa-di-π-methane reaction as well as 1,3-acyl migration. Irradiation of (+)-**123a** at 300 nm in ether gave (−)-**124a** (Scheme 29). Other ketones **123b,c,d** also gave the corresponding 1,3-shift products **124b,c,d** on direct irradiation. No oxa-di-π-methane products were detected on direct irradiation. It was further observed that introduction of halogens at the double bond (as in **123c** and **123d**) or at the bridgehead (**124c** and **124d**) reduces the efficiency of the 1,3-acyl migration. However, this heavy-atom effect does not lead to more efficient intersystem crossing to give triplet ketone because no oxa-di-π-methane reaction was observed.

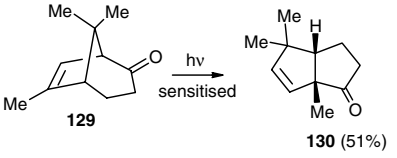
Ueyhara and co-workers[72] have studied the photoreaction of a number of bicyclo[3.2.1]octenone systems, wherein the position of the chromophores is switched; that is, the alkene chromophore is in the



SCHEME 29



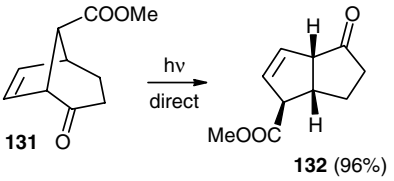
SCHEME 30



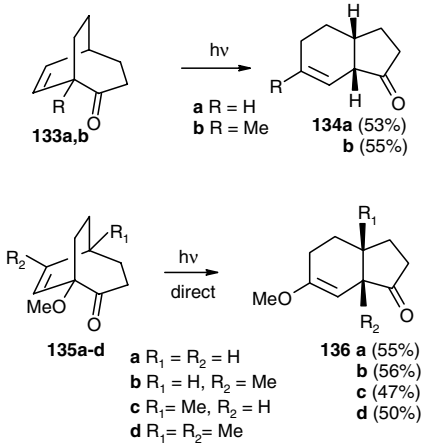
SCHEME 31

ethano bridge and the carbonyl group is in the 3-carbon bridge. Direct irradiation of the enone **125a** with a benzyl substituent at the bridgehead did not give a 1,3-acyl shift product; instead, the cyclopentadiene derivative **126** was obtained. The sensitized irradiation of **125a**, however, furnished the 1,3-acyl shift product **127a** (32%) and the oxa-di-π-methane product **128a** (18%). The ketone **125b,** on the other hand, underwent 1,3-acyl migration both upon direct and sensitized irradiation to give **127b** in good yields (50 to 60%) (Scheme 30). The analogue **125c** also behaved similarly and gave the 1,3-acyl shift product **127c** in addition to a small amount of another product. It is interesting to note that the 1,3-acyl shift in such systems provides a novel route to *cis*-bicyclo[3.3.0]octenones, which are generally obtained via oxa-di-π-methane reaction in bicyclo[2.2.2]octenones. The authors have successfully employed the 1,3-acyl shift in **129** to prepare the diquinane intermediate **130** (Scheme 31),[72] which was employed for a formal synthesis of capnellene, a triquinane natural product isolated from *capnella imbricate*.[73,74] The ketoester **131** also undergoes efficient 1,3-acyl migration on direct irradiation in benzene to give the diquinane **132** (Scheme 32) in excellent yield. This is a known precursor for the synthesis of (±)-8-epiloganin aglucones and (±)- mussaenoside.[75]

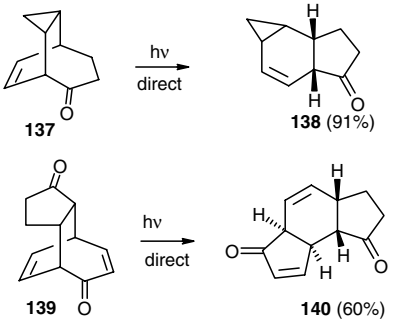
Uyehara and co-workers have also reported efficient photochemical 1,3-sigmatropic acyl shifts in a variety of bicyclo[3.2.2]nonenones of type **133** and **135** that provided an excellent synthetic entry into the *cis*-hydrindanone ring system (Scheme 33)[76] and also employed 1,3-migration in total syntheses of pinguisone, deoxypinguisone and ptilocaulin.[77,78]



SCHEME 32



SCHEME 33



SCHEME 34

Annulated bicyclo[3.2.2]nonanes with β,γ-enone chromophores have also been reported to undergo an efficient 1,3-acyl shift. Thus, irradiation of **137** in benzene/methanol gave the tricyclic compound **138** in excellent yield (Scheme 34).[79] The more complex system **139** also underwent 1,3-acyl migration on irradiation in $CDCl_3$ through quartz to give the *cis:anti:cis* tricyclic compound **140**. However, the diendione **139** was inert on irradiation through Pyrex.[80] Other, more functionalized systems with a β,γ-enone chromophore in the bicyclo[3.3.1]nonane ring system have also been found to undergo 1,3-acyl migrations.[81]

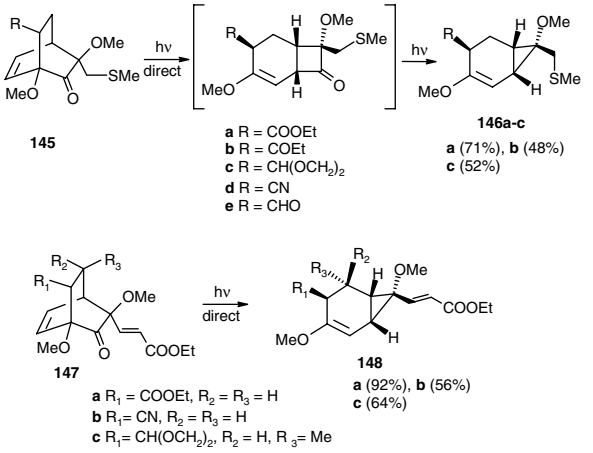
SCHEME 36

1,3-Acyl Migrations in Bicyclo[2.2.2]octenones and Their Congeners

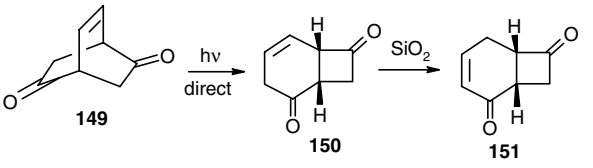
Studies on the photochemical reactions of bicyclo[2.2.2]octanes with β,γ-enone groups provided greater insight into the excited-state reactivity correlation as well as the mechanism of both the 1,3-acyl migration and the oxa-di-π-methane reactions. The photochemical reaction of the parent bicyclo[2.2.2]octenone **141** and its benzoannulated analogue reported by Givens and co-workers is a seminal example.[82,83] The direct irradiation of **141** in ether gave the enone **142**, with a bicyclo[4.2.0]octane framework, as the sole product. The reaction was irreversible. Further irradiation of **142** led to ketene elimination and formation of cyclohexadiene (Scheme 35). In sharp contrast, the sensitized irradiation brought about an oxa-di-π-methane reaction exclusively.[82] Based on these studies, the authors suggested a concerted symmetry allowed process.[82, 10]

Subsequently, Demuth and co-workers examined the photoreaction of the bicyclo[2.2.2]octenones **143a**,**b** on sensitized as well as direct irradiation. Direct irradiation of **143a** and **143b** exclusively gave the 1,3-acyl shift products **144a** and **144b,** respectively (Scheme 36).[84,85] However, the formation of 1,3-acyl shift products along with oxa-di-π-methane products were also observed during acetone-sensitized irradiation of **143a**,**143b**, and congeners.[84,85] Rogers and co-workers examined the photoreaction of the bicyclo[2.2.2]octenones **143c** and **143d** with methoxy substitutents on direct and sensitized irradiation. Direct irradiation of **143c** and **143d** in benzene, ether, methanol, or pentane led to the formation of the 1,3-acyl shift product **144c** and **144d**, respectively. It was noted that **143c** and **143d** also gave products due to ketene elimination. The bicyclic compound **144d** was also formed in small amounts during sensitized irradiation of **143d**.[86,87] From these studies it was suggested that a 1,3-acyl shift is initiated through α-cleavage and proceeds through a biradicaloid intermediate that subsequently undergoes ring closure to give the final product.[86–88]

Yamauchi et al. have recently examined the photoreaction of a large number of functionally more complex bicyclo[2.2.2]octenones (**145** and **147**) that contain methoxy substituents at both α– and α′-positions. However, these enones were found to undergo decarbonylation on direct irradiation in benzene to give bicyclo[4.1.0]hept-2-enes **146** and **148**, respectively (Scheme 37).[89] The decarbonylated products are thought to arise via cyclobutanone derivatives that are initially formed as a result of 1,3-acyl migration. In some cases, the 1,3-acyl shift product was isolated, and these were found to give the decarbonylated products after prolonged irradiation. However, irradiation of cyano-substituted bicyclooctenone **145d** gave a complex mixture of products. Similarly, formyl-substituted **145e** underwent deformylation along



SCHEME 37



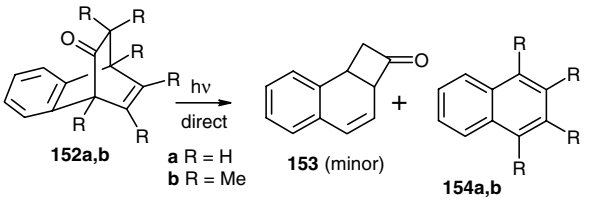
SCHEME 38

with decarbonylation.[89] The photoreactions of **145a,b,c** and **147a,b,c** provide a new and stereoselective route to trinorcarenes, which are otherwise not readily accessible. In this context, it can be mentioned that many other highly substituted bicyclic octenones have been reported to undergo ketene elimination on direct irradiation.[90,91]

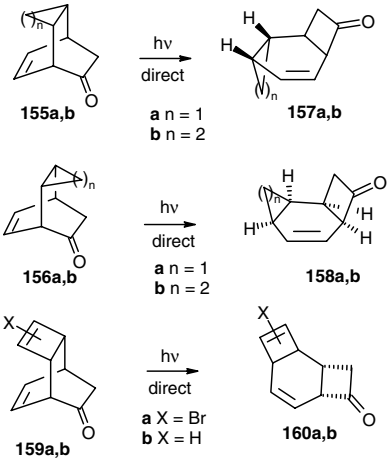
Dekkers and Schippers have examined the photoreactivity of the bicyclo[2.2.2]oct-2-ene-5,7-dione **149** with circularly polarized light to determine its chiroptical properties and to develop a method for enantiomeric enrichment through photodestruction.[92] Irradiation of **149** with 313-nm light in pentane was found to give the 1,3-acyl shift product **150** along with phenol, which is formed from **149** via ketene elimination and aromatization. The product **150** could not be isolated because it rearranged to the conjugated enone **151** during chromatography (Scheme 38). [92]

The aforementioned results indicate that 1,3-migration is a general reaction during direct irradiation of rigid bicyclo[2.2.2]octenones, although it is dependent on structure and the other functional groups present in the chromophoric system. In addition to the examples presented above, photoreaction of a variety of other annulated bicyclo[2.2.2]octenones has been studied and found to undergo 1,3-acyl migration on direct irradiation, and some of these examples are presented below. The photochemistry of benzobicyclo[2.2.2]octadienone **152a** was investigated by Givens and co-workers[82,83] and Ipaktschi.[93] Ipaktschi reported that direct irradiation of **152a** gives naphthalene and ketene. Givens and co-workers irradiated an ether solution of **152a** in a Pyrex vessel and two products were detected at 50% disappearence of **152a**. The major product was naphthalene **154a**, as reported by Ipakstchi, and the minor product was found to be **153,** the result of 1,3-acyl migration (Scheme 39).[82] The analogues of **152** with methyl substituents also behaved in a similar fashion.[90,91,94] Thus, the hexamethylated compound **152b** gave tetramethyl naphthalene **154b** as a major product on direct irradiation in ether.[90]

The photochemical reaction of other annulated derivatives, such as **155a**, **155b**, and their diasteroisomers **156a** and **156b**, was studied and found to undergo 1,3-acyl migration.[79,95] Agosta and Takakis



SCHEME 39

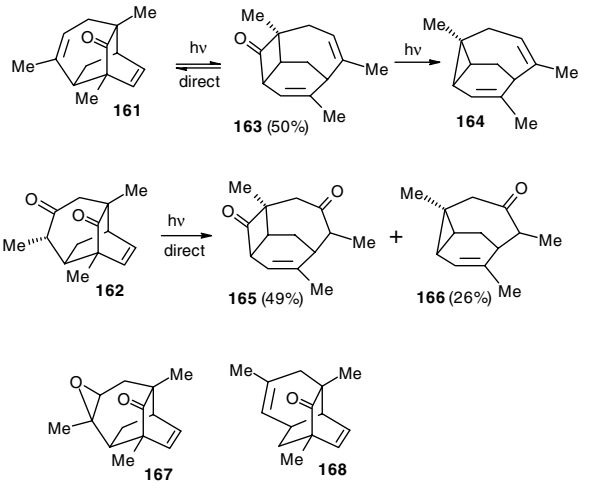


SCHEME 40

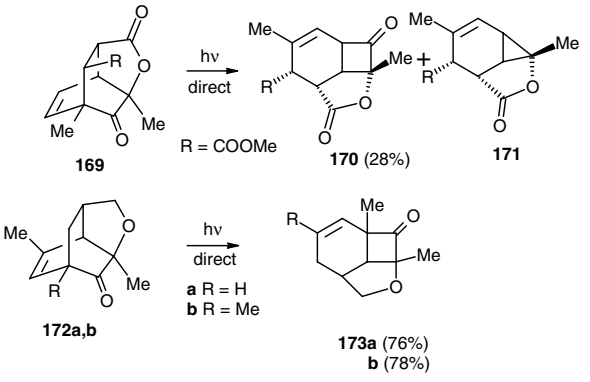
obtained the 1,3-acyl shift product **157a** (60%, at 10% conversion), in addition to other products, by irradiation of **155a** in benzene containing methanol. Prinzbach also investigated the photoreaction of **155a**, the higher homologue **155b** and their diastereomers **156a** and **156b**. These enones also behaved in a similar fashion and underwent 1,3-acyl migration and ketene elimination. The ketone **155b** gave the *cis*:*anti*:*cis* tricyclic compound **157b** (75% yield at 55% conversion), whereas the stereoisomers **156a** and **156b** furnished the corresponding 1,3-acyl shift product **158a** (~75% yield, at ~80% conversion) and **158b** (30 to 40%, at 80% conversion), respectively (Scheme 40).[95] Mehta and Srikrishna have examined the photochemistry of the tricyclic compounds **159a** and **159b** that are available through cycloaddition of cyclooctatetraene and its dibromoderivative with acrylonitrile. Direct irradiation of **159a** in benzene gave the 1,3-acyl shift product **160a** in 40% yield, along with other products arising via decarbonylation and ketene elimination. Similar irradiation of **159b** gave the 1,3-acyl shift product **160b** in low yield (20%), while cyclooctatetraene was as the major product.[96]

Photochemical reaction of complex tricyclic compounds **161**, **162**, **167**, **168**, and their congeners containing a β,γ-enone chromophore follow a similar course on direct excitation. Thus, irradiation of **161** in ether leads to 1,3-acyl migration to give **163**, which subsequently undergoes decarbonylation to yield the cyclopropyl compound **164**. Interestingly, the ene-dione **162** underwent selective photoreaction characteristic of β,γ-enones and furnished **165** and **166** on direct excitation in ether as a result of 1,3-shift followed by decarbonylation (Scheme 41). The tricyclic compounds **167**, **168,** and their derivatives were also found to behave similarily.[97]

Yates and Stevens[98] studied the photoreaction of heteroannulated bicyclo[2.2.2]octenone **169** under direct and sensitized conditions. Irradiation of **169** in ether gave a mixture of **170** and the decarbonylated product **171,** from which the 1,3-acyl shift product **170** was isolated by crystallization (Scheme 42).



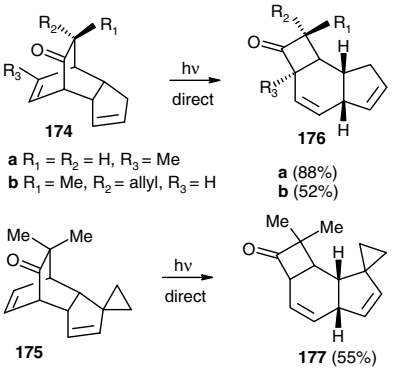
SCHEME 41



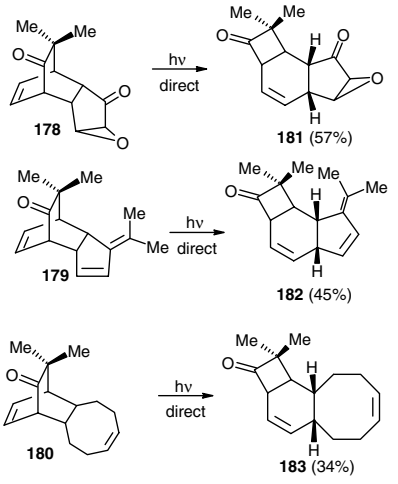
SCHEME 42

Further irradiation of a mixture of **170** and **171** gave **171**, thus indicating that the product **171** is formed from the 1,3-acyl shift product by decarbonylation.[98] Similarly, irradiation of **172a** and **172b** in benzene for short duration gave the 1,3-acyl shift products **173a** and **173b** in good yields (Scheme 42). It was observed that longer periods of irradiation led to decarbonylation.[99]

The photochemical reactivity of a variety of tricyclic systems such as **174**, **175**, **178**, and **179** containing a β,γ-unsaturated carbonyl group in an *endo*-tricyclo[5.2.2.0^{2,6}] undecane framework has been studied.[100–102] Irradiation of **174** and **175** in benzene furnished the 1,3-acyl migration products **176** and **177**, respectively (Scheme 43), along with unreacted starting material. Interestingly, the dione **178,** with the highly reactive α,β-epoxyketo chromophore, also underwent a 1,3-acyl shift on irradiation in benzene to give the 1,3-acyl migration product **181** with reasonably good efficiency. It should be mentioned that the trienone **179**, unreactive on triplet sensitized irradiation, smoothly undergoes a 1,3-acyl shift to give the corresponding tricyclic compound **182** on irradiation in benzene. This observation further strengthens the general view that 1,3-acyl migration occurs from excited singlet state. Furthermore, the dienone **180**, with an eight membered ring, also gave the tricyclic compound **183** as a result of 1,3-acyl migration (Scheme 44). It should be noted that, in general, these compounds are labile and they decompose during storage even at low temperature.[100,101]



SCHEME 43



SCHEME 44

The direct irradiation of tricyclic compounds such as **184** and **185**, with methoxy groups at the α-carbon, however, led to decarbonylation. Thus, irradiation of a benzene solution of **184** and **185** in a Pyrex immersion well with a mercury vapor lamp (400 W) gave the tricyclic products **186** and **187**, respectively, containing a cyclopropane ring fused to a *cis*-hydrindane ring system (Scheme 45). The photoreaction proceeds through an initial 1,3-acyl shift to give the corresponding cyclobutanone which subsequently undergoes decarbonylation to give the final product.[102] It appears that the presence of methoxy groups at the bridgehead is partly responsible for the tendency of such β,γ-enones to decarbonylate because other simple bicyclic compounds with a methoxy substituent at the bridgehead also exhibit similar behavior.[86,89]

The photoreaction of tricyclic undecadienones **188** and **189** with hydroxyl groups at the α′-carbon have also been investigated.[103–107] While the triplet excitation of these ketones led to an efficient oxa-di-π-methane rearrangement, the direct irradiation gave complex results. Thus, the irradiation of tricyclic hydroxyketone **188** in ethyl acetate gave a very small amount of the highly unstable 1,3-acyl shift product **190,** which was isolated as the hydrogenated product **191** (7%).[103] The direct excitation of **189a** and **189b** in benzene for 2h furnished an inseparable mixture of dienones **192a**, **193a** (66%) and **192b**, **193b** (60%), respectively (Scheme 46).[104]

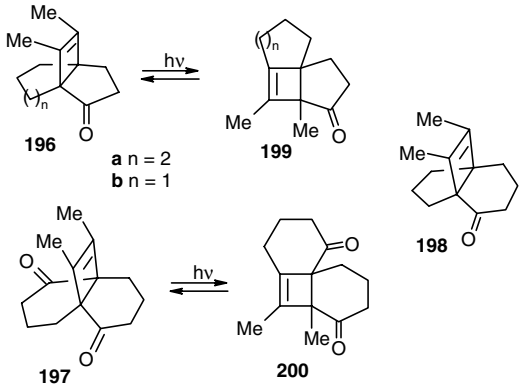
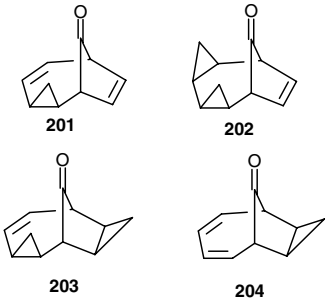
SCHEME 47

Another class of tricyclic compounds with a β,γ-enone chromophore in the bicyclo[2.2.2]octane framework that undergo a reasonably efficient 1,3-acyl migration on direct irradiation is shown in Scheme 47. The direct excitation of the *endo*-tricyclic chromophoric systems **194a** and **194b**, readily available from *p*-cresol, in benzene for short duration gave the linearly fused tricyclic compounds **195a** and **195b** containing a cyclobutanone ring in reasonably good yield along with some unreacted starting material. It was noted that irradiation for longer periods leads to decarbonylation and ketene elimination at the expense of the 1,3-acyl shift products.[108–110]



SCHEME 48



SCHEME 49

79.8 1,3-Acyl Migrations in Miscellaneous β,γ-Unsaturated Ketones

Cargill and co-workers examined the photoreactions of a number of interesting tricyclic compounds, such as **196 197,** and **198,** with a propellane framework. They observed reactions such as the 1,3-acyl shift, photoreduction and [1,3]-hydrogen migration upon direct irradiation.[111–113] Thus, the enones **196** and **197** underwent a reversible 1,3-acyl shift (Scheme 48).[111,112] However, the related enone **198** did not undergo 1,3-shift; instead, other reactions such as photoreduction and 1,3-hydrogen shift were observed.[113] The difference in the behavior of **196**, **197,** and **198** was explained in terms of the ε_{max} of the ketones.[113]

Agosta and Takakis investigated photochemical reactions of ketones **201** through **204** (Scheme 49). However, while irradiation of the **201**, **202,** and **204** gave products due to decarbonylation and rearrangement of cyclopropropyl groups, the enone **203** was found to be unreactive under a variety of conditions. This unreactivity of **203** was explained in terms of a reversible 1,3-acyl shift.[114] Sasaki and associates have examined the photoreactions of compounds **205** and reported 1,3-acyl migration on direct irradiation to give the corresponding photoproducts **206** (Scheme 50).[115]

A highly interesting 1,3-acyl migration in the protoadamantane derivative **207** was observed on both sensitized and direct irradiation, to give **208** (Scheme 51).[116] Recently, photoreaction of 4-methylene-2-protoadamantanone **209** was examined under both direct and sensitized irradiation. However, irradiation

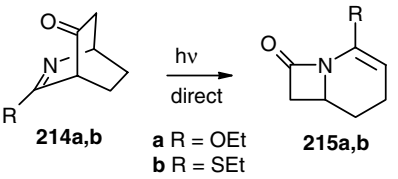
213

SCHEME 52

of **209** in benzene gave tarry material due to rapid photodecomposition, while sensitized irradiation in acetone led to addition of the anacetonyl radical at the γ-carbon.[117] Padwa and co-workers reported a remarkably efficient 1,3-acyl migration in 8-oxa-bicyclo[3.2.1]oct-6-en-2-ones **210** (Scheme 52) on both direct as well as sensitized irradiation.[118] While irradiation of **210a,b,c** in benzene led to a clean 1,3-acyl migration and afforded the bicyclic products **211a,b,c** in excellent yields, the direct excitation of the isomeric compounds **210d** and **210e** was found to give the tricyclic compounds **212** (Scheme 52). Subsequent studies showed that the tricyclic compounds **212** are not the primary photoproducts but are formed via photoreaction of the initially generated 1,3-acyl shift products **210d** and **210e** and that short irradiation led to only 1,3-acyl migration. The formation of the tricyclic compound **212** containing a cyclobutanone ring occurs via cycloaddition in the ketene intermediate **213**, which is formed by hydrogen abstraction in the biradical generated after initial Norrish Type I cleavage.[118]

Recently, Link and Keissling studied the photobehavior of aza-bicyclo[2.2.2]octenones **214** and reported 1,3-acyl migration upon direct irradiation, which gave the lactam **215** (Scheme 53).[119]

From the foregoing examples, it appears that 1,3-acyl migration is a general photoreaction that occurs mostly on direct excitation of rigid β,γ-unsaturated ketones although other reactions such as decarbonylation



214a,b **a** R = OEt **b** R = SEt **215a,b**

SCHEME 53

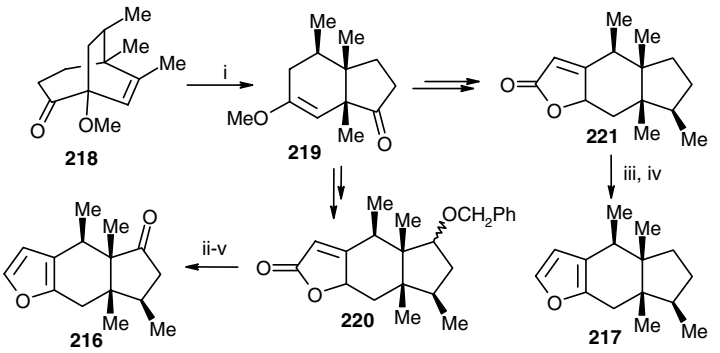
and ketene elimination may also compete. The structure of the chromophoric system and the presence of other functional groups also influence the photoreaction in a subtle fashion. The direct excitation of β,γ-unsaturated aldehydes generally does not lead to 1,3-acyl migration; instead, another photoreaction such as deformylation is observed. Recently, however, Armesto and co-workers reported a few examples of 1,3-acyl migration on sensitized irradiation of β,γ-unsaturated aldehydes.[120]

79.9 Applications of 1,3-Acyl Migrations toward Synthesis of Natural Products

It may be evident from the above that 1,3-acyl migration in rigid β,γ-unsaturated ketones have immense potential as a methodology because it provides the opportunity to create a variety of molecular frameworks in stereoselective fashion via appropriate design of the starting chromophoric system. Except for a few, most of the earlier studies on 1,3-acyl migration in β,γ-enones deal with elucidation of the mechanism and establish the structure-reactivity-excited state relationship. The potential of the 1,3-acyl shift in organic synthesis was realized only recently. In contrast to the oxa-di-π-methane reaction of β,γ-unsaturated ketones, there are only a few examples of applications of 1,3-acyl migration toward synthesis of natural products. Some of these are presented below.

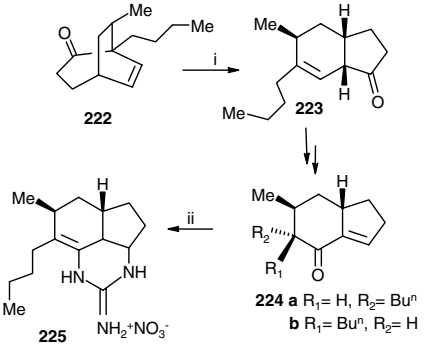
Uyehara and co-workers[77,121] developed a synthesis of (±)-pinguisone **216** and (±)-deoxypinguisone **217** containing an unusual terpene skeleton, employing 1,3-acyl migration in a bicyclo[3.2.2]nonane framework. Thus, the 1,3-acyl shift in the bicyclic precursor **218**, on direct irradiation in tetrahydrofuran, gave the ketoenol ether **219** in good yield (59%). It may be noted that the *cis*-hydrindane framework and three contiguous stereocenters of the target molecules are generated in the photochemical reaction (**218** → **219**). The photoproduct **219** was then elaborated into **220** and **221,** which were subsequently transformed into pinguisone **216** and deoxypinguisone **217,** respectively (Scheme 54).[77,121] Similarly, the synthesis of (±)-ptilocaulin **225**, a cytotoxic cyclic guanidine isolated from the Caribbean sponge *Ptilocaulis* aff. P. *Spiculifer*[122] was also carried out via photochemical 1,3-acyl shift in the bicyclo[3.2.2]nonenone framework.[78,123] The bicyclic precursor **222** was synthesized from tropone. Irradiation of **222** in benzene yielded the intermediate **223** in excellent yield (65%). This has most of the structural, functional, and stereochemical features of ptilocaulin. Transformation of the photoproduct **223** into enone **224** followed by treatment with guanidine gave ptilocaulin (Scheme 55). The same research group has also employed the 1,3-acyl migration protocol with the bicyclo[3.2.1]octenone **129** (Scheme 31) (*vide infra*) to prepare a diquinane precursor for the synthesis of (±)-$\Delta^{9(12)}$-capnellene, a triquinane natural product.[72] Chang and co-workers have also utilized the 1,3-acyl shift as a key reaction for the synthesis of *the* diquinane precursor **132** (Scheme 32) *vide infra*, which is readily converted into a known intermediate for the synthesis of (±)-mussaenoside and (±)-8-epiloganin aglucones.[75]

The photochemical 1,3-acyl shift in the *endo*-tricyclo[5.2.2.$0^{2,6}$]undecane ring system provides a stereoselective route to protoilludanes,[100,101] a unique class of sesquiterpene containing a cyclobutane ring angularly fused to a *cis*-hydraindane ring in their molecular framework.[124] We developed a route to the tricyclic chromophoric systems **228** and **230a,b,c,** and examined their photoreaction upon direct irradiation as a route to protoilludene. Thus, oxidation of hydroxymethylphenol **226** in the presence of cyclopentadiene gave the *endo*-ketoepoxide **227**, which was transformed into **228** and **230** by manipulation



Reagents/conditions: i, hν, THF; ii, BBr_3, CH_2Cl_2; iii, DIBAH; iv, 1M H_2SO_4; v, Ac_2O, DMSO.

SCHEME 54



Reagents/conditions: i, hν, THF; ii, guanidine

SCHEME 55

of the oxirane and cyclopentene ring. Irradiation of dienone **228** in benzene in a Pyrex immersion well gave the compound **229** (33%) with the tricyclic framework of protoilludanes, along with some unreacted starting material. Interestingly, the tricyclic ene-dione **230a** with an additional carbonyl group in the five-membered ring, smoothly underwent 1,3-acyl migration to give the corresponding product **231a** (30%). The α,α-dimethyl substituted ene-dione **230b** also underwent 1,3-acyl migration but formation of a very small amount of aldehyde, the result of α-cleavage in the five-membered ring, was observed. The enone **230c** underwent a more efficient 1,3-acyl migration on similar irradiation to give the tricyclic compound **231c** (44%) (Scheme 56), which is a potential precursor to protoilludene.[125]

In continuation of our interest in designing new methodology based on the chemistry of cyclohexadienone and photoreaction of β,γ-enones,[126–128] we developed a new stereoselective route to sterpuranes, another class of sesquiterpenes containing a tricyclic framework wherein the cyclobutane ring is fused with a hydrindane unit in a linear fashion. In this context, the tricyclic β,γ-enones of type **235** were synthesized and their photochemistry was examined upon direct as well as sensitized irradiation.[126] The desired tricyclic compound **235**, containing a β,γ-enone chromophore, was prepared from hydroxymethylphenol **232.** Oxidation of **232** with sodium metaperiodate generated the cyclohexadienone **233**, which

ii hν, benzene (55%)

SCHEME 57

underwent intramolecular cycloaddition to give the adduct **234,** which upon further manipulation provided the chromophoric system **235**. Irradiation of **235** in benzene gave the compound **236** as a result of 1,3-acyl migration (Scheme 57).[126] This methodology provides a novel and stereoselective route to sterpuranes. Interestingly, sensitized irradiation of **235** led to a triquinane intermediate that can be used in the synthesis of coriolin, a triquinane natural product.[126] In addition to these examples of 1,3-acyl migration in β,γ-enones that clearly indicate the synthetic potential of this reaction, the decarbonylation reaction, which is occasionally observed upon direct irradiation, can also be developed as a synthetic method.[128]

79.10 Conclusion

The 1,3-acyl migration is another characteristic and fascinating facet of the photochemistry of β,γ-unsaturated ketones. The reaction is fairly general for rigid β,γ-enones, and a wide variety of substrates undergo 1,3-acyl shift although sometimes it may be accompanied by decarbonylation and ketene elimination. Although the structure of the chromophoric system and the presence of functional groups control the nature of the excited states and their mode of deactivation in a subtle fashion, in general, the rearrangement is observed either from the excited singlet (S_1, $n\pi^*$) or triplet (T_2, $n\pi^*$) states. It is evident from the foregoing examples that 1,3-acyl migration, especially in rigid systems, has immense potential as a versatile synthetic methodology because it provides opportunities to create a diverse array of molecular structures with high stereoselectivity. It provides methods for ring contraction, ring expansion, annulation, etc., depending on the structure of the chromophoric systems. Further, it can be noted that the structures generated via 1,3-acyl migration are difficult to obtain via ground-state chemical reactions. Although the synthetic applications of 1,3-acyl migration have been explored only to a limited extent thus far, the examples presented herein clearly indicate its potential as a stereoselective method and its strategic role in synthesis design.

Photochemical Rearrangements of 6/6- and 6/5-Fused Cross-Conjugated Cyclohexadienones

Gonzalo Blay
Universitat de València

80.1 Introduction

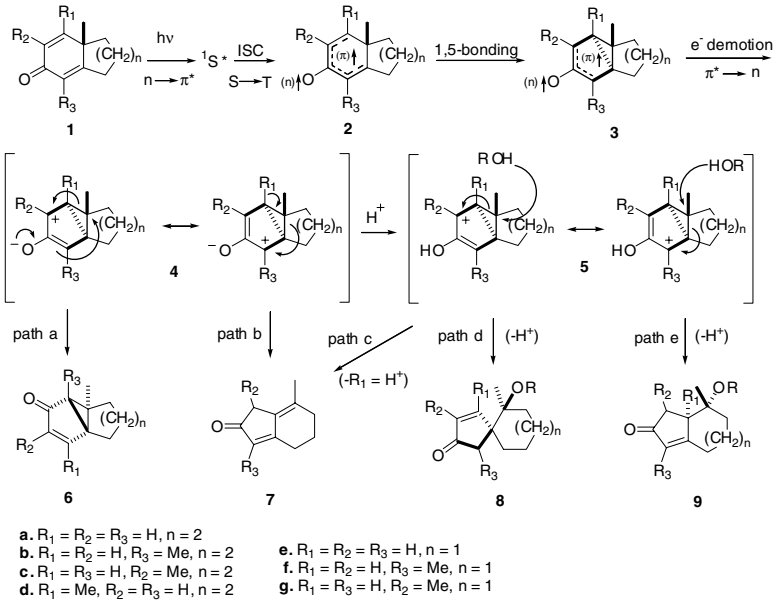
Interest in the photochemical reactivity of cross-conjugated cyclohexadienones began in the 19th century with reports of the light-induced reactions of the naturally occurring sesquiterpene α-santonin.[1] However, the complexity of the structures involved, combined with the variety of products obtained under different irradiation conditions, prevented accurate characterization of this reaction until the mid-1950s, when the pioneering studies by Barton,[2-4] Jeger,[5] van Tamelen,[6] and their groups allowed the elucidation of the structures of the photoproducts of santonin and related steroid dienones.[7,8]

The fascinating, deep-seated rearrangements exhibited by these systems and the recognition of the potential synthetic value of these types of reactions led to the investigation of the photochemistry of a variety of compounds containing the cross-conjugated cyclohexadienone system.[9-11] The photochemistry of 6/6- and 6/5-fused cyclohexadienones, which forms the subject of this chapter, received particular attention between the 1960s and 1980s, with the pioneering works of Kropp and the extensive study carried out by Caine on bicyclic cyclohexadienones being particularly outstanding.[12] In recent years, the number of explorative and mechanistic studies on this reaction has fallen, although the synthetic potential of the process is clear, given the large number of syntheses published that still use this reaction as a key step.

80.2 Mechanism

The photoreactions of cyclic enones and dienones have played a special role in the development of synthetic and mechanistic photochemistry. These compounds undergo many complex structural rearrangements that appear to be unrelated on superficial inspection of product structures. However, after

0-8493-1348-1/04/$0.00+$1.50



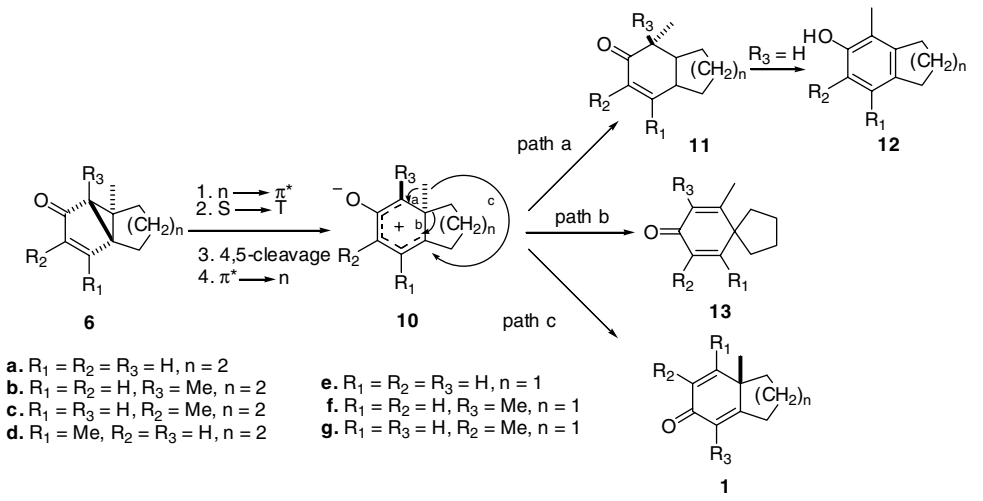
SCHEME 1

extensive studies involving monocyclic 4,4-disubstituted-2,5-cyclohexadienones, Zimmerman and Schuster proposed a generally accepted mechanism that accounts for the photochemical behavior of most cross-conjugated cyclohexadienones — as illustrated in Scheme 1.[13]

In general, it is accepted that photorearrangements of cyclohexadienones proceed via triplet n,π* excited states **2**,[14] which are populated by intersystem crossing from the initial n,π* singlet excited states ^{1}S* obtained by absorption of light at around 300 nm in the ultraviolet region. These n,π* excited states can also be obtained when shorter wavelength light is used (λ ~ 240 nm), in which case the transitions occur by intersystem-crossing and internal conversion of the higher-energy π,π* excited states produced by the initial irradiation. The n,π* excited state of the dienone evolves with the formation of a covalent bond between C1 and C5 (1,5-bonding or β–β bonding) to give a still electronically excited-state n,π* intermediate **3**, which after a π*,n electron-demotion process to the ground state gives a mesoionic zwitterionic intermediate **4**.[15] The intermediate **4** is the key to understanding the rearrangement of cross-conjugated dienones. In nonnucleophilic solvents, intermediate **4** rearranges to bicyclo[3,1,0]hex-2-ones **6** (lumiketones), a process designated a [1,4]-sigmatropic shift, the equivalent to the type A rearrangement of monocyclic dienones (path a).

However, in protic nucleophilic solvents, irradiation of cross-conjugated dienones is commonly found to induce rearrangement to spiro compounds **8** and/or cyclopentenones **9**. These rearrangements can be viewed as resulting from protonation of the oxygen of intermediate **4** to give a carbocation ion **5**, which can subsequently evolve through the following pathways: (1) nucleophilic attack of the solvent from the β-side of the molecule with concomitant cleavage of the external bond of the cyclopropane ring to give spiro compounds **8** (path d); (2) nucleophilic attack of the solvent from the α-side of the molecule with concomitant cleavage of the internal bond of the cyclopropane ring to give cyclopentenones **9** (path e); or (3) less commonly, proton loss from C1 (R_1 = H, n = 1) with concomitant cleavage of the internal bond of the cyclopropane ring to give the linearly conjugated dienones **7** (path c). Direct collapse of zwitterion **4** (n = 1) to compounds **7** may also occur in aprotic media (path b).

It has been pointed out that bicyclohexenones such as **6** may arise directly from the starting dienones through photochemically allowed [σ2a+σ2a] cycloaddition processes.[16] However, evidence for the participation of zwitterionic species **4** is available from alternate synthesis methods,[17] isolation[18] and chemical trapping.[19]



SCHEME 2

Lumiketones are prone to undergo secondary or even tertiary and quaternary photolysis, leading to further rearrangements, a situation that adds considerable complexity to cyclohexadienone photochemistry. In general, the products can be rationalized starting with the postulate that an excited state is produced from **6** that can lead to a zwitterionic intermediate **10** (Scheme 2). Such an intermediate can rearrange in three possible ways: (1) a [1,2]-methyl shift to give the linearly conjugated cyclohexadienone **11** (path a) or its phenolic tautomer **12** (in cases where $R_3 = H$); (2) a [1,2]-methylene migration to give the spiranic cross-conjugated cyclohexadienone **13** (path b); or (3) a [1,2]-methyl shift to give the initial cross-conjugated cyclohexadienone **1** (reverse reaction). These rearrangements are influenced by the nature of the substituents and, in particular, by the size of ring B and its substitution pattern.

80.3 Scope and Limitations

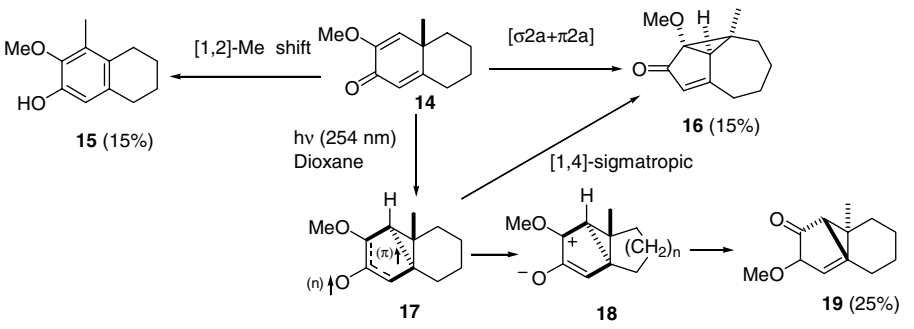
The Effects of Solvent and Wavelengths

Bicyclo[3,1,0]hex-2-en-3-ones related to **6** (lumiketones) are normally prepared by irradiation of dilute solutions of dienones in dioxane or toluene. Best results are obtained with a low-pressure mercury lamp that emits most of its radiation at 253.7 nm. Control of the irradiation time and of the wavelength are important to avoid further rearrangement of the lumiketones to dienones and phenolic products, which are formed on irradiation with light of wavelength greater than 300 nm.[20]

Hydroxycyclopentenones related to **8** and **9** are obtained by irradiation of dilute aqueous acetic acid solutions of dienones with a medium- or high-pressure mercury lamp in a quartz reactor or screened by a Pyrex filter. Acetoxy or alkoxy ketones are obtained under these conditions using acetic acid or alcohols (or alcoholic acetic acid), respectively, as the solvent.[12] However, deviations from this general trend are possible, depending on the nature of the substituents in or around the chromophore.

The Effects of Substituents

The mechanism shown in Schemes 1 and 2 explains the formation of most of the products obtained upon irradiation of cross-conjugated dienones. However, the presence of substituents on the chromophore or in remote positions, or indeed the size of ring B, can have an influence on the outcome of these transformations.



SCHEME 3

Influence of Substituents on the Dienone Chromophore

Aprotic Solvents

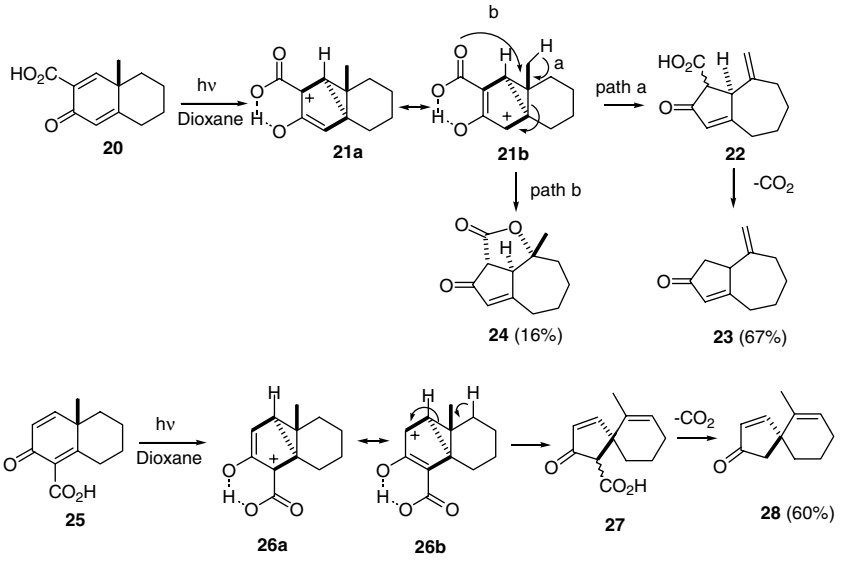
Irradiation at 253.7 nm of unsubstituted or methyl-substituted 6/6-fused bicyclic **1a,b,c,d** and steroid cross-conjugated cyclohexadienones in inert solvents (such as dioxane) leads to a rearrangement that gives rise to the corresponding lumiketones **6a,b,c,d** in good yields.[9] Changes in the position of a methyl group on the chromophore do not have a noticeable effect on the course of the reaction. Lumiketones **6e,f,g** are also the main photoproducts obtained by irradiation of 6/5-fused bicyclic cyclohexadienones **1e,f,g**. In addition to these lumiketones, linearly conjugated dienones **7e** and **7f** were produced upon irradiation of **1e** and **1f**, respectively.[21] Under similar conditions, B-*nor*-1-dehydrotestosterone acetate, which contains a 6/5-fused cyclohexadienone ring, gave the corresponding linearly conjugated dienone as the only product.[22] The exclusive formation of this compound must result from the added strain due to the *trans* fusion of the C ring to the five-membered ring in the steroidal system.

The presence of a methoxy group at C4 in the dienone does not appear to influence the course of the reaction in dioxane. Indeed, irradiation of 4-methoxy-2,4-cholestadien-3-one in dioxane was found to give the corresponding lumiproduct exclusively.[23] However, irradiation of 2-methoxydienone **14** in dioxane at 253.7 nm gave rise to phenol **15** and the tricyclic enone **16**, in addition to the lumiproduct **19** (Scheme 3). Both of these compounds are primary photoproducts that are not obtained by photolysis of lumiproduct **19**.[24]

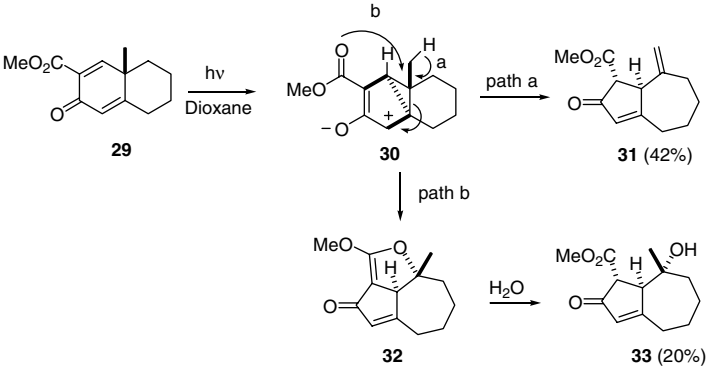
Phenol **15** is probably produced by a simple photochemically induced 1,2-methyl shift. The unusual enone **16** can be considered to arise by either a symmetry-allowed [1,4]-sigmatropic rearrangement in the excited triplet cyclopropane intermediate **17** (related to **3**) or directly from dienone **14** by a photoinduced [σ2a+π2a] cycloaddition process involving the 5,10-σ and the 1,2-π bond of the dienone with inversion at C10. The exact manner in which the methoxy group influences these rearrangements is not clear. The presence of this group may increase the lifetime of the triplet species **17** to such an extent that it allows time for rearrangement prior to electron demotion to a zwitterionic species **18** (related to **4**), which leads to the lumiproduct **19**, or it may cause selective excitation of the 1,2-π bond of the dienone.

The presence of electron-withdrawing groups on the chromophore in 6/6-fused cyclohexadienones suppresses rearrangement to the lumiproducts in aprotic solvents. Irradiation of the 2-formyl derivative of the bicyclic cyclohexadienone **1a** (compound **46** in Scheme 9) gave a mixture of products in low yields along with a polymeric material,[25] while a related 2-formyl steroidal dienone was stable to light at 253.7 nm but gave a complex mixture when irradiated with a broad-spectrum lamp.[26] The 4-formyl derivative of dienone **1a** (R_3 = formyl) does not give rearranged products.[25]

In contrast, irradiation of a dienone **20**, which bears a carboxy group at C2, in dioxane gave the azulene dienone **23** and enone **24** in 67% and 16% yields, respectively, while under similar conditions the 4-carboxydienone **25** yielded the spirodienone **28** in 60% yield (Scheme 4).[25] The ability of the carboxy group to internally protonate the carbonyl group at C3 in the zwitterionic intermediates **21** and **26** is likely to be the major factor driving the rearrangement to azulene or spiro compounds rather than to



SCHEME 4

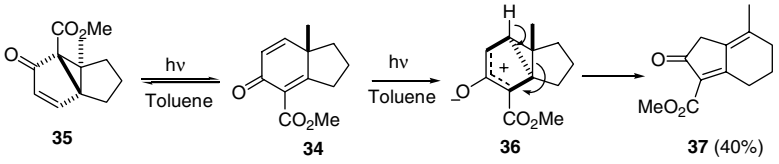


SCHEME 5

lumiketones. Cleavage of the 5,10-bond of the cyclopropane ring (path a), which is favored in the more stable conjugate structure **21b**, would lead to the β-keto acid **22**. Compound **22** would then decarboxylate to give the major product **23**. On the other hand, direct intramolecular attack of the C2 carboxylate at C7 (path b) would form compound **24**.

Spirodienone **28** arose through decarboxylation of the corresponding β-keto acid **27**, which was obtained by proton loss from C9 and concomitant cleavage of the 1,10-bond — a process that would be favored in the chelated conjugated cyclopropyl intermediate **26b** (Scheme 4).

Similarly, irradiation of the 2-carbomethoxydienone **29** in toluene or dioxane afforded azulene dienone **31** (33 to 42%) and hydroxyenone **33** (19 to 20%) as primary photoproducts (Scheme 5).[27] Suppression of lumiproducts is explained by considering intramolecular attack of the ester group. Intramolecular deprotonation of the C10 methyl group by the carbomethoxy group (path a) in the zwitterionic intermediate **30** would account for the major product, while attack by the carboxylate group on the electron deficient C10 position (path b) would generate **32**, the subsequent hydrolysis of which would afford alcohol **33**.



SCHEME 6

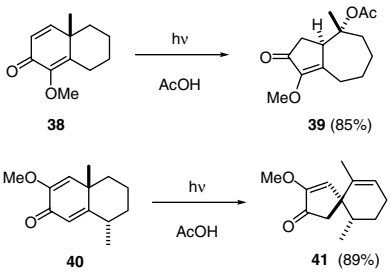
The 4-carbomethoxy derivative of dienone **1a** (R_3 = carbomethoxy), in a similar way to the 4-formyl derivative (R_3 = formyl), fails to yield photorearranged products. This lack of reactivity is attributed to a photochemical deconjugation of the 4,5-double bond to the 5,6-position and enolization of the C4 carbonyl group.[25] However, the corresponding 4-carbomethoxy 6/5-fused dienone **34**, in which double bond deconjugation is less favorable for steric reasons, rearranges in toluene to give the 5/6-fused dienone **37** (Scheme 6), which would be formed following a path similar to path b in Scheme 1. In this process, the corresponding lumiketone **35** is formed reversibly and can be isolated if irradiation is interrupted in midcourse.[27] The divergent behavior of compound **34** suggests that the location of the carbomethoxy group in relation to the migrating bond does influence the ease of the [1,4]-sigmatropic rearrangement (path a in Scheme 1): When the ester group occupies the position at which the new bond is formed, rearrangement to lumiproducts is observed. When the ester occupies an alternative position, as is the case with compound **29**, the [1,4]-shift is rendered less favorable and other processes dominate in its absence.[27]

Protic Solvents

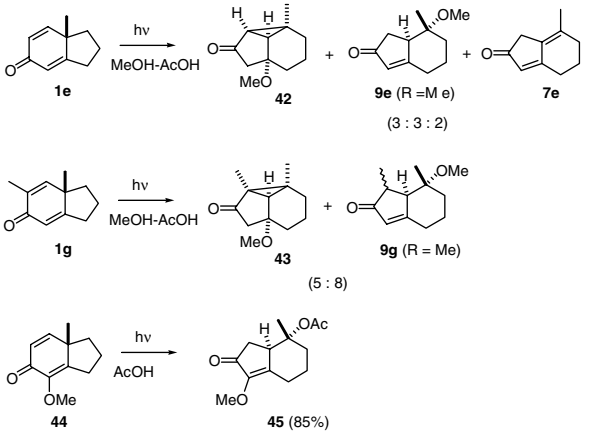
In protic solvents, 6/6-fused cyclohexadienones undergo photorearrangement to 5/7-fused or spiro enones through protonated mesoionic species such **5** (Scheme 1). The mode of cleavage is controlled by the electronic influence of the substituents. For example, on irradiation in aqueous acetic acid, the 4-methyldienone **1b** yielded exclusively the 5/7-fused hydroxyketone **9b** (R = H)[28,29] while the 2-methyl compound **1c** yielded exclusively the spiro hydroxy ketone **8c** (R = H).[20] Under similar conditions, the unsubstituted dienone **1a** yielded an approximately 1:1 mixture of **8a** (R = H) and **9a** (R = H).[30] In each case, the hydroxy ketones were accompanied by varying amounts of phenols that arise as secondary photoproducts from the related lumiketones **6**. Thus, the presence of an electron-releasing group at C2 or C4 increases the stability of the resonance form with a positive charge at that position and cleavage via path d or path e, respectively, takes place (Scheme 1). When ring A is unsubstituted, both resonance forms are approximately equal in energy and, in this case, products derived from both possible cleavage pathways are isolated.

According to this mechanism, it is anticipated that methoxy and methyl substituents must exert a similar influence on the course of the photochemical rearrangement in protic solvents. Indeed, the 4-methoxydienone **38** yielded exclusively the 5/7-fused compound **39** on irradiation in acetic acid,[31] while under similar conditions, the 2-methoxydienone **40** gave the spiro enone **41** in high yield (Scheme 7).[32] The use of aqueous acetic acid in these cases led to a decrease in the amounts of rearranged products due to a light-catalyzed hydrolysis of the enol ether function.

The 4-methyl substituted 6/5-fused dienone **1f** showed similar behavior to the parent 6/6-fused dienone, and gave the 5/6-fused hydroxy ketone **8b** (R = H) in 59% yield upon irradiation in aqueous acetic acid and the related ethoxy ketone **8b** (R = Et) upon irradiation in ethanol. However, the unsubstituted dienone **1e** and the 2-methyl derivative **1g** underwent additional photochemical rearrangements when irradiated in protic solvents. Thus, irradiation of **1e** in methanolic acetic acid yielded the tricyclic methoxy ketone **42**, the 5/6-fused ketone **9e** (R = Me) and the dienone **7e** in *ca.* 3:3:2 ratio. Under similar conditions, photolysis of **1g** gave **43** and **9g** (as a *ca.* 9:1 mixture of C2 epimers) in a 5:8 ratio (Scheme 8). Compounds such as **9e**, **9g**, and **7e** are rationalized as resulting from cleavage of the internal bond of the cyclopropane ring in the mesoionic intermediate **4e** or **4g** (Scheme 1), while the tricyclic ketones **42** and **43** would be formed through a pathway similar to that for ketone **16** (Scheme 3).[33]



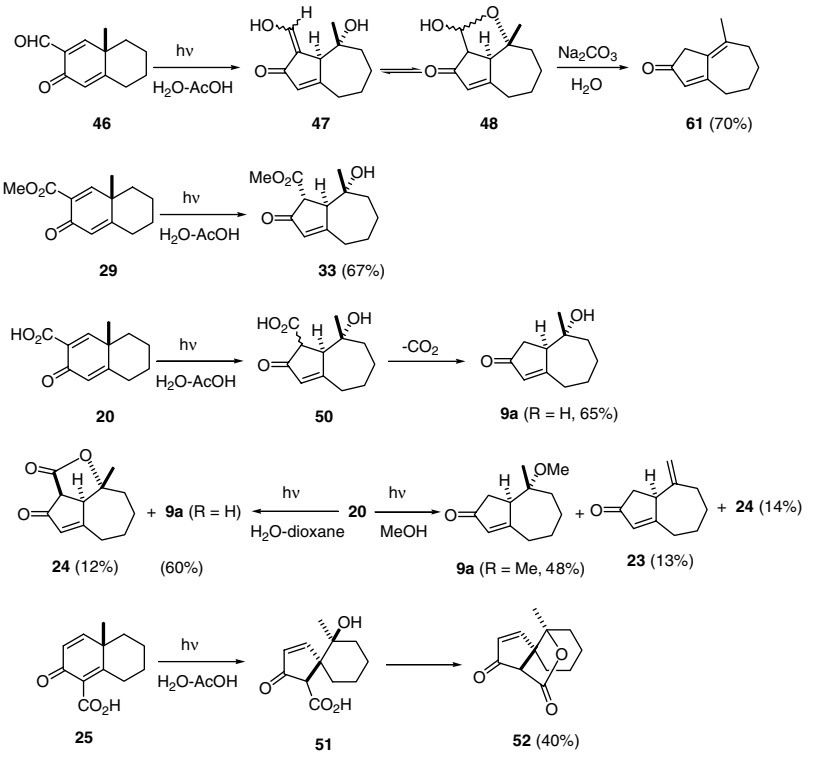
SCHEME 7



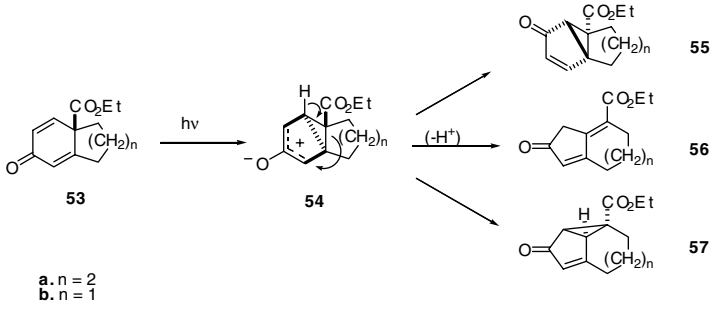
SCHEME 8

The photochemical rearrangement of 2-methoxy 6/5-fused dienones in protic solvents has not been reported. However, irradiation of the 4-methoxy 6/5-fused dienone **44** in acetic acid gave the 5/6-acetoxy ketone **45** in 85% yield and showed behavior similar to the corresponding 6/6-systems.[31]

6/6-Fused dienones bearing an electron-withdrawing substituent at C2 rearrange to azulene derivatives upon irradiation in protic solvents. In this case, the presence of an electron-withdrawing group would favor build-up of more positive charge at C4 than at C2 in the protonated mesoionic intermediate related to **5,** and this would then undergo solvolytic attack at C10 with cleavage of the internal 5,10-bond of the cyclopropane ring to give the 5/7-fused compounds. For example, irradiation of 2-formyl 6/6-fused dienone **46** in aqueous acetic acid leads to 5/7-fused hydroxymethylene compounds that can be deformylated to the corresponding ring A unsubstituted 5/7-fused systems **49**.[25,34] Dienone **29** was converted into **33** in high yield upon irradiation in aqueous acetic acid. Under similar conditions, the 2-carboxydienone **20** gave the 5/7-fused hydroxy ketone **9a** (R = H) in 65% yield, along with small quantities of other products (<7%). Compound **9a** would be formed after decarboxylation of the β-keto acid **50** resulting from the initial photorearrangement of **20**. In aqueous dioxane, **20** gave compound **9a** (R = H) in 60% yield and lactone **24** in 12% yield, while in anhydrous methanol the methyl ether **9a** (R = Me) was obtained as the major product in 48% yield along with dienone **23** (13%) and lactone **24** (14%).[25] Irradiation of dienone **25**, which contains a carboxyl group at C4, gave the lactone **52** in 40% yield. This compound would be formed after solvolytic attack at C10 in the protonated mesoionic intermediate related to **5**, with subsequent cleavage of the external bond of the cyclopropane ring to produce a γ-hydroxy-β-keto acid **51** that could lactonize to **52** (Scheme 9).



SCHEME 9

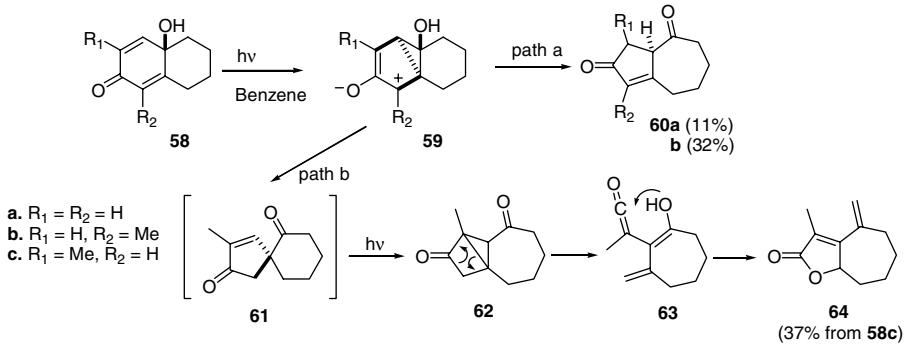


SCHEME 10

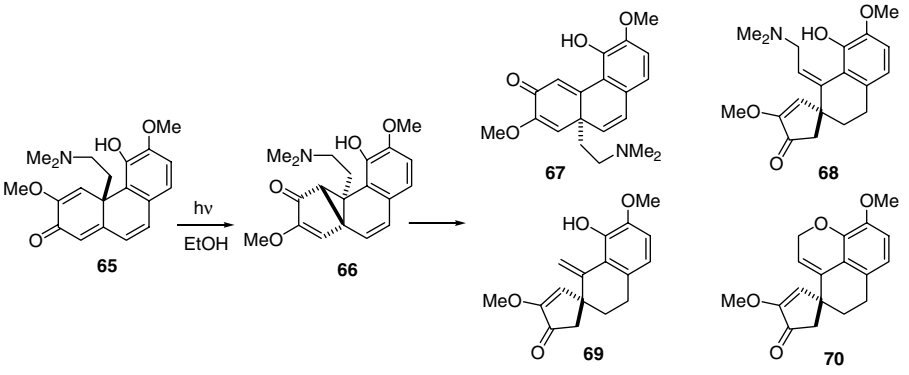
The irradiation of 4-formyl and 4-carbomethoxydienones in protic solvents fails to react, as they also failed in aprotic solvents.

Other Ring A Substituent Effects

The presence of electron-withdrawing groups at the angular position of bicyclic dienones strongly influences the photochemical reactivity and modes of rearrangement. The lumiketone **55a** is the main photoproduct resulting from the irradiation of the 6/6-fused dienone **53a** in either dioxane or aqueous acetic acid. Compound **55a** is obtained along with small amounts of the linearly conjugated dienone **56a**, the tricyclic ester **57a,** and other minor products (Scheme 10).[12,35]



SCHEME 11

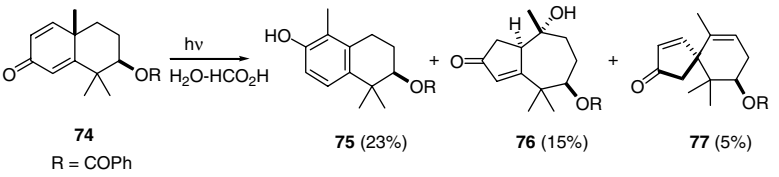


SCHEME 12

It appears that the ester group in the zwitterionic intermediate **54a** stabilizes the cyclopropane ring toward solvolytic cleavage, although the [1,4]-sigmatropic rearrangement to the lumiketone still occurs. Dienone **56a** could arise through collapse of **54a** with loss of a proton. The tricyclic compound **57a**, which has the same carbon skeleton as ketone **16**, is obtained possibly by a similar pathway (Scheme 3). On the other hand, the 6/5-fused dienone **53b** gave exclusively dienone **56b** under similar conditions,[12] providing further evidence of the propensity of the 6/5-fused dienones to yield 5/6-fused systems.

The presence of a hydroxyl group at the angular position prevents photorearrangement to the lumiketone products. Thus, photolysis of the bicyclo-dienones **58a** and **58b** in benzene gave azulene diketones **60a** and **60b**, respectively, as the chief isolable products (Scheme 11), albeit in low yields (11% and 32%, respectively). These compounds are formed by collapse of the zwitterionic cyclopropanol intermediate **59** with cleavage of the 5,10-bond (path a). Under the same conditions, compound **58c** gave butenolide **64** as the sole isolable product in 37% yield. It is considered that this product is formed via the spirodiketone **61**, which in turn is produced from cleavage of the 1,10-bond in **59** (path b).[36] Spirodiketone products have been isolated from irradiation mixtures of steroidal and diterpenoid hydroxydienones with structures related to **58** and, moreover, it has been shown that these compounds can undergo photoconversion to the butenolides.[36,37] This photoconversion is rationalized in terms of cyclization of a ketoketene formed by isomerization of the spiroketone (Scheme 11).

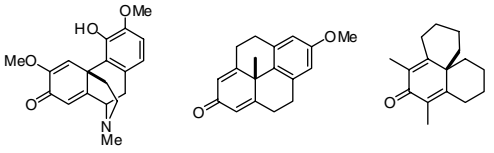
Irradiation of the tricyclic dienone **65**, which bears an *N*,*N*-dimethylethylene moiety at the angular position, in EtOH produced four amorphous products in low yield (Scheme 12). It is suggested that these products arise from the decomposition of the non-isolated lumiketone **66** by any of the following



SCHEME 13

pathways: (1) migration of the side chain from the C4b to C8a with concomitant dienone formation would lead to compound **67**; (2) the genesis of the second photoproduct **68** would involve stereospecific loss of one of the two C11 hydrogens of lumiketone **65** with formation of a 4b,11-double bond and cleavage of the 4b,5-bond; or (3) compounds **69** and **70** would be formed by a mechanism related to that discussed above, where the 4b,11-double bond would be formed through loss of the dimethylaminomethyl moiety or dimethylamine from species **68**, respectively.[38]

The presence of other rings fused to the cyclohexadienone chromophore may lead to failure of the photochemical rearrangement, probably as a consequence of steric factors preventing β,β'-bonding in the excited states. This is the case with dienones **71**,[38] **72**[39] and **73**.[40]

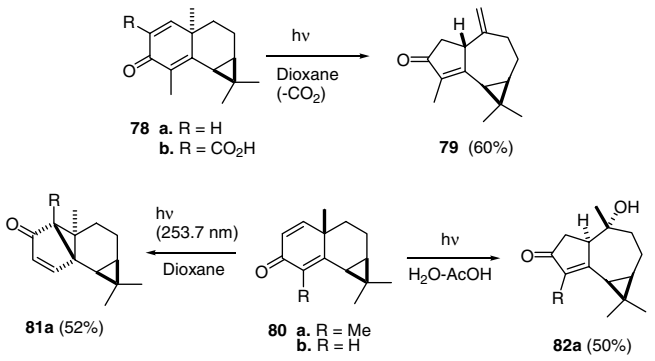


Effects of Ring B Substituents

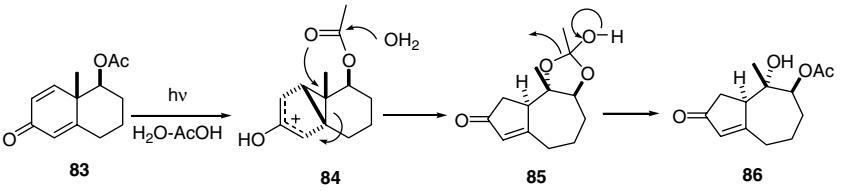
Substituents on ring B may impose steric and conformational restrictions onto the rearrangement of fused dienones. Irradiation of the 6-disubstituted dienone **74** in aqueous acetic acid gave principally the *o*-cresol-type product **75** and the 5/7-fused ketone **76**, along with small amounts of the spiroketone **77** (Scheme 13). The unfavorable ratio of **77**/**76**, in comparison to that obtained upon irradiation of **1a**, is attributed to the fact that the 6β-methyl substituent strongly hinders the approach of solvent at C10 from the top side of the mesoionic cyclopropyl intermediate derived from **74**. However, spiroketone formation still occurs to some extent, but with accompanying loss of a proton at C9 replacing the usual attack of solvent. Phenol **75** is probably formed by rearrangement of the lumiproduct derived from **74** following a pathway similar to that described in Scheme 2.[41]

The photochemical behavior of tricyclic dienones **78** and **80** is strongly dependent on the relative disposition between the cyclopropane ring and the bridge methyl group (Scheme 14). For example, dienone **78a**, in which the two aforementioned elements are in a *trans* disposition, has been found to be stable upon direct irradiation in aprotic[42] or protic[43] media. The failure of **78a** to undergo rearrangement has been attributed to the fact that the zwitterionic intermediate that should be formed is expected to be highly strained because the two adjacent cyclopropane rings on the six-membered ring would have a *cis* relationship to each other. Interestingly, compound **78b**, which contains a carboxyl group at C2, was converted into tricyclic dienone **79** upon irradiation in dioxane. In this case, the carboxyl group may sufficiently influence the energy and electronic distribution of the photoexcited species to allow the formation of a cyclopropyl intermediate analogous to **21** (Scheme 4), although it is also possible that a different reaction pathway may be taken in this case.[43]

In contrast to **78a**, its C10 epimer **80a**, which has a *cis* relationship between the methyl and the cyclopropane ring, rearranges in the normal way to give the lumiketone **81a** or the 5/7-fused hydroxy ketone **82a** upon irradiation in dioxane[44] or aqueous acetic acid, respectively.[45] The related dienone **80b** reacted similarly to **80a** in dioxane but it was prone to undergo thermal cleavage of the cyclopropane



SCHEME 14

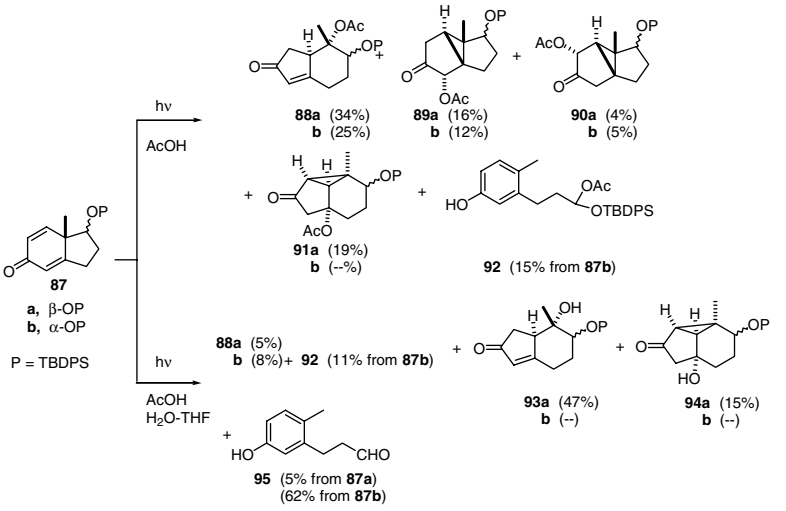


SCHEME 15

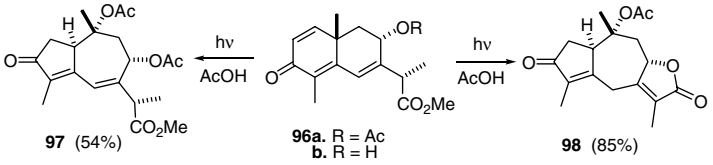
ring in aqueous acetic acid. However, it was transformed into the acetyl derivative of **82b** in 71% yield upon irradiation in glacial acetic acid.[44]

Several bicyclic 6/6- and 6/5-fused dienones containing oxy substituents (ether or ester groups) at the contiguous atom to the bridge carbon have been prepared and irradiated. The 6/6-fused 9-acetoxydienone **83** underwent photorearrangement to give largely the 5/7-fused enone **86** upon irradiation in aqueous acetic acid (Scheme 15). The exclusive formation of **86** is attributed to participation of the acetoxy group in the selective cleavage of the internal bond of the cyclopropane ring in the corresponding cationic intermediate **84**.[46]

Irradiation of the 6/5-fused dienone **87a**, which bears a β-TBDPS group at C8, in glacial acetic acid furnished the 5/6-acetoxy ketone **88a** as the major product, along with three tricyclic ketones **89a**, **90a**, and **91a** (Scheme 16). Spirocyclic products were not obtained. Compounds **88a** and **91a** are probably formed by similar pathways as compounds **9e** and **42** (Scheme 8). Tricyclic acetoxy ketones **89a** and **90a** are probably derived from trapping of the cyclopropyl carbocation intermediate. It appears that, in this case, the β-substituent reduces the rate of cleavage of the cyclopropane ring in the protonated intermediate (analogous to **5**) to such an extent that the trapping process can occur. The effect may be steric or electronic. Clearly, the bulky β-substituent could reduce the rate of solvent attack, but it is also feasible that the electron-withdrawing effect of the silyl ether may destabilize the transition state for opening of the cyclopropane ring by increasing the positive charge at C9. The photochemical behavior of the epimeric ketone **87b** in acetic acid was similar to that of **87a**, except that the tricyclic cyclopropyl ketone related to **91a** was not detected (Scheme 16). It seems that the strong interaction between the α-methyl and the α-TBDPS groups, which does not occur when the OTBDPS group is in the β-position, could prevent the [1,4]-sigmatropic rearrangement from occurring. The phenolic hemiacetal acetate **92**, produced by thermal cleavage of the 1,9-bond, is also isolated in 15% yield. However, both compounds differ in their photochemical behavior in water:THF solutions containing acetic acid. Under these conditions, thermal cleavage was the main process for compound **87b**, with a small amount of compound **88b** being the only photoproduct detected. However, under similar conditions, photolysis of **87a** proceeded smoothly to give



SCHEME 16



SCHEME 17

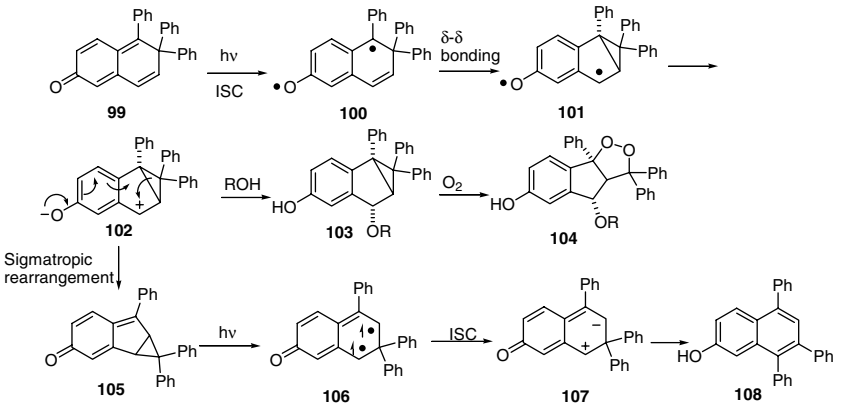
88a, **93a**, **94a**, and **95**.[47] Thus, the configuration of the δ-oxy substituent at C8 can profoundly affect the rates of the competing photochemical and thermal processes in these systems.

Extended π Systems

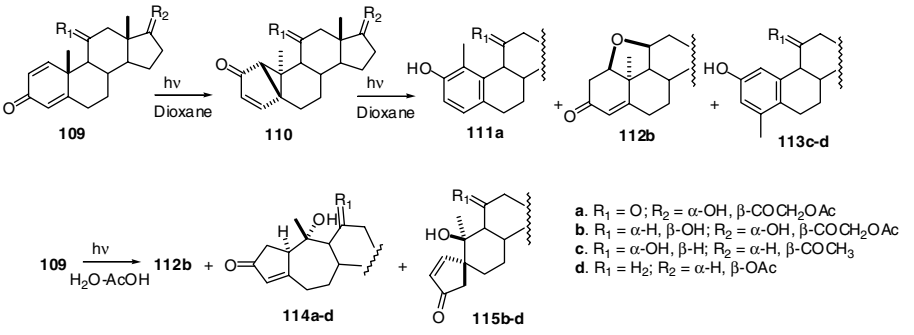
Irradiation of trienone **96a**, which bears an additional double bond conjugated with the 4,5-double bond of the dienone, in glacial acetic acid yielded exclusively the azulene linearly conjugated dienone **97** in 54% yield (Scheme 17). Under similar conditions, trienone **96b** yielded lactone **98** in 85% yield.[48] Thus, it seems that the 6,7-double bond does not interfere in the photochemical rearrangement.

In contrast, the extension of the π-system at both ends of the dienone moiety changes its photochemistry dramatically.[49] Irradiation of **99** in methanol or isopropyl alcohol gave a major photoproduct **104** that incorporated a molecule of solvent and a molecule of molecular oxygen, along with a small amount of triphenylnaphthol **108**. Compound **104** was formed by reaction of oxygen with the intermediate **103**, which can be obtained under conditions of total exclusion of oxygen. In non-nucleophilic solvents such as acetonitrile, the triphenylnaphthol **108** is obtained exclusively (Scheme 18).

The mechanism for the formation of **103** is seen to be analogous to that proposed for the "type A" 2,5-cyclohexadienone rearrangement. The initial δ–δ bonding step here is the counterpart of the β–β bonding in monocyclic dienones. However, unlike monocyclic zwitterionic intermediates, zwitterion **102** captures solvent faster than it rearranges. This solvent capture gives intermediate **103**, which, after reaction with oxygen, yields product **104**. The minor product **108** derives from the bicyclic rearrangement: in the absence of nucleophilic solvents, zwitterion **102** undergoes a sigmatropic rearrangement to triphenyl quinone methide **105**, a process that is analogous to the "type A" rearrangement characteristic of monocyclic 2,5-cyclohexadienones. The secondary photoexcitation of **105** and intersystem crossing leads to



SCHEME 18



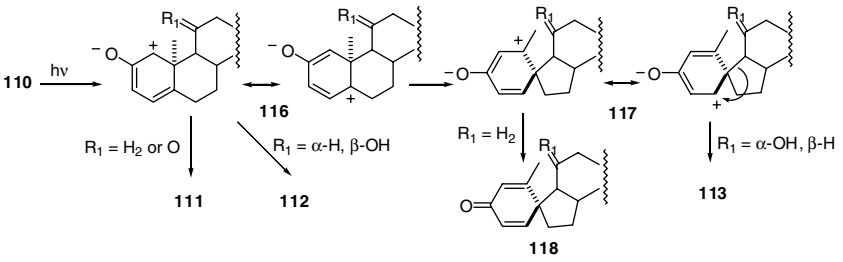
SCHEME 19

the ground-state zwitterionic species **107**, which, after phenyl migration, gives **108.** This process is the counterpart of the "type B" rearrangement that is common in the photochemistry of bicyclo[3,1,0]hexen-2-ones.

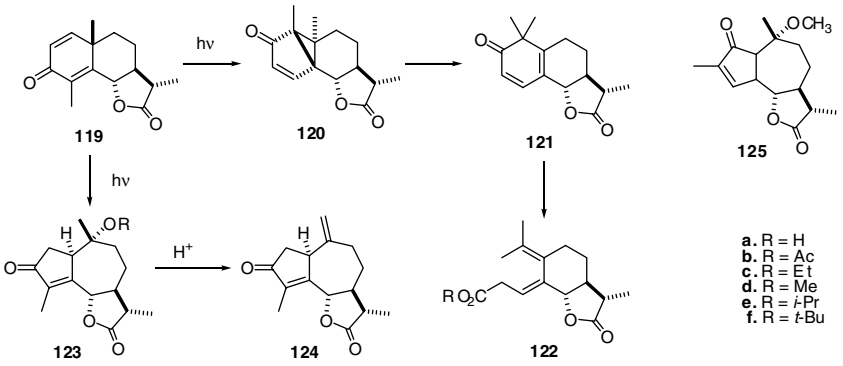
Remote Substituent Effects

The photochemistry of several steroid cross-conjugated cyclohexadienones substituted at C11 has been studied.[50] Photolysis of the prednisone acetate **109a**, prednisolone acetate **109b**, and 11α-hydroxypregna-1,4-diene-3,20-dione **109c** in dioxane afforded the expected lumiproducts. Apparently, the presence of a substituent at this position does not affect the photochemistry of these compounds in neutral conditions, but it does affect the photolysis of the corresponding lumiproducts. Irradiation of **110a** and **110b** in dioxane gave the *o*-methylphenol **111a** and the 1,11-oxy steroid **112b**, respectively. In contrast, the α-hydroxy compound **110c** gave a *m*-methyl-phenol **113c** as does the C11 unsubstituted steroid lumiproduct **110d**.

In aqueous acetic acid, irradiation of compounds **109** gave the expected bicyclo[5,3,0]-systems **114** and spiro steroids **115**, although variable product ratios and yields were obtained. In addition, the 11β-hydroxysteroid **109b** gave the 1,11-oxy steroid **112b** as the major product (Scheme 19). Compounds **111**, **112**, and **113** are photoproducts derived from the corresponding lumi-intermediates formed through zwitterionic intermediate **116**, which can rearrange in a number of ways (Scheme 20): (a) 1,2-migration of the angular methyl group leading to phenol **111** or (b) rearrangement through spiro structure **117**, which can collapse to the spiro cross-conjugated dienone **118** or undergo further 1,2-bond migration to



SCHEME 20



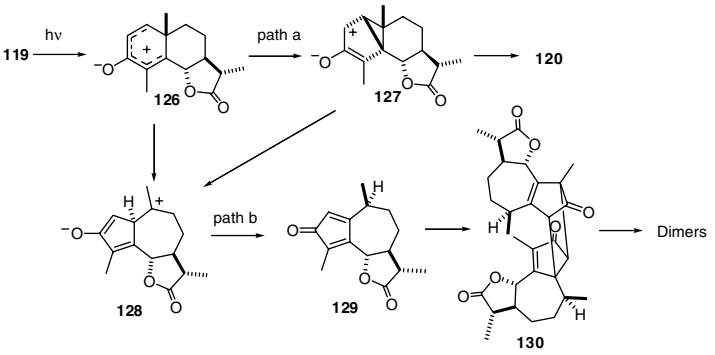
SCHEME 21

give 4-methylphenol **113**. When a C11 ketone is present the latter process does not occur – probably because cleavage of the 9,10-bond and migration of C9 to C5 would involve the formation of a partial positive charge adjacent to the electron deficient C11 carbonyl carbon. On the other hand, nucleophilic attack by the β-OH group on the C1 carbocation **116** would lead to the formation of the 1,11-oxy steroid-type compounds **112**. In the 11α-hydroxy steroids, the OH group is too far away from C1 and, therefore, these kinds of products are not obtained.

The ratio of **114:115** is also dependent on the substitution at C11. For example, a ratio of *ca.* 50:50 is obtained from the C11 unsubstituted dienone **109d** and also from the 11β-hydroxy compound **109b**. However, when the 11α-hydroxyl group is present, the yield of **114c** is four times that of **115c**, while the C11 keto compound **109a** yields only **114a**. The increased amount of **114** is attributed to hydrogen bonding between the C11 oxygen and the solvent in the corresponding carbocation intermediates related to **5**. Hydrogen bonding in **109a** and **109c** would favor solvent attack from the α-side giving rise to compounds **114a** and **114c**, whereas the C18 methyl group would block the formation of hydrogen bonds on the β-side in compound **109b**.

80.4 Photochemistry of Santonin

Santonin (**119**) undergoes a number of interesting rearrangements that are solvent dependent (Scheme 21). There are three main products resulting from irradiation of santonin: lumisantonin (**120**), photosantonic acid derivatives **122**, and isophotosantonic lactone derivatives **123**. Lumisantonin is best obtained by the photolysis of **119** in dioxane,[5] while photosantonic acid derivatives **122** and isophotosantonic lactone derivatives **123** are produced when irradiation of santonin is carried out in protic media of the type R–OH or R–COOH.[51] Photosantonic acid (**122a**)[6] can be prepared by irradiation of santonin



SCHEME 22

in aqueous solution containing one equivalent of potassium hydroxide,[1,3] while isophotosantonic lactone (**123a**) and *O*-acetyl isophotosantonic lactone (**123b**) are the major products of irradiation in aqueous and glacial acetic acid, respectively. Photosantonic acid (**122a**) is also obtained as an additional product under these conditions.

Irradiation of santonin in alcoholic solutions[51] gives addition products of type **123c,d,e,f** as well as the main product, lumisantonin (**120**) and the corresponding esters **122c** (photosantonin)[3-5] and **122d** and**122e**. The amount of **123** diminishes with the bulkiness of the solvent and also depends on the acidity of the medium up to a limiting value above which *exo* anhydro-isophotosantonic lactone **124** is also formed.[51]

The formation of compounds **120** and **123** can be explained in terms of the mechanism outlined in Scheme 1. Thus, lumisantonin (**120**) is obtained through path a from the zwitterionic intermediate related to **4**, while the isophotosantonic intermediates **123** are produced by attack of the solvent on the cationic intermediate related to **5** (path e). Elimination of the OR group occurs on increasing the acidity of the reaction medium and this must be responsible for the formation of compound **124**. The presence of the *trans* γ-lactone in this case prevents spiran formation because the resulting spiro intermediate would require the highly strained *trans* fusion of two five-membered rings.

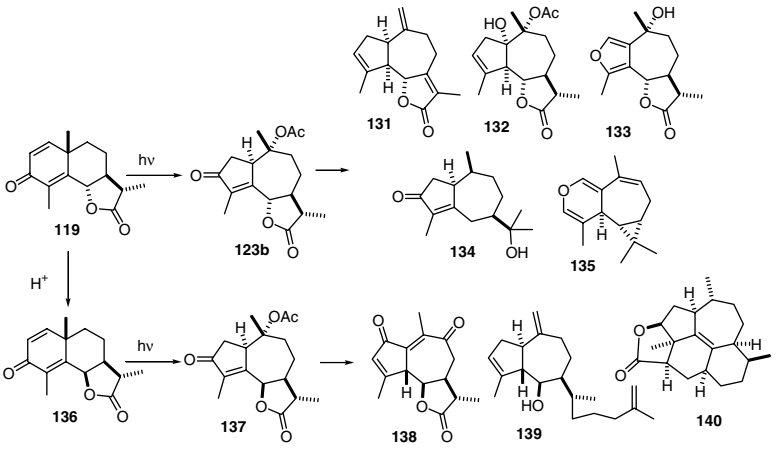
On the other hand, photosantonic acid derivatives **122** arise from subsequent photolysis of lumisantonin (**120**) and may indicate the participation of the intermediate with a linear dienone structure (i.e., **121**), which is called mazdasantonin. Mazdasantonin has been obtained by irradiation of lumisantonin (**120**) in aprotic media such as ether or benzene and this compound is rapidly transformed into photosantonic acid when the irradiation is continued in the presence of water.[52]

Another, less common, photoproduct of santonin is neoisosantonic lactone methyl ether (**125**) and this has been obtained in 73% yield upon irradiating santonin in $CHCl_3$/MeOH in the presence of maleic anhydride.[53]

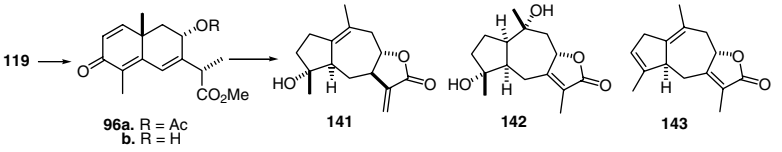
The irradiation of santonin in the solid state leads mainly to cyclopentadienone **129**, which spontaneously dimerizes to give compound **130** as well as small amounts of other dimers and lumisantonin (**120**) (Scheme 22). The formation of **129** can be understood in terms of the migration of a hydrogen atom from C1 in the zwitterionic intermediate **128** (path b). The selective transformation of **119** into **130**, which predominates over lumisantonin formation (path a), is interpreted by considering that path b requires less atomic movement in the geometry of santonin and, therefore, is preferred in the solid state.[54]

80.5 Synthetic Applications

The photochemical rearrangement of fused cross-conjugated dienones is a powerful synthetic tool. Due to the high stereoselectivity of this reaction and to the structures of the resulting products, which can be



SCHEME 23



SCHEME 24

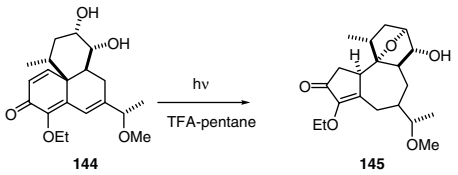
controlled by varying solvents, irradiation wavelength, and substituents, these reactions have been used in a large number of total syntheses of natural products.

The original photochemical rearrangements of α-santonin (**119**) or 6-*epi*-α-santonin (**136**) in protic media to give the corresponding isophotosantonic lactone derivatives have been extensively applied to the synthesis of terpenes, especially 6,12-guaianolides. Recent examples (Scheme 23) include the synthesis of *ent*-isodehydrocostus lactone (**131**),[55] 8-deoxy-11,13-dihydrorupiculin B (**132**),[56] 3-oxaguaianolides **133**,[57] (+)-hydrocolorenone (**134**)[58] and oxoisodehydroleucodin (**138**),[59] as well as the synthesis of the *ent*-seco-aromadendrane plagiochilline N (**135**),[60] the diterpene (+)-pachidictyol A (**139**)[61] and the synthesis of a tetracyclic precursor of 3α-hydroxy-15-rippertene **140**.[62]

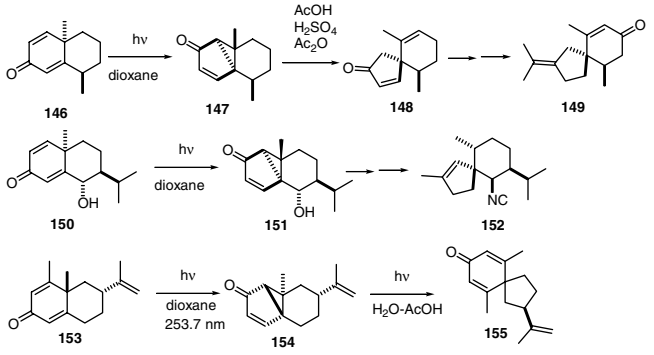
Furthermore, santonin has been readily transformed into 8-oxyfunctionalized trienones **96a** and **96b**, which after photochemical rearrangement and lactonization provided a convenient method for the preparation of, among others, the 8,12-guaianolides 8-*epi*-pseudoivalin (**141**), (+)-zedolactone A (**142**), and podoandin (**143**) (Scheme 24).[48]

Other molecules possessing a 5/7-fused ring system have been synthesized by pathways involving the photochemical conversion of 6/6-fused dienones. Among these, it is worth mentioning the synthesis of the aromadendrane-type sesquitepenes cyclocolorenone,[43] (−)-4-epiglobulol and (+)-4-epiaromadendrane[45] from compounds **78** and **80**. The rearrangement of a highly functionalized tricyclic cyclohexadienone **144** in TFA/pentane is the key step in a general synthetic route to daphnanes and (+)-resiniferatoxin (Scheme 25).[63]

The rearrangement of 6/5-fused dienones has also been applied to the synthesis of natural products. The 6β-isopropyl derivative of acetoxy ketone **45**, obtained upon irradiation of the 6β-isopropyl derivative of dienone **44**, was used in the synthesis of oplopanone.[31] On the other hand, expansion of the A ring in the 5/6-fused methoxy ketone resulting from irradiation of the 6β-isopropyl derivative of **1e**, allowed the synthesis of the cadinane sesquiterpene 3-oxo-α-cadinol and α-cadinol.[64]



SCHEME 25



SCHEME 26

Lumiproducts obtained by irradiation of cyclohexadienones in neutral media can be transformed in several ways into useful synthetic intermediates (Scheme 26). For example acid treatment of lumiproducts such as **147** gives spirocyclic compounds. This strategy has been used in the synthesis of spirovetivane sesquiterpenes such as (±)-β-vetivone (**149**).[65]

The lumiproduct **151** was converted in several steps, including reductive cleavage of the cyclopropane ring with Li/$EtNH_2$, into a 5/6-spirocyclic system that was subsequently transformed into (−)-axisonitrile-3 (**152**).[66]

Irradiation of lumiproducts in aqueous acetic acid with UV light above 300 nm brings about photorearrangement to spirocyclic dienones. This type of transformation was used for the conversion of the nootkatane sesquiterpenes 3,4-dehydronootkatone (**153**) into the spirovetivane anhydro-β-rotunol (**155**) and in the synthesis of β-vetivone and 4-*epi*-β-vetivone from dehydro-β-vetivone.[67]

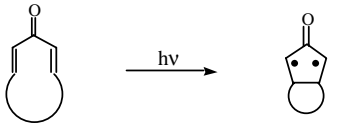
Photocycloaddition/ Trapping Reactions of Cross-Conjugated Cyclic Dienones: Capture of Oxyallyl Intermediates

Albert R. Matlin
Oberlin College

81.1 Introduction

Cross-conjugated cyclic dienones with 6-, 7-, and 8-membered rings exhibit a rich and diverse photochemistry. The deep-seated photochemical rearrangements found in these systems have attracted numerous mechanistic studies. Cyclohexadienones have received the most attention and provide the general framework for the mechanistic understanding of the photochemistry for this class of compounds.[1] The key intermediate in these systems is an oxyallyl transient that is formed by ring closure across the β, β′-carbons in the dienone systems: **A** → **B**.



A **B**

More recently, the synthetic potential of the oxyallyl intermediates has been explored in intra- and intermolecular trapping studies. This chapter focuses on studies directed at capturing oxyallyl intermediates generated by the irradiation of cyclic dienones.

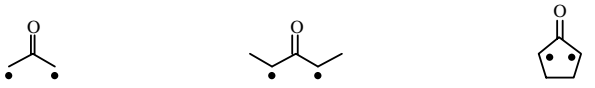
81.2 Oxyallyl Intermediates

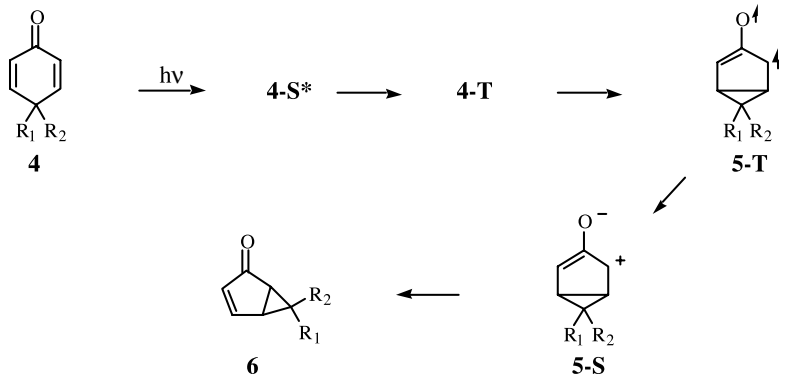
Oxyallyl intermediates have been invoked in the mechanisms for a wide range of reactions, including the photoisomerizations of cross-conjugated dienones,[2] stereomutation, and cycloaddition reactions of cyclopropanones,[3,4] reductive-elimination reactions of α, α′-dibromoketones,[5,6] and the Favorskii reaction.[7] Despite all this attention (and speculation), there has not been any definitive kinetic[8] or spectroscopic observation of an oxyallyl intermediate.[9] Historically, oxyallyl systems have been described as zwitterions. However, molecular orbital calculations consistently indicate that the parent system **1** is a ground-state triplet lying 1 to 2 kcal/mol below the lowest singlet state.[10-12] The singlet–triplet separation is delicately balanced and calculations indicate that the ordering can be reversed to give a singlet ground state by either alkyl substitution[11] (e.g., **2**) or by incorporation of the oxyallyl into a cyclic system (e.g., **3**).[13,14] The potential energy surface shows that the singlet state of **1** lives in a flat, shallow minimum with only a 0.3-kcal/mol barrier to closure to cyclopropanone.[15] This small barrier should give rise to a very short lifetimes for acyclic oxyallyls and suggests that bimolecular trapping reactions will not be fast enough to compete with closure to the more stable cyclopropanone isomer. In contrast, cyclopentyl oxyallyl **3** is calculated to be more stable than the covalent cyclopropanone isomer, bicyclo[2.1.0]pentan-5-one. This is consistent with the observations that cyclic oxyallyl systems can be captured in bimolecular reactions. In addition, calculations show that the CO bond lengths in **1**, **2**, and **3** are relatively short, indicating considerable double-bond character with the unpaired electron spin density residing largely on the α-carbons. While there is some contribution from zwitterionic resonance structures, which slightly polarize the π-system, the lowest energy oxyallyl singlet state is best described as a biradical, and not a zwitterion.



1 **2** **3**

81.3 Photocycloadditions of 2,5-Cyclohexadienones

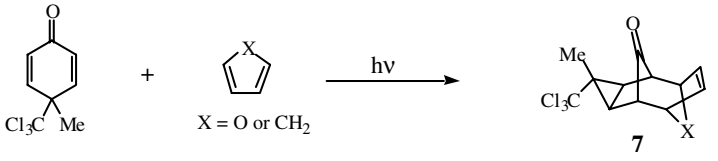
The literature on the photochemical reactions of 2,5-cyclohexadien-1-ones is extensive and has been reviewed several times.[1,2,16,17] The chemistry of these systems is dominated by the Type A rearrangement to form bicyclo[3.10]hex-3-en-2-ones. The basic understanding of the mechanism can be attributed to the work of Zimmerman and Schuster and is outlined in Scheme 1.[1] Dienone **4** is photoexcited to an n,π* singlet state **4-S*,** which rapidly undergoes intersystem crossing to the n, π* triplet **4-T**. Bond formation across the β, β-positions produces the bicyclic triplet **5-T**, which demotes to the ground-state oxyallyl species **5-S**. The transient oxyallyl zwitterion suffers a thermal [1,4]-sigmatropic rearrangement



SCHEME 1

to give the observed bicyclohexenone **6**. Schuster demonstrated that alcohols and chloride ion could trap oxyallyl intermediate **5-S** in suitably designed systems where the apparent rate of the sigmatropic rearrangement to **6** was retarded (e.g., **4**, $R_1 = CH_3$, $R_2 = CCl_3$). These experiments were interpreted as support for the zwitterionic nature of oxyallyl intermediate **5-S**.

Swenton has shown that irradiation of 4,4-dimethyl-2,5-cyclohexadienone **4** ($R_1 = R_2 = CH_3$) in the gas phase produces the Type A rearrangement product bicyclic enone **6** ($R_1 = R_2 = CH_3$).[18] Swenton argued that a zwitterion would be energetically unreasonable in the gas phase and interpreted this result as supportive of a biradical oxyallyl transient. On the other hand, the solution trapping studies with alcohols and halides appear more consistent with ionic intermediates. It is possible that these discordant results may be a function of solvation. Lim et al. addressed this question by carrying out a combined *ab initio*/Monte Carlo study of the solvent effects for the ring opening of cyclopropanones to oxyallyls.[15] The relatively small solvent effects computed were interpreted to "confirm the principally biradical rather than zwitterionic nature of oxyallyls." The disconnection between these studies points to the chameleon nature of oxyallyl systems in which the relative energy of closely lying electronic states (triplet, open shell singlet, closed shell singlet) changes with substitution and reaction conditions (e.g., solvent). Attacking nucleophiles may also perturb the electron distribution in the oxyallyl, causing increasing contributions from the zwitterionic structure as the reaction proceeds. The net effect is that oxyallyl intermediates may behave operationally as zwitterions under nucleophilic conditions.

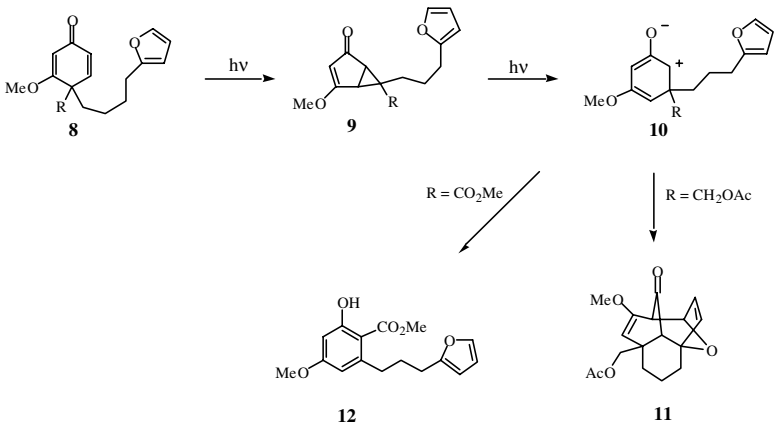


7

Samuel provided the first example that the oxyallyl intermediate in the Type A rearrangement could be trapped intermolecularly with a diene in a [3+4]-cycloaddition.[19] Samuel found that the apparent lifetime of simple 4,4-dialkyl substituted cyclohexadienones was too short to permit intermolecular capture. However, irradiation of Schuster's 4-methyl-4-trichloromethyl-2.5-cyclohexadienone **1** ($R_1 = CH_3$, $R_2 = CCl_3$) in the presence of either furan or cyclopentadiene produced 1:1 adducts **7** (X = O or CH_2). This type of [4+3]-cycloaddition reaction has long been considered as evidence for an oxyallyl transient and is compatible with either a biradical or zwitterionic species.[20]

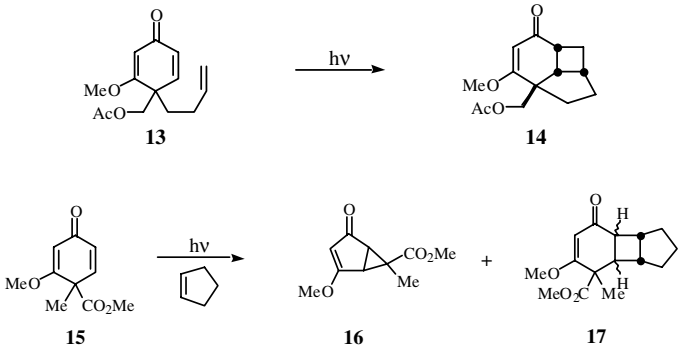
Schultz carried out extensive studies exploiting the rich photochemistry of 2,5-cyclohexadienones to generate complex multi-cyclic systems amenable to further synthetic elaboration. These studies have explored the intramolecular photocycloadditions of 2,5-cyclohexadienone with alkene and diene traps appended to the 4-position of the ring.[21] This work has been previously reviewed.[17] This chapter focuses on the ability to capture the transient oxyallyl species.

Irradiation of dienone **8** containing a furan tethered to the 4-position produced cycloadduct **11** when R = CH_2OAc and phenol **12** when R = CO_2Me (Scheme 2).[21] The reactions proceed by initial Type A photorearrangement to enone **9**. Secondary photolysis of **9** produces a Type B photorearrangement (**8** → **11**) via the delocalized Type B oxyallyl **10**. The vinylogous oxyallyl **10** (R = CH_2OAc) lives long enough to be trapped intramolecularly by the furan ring. There was no evidence that the furan was able to trap the initial Type A oxyallyl derived from **8**. In principle, this behavior may be due to a short lifetime for the Type A oxyallyl or geometric constraints to the intramolecular [4+3]-cycloaddition with the Type A oxyallyl. As noted above, electron-withdrawing substituents at C4 are known to slow the rate of rearrangement of Type A oxyallyls intermediates and permit trapping of the Type A oxyallyl. Because only Type B photochemistry was observed with **8**, it seems likely that geometric factors are inhibiting the intramolecular trapping of the Type A oxyallyl. Interestingly, the substituents at C4 in **8** have the opposite effect on the partitioning of the Type B delocalized oxyallyl intermediate **10**. In this case, the electron-withdrawing carbomethoxy substituent raises the barrier for rearrangement (**10** → **12**), thereby increasing the lifetime of **10**.



SCHEME 2

Schultz also found that C-3 methoxy substitution decreases the quantum efficiency for the Type A photorearrangement of **8** to **9**. The electron-donating methoxy group causes mixing of the π,π* triplet state with the n,π* triplet that is believed to be associated with the Type A photoreaction.[22] The change in the nature of the reacting triplet state makes it possible to trap the photoexcited state with alkenes prior to formation of the Type A oxyallyl. Irradiation of **13** produces a "conventional" intramolecular [2+2]-photocycloaddition[23] adduct **14** with no leakage into the Type A reaction manifold. The triplet state of **15** could also be captured in an intermolecular reaction with cyclopentene. Irradiation of **15** and cyclopentene at 25C produced ~20% of **16** (Type A photoproduct) and 62% [2+2]-cycloadducts **17**.[24] When the irradiation was conducted at −80C, [2+2]-adducts were observed in high chemical yield (96%) with less than 4% of Type A products detected. While the efficiencies of both reaction paths were reduced at low temperature, the Type A reaction was affected to a greater extent.



81.4 Photocycloaddition and Photocyclizations of Pyran-4-ones

Pyran-4-ones are structurally analogous to 2,5-cyclohexadienones and exhibit similar Type A photoreactivity. Barltrop reported a mechanistic study of this reaction, which is summarized in Scheme 3.[25] Irradiation of 3,5-dimethylpyran-4-one (**18**) forms the transient oxyallyl **19**. In the absence of trapping agent, **18** rearranges to 6-oxabicyclo[3.1.0]hexenone (**20**) (Type A rearrangement) that, under continued irradiation, suffers secondary photorearrangement to a 2-pyranone. Oxyallyl **19** can be trapped with alcohols and furan (in trifluoroethanol) to give, respectively, cyclopentenone **21** and the [4+3]-cycloadduct **22.** Irradiation of **18** in neat furan gave rise to [2+2]-photocycloaddition between one of the furan double bonds and the pyranone. Under these conditions, the furan was able to capture the excited state **18*** prior to the intramolecular rearrangement to oxyallyl **19**.

The West group made an extensive study of the intramolecular capture of the putative zwitterionic OA intermediate to produce highly functionalized multi-cyclic systems. Irradiation of pyranone **23** containing an alcohol tethered to the 2-position of the ring furnished bicyclic cyclopentenone ethers **24** in good to excellent yield (Table 81.1).[26] Polar solvents were needed to promote "effective partitioning through the zwitterionic pathway." Initial experiments employed methanol as solvent but this typically resulted in competing intermolecular capture by solvent. Use of the less nucleophilic trifluoroethanol (TFE) as solvent completely suppressed this side reaction.

In contrast to Schultz's studies with 2,5-cyclohexadienones, West demonstrated that the Type A oxyallyl intermediate in pyran-4-one systems could be captured by alkenes and furans. Irradiation of pyran-4-ones with alkenes tethered to the 2-position **25** gave diquinanes **26**, **27**, and **28** via the endocyclic addition of the oxyallyl to the alkene (Scheme 4, Table 81.2).[27] The mode of cyclization could be switched to exocyclic by placement of electron-donating substituents on the interior of the alkene (**29**) to give hydrindanes **30.**

b: R = CH_2SiMe_3, X = CH_2, (69%)

Irradiation of pyran-4-ones with furans tethered to the 3-position **31** produced [4+3]-cycloadducts **32** and **33** (Table 81.3).[28] The loss of the usual *endo*-selectivity in the cycloaddition was attributed to steric constraints in the compact intramolecular transition states. The reaction proved to be inefficient in nonpolar solvents such as CH_2Cl_2 and required the use of TFE for optimum results.

The ability to trap oxyallyl intermediates with alkenes and furans intramolecularly in the pyran-4-one systems but not in the 2,5-cyclohexadienone systems discussed above is most likely due to geometric factors relating to the length and point of attachment of the tether.

West also demonstrated that oxyallyls derived from pyran-4-ones can participate in electrophilic aromatic substitution reactions. Irradiation of pyran-4-ones **34** with aryl groups appended in the 2-position produced tricyclic tetrahydrobenz[e]indenone **35** in fair to moderate yield (Table 81.4).[29] Capture of the oxyallyl intermediate by solvent and Type A rearrangement to pyran-2-ones competed with the desired intramolecular EAS reaction. Interestingly, the yield of **35** was concentration dependent (higher yields with dilution). It is not clear how concentration affects the bifurcation of the oxyallyl intermediate between intramolecular trapping and rearrangement.

81.5 Photocycloadditions of 2,7-Cyclooctadienone

Initial studies by Crandall[30] and Noyori[31] on the photochemistry of 2,7-cyclooctadienone **36** were consistent with formation of a bicyclic[3.3.0]oxyallyl intermediate **37** that could be trapped with alcohols (**39**) or furan (**38**) (Scheme 5). In addition, Crandall showed that irradiation of **36** at −78C, followed by addition of furan in the dark, also produced cycloadduct **38**. Low-temperature ^{13}C NMR studies by Matlin and Jin identified *cis*,*trans*-2,7-cyclooctadienone **40** as the storable reactive intermediate.[32] The intensity of the NMR signals for **40** decreases at temperatures above −30C. Thermal conrotatory cyclization of **40** produces *cis*-fused bicyclic oxyallyl **37**, which can be trapped. DFT calculations place the strained *cis*,*trans*-cyclooctadienone **40** 15 kcal/mol above the *cis*,*cis*-isomer **36**.[33] The singlet biradical **37** is calculated to be only 12 kcal/mol higher in energy than **40**, which is qualitatively consistent with the behavior observed in the low-temperature NMR studies. The computational studies also support the biradical description of oxyallyl **37** in the absence of solvent. Crandall and Haseltine have reported that electron deficient π-systems such as dimethylacetylene dicarboxylate and 1,2-dichloroethylene do not give any 1:1 adducts

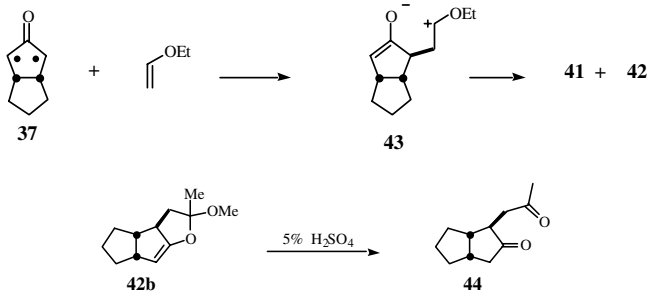
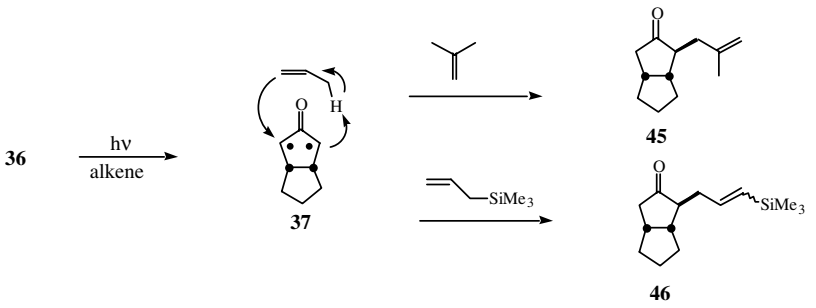
with **37**.[30,34] This behavior contrasts the reactivity seen with isoelectronic trimethylenemethane reactive intermediates, which give 1:1 adducts in high yields with electron-deficient π-systems.[35]

The Matlin group has shown that irradiation of cyclooctadienone **36** in the presence of vinyl ethers produces 7-norbornanones **41** and oxa-triquinanes **42** (Table 81.5).[33] The reaction is envisioned as proceeding via the step-wise cycloaddition to oxyallyl **37**. The electron-rich vinyl ether stabilizes the incipient cationic center in **43**, which then undergoes internal O- and C-alkylation of the enolate moiety to give **41** and **42**. The product distribution and yields did not show any significant variation with the polarity of the solvent (hexanes, benzene, CH_2Cl_2, or neat vinyl ether). It is interesting to note that no enone-alkene [2+2]-adduct was observed, even when ethyl vinyl ether was used as solvent. This is in contrast to the behavior of pyran-4-one, where irradiation in neat furan produced [2+2]-adducts. The photoexcited state lifetime of **36** is limited by rapid *cis*,*trans*-isomerization to **40**, which does not permit intermolecular capture to be competitive.



37 **43** **42b** **44**

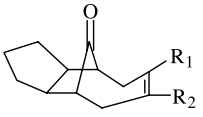


SCHEME 6

The vinyl ether acetal functionality in the oxa-triquinanes can be readily hydrolyzed to dicarbonyl containing diquinanes, for example, **42b** → **44**.

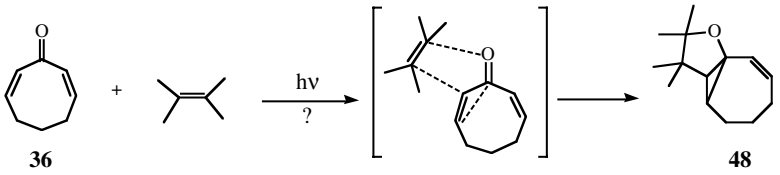
In contrast to the vinyl ethers, simple alkenes such as isobutylene and allyltrimethylsilane trap oxyallyl **37** in a concerted ene-reaction to ketoalkenes **45** and **46** in yields of 15 to 25% (Scheme 6).[33] The *E*- and *Z*- silylketones **46** are formed in about equal amounts. Noyori has reported a similar ene-reaction for oxyallyl-iron complexes with isobutylene.[36]

Isoprene and 2,3-dimethyl-1,3-butadiene were also found to trap oxyallyl **37** in a [3+4]-cycloaddition to give bridged adducts **47** in ~50% yield.[33] These reactions are interesting in that most examples of [4+3]-cycloadditions with putative oxyallyl intermediates have used cyclic dienes.



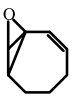
47

Irradiation of **36** in the presence of 2,3-dimethyl-2-butene gives the anomalous and novel 1:1 tricyclic adduct **48** in 33% yield.[37]



36 **48**

The tricyclic product is formally a [2+2+2]-cycloaddition where the alkene is adding to the carbonyl-oxygen and α-carbon in dienone **3** concomitant with σ-bond formation between the carbonyl-carbon and the β-enone carbon. This mode of reactivity, 1,3-addition of an alkene to an enone, is unprecedented, and a specific mechanistic explanation for this process is currently lacking. Oxyallyl **37** and *cis trans*-dienone **40** do not appear to be involved in this process, and the reactive intermediate being trapped must appear earlier in the reaction cascade. It is unclear whether this intermediate is an excited state of **36** or possibly an oxabicyclobutane **49**. In either case, it is curious why this reaction is seen with 2,3-dimethyl-2-butene and not with any of the other alkene traps.

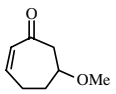


49

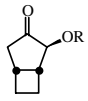
81.6 2,6-Cycloheptadienone

The photochemistry of 2,6-cycloheptadienone does not appear to be as rich as its higher and lower homologuess and has not been widely studied. Noyori reported that irradiation of cycloheptadienone **50** in methanol results in conjugate addition to the enone producing enone ether **51**.[38] Irradiation of **50** in acidic media, such as acetic acid or *t*-butanol with a trace of sulfuric acid, results in formation of bicyclic adducts **52**.

50



51



52 a: R = OAc
b: R = *t*-Bu

While these products are similar to the trapped products seen in the reactions with cyclooctadienone, it seems unlikely that a true oxyallyl intermediate is being captured. Noyori has presented a mechanism where the excited dienone **50*** is protonated under the acidic conditions (Scheme 7). Cation **53** then undergoes a Nazarov-type cyclization to the bicyclic cation **54,** which is captured by ROH. In unpublished work, Matlin and Hall have found that irradiation of **50** in the presence of ethyl vinyl ether does not give any 1:1 adducts. The apparent reluctance of the seven-membered ring dienone to form a trappable oxyallyl intermediate is surprising in light of the results with the higher and lower homologs.

Kenichi Somekawa
Kagoshima University

82.1 Introduction

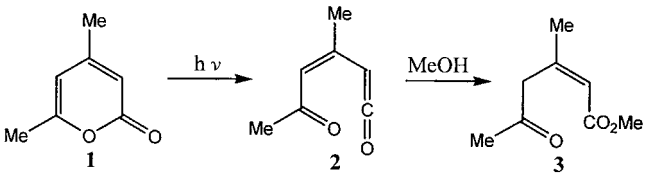
The photochemistry of 2-pyrones, which are simple 2, 4-pentadien-5-olides and have an α, β: γ, δ-unsaturated carbonyl system, is interesting because of the wide range of unique carbon-carbon bond-forming processes they undergo. Diels-Alder reactions of 2-pyrones with many kinds of dienophiles have been widely studied for about 70 years and are known to give [4+2]-cycloadducts stereoselectively, together with bis-adducts and benzene derivatives.[1] The use of Diels-Alder cycloadditions of 2-pyrones was applied to the synthesis of many useful compounds, such as barrelene,[2] colchicine,[3] etc. This chapter discusses the some selective cycloaddition reactions of photochemically excited 2-pyrones with various alkenes, together with the photochemistry of 2-pyrone itself. It is well known that the 2-pyrone ring itself undergoes a wide range of photochemical reactions, such as an electrocyclic ring-opening reaction of **1** to give **3** by way of ketene formation **2**,[4] valence isomerization[5] of **4** to give **5** and dimerization[6] of **1** to give **7**, **8**, and **9** (Schemes 1, 2, and 3). The valence isomerization reaction of 2-pyrone **4** provided a path to the synthesis of cyclobutadiene **6**,[7] which was also synthesized in the hemicarcerand as a host compound.[8] Photodimers **7** and **8** afford a cyclooctatetraene derivative **10** by way of thermolytic extrusion of carbon dioxide.[6] The cross photocycloadditions of the heterocyclic 2, 4-cyclohexadienones with various ethylenes are peri-, site-, regio-, and stereoselective, depending on the substituents of 2- pyrones and ethylenes and also the reaction conditions. These phenomena are theoretically interesting and are explained later by the MO method.

82.2 Intermolecular Photocycloadditions of 2-Pyrones

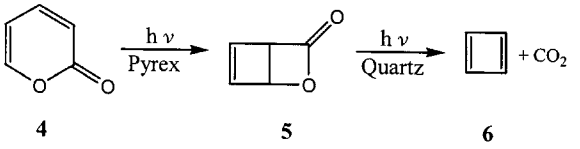
Intermolecular photocycloaddition reactions of 2-pyrones with alkenes have been much less extensively studied than those of coumarins. A typical reaction of coumarin **11** with an alkene is the formation of **12**[9] (Scheme 4). The photocycloaddition reaction of dehydroacetic acid **13** with cyclohexene was first reported by Takeshita et al.[10] in 1973 (Scheme 5). Irradiation of a mixture of **13** and cyclohexene leads to the formation of a diastereomeric mixture of [2+2]-cycloadducts **14**, together with the usual dimer of the 2-pyrone.

Photocycloaddition reactions of the 2-pyrones **15** with alkenes are expected to lead to the [4+2]-cycloadduct **16**, the 5, 6-[2+2]-cycloadduct 17 (formed by addition to the C5-C6 double bond), and/or

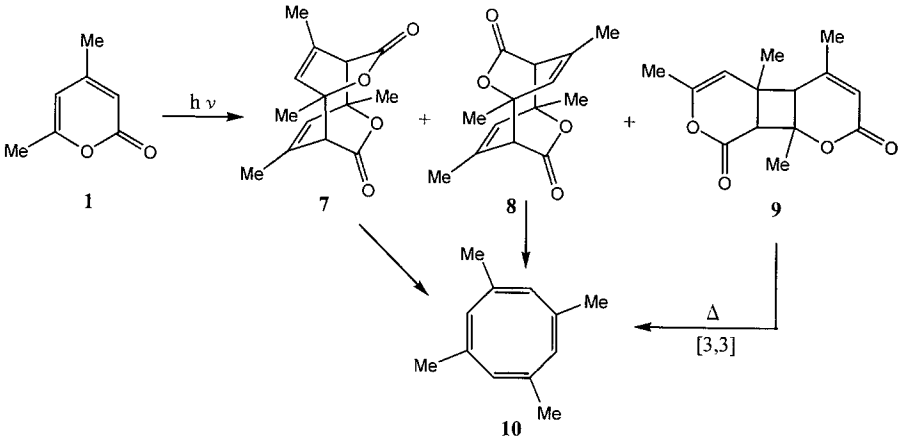
0-8493-1348-1/04/$0.00+$1.50



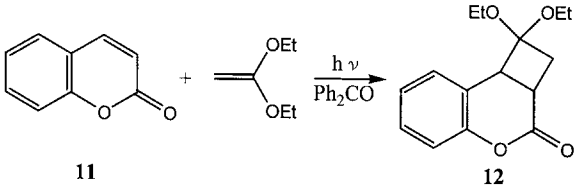
SCHEME 1



SCHEME 2



SCHEME 3



SCHEME 4

the [2+2]-cycloadduct **18** (formed by addition to the C3-C4 double bond) as illustrated in Scheme 6. The photochemical reaction of methyl 2-pyrone-5-carboxylate **15a** (with an electron-withdrawing substituent) with acrylonitrile **19e** in the presence of benzophenone gives a mixture of [4+2]-cycloadducts **16ae** (endo-CN/exo-CN; ratio = 1.4) as major products together with a [2+2]-cycloadduct **17ae**[11] (Scheme 7). On the other hand, photosensitized reaction of 4, 6-dimethyl-2-pyrone **15c** (with electron-donating groups) with **19e** affords a mixture of [2+2]-cycloadducts **17ce** (endo-CN/exo-CN; ratio = 1.0) as major products and a cyclobutanecarboxylic acid **20**. This secondary product is formed by hydrolysis

of the [2+2]-cycloadduct **18**.[12] The reaction of **15b** with **19e** gives a mixture of [4+2]-cycloadducts **16be** (endo-CN/exo-CN; ratio = 1.0), together with a mixture of [2+2]-cycloadducts **17be** (endo-CN:exo-CN ratio = 1.0) (major products), while the reaction of **15d** with **19e** yields a mixture of **17de** (endo-CN:exo-CN ratio = 2.0).[13] These photocycloaddition reactions take place only under irradiation in the presence of triplet sensitizers (ET > 56 kcal/mol). Similar photoreactions of 2-pyrones **15a** and **15c** with methacrylonitrile or 2-chloroacrylonitrile also afford compounds of type **16**, **17**, and/or **18**.[14]

25 **26**

SCHEME 9

2-Pyrone **15a** readily reacts thermally with ethyl vinyl ether **19f** at room temperature to give the [4+2]-cycloadduct **22** as the sole product. The photoreaction of ethyl 4, 6-dimethyl-2-pyrone-5-carboxylate **15b** with **19f** affords a mixture of [2+2]-cycloadducts **18bf** (endo-OEt:exo-OEt ratio = 0.65) as major products, together with a [4+2]-cycloadduct **21**[13] whose orientation is different from the product **22** obtained from the thermal reaction of **15a** with **19f** (Scheme 8).[11] 2-Pyrone **15c** reacts photochemically with **19f** to give a mixture of **18cf** (endo-OEt:exo-OEt;ratio = 0.79),[12] and the reaction of **15d** with **19f** gives 18df (endo-OEt:exo-OEt ratio = 1.0).[13] Photoreaction of 15a with 2,3-dihydrofuran affords the [2+2]-cycloadduct **23** and the [4+2]-cycloadduct **24**[15] in 24% and 12% yields, respectively (Scheme 9). Product **24** showed different orientation to that observed in the thermal [4+2]-cycloadducts **25** and **26**. From these results the details of the reaction modes within the various photocycloaddition reactions of 2-pyrones with alkenes are summarized as shown in Scheme 10. 2-Pyrone **15a**, having an electron-withdrawing group, reacts with acrylonitrile **19e** at the C3-C6 atoms of the diene system and at the C5-C6 double bond in **15a** to give the [4+2]-cycloadduct and the [2+2]-cycloadduct, respectively. Diels-Alder reaction occurs preferentially in the reaction of **15a** with ethyl vinyl ether **19f**. 2-Pyrone **15c** (with electron-donating groups) reacts with **19e** mainly at the C5-C6 double bond in **15c** to give a [2+2]-cycloadduct. On the other hand, **15c** reacts with **19f** at the C3-C4 double bond in **15c** to afford another type of [2+2]-cycloadduct. The reaction mechanism containing peri-, site-, and regioselectivities will be described later making use of MO analysis.

SCHEME 12

Photosensitized reaction of **15c** with maleimide **19g** at low temperature (–10 to –20°C) affords the exo-[4+2]-adduct **16cg** as a major product, together with the [2+2]-adduct **17cg** (Scheme 11).[16] The same reaction was carried out at room temperature to afford the bis-adduct **27**, which was formed via decarboxylation of **16cg** followed by addition of another molecule of **19g**, in addition to the formation of **17cg**. The low-temperature photoreactions of 2-pyrones **15a**, **15b** with **19g** or 19g′ also gives [4+2]-adducts **16ag′**, **16bg**, and [2+2]-adduct **17bg**. Similar photoreactions of 2-pyrones **15b**, **15c** with maleic anhydride afford exo-[4+2]-adducts (major products) and/or [2+2]-adducts. Photosensitized reaction of **15a** with dimethyl acetylenedicarboxylate affords 1, 2, 4-tris(methoxycarbonyl)benzene **28** in 50% yield by way of decarboxylation of the [4+2]-adduct, which was difficult to isolate even from the reaction mixture obtained from the low-temperature irradiation (Scheme 12).[11,13] Similar reactions of **15a** with

phenylacetylene and that of **15d** with dimethyl acetylenedicarboxylate give benzene derivatives **29** and **30** in 2% and 35% yields, respectively.

The photochemical reaction that takes place between 2-pyrones and selected alkenes are summarized in Table 82.1 according to the types of cycloadducts. In the sensitized photoreactions of 2-pyrones with several alkenes, there are four kinds of primary products, **16**, **17**, **18**, and **21**. Products **16** is one of the peri- and regioselective [4+2]-cycloadducts, **17** and **18** are site- and regioselective [2+2]-cycloadducts, and **21** is also another regioselective [4+2]-cycloadduct. The product distribution is proposed to depend mainly on the electronic properties of the two substrates. Namely, the decrease in the electron-withdrawing property of the substrates on the two substrates, **15** and **19** (left to right and high to low in Table 82.1), changes the product-distribution as follows: **16** → **16** + **17** → **17** + **18** → **18** + **21** (minor) → **18**.

The peri-, site-, and regioselectivities in the photocycloadditions of the triplet 2-pyrones with alkenes are confirmed to be mainly controlled by the interaction between frontier molecular orbitals (FMOs), calculated using PM3-CI level (Figure 82.1 and Table 82.2).[17,18] The regioselective [4+2]-cycloadducts **16** and site-selective [2+2]-cycloadducts **17** across the C5-C6 double bonds of the 2-pyrones with electron-poor alkenes are deduced to be formed by the preferred HSOMO-LUMO interactions and via more stable biradicals by C6-Cβ bonding (Scheme 13). On the other hand, the other kinds of regioselective [4+2]-adduct **21** and the [2+2]-adducts **18** across the C3-C4 double bonds of the 2-pyrones with electron-rich alkenes are inferred to arise from LSOMO-HOMO interactions and via biradicals by C3-Cβ bondings. Selectivities between **16** and **17**, and **18** and **21** are also proposed to be influenced by the SOMOs of the biradicals.

82.3 Intramolecular Photocycloadditions of 2-Pyrones

Intramolecular [2+2]-photocycloadditions of cyclic α,β-unsaturated enones with remote double bonds have been extensively used to synthesize a variety of interesting compounds, including natural products. An analysis of the mechanism of the additions has also been carried out. 2-Pyrones having pendant enes and dienes undergo synthetically useful photocycloaddition processes to give tricyclic lactones and lactone-bridged cyclooctadienes by [2+2]-and [4+4]-cycloadditions, respectively. The photochemical reactions

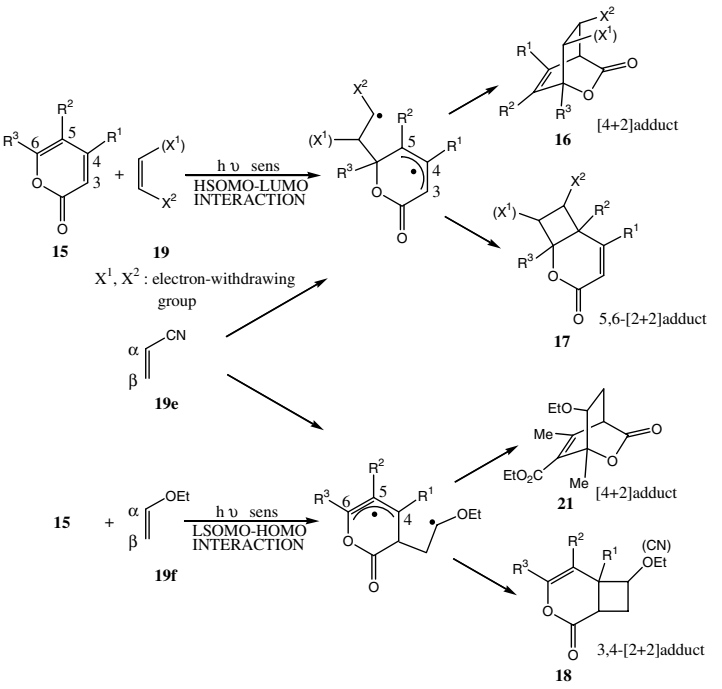
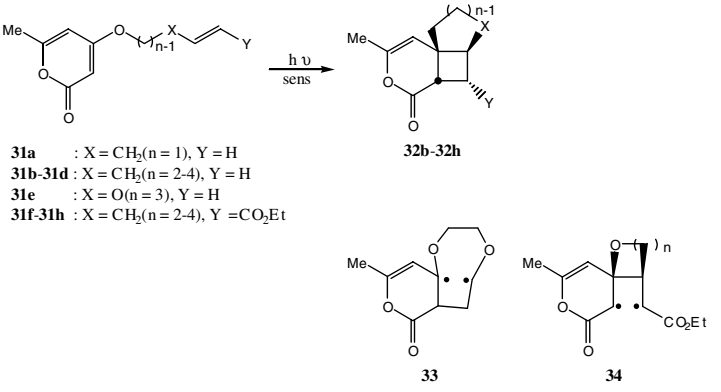
[a] HSOMO(**15**)-LUMO(**19**) interaction
[b] LSOMO(**15**)-HOMO(**19**) interaction

of 4-(ω-alkenyloxy)-2-pyrone **31b** afford intramolecular [2+2]-cycloadduct **32b** in quantitative yield (Scheme 14).

Similar photoreactions of **31c**- through **31h** give **32c** through **32h**, in 70%, 31%, 26%, 70%, 48%, and 32% yields, respectively.[19,20] On the other hand, 2-pyrone **31a** was found to be completely photostable. The intramolecular [2+2]-cycloadditions of **31b** through **31h** proceed by way of triplet excited states of **31** with high site-, regio-, and stereoselectivities. The reaction mechanism is analyzed using MO calculations, and the reasonable biradical intermediates to give **32e** and **32f** through **32h** are considered to be **33** and **34**, respectively. 6-(ω-Alkenyl)-2-pyrones **35b** and **35c** also afford intramolecular [2+2]-cycloadducts **36b** and **36c** in 55% and 33% yields, respectively (Scheme 15),[21] while 2-pyrone **35a** was completely photostable. From these results, photochemical reactions of 4-(ω-alkenyloxy)-2-pyrones **31** and 6-(ω-alkenyl)-2-pyrones **35** provide a simple route to synthesize oxatricyclic lactones, depending on the number of methylene groups between the 2-pyrone ring and the olefinic moiety.



SCHEME 13



SCHEME 14

Photoreactions of 2-pyrones **37a** and **37b** bearing acyclic ω-dienes do not afford cycloadducts, instead undergo geometric isomerism (Scheme 16).[22] Different reactivity is seen with 2-pyrones bearing cyclic ω-dienes where [4+4]-cycloadducts, which are fused bicyclic cyclooctanoids with lactone bridges, together with [2+2]-cycloadducts are formed. Irradiation of 2-pyrones **38** connected to a pendant furan by a three-carbon tether gives a mixture of [4+4]-and [2+2]-cycloadducts **39**, **40**, and **41** (Scheme 17).[23] The yields and product distribution are greatly affected by hydrophobic effects of solvents as shown in Scheme 17. Similar photoreactions of 2-pyrones **42** connected to a pendant furan by a three-carbon tether afford a mixture of endo- and exo-[4+4]-adducts **43** and **44** in good yield when OR′ = carboxylate or sulfonate (Scheme 18).[24] In some cases, small amounts of cyclooctatriene **45** resulting from decarboxylation

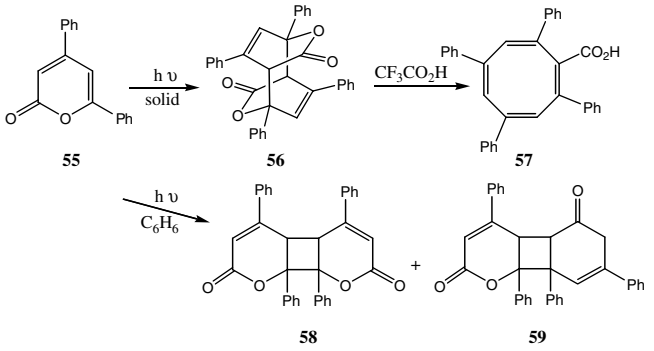
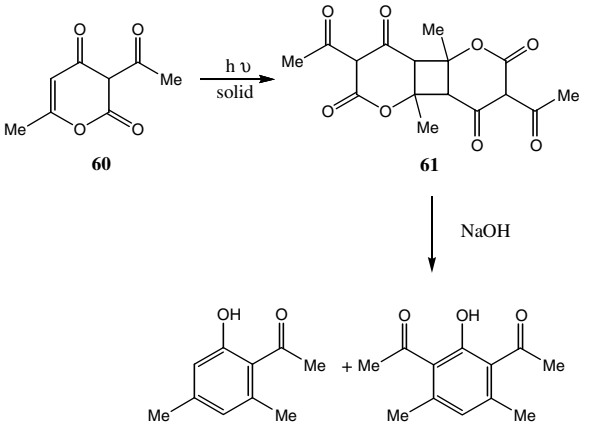
of one or both diastereomers are isolated. Sensitized photoreactions of bis-2-pyrones **47a** (n = 1), **47b** (n = 2) give [4+2]-cycloadducts **48a**, **49a** and **48b**, **49b** (Scheme 19).[25] On the other hand, **47c** (n = 3) and **47d** (n = 4) afford only [2+2]-cycloadducts, **50c** and **50d**. The [4+2]- and [2+2]-cycloadducts distribution depends on the number of methylene units in the chain. Photoreactions of 2-pyrones **51b** (n = 3) and **51e** (n = 6) give three kinds of site-selective [2+2]-cycloadducts **52b**, **53c** through **53e**, and **54d** and **54e** (Scheme 20).[26] The selectivity also depends on the methylene chain length. The reaction mechanism is explained from the results calculated by the PM3-CI method.

82.4 Solid-State Photocycloadditions of 2-Pyrones

While photochemical [2+2]-cycloadditions in solution have been utilized to synthesize many kinds of important compounds, the reactions encountered are not so regio- or stereoselective. On the other hand, solid-state photoreactions are strictly controlled by their crystal structures and can, therefore, be highly selective. The use of single- and two-component organic crystals has recently been shown to provide an environment for controlling the selectivity of photochemical reactions because of the tight and regular



SCHEME 21



SCHEME 22

arrangement of the molecules within the crystals[27] using a non-covalent interaction such as a hydrogen bond, charge transfer interaction, or π-π stacking. Much attention has been devoted to the photodimerisation reactions[27] in the crystals, including asymmetric synthesis in host-guest inclusion complexes, but only limited investigation of [2+2]-cycloaddition between two different organic molecules has been reported.[28]

Photolysis of 2-pyrone **55** in the solid state affords the [4+4]-dimer **56** in 100% yield, based on recovered **55** (Scheme 21).[29] Photolysis in benzene gives two kinds of [2+2]-dimers **58** and **59** in 20% and 60% yields, respectively. The treatment of **56** with trifluoroacetic acid gives the cyclooctatetraene carboxylic acid **57** in 50% yield.

2-Pyrone 60 is irradiated for a week in the solid state to give [2+2]-dimer **61** in 4% yield (Scheme 22).[30] Hydrolysis of **61** affords the substituted phenols illustrated. Irradiation of a suspension of crystalline **62** in water gives two types of [2+2]-dimers **63** and **64** in 18% and 21% yields, respectively (Scheme 23).[31]

The x-ray crystallographic analysis shows that the distances between the reacting double bonds to yield **63** and **64** are ca. 4.2Å and 4.0Å, respectively,. The solid-state photoreaction of 2-pyrone-5-carboxylate **15** with maleimides **19** yields the endo-[4+2]-cycloadducts **65**. This is in contrast to the sensitized photoreaction that leads exclusively to the exo-[4+2]-cycloadducts **66** (Scheme 24).[32] Solid-state photoirradiations of 1:1 complex crystals formed between the 2-pyrone **15d** and 4-(ω-arylalkyloxy)- 2-pyrones **66a** through **66e** and maleimide **19g** gives [2+2]-cycloadducts **67dg** and **67a** through **67e** with exclusive stereoselectivity (Scheme 25).[33,34]

SCHEME 24

These highly stereoselective cycloadditions also occur on photoirradiation of grind up mixtures of crystals of 2-pyrones with maleimide. On the other hand, the photoreactions in solution afford another type of [2+2]-cycloadduct **68** or bis-adducts **69** as major products. The latter products are formed through decarboxylation of the [4+2]-cycloadducts, followed by addition of another molecule of **19g**.

The high reaction selectivity for **67** in the solid-state photoreactions is confirmed by x-ray crystallographic analyses (Figure 82.2 and Figure 82.3), powder x-ray diffraction analyses and MO method (Figure 82.4)* of the complex crystals, which are composed of two sets of a 1:1 complex between 2-pyrone (**15d** or **66**) and **19g**, arising from an CH-π interaction between **19g** and aromatic rings of **66** and/or π-π stacking between the aromatic rings together with four kinds of hydrogen bonding between the ground state 2-pyrone moieties and **19g**. The high stereoselective photocycloaddition reactions are possible because the two reacting double bonds are nearly parallel and separated by less than 4.0 Å. The photoreaction mechanism is quantitatively analyzed to proceed via some interactions such as four kinds of hydrogen bonding and electrostatic interactions of the singlet excited state of 2-pyrone with the ground state of maleimide, by MO transition state calculation using the Win MOPAC AM1 method (Figure 82.5).**[35]

82.5 Synthetic Applications

The formation of cycloadducts by photochemical [2+2]-, [4+2]-, and [4+4]-cycloaddition reactions of 2-pyrones shows considerable potential. The addition reactions can provide adducts that can undergo ring transformations to natural products, among other compounds of interest. Cyclobutanes can often be used to enhance the reactivity of the heterocyclic rings in the adducts. This path usually uses the

conversion of the cyclobutane into a cyclobutene. This technique is seen in the reaction of [2+2]-cycloadducts derived from 2-pyridones and coumarin with chloroethylenes.[36] The [2+2]-cycloadducts **70** formed by reaction of 2-pyrones and chloroethylenes provide a route to prepare ethenyl-2-pyrone **72** and ethynyl-2-pyrone **73** via the ring-opening of cyclobutenes **71** by triethylamine (Scheme 26).[37] Another [2+2]-cycloadducts **74** can be transformed into the pyrano[4,3-b]pyran-2,5-diones **75** in the presence of DBU via cyclobutene formation and S_N2' displacement (Scheme 27).[38]

The [4+2]-cycloadducts of 2-pyrones, which are cyclohexadiene equivalents by decarboxylation, are attractive starting materials for the preparation of polyfunctionalized bicyclo[2.2.2]octenes. For example, photochemically obtained [4+2]-cycloadducts **16** between 4,6-dimethyl-2-pyrone and cyclic olefins react with second olefins, such as acrylonitrile or p-benzophenone, to give cross-adducts, **76**, **76′**, **77**, with the concurrent decarboxylation (Scheme 28).[16, 39] Irradiation of the cross-adducts **77** gives cage compounds **78**.

The intramolecular photo [4+4]-cycloaddition of a pendant furan to a 2-pyrone has been applied to the development of a route leading to 5-8-5-tricyclic cyclooctanoid natural products. For example, irradiation of 2-pyrone **79** affords two kinds of [4+4]-cycloadducts **80**, **81**, whose structure is a skeleton of fusicoccane and ophiobolane (Scheme 29).[24]

Photochemical Rearrangement and Trapping Reactions of 4-Pyrones

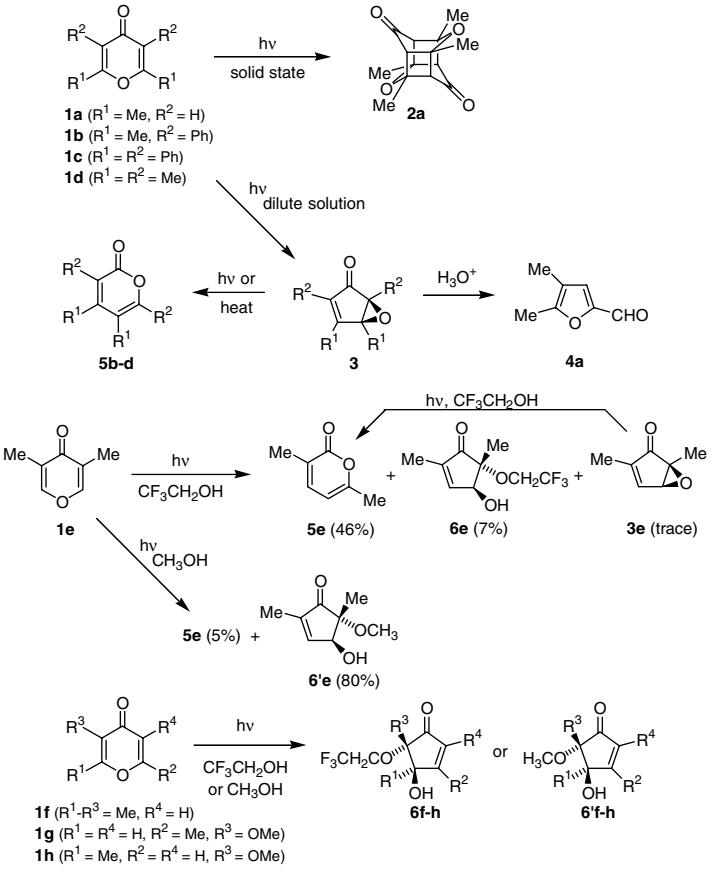
Frederick G. West
University of Alberta

The previous edition of this Handbook included a thorough discussion of the literature of phototransposition and photo-ring contraction chemistry of 4-pyrones and their 4-hydroxypyrylium conjugate acids through 1990.[1] This chapter briefly reiterates the historical background of this area and the original mechanistic work, and then focuses on the synthetic studies that have appeared in the time period since the previous edition went to press.

83.1 Background

The earliest report of a photochemical transformation involving 4-pyrones was made by Paterno,[2] who observed an apparent dimerization involving 2,6-dimethylpyran-4-one **1a** (Scheme 1). However, the structure of the dimer was not elucidated until 1958, when Yates and Jorgenson demonstrated it to be the cage system **2a** resulting from successive inter- and intramolecular head-to-tail [2+2]-photocycloadditions.[3] This was followed by several examples of alternative, non-dimeric photoproducts, which included dimethylfurfural **4a**[4] and 2-pyrones **5b,c,d**.[5,6] It was suggested that both of these products could arise from an intermediate epoxycyclopentenone **3** via acid-catalyzed rearrangement or secondary photochemical processes, respectively. (See the Section 83.2 for a more detailed discussion.) In one instance, it was possible to isolate the putative intermediate **3e** during the photorearrangement of **1e** to **5e**.[7] Finally, solvent adducts **6** were isolated following irradiation of 4-pyrones in hydroxylic solvents.[7,8] The more nucleophilic methanol gave greater yields of adducts **6'** than did trifluoroethanol. These studies lent

0-8493-1348-1/04/$0.00+$1.50



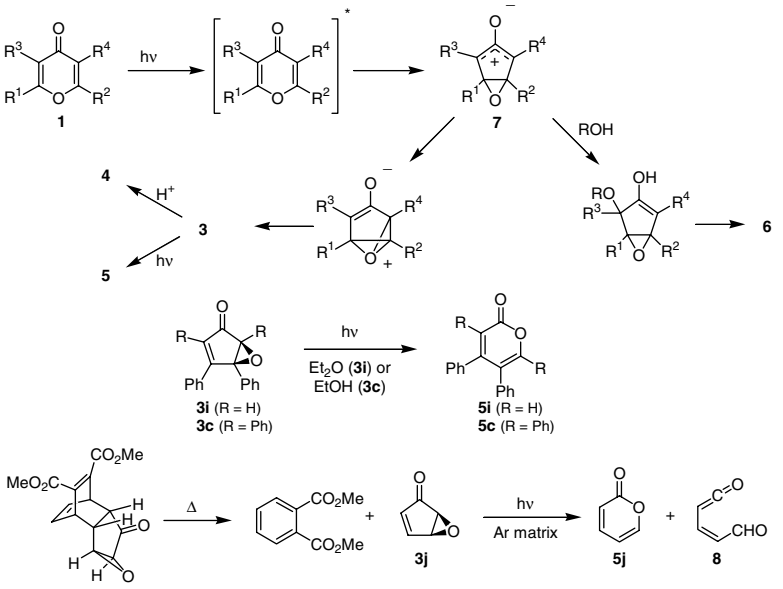
SCHEME 1

support to the notion of a photochemical ring contraction mechanism via oxyallyl zwitterion intermediates, analogous to that elucidated for related 2,5-cyclohexadien-4-ones.[9]

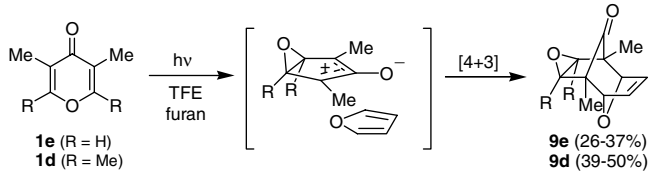
83.2 Mechanism

Formation and Rearrangement of Epoxycyclopentenone Intermediates

4-Pyrones bear an obvious structural similarity to cross-conjugated cyclohexadienones, but the presence of a ring oxygen in conjugation with the ketone is expected to perturb the ordering of the pyrone excited states relative to the all-carbon analogue. 4-Pyrones display an intense absorption between 250 and 260 nm, characteristic of a $\pi \rightarrow \pi^*$ transition, and direct irradiation at this wavelength leads to rearrangement products such as **3**, **4**, and **5** and trapping products **6**.[10] In contrast, cyclohexadienones are believed to undergo Type A rearrangement via a lower-energy $n\pi^*$ excited state. It is suggested that the $S_1(\pi\pi^*)$ state that is populated by direct irradiation of 4-pyrones near 250 nm participates in a symmetry-allowed electrocyclization process to form the bicyclic zwitterion **7** (Scheme 2).[5–7] This key intermediate can then undergo a variety of processes that lead to the observed primary photoproducts. Also notable is the consistent requirement for polar media in the photochemical rearrangement processes of 4-pyrones, again in contrast to cyclohexadienones and indicative of excitation to a low-lying $\pi\pi^*$ state. In the absence of effective trapping agents, zwitterion **7** can rearrange to epoxycyclopentenone **3** via an oxoniabenzvalene intermediate arising from attack by the proximal epoxide lone pair on one of the termini of the allyl



SCHEME 2

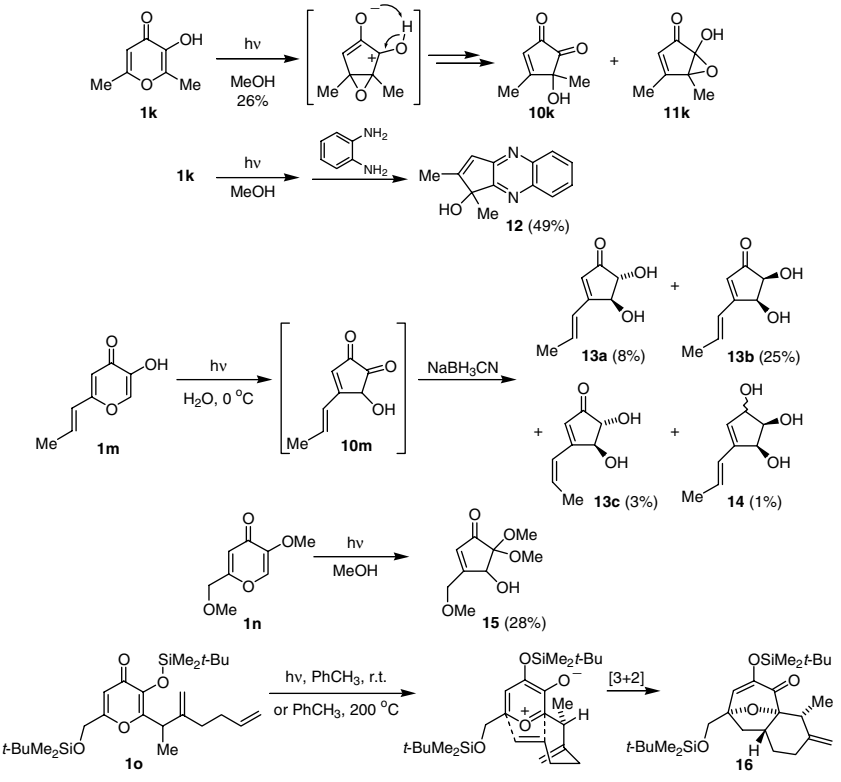


SCHEME 3

cation. Evidence for the intermediacy of **3** in the formation of **4** and **5** includes the isolation of **3e** from the reaction mixture during the photochemical conversion of **1e** to **5e**, as noted above.[7] In addition, Padwa and Hartman independently synthesized epoxide **3i** and showed that it formed 2-pyrone **5i** when irradiated through a Pyrex filter.[11] Likewise, Dunston and Yates found that the tetraphenyl derivative **3c** was converted to **5c** upon irradiation with sunlight or a UV lamp.[12] More recently, the parent epoxycyclopentenone **3j** was generated by vacuum pyrolysis and shown to undergo photolytic conversion in an argon matrix to 2-pyrone **5j** and formyl vinylketene **8**, the latter presumably resulting from photochemical electrocyclic opening of **5j**.[13]

Evidence for Oxyallyl Zwitterion Intermediates

There is considerable evidence for the formation of the bicyclic oxyallyl zwitterion prior to the epoxycyclopentenone. Pavlik and Barltrop showed that irradiation in trifluoroethanol (TFE) or methanol furnished solvent adducts as primary photoproducts,[8] and Barltrop and co-workers excluded the possible formation of the TFE adduct **6e** from epoxycyclopentenone **3e**.[7] Barltrop demonstrated that irradiation of 3,5-dimethyl-4-pyrone **1e** in furan/trifluoroethanol mixtures furnished the [4+3]-cycloadduct **9e** as one of the major photoproducts (Scheme 3).[14] A similar result was reported by West and co-workers using tetramethylpyrone **1d**.[15] Interestingly, in both cases, a single diastereomer was observed, corresponding to approach of furan from the face opposite the epoxide oxygen and reaction via an *endo*



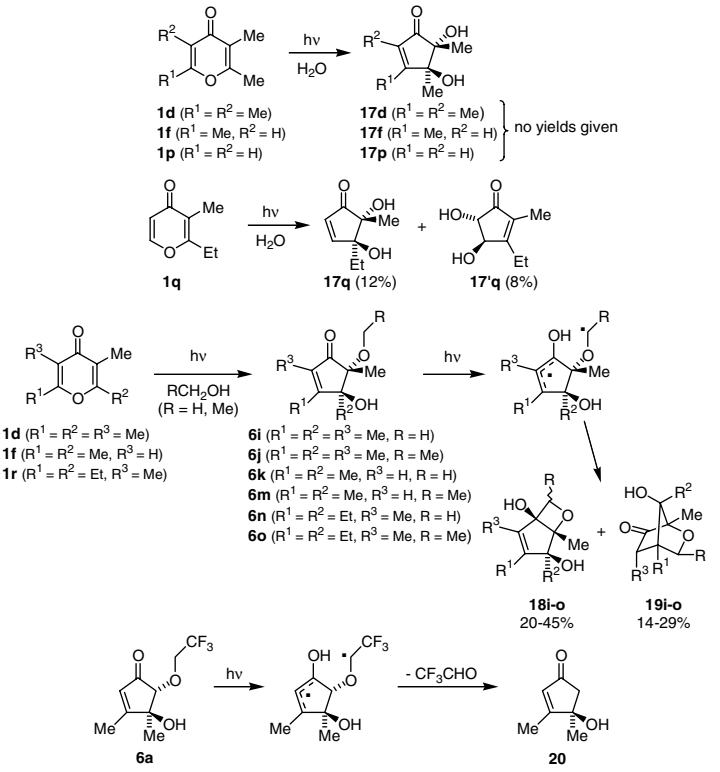
SCHEME 4

transition state allowing secondary orbital overlap between the middle carbon of the allyl system and the inner carbons of the furan 1,3-dene system. Finally, two cases involving photo-ring contraction of 3-hydroxy-4-pyrones were reported, in both cases providing cyclopentenediones that almost certainly result from the intermediate zwitterions (see Section 83.3 for details).[16]

83.3 Synthetic Studies

3-Hydroxy-4-Pyrone Ring-Contractions

As noted above, the photochemical ring contraction of 3-hydroxy-4-pyrones occurs readily, leading to unusual cyclopentenedione products.[16] These compounds are quite unstable and are subject to various self-condensation processes, but *in situ* derivatization has been an effective approach to improving the overall yields. For example, Shiozaki and Hiraoka found that irradiation of 2,6-dimethyl-3-hydroxy-4-pyrone **1k** in methanol produced a mixture of dione **10k** and epoxyhemiketal **11k** in 26% yield after work-up and crystallization (Scheme 4).[16a] However, treatment of the crude reaction mixture with *o*-phenylenediamine gave quinoxaline **12** in 49% yield. Barton and Hulshof irradiated 5-hydroxy-2-(*E*)-propenyl-4-pyrone **1m** in water at 0°C, with addition of sodium cyanoborohydride during the first 15 minutes, obtaining a mixture consisting of the natural product terrein **13a**, isoterrein **13b**, the (*Z*) isomer **13c**, and over-reduction product **14** in a combined 37% yield.[16b] Compounds **13a** and **13b** are presumed to arise from hydride reduction of intermediate dione **10m**, while **13c** was shown to form from terrein during irradiation. Irradiation of a dilute aqueous solution of **1m** in the presence of sodium borohydride provided **13b** in 35% yield. Photo-ring contraction of the kojic acid derivative **1n** was also investigated, furnishing dimethyl ketal **15** in 28% yield. It should be noted that 3-silyloxy-4-pyrone derivatives are

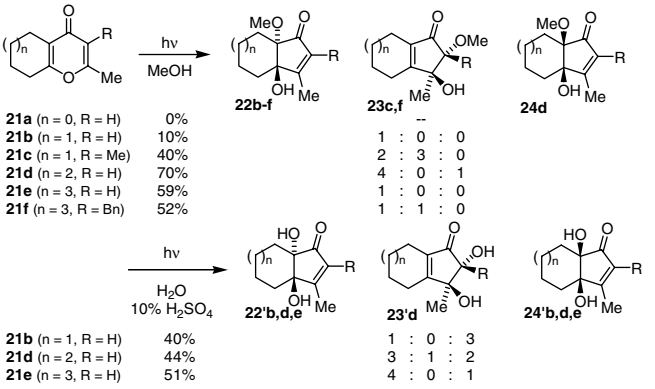


SCHEME 5

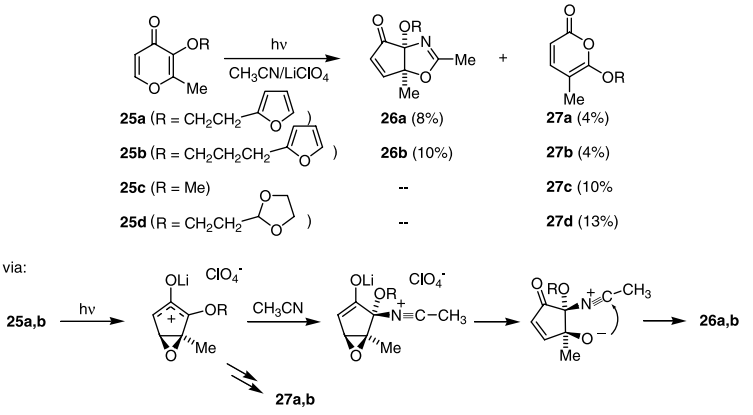
also subject to alternative photochemical transformations involving silatropic rearrangement to generate transient 3-oxidopyrylium ylides. These transient intermediates can undergo formal [5+2]-cycloaddition processes, as exemplified by Wender and McDonald's conversion of **1o** to tricyclic adduct **16**.[17] However, thermal isomerization appears to be the favored method for effecting this rearrangement.[18]

Solvent Trapping

As mentioned in the introduction, Pavlik showed that irradiation of substituted 4-pyrones in protic solvents provided 5-alkoxy-4-hydroxycyclopent-2-en-1-ones or 4,5-dihydroxycyclopent-2-en-1-ones via nucleophilic attack of the oxyallyl zwitterion by solvent.[8,19] Aside from providing good support for the intermediacy of an epoxy-fused oxyallyl species, this trapping process offers a convenient method for the preparation of highly oxidized cyclopentanoids. Several unsymmetrically substituted 4-pyrones were irradiated in water and a consistent preference for attack at the more substituted terminus of the oxyallyl intermediate was seen, presumably due to greater charge density at that site. Moreover, *trans* products **17** arising from attack by solvent *anti* to the epoxide oxygen dominated over the relatively minor amounts of *cis* dioxygenated products (Scheme 5). In a more recent study, West and co-workers observed that alcohol adducts of simple polyalkyl 4-pyrones were subject to secondary photochemistry under the conditions of their formation.[20] When γ-hydrogens were present on the 5-alkoxy side-chain (e.g., **6n** and **6o**), their abstraction by the excited enone carbonyl was seen, with subsequent recombination to form either fused bicyclic oxetanes **18** or oxabicycloheptanones **19** in a process analogous to that previously reported by Agosta and Smith.[21] Keil and Pavlik have also observed secondary photoprocesses involving the trifluoroethanol adduct **6a** of 2,6-dimethyl-4-pyrone, in that case undergoing Norrish Type II cleavage to provide 4-hydroxy-3,4-dimethylcyclopent-2-en-1-one **20**.[8b]



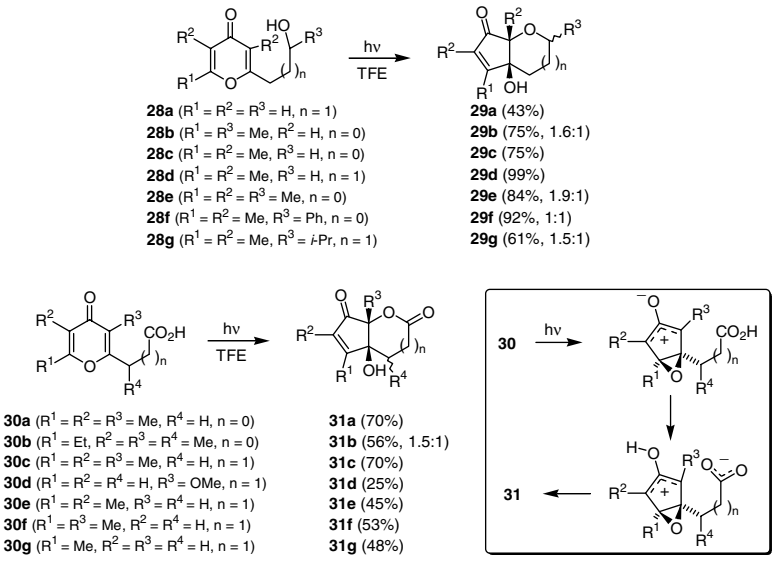
SCHEME 6



SCHEME 7

The observation of good regio- and diastereoselectivity in the solvent trapping studies prompted West and co-workers to investigate the use of this process in conjunction with Hünig's one-step route to fused bicyclic 4-pyrones from cycloalkanone enamines.[22] A series of substrates **21**a–n was prepared and irradiated in methanol or water to furnish adducts **22**, **23**, and **24** (Scheme 6).[23] Certain generalizations can be made from this study: (1) higher alcohols such as ethanol gave much lower yields that cannot be considered synthetically useful; (2) annulation of the pyrone ring onto a cyclopentane resulted in an unreactive substrate, presumably due to prohibitive ring strain in the ring-contraction transition state; (3) substrates lacking a substituent at C5 (R = H) generally displayed good regioselectivity in favor of attack at the more substituted bridgehead position; (4) small but significant amounts of the *cis*-products were seen in some cases, especially with water;[24] and (5) catalytic sulfuric acid was helpful in a number of cases, especially those involving trapping with water. The beneficial effect of acid suggests the possible involvement of 4-hydroxypyrylium cations, which have been shown to undergo photochemical ring contraction to hydroxyallyl cations comparable to those of the neutral 4-pyrones.[6,25] Notably, secondary photoproducts analogous to **18** and **19** were not seen, although one case did undergo apparent Norrish Type II cleavage.

West and Koch also reported an example of solvent capture of zwitterions derived from 4-pyrones **25a** and **25b** by acetonitrile in the presence of lithium perchlorate (Scheme 7).[26] A Ritter-type process was invoked to explain the isolation of bicyclic oxazolines **26**, together with 2-pyrones **27**. It is important to



SCHEME 8

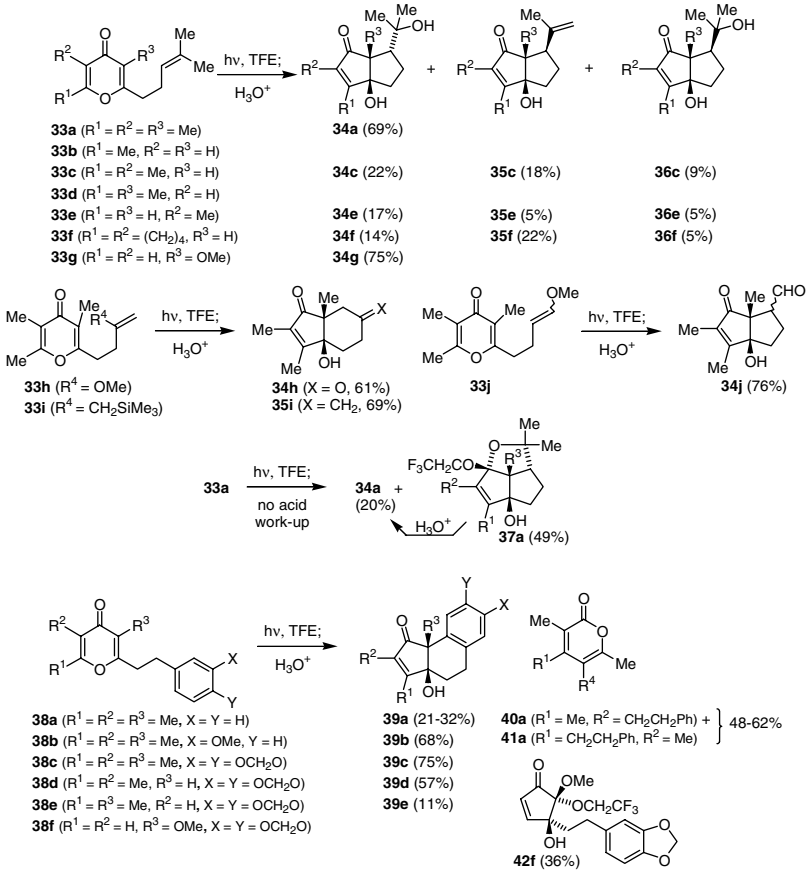
note that oxazolines **26** derive from apparent *syn* attack by acetonitrile. It was suggested that the poor mass recovery in these cases might be due to decomposition or oligomerization of the corresponding *anti*-adducts, which cannot undergo cyclization to the *trans*-fused oxazolines due to excessive ring strain. Similar substrates **25c** and **25d** lacking remote furan rings failed to provide any of the oxazoline products, furnishing only low yields of the ring-transposed 2-pyrones **27c** and **27d**.

Intramolecular Trapping by Oxygen Nucleophiles

West and co-workers prepared a series of substituted 4-pyrones containing pendant hydroxyl groups in order to explore the intramolecular version of the solvent trapping process.[27] The ready availability of the simple polyalkyl 4-pyrones and their straightforward deprotonation and functionalization at the 2-alkyl position permitted the synthesis of a variety of photosubstrates **28a–g** (Scheme 8). In all cases except the monosubstituted 4-pyrone **28a**, the desired bicyclic cyclopentenone ethers **29** were formed in good to excellent yield. The isolation of relatively little solvent adduct at the expense of cyclization product **29** when substrates **28c,e,f** were irradiated in methanol illustrated the efficiency of the intramolecular trapping process. The authors noted the significant complexity increase seen in the conversion of planar heterocycles **28** to fused bicyclic products **29**. However, little or no diastereoselectivity was observed in those cases involving secondary alcohols. A related study employed carboxyl groups as internal traps.[28] In these cases, 4-pyrones **30a–g** with pendant carboxylic acids attached via the 2-position were prepared via either carboxylation of simple polyalkylpyrone anions or by ozonolysis of ω-alkenyl-4-pyrones with oxidative work-up. Irradiation in trifluoroethanol furnished bicyclic lactones **31a–g** in generally good yields. The authors suggested the possibility of a proton transfer prior to cyclization to form hydroxyallyl cation-carboxylate zwitterion **32**.

Intramolecular Trapping by Carbon Nucleophiles

The examples above were simple intramolecular analogies of the well precedented solvent trapping reactions of 4-pyrones. West and co-workers also sought to accomplish carbon-carbon bond-forming processes that had no intermolecular counterpart. To this end, they prepared a series of 4-pyrones **33a–j** with pendant alkenes to examine the feasibility of a cation-olefin cyclization process involving the oxyallyl intermediate (Scheme 9).[29] Irradiation of pyrones **33** yielded fused bicyclic products **34**, **35**, and **36** in

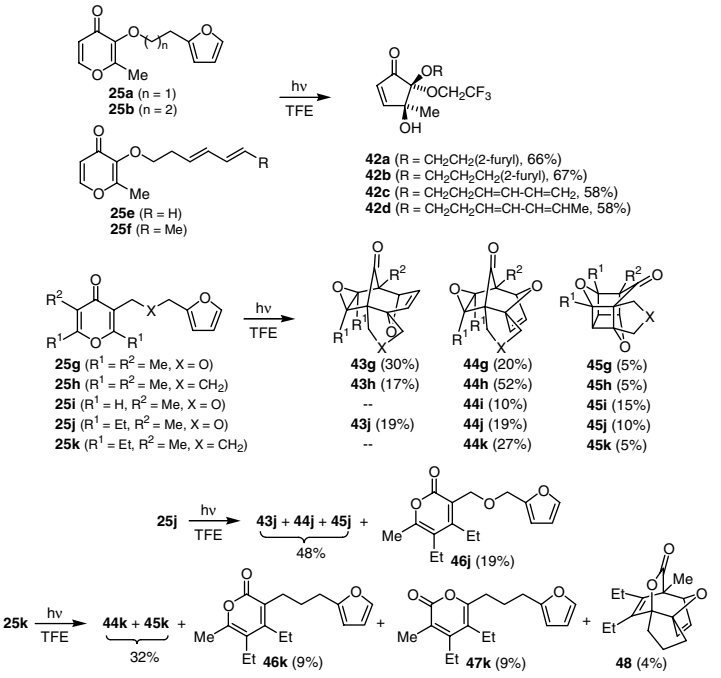


SCHEME 9

good to excellent yield, with the exception of **33b** and **33d**, which were inert to the conditions. The origin of this apparent requirement for a non-hydrogen substituent at the remote C5 position was not discerned by the authors. Interestingly, 4-pyrones **33a–g** with simple trisubstituted alkene traps underwent an unexpected additional cyclization involving the carbonyl oxygen to form tricyclic mixed ketals as exemplified by **37a** that were isolable when acidic work-up was omitted. In a related study, the photochemical behavior of arylethyl 4-pyrones **38a–f** was investigated.[30] Electrophilic aromatic substitution onto electron-rich arenes by the oxyallyl species proved to be efficient, yielding tricyclic adducts **39b,c,d.** However, in the case of monosubstituted arene **38a**, competing phototransposition to 2-pyrones **40a** and **41a** predominated. In analogy to the unreactive alkenyl pyrones **33b** and **33d**, substrate **38e** gave only small amounts of **39e** with most of the starting material unconsumed after extended irradiation, again illustrating the surprising requirement for substitution at C5 in the case of carbon π nucleophiles.[31] Maltol derivative **38f** gave only mixed ketal solvent trapping product **42f**, in analogy to the diene-substituted examples discussed below (Scheme 10).

Trapping by [4+3]-Cycloaddition

Trapping of the oxyallyl intermediate with furan in a [4+3]-cycloaddition was known but was found to be an inefficient process with solvent trapping, phototransposition, and [2+2]-photocycloaddition processes all competing with the desired pathway.[14,15] West and co-workers examined the intramolecular version to ascertain whether tethering a 1,3-diene to the 4-pyrone could enhance the [4+3]-process at the expense of the other pathways (Scheme 10).[15] The need to attach the diene trap via C3 complicated

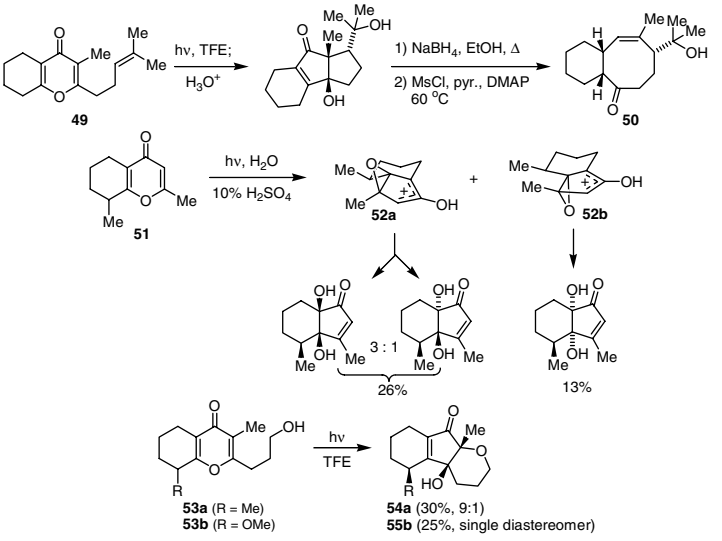


SCHEME 10

the synthetic plans, as this position is much less easily functionalized in the case of polyalkyl 4-pyrones. Ether-linked substrates **25a,b,e,f** could be readily prepared from the naturally occurring maltol but irradiation in trifluoroethanol furnished only the solvent trapping products 42a–d, albeit in good yield. Simple nucleophilic capture of the zwitterion in preference to cycloaddition was attributed to the polarizing effect of the C3 oxygen substituent. Attachment via a carbon linker was also possible and substrates **25g–k** all yielded [4+3]-adducts **43** and/or **44** in moderate yield, with an apparent preference for the *exo*-cycloadduct **44**. The failure to observe the high *endo* selectivity observed with intermolecular trapping of **1d** and **1e** (see Scheme 3) was explained in terms of unfavorable non-bonded interactions between side-chain atoms and the alkyl substituent at C2 (R^2). In all cases, small amounts of the cage products **45g–k** resulting from two successive [2+2]-photocycloadditions of the 4-pyrone and furan systems were also isolated. Notably, 2,6-diethyl substituted substrates **25j** and **25k** also yielded significant amounts of the corresponding 2-pyrone ring-transposition products **46** and **47** and, in the case of **47k**, a small amount of photochemical [4+4]-cycloadduct **48**, a *ternary* photoproduct, was obtained. The observation of an intramolecular crossed [4+4]-photocycloaddition involving a 2-pyrone tethered to a furan spurred the development of this reaction as an approach to functionalized cyclooctadienes.[32]

Stereocontrol in Oxyallyl Zwitterion Formation

West and co-workers also showed that the photocyclization products from intramolecular nucleophilic trapping of oxyallyl zwitterions can be further processed to medium-sized rings using a photocyclization/Grob fragmentation process (e.g., **49**→**50**, Scheme 11).[33] However, because that methodology in not photochemically based, it will not be discussed in detail. Most recently, efforts have focused on methods for controlling the configuration of the ring-contracted oxyallyl species. Fused bicyclic 4-pyrones in which the adjacent ring contains a stereogenic center are potentially subject to conformational control of the ring-contraction process. In the aqueous trapping of substrate **51**, a 2:1 ratio of products derived from diastereomeric zwitterions **52a** and **52b** was seen.[23b] Intramolecular trapping of substrates **53a** and **53b**



SCHEME 11

showed excellent diastereoselectivity but moderate yields of cyclized products **54**.[34] The relative configuration of the major products in these cases were inferred in analogy to the solvent trapping products of **51**, which were validated by x-ray crystallography.

Photoinduced Electron-Transfer Processes of Phthalimides

Michael Oelgemöller

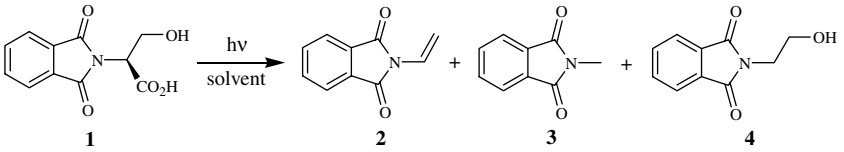
Axel G. Griesbeck
University of Cologne

84.1 Introduction and General Features

In terms of synthetic applications, the phthalimide system has attracted much attention over the past three decades, as noticeable by a number of summarizing reviews.[1] Although the photochemistry of phthalimide derivatives is similar to that of carbonyl compounds, it covers additional reactivity features due to the remarkably high oxidizing power of the excited singlet and triplet states. Thus, the presence of energetically feasible electron donor groups leads to the generation of radical ions that can undergo nonproductive (back) electron transfer, direct radical ion combination, or mesolytic extrusion of a suitable leaving group (e.g., a proton, silyl cation, or carbon dioxide), respectively. The competition between these processes can be controlled by varying the redox potentials, the stability of the radical cations, and the leaving group ability.

The photophysical[2] and electrochemical[3] properties of phthalimides are well documented. In acetonitrile, *N*-alkylphthalimides show relatively unstructured UV absorption spectra with absorption maxima around 235 nm (π,π^*) and 290 nm (n,π^*), respectively.[2a] In ethanol or acetonitrile at room temperature, they exhibit weak fluorescence with low quantum yields ($\Phi_f < 1 \times 10^{-3}$).[2b] In the absence of oxygen in

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1

TABLE 84.1 Solvent-Dependent Photolysis of **1**: Product Composition (Normalized to 100%)[6b]

Solvent	Conversion (%)	2 (%)	3 (%)	4 (%)
Acetone	60	74	—	26
MeCN	100	83	8	9
Benzene	100	76	12	12
MeOH	100	—	38	62
Water	100	—	—	100

alcohol, *N*-alkylphthalimides show broad structureless phosphorescence centered around 450 nm with quantum yields between Φ_p = 0.4–0.7 and triplet lifetimes of τ_p = 0.7–1.04 s (at –196°C).[2a-c]

N-Methylphthalimide is reversibly reduced to the corresponding radical anion at *ca.* −1.35 V in DMF,[3a,b] and at *ca.* −1.5 V in acetonitrile (vs. SCE),[3b] respectively, but the presence of a hydrogen donor site in the side chain has a dramatic effect on the redox properties.[4] Based on the available photophysical and electrochemical data, it is possible to estimate the feasibility of a photoinduced electron transfer (PET) for various phthalimide/donor pairs. The limiting maximum oxidation potential of the electron donor thus depends on the nature of the electronically excited state of the phthalimide electron acceptor[2a] and can be estimated from the Rehm-Weller equation.[5] Thus, if the first excited singlet state is involved (E_{00} = 3.8 eV), the limiting oxidizing power for an isoenergetic electron transfer is *ca.* 2.4 V (vs. SCE). If the first excited triplet state is involved (E_{00} = 3.1 eV), the limiting oxidizing power decreases to *ca.* 1.7 V (vs. SCE). In cases where the spectroscopically nondetectable second triplet state is populated (E_{00} = 3.6 eV), the oxidizing power increases by about 500 mV.

84.2 PET Involving Oxygen as Electron Donor

Due to the decreasing oxidation potential of the oxygen atom in the groups –OH > –OCH_2R > –OCH_2TMS, PET reactions involving oxygen-bearing substituents are energetically limited to derivatives activated by α-trialkylsilyl methoxy groups. Nevertheless, the product spectra of photoreactions involving hydroxy-and dialkylether-substituted *N*-alkylphthalimides show similarities to that of the corresponding sulfur- or nitrogen-activated analogues and therefore reactions of these derivatives will be described here.

Hydroxy- and Dialkylether-Substituted *N*-Alkylphthalimides

Photochemical transformations of the hydroxy-substituted amino acids serine **1** and threonine have been described, and mechanistic outlines based on an electron or a hydrogen transfer key-step have been discussed.[6] The broad spectrum of photoproducts obtained from the C-unprotected serine derivative **1** originated from both reactive sites of the molecule: the carboxyl and the hydroxy group (Scheme 1; Table 84.1). Product **4** derived from primary α-photodecarboxylation, and further β-elimination led to the olefinic compound **2**. *N*-Methylphthalimide **3** was formed via initial extrusion of formaldehyde followed by rapid α-photodecarboxylation (*vide infra*). When this α-photodecarboxylation site was blocked, as for the corresponding methyl ester, solely retro-Aldol cleavage occurred. Although azomethine

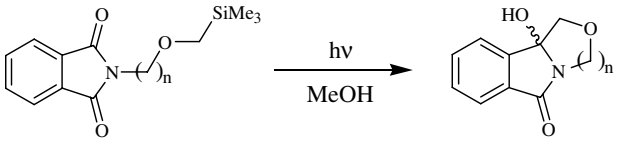
SCHEME 2



9 (n = 2-5, 8) **10** (78-99%)

SCHEME 3

ylides have been postulated as intermediates, trapping experiments with several dipolarophiles were less efficient.[6c]

Due to the high oxidation potential of dialkylethers (>2.5 V vs. SCE),[7] *N*-methoxyalkylphthalimides **5** react preferentially via homolytic C-H abstraction rather than via a PET mechanism. Whereas the carbon-hydrogen bond cleavage always occurs from the activated positions α to the ether oxygen,[8] the regioselectivity of this process (methyl vs. methylene) critically depends on the position of the oxygen atom separating the chromophore and the ether linker (Scheme 2). Hydrogen transfer occurred exclusively from the terminal methyl δ-position (resulting in product **6**) if the ether oxygen was located in the γ-position (δ and γ with respect to the carbonyl function of the phthalimide) and from the δ-methylene position (yielding the branched derivatives **7**) for substrates with the ether oxygen in the ε-position of the side chain. In the case of *N*-methoxyethylphthalimide (**5**, n = 2), which carries the ether oxygen in the δ-position, the primary photolysis product underwent immediate ring expansion and secondary Norrish Type II cleavage to give the unsubstituted benzazepinedione **8** in 33% yield.[8a]

ω-Trialkylsilylmethoxy-Substituted *N*-Alkylphthalimides

PET reactions of α-trialkylsilyl (TMS) methoxy-substituted phthalimides **9** have been developed by Yoon and Mariano (Scheme 3).[9] The introduction of the α-TMS group lowers the oxidation potential of the ether oxygen by about 500 mV[7] and, consequently, electron transfer from the heteroatom to the electronically excited phthalimide becomes energetically feasible. The incorporation of the trialkylsilyl-leaving group additionally enhances the efficiency and regioselectivity of the entire photocyclization and improves the yields and conversion rates in comparison with *N*-alkoxyalkylphthalimides **5**.[10]

The synthetic scope was further expanded to the preparation of structurally complex heterocycles and to photoaddition reactions.[11] However, limitations appeared when other potent electron donors were incorporated in the side chains, as evident for polyheteroatom-linked substrates.[12] In these cases, photoproducts arising from competing PET were also formed. Furthermore, the product composition from substrates **9** was sensitive to the solvent conditions; for example, larger amounts of silylated compounds were obtained in acetone. Even in methanol, the yields decreased significantly with increasing length of the carbon chain and simple desilylation or dimerization products were found, respectively.[10] An improvement in yield and selectivity was achieved when the terminal trimethylsilyl-group was replaced by the tributylstannyl group.[13]

84.3 PET Involving Sulfur as Electron Donor

Alkylthio-Substituted *N*-Alkylphthalimides

Due to the favorable low oxidation potentials of the thioether fragment (Me_2S: $E_{Ox.}$ = 1.25 V in MeCN vs. SCE),[14] alkylthio-substituted *N*-alkylphthalimides are excellent substrates for *intramolecular* PET reactions. From the acyclic phthalimide derivatives **11**,[15] the corresponding unbranched azathiacyclols **12** were formed as major products (Scheme 4; Table 84.2). The only exception was the butylene-linked substrate, which exclusively gave the branched product **13** by means of ε-CH_2 activation. Similar to its oxygen-analogue (*vide supra*), the corresponding branched cyclization product of *N*-methylthioethylphthalimide (n = 2) underwent further ring enlargement and secondary Norrish Type II cleavage to give the unsubstituted benzazepinedione **8** in 6% yield. The yields and conversion rates depended on the spacer length and vary between 25 and 86%. Solely the simplest substrate *N*-methylthiomethylphthalimide (n = 1) gave a surprisingly low yield when irradiated in benzene. Upon irradiation in acetone, cleavage of the methylthio group was found to be the dominant pathway.[15b]

Using the phthalimide/methylthioether pair, a variety of photochemical transformations resulting in medium- and macrocyclic sulfur-containing amines,[15] lactams, lactones, and crown ether analogues, respectively, with a maximum ring-size of 38 atoms have been described.[16] In most of these examples, irradiations were performed under sensitized conditions using acetone as solvent and triplet sensitizer. Cyclization is (most likely) initiated via an *intermolecular* PET involving triplet-excited acetone. In contrast to that, an *intramolecular* PET from the thioether fragment to the electronically excited chromophore has been established for direct excitation of the chromophore.[17] In both cases, the thioether fragment is oxidized to the sulfur-centered radical cation, which shows rapid mesolytic proton transfer from one of its α-CH-positions.

The undesired incorporation of the thioether group into the product ring system could be circumvented using the 1,3-dithiolanyl group as the electron donor substituent.[18a] Upon photolysis of these

SCHEME 6

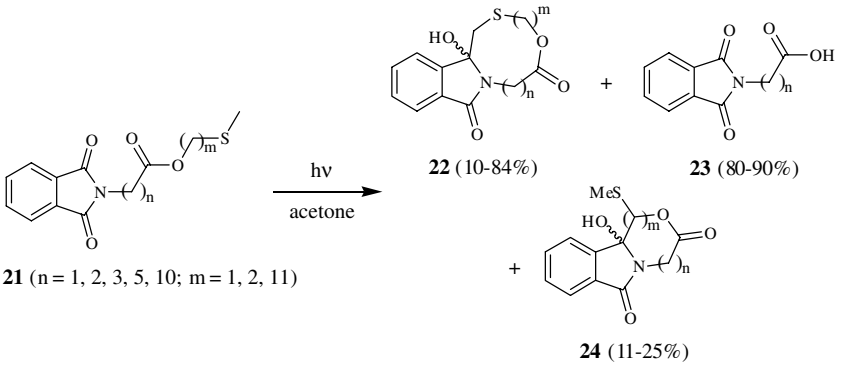
substrates (**14**), activation of the methine CH group dominated and the spiro-annelated thioacetals **15** were obtained as major products in moderate to good yields (Scheme 5). The corresponding sulfur-free compounds **17** were available by subsequent treatment with Raney nickel. An interesting application of this concept was described for the synthesis of aporhoeadane analogues.[18b,c]

Griesbeck and co-workers[19] further investigated PET reactions of sulfur-containing proteinogenic and non-proteinogenic amino acids and discovered an unusual solvent dependence of the product composition. Even more remarkable was the photochemical behavior of phthaloyl *L*-methionine **18**: irradiation in acetone gave the tetracyclic lactone **20** in 72% yield (Scheme 6).[19c] In this particular case, PET oxidation at sulfur proceeds faster than α-decarboxylation (*vide infra*).

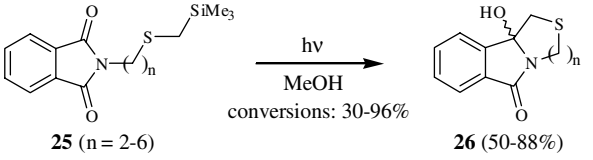
The PET-induced macrocyclization of ester-linked substrates **21** was influenced by the terminal methylthioalkyl-group, and photolysis of the methylthiomethyl ester derivatives (m = 1) resulted in deprotection as an additional reaction mode (Scheme 7).[16b] Among the starting materials, only compounds derived from β-alanine or γ-aminobutyric acid gave the corresponding macrocycles **22**, whereas shorter as well as longer tethers disfavored the radical combination step and preferentially yielded the free *N*-phthaloyl amino acids **23**. Elongation of the methylthioalkyl moiety restored the cyclization efficiency and already the methylthioethyl esters (m = 2) gave the corresponding macrocycles in good yields. In some cases, however, products from hydrolysis or regioisomeric cyclization (**24**) were obtained.[16b,c]

ω-Trialkylsilylmethylthio-Substituted and Related *N*-Alkylphthalimides

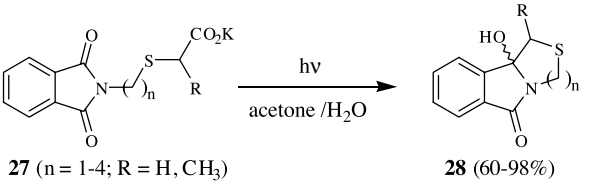
Upon irradiation in methanol, ω-trialkylsilyl methylthio-substituted *N*-alkylphthalimides **25** gave the corresponding desilylated photocyclization products **26** with high regioselectivities.[9,20] Although the yields were moderate to high, the conversions were relatively low (30 to 37%), except for the largest ring system



SCHEME 7



SCHEME 8



SCHEME 9

(Scheme 8). From the thioethyl-linked substrate, the benzazepinedione **8** was additionally observed as a minor product in 6% yield. In sharp contrast, silylated cyclization products were exclusively or mainly obtained when substrates **25** were irradiated in acetone, which accounts for solvent participation in the desilylation step. Conversely, the conversion rates significantly increased in acetone.

A more powerful directing and activating group for PET reactions is the carboxylate group in the α-position with respect to the thioether.[21] Thus, phthalimidoalkylsulfanyl acetates **27** were regioselectively transformed into the corresponding tricyclic ring systems **28** with high quantum yields (Φ *ca.* 0.1)[17a] and in excellent chemical yields of 60 to 98% (Scheme 9). The cyclization efficiency was drastically reduced for the free acids or for substrates with the carboxylate group in the β-position, and cyclization occurred with much lower quantum yields (Φ < 0.03).[17a]

Both α-silylthiomethoxy- (**25**) and α-carboxymethyl- (**27**) substituted derivatives showed similar photocyclization behavior when compared with α-stannylthiomethoxy-substrates where the trialkylstannyl cation serves as the leaving group.[13,22]

84.4 PET Involving Nitrogen as Electron Donor

Alkylamino-Substituted *N*-Alkylphthalimides

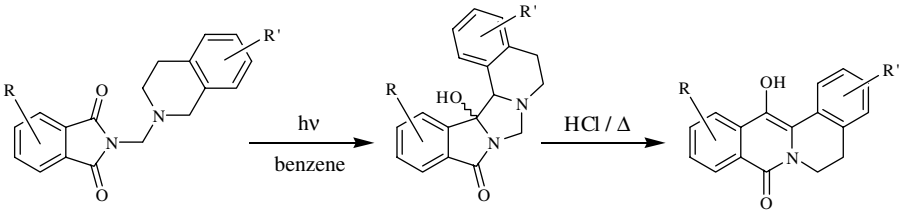
Due to the low oxidation potentials of tertiary amines (R_3N: $E_{Ox.}$ = 0.7–1.3 V vs. SCE),[14] photoinduced electron transfer reactions of aminoalkyl-substituted phthalimides are highly exergonic. On the other hand, amines are also potent hydrogen donors and, consequently, photoreductions are commonly observed side reactions, especially in *intermolecular* reactions.[11b,23]

Irradiation of the tertiary *N*-methyl, *N*-phenyl amines **29** gave the corresponding cyclization products **30** in yields of 6 to 20% (Scheme 10; Table 84.3). The regioselectivity of the mesolytic CH-activation step was pronounced, except for the case where n = 4.[24] This observation goes parallel with the thioether case (*vide supra*). The conversions were low for the precursors to medium-sized ring systems; higher conversions and yields up to 39% were obtained for dibenzylated amines.[24c]

The regioselectivity of the cyclization step was further studied with unsymmetrically substituted phthalimides and pyridinecarboximides resulting in divergent selectivity patterns.[24b] As an interesting application of the *intramolecular* photocyclization, the synthesis of tetracyclic protoberine (Scheme 11) and yohimbane skeletons was reported.[25] In both cases, PET cyclization of compounds (as **32**) was followed by Brønsted-acid catalyzed retro-Mannich reaction[25c] to give the corresponding isoquinoline derivatives **34**.

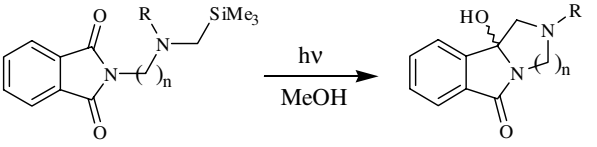
ω-Trialkylsilylmethylamino-Substituted and Related *N*-Alkylphthalimides

The synthetic disadvantages of aminoalkyl-substituted substrates (i.e., low conversion rates, regioselectivity problems) could be overcome by introduction of the α-trialkylsilyl group as a more efficient leaving group. Irradiation of the α-silylamide-linked phthalimides **35** in methanol (Scheme 12) led to efficient (Φ *ca.* 0.1 to 0.2) and high yielding production of the corresponding cyclization products **36** with conversions >80%.[26] Compared with these improvements, limitations came from the substitution pattern at nitrogen; for example,



32 **33** (25-85%) **34** (28-59%)

SCHEME 11



35 (n = 2-6; R = Ms, Ac) **36** (59-92%)

SCHEME 12

silylamines with n = 2 and R = Me gave larger amounts of photoreduction and C-H abstraction products and additionally showed a significant drop in the quantum yield (Φ = 0.05).[26a] When suitable amino substituents were applied, macrocyclic polyamides were efficiently synthesized following this method.[12]

The efficiencies of cyclization conducted via desilylation, decarboxylation, as well as deprotonation of various aminoethyl- and amidoethyl-linked phthalimides have been compared by Mariano and co-workers.[26b] In particular, the quantum yields for the PET-induced cyclization increased in the series H, TMS, or CO_2 as the terminal leaving group, respectively.

84.5 PET Involving the Carboxylate Group as Electron Donor

Intramolecular Decarboxylative Cyclization Reactions

N-Phthaloyl-activated α-amino acids give clean and efficient α-photodecarboxylation (PDC) when irradiated in organic solvents.[27] Griesbeck and Henz[27b] adopted this process as a straightforward route to α-monodeuterated amines by irradiation in the presence of D_2O. The α-decarboxylation is initiated by hydrogen atom abstraction and proceeds via azomethine ylide intermediates, which could be trapped by cycloaddition with suitable dipolarophiles and which were additionally observed by laser flash photolysis studies.[27c] "Remote" ω-carboxyl groups could be activated for elimination by converting them into the corresponding potassium salts and irradiation in aqueous solvents.[28] An illustrative example of this concept is the photodecarboxylation of the potassium salt of *N*-phthaloyl glutamic acid **37**: irradiation in a water/acetone mixture gave the cyclization product **39** in 89% yield (Scheme 13). In contrast, *N*-phthalimido γ-butyric acid **38** was obtained in 86% yield as the sole product when the free acid of **37** was irradiated in acetone.

Although the oxidation potentials of carboxylates are relatively high compared to other electron donor groups (e.g., acetate: $E_{Ox.}$ = 1.54 V in MeCN, 2.65 V in H_2O vs. SCE),[29] the decarboxylative cyclization proceeds very efficiently and many functional groups are tolerated. As the key step in the reaction, rapid *intramolecular* photoinduced electron transfer proceeds via the $^3\pi,\pi^*$ state or the higher excited $^3n,\pi^*$ triplet state in the nanosecond time regime.[17]

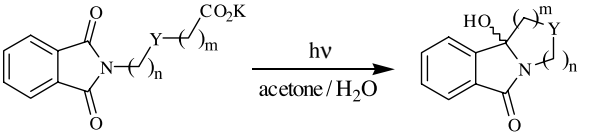
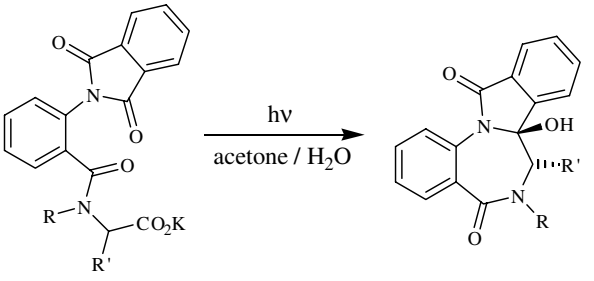
SCHEME 13



Y = CH_2, CO_2, O_2C, O, CONH, S, C≡C

SCHEME 14



40 **41** (54-83%)

SCHEME 15

Using the decarboxylative photocyclization, the synthesis of medium- and macrocyclic amines, lactones, polyethers, lactams, as well as cycloalkynes were accessible in ring sizes up to 26 (Scheme 14)[30] and even in multigram quantities.[31] The regioselectivity of the radical cyclization step was studied for unsymmetrically substituted pyridinecarboximides and trimellitic acid imides, respectively, where the site of the C-C-bond formation is controlled by the maximum spin density of the radical anion intermediates.[32]

An interesting application (Scheme 15) was the diastereoselective synthesis of [1,4]benzodiazepines and pyrrolo[1,4]benzodiazepines (**41**).[33] The photolysis of chiral, α-amino-acid-derived substrates proceeded with high diastereoselectivity and the *trans*-diastereoisomers were formed exclusively. Additionally, for two substrates derived from proline and a proline analogue, remarkably high memory of chirality effects were determined with *ee* values of 86% and >98%, respectively.

Exchange of the terminal amino acid in substrates **40** by β-, γ- or δ-amino acids led to a significant decrease in the cyclization efficiency, and other processes such as photoinduced decomposition became relevant.[33c] On replacement of the *ortho*-phenylene linker by the conformationally more flexible ethylene linker, memory of chirality vanished and a mixture of stereoisomeric products was obtained.[33d]

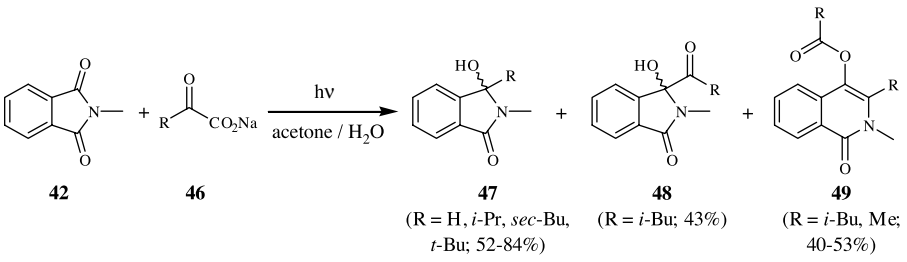
Intermolecular Decarboxylative Addition Reactions

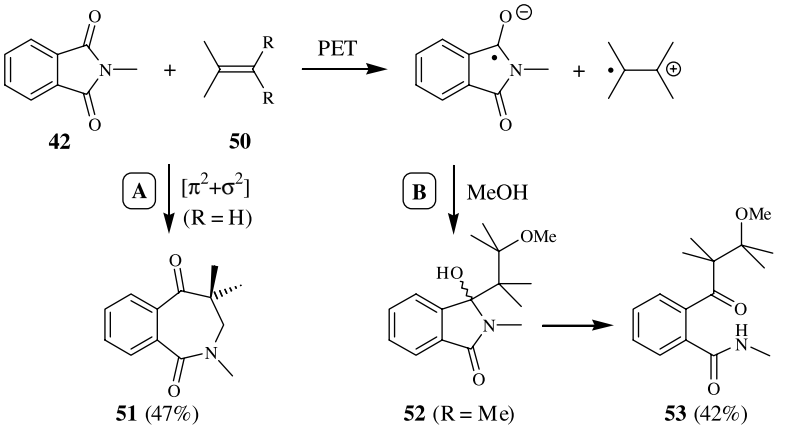
The photodecarboxylation also took place in its *intermolecular* mode and efficient photochemical additions of carboxylates, α-keto carboxylates, and heteroatom-substituted carboxylates to phthalimides were reported.[34] The photoaddition proceeded with high chemoselectivity solely at the imide carbonyl group when *N*-phthaloyl amino acid esters were used as starting materials and products arising from *intramolecular* hydrogen abstractions were not observed. The influence of additional heteroatoms in the alkylcarboxylate was a function of the respective electron donor capacity[14] and either strongly increased or decreased the addition efficiency. α-Thioalkyl and α-oxoalkyl-substituted carboxylates **43** led to the corresponding addition products **44** in moderate to good yields of 57 to 90%. In contrast, the β-thioalkyl-substituted carboxylate was inert under the reaction conditions, whereas the corresponding β-oxoalkyl carboxylate reacted efficiently to give the addition product in 51% yield (Scheme 16; Table 84.4). From a comparison of the sulfur- and the oxygen-substituted carboxylates, it was concluded that oxidation of the heteroatom plays the dominant role for thioethers. In the case of the β-thioalkyl substrate and in contrast to the *intramolecular* version (*vide supra*), the sulfur atom acts as a hole trap (fast nonproductive back electron transfer)[14,35] and prevents oxidation of the carboxylate. The alkylamino-substituted carboxylates underwent photoreduction exclusively to give products **45**. For the trimethylamine equivalent (**43**, R = Me, X = NMe, n = 1), radical combination with the solvent acetone was additionally observed.[34c]

The products from the irradiation of phthalimides in the presence of α-keto carboxylates **46** included alkylation, acylation, and ring expansion, respectively, depending on the substitution pattern of the α-keto carboxylate (Scheme 17).[34b] Glyoxylate as well as secondary and tertiary α-keto carboxylates gave the corresponding reduction or alkylation products **47** in yields of 52 to 86%, whereas pyruvate and α-keto-leucine gave dihydroisoquinolinyl esters **49** as ring-expansion products in yields of 40 to 53%. In the latter case, the acylated product **48** was additionally found in 43% yield.

The course of the reaction is controlled by the stability of the acyl radical intermediates.[36] When less reactive acyl radicals are generated, C–C-bond formation could successfully compete with decarbonylation, whereas, in the case of more reactive acyl radicals, decarbonylation preceded C–C-bond formation.



SCHEME 17



SCHEME 18

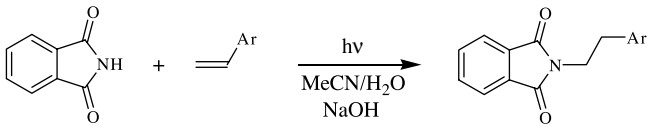
The unusual ring-expansion products **49** most reasonably originate from the monoacylated compounds **48** via rearrangement to the corresponding isomeric isoquinolines.

84.6 PET Involving Electron-Rich Alkenes and Arenes

Electron-Rich Alkenes

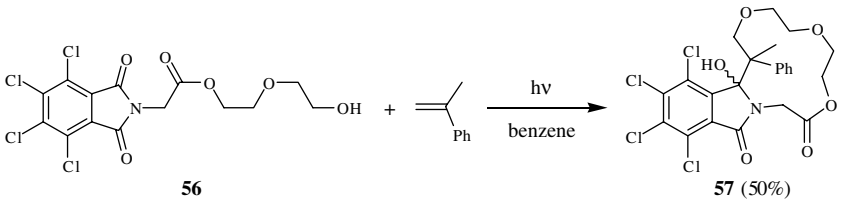
The progress of *intra-* and *intermolecular* photoreactions of phthalimides and alkenes **50** is essentially dictated by the thermodynamics of the electron-transfer step.[37] In cases where this electron transfer is endergonic with ΔG_{ET} >5 kcal/mol, $[\pi^2+\sigma^2]$-addition reactions to benzazepinediones **51** take place (Scheme 18; path A). If the electron transfer becomes more and more exergonic, electron transfer starts to dominate. In the presence of suitable nucleophiles (e.g., when alcohols were used as solvents), the intermediate radical ionic pair that is formed is trapped in an *anti*-Markovnikov fashion (Scheme 18; path B). The efficiency of this trapping reaction depends on the polarity as well as the nucleophilicity of the solvent.[38] In the absence of nucleophiles or suitable trapping agents, back electron transfer, regenerating the starting materials, efficiently competes with proton transfer and radical combination.[37] In cases where the electron transfer is only slightly endergonic, both pathways can compete and mixtures of the $[\pi^2+\sigma^2]$-addition and PET products are obtained.

An interesting variation of these PET reactions is the photochemical phthalimidation of inactivated double bonds using the phthalimide anion as trapping agent (Scheme 19).[39a] The reaction can be controlled by variation of the anion concentration: at higher NaOH concentration, $[\pi^2+\sigma^2]$-addition was



54 **55** (30-90%)

SCHEME 19



56 **57** (50%)

SCHEME 20

the sole process observed,[39b,c] whereas efficient phthalimidation to give **55** occurred at low NaOH concentrations, respectively. In the latter case, the phthalimide anion itself acts as a nucleophile and traps the olefin radical cation intermediate.

Various examples of similar *intramolecular* photocyclizations have been reported.[40] Recently, Xue and co-workers[41] described macrocyclization reactions using tetrachlorophthalimides with remote hydroxyalkyl substituents (**56**) in the presence of alkenes. During photolysis in benzene, the alkene radical cation intermediate was trapped by the terminal hydroxy function, followed by an *intramolecular* radical–radical combination to give macrocyclic lactones (e.g., **57** in 50% yield [Scheme 20]).

Electron-Rich Arenes

Toluene derivatives add to electronically excited phthalimides to give the corresponding addition products in poor to moderate yields of 5 to 35%.[23,42] A primary hydrogen abstraction from the benzylic position or, alternatively, electron transfer pathways were postulated. The efficiency via the electron-transfer route could be significantly enhanced for cyano-substituted phthalimides **58** as the electron-transfer step became more exergonic. Most remarkably, substitution of the cyano group was observed beside addition to the carbonyl-position when diphenylmethane (**59**; R′ = Ph) was used as the toluene derivative (Scheme 21).[42] The latter process was rationalized on the basis of an *in-cage* vs. *out-of-cage* scenario.

PET cyclizations of substituted *N*-arylalkylphthalimides have been studied, and the efficiency of the cyclization (yields between 11 and 47%) strongly depended on the linking carbon chain separating the electron acceptor and electron donor.[43] Griesbeck and co-workers[6b,44] recently applied this PET reaction to aromatic amino acid derivatives as an efficient route to benzazepinediones **63**. The PET reactivity was pronounced for the DOPA derivatives **62** and cyclization occurred with high yields (Scheme 22). Most remarkably, even the free acid underwent exclusive photocyclization in acetone and no α-decarboxylation was observed (*vide supra*).[27]

Another solvent dependent *intermolecular* addition reaction involving phenylcyclopropane (**64**) as the electron donor was recently reported.[45] Irradiation of *N*-methylphthalimide **42** in acetonitrile in the presence of **64** afforded a 1:1 mixture of isomeric *spiro*-tetrahydrofuranyl lactams **65** in 22% yield. An *intramolecular* version of this PET reaction has also been described.[45c] When the photolysis was performed in methanol, solvent-incorporated addition to produce **66** took place (Scheme 23).

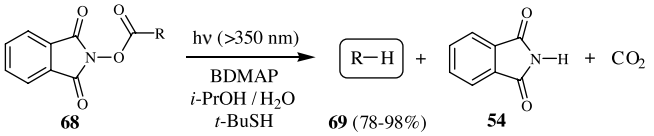
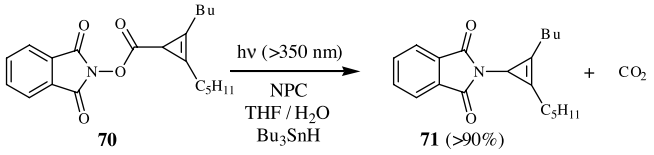
84.7 Miscellaneous Reactions

A base-promoted *t*-butylation of the aromatic ring of phthalimides involving a thermal electron-transfer step was developed by Russell and co-workers.[46a] This radical chain reaction is initiated by photochemical cleavage of alkylmercury halides, leading to *t*-butyl radicals that add to the aromatic ring in a highly regioselective fashion (Scheme 24). The yields of the corresponding alkylated phthalimides **67** were



68 **69** (78-98%) **54**

SCHEME 25



70 **71** (>90%)

SCHEME 26

generally high. A similar reaction has been described for 1-iodoadamantane and the phthalimide anion.[46b] In this case, however, the regioselectivity decreased and, additionally, a larger amount of adamantane was isolated.

Okada and Oda[47] described an efficient method for PET-induced decarboxylation of non-activated carboxylic acids. When irradiated as the corresponding *N*-acyloxyphthalimide derivatives **68** in the presence of 1,6-bis(dimethylamino)pyrene (BDMAP) as sensitizer and *t*-BuSH as hydrogen donor, the corresponding alkanes **69** were obtained in high to excellent yields of 78 to 98% (Scheme 25). The reaction could also be performed with visible light when a $Ru(bpy)_3Cl_2$/1-benzyl-1,4-dihydronicotinamide (BNAH) combination was used.[47b]

An unusual and high yielding formation of *N*-(2-cyclopropenyl)phthalimides **71** via this photosensitized decarboxylation method was reported (Scheme 26).[48] The intermediacy of cyclopropenyl radicals was confirmed by a trapping reaction with 5,5-dimethyl-1-pyrroline-*N*-oxide and also by ESR spectroscopy.[48b] Most reasonably, the carboxyl radical of this cyclopropenyl radical intermediate undergoes rapid decarboxylation followed by initial trapping by the phthalimidyl radical within the solvent cage.

The Photochemistry of Silicon-Substituted Phthalimides

University of New Mexico, Albuquerque

85.1 Overview

SET Photochemistry of Organosilanes

Silicon-containing organic compounds serve as key reagents in numerous, synthetically useful chemical reactions.[1] Perhaps the most common role played by these substances is as equivalents of allylic and enolate anions. For example, activation of allylsilanes using potent silophiles leads to the formation of silylate anions, which react with electrophilic reagents to yield products resulting from nucleophilic addition and substitution. In addition, when partnered with strong electrophiles, allylsilanes and enolsilanes undergo addition reactions proceeding via the intermediacy of β-silicon stabilized carbenium ions that readily transfer their silyl groups to even weakly silophilic substances.

A variety of photochemical and electrochemical investigations over the past two decades have uncovered another interesting feature of organosilanes. Substances in this family that possess silyl-substitution at sites adjacent to electron donor centers undergo ready oxidation to generate silicon stabilized cation radical intermediates (Scheme 1). Comprehensive theoretical and electrochemical studiesby Yoshida and co-workers[2,3] have shown that stabilization by trialkylsilyl groups in these reactive intermediates is a consequence of hyperconjugative interactions. Specifically, the effect results from overlap of the relatively (compared to C–C bonded analogues) high energy, doubly occupied $\sigma_{C\text{-}Si}$ orbitals with half-filled heteroatom n- or alkene π-orbitals in the cation radicals. Moreover, the odd electron and positive charge delocalization, resulting from this interaction, weakens the $\sigma_{C\text{-}Si}$ bond and makes the silicon center more electropositive. Consequently, these short-lived intermediates participate in fast desilylation reactions to produce neutral, carbon-centered free radical intermediates.

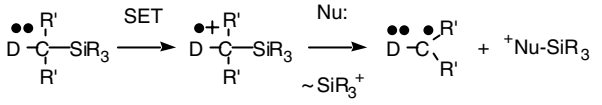
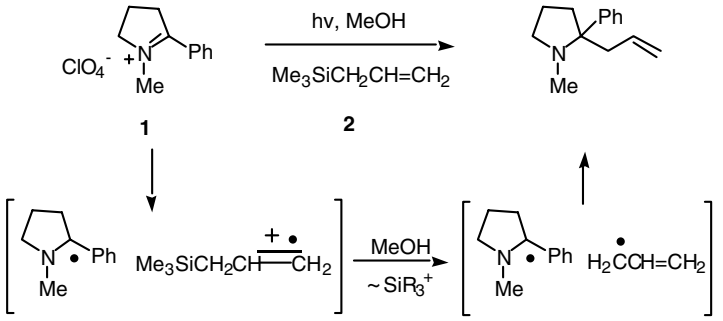
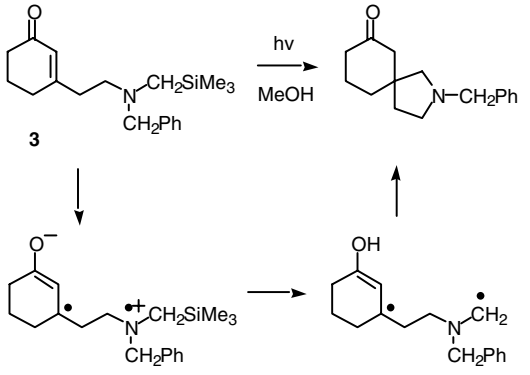


SCHEME 1

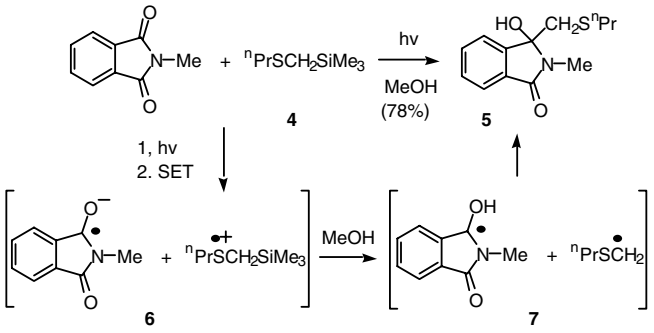


SCHEME 2



SCHEME 3

The redox properties of organosilanes have a profound impact on the nature of SET-promoted photochemical reactions. Owing to their low oxidation potentials, substances in this family serve as excellent electron donors to excited states of a variety of acceptors, including iminium salts, conjugated ketones, and cyanoarenes. In addition, the large rates of desilylation of cation radicals, formed in this manner, often drive efficient and selective formation of radicals that undergo C–C bond formation with either acceptor-derived radicals or neutral unsaturated substrates. Early examples of this reactivity profile are found in the direct irradiation-induced photoaddition of allyltrimethylsilane **2** to 1-methyl-2-phenylpyrrolinium perchlorate (**1**) (Scheme 2)[4,5] and the SET-sensitized photocyclization of the silylamino-tethered cyclohexenone **3** (Scheme 3).[6,7] When viewed from the perspective of SET photochemistry, α-silyl substituted electron donors are chemical equivalents of carbon-centered free radical intermediates. This conceptual connection enables the design of new excited state reactions, in which C–C bond formation occurs by radical coupling and addition pathways.



SCHEME 4

Phthalimide SET Photochemistry

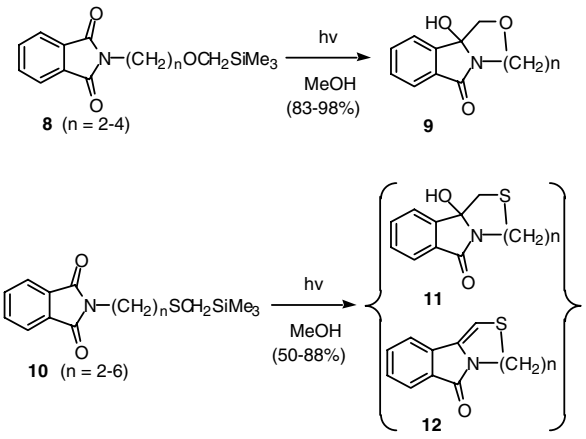
The SET photochemistry of a wide variety of electron acceptors has been explored since the early recognition that SET pathways play prominent roles in excited-state reactions of organic substances. Included in this group are cyanoarenes, arylketones, and iminium and related *N*-heteroaromatic salts.[8] Owing to their large positive excited-state reduction potentials ($E^*(-)$ *ca.* 1.6–2.1 V),[9] phthalimides participate as electron acceptors in photoinduced SET processes with donors having ground-state oxidation potentials lower than *ca.* 2 V.

Early pioneering studies by Kanaoka[12–15] and Coyle[16,17] provided the first examples of intramolecular SET photochemical reactions of thioether and amine-tethered phthalimides. More recently, Griesbeck and co-workers[18–20] have fully probed the SET photochemistry of ω-carboxylate-linked phthalimides and have highlighted the synthetic potential of processes driven by sequential SET decarboxylation routes. Investigations in our laboratories have concentrated on developing the preparative potential of inter- and intramolecular reactions of phthalimides with silicon-substituted electron donors. A summary of observations made during the course of these efforts is given below using a format in which mechanistic analysis is interwoven with synthetic methodology development.

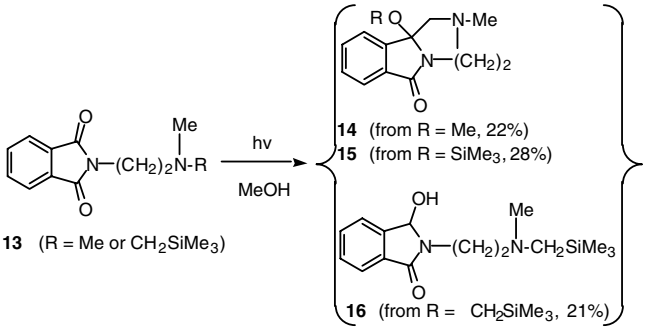
85.2 Photoadditons and Photocyclizations of Phthalimides with α-Silyl-ether, -Thioether, -Amine, and -Amide Substrates

Studies of SET-induced excited-state reactions of phthalimides with α-trialkylsilyl substituted ethers, thioethers, and amines have shown that cation radical desilylation is the foundation of interesting photochemical reactions that proceed by pathways involving the generation and coupling of radical intermediates. In an early effort, we observed that simple, α-silyl-substituted ethers, thioethers, amines, and amides undergo efficient photoadditions to phthalimide and its *N*-methyl derivative.[21] One example in this series of closely related reactions is the photoaddition of silylmethylpropylthioether **4** to *N*-methylphthalimide, which produces the product **5** (Scheme 4). In the mechanistic route for this process, thermodynamically/kinetically driven SET from **4** to the excited phthalimide leads to formation of the ion radical pair **6**. Solvent (MeOH)-promoted desilylation of the cation radical and protonation of the phthalimide anion radical then provides radical pair **7**, the direct precursor of adduct **5**.

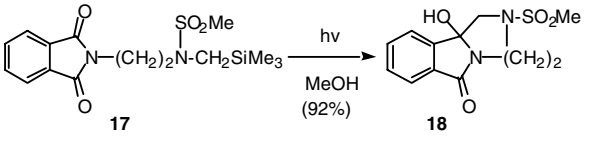
Photocyclization reactions of phthalimides containing *N*-tethered α-silyl donors proceed with high chemical efficiencies to generate a variety of novel heterocyclic products. For example, irradiation of MeOH solutions of the phthalimido silyl ethers **8** leads to formation of the amidol-containing, oxygen heterocycles **9** in excellent yields (Scheme 5).[22] Analogous photocyclization reactions are observed with the phthalimido thioethers **10**.[23] Although dehydration of the primary photoproducts (**11** → **12**) occurs with varying ease in these systems, the overall yields of the reactions remain high even when the size of the ring that is formed in the ultimate diradical cyclization steps is large.



SCHEME 5

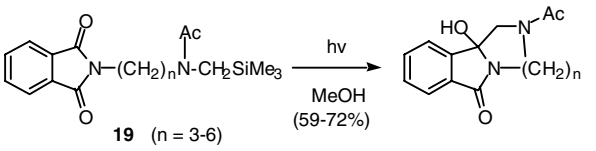


SCHEME 6

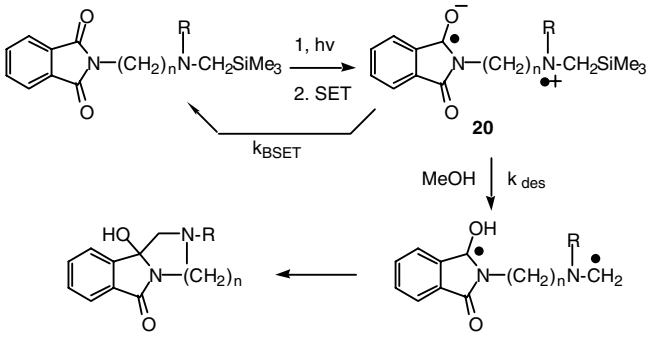


SCHEME 7

A parallel investigation of the photochemistry of α-silyl-amine and α-silyl-amide linked phthalimides has provided a more in-depth understanding of the factors that govern both the chemical and quantum yields of SET-promoted photocyclization reactions.[24,25] We observed that irradiation of a MeOH solution of the silylamino-phthalimides **13** leads to nonselective formation of a mixture of products, including the fused diazines **14** and **15**, and amidol **16** (Scheme 6). In stark contrast, the tricyclic sulfonamide **18** is formed in high yield when the silylamido-phthalimide **17** is irradiated in MeOH (Scheme 7). These divergent results suggest that the preparative utility of photocyclization reactions, operating by sequential SET desilylation pathways, could be enhanced using substrates that contain α-silylamide rather than α-silylamine donor sites. Support for this proposal is found in photoinduced cyclization of the acetamide



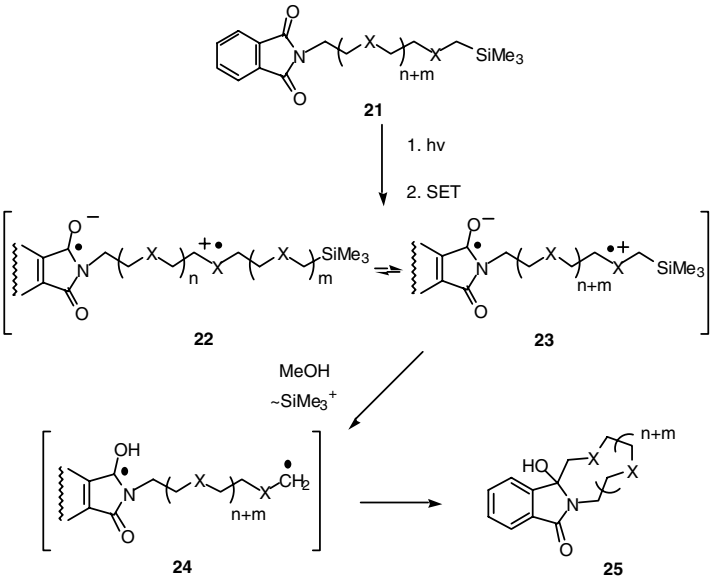
SCHEME 8



SCHEME 9

derivatives **19** shown in Scheme 8. Quantitative studies showed that the quantum yields of photocyclization reactions of the linked phthalimides **13** and **17** are also greatly dependent on the nitrogen substituent with the amide substrate **17** reacting with a greater efficiency ($\phi = 0.12$) than the amine analogue **13** ($\phi = 0.04$).

When first viewed, the results presented above appear counterintuitive and they lead one to question why the SET-promoted photoreactions are more efficient when they involve poorer electron donors (oxidation potentials of amines are often *ca.* 0.5 V lower than that of the corresponding amides). The answer to this question comes from an analysis of the key factors involved in determining the chemical and quantum efficiencies of excited-state reactions that proceed via pathways in which initial SET is followed by secondary reaction of charged radical intermediates. In the case at hand, SET from both α-silylamide and α-silylamine donors to the singlet excited state of the phthalimide chromophores in **13** and **17**, respectively, should both be highly exothermic. As a result, both intramolecular SET processes should occur at rates ($>1 \times 10^{10}$ s^{-1})[26] that are highly competitive with other pathways responsible for decay of the excited phthalimide. In this respect, Coyle and co-workers[11] have suggested that the n-π* singlet excited state of phthalimides is quenched by SET from pendant amino groups, and that this quenching process is on the pathway for cyclization reaction of these substrates. The intermediate zwitterionic biradicals **20** (Scheme 9) formed by excited-state SET in silylamino and silylamido phthalimides can react by several different routes. For example, exothermic back-SET, with rates that are essentially independent of the nitrogen substituent, would generate the ground-state starting materials. Competitive with this decay mode is methanol-induced α-desilylation. Our earlier laser flash photolysis studies[27,28] demonstrated convincingly that the rates of aminium radical fragmentation are highly dependent on the nitrogen substituent. Specifically, methanol-induced desilylation of silylamine cation radicals is two orders of magnitude slower than the analogous reaction of α-silylamide cation radicals. In more general terms, the rates of ion radical reactions are inversely proportional to the stability of these short-lived intermediates, as judged by the redox potentials of neutral precursors. In summary, the larger rate constants for desilylation of zwitterionic biradicals derived by photoinduced, intramolecular SET in α-silylamido-phthalimides translates into a larger rate constant ratio, $k_{des}/(k_{des} + k_{BSET})$. Consequently, larger quantum efficiencies are observed for diradical and product formation.



SCHEME 10

85.3 The Use of Phthalimide Photochemistry in Macrocyclec Polyamide, Polyether, and Polythioether Synthesis

The chemical yields of photoaddition and photocyclization reactions of systems comprised of phthalimides and α-silyl heteroatom donors are in the range normally deemed acceptable for synthetic applications. Based on this conclusion, we have designed strategies for the preparation of families of macrocyclic substances that rely on the use of this excited-state chemistry as the principal ring-building methodology. As depicted in Scheme 10, irradiation of phthalimides **21**, which have *N*-linked, silylmethyl terminated, polyheteroatom chains, should result in regioselective production of macrocyclic poly-amides, -ethers, and thioethers **25**. Accordingly, photoinduced SET in these substrates would yield a mixture of rapidly interconverting zwitterionic biradicals **22** + **23**, whose relative abundance would be governed by the relative energies of the cation radicals (as judged by the oxidation potential at each heteroatom center). Importantly, the rates of secondary α-deprotonation and α-desilylation adjacent to each of the rapidly interconverting cation radical sites will not depend on their relative populations. Rather, the relative rates of these processes, and thus the relative yields of 1,n-biradicals, will be determined by the rates of the competing fragmentation reactions. Since desilylation of the terminal cation radical **23** should be the most rapid process,[27,28] selective generation of the diradical precursors (**24**) of the macrocyclic products **25** should be observed.

The phthalimides, that serve as starting materials for these photomacrocylization reactions are readily prepared by *N*-alkylation of potassium phthalimide with polyamide, polyether, and polythioether-linked mesylates or halides. As seen by viewing the processes included in Schemes 11 through 16, irradiation of the phthalimido-silylpolyamides, -ethers and -thioethers in MeOH solution does indeed result in modestly to highly efficient production of the corresponding macrocyclic products.[29,30]

Although less well studied, SET-promoted ground- and excited-state reactions driven by α-destannylation of intermediate cation radicals are also known. One example is found in the photoaddition of allylstannane **26** to the pyrrolinium salt **28** (Scheme 17), which produces the pyrrolidine adduct **29**.[31] The quantum yield for the SET-promored addition of 26 to 28 is *ca.* tenfold greater than that for photoaddition of the corresponding allylsilane **27**. The enhanced efficiency is a result of the larger rate of destannation vs. desilylation of the intermediate π-cation radical.

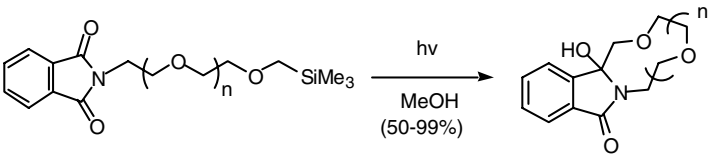
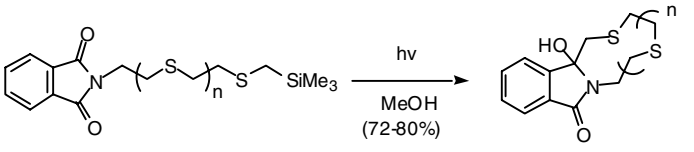
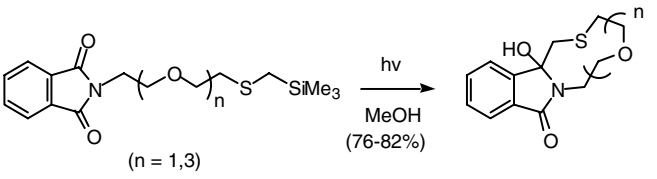


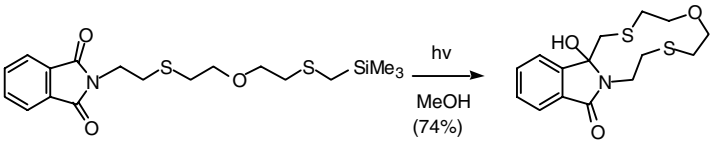
SCHEME 12



SCHEME 13



SCHEME 14



SCHEME 15

Trialkylstannyl substitution has a similar effect on the chemical efficiencies of photocyclization reactions of phthalimido-linked polyethers and related maleimides. As seen by viewing the data compiled in Table 85.1, the yields for formation of the macrocyclic polyethers **32a–f** are generally higher when the tin-substituted substrates **30a–f**, rather than silicon-substituted substrates **31a–f**, are irradiated.[32] This is especially true in the case of the larger ring forming reactions.

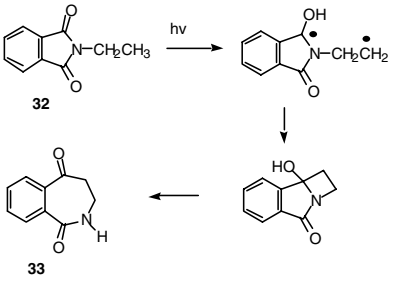
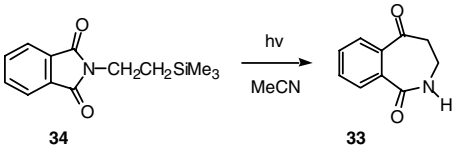
85.4 Photoreactions of ω-Phthalimido-Alkylsilanes

Hydrogen atom abstraction dominates the excited-state reactivity profiles of *N*-alkylphthalimides. This is exemplified by the photochemistry of *N*-ethylphthalimide **32**, where irradiation leads to formation of the benzazepinedione **33** (Scheme 18).[13] Here, initial γ-hydrogen abstraction is followed by biradical coupling and ensuing amidol ring opening. However, the yield of this process (*ca*. 5%), as well as those of related *N*-alkylphthalimide photocyclizations, are not preparatively acceptable.

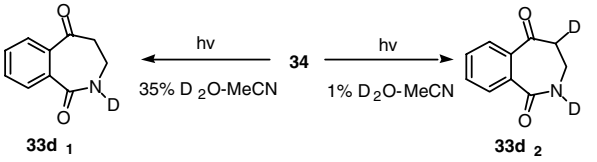
In contrast, *N*-silylethylphthalimide **34** efficiently (68%) produces benzazepinedione **33** (Scheme 19) when irradiated in MeCN solution.[33] Introduction of the trimethylsilyl substituent transforms a minor photoreaction into one that has synthetic value. Insight into the factors responsible for the yield enhancement was gained from the results of experiments in which photoreaction solvent was varied. Irradiation of **34** in 35% D_2O-MeCN leads to exclusive production of the mono-*N*-deuteriated product $\mathbf{33d_1}$ while photoreaction of **34** in 1% D_2O-MeCN yields the N,C-dideuteriated benzazepinedione $\mathbf{33d_2}$ (Scheme 20). In addition, ^{1}H NMR monitoring of the photoreaction of **34** in CD_3CN shows that the α-silyl product



SCHEME 18



SCHEME 19



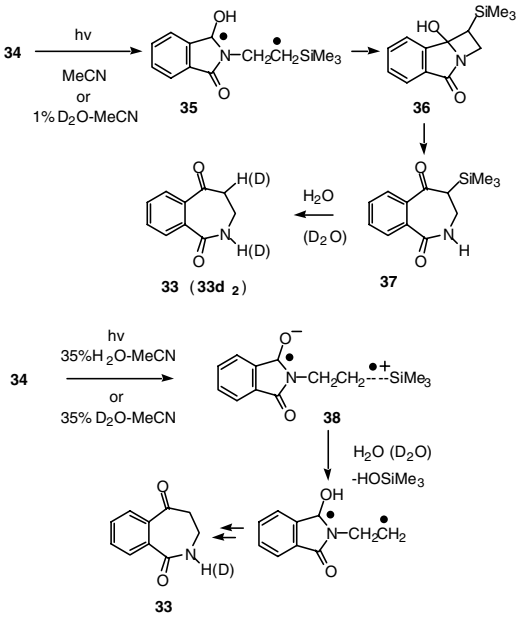
SCHEME 20

37 is produced initially and that this substance is converted to **33** or **33d**$_2$ when treated with H_2O or D_2O, respectively (Scheme 20).

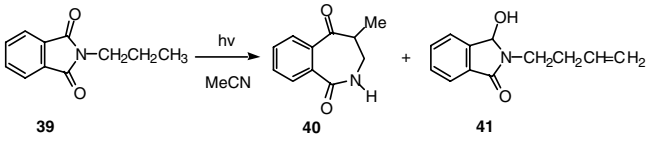
The results suggest that two pathways (Scheme 21) are responsible for the photochemical transformation of silylethylphthalimide **34** to benzazepinedione **33**. In low water content solvents (e.g., 1% D_2O-MeCN), the reaction is initiated by γ-hydrogen atom transfer, which yields sequentially the silicon-containing tricyclic amidol **36** and silyl-benzazepinedione **37**. In contrast, desilylation must precede C–C bond formation in the reaction of **34** in the highly polar silophilic solvent systems 35% D_2O-MeCN. In this case, intramolecular SET from the σ-$_{C-Si}$ bond ($E_{p/2}$ = 2.5 V vs. SCE)[34] to the singlet excited phthalimide leads to the solvent-stabilized, but transient[34,35] zwitterionic biradical **38**. Desilylation of **38** then generates the precursor of the non-silicon-containing benzazepinedione **33**.

Another example that demonstrates the level of control offered by solvent variation is found in the photochemistry of the silylpropyl-phthalimide **42**. Kanaoka has reported that irradiation of the *N*-propyl substrate **39** leads to low-yield (29%) formation of methyl-benzazepinedione **40**, along with the unsaturated amidol **41** (18%) (Scheme 22).[13] Similarly, irradiation of the silicon analog **42** in MeCN gives rise to a mixture of products, including benzazepinedione **43** (28%), amidol **44** (18%), and benzopyrrolizidinone **45** (21%) (Scheme 23).[33] The major products generated in both photoreactions arise by initial γ-hydrogen atom abstraction. The biradical formed in this way cyclizes or disproportionates to produce the respective benzazepidione and unsaturated amidol products.

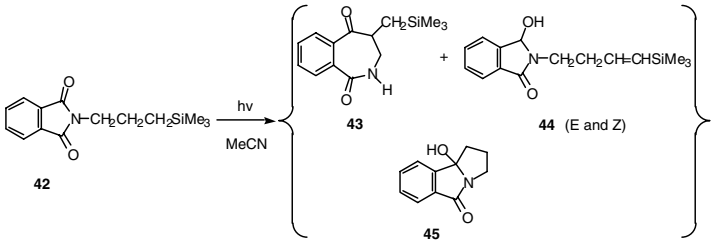
In contrast, irradiation of the silylpropylphthalimide **42** in 35% H_2O-MeCN results in nearly quantitative (96%) formation of the benzopyrrolizidinone **45** (Scheme 24). In addition, the quantum efficiency



SCHEME 21



SCHEME 22



SCHEME 23

for photoreaction of **42** in the aqueous solvent system is *ca.* 20-fold greater than for the process in MeCN. As in the case of **34**, a change to an aqueous solvent system produces a dramatic change in the excited-state reactivity of the silylpropylphthalimide. The "water effect" also profoundly impacts the photochemistry of a number of silicon-substituted maleimides.[36]

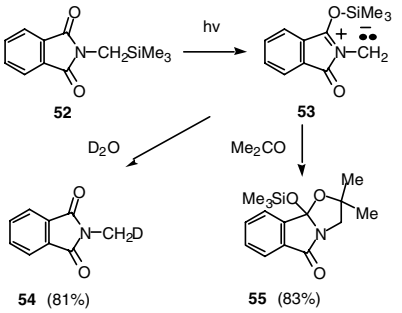
SCHEME 25

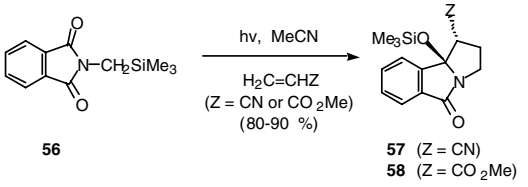
85.5 Azomethine Ylide Forming Photoreactions of *N*-Trimethylsilylphthalimides and Related Conjugated Imides

The studies described above show that the unique redox properties of alkylsilanes and conjugated imide excited states serve to drive synthetically interesting photoreactions. The efforts have also uncovered interesting excited-state reactions of *N*-silylalkyl-phthalimides, in which 1,ω-biradicals are produced as reactive intermediates by SET and subsequent desilylation of σ_{C-Si} cation radicals. A consideration of how this reactivity pattern might be applied to silylmethyl-phthalimides **46** results in the prediction that 1,3-biradicals or azomethine ylides would be formed as reactive intermediates (Scheme 25). In this case, the zwitterionic biradicals **47** generated by SET in the triplet or singlet excited states of **46** could undergo nucleophile-induced desilylation to form 1,3-biradicals **48** (if triplets) or azomethine ylides **50** (if singlets). Alternatively, the oxyanion center in **47** could serve as an internal nucleophile for desilylation at the σ_{C-Si} cation radical site. This process, being both energetically and entropically favored, would result in production of the silicon containing biradical or dipolar intermediates, **49** or **51**.

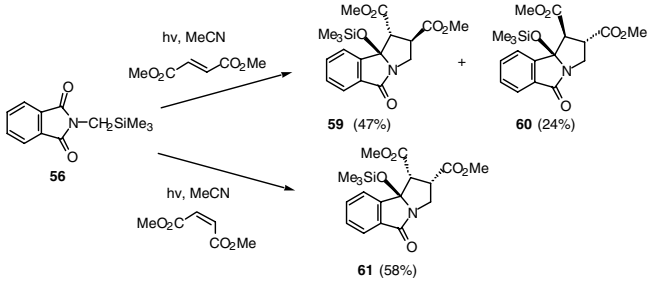
Observations made in studies with the parent silylmethylphthalimide **52** confirm the operation of a unique excited-state process involving sequential SET-silyl transfer.[37,38] We found that irradiation of **52** in D_2O-MeCN results in efficient production of *N*-(d_1-methyl)phthalimide **54**, while excited-state reaction of this phthalimide in acetone gives rise to the adduct **55** (Scheme 26). The intermediate in these



SCHEME 26



SCHEME 27



SCHEME 28

processes is the azomethine ylide **53**, which reacts by C-deuteriation with D_2O or dipolar cycloaddition with acetone to form **54** and **55**, respectively. Laser flash photolysis techniques were used to gain evidence for the intermediacy of azomethine ylides in these processes.[39]

Preparative photochemical experiments have provided supporting evidence for this proposal.[37,38] Irradiation of **56** in MeCN solutions containing 90 mM acrylonitrile or methyl acrylate leads to efficient (80 to 90%) formation of the respective benzopyrrolizidines **57** and **58** (Scheme 27). The ylide trapping reactions are *endo*-selective and stereospecific (preferential production of **59** + **60** and **61** from photoreactions of **56** with dimethyl fumarate and dimethyl maleate, respectively [Scheme 28]).

This novel and preparatively useful azomethine ylide-forming photoreaction is not restricted to phthalimide substrates.[40] Other conjugated imides that contain *N*-silylmethyl substitution are transformed to their corresponding azomethine ylides by photoinduced C-to-O silyl migration reaction.

Observations made in these studies suggest that the novel C-to-O silyl migration reaction of conjugated imides is a general excited-state process. It is reasonable to propose that these reactions occur in imides that have low-energy π-π^* singlet or triplet excited states. As suggested above, the driving force for silyl

migration could reside in both the respective redox potentials of the conjugated imide acceptor and σ_{C-Si} donor sites and the entropic favorability of silyl transfer in the intermediate zwitterionic biradicals.

Acknowledgments

The authors express their deep appreciation to their enthusiastic, hard-working, and productive coworkers whose studies in the area of amine electron-transfer photochemistry established the basis for the results presented in this review. Also, the generous financial support given to the PSM research group by the National Institutes of Health and the National Science Foundation and to the UCY research group by the Korea Science and Engineering Foundation (Basic Research Program 2001-1-12300-006-3, International Cooperative Research Program, and CBM of POSTECH) is acknowledged.

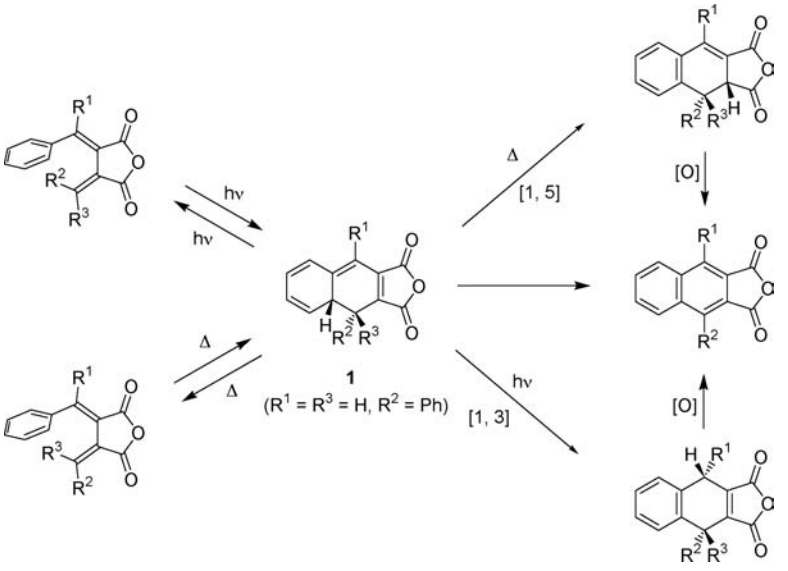
Yokohama National University

Mahmut Kose
Zonguldak Karaelmas University

86.1 Fulgides

Fulgides were first synthesized, named, and found to exhibit photochromism by Stobbe more than 100 years ago.[1] At that time, fulgides like **1** were shown to undergo thermally reversible cyclization with some irreversible side reactions. In 1981, Heller et al. synthesized a furylfulgide **2**, the colored form of which (**2C**) did not revert to the starting **2E** by a thermal pathway. In addition, **2E** showed few side reactions (hydrogen migration and oxidation to generate an aromatic ring became impossible) as well as exhibiting high conversion to **2C**.[2–4] This was the first reported example of a thermally irreversible photochromic compound. The important modifications to the basic structure to produce **2** were the replacement of all the hydrogen atoms attached to the carbon atoms involved in the ring closing by methyl groups and the employment of the heteroaromatic furan instead of a phenyl substituent.

0-8493-1348-1/04/$0.00+$1.50



Since then, fulgides have been regarded as prime candidates for application as photon-mode rewritable recording media.[5]

Recently, the structures of fulgides have been modified to give them more sophisticated properties. This work is aimed at using fulgides as photo-switches for particular functions,[6] such as changes in the character of liquid crystalline phases, changes in fluorescent properties or changes in the nature of supramolecular systems. This chapter describes various aspects of recent developments in the chemistry of fulgides. However, it is not meant to be encyclopedic and some degree of selection will be used. Readers who wish to know more about the area should refer to the reviews and books on the subject.[5–10]

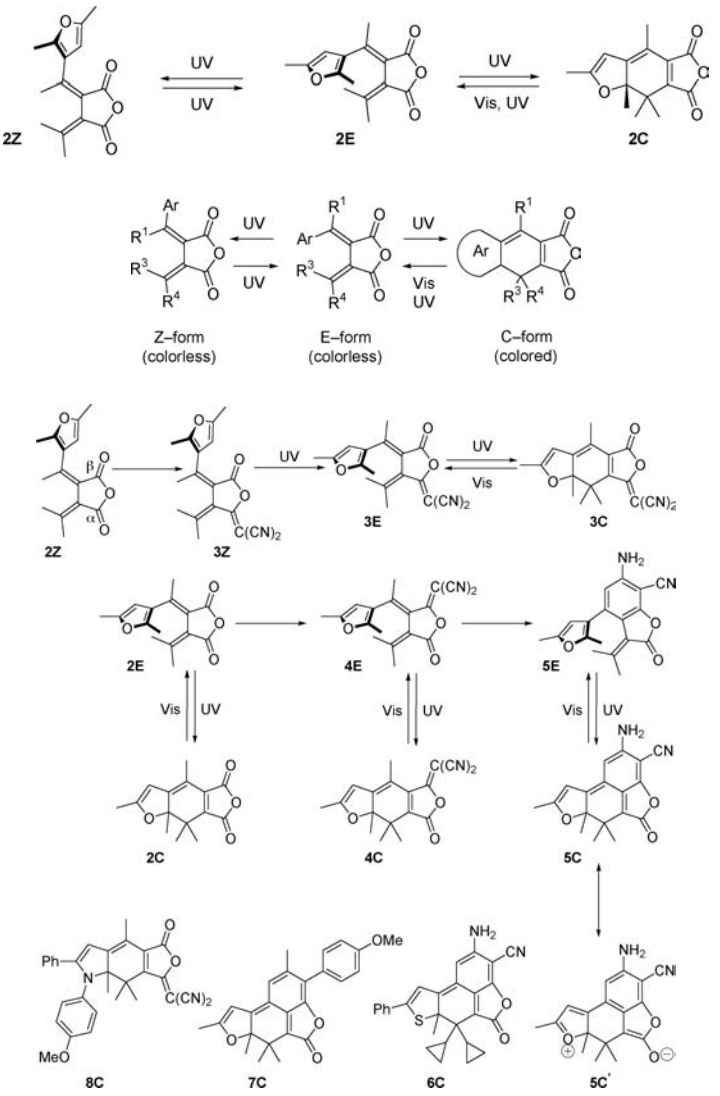
86.2 Fulgides Modified on the Acid Anhydride Moiety

Fulgides have at least one aromatic ring on the bismethylenesuccinic anhydride. Although a number of fulgides have been synthesized with different aromatic rings[11] changes to the succinic anhydride moiety have been limited, and the only other functionality used has been the succinimde group.[12] However, recent studies of fulgides have been extended to the structural modification of the anhydride moiety, resulting in many unique fulgides.

Dicyanomethylene-Condensed Fulgides

The absorption maxima of the C-forms of fulgides lie in the visible region as a result of the electronic push–pull effect of the aromatic ring and the anhydride moiety. If the electron-withdrawing properties of the anhydride moiety are enhanced, the resultant compounds could absorb in the near-IR or the IR region of the spectrum. Heller et al. have carried out such modifications extensively. Some of these results are reported here.

Condensation of malononitrile with **2Z** in the presence of diethylamine gave a (Z)-α-dicyanomethylene derivative **3Z**. Similarly, **2E** gave the corresponding (E)-β-dicyanomethylene derivatives **4E**.[13] While the replacement of either of the carbonyl groups (α or β) by the powerful electron withdrawing dicyanomethylene group causes a large red shift in the absorption maxima of the C-forms, **3C** (λ_{max} = 610 nm in toluene) has an absorption maximum that is more red-shifted than **4C** (λ_{max} = 601 nm in toluene) because of the linear conjugation within **3C** rather than the cross-conjugation of **4C**. These conversions were applied to several furyl- and thienylfulgides.



When the cross-conjugated (*E*)-β-dicyanomethylene derivative **4E** was treated with diisopropylamine, a new infrared-absorbing photochromic lactone **5E** was obtained. Although the central benzene ring of **5C**, formed by photocyclization, loses its aromaticity, it could be recovered by an intramolecular charge transfer from the lone pair of the oxygen atom to the lactone carbonyl oxygen atom (**5C'**). As a consequence, **5C** has a broad absorption band in the infrared region in toluene. The longest absorption maximum (λ_{max} = 776 nm in toluene) was recorded for **6C**, whose spectrum (photostationary state (pss) of 366-nm irradiation in toluene) together with that of **6E** is shown in Figure 86.1.

As an important extension, Heller, Köse, and co-workers developed a general method for the preparation of this type of photochromic lactone.[14] Condensation of a ketone, possessing a methylene adjacent to the carbonyl group, with an (*E*)-fulgide by KOBu^t in toluene afforded the phenyl lactone in low yield. Although the skeleton of the product is the same as **5E**, the substituents on the phenyl ring are not limited to amino and cyano groups. For example, condensation of 4-methoxybenzyl methyl ketone with **2E** afforded **7** with a beautiful green color similar to Caledon Jade Green dye upon UV irradiation (λ_{max} = 622 nm in toluene). Fan et al.[15] reported that the absorption maximum of **8C** in acetonitrile was 820 nm. Similar compounds were also reported by Hosmane et al.[16,17]

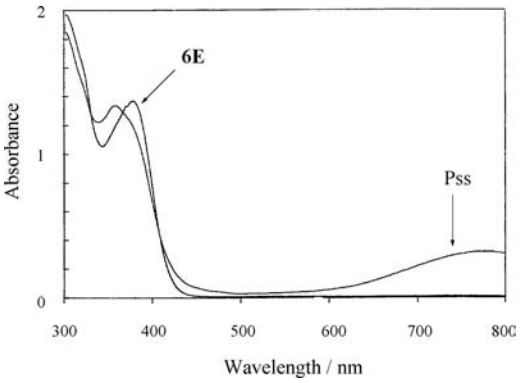


FIGURE 86.1 Absorption spectra of **6E** and the photostationary state (pss: **6C** has λ_{max} at 776 nm) of 366-nm light irradiation. (Kindly provided by Professor Harry G. Heller, University of Wales, Cardiff, U.K.)

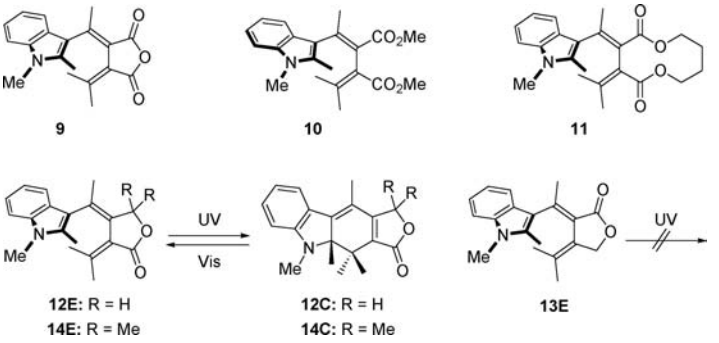
Fulgenates and Fulgenolides

Several diesters (fulgenates) corresponding to the indolylfulgide **9**, exemplified by **10**, were synthesized and the photochromic properties were examined by Yokoyama et al.[18] Although the quantum yields of photoreactions were generally low for the esters of simple alcohols, the cyclic diesters of diols such as **11** with short alkyl chains showed as good photochromic properties as the parent fulgide **9**.[19] The absorption of both colored and colorless forms of fulgenates moved towards shorter wavelengths compared to the parent fulgide **9** (**9C**; 585 nm, **10C**; 437 nm, **11C**; 447 nm, in toluene).



Reduction of one of the carbonyl groups of **9** to an sp^3 alkyl carbon atom yields the regioisomers of lactones (fulgenolides) **12** and **13**. They were synthesized regioselectively by Yokoyama[20] and only **12**, possessing the carbonyl group close to the isopropylidene group showed excellent photochromic properties. Again the absorption maximum was at wavelengths shorter than that of the parent fulgide **9** (**12C**; 462 nm in toluene). The dimethyl-fulgenolide **14** (**14C**; 464 nm in toluene) also showed good photochromic properties.[20]

(*R*)-Binaphthol-Condensed Fulgides

Since 2,2′-dihydroxy-1,1′-dinaphthyl (binaphthol) is known to be chiral with regard to the C_2 axis, compounds with a binaphthyl as a partial structure are chiral. If the compound also has intrinsic chirality in addition to the binaphthol, the resultant molecule will form a pair of diastereomers. Because the *E*-form of fulgides has helical chirality with regard to the hexatriene moiety that undergoes ring closing because of steric factors, introduction of binaphthol should generate diastereomers. Such fulgides **15** and **16** were synthesized by Yokoyama et al. to elucidate the relationship of the two chiral factors.[21] The binaphthol was attached like an ortho ester to the lower carbonyl group as shown.

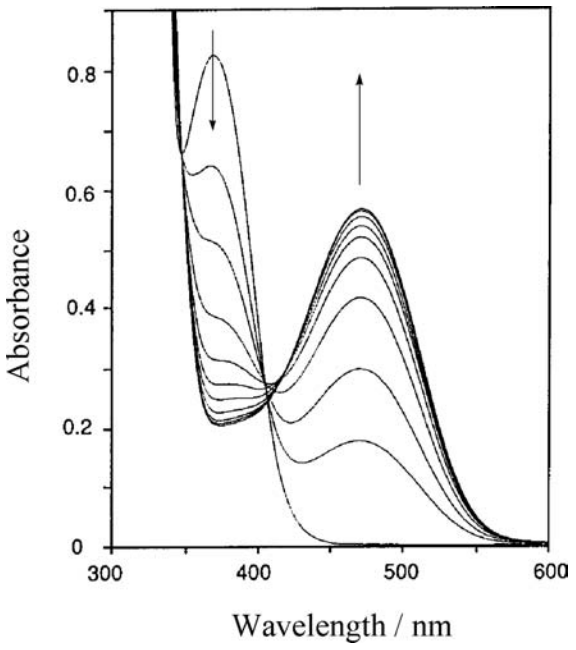


FIGURE 86.2 Absorption spectral change of **15E** upon irradiatioin of 366-nm light.

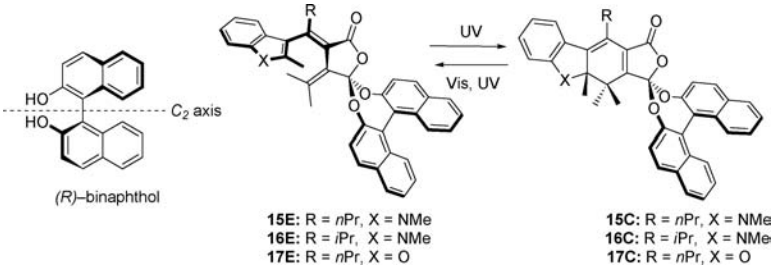
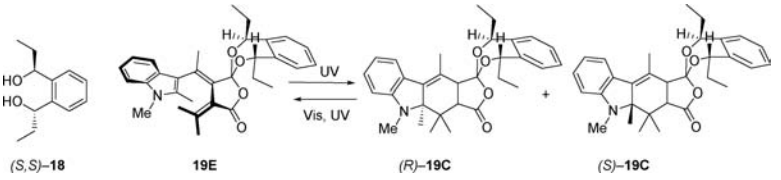
In the event, the rigid chirality of binaphthol controlled the flexible helical chirality of the hexatriene moiety. When the (*R*)-enantiomer of binaphthol was employed, the helical array of the hexatriene adopted the right-handed screw (*P*-helicity) because of the steric repulsion between one of the naphthalene rings and the *Z*-methyl group of the isopropylidene moiety. This was reflected in the ratio of the diastereomer of the C-forms (96/4 for **15C** (λ_{max} = 471 nm) and 98/2 for **16C** (λ_{max} = 456 nm)) upon 366-nm light irradiation in toluene. This diastereoselective photocyclization concept was also applied to a benzofuryl-fulgide **17** by Yokoyama et al.[22] The absorption spectra of **15E** and the pss of 366-nm light irradiation are shown in Figure 86.2.

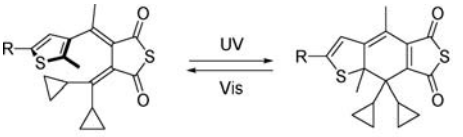


Similarly, but differently, condensation of a chiral diol **18** to the indolylfulgide **9** yielded an ortho-ester type compound **19**, where condensation occurred to the upper carbonyl.[23] The diastereoselectivity of the photocyclization of **19** (λ_{max} of **19C** in toluene = 490 nm) was 95% *de*.



Fulgides with Thioanhydride Moiety

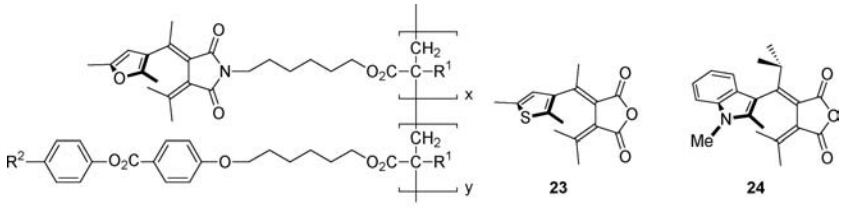
Heller et al.[24] reported that the fulgides **20**, in which the ether oxygen of the anhydride moiety was replaced by sulfur, showed the significant red-shift of the absorption maximum of the C-forms by 40 nm (R = Me) to 60 nm (R = Ph).



20E (R = CH_3 or Ph) **20C** (R = CH_3 or Ph)

86.3 Fulgides and Liquid Crystals

The photochemical reaction of photochromic compounds changes the structure of the compound. This feature has been used to control the properties of liquid crystals. Thus, the irradiation of photochromic compounds doped in liquid crystals changes the ordering ability of the liquid crystalline material. These changes have been examined for a number of photochromic compounds such as azobenzenes. Fulgides have also been used for this purpose. The earliest examples were reported by Ringssorf et al.[25] for polymer liquid crystals **21** and **22**, and by Gleeson et al.[26] for the control of properties of nematic liquid crystals by a thienylfulgide **23** and some derivatives. Schuster et al.[27] reported that the pitch of a cholesteric liquid crystal was changed a little by the photochromic reaction of the added indolylfulgide **9**. Yokoyama et al.[28,29] reported that doping of the binaphthol-condensed indolylfulgides **15** and **16** induced the cholesteric liquid crystalline phase from a nematic liquid crystalline phase and the cholesteric pitch was changed drastically by their photochromic reactions. It was also shown that the optically resolved indolylfulgide **24** functioned as a chiral photochromic dopant, although the effect was small.[29]

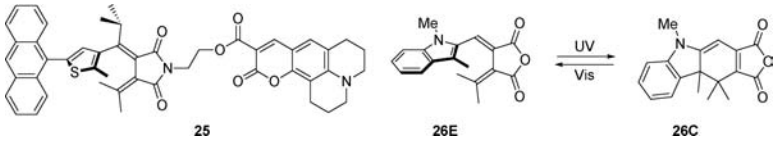


22: R^1 = H, R^2 = CN
22: R^1 = Me, R^2 = OMe

23 **24**

86.4 Control of Fluorescent Properties

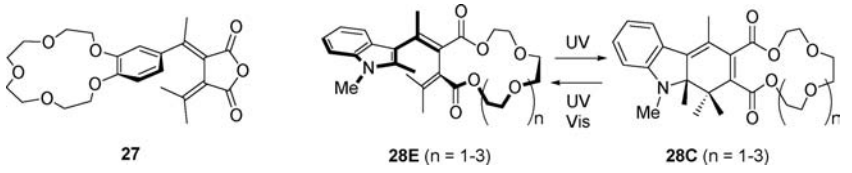
The first fulgide found to exhibit fluorescence at room temperature, although in the weak/strong manner, was reported by Port et al.[30] as the derivative **25** that possesses a light-absorbing antenna and a fluorescent dye at either end of a thienylfulgide core. A binaphthol-condensed indolylfulgide **15** synthesized by Yokoyama et al., attaching neither antenna nor fluorescent dye, showed the complete on/off switching of the fluorescent ability, because only the C-form emitted fluorescent light.[31] The second on/off switching of fluorescence with fulgide was reported by Rentzepis et al.[32] for a unique indolylfulgide **26** and some other derivatives. The indolyl group of **26** was connected to the alkylidenesuccinic anhydride at the 2-position of indole. It was also reported that the absorption maximum wavelength of the C-form of 2-connected indolylfulgide exhibited solvent effects: in more polar solvents, the absorption maximum was observed at longer wavelength.[33]



86.5 Supramolecular Properties Controlled by Fulgides

Crowned Fulgides

A fulgide **27** with the benzo-15-crown-5 as the aromatic ring was prepared by Guo et al.[34] Incorporation of alkaline-earth metal cations in the crown-ether moiety resulted in a shift of the absorption of the C-form by more than 40 nm toward shorter wavelengths.

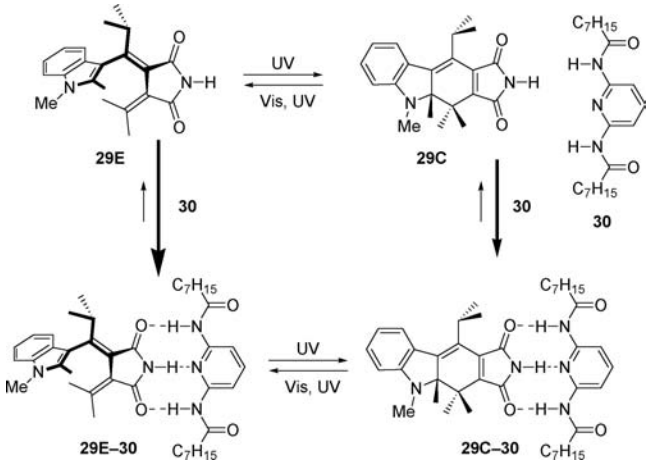


Crowned Fulgenates

Three fulgenates having the crown-ether-like cyclic diester moiety **28** (n = 1, 2, 3) were synthesized by Yokoyama et al.[35] The size-selective incorporation of alkali metal cations, the smaller complexation ability of the C-forms compared to the corresponding *E*-forms, and the on/off of photocyclization of the *E*-form in the absence/presence of the specific alkali metal cation were observed.

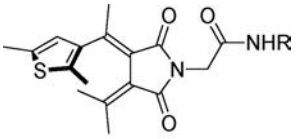
Fulgimide with Triplex Hydrogen Bonds

Yokoyama et al.[36] reported that fulgimide **29** changed its ability to form triplex hydrogen bonds with the 2,6-diacylaminopyridine **30** upon photocyclization due to the structural change. While **29E** has enough flexibility around the bismethylenesuccinimide structure to adjust the conformation to permit the triplex hydrogen bonds with **30**, **29C** has little flexibility because it has a maleimide structure. Consequently, the association constant of **29E** with **30** was 855 mol^{-1} dm^3, whereas that of **29C** with **30** was 156 mol^{-1} dm^3 at 21°C in toluene.



Fulgimides Attached to Peptides

Willner et al.[37] attached a thienylfulgimide to concanavalin A, a protein that forms complexes with pyranoses such as α-D-mannopyranoside, to form **31**. UV irradiation increased the association constant. Also, a thienylfulgide-modified α-chimotrypsin **32** was synthesized by Willner et al.[38] The esterification rate was controllable by photoirradiation.



31E: R = Concanavalin A
32E: R = α–Chymotrypsin

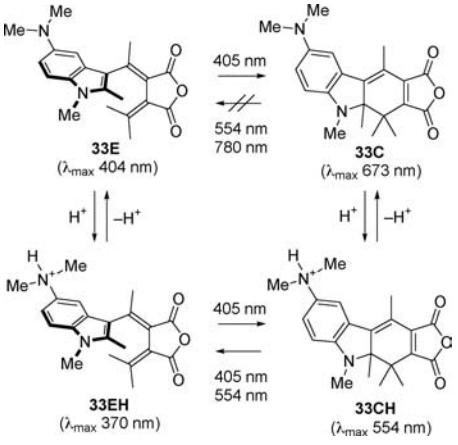
86.6 Fulgides for Optical Devices

Nondestructive Readout of Memories

A number of requirements, such as durability, diode laser sensitivity, efficient photoreactivity, etc., are necessary to make use of the thermally irreversible photochromic compounds as photon-mode rewritable optical recording media. Among these requirements, the challenging problem is to make the recording system have a nondestructive readout method. Several methods using fulgides have been proposed to date.

Acid-Base Equilibrium

Although the colored form of dimethylamino-substituted indolylfulgide **33C** in toluene did not revert to **33E** on visible light irradiation,[39] the protonated **33CH**, generated by adding CCl_3CO_2H, restored the photochromic reactivity.[40] In addition, the absorption maximum of **33CH** became shorter than that of **33C** because of the loss of the electron-donating ability of the dimethylamino group. If the amount of acid was small, both **33C** and **33CH**, together with **33E** and **33EH**, should exist with the equilibrated amount at the pss in the system. Therefore, the writing was carried out by UV-light irradiation on **33E** and **33EH** while the readout was achieved by visible light of longer wavelength where only **33C** absorbed light but no photoreaction occurred. The erasing was effected by shorter wavelength visible light absorbed by **33CH** because of the equilibrium maintained between **33C** and **33CH**.



Wavelength Dependency of Discoloration Quantum Yield

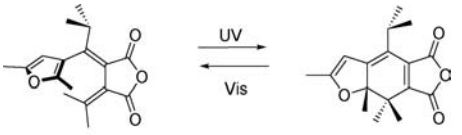
Some of the fulgides described have been shown to exhibit quantum yields for decoloration using visible-light irradiation that are wavelength dependent.[41] Yokoyama et al. reported that dimethylaminoindolylfulgide **33C** returned, although very slowly, to **33E** in a PMMA film using visible-light irradiation. The quantum yield for this process was found to decrease when the irradiation was brought about by light of longer wavelength. Surprisingly, the quantum yield was zero although there was still observable absorption. Thus, irradiation at relatively short wavelengths in the absorption of visible region was used to erase the record, whereas irradiation at the far end of the absorption was used to read the record. After 10^5 times of reading the record on the disk with a 784-nm laser, the absorption was still more than 80% of the initial.[42]

Readout with Optical Rotation

Non-racemic mixtures of the chiral compound have the optical rotation values (rotation angles of the linearly polarized light after passing through the material) at wavelengths outside the absorption band. This means that detection of optical rotation can be carried out independently from the photochromic reactions: that is, the record can be read nondestructively. To examine the validity of this idea, Yokoyama et al. measured the change in optical rotation between **15E** and the pss of 366-nm light irradiation. In toluene, the specific rotation of **15E** at 589 nm (sodium D-line) was −572°, while it was −186° at the pss. When **15** is doped in a PMMA film, the net change of optical rotation by repeated alternative UV-VIS photoirradiation was about 0.01° on average.[21]

Readout with Change in IR Absorbance

The reversible change of the structures of the photochromic fulgides by iterative photoirradiation not only changes the absorption spectra of electronic transition but also the IR spectra. Port et al. found that while the fulgide **34E** has a small absorption at 1523 cm,$^{-1}$ **34C** has a medium absorption at that wavenumber. The transmittance of an IR laser of 1534 cm^{-1} was decreased when a dichloromethane solution of **34E** was irradiated with 366-nm light. The reverse process could be brought about by irradiation at 546 nm.[43]



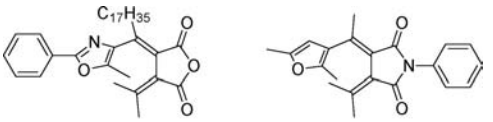
34E **34C**

Fatigue Resistivity

Resistance to fatigue toward the iterative photoirradiation is one of the most important features for a photochromic compound that might be used for optical memory media or switching devices. Diarylethenes are known to be more resistant to fatigue than fulgides. Efforts to improve the durability of fulgides have continued and some important results have recently been obtained.

Elimination of Oxygen from the Photochromic System

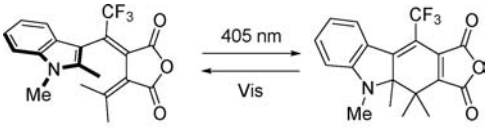
The photochromic layer containing a fulgide or a fulgimide can be isolated from air. Matsushima et al. demonstrated that this could be achieved by sticking two glass plates, carrying the photochromic layer on one side, together in the face-to-face manner, and the peripheral sides of the glass plates were sealed with an epoxy resin. The photochromic layer consisted of either (1) a spin-coated polymer containing a fulgide, or (2) an organic glass gel containing a fulgimide. Although the fatigue resistivity of thienylfulgide **23** in polystyrene was not greatly improved, that of furylfulgide **2**, oxazolylfulgide **35** in polystyrene, and furylfulgimide **36** in a gel were enhanced.[44]



35E **36E**

Trifluoromethyl-Substituted Indolylfulgide

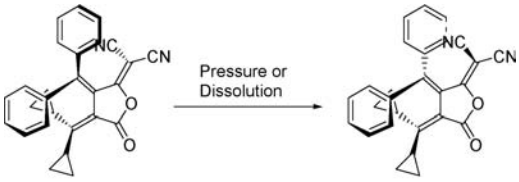
Yokoyama et al. synthesized a trifluoromethyl-substituted indolylfulgide **37**, which was shown to be highly durable toward photoirradiation.[45] Unfortunately, the colorless **37E**[46] was found to undergo undesired thermal rearrangement reactions, although its colored form was thermally stable.[47] Later, Lees et al.[48] clarified the structures of products of the thermal reaction and also the mechanism of their formation. They also synthesized some related fluorinated fulgides[49] as well as introduced the improved synthetic pathway of several indolylfulgides, including **37**.[50]



37E[46] **37C**

86.7 Tribochromic Fulgides

Heller et al.[51] reported a unique one-way color change within fulgide derivatives. When the dicyanomethylene-condensed fulgide **38** was recrystallized at the final stage of the synthesis, the first crop of crystals was bright yellow and the second crop was deep red. The structure of the yellow crystals (**38Y**) was determined by x-ray crystallographic analysis. Because both phenyl groups are located on the same side of the molecular plane, the authors called it "folded." When the crystalline compound was ground mechanically or when it was dissolved in solvent, the color changed to dark red (λ_{max} = 503 nm in toluene). The structure of the red crop of crystals, obtained by several methods as the most stable species, was also determined by an x-ray crystallographic analysis (**38R**), and the phenyl groups were found to lie on the opposite side of the molecular plane ("twisted"). As the color change from red to yellow was never achieved, the yellow **38Y** form was described as metastable. The authors termed this as "tribochromism." This effect is different from piezochromism, which involves the stable isomer converting to a metastable species that goes back thermally or by dissolution into the solvent. The tribochromic compounds do never revert to the metastable species; they can only be obtained by synthesis.



38Y (folded)
metastable form

38R (twisted)
stable form

Although a number of the related compounds have been synthesized, some gave only yellow crystals and others only red crystals. Only **38** gave both the yellow and red crystals, as reported above.

1,4-Quinone Cycloaddition Reactions with Alkenes, Alkynes, and Related Compounds

Andrew Gilbert
The University of Reading

87.1 Introduction

The photochemistry of quinones has a long history and the earlier literature on the cycloaddition processes was well-referenced in the previous edition of this Handbook.[1] It is, however, felt that it will be useful, particularly for readers new to the subject, to present here a brief general outline of the established mechanistic features of these processes before the more recent activities in this area are considered.

Intersystem crossing between the S_1 and T_1 states of 1,4-quinones is highly efficient and essentially all their photochemistry arises from the lowest excited triplet state. There is the general trend, illustrated in Figure 87.1, that in the cycloaddition reactions of 1,4-quinones, the $^3n,\pi^*$ state yields products from the carbonyl group while reaction at the ethene moiety arises from the $^3\pi,\pi^*$ state. Thus, with ethenes, discrimination between the formation of spiro-oxetanes **1** and cyclobutanes **2** can depend on the nature of the lowest excited triplet state. For example, 1,4-benzoquinone ($^3n,\pi^*$ state 76 kJ mol^{-1} below $^3\pi,\pi^*$ state) yields spiro-oxetanes almost exclusively, whereas 1,4-naphthoquinone, in which the energies of the $^3n,\pi^*$ and $^3\pi,\pi^*$ states are similar, affords both spiro-oxetanes and cyclobutanes. It is to be noted, however, that in general, spiro-oxetane formation is favored by an increase in the electron-donor characteristics of the ethene and that the introduction of electron-donor substituents on the quinone destabilizes the $^3n,\pi^*$ state and can increase its energy above that of the $^3\pi,\pi^*$, resulting in preferred addition at the ethene moiety.

It is widely accepted that the addition reactions of T_1 quinones to S_0 ethenes or ethynes occur either by a pathway involving a triplet exciplex, which collapses to a triplet biradical, or by radical ion formation

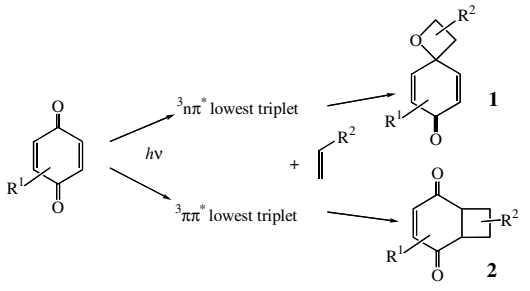

FIGURE 87.1 1,4-Quinone–ethene photocycloadditions.

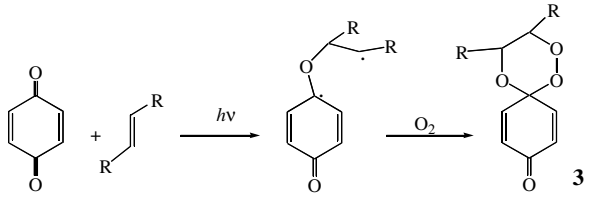

FIGURE 87.2 Trapping of the 1,4-biradical intermediate with oxygen.

and coupling processes. Evidence for the former route in 1,4-benzoquinone /alkene systems has been provided by laser flash photolysis (transients with nanosecond lifetimes assigned to exciplexes)[2] and the determination of isomer ratios of the spiro-oxetanes from *Z*- and *E*-but-2-ene[3] as well as by the trapping of the biradical intermediate with oxygen to give a 1,2,4-trioxane **3** in competition with spiro-oxetane formation (Figure 87.2).[4] The radical ion route is favored in polar solvents, and transients with microsecond lifetimes assigned to contact radical ion pairs have been observed in acetonitrile solution from chloro-1,4-naphthoquinones in the presence of electron-rich ethenes.[5]

It is not the intention in the current account to present a comprehensive review of the literature since the early 1990s, but rather by citing selected publications, to illustrate the breadth of interests in this area of quinone photochemistry and to provide further insight into the detailed mechanisms of these cycloaddition processes.

87.2 Cycloadditions of 1,4-Quinones to Ethene Derivatives

1,4-Benzoquinones and 1,4-Naphthoquinones

Styrene derivatives are commonly used addends in the photocycloaddition studies of 1,4-quinones. With *Z*- and *E*-anethole, 1,4-benzoquinone (BQ), 1,4-naphthoquinone (NQ), and 9,10-anthraquinone in acetonitrile solvent yield spiro-oxetanes in which the *trans*-isomer (e.g., **4** from naphthoquinone) predominates.[6] The process has been studied in detail by CIDNP techniques from which it is deduced that product formation proceeds from triplet radical ion pairs to the triplet biradical, and that there is no significant contribution from direct conversion of exciplex intermediates into the biradicals. Spiro-oxetane formation between simple alkenes and BQ generally has low regioselectivity but this is markedly improved with alkylidene cyclohexanes (Figure 87.3) such that the major isomer can be used as a new access to useful synthetic building blocks.[7] For the BQ/homobenzvalene **5** system, however, where the difference in stability between the intermediate biradicals can be expected to be considerably less, the selectivity ratio for the spiro-oxetanes **6** and **7** is reduced to 3:1, respectively, and the addition to NQ yields only the cyclobutane derivative **8**.[8] Quadricyclane and norbornadiene undergo the same photocycloaddition reaction to BQ, affording the oxolane **9** and the spiro-oxetane **10**.[9] Evidence from CIDNP

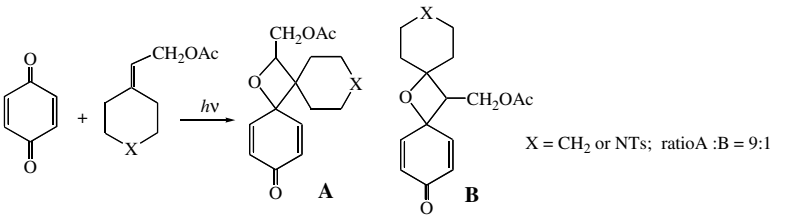

FIGURE 87.3 Photocycloaddition of BQ to alkylidene cyclohexanes.

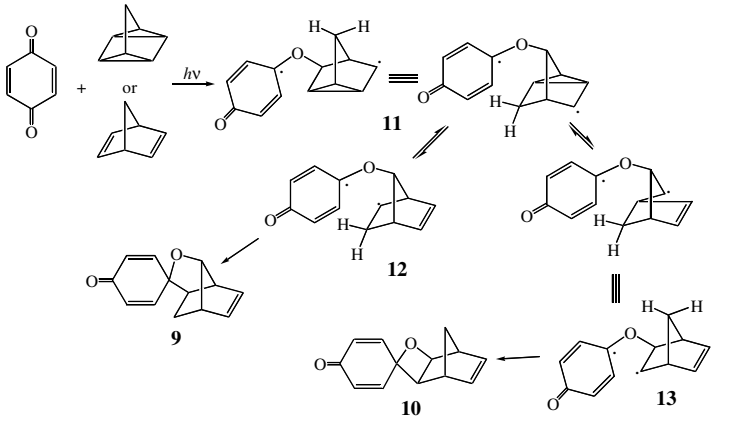

FIGURE 87.4 Photoaddition of BQ to norbornadiene and quadricyclane.

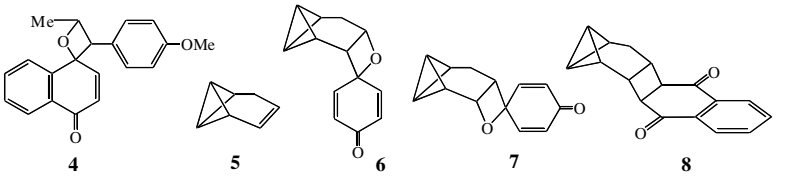
studies leads to the conclusion that the two adducts are formed by geminate processes, as outlined in Figure 87.4, in which the radical ion pair of the quinone and quadricyclane/norbornadiene collapses to the biradical **11**, which undergoes cleavage of the three-membered ring to give the 1,5- and 1,4-biradicals **12** and **13**, which are the respective precursors of the oxolane and the spiro-oxetane.



Dibenzoylmethane undergoes a de Mayo-type photoaddition reaction at the carbonyl group of BQ, NQ, and 9,10-anthraquinone to give hydroxyoxetanes that, on further irradiation, afford 1,5-diketones in reasonable yield by a retro-Aldol process.[10] The reaction is outlined in Figure 87.5 for NQ and the addition is reported to be reversed by 254-nm radiation, as is the conversion of the hydroxyoxetane to the 1,5-diketone with 300-nm radiation.

As expected, both duroquinone[11] and 2-acetoxy-1,4-naphthoquinone[12,13] undergo [2π+2π]-photocycloaddition with ethenes to give cyclobutane derivatives. In the former system, the primary adduct **14** from stilbene is reported to be unstable and undergoes oxidation and ring opening to give the cyclooctatriene **15**, while the addition of styrene to the NQ is both regio- and stereo-specific, giving **16**[13] and occurs in high yield in sunlight.[14] Interestingly, ethenes do not undergo [2π+2π]-photocycloaddition to NQs that are 2-substituted with hydroxy, amino, or mercapto groups. Instead, the reaction of these quinones involves [3+2]-addition and gives high yields of 2,3-dihydronapho[2,3-*b*]furan-4,9-diones **17**,[15]

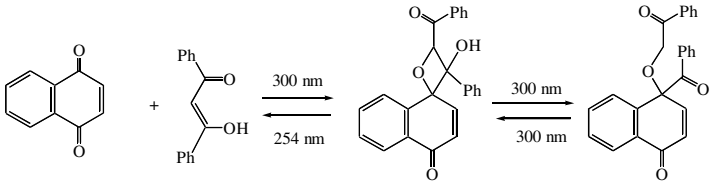


FIGURE 87.5 Photoaddition of BQ to dibenzoylmethane.

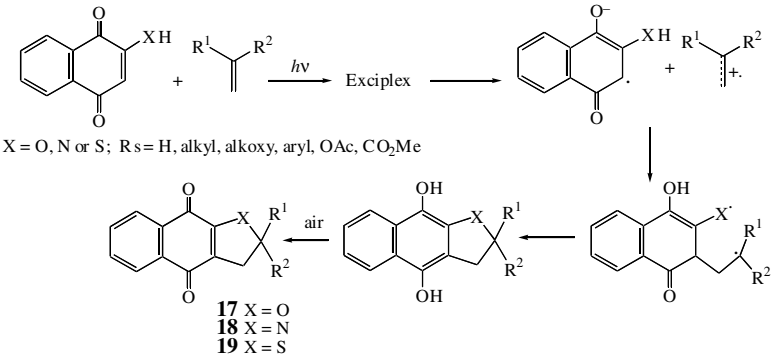

FIGURE 87.6 2-Hydroxy-, amino-, and mercapto-NQ photocycloadditions.

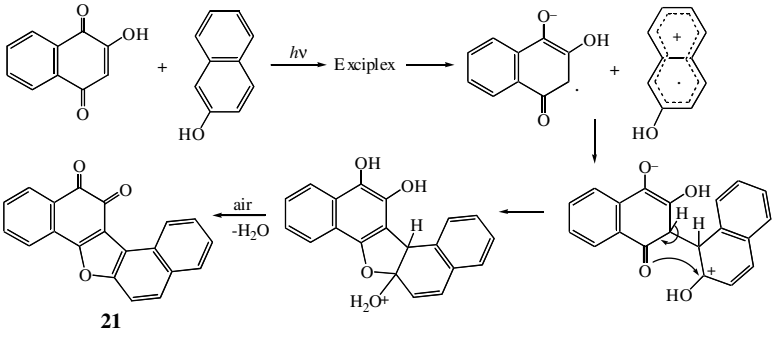

FIGURE 87.7 Photoaddition of 2-hydroxy-NQ to 2-hydroxynaphthalene.

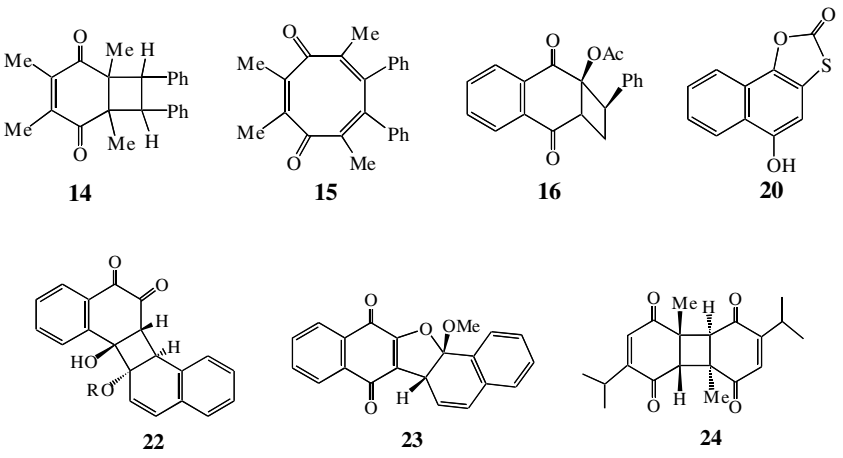
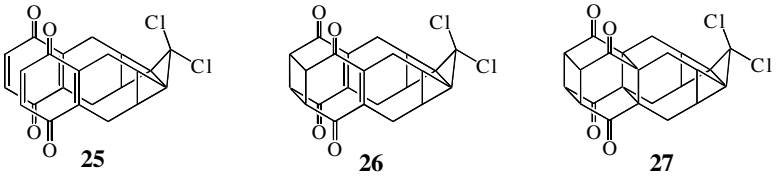
2,3-dihydro-1*H*-benz[*f*]indole-4,9-diones **18**[16] and 2,3-dihydronapho[2,3-*b*]thiophene-4,9-diones 19,[17] respectively. The proposed mechanism of these general processes is summarized in Figure 87.6, and it should be noted that the mercapto-quinone has to be generated *in situ* photochemically from 5-hydroxy-naphth[2,1-*d*]-1,3-oxathiol-2-one **20**. It is relevant to note here that [3+2]-cycloaddition has also been reported for 2-hydroxynaphthalene as the addend with 2-hydroxy-NQ but in this case, the product has the *ortho*-quinone structure **21** and is considered to arise by the mechanism in Figure 87.7.[18] In contrast, 2-methoxy- and 2-acetoxy-naphthalenes yield the [2+2]-adducts **22** with 2-hydroxy-NQ, whereas 1-methoxy-naphthalene behaves like an ethene, giving **23**, presumably by a route similar to that outlined in Figure 87.6.



1,4-Quinones also photodimerize by [2π+2π]-cycloaddition and, after some 130 years since the first report of the solid-state photoreaction of thymoquinone, the product has been unambiguously assigned as arising from a regio- and stereo-specific process to give the head-to-tail structure **24**.[19] Intramolecular photodimerization of the di-quinone moiety in **25** occurs to give the tube-like structure **26,** which on exposure to sunlight undergoes a second [2π+2π]- cycloaddition to yield **27**.[20]



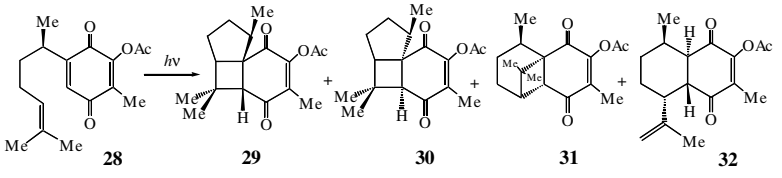


FIGURE 87.8 Intramolecular photocycloaddition of isoperezone.

The intramolecular photoaddition of 1,4-quinone/ethene systems has not attracted much interest in recent years and yet its potential for accessing complex molecular skeletal is appreciable. The reaction with isoperezone acetate **28** is, however, not selective and yields the [2π+2π]-cycloadducts **29**, **30,** and **31,** as well as the ene product **32** in respective ratios of 1.5: 1.0:1.2:4.0 (Figure 87.8).[21] Both allyl and vinyl BQs have interesting photochemistries. In the former series, the biradical **33** produced on irradiation can be readily trapped by a variety of ethenes to give tricyclic adducts **34** in yields dependent on the nature of the R groups on the addend (Figure 87.9).[22] The type of photoreaction that the vinyl BQs undergo is dependent on the position of the aryl group on the ethene substituent.[23] For example, while the 1-phenyl derivative **35** yields the benzofuran **36** in quantitative yield, the styryl compound **37** undergoes [4π+2π]-cyclodimerization, giving **38**, again in quantitative yield, and the 2,2-diphenylvinyl BQ **39** affords 30 to 40% yields of the phenanthrene-1,4-quinones **40** by 6π-photoelectrocyclization.

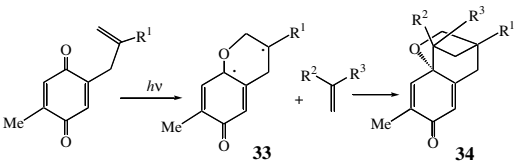

FIGURE 87.9 Trapping of the 1,4-biradical from 2-allyl-BQs with ethenes.

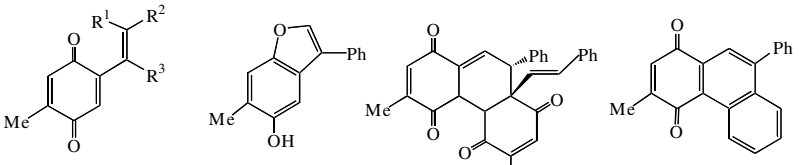
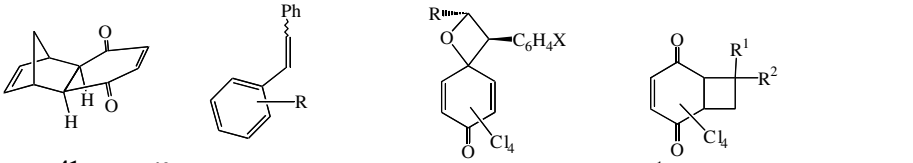


Few studies have been carried out into the photochemistry of 1,4-quinone/1,3-diene systems. It is therefore noteworthy and of appreciable synthetic interest that the [4π+2π]-photoaddition of BQ and NQ to cyclopentadiene and cyclohexa-1,3-diene in dry ethanol in the presence of triethylamine occurs with the opposite stereochemistry to that produced from the thermal reaction and the *exo*-isomers (e.g., **41** from cyclopentadiene and NQ) are obtained in 26 to 81% yields.[24]

Halogenated 1,4-Quinones

In recent years, the photoprocesses of halogenated quinones with ethenes, particularly the additions to chloranil (CA), have attracted appreciable attention. The electron-donor/acceptor characteristics of the ethenes can markedly influence both the site of attack on this quinone and the reaction efficiency; this latter feature can also be significantly dependent on the solvent polarity. These aspects of CA addition photochemistry are illustrated by the examples outlined below.

In benzene solution, the *Z*- and *E*-stilbenes **42** form approximately equal amounts of the two regioisomers of the *trans*-substituted spiro-oxetanes (e.g., **43** from 4-Me-**42**) with CA in yields of 80 to 88%.[25] These addition reactions do not occur in acetonitrile solution and *Z*- and *E*-4-methoxystilbenes do not photoreact with CA in either solvent. However, high yields of the *trans*-spiro-oxetanes **44** are formed from CA with *Z*- or *E*-ethyl cinnamate, ethyl 3-nitrocinnamate, benzalacetone, or chalcone in both benzene and acetonitrile. In contrast, allyl ethyl ether, methyl methacrylate, vinyl acetate, styrene, and α-chlorostyrene all yield cyclobutanes **45** with CA in benzene solution; but under the same conditions, indene and *E*-β-bromostyrene afford spiro-oxetanes.[26] Such variation in reaction site continues to be discussed in terms of the electron-donor/acceptor characteristics of the addends and the role of single electron transfer in the reaction pathway.



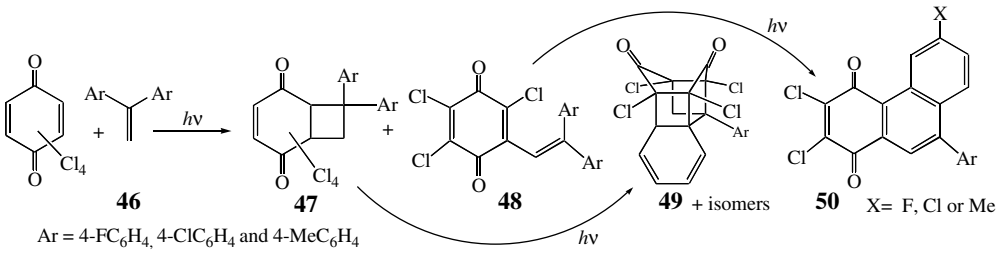


FIGURE 87.10 Photocycloaddition of CA to 1,1-diarylethenes.

It has been shown from a detailed investigation into the formation of spiro-oxetanes from the addition of CA to stilbene and some chloro derivatives in dioxane solution, that specific activation of either the precursor donor/acceptor stilbene/CA complex at 546 nm or the CA carbonyl at 436 nm gives rise to a common electron-transfer mechanism and produces the same regioisomers in identical ratios but with quantum yields of 0.005 and 0.35, respectively.[27] It is concluded from time-resolved (fs/ps) spectroscopy of the former activation that the primary intermediate is the singlet radical ion pair and this unambiguously establishes, for the first time, the electron-transfer mechanism in the Paterno-Büchi process. Direct excitation of the quinone affords the triplet radical ion pair, and this is observed on the nanosecond/microsecond (ns/μs) time scale. The spin multiplicities of the radical ion pairs determine the reaction sequence time scales and thus the efficiencies of their collapse to give the 1,4-biradicals, which are the immediate precursors of the oxetanes. Kinetic studies of these systems have established that the coupling of the triplet radical ions to give the biradical is the crucial step in product formation and must compete with ionic separation, ion exchange, and back electron transfer.[28] Experimental evidence for these conclusions is provided by the marked influence of solvent polarity and donacity, as well as added salt, on the quantum yield of oxetane formation. For example, in dioxane, tetrahydrofuran, and dichloromethane solutions, the quantum yields are 0.34, 0.05, and 0.01, respectively, and with the addition of 0.1*M* tetra-*n*-butylammonium hexafluorophosphate to the tetrahydofuran solution, the value is reduced to 0.01.

The irradiation of benzene solutions of CA in the presence of the 1,1-diarylethenes **46** yields the [2π+2π]-cyclobutane adducts **47** and the substituted quinones **48**, both of which undergo further photochemistry to give the products **49** and **50** of intramolecular arene-ethene cycloaddition and 6π-electrocyclization, respectively (Figure 87.10).[29] It is proposed that products **48** arise from a single electron-transfer process from the donor ethene to the T_1 chloranil, and that the formation of the cyclobutane adducts are formed from the 1,4-biradicals without the involvement of an electron-transfer process. This conclusion is supported by the observation that the ratio of **47**:**48** increases with an increase in both the oxidation potential of the diarylethenes and in the positive ΔG^0 value for electron transfer between the addends; furthermore, the formation of **48** is greatly favored by an increase in solvent polarity.

In contrast to the straightforward photoaddition of homobenzvalene **5** to BQ to give the expected two spiro-oxetanes,[8] the corresponding reaction with CA yields a number of products as outlined in Figure 87.11.[30] The oxolane **51** is photorearranged to **52** by way of a zwitterionic intermediate in a process observed with other cyclohexadienones. The photoaddition of norbornadiene to CA yields the spiro-oxetanes **53** and **54** as well as the tetrahydrofuran derivatives **51** and **55**, but only low yields of the oxetane **53** are formed from CA and quadricyclane (contrast BQ additions). The novel adduct **56** is formed in 67% yield from irradiation of benzene solutions of CA in the presence of norborene.[31] The proposed pathway involves addition of the ethene across the 2,5-positions of the triplet quinone to give the biradical **57** which rearranges to the β-oxoketene **58** and this, in turn, undergoes intramolecular cyclization with concomitant [1,2]-migration of a chlorine atom (Figure 87.12). Similar adducts are formed between CA and cyclopentene and bicyclo[2.1.1]hex-2-ene but in both cases, the major products are the conventional spiro-oxetane and cyclobutane isomers.

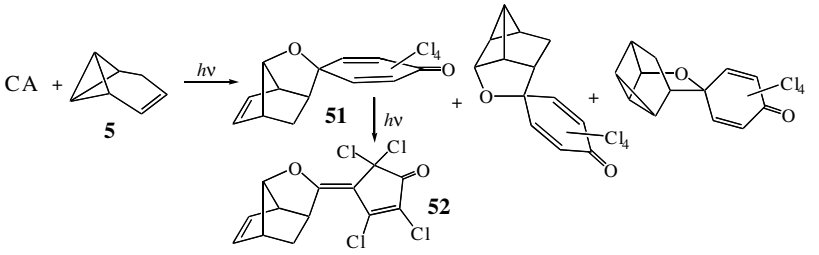

FIGURE 87.11 Photocycloaddition of CA to homobenzvalene.

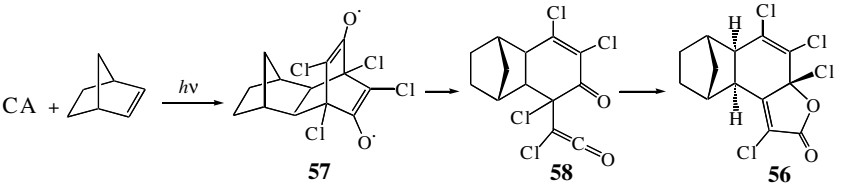

FIGURE 87.12 Photocycloaddition of CA to norbornene.

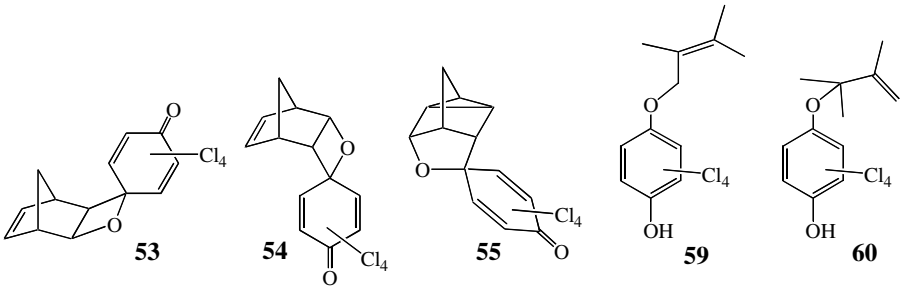
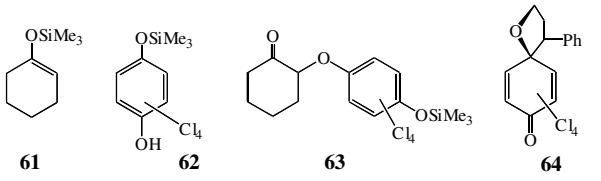


In the presence electron-rich alkenes such as 2,3-dimethylbut-2-ene, irradiation of CA gives the allylethers **59** and **60**, whereas with BQ, a substantial amount of the spiro-oxetane is also formed.[32] The product distribution of the allyl ethers is rationalized by steric effects on the H^+ abstraction and on the recombination of radicals as well as spin densities. The crucial role of solvent polarity in CA photochemistry is well illustrated by the results of a study into the reaction between the quinone and cyclohexanone enol trimethylsilyl ether **61** using time-resolved (ps) spectroscopy.[33] The influence of the solvent occurs following the formation of the radical ion pair ($CA^{-\cdot}$ $\mathbf{61}^{+\cdot}$). The $CA^{-\cdot}$ species is short lived in nonpolar solvents and cyclohex-2-en-1-one and **62** are the reaction products, whereas in acetonitrile, the lifetime is much longer, which allows diffuse separation of the radical ion pair and transference of the TMS to the solvent. The resulting ketyl radical couples to $CA^{-\cdot}$ yielding **63**.



Cyclopropylbenzene is a good electron donor and, not surprisingly, yields triplet radical ion pairs with photoexcited CA.[34] In dichloromethane, these intermediates lead to the spiro-tetrahydrofuran adduct **64** in 68% yield, but in acetonitrile, this drops to 5%. Both NQ and 2,3-dichloro-NQ react similarly with cyclopropylbenzene on irradiation and again the yields of adducts corresponding to **64** are very dependent on solvent polarity.

A wide variety of ethenes undergo photoreaction with 2-mono- and 2,3-dihalogeno-NQs. For example, with arylethenes, [2π+2π]-cyclobutane adduct isomers are formed from styrene, 1,1-diphenylethene undergoes photosubstitution giving products analogous to **48,** and *E*-stilbene yields spiro-oxetanes.[13]

87.3 Cycloadditions of 1,4-Quinones to Ethyne Derivatives

The photocycloadditions of ethynes to 1,4-quinones are directly analogous to those of ethenes and, in general, similar influences affecting the site of reaction and the efficiency of the process operate in both systems. The oxetenes formed by addition of ethynes to the carbonyl group are unstable under ambient conditions and undergo ring opening to yield quinone methides as outlined in Figure 87.13.

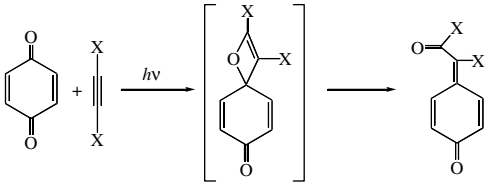


FIGURE 87.13 Photocycloaddition of ethynes to BQ.

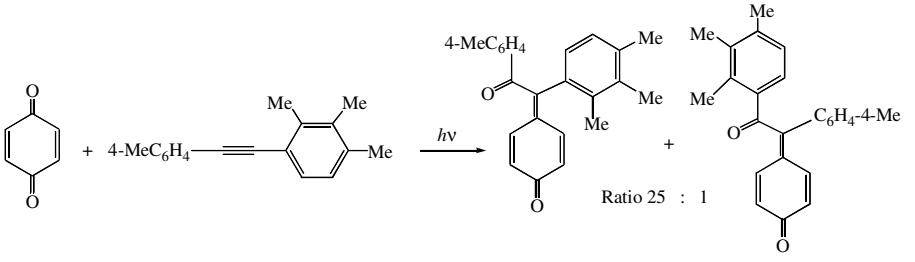

FIGURE 87.14 Photocycloaddition of BQ to diarylethynes.

Arylethynes are commonly used in the studies of these processes and the additions of 2,5-dichloro-BQ to methyl-substituted diphenylacetylenes have been investigated in detail by time-resolved (picosecond/nanosecond) spectroscopy to ascertain the role of radical ion pairs in the formation of the 1,4-biradical precursor of the spiro-oxetene.[35] Irradiation at 532 nm in the charge-transfer absorption band of this system in dichloromethane solution results in spontaneous electron transfer to give the singlet radical ion pair; but from the low quantum yield of adduct formation (*ca.* 1×10^{-3}), it is evident that the rapid decay of this species arises from back electron transfer. Direct excitation of the quinone (at 355 nm) yields the triplet radical ion pair, which may couple to the triplet biradical, dissociate to free ions, or undergo back electron transfer: in this case, the quantum yield of adduct formation is 0.1. However, from unsymmetrical diarylacetylenes, both routes give good yields of the same quinone methides with high regioselectivity (e.g., Figure 87.14); this establishes the same sequence of reactive intermediates. Crystalline 1:2 electron donor/acceptor complexes of these diarylacetylene/quinone systems have been prepared and characterized by x-ray crystallography.[36] Excitation of these crystals at either 355 or 532 nm leads to mixtures of the isomeric quinone methide adducts in ratios very similar to those reported from solution. Time-resolved diffuse reflectance spectroscopy again shows that the radical ion pair is the

reaction intermediate from both wavelengths of activation. It is indeed noteworthy that a pair of dissimilar reactants has the appropriate orientation for [2π+2π]-coupling in the crystals of the complex.

It appears that the addition of ethynes to the carbonyl group in quinones is more efficient than the corresponding ethene process because irradiation of BQ or NQ in the presence of the eneyne **65** preferentially yields quinone methides.[37] The photoaddition of 1,4-bis(phenylethynyl)benzene to BQ in dichloromethane solution gives the quinone methide **66**.[38] However, the expected cyclobutene formation between duroquinone and 1,4-diethynylbenzene is somewhat more complex and affords not only **67**, but also the ring-opened isomer **68** as well as the 2:1 adducts **69** and **70** in yields of 17, 19, 15, and 30%, respectively.[39]

The "Photochemical Friedel-Crafts Acylation" of Quinones: From the Beginnings of Organic Photochemistry to Modern Solar Chemical Applications

Michael Oelgemöller
Bayer CropScience K.K.

Jochen Mattay
Universität Bielefeld

88.1 Introduction

Due to their diverse biological activity and importance as natural products,[1] quinones and their derivatives have attracted constant interest in terms of synthetic organic photochemistry, as can be seen by a number of summarizing reviews.[2] Among the broad variety of applications, the photochemical reaction between a quinone and an aldehyde has been intensively studied over the past 100 years. This review provides an

1 **2**

SCHEME 1

overview of the photoacylation of quinones from the discovery by Heinrich Klinger in 1888 to modern solar chemical applications by Mattay and co-workers. To account for the historical development of the photochemical techniques and consequently this application, selected synthetic key-features (e.g., radiation source, solvents applied) are summarized in tables for many of the reported examples.

88.2 Discovery and Early Solar Chemical Studies: 1886–1934

The discovery of the photochemical acylation of quinones with aldehydes dates back to the beginnings of modern organic photochemistry in the late 19th century.[3] During that time, organic photochemistry was closely linked to the use of natural sunlight as the only source of available radiation and thus took place mainly on the rooftops of the chemical institutes and/or in southern countries (as, for example, at Giacomo Ciamician's roof laboratory in Bologna, Italy[3a]).

Discovery and First Reports by Heinrich Klinger: 1886–1911

In 1886, Heinrich Klinger (Bonn, Germany) observed the photoreduction of 9,10-phenanthrenquinone (**1**) in ether to its corresponding dihydroquinone (**2**) and acetaldehyde (Scheme 1).[4]

His interest in photochemistry was thereby stimulated by the accidental discovery of the photochemical reduction of the diketone benzil to hydrobenzoin.[4] In an attempt to obtain the assumed isomer "isobenzil" from a solution of benzil in wet ether, he observed the not-always reproducible precipitation of a crystalline material, which he later correctly assigned to a 2:1 complex of hydrobenzoin and benzil. In his publication, he described in detail the frustrating and time-consuming search for the missing factor that caused the reduction, until he finally noticed that those reaction tubes, in which the reduction took place, were exposed to direct sunlight in the early morning hours.* Klinger also mentioned the experimental difficulties an early photochemist had to deal with and, for instance, reported heavy destructions of some of his flasks (filled with volatile ethereal solutions)[4] or apologized for presenting limited or older data due to bad weather conditions or due to total loss of his reaction flask during a storm.[5]

As an extension of his work, he studied the influence of the solvent on the photoreaction. When he finally replaced the solvent ether with acetaldehyde and later with other aldehydes, he observed — to his own surprise — a different, new kind of photoreaction (Scheme 2), which led him to the following astonishing conclusion: "In this case the effect of light is a strange and synthetic one, best to my knowledge so far only found in a living plant; in so far a balanced one as the two compounds combine to one, in which the quinone appears reduced and the aldehyde oxidized.**" The photoproducts, monoesters of

*Original text:[4a] *"Den wirklichen Grund jener Veränderung des Benzils aufzufinden, gelang mir erst nach längerer Zeit, da zufälliger Weise die Röhren mit Benzillösung in einem fast nach Norden gelegenem Zimmer aufgestellt waren und nur die an den Fenstern stehenden in den Morgenstunden directes Sonnenlicht erhalten konnten, dessen Einfluss desshalb anfangs gar nicht in Betracht gezogen wurde."*

**Original text:[5a] *"Die Wirkung des Lichtes ist in diesem Fall eine ganz eigenartige, synthetische, wie sie meines Wissens bisher nur in der lebenden Pflanze beobachtet wurde; eine insofern ausgleichende, als die beiden Substanzen sich zu einer Verbindung vereinigen, in welcher das Chinon als reducirt, der Aldehyd dagegen als oxydirt erscheint."*

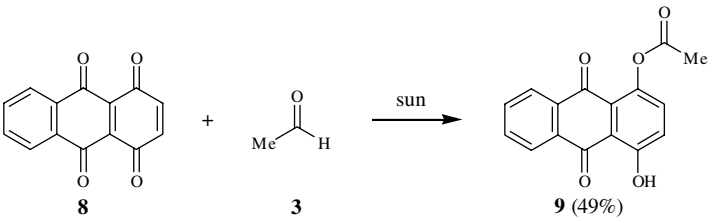
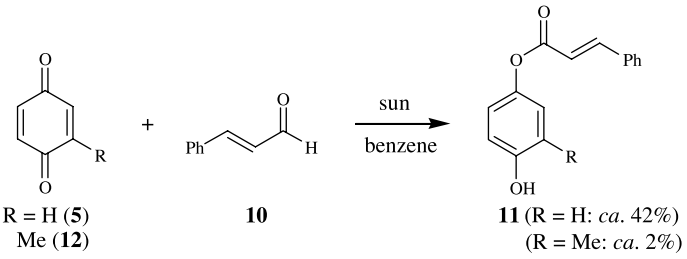
[b] n.g.: illumination period and/or yields not specified or not given.

phenanthrene hydroquinone (**4**), were obtained in moderate to good yields after relatively short illumination times (Table 88.1).[5] In most cases, the aldehyde served as reagent and solvent, but benzene proved to be a suitable dilutant. Klinger also investigated a simple wavelength dependency of the photoacylation using aqueous solutions of inorganic salts as filters (i.e., cuprous ammonium sulfate and potassium dichromate solutions). Based on his observations, he noted that the photoreaction was most pronounced in the blue region, whereas with potassium dichromate the photoreaction proceeded about 30 to 40 times slower.[5]

Klinger also investigated the photoreaction of 1,4-benzoquinone (**5**) for which he expected analogue monoesters.[5] Based on skilled derivatization experiments, the products from this reaction turned out to be acylated hydroquinones **6** accompanied by quinhydrone (**7**) as a major side-product (Scheme 3; Table 88.1).[6] He also studied control reactions in the dark, which yielded only trace amounts of quinhydrone (**7**) after several months, unambiguously proving that light was essential for the activation.[6a]



SCHEME 4



SCHEME 5

Further Early Solar Chemical Experiments: 1920–1934

In 1921, 33 years after Klinger's discovery, Dimroth and Hilcken reported a similar transformation of quinizarinquinone (**8**) with acetaldehyde.[7] Exposure to direct sunlight for 12 days gave the corresponding monoester **9** in 49% yield (Scheme 4). However, when they repeated the experiment during the less light intensive autumn season over an extended period of 1.5 months, they obtained a mixture of quinizarin (the reduction product of **8**) and the monoester **9**.

A few years later in 1930, another example of the photochemical acylation was described by the Italian (photo)chemists Bargellini and Monti in Rome.[8] When a benzene solution of benzoquinone (**5**) and cinnamaldehyde (**10**) was illuminated for 1 month with direct sunlight, the corresponding hydroquinone monoester (**11**) was isolated in about 42% yield (Scheme 5). This observation must have been surprising because it obviously conflicts with earlier findings by Klinger, who had obtained acylated hydroquinones (**6**) instead (*vide supra*).[6] Another example of this reaction came about 5 years later from the University of Torino in Italy. Angeletti and Migliardi exposed a benzene solution of toluquinone (**12**) and cinnamaldehyde (**10**) to sunlight over a period of *ca.* 6 months and obtained the corresponding monoester **11** (*ca.* 2%) along with cinnamic acid (*ca.* 14%) and toluohydroquinone (*ca.* 8%), respectively.[9a] The formation of the latter two compounds was assigned to a dominant photochemical redox reaction, whereas photoacylation was suspected to play only a minor role. Due to steric blocking by the methyl group in **12**, regioselective ester formation was suggested, although analytical proof was missing. Inspired by the original work of Klinger on phenanthrenequinone (**1**), Sircar and Sen examined similar reactions with acenaphthenequinone (**13**) in 1931 in Calcutta, India.[10] They had launched a detailed comparison study on the *thermal* transformations of these two quinones (**1** vs. **13**) and expanded it to the photoacylation of **13** with several aromatic aldehydes. Exposure of mixtures of **13** with salicyl-, cinnam-, benz-, or anisaldehyde in benzene over several weeks yielded the monoesters **14** (Scheme 6; Table 88.2).

Along with all these promising and successful early experiments, a few unsuccessful or rather unusual results were reported as well. In 1930, the American scientists Bogert and Howells (New York) tried to apply the photoacylation protocol to the synthesis of dibenzoylbenzohydroquinone from monobenzoylated **5** and benzaldehyde.[11] However, these authors seemed to be rather skeptical of the young discipline

of photochemistry because they discontinued their single attempt simply because no crystals were formed during the illumination.*

Later, in 1934, Angeletti and Baldini obtained neither acylated hydroquinones (as **6**) nor hydroquinone monoesters (as **11**) when they exposed a benzene solution of toluquinone (**12**) and benzaldehyde to sunlight over a period of *ca.* 6 months.[9b] In addition to a larger amount of unknown material, they identified benzoic acid (3.3%), toluohydroquinone (*ca.* 16%), and trace amounts of the dibenzoylester of toluohydroquinone as photoproducts, respectively.

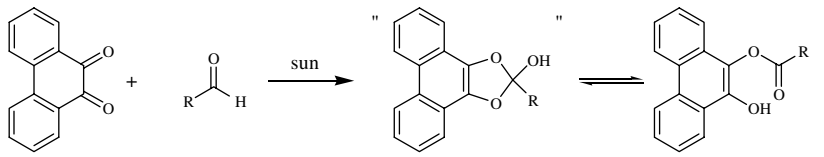
88.3 Solar Chemical Studies by Alexander Schönberg: 1939–1957

In 1937, Alexander Schönberg, an emigrant from National Socialistic Germany, was appointed Professor at the University of Cairo in Egypt, where he naturally found extremely suitable conditions for solar chemical reactions. His comprehensive work on light-induced reactions earned him the general recognition as a pioneer in preparative photochemistry.[12]

Only 2 years after his appointment, Schönberg suggested an alternative structure for the photoproducts obtained from phenanthrenequinone (**1**) and aromatic aldehydes (Scheme 7).[13a] In contrast to Klinger's original report,[5] he favored a cyclic acetal structure (**15**). Taking into account the limitations of analytical chemistry of the time, his assignment was reasonably based on further transformations into compounds already reported in the literature. In particular, the suspected photoproduct **15** obtained with *p*-chlorobenzaldehyde gave, after methylation with diazomethane and hydrolysis with sodium hydroxide, and in addition to 9,10-dihydroxyphenanthrene (**2**), a crystalline compound that he assigned to the known methyl *p*-chlorobenzoate.[13a,b] In addition, the photoproduct itself did not show a colored complex with ferric chloride,** at that time a commonly accepted proof for phenols.[14] The assignment to the cyclic acetal structure was adopted and further propagated by his former co-worker Ahmed Mustafa.[15]

*Original text:[11] *"After standing for many days the solution became quite dark, but no crystalline material separated and the experiments were discontinued."*

**This result was, in fact, indirectly reported by Moore and Waters.[16] Schönberg himself did not mention this particular ferric chloride test in his early publications.[13a-c]



SCHEME 7

Although Schönberg later proposed an existing ring-chain tautomerization between the two structures **15** and **4**,[13d] Moore and Waters reported chemical and IR-spectroscopic evidence (e.g., by *direct* comparison with an authentic sample donated by Schönberg) for the originally assigned monoester (**4**) structure in 1953.[16] These authors also repeated Schönberg's methylation experiment with diazomethane followed by hydrolysis with potassium hydroxide and obtained benzoic acid and 9-hydroxy-10-methoxyphenanthrene, the expected cleavage products of **4** (Scheme 12; *vide infra*). However, Schönberg and Mustafa continued to favor their tautomerization scenario. Another 10 years later, in 1963, Rubin ended this longstanding debate, for example, with the help of modern NMR-spectroscopy, in favor of the monoester structure (**4**).[2e,17]

During more than two decades (1939 to 1960) of their work on the photoacylation reaction, Schönberg and Mustafa studied a variety of different *ortho*-quinone/aldehyde pairs (Chart 1; Table 88.3). Among these numerous examples, three systems deserve further mention.

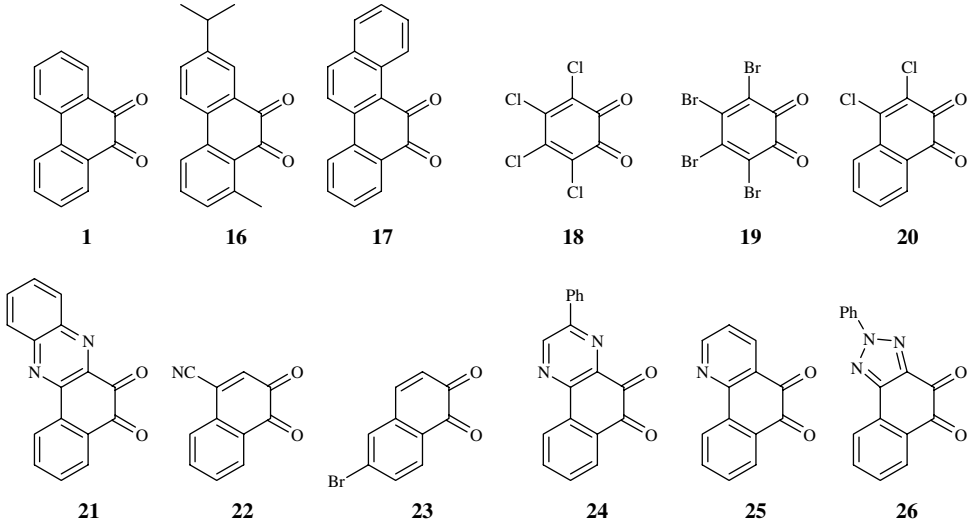


CHART 1

1,2-Benzophenazine-3,4-quinone (**21**) did not yield the expected pale yellow or yellow-colored products, but formed deep purple crystals after photolysis in the presence of anis- or benzaldehyde, respectively.[13e] In ethyl benzoate solutions, the photoproducts showed thermochromism: at 0°C the solutions were purple-brown, whereas upon heating to 170°C, they changed to orange. Because this effect was found to be reversible, Schönberg suggested an existing enol imine–enamine (**27**/**28**) tautomerization (Scheme 8),* which was known for 3,4-dihydroxy-1,2-benzophenazine at that time.[18]

*Schönberg himself used the term lactam-lactim tautomerization.[13e]

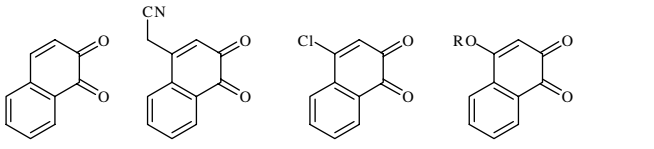
SCHEME 9

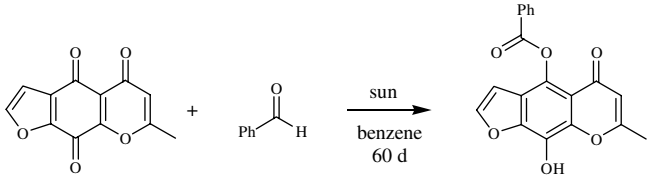
When 4-cyano-1,2-naphthoquinone (**22**) was used as the starting material, the chemoselectivity of the photoacylation depended strongly on the aldehyde used.[13f] Aromatic aldehydes as well as cinnamaldehyde (**10**) gave the expected monoesters (Table 88.3) in moderate to good yields of 39 to 82%. On the other hand, illumination in the presence of aliphatic aldehydes (acetaldehyde or propionaldehyde) led to the isolation of acylated hydroquinones (**29**) as sole products, although the yields were poor at 17 and 40%, respectively (Scheme 9; Table 88.4).[13f] Schönberg did not explain this phenomenon but pointed out similarities to the photoreaction of 1,4-benzoquinone (**5**) with acetaldehyde giving its acylated hydroquinone,[6] and chloranil (**38**) with benzaldehyde giving its corresponding monoester (*vide infra*).[16]

The differing chemoselectivity in the case of 4-cyano-1,2-naphthoquinone (**22**) was striking and, thus, Awad and Hafez later investigated the influence of substituents at the 4-position in more detail (Chart 2).[19]



30 **31** **32** **33** (R = 2-Naphthyl)
34 (R = 3,5-$[CH_3]_2C_6H_3$)
35 (R = 2,5-$[CH_3]_2C_6H_3$)

CHART 2



36 **3** **37** (44%)

SCHEME 10

In contrast to Schönberg's original report,[13f] these authors were, however, unable to obtain any photoproducts from the reaction of acetaldehyde with either 1,2-naphthoquinone (**30**), 4-cyanomethyl-1,2-naphthoquinone (**31**), or 4-chloro-1,2-naphthoquinone (**32**), respectively. In all other cases examined (with **33**, **34**, and **35**), isomeric mixtures of the corresponding monoesters were obtained in moderate to good yields of 38 to 82% (Table 88.3). Thus, acylation at the C–C double bond of the quinone was concluded to occur solely with strong electron-withdrawing groups present in the 4-position, whereas other substituents were expected to favor the formation of monoesters. The chemoselectivity of this reaction was later explained in more detail by Bruce[23] and Maruyama and Takuwa.[28,29]

When acylation at the C–C double bond of the 1,4-quinone became impossible, formation of the corresponding monoesters occurred instead. As a further example reported by Schönberg, exposure of a solution of khellinquinone (**36**) and benzaldehyde in benzene to sunlight over 2 months gave the ester **37** in 44% yield (Scheme 10).[13g] The regioselectivity of this photoinduced reaction was confirmed by further derivatization and independent *thermal* synthesis of **37**.

Likewise, chloranil (**38**) gave its corresponding monobenzoate **39** in 35% yield upon irradiation (Scheme 11), as demonstrated by Moore and Waters. Because the formation of a cyclic acetal is impossible in this case, these authors used this transformation as a further proof against Schönberg's postulated cyclic acetal structure (**14**).[16]

88.4 Laboratory Studies Using Artificial Light Sources

With the development of suitable artificial light sources[12,21] photochemistry finally moved into laboratories and became independent of varying weather and radiation conditions. Additionally, separation techniques and analytical tools improved, which allowed the isolation and assignment of secondary photoproducts.

Early Mechanistic Proposals: 1953–1965

Accounting for the high yields of the photoacylation of **1** with aromatic aldehydes (Scheme 12), Moore and Waters suggested "a photochemical chain reaction of very long chain-length", initiated via hydrogen abstraction from the aldehyde by the excited quinone (see Scheme 14: *out-of-cage scenario*).[16] However, quantum yield data and effects of inhibitors did not support this proposal as, for example, a quantum yield for the disappearance of the quinone (Φ_d) of $\Phi_d = 1$ has been reported for irradiation of **1** in benzaldehyde at 436 nm.[2e,17]

In contrast, however, Rubin independently demonstrated for a model ester (**4**, R = Ph) that the photoreaction was reversible and phenanthrenequinone (**1**) was obtained in 34% yield with a conversion of 70%.[17b]

Already one year after Moore and Water's mechanistic proposal, Schenck and co-workers favored an alternative *in-cage scenario* (see Scheme 14).[20] They had studied the photochemical acylation of chloranil (**38**)[20a] with benzaldehyde and of 1,4-naphthoquinones[20b] with acetaldehyde (Scheme 13; Table 88.4), respectively. In all cases, quantum yields (Φ) were found to be low, with $\Phi < 0.2$ (for **38**) and $\Phi < 1$ (for

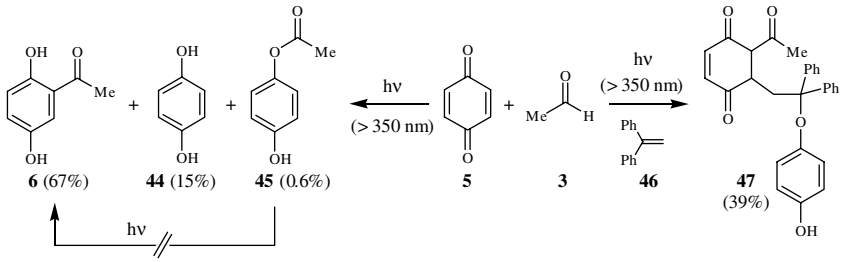
41) disfavoring a radical chain mechanism. For the naphthoquinone/acetaldehyde pair, these authors also excluded an initial Photo-Fries rearrangement of a monoester intermediate,[22] although experimental details were not given.

A *thermal* acylation via a radical chain sequence was achieved for chloranil (**38**) and benzaldehyde (similar to Scheme 11) at elevated temperatures using benzoyl peroxide as a radical initiator. As an example, the monoester **39** was readily obtained in yields of 75 to 80% at 120°C. Thus, Schenck concluded that a free radical chain mechanism during photolysis should occur solely at higher temperatures.[20a]

Mechanistic and Synthetic Studies by J. Malcolm Bruce: 1965–1974

In 1965, Bruce and co-workers launched a detailed mechanistic study on the photoinduced acylation of para-benzoquinone (**5**).[23] Careful analysis of the reaction products revealed that in addition to the acylated hydroquinone (**6**), a larger amount of the corresponding unsubstituted hydroquinone (**44**) was formed. As a minor by-product, the monoester **45** was additionally obtained in 0.6% yield (Scheme 15). In a number of experiments under various conditions, Bruce furthermore demonstrated that the acylated hydroquinone **6** was unambiguously not formed from the monoester **45** via an initial Photo-Fries rearrangement.[22]

Upon irradiation at *ca.* −70°C, **6** was isolated in 72% yield, almost identical with the 76% yield obtained in a parallel run at 15°C. Hence, Bruce concluded that an *in-cage-controlled* radical combination might play only a minor role in the mechanistic scenario (see Scheme 14). To further verify this assumption, Bruce irradiated a solution of benzoquinone and acetaldehyde in the presence of several scavengers, of which 1,1-diphenylethylene (**46**) proved to be the most suitable one. Along with a small amount of compound **6**, an isomeric mixture of the *thermally* unstable trapping product **47** was isolated in 39% yield (Scheme 15).[23b] That free radical intermediates were involved was further indicated by the *thermal*



SCHEME 15

generation of acyl radicals initiated by di-*t*-butyl diperoxalate. With benzoquinone (**5**) and this perester in the molar ratio of 2:1 in acetaldehyde, acetylquinol (**6**) was isolated in 37% yield. In the presence of added quinol **44** and a sufficient excess of perester to oxidize it completely to quinone, the yield increased to 69%, thus supporting sequences involving disproportionation of radical intermediates. With only $^1/_{10}$ molar equivalent of the perester, the yield of **6** dropped to 6%, indicating that the initial aldehyde is most likely not the sole source for hydrogen abstraction.[23a,b] In conclusion, Bruce favored an *out-of-cage scenario* (Scheme 14) for the 1,4-benzoquinone/acetaldehyde pair.

In the following years, Bruce and co-workers expanded their studies to a number of 1,4-quinone/aldehyde couples (Chart 3; Table 88.5).[23c-g] For the quinones **53**, **54**, and **56**, acylation also occurred in the dark but these *thermal* reactions were very significantly slower and gave rather sluggish mixtures when compared to the photoreactions. By consequently varying the substitution pattern of both reaction partners, Bruce concluded that the chemoselectivity for the acylation of *para*-quinones was influenced by three main factors.[2b,c]

1. The nucleophilicity of the acyl radical,[24] because with decreasing nucleophilicity of the derived acyl radical, the formation of monoesters (**45**) became favored. For example, whereas most aliphatic acyl radicals predominantly gave acylated hydroquinones (**6**) with benzoquinone (**5**), the more electrophilic aromatic acyl radical carrying electron-withdrawing substituents in *para*-position all gave the corresponding esters (**45**).
2. The redox properties of the quinone:[25] Quinones with high reduction potentials preferentially gave their esters (**45**). For example, 2,3-dicyano-1,4-benzoquinone (**55**) exclusively yielded its corresponding monoester (**45**) when irradiated in acetaldehyde, thus reflecting its high reduction potential of $E_{1/2}$ = 0.71 V (in MeCN vs. SCE[25a]).
3. The observation that cinnamaldehyde and acrolein exclusively gave the corresponding monoesters (**11**) suggested that the oxidation potential of the acyl radical intermediate was of importance.[24] Thus, if the balance between the redox properties of quinone and acyl radical is appropriate for a *thermal* electron transfer (ET) to occur, the corresponding acyl cation and quinone radical cation are generated, which leads to ester formation (Scheme 14).

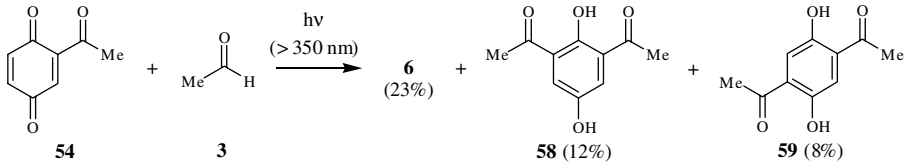
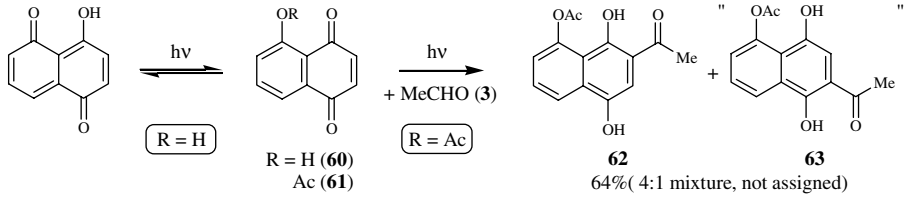
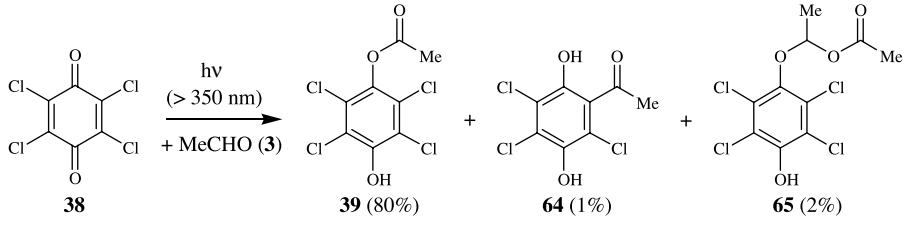
In some cases examined, diacylated compounds were isolated in yields up to 23% and a *thermal* oxidation-reduction equilibrium between the monoacylated product and the initial quinone, followed by a rapid, secondary acylation of the intermediary generated acylated quinone was suggested to explain their formation. Secondary acylation was indeed demonstrated with acetyl-1,4-benzoquinone (**54**), and acetaldehyde and the corresponding diacylated products **58** and **59** were isolated in 20% total yield (Scheme 16).[23d]



SCHEME 16



SCHEME 17

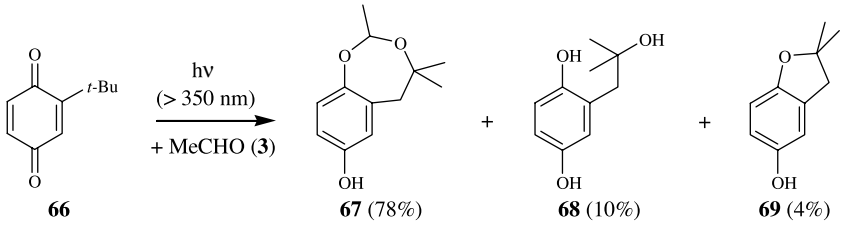


SCHEME 18

Juglone (**60**) did not undergo the photochemical acylation,[23e] indicating a rapid, deactivating *intramolecular* hydrogen-transfer (phototautomerization) process.[26] When the hydrogen bonding site was blocked as for the corresponding acetyl-derivative (**61**), irradiation in acetaldehyde gave a 4:1 mixture (not assigned) of the two regioisomeric hydroquinones **62** and **63** in 64% yield (Scheme 17).[23e] However, recent studies on this transformation indicated that in case of the 2,5-regioisomer **63**, subsequent rearrangement of the acetyl group via a [1,5]-migration occurs (*vide infra*), which remained unrecognized in Bruce's experiments.[33g]

Bruce and Ellis also reinvestigated the photoinduced acylation of chloranil (**38**) to explain the quantitative yield of paraldehyde formed during irradiation.[23c] Careful analysis of the reaction mixture led to the identification of two minor products (Scheme 18): trichloroacetylquinol (**64**) and acetoxyethyl ether (**65**). Whereas the latter was explained via the attack of an acyl radical at the initial aldehyde or alternatively via hydrogen abstraction from paraldehyde, respectively, the formation of **64** was rationalized through expulsion of a chlorine atom from the quinone **38**, followed by rapid reduction of the generated acylated quinone. The released chlorine radical subsequently abstracts a suitable hydrogen to give hydrogen chloride, which is then involved in the generation of paraldehyde.

When *t*-butyl-1,4-benzoquinone (**66**) was used as the starting quinone, reorganization of the *t*-butyl group occurred during photolysis in acetaldehyde (Scheme 19).[23f] The product composition was somewhat sensitive to the amount of water present during the experiment (Table 88.6). In particular, whereas the dihydrobenzodioxepinol **67** was obtained in 80% yield upon irradiation in dry acetaldehyde, a similar run in aqueous aldehyde gave 72% of the alcohol **68** as main product. Because **67** remained photostable



66 **67** (78%) **68** (10%) **69** (4%)

SCHEME 19

TABLE 88.6 Photoreactions Involving the *t*-Butyl-1,4-benzoquinone (**66**)/Acetaldehyde Pair[23f]

Conditions	**67** (%)	**68** (%)	**69** (%)
Aldehyde, 8 d	78	10	4
Aldehyde, $MgSO_4$, 8 d	80	10	—
Aldehyde, 1.6 vol-% H_2O, 4 d	—	72	—

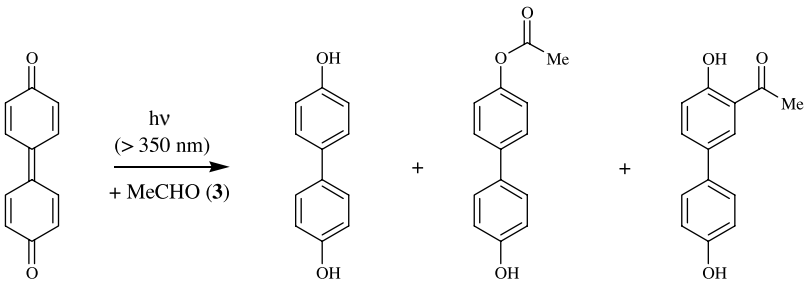
under similar irradiation conditions, an interconversion into **68** was ruled out. 2,5-Di-*t*-butylated quinone similarly gave its corresponding dioxepinol in 38% yield (along with 6% of its hydroquinone **44**), whereas the 2,6-regioisomeric analogue remained almost completely photostable.

In contrast to the light-induced reaction, *thermal* generation of acyl radicals with di-*t*-butyl diperoxalate gave small amounts of the regioisomeric acylated hydroquinones. Thus, *intramolecular* hydrogen abstraction from the *t*-butyl group preceded *intermolecular* hydrogen abstraction from the aldehyde during photolysis. The final photoproducts arise from nucleophilic attack of either aldehyde (to **67**) or water (to **68**), respectively.[23f,27]

Bruce and co-workers further extended their studies on the photoacylation to 4,4′-diphenoquinone derivatives.[23g] Irradiation of the parent diphenoquinone (**70**) in acetaldehyde gave results similar to those found with 1,4-benzoquinone (**5**) and a mixture of hydroquinone (**71**), monoester (**72**), and acylated hydroquinone (**73**) was obtained. The increased amount of monoacetate **72** reflects the higher oxidation potential of the diphenoquinone and thus a greater contribution via the electron-transfer mechanism (*vide supra*). Irradiation of **70** in benzaldehyde gave analogous products (Table 88.5). In contrast, whereas photolysis of 3,3′,5,5′-tetramethyldiphenoquinone in acetaldehyde gave the corresponding hydroquinone in 80% yield, together with some biacetyl, the tetra-*t*-butyl analogue was entirely photostable.[23g]

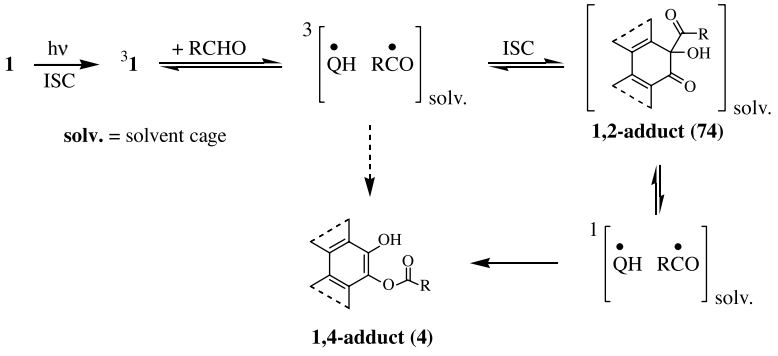
Mechanistic and Synthetic Studies by Kazuhiro Maruyama and Akio Takuwa: 1972–1990

Between 1972 and 1990, Maruyama and Takuwa reinvestigated the mechanistic scenario of the photoacylation for several quinone/aldehyde pairs.[28,29] For 9,10-phenanthrenequinone (**1**), Maruyama was able to show, via CIDNP investigations and in comparison with other hydrogen donors (e.g., ethers, alkyl benzenes, xanthene), that the photoacylation precedes via the unstable vibrationally excited 1,2-photoadduct **74** (Scheme 21).[28a,f] Subsequent rearrangement through dissociation into singlet radical pairs leads to the stable 1,4-adduct, the monoester **4**. CIDNP effects due to *in-cage* coupling products were generally observed for photoreactions involving **1**. The same mechanism was proposed on the basis of analogue CIDNP examinations for 1,4-benzo- (**5**) and 1,4-naphthoquinone (**41**), which both gave acylated hydroquinones.[28e] Quantum yield determinations for the latter two cases revealed that the acylated hydroquinone **43** of 1,4-naphthoquinone acts as a quencher since the quantum yield significantly drops with increasing conversion. In contrast, quantum yields stayed constant during irradiation involving 1,4-benzoquinone (**5**).[28e]

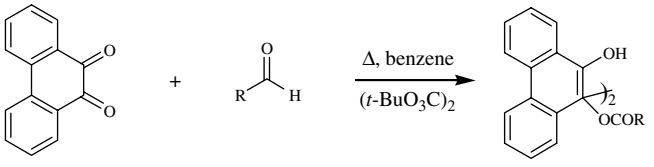


70 **71** (14%) **72** (7%) **73** (28%)

SCHEME 20



SCHEME 21

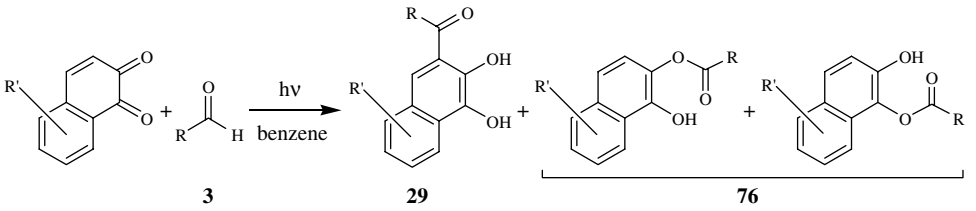


1 **3** **75** (66-90%)

SCHEME 22

Further proof for an *in-cage* process came from the *thermal* generation of acyl radicals and consequent comparison of the product spectrum with that obtained from the photoreaction. In contrast to the photoacylation (and also to Schenck's *thermal* reaction involving chloranil,[20a] *vide supra*), *thermal* reactions of various acyl radicals with ground state 9,10-phenanthrenequinone (**1**) gave *ca.* 1:1 mixtures of the isomeric dimers **75** (Scheme 22), thus disproving a similar *out-of-cage* scenario in the photochemical case.[28h]

In detailed experimental studies on substituted 1,2-naphthoquinones, Maruyama and Takuwa were able to study the role of the aldehyde with respect to the chemoselectivity (Scheme 23; Chart 4; Table 88.7). Irradiation of benzene solutions of various 1,2-naphthoquinones and aliphatic aldehydes gave 3-acyl-1,2-naphthalenediols (**29**) and the 1,2-naphthalenediol monoacyl esters (**76**).[28c,29a] On the contrary, only the latter regioisomeric monoesters were formed in the reaction of 1,2-naphthoquinones with aromatic



SCHEME 23

aldehydes.[29b] This remarkable regioselectivity difference was ascribed to the decreasing nucleophilic character of the aroyl radical in the order: $CH_3\dot{C}=O > CH_2=CH\dot{C}=O > Ph\dot{C}=O$.[29a,b]

A special case was the irradiation of 3-substituted 1,2-naphthoquinones with aliphatic aldehydes (Scheme 24).[28c,29a,b] Photolysis of the 3-halogenated derivatives afforded the corresponding monoesters (**76**) as the main products. Additionally, large amounts of paraldehyde (*ca.* 90%) were obtained, which accounted for the formation of hydrogen halide during the course of the reaction. In line with this observation, small amounts (1 to 3%) of 3-acyl-1,2-naphthalenediols (**29**) were isolated, unambiguously proving partial replacement of the halogen. Furthermore, 3-halogeno-4-acyl-1,2-naphthoquinones (**79**) were obtained in yields of 2 to 5% and an *in situ* oxidation was suggested to explain their formation. The corresponding 3-methyl-1,2-naphthoquinone (**78**) gave a mixture of its monoesters (**76**) and the 4-acylated quinone (**79**), respectively.

The photochemical reaction of 1,2-naphthoquinone (**30**) with acetaldehyde was reinvestigated to further determine the relative contribution of *in-cage* and *out-of-cage* mechanisms as a function of the temperature.[28j] At 22°C, the *C*-acylated product (**29**) was obtained in 22% along with 34% of the *O*-acylated monoesters (**76**). In addition, the diacylated compound **80** was isolated in 0.9% yield. Its formation was ascribed to an *out-of-cage* process, as proven by CIDNP investigations and by comparison with the results obtained by *thermal* generation of acyl radicals. Thus, the amount of **80** formed during the photoacylation was determined at various temperatures and was used as a measure of the participation of the *out-of-cage* mechanism. Below *ca.* 4°C, **80** could not be detected in the reaction mixture, thus indicating that the photoacylation proceeds exclusively via the *in-cage* pathway. At elevated temperatures, the amount of *out-of-cage* product **80** was estimated as 6.7% (20°C), 7.7% (22°C), 19.4% (50°C), 27.8% (70°C), and 36.6% (90°C), respectively.

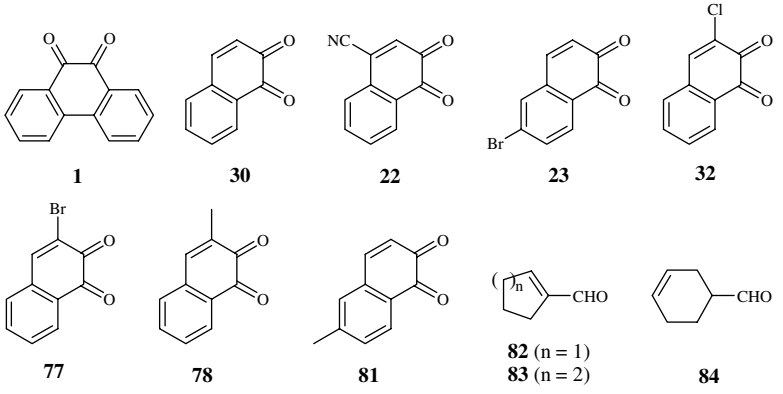


CHART 4

When glyoxals (**85**) were used as starting materials and irradiated in the presence of 9,10-phenanthrenequinone (**1**), the corresponding monoesters were again obtained as sole products in yields of 35 to 50% (Scheme 26). Hence, decarbonylation followed the initial hydrogen abstraction step. Remarkably,

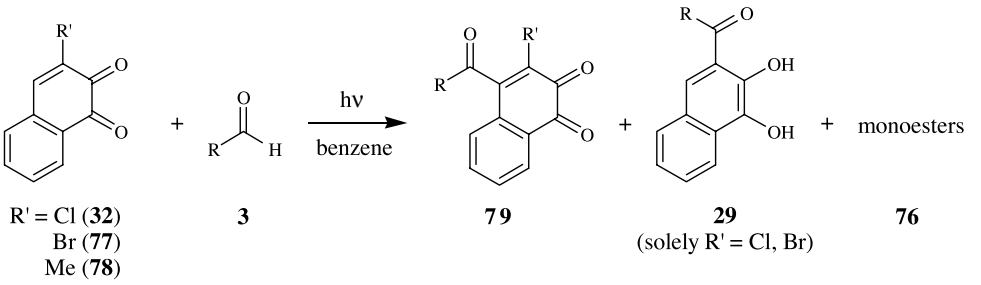
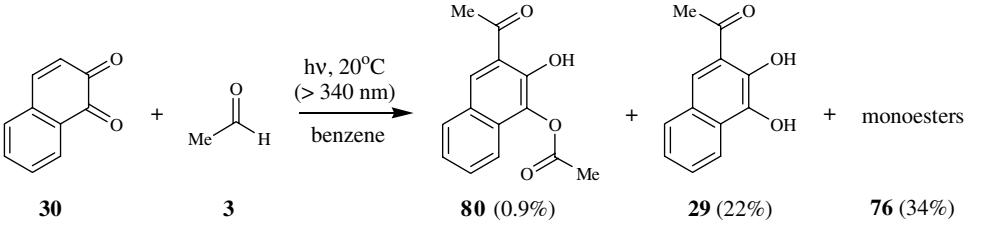
[e] Yield of dehydrohalogenated acylated hydroquinone.

the hydrogen transfer process was found to be reversible as proven by CIDNP investigations. Owing to the stability of the acyl radical intermediate *t*-butylglyoxal partly underwent secondary decarbonylation yielding the *t*-butylether **86** in 12% yield.[28b]

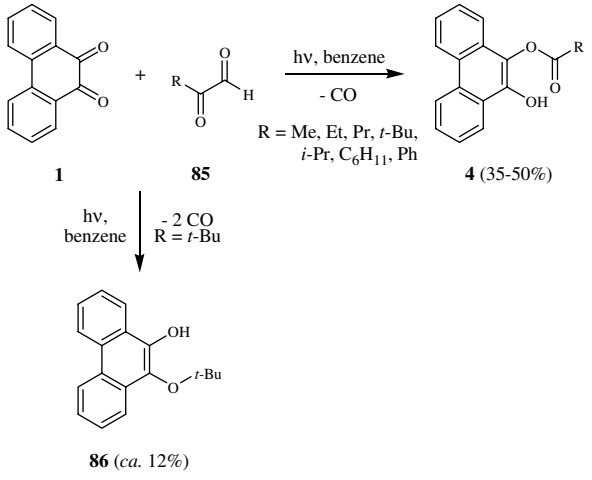
Decarbonylation was also reported when 1,2-naphthoquinone (**30**) was irradiated in the presence of phenyl- (R = H) or diphenylacetaldehyde (R = Ph).[28i] The initial benzylated or diphenylmethylated product **87** underwent rapid oxidation and isomerization during usual work-up, affording the quinone methides **88** as main products. In the case of diphenylacetaldehyde, acetylation of the reaction mixture with acetic anhydride gave the diacetylated product **89** of the primary addition product (**87**; R = Ph). In addition, when the product mixtures were quickly separated, the corresponding quinone intermediates



SCHEME 24

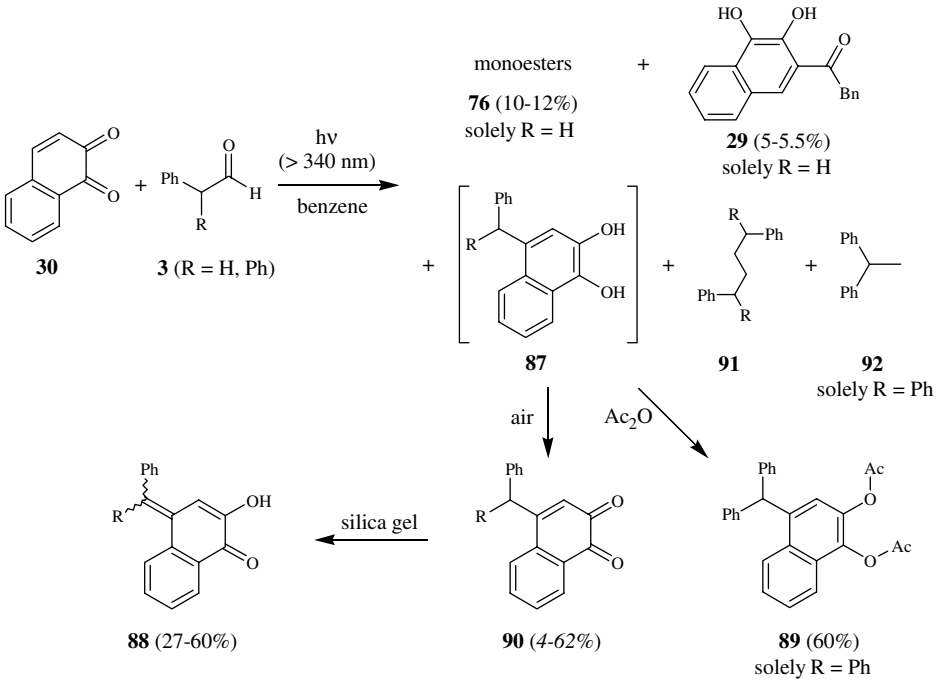


SCHEME 25



SCHEME 26

90 were isolated and characterized (yields are indicated in *italics* in Scheme 27). Whereas phenylacetaldehyde (R = H) gave a mixture of benzylated and benzoylated products with 1,2-naphthoquinone, diphenylacetaldehyde (R = Ph) exclusively yielded decarbonylation products. This finding correlates convincingly with the stability of the acyl radical intermediate.[24] The different regioselectivity of the addition of acyl vs. benzyl radicals was sufficiently interpreted on the basis of the charge density of the involved radicals.[28l] Maruyama and Takuwa furthermore demonstrated that the isomerization process **90** → **88** on silica gel proceeded much faster for the benzylated adduct (**90**; R = H).[28i]



SCHEME 27

A third type of decarbonylation was found during the photolyses of various alkyl-substituted 1,2-benzoquinones (**93**) with acetaldehyde (Scheme 28; Table 88.8).[28k] Although the corresponding acylated hydroquinones (**94**) and monoesters (**95**) were still found as major products, dimers of cyclopentadienone (**96**), generated via photodecarbonylation of the quinones, were obtained for 3,5-di-*t*-butyl- (**93**; $R,^1$ R^3 = *t*-Bu, R^2 = H) and 3-*t*-butyl-5-methyl-1,2-benzoquinone (**93**; R^1 = *t*-Bu, R^2 = H; R^3 = Me) in low yields, respectively. In contrast to other *ortho*-quinones studied (*vide supra*), mechanistic investigations revealed that 1,2-benzoquinones **93** react through the *out-of-cage* pathway because no CIDNP signal was observed. This explanation was further confirmed by experiments involving *thermally* generated acyl radicals. With di-*t*-butyl diperoxyoxalate at 38°C, the acylated hydroquinone (**94**) was found as main product in 26% yield in addition to the monoester-pair (**95**) with 7% and a diacylated compound (similar to **80** in Scheme 25) with 6%. The latter substrate was formed via secondary acylation from the *C*-acylated product (**94**) as shown in an independent experiment.

A novel type of photoproduct was observed for *ortho*-chloranil (**18**).[28d] Whereas various aldehydes studied gave the expected monoesters (**98**) in moderate to good yields, *iso*- and 2-ethylbutyraldehyde afforded the tetrachloro-3,3-dialkyl-2,3-dihydro-benzo[1,4]-dioxin-2-ols **99** (Scheme 29). The formation of these unusual products was explained by initial abstraction of the tertiary methine hydrogen in preference to the formyl hydrogen, followed by rapid transformation into the 1,4-adduct **99**.

In 1990, Takuwa described an interesting modification of the photoacylation protocol.[29c] Upon irradiation of an acetonitrile/benzene solution of 1,2-naphthoquinone (**30**) and acetaldehyde, 3-acetyl-1,2-naphthalenediol (**29**) was isolated in 7% yield. The yield could be significantly increased when irradiations were performed in the presence of a metal perchlorate. Among the various perchlorates used, magnesium perchlorate (1 equivalent) gave the highest yield (30%). Similar yields of 25 to 29% were obtained with

other aldehydes (Scheme 30; Table 88.9). Because tetrabutylammonium perchlorate gave only 5% yield, the presence of a metal cation was found essential for the activation process.*

As an extension of their studies, Maruyama described the photoacylation of 1,4-naphthoquinone (**41**) with α,β-unsaturated aliphatic aldehydes (Scheme 31; Table 88.10).[28g] In contrast to 1,4-benzoquinone

*However, the same experiments in pure benzene gave mixtures of acylated hydroquinones (**29**) and monoesters (**76**) in yields of 8.1–24% and 7–39% (Table 88.7), respectively.[29a]

(*vide supra*), irradiations in benzene solutions selectively gave the corresponding acylated hydroquinones (**43**) in yield between 43 and 53%. The photoproducts served as starting materials for the synthesis of α- and β-lapachones (*vide infra*).

Synthetic Studies by George A. Kraus and Others: 1986–2002

From 1992, Kraus and co-workers explored the synthetic value of the photochemical acylation of 1,4-quinones (Scheme 32; Table 88.11),[30] and developed it as a suitable alternative to existing *thermal* Friedel-Crafts acylations.[30c,d] During their studies on the pyranoquinone skeleton, they initially used the classical Friedel-Crafts approach but the poor solubility of some of the starting materials, the drastic reaction

conditions, and the modest yields forced them to examine alternative pathways.* In contrast to the results reported by Klinger or Bruce (*vide supra*), the formation of monoesters was, however, never described by Kraus.

A major improvement in the photochemical approach was achieved by the addition of catalytic amounts of benzophenone (BP). Applying this *mediated* procedure, the yields generally increased and several, so-far unreactive, quinones could be activated for the acylation. As an example, 5,8-dimethoxy-1,4-naphthoquinone (**101**) remained unreactive upon irradiation in benzene and in the presence of benzaldehyde, but when using a catalytic amount of benzophenone, the acylated hydroquinone was readily obtained in 61% yield.[30b]

A major disadvantage of Kraus's procedure in terms of an environmentally benign method involved the use of benzene (or alternatively acetonitrile) as solvent. Supercritical carbon dioxide (SC-CO_2) was recently reported as an alternative solvent and was applied to the benzophenone-mediated photoacylation of 1,4-benzoquinone (**5**) with benzaldehyde or butyraldehyde, respectively.[30e] High yields of up to 81% were achieved at higher CO_2 pressure, or with the addition of 5% *t*-butyl alcohol as co-solvent (Table 88.12); the latter is necessary due to the limited solubility of the quinone in SC-CO_2. Despite these achievements, this technique suffers from technical disadvantages (e.g., high pressure or small reactor volume), especially for a large-scale application.

Another benzophenone-mediated photoacylation was reported by Kobayashi and co-workers for 2-aryl- and 2-alkylamino-1,4-naphthoquinones (**102**).[31a] The photoinduced acylation was achieved in moderate to high yields of 54 to 89% with various aromatic and aliphatic aldehydes solely in the presence of 2 equivalents of benzophenone (Scheme 33; Table 88.13). No acylation occurred in the absence of the mediator, whereas the yields significantly decreased when only 1 equivalent was used. In one exemplary case, benzophenone was re-isolated in 85% yield. Furthermore, careful analysis of the crude product mixture confirmed the absence of any significant degradation products of BP (e.g., benzopinacol, benzhydrol). Based on these findings it was concluded that triplet-excited benzophenone is involved in the hydrogen abstraction step. The primarily formed acylated hydroquinones (**105**) were readily oxidized during work-up to give the corresponding quinones (**103**). Most of these derivatives underwent further quinone–imine tautomerization to **104**.

The initial formation of the hydroquinone was confirmed with the diphenylamino derivative (**106**) as starting material and further transformation into its diester (**107**) with acetic anhydride (Scheme 34).[31a] Additionally, oxidation by air in the presence of $FeCl_3$ gave the corresponding 3-acyl-1,4-naphthoquinone (similar to **103**).

*However, Kraus incorrectly stated about the photoacylation:[30a] *"Isolated examples of this reaction have been reported."*

Kobayashi furthermore adopted the photochemical acylation procedure described by Kraus[30a] as an important key step in the synthesis of several quinone derivatives (details are given in Section 88.7; *vide infra*),[31b,c] and in all of these cases, the acylated hydroquinones were used without any purification. Table 88.14 summarizes the reported details.

To control the site of the acylation step, Tachikawa developed a highly *regioselective* procedure using unsymmetrically substituted 1,4-naphthoquinones (**108**) with bromo or chloro substituents at the C–C double bond (Scheme 35; Table 88.15).[32a] The excellent regioselectivity was achieved through replacement

of the halogen by the acyl group. In most cases, mixtures of the acylated hydroquinones (**109**) and the corresponding acylated quinones (**110**) were obtained in moderate to good total yields. This finding was explained by disproportionation of the acylated radical intermediates. The procedure was further extended to photochemical acylations involving *mono*-halogen substituted quinolinequinones (**111**).[32b] The efficiency of the regiocontrol was demonstrated by comparison with the *non*-halogenated parent compounds ($X^1 = X^2 = H$) and mixtures of both regioisomeric pairs of acylated hydroquinones (**109**) and quinones (**110**) were obtained. However, the 2,5- (from **108**) or 1,6-regiosiomers (from **111**) were always slightly preferred in the *non*-activated cases.

SCHEME 37

A different regioselectivity concept has been achieved by Mattay and co-workers via saturation of the solution with lithium perchlorate prior to photolysis.[33a,b] This was demonstrated for the unsymmetrically substituted 5-methoxy-1,4-naphthoquinone (**108**) by irradiation in $LiClO_4$-saturated butyraldehyde. Only the 2,5-regioisomer (**112**) was obtained in 56% yield, whereas the corresponding 2,8-regioisomer (**113**) could not be detected in the reaction mixture (Scheme 36). The directing effect of the additives was explained by selective complexation of the lithium cation and consequent alteration of the LUMO properties of the quinone. Hence, this phenomenon parallels the results on acceleration of the addition efficiency by metal perchlorates as reported by Takuwa (*vide supra*).[29c]

Mattay and co-workers studied various photoinduced acylations involving the unsymmetrically substituted 1,4-quinones **108** and **61** and, in all cases studied, mixtures of the two regioisomeric hydroquinones were isolated in moderate to good total yields of 59 to 84% (Scheme 37, Table 88.16).[33] In correlation with the nucleophilic character of the corresponding acyl radicals,[29a,b] but in contrast to Tachikawa's results,[32a] aliphatic aldehydes predominantly gave the 2,8-regioisomers (**113**). Only in the presence of benzaldehyde was the 2,5-regioisomer (**112**) formed as the major regioisomer in 36% yield; this differing regioselectivity was explained by the more electrophilic character of the aroyl radical.[29a,b]

With both naphthoquinones, remarkable side reactions have been observed (Scheme 37). Although Bruce had already studied the photoinduced acylation of the acetylated naphthoquinone **61**, for which he assigned the corresponding acylated hydroquinone pair (*vide supra*),[23e] more recent studies revealed that further 1,5-acyl migration of the 2,5-regioisomer (**63** → **114**) occurred.[33g] From the photoacylation of the methoxy derivative **108**, diacylated products (**115**) were obtained with acetaldehyde and benzaldehyde, respectively.

[b] 1,5-Acyl group migration not recognized in Ref. 23e,33c.
[c] Benzophenone mediated.
[d] 15–17% non-rearranged product in the crude reaction mixture.

1,5-Acyl migration was also observed for the diacetylated 5,8-dihydroxy-1,4-naphthoquinone derivative **116**. Upon irradiation in benzene and in the presence of various aliphatic aldehydes, the corresponding acylated products **117** were obtained in yields of 58 to 60% (Scheme 38; Table 88.16). The acetyl group in the 5-position rearranged during the photoacylation; but in all cases, the non-rearranged acylation product was observed in 15 to 17% yield in the crude product mixture. Most reasonably, and supported by the side-selectivity of the rearrangement, the acyl migration follows the monoacylation step (photochemically or thermally).

Following the original protocols described by Kraus,[30] Mattay and co-workers examined numerous photoacylations of 1,4-quinones for which they introduced the term "Photo-Friedel-Crafts acylation".[33] In all cases, the corresponding acylated products were obtained in moderate to good yields (Table 88.17). Because these authors were particularly interested in a large-scale solar chemical outdoor application of the acylation reaction,[33h] they replaced the toxic solvents (benzene or acetonitrile) with nontoxic *t*-butyl alcohol.

A remarkable exception was the irradiation of 1,4-naphthoquinone (**41**) in the presence of benzaldehyde, and the dibenzoylated compound (**118**) was isolated as a side product in yields of 14 to 17% (Scheme 39).[33e] However, in an independent experiment it was shown that secondary addition occurred from the monoacylated product (**43**) itself and not (as originally proposed by Bruce for 1,4-benzoquinone[23d]) from an *in situ*-generated acylated quinone.

In the case of 1,4-benzoquinone (**5**), good evidence for an electron-transfer (ET) key-step from the acyl radical to a ground-state quinone was found when the *t*-butyl ester **119**, a trapping product characteristic for acyl cations,[24] was obtained during photolysis in *t*-butyl alcohol. This ester was not detected when 1,4-naphthoquinone (**41**) was applied, thus supporting the striking difference in the chemoselectivity of the acylation for both 1,4-quinones.

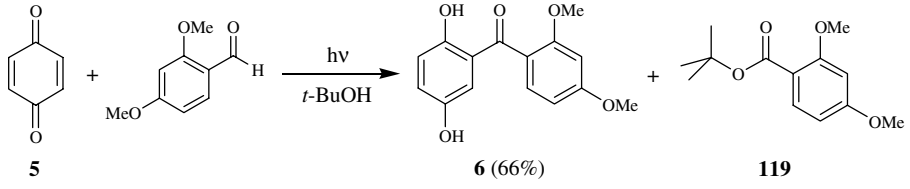
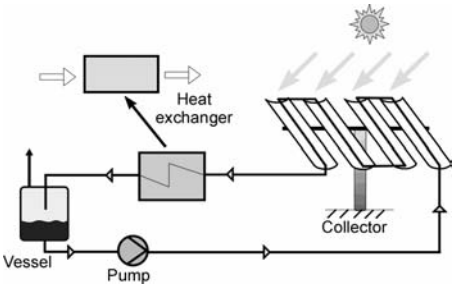


SCHEME 40

To account for the contradictory results on the mechanism of the photoacylation, Mattay and coworkers stated that "Comparing the available data from the literature it can be concluded that both in-cage and out-of-cage mechanisms operate more-or-less simultaneously depending on the specific reaction conditions of each irradiation experiment (i.e., temperature, solvent, quinone/aldehyde applied)."[33f] Hence, in-cage and out-of-cage scenarios can be seen as the extreme mechanistic cases.

88.5 Modern Solar Chemical Applications

Recently, the call for "sustainable developments," reduction of CO_2 emission, and the growing requirement for environmentally friendly technologies has led to increasing interest in (and remembrance of) the sun as an environmentally friendly energy and light source. As shown by the pioneering work of Klinger and Schönberg (*vide supra*), quinones are especially versatile substrates for the use of sunlight, and the photochemical acylation can thus be utilized in the field of *green photochemistry*[34] using modern solar chemical reactors.[35] The principle of a line-focusing parabolic trough collector (PROPHIS) is illustrated as an example in Scheme 41.[33d]



SCHEME 41

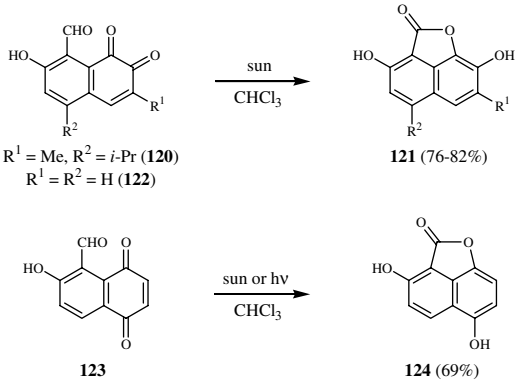
[b] Amount of photons collected within 300–500 nm.
[c] n.g.: not given.

Mattay and co-workers recently realized the first solar chemical large-scale application of the photoacylation reaction.[33] Illumination of a *t*-butanol/acetone solution of 1,4-naphthoquinone (**41**; 500 g) with butyraldehyde (**3**; R = Pr) using a PROPHIS sunlight-concentrating system[35a,b] (MAN-Helioman, concentration factor CF = 15 suns; 24 m^2 mirror area) gave the acylation product **43** within 3 days (Germany, August 1996) and in 90% yield without large amounts of by-products. During the experimental phase, the three concentrating troughs (24-m^2) collected almost 300-mol photons in the important absorption region (within the solar spectrum) of 1,4-quinones between 300 and 500 nm.

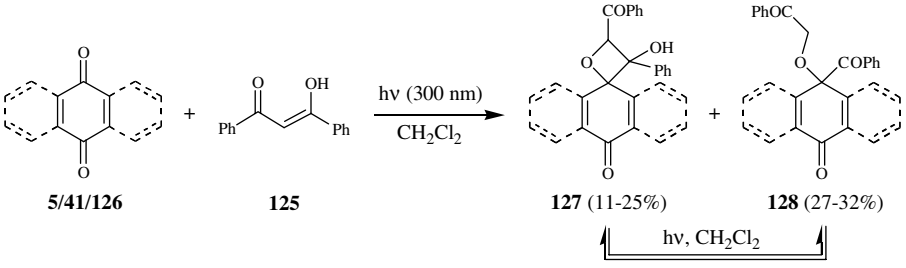
Furthermore, the solar chemical reaction of 1,4-benzoquinone (**5**) with 2,4-dimethoxybenzaldehyde (**3**; R = 2,4-$(MeO)_2C_6H_3$) was explored to compare different sunlight-collecting systems (Table 88.18). In parallel runs under standardized conditions, the line-focusing parabolic trough collector (PROPHIS; CF = 15), the compound parabolic collector (CPC; CF = 1–2), and the double sheet flat-bed reactor (CF = 1) gave relatively low conversion rates to **6** of 7%, 17%, and 3.6%, respectively, mainly caused by bad weather conditions.[35b] The CPC and flat-bed systems represent stationary, low concentrating collectors that can also use part of the diffuse solar radiation, which accounts for about 60% of the sunlight in central Europe. Consequently, the influence of the radiation type was reflected in the conversion ratio of 30:70 (PROPHIS vs. CPC), which showed good agreement with the calculated 35:65 ratio of direct (used by PROPHIS) vs. direct+diffuse radiation (used by CPC). This ratio additionally matched with the number of collected photons for each system as the PROPHIS-plant collected 20.1 mol of photons in the 300- to 500-nm range, the CPC reactor 41.6 mol, giving a ratio of 33:67.

88.6 Miscellaneous

A unique example of an *intramolecular* version of the photoinduced acylation has been reported by Thomson and co-workers.[36] These authors examined the extractives of the tree Blue Mahoe (*Hibiscus elatus*, Malvaceae) to explain the intensive color change of its freshly cut wood from blue-gray or pink-gray to light yellow or buff-gray on exposure to light. A number of sesquiterpenoid ketones (hibiscones A–D) and *ortho*-naphthoquinones (hibiscoquinones A–D) have been isolated and identified. Among the



SCHEME 42



SCHEME 43

ortho-naphthoquinones, especially the pink colored hibiscoquinones A (**120**) was extremely photolabile and reacted quickly in daylight to the corresponding colorless lactone **121** (Scheme 42). This *intramolecular* photoacylation even occurred in the solid state. Thomson and co-workers furthermore compared hibiscoquinones A (**120**) with the related *ortho*- and *para*-quinone aldehydes **122** and **123**. Whereas the *ortho*-quinone **122** readily underwent the photoacylation reaction on exposure to sunlight, the *para*-quinone **123** cyclized slowly to **124** in daylight, but rapidly on irradiation with a medium-pressure mercury lamp. Because the content of hibiscoquinones A (**120**) in the heartwood of *Hibiscus elatus* is usually small, the color change was suggested to originate primarily from photoreduction of the hibiscoquinones in general.

Recently, photochemical [2+2]-additions of dibenzoylmethane (**125**) to quinones have been described by Kim and co-workers,[37] and because acylation-like products were obtained, the reaction will be described here. Although the product composition and spectrum depended on the quinone applied, 1,5-diketones were obtained in all cases examined. Upon irradiation in dichloromethane, the 1,4-quinones **5**, **41**, and anthraquinone (**126**) gave mixtures of the *spiro*-oxetane **127** and the 1,5-diketone **128**, the latter formed via subsequent retro-Aldol cleavage, in yields of 11 to 15% and 27 to 32% (Scheme 43; Table 88.19), respectively.[37a,c] Remarkably, the photoproducts were *inter*-convertible, as demonstrated by independent irradiations under identical conditions.

However, t*etra*-substituted quinones behaved differently, and mixtures of the regioisomeric 1,5-diketones **131** and **132** were isolated in moderate yields (Scheme 44; Table 88.19).[37a,c] The formation of **131** was explained through a competing [2+2]-cycloaddition of **125** to the C–C double bond of the quinone, followed by subsequent ring-opening.

In contrast, when halogenated *ortho*-quinones were used as starting materials, 1,4-dioxenes (**133**) were obtained as major products as well as small amounts of the 1,5-diketones **134** (Scheme 45; Table 88.19).[37b]

TABLE 88.19 Photoreactions of Quinones with Dibenzoylmethane (**125**)[a,37]

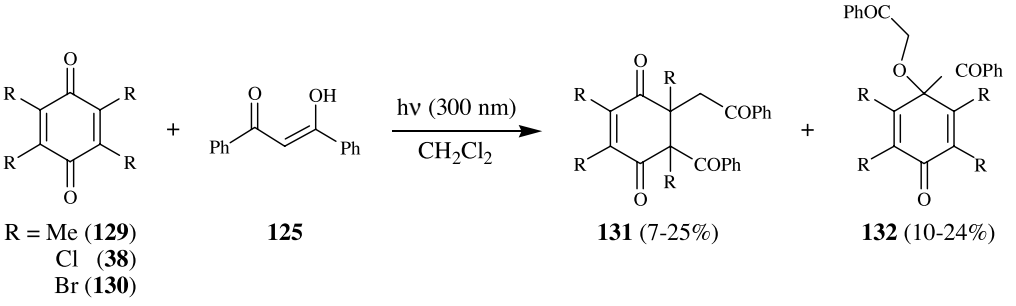
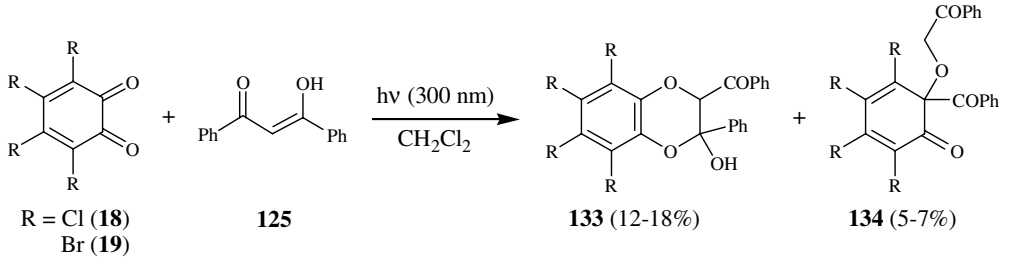
[a] Conditions: CH_2Cl_2, Rayonet (300 ± 10 nm).



SCHEME 44



SCHEME 45

9,10-Phenanthenequinone (**1**) and acenaphthenequinone (**13**) behaved differently and photoaddition of **125** gave the 1,5-diketone **135** as major product beside the 1,5-ketoester **136** (Scheme 46; Table 88.19). The preferential formation of **135** was rationalized by comparison of the 1,4-biradical intermediates involved.[37b]

When dibenzoylmethane (**125**) was replaced by 1,3-cyclohexanedione and dichloromethane by methanol, photoaddition to benzoquinone (**5**) to give the *spiro*-oxetane (similar to **127**) fell to 2% and instead methylation to the corresponding methoxycyclohexenone occurred.[37d]

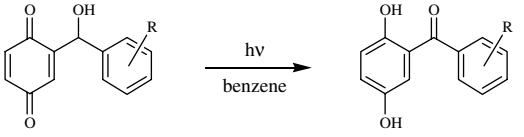
SCHEME 46



137 (R = 4-Me, 3-Me, 2-Me or 4-F) **6** (35.6-45.4%)

SCHEME 47

Acylated hydroquinones were additionally formed through an *intramolecular* oxidation/reduction reaction of α-hydroxy-benzyl-1,4-benzoquinones (**137**). Irradiation in benzene solution gave the corresponding hydroquinones **6** in moderate yields (Scheme 47).[38] In contrast to **137**, acylated quinones (such as **54**) undergo a multitude of photochemical transformations (e.g., dimerizations).[39]

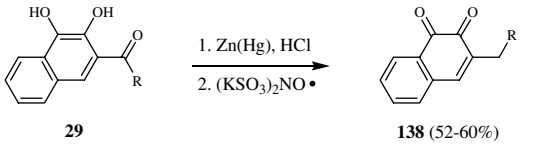
88.7 Synthetic Applications

Although acylated quinones are known as important natural compounds and useful key intermediates in organic synthesis,[1] only a few examples incorporating photoacylation have been reported up to the present time. Most commonly acylated quinones are prepared via Friedel-Crafts acylation,[40] persulfate oxidation,[41] Fries-[42] or Photo-Fries rearrangement,[43] but many of these *classical* methods suffer from aggressive reaction conditions, the formation of undesired by-products, and certain limitations concerning the starting materials (availability or functionalities). Because some of these disadvantages additionally conflict with the currently increasing interest in environmentally friendly technologies, the photoinduced acylation may serve as a mild and potential future alternative[44] and is therefore often regarded as a "photochemical alternative to certain Friedel-Crafts reactions"(G. A. Kraus)[30c,d] or the "Photo-Friedel-Crafts acylation" (J. Mattay).[33c-f]

Because 1,2-naphthoquinone (**30**) is highly sensitive to acid and heat, Takuwa and Kai applied the $Mg(ClO_4)_2$-mediated acylation to the synthesis of 3-alkylated-1,2-naphthoquinones (**138**).[29c] The photochemically generated acylated hydroquinones **29** were readily transferred into the corresponding alkylquinones in moderate overall yields via a sequence of Clemmensen reduction and oxidation with Fremy's salt (Scheme 48; see Table 88.9 for R).

Maruyama and Naruta completed the syntheses of the naturally occurring α- and β-lapachones and their analogues (**139** and **140**) based on the photoacylation.[28g] Starting from 1,4-naphthoquinone (**41**) and suitable α,β-unsaturated aliphatic aldehydes, theses potent *anti*-microbial and *anti*-tumor agents[1] were conveniently obtained in four to five steps (Scheme 49; see Table 88.10 for R^1, R^2).

As described by Kobayashi and co-workers,[31b] 4,7-dioxo-4,7-dihydrobenzo[*b*]thiophene-2-carboxylates (**143**) are readily available in a one-pot procedure from acylated 1,4-hydroquinones (**54**) and mercaptoacetates (**142**) using 1-trimethylsilylimidazole as a protecting reagent as well as a base (Scheme 50; see Table 88.14 for R^1). Likewise, the corresponding dihydronaphthothiophene carboxylates



29 **138** (52-60%)

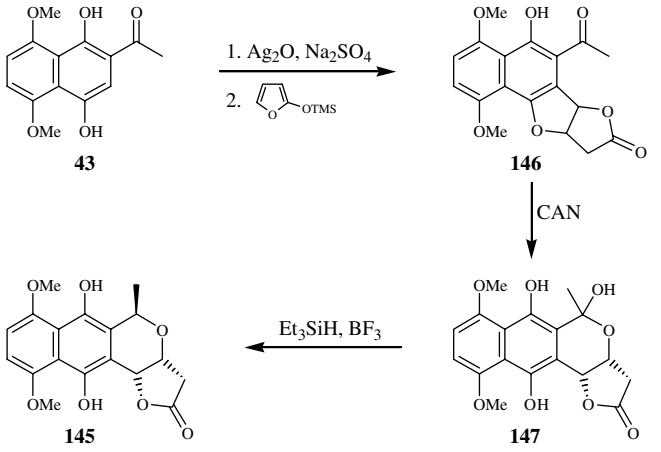
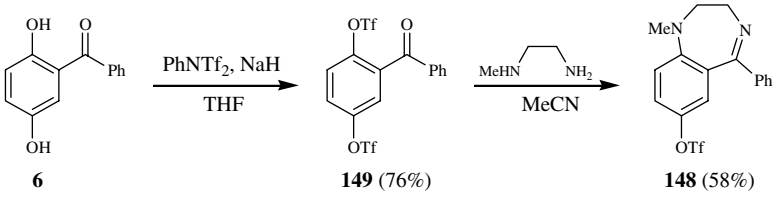
SCHEME 51

have been prepared in moderate to good yields of 53 to 84%, but oxidation with CAN was not required in this case.[31b] Recently, Kobayashi reported the synthesis of symmetric benzo [1,2-*b*: 5, 4-*b*′] dithiophene-4,8-diones starting from **143**.[31d]



SCHEME 52



SCHEME 53

Kobayashi and co-workers further developed a simple pathway to benzo[*b*]xanthene-6,11,12-trione derivatives (**144**) involving the photoinduced acylation of naphthoquinone (**41**).[31c] Subsequent oxidative cyclization with an excess amount of Ag_2O gave the xanthenequinone derivatives in moderate overall yields (Scheme 51; see Table 88.14 for R,[1] R[2]).

Due to their strong antibiotic activity, pyranonaphthoquinones (e.g., *frenolicin B* or *kalafungin*) have attracted ongoing attention in synthetic organic chemistry.[45] Kraus and co-workers applied the benzophenone-mediated photoacylation of 5,8-dimethoxy-1,4-naphthoquinone (**101**) to the synthesis of the *kalafungin* analogue **145** (Scheme 52).[30d] Because many pyranonaphthoquinones require regioselective acylation of the unsymmetrically substituted 5-methoxy-1,4-naphthoquinone (**108**) to its 2,8-regioisomer (**113**),[45d] Tachikawa's procedure may represent the method of choice.[32]

Bruce and co-workers furthermore used the photochemical acylation for the synthesis of the benzodiazepine skeleton (Scheme 53).[46] Benzodiazepines (e.g., diazepam [Valium]) are widely used as antianxiety agents, which makes them attractive target molecules.[47] Transformation of **6** (R = Ph) into its bistriflate (**149**) and subsequent reaction with *N*-methylethylenediamine afforded the diazepine **148**. The conversion of the remaining triflate into either nitriles or esters was subsequently accomplished using suitable organopalladium compounds.[46]

Chart 5 shows the structures of various interesting target molecule that have been either synthesized or might be accessible via acylated hydroquinones. Among these examples are the enantiomeric naphthoquinones *alkannin* (**150**) and *shikonin* (**151**),[48] 1-aminoanthraquinones (**152**),[49] the 1,6-dihydroxyantharaquinone *chrysophanol* (**153**) and its isomeric 1,8-dihydroxy analogue *aloesaponarin I* (**154**),[50] 1,3-disubstituted naphthopyrandiones (**155**),[51] isoquinoline-5,8-diones (**156**),[52,53] the related *11-deoxydaunomycinone* (**157**) and (±)-*auramycinone* (**158**),[54,55] 5,8-dihydroxythioflavanone (**159**),[56,57] and benzophenothiazinone derivatives (**160**).[58]

89

Photoisomerism of Azobenzenes

Helmut Knoll
Universität Leipzig

89.1 Introduction

The parent molecule of aromatic azo compounds is azobenzene, whose UV/VIS spectroscopic features and photochemistry are basically determined by the azo group -N = N- in conjugation with two phenyl substituents. The most important applications of azobenzene derivatives (azobenzenes) are their use as dyestuffs. Azo dyes absorb visible light and generally show remarkable light-fastness, which is due to an effective deactivation mechanism of the excited-state molecules that includes photoisomerization. Zollinger[1] has discussed this aspect from the viewpoint of dyestuff chemistry.

The double bond between the two nitrogen atoms gives rise to *E*-or *Z*-configuration of the two substituents. In the following, the more general terms "*E*" and "*Z*" will be used, although the terms "*trans*" and "*cis*" are still in use and unequivocally distinguish the two geometric isomers of azobenzenes. This chapter describes the photochromism of azobenzenes; that is, the interconversion of both isomers by light; see Figure 89.1. The thermal *Z*→*E* isomerization reaction is also included because it is more or less effective in photochemical reaction systems of azobenzenes.

Rau[2,3] reviewed the literature on the photoisomerism of azobenzenes more than a decade ago as did Suginome.[4] This chapter summarizes the essential knowledge up to the present day and describes the latest findings. A historical survey will not be given; instead, recent papers and review articles will be cited as references. The reader is referred to the literature therein. The progress of experimental techniques and of theoretical calculations within the past decade permits a more detailed investigation and description of the dynamics of the processes given in Figure 89.1. By means of new synthetic procedures, many complex molecules with azobenzene as a building block have been prepared, which makes them accessible for manipulation by light and heat on a molecular level.

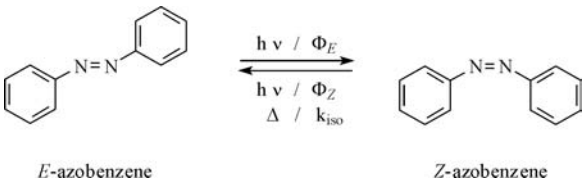

FIGURE 89.1 $E \rightarrow Z$ and $Z \rightarrow E$ isomerization of azobenzene by light (hν) with quantum yields Φ_E and Φ_Z, respectively, and $Z \rightarrow$E isomerization by heat (Δ) with the rate constant k_{iso}.

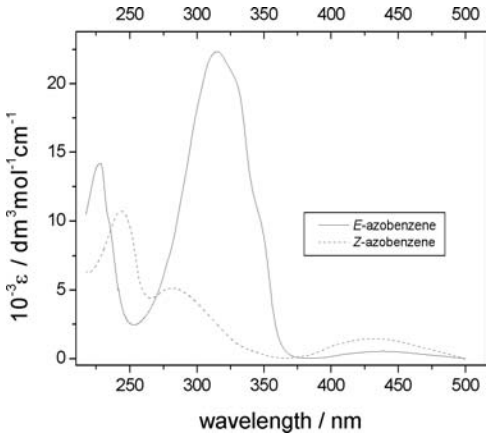

FIGURE 89.2 Absorption spectra of *E*- and *Z*-azobenzene in ethanol. (Adapted from Jaffé, H.H. and Orchin, M., *Theory and Applications of Ultraviolet Spectroscopy*, John Wiley & Sons, New York, 1962.)

In the following section, the UV/VIS spectroscopy of azobenzenes, the knowledge of which is a prerequisite for photochemical isomerization reactions, is described. Conditions and quantum yields of the photoisomerization will be dealt with in Section 89.3 for the azobenzene molecule and some of its derivatives. The mechanism of these simple light-induced unimolecular reactions (i.e., the dynamics of molecular changes) has only recently been studied directly by means of experimental laser spectroscopy methods. The results obtained thus far are summarized and compared with conclusions from quantum chemical calculations in Section 89.4. Thermal $Z \rightarrow E$ isomerization reactions influence the concentration ratio of *E*- and *Z*-isomers in the photostationary state on irradiation of azobenzenes. They are described separately in Section 89.5. Finally, a selection of interesting prospective applications of the photoisomerism of azobenzenes is presented in Section 89.6.

89.2 UV/VIS Spectroscopy of Azobenzenes

Rau classified azobenzenes as azobenzene-type, aminobenzene-type, and pseudostilbene-type molecules according to their UV/VIS spectra, based on different energies for the transitions of n- and π-electrons into the π*-obitals.[2,3]

Azobenzene-Type Molecules

The stable *E*-isomer of the parent molecule azobenzene shows a low-intensity $n \rightarrow \pi^*$ band ($\lambda_{max} = 444$nm/ $\varepsilon \approx 440$ dm^{3}mol^{-1}cm^{-1}) in the visible (VIS) and a high-intensity $\pi \rightarrow \pi^*$ band ($\lambda_{max} = 316$ nm/$\varepsilon \approx 22\,000$) in the UV[5] (see Figure 89.2). The bands are well separated. Changes in the substitution on azobenzene by various groups, except for an amino group, and changing the solvent have only minor effects.

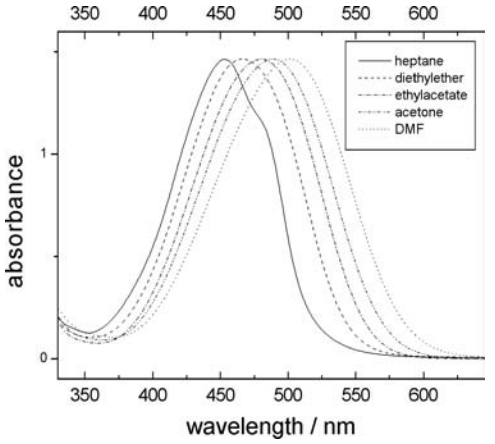

FIGURE 89.3 Absorption spectra of 4-(diethylamino)-4′-nitroazobenzene (about 5×10^{-5} mol dm^{-3} matched to equal absorbance) in solvents of different polarity (DMF = dimethylformamide).

The *Z*-isomer of azobenzene can be isolated by chromatographic separation of the *E*/*Z*-mixture after irradiation of *E*-azobenzene at low temperatures.[5,6] It shows higher intensity of the n→π* band (λ_{max} = 437 nm//ε = 1100) and blue-shifted π→π* bands (λ_{max} = 270 nm//ε = 5000 "sh," λ_{max} = 247nm/ε = 11,500)[5] (see Figure 89.2).

Aminoazobenzene-Type Molecules

The n→π* and π→π* bands of *E*-aminoazobenzene-type molecules are less clearly separated. Moreover, polar solvents lower the transition energy, in particular that of the n→π* band so that π→π* and n→π* bands may overlap and appear as one band.

Pseudostilbene-Type Molecules

Substitution of 4-aminoazobenzene by an electron-withdrawing substituent such as the nitro group in the 4′-position lowers the energy of the $^1(\pi\pi^*)$ state of the *E*-isomers. These donor/acceptor-substituted ("push-pull") azobenzenes find application as dyes with colors shifted toward the red. Here, the sequence of the $^1(n\pi^*)$ and $^1(\pi\pi^*)$ states can be reversed in energy, and the spectrum of the *E*-isomer is dominated by the π→π* band. The charge-transfer character of such low-lying $^1(\pi\pi^*)$ states causes a strong dependence of the band maximum (λ_{max}) on the substituent in the 4-position with another unchanged substituent at the 4′-position. Replacing the simple amino group with the diethylamino group in 4-(amino)-4′-nitroazobenzene brings about an increase in the band maximum of 50 to 60 nm in hexane and acetonitrile, respectively.[8,9] If, accordingly, in 4-phenylaminoazobenzene, the hydrogen atom in the 4′-position is replaced with the nitro group, an increase of λ_{max} of more than 50 nm in acetonitrile and even 70 nm in dimethylsufoxide was observed.[10] For a given azobenzene dye, the absorption maxima are dependent on the solvent polarity. The π→π* band maximum of 4-(diethylamino)-4′-nitroazobenzene changes from 453 nm in heptane to 502 nm in dimethylformamide (see Figure 89.3).

This behavior of λ_{max} or E_{max} (E_{max} = hc/λ_{max} with Planck′s constant h and velocity of light c) and the dependence on varying substituents or different solvents can be correlated with the Hammet σ_P parameter[10] and the Kamlet-Taft π* parameter,[8] respectively. With protic solvents and in aqueous solutions, the dependence of the π→π* band maxima on polarity and water content is less clear. The effect of water on the position of the low-energy band in two 4-(donor)-4′-nitroazobenzenes was studied in polyethyleneglycol/water mixtures. Although the polarity of the mixture obviously increased with increasing water content, the λ_{max} values showed a maximum. This could be due to an increased probability of

hydrogen bonding at the electron lone pairs of nitrogen atoms, in particular reducing the pushing ability of the amino group.[11]

Azobenzenes do not emit noticeably at room temperature, but all three types show fluorescence in strong acids at 77K.[12] Modern experimental techniques, however, allow one to study the very weak fluorescence of azobenzene and azobenzene functionalized molecules even at room temperature.[13–15] Görner et al.[16] observed a transient after laser flash photolysis of donor/acceptor-substituted azobenzenes which they assigned to the lowest energy triplet state of the *E*-isomer. Recent studies were directed at examining the behavior of the transient absorption of the singlet excited states of both geometric isomers with respect to time (see Section 89.4).

In aminoazobenzene and 4,4′-donor/acceptor-substituted azobenzenes, the *Z*- form prepared by photoisomerization is more or less thermally instable. Therefore, and due to the overlapping spectra of the *E*- and the *Z*-isomer, the latter can be prepared in a pure state only in some cases. A photostationary state(PSS) with a mixture of *Z*- and *E*- isomers is established on irradiation with conventional lamps. In particular, in rigid matrices or at low temperatures, the PSS can be maintained for some time in the dark to allow recording of the UV/VIS spectra. Assumptions are necessary, both to derive the UV/VIS spectrum of the *Z*-form and to calculate the quantum yields of isomerization (see Section 89.3). The *Z*-pseudostilbene-type molecules generally exhibit lower absorbance and red-shifted, low-energy absorption bands.[17] In methanol/water mixtures with about molar hydrochloric acid, the aminoazobenzene-type molecules and donor/acceptor-substituted azobenzenes become protonated. In the spectra of 4-(phenylamino)-azobenzenes, the long-wavelength band shifts bathochromically to 530–540 nm.[10]

89.3 Photoisomerization of Azobenzenes: Conditions and Quantum Yields

Quantum yields Φ_E and Φ_Z of the $E \rightarrow Z$ and $Z \rightarrow E$ photoisomerization of azobenzenes, respectively, can be determined by steady irradiation monitoring of the absorbance and its dependence on time during the approach to the PSS, or from the absorbance in the PSS. The *E*/*Z*-isomer concentration ratio in the PSS is determined by the incident light I_0, the extinction coefficients ε_E and ε_Z of both isomers, the quantum yields Φ_E and Φ_Z, and the rate constant k_{iso} of the thermal $Z \rightarrow E$ isomerization (see Equation 89.1).[10,18,19]

Photoisomerization of the parent azobenzene molecule has been fairly well studied.[2,3] It is brought about by UV light in the $E \rightarrow Z$ direction and with visible light ($\lambda > 400$ nm) in the $Z \rightarrow E$ direction. As the *Z*-isomer can be isolated, in this special case, isomerization can be studied starting with either the *E*- or the *Z*-isomer. Average quantum yield data are $\Phi_E = 0.25$ and $\Phi_Z = 0.52$ for excitation at 436 nm, and $\Phi_E = 0.11$ and $\Phi_Z = 0.44$ for excitation at 313 nm in n-hexane, respectively.[20] The sum of Φ_Z and Φ_E is not unity, which is usually taken as an indication that both isomerization reactions do not occur on the same potential energy surface. More interesting is the fact that Φ_E is larger for excitation with lower-energy light ($n \rightarrow \pi^*$) compared to excitation with higher-energy light ($\pi \rightarrow \pi^*$). This behavior is an example of a violation of Kasha's rule, which assumes complete deactivation to the lowest excited state before other deactivation and reaction processes occur (see Section 89.4). However, sterically hindered or cyclic azobenzenes, which cannot rotate, give quantum yields independent of the excitation energy. Quantum yields between 0.2 and 0.3 for the *E*-isomer and between 0.5 and 0.6 for the *Z*-isomer were determined.[2] Moreover, photoisomerisation can be sensitized by aromatic triplet sensitizers. The quantum yield of the triplet *E*-isomer is 0.015 while, starting with the triplet *Z*-isomer, a quantum yield of about unity was measured.[6]

Because thermal $Z \rightarrow E$ isomerization can occur, determining quantum yields of aminoazobenzenes is more difficult. They can be determined if the photostationary state shows a different absorbance compared to the starting pure *E*-isomer and if k_{iso} can be measured. 4-Diethylaminoazobenzene and 4-(diethylamino)-4′-methoxyazobenzene gave $\Phi_E > 0.7$ on excitation at 436 nm but lower values of <0.4 were obtained using 366 nm and shorter wavelengths when these were determined at room temperature.[18]

E→*Z* and *Z*→*E* Photoisomerization of Pseudostilbenes

The sum of the quantum yields $\Phi_Z + \Phi_E \approx 1$ was determined for 4-diethylaminoazobenzenes with different substituents at the 4′-position. The value of Φ_Z increased on increasing the electron-withdrawing power of the 4′-substituents or by increasing the solvent polarity.[18] For a series of 4-phenylaminoazobenzenes with different 4′-electron-withdrawing substituents, Φ_E on the order of 10^{-2} was measured from the absorbance in the PSS by means of the Equation 89.1:

$$I_0\ (1 - 10^{-A})\ \Phi_{E\rightarrow Z} = k_{iso}[Z]_0\ N(V/1000) \qquad (89.1)$$

where I_0 is the incident light (quanta per time), k_{iso} is the thermal isomerization constant, $[Z]_0$ is the concentration of the *Z*-isomer in the PSS, N is Avogadro′s number, and V is the sample volume in milliliters (ml).[10] Equation 89.1 was derived by assuming negligible absorbance of the *Z*-isomer at 400 nm. Equations for the determination of both quantum yields Φ_E and Φ_Z at any irradiation wavelength can be found in the literature and are derived from measurements at the PSS or by measurements on approaching the PSS.[18,19] In studies of polyfunctional molecules, photosensitive metal complexes and azobenzene units were combined. Photoisomerization quantum yields of Ru(II) and Rh(III)complexes with azobenzene-bridged bis(terpyridine) ligands strongly depended on the metal, polarity, viscosity, donor site of the solvents, and size of the counterions.[21,22]

89.4 Mechanism of the Photoisomerization of Azobenzenes

Azobenzene

It was shown by sensitization experiments that *E*→*Z* and *Z*→*E* isomerization can proceed via the triplet state. As the quantum yield for sensitized and direct photoisomerization are different, it was concluded that direct photoisomerization proceeds mainly — if not completely — via singlet excited states.[6] From the observation that $\Phi_Z + \Phi_E < 1$ and from nonlinear Arrhenius plots, it was concluded that more than one excited state is involved. As photoisomerization shows the same quantum yields irrespective of ($n\rightarrow\pi^*$) or ($\pi\rightarrow\pi^*$) excitation in the case of azobenzenes unable to rotate, it was assumed that isomerization occurs from the $^1(n\pi^*)$ state.[2,3]

Since the beginning of the debate on the mechanism of azobenzene photoisomerization, two limiting cases were discussed: rotation around the azo bond with a reduced bond order in analogy to stilbenes, or inversion in the plane due to rehybridization of one azo-nitrogen with small changes of the azo π-bond (Figure 89.4).

This discussion stimulated quantum chemical calculations of potential energy surfaces for both isomerization paths in the ground and excited states. The potential energy diagrams of Monti et al.,[23] calculated by means of an early *ab initio* method with configuration interaction (CI), were the basis of discussion for a long time. Their results were generally interpreted as follows: excitation into the $^1(n\pi^*)$ state of both isomers leads to inversion as this reaction coordinate has a minimum half way between *E* and *Z*, where the slope is steeper on the *Z*-side. Energetically, this minimum is near the maximum of the ground state and near the triplet state, where a fast deactivation to the ground state is possible. This conclusion is in accordance with the lack of vibrational structure of the ($n\rightarrow\pi^*$) absorption bands of both isomers, which means that the Franck-Condon states are apart from a minimum. So far, the potential energy curve of the inversion pathway is qualitatively in accordance with most recent quantum chemical calculations (see Figures 89.5A and 89.5B). Because Monti et al.[23] calculated a significant maximum for the rotation path (in contrast to recent calculations, see Figure 89.5A), rotation was hardly discussed anymore for $n\rightarrow\pi^*$ excitation. They found[23] that after population of the $^1(\pi\pi^*)$ state in both isomers, an energetic downhill molecular change is possible only on the rotation pathway where avoided crossings with the rotational coordinate of the $^1(n\pi^*)$ state on both the *E* and the *Z* sides give two minima. At these minima, bifurcation is postulated, which channels deactivation 1:1 into the $^1(n\pi^*)$ and the ground state. This idea is in accord

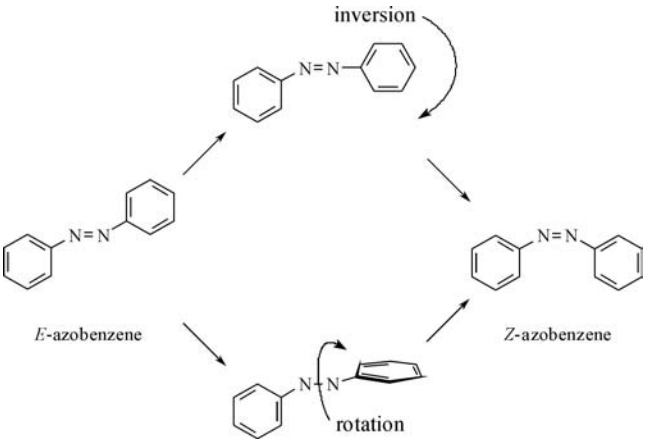

FIGURE 89.4 Rotation and inversion mechanism of azobenzene.

with lower quantum yields Φ_E and Φ_Z after excitation into the $^1(\pi\pi^*)$ state as the $^1(n\pi^*)$ state is bypassed, partly. Therefore, the inversion mechanism should hold irrespective of the excitation path. Rau[19] developed a deviating schematic potential energy diagram. An energetic minimum on the rotation path can be reached that is coupled with the ground state. Accordingly, isomerization on the rotation path after excitation into the $^1(\pi\pi^*)$ state was assumed.

New results of calculations as well as picosecond (ps)- and femtosecond (fs) laser spectroscopy studies have extended the basis for mechanistic discussions. Nägele et al.[24] performed fs transient absorption measurements of the photoisomerization in the $^1(n\pi^*)$ state. They found a very rapid formation of a transient (170 fs after exciting the *Z*-isomer, 320 fs starting from *E*-isomer) and a slower component (2 ps) in both cases. This ultrafast isomerization indicates that the reaction should proceed on a barrierless gradual (inversion) pathway in the direction of a minimum with a steeper slope on the *Z*-side as calculated by Monti et al.[23]

Exciting the $^1(\pi\pi^*)$ state of *E*-azobenzene in n-hexane, Lednev et al.[25] observed transient absorptions at 370 to 450 nm. The decay with a fast (*ca.* 1 ps) and a slower (13 ps) component were assigned to the decay of the $^1(\pi\pi^*)$ state and a bottleneck state of $^1(n\pi^*)$ or $^1(\pi\pi^*)$, respectively. From these bottleneck states, return to the ground state, at least partly on the rotational pathway, and formation of the *Z*-isomer seems possible. Reformation of the ground state occurs with a time constant of 15 ps, similar to the slower decay component of the $^1(\pi\pi^*)$ state. In a second study, Lednev et al.[26] excited both the $^1(n\pi^*)$ state and the $^1(\pi\pi^*)$ state of the *E*-isomer at different energies above the origin. When the $^1(n\pi^*)$ state was excited just above the origin, a transient at 400 nm decayed with a time constant of 2.5 ps, which is attributed to the inversion pathway. An additional fast component with 600 fs when excited >6000cm^{-1} above the origin may arise from motions along other coordinates. After excitation to the $^1(\pi\pi^*)$ state, a transient absorption at 400 nm was observed, which decayed with a major component of 0.9 ps and a weaker component of *ca.* 15 ps. The 400-nm transient rises synchronously with the decay of another band at 475 nm within 200 fs. Again, deactivation of the $^1(\pi\pi^*)$-state via the rotational pathway with the possible formation of the *Z*-isomer is assumed.

In a time-resolved Raman study, Fujino et al.[27] observed an N = N stretch frequency of a 410-nm transient assigned to the vibrationally excited $^1(n\pi^*)$ state. The value of 1427 cm^{-1} is close to that of the ground state. These authors concluded that isomerization occurs by inversion with almost unchanged azo bond and question the theory of a rotational pathway.

Despite the very low fluorescence quantum yields at room temperature, stationary fluorescence spectra and time-resolved fluorescence decay of azobenzene could be studied with high-performance laser and detection equipment. Fujino et al.[15] obtained fluorescence ($n\leftarrow\pi^*$) and ($\pi\leftarrow\pi^*$) bands, which are good mirror images of the corresponding absorption bands, and lifetimes of 110 fs ($^1\pi\pi^*$) and 500 fs($^1n\pi^*$).

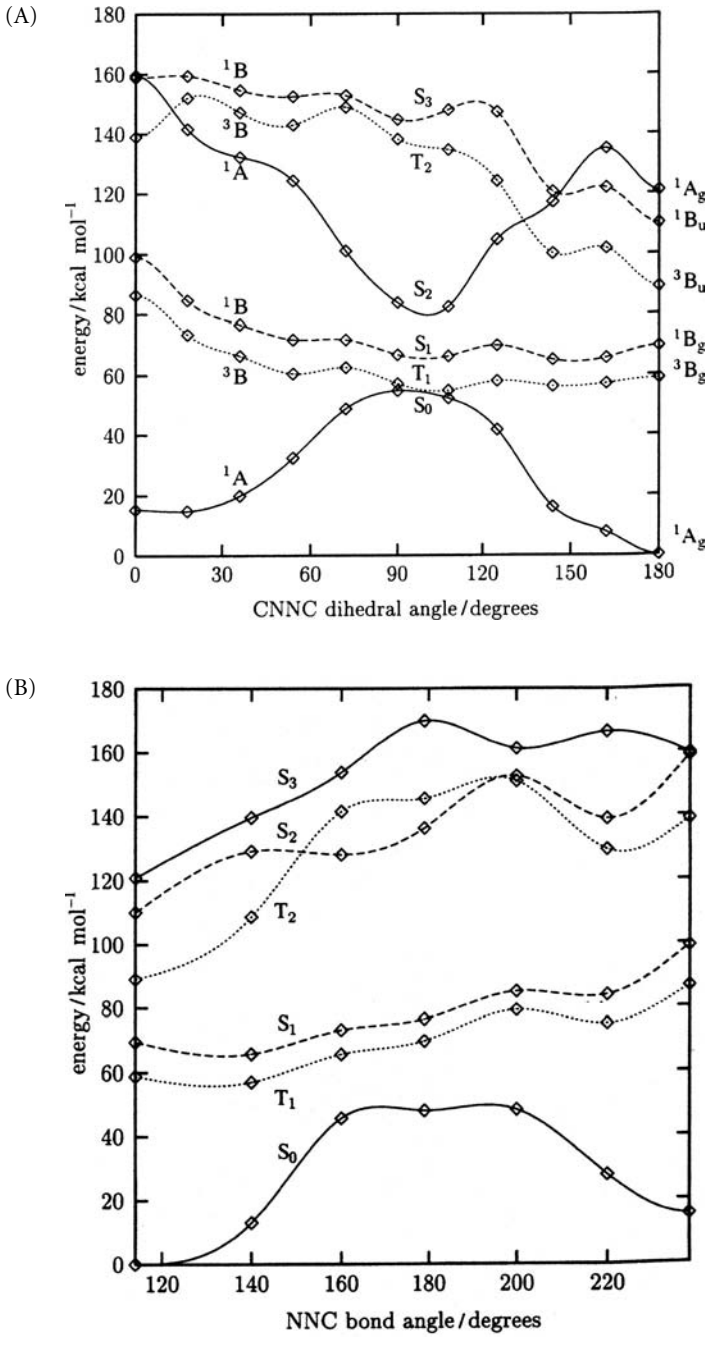

FIGURE 89.5 (A) Potential energy curves for the torsion pathway, CIPSI energies. Left-hand side, *Z*-isomer; right-hand side, *E*-isomer. (B) Potential energy curves for the inversion pathway, CIPSI energies. Left-hand side, *E*-isomer; right-hand side, *Z*-isomer. (From Cattaneo, P. and Persico, M., *Phys. Chem. Chem. Phys.*, 1, 4739, 1999. Reproduced with permission of The Royal Society of Chemistry on behalf of the PCCP Owner Societies.)

Primarily from a comparison of the fluorescence quantum yields, an $^1n\pi^* \leftarrow {}^1\pi\pi^*$ electronic relaxation quantum yield of almost unity was derived. Therefore, these authors concluded that a significant contribution of the rotation pathway starting directly from the $^1(\pi\pi^*)$ state does not exist.

The discussion of all these experimental results refers to and was influenced by the potential energy curves of Monti et al.[23] Now, more recent theoretical studies with more reliable quantum chemical *ab initio* methods are available. By means of CASSCF and multireference perturbation theory, Cattaneo and Persico[28] support the current view that inversion is the preferred pathway for ground-state thermal isomerization and probably also after $n\rightarrow\pi^*$ excitation, although their potential energy curve of the rotation pathway of the $^1(n\pi^*)$ state does not show a significant maximum (see Figure 89.5A).

They find that two states are important in the $\pi\rightarrow\pi^*$ photochemistry of *E*-azobenzene; see Figure 89.5A (2^1A and 2^1B on the rotation path). From the conical intersection at transoid geometry, as well as from the *Z*-isomer, a fast geometrical relaxation into the minimum of $^1(\pi\pi^*)$ should allow isomerization to proceed on the rotational pathway. Ishikawa et al.[29] performed CASSCF–multireference single and double excitation (MRSD) CI calculations and obtained similar results. They found a conical intersection between the $^1(n\pi^*)$ and ground states near the midway of the rotation coordinate. It was concluded that the transition occurs in the vicinity of this conical intersection. Calculated nitrogen–nitrogen bond orders are significantly reduced in the $^1(n\pi^*)$ states of both isomers compared to the ground state. This result is *not* in accord with conclusions from excited-state Raman experiments.[27]

It appears that these recent quantum chemical calculations support the possible contribution of the rotation pathway of the photochemical $E\rightarrow Z$ and $Z\rightarrow E$ isomerizations from the $^1(n\pi^*)$ state. However, these quantum chemical results on potential surfaces of electronically excited states must still be handled with caution. The vertical transition energies, which can be considered a probe for the reliability of the theoretical calculations, do not fully reproduce experimentally determined data and not all geometry parameters could be optimized.[28,29]

89.5 Thermal *Z*→*E* Isomerization

For the parent compound azobenzene and some monosubstituted derivatives, the *Z*-isomers can be isolated at low temperatures. Therefore, rate constants k_{iso} could be determined, starting with the *Z*-isomers in these cases. Arrhenius activation energies between 88 and 100 $kJmol^{-1}$ and A-factors between 10^{12} and $3 \times 10^{13} s^{-1}$ were determined.[30] The *Z*-isomers in particular of donor/acceptor-substituted ("push-pull") azobenzenes are less stable and must be prepared photochemically as short-lived intermediates from the stable *E*-isomers by pulsed or steady irradiation, depending on their lifetime. The formation of *Z*-isomers is indicated by the bleaching of the sample because *Z*-isomers exhibit generally lower absorbance. The return of the original absorbance is followed in the dark. It occurs according to a clean, first-order reaction in homogeneous solution. Whitten and Schanze et al.[8,31] studied thermal $Z\rightarrow E$ isomerization rate constants k_{iso} of "push-pull" azobenzenes. They considered their remarkable solvent dependence as an indication for the rotation mechanism, where a dipolar transition state with a strongly reduced azo bond order would be stabilized in polar solvents. The same effect of an increase of k_{iso} has been found using substituents with increasing +I-effect.[9] Depending on the solvent, lifetimes $\tau_z = 1/k_{iso}$ of microseconds to seconds were determined by means of conventional microsecond flash photolysis. A linear relation between the energy of the absorption maximum of the *E*-isomer E_{max} and $\ln k_{iso}$ was determined in aprotic solvents. It was explained by a similar trend of the charge transfer during electronic excitation of the *E*-isomer and the charge transfer in the transition state of the thermal $Z\rightarrow E$ isomerization.[31] In the case of lifetimes τ_z greater than several seconds, photostationary states with absorbances significantly different from the pure *E*-isomer can be established experimentally and quantum yields can be determined. In this way, Marcandalli et al. determined quantum yields for both $E\rightarrow Z$ and $Z\rightarrow E$ isomerization of 4-diethylaminoazobenzenes with varying 4′-substituent, which add up to unity. These authors could not verify a viscosity effect of the rate and concluded that the inversion mechanism holds.[18]

4-(Phenylamino)-4′-nitroazobenzene with the bulky phenyl group at the amino nitrogen turned out to be a better candidate to detect a rate decreasing viscosity effect as an indication of the rotational pathway. A decrease in k_{iso} with increasing bulk viscosity was determined, comparing simple solvents with highly viscous polyglycols, applying a multilinear regression analysis and taking the polarity of the solvents (E_{max}) into account.[9,11]

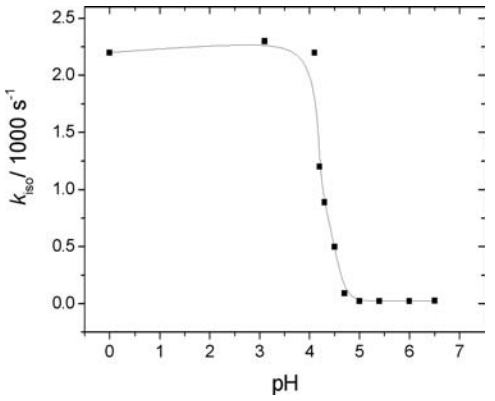

FIGURE 89.6 Plot of the thermal $Z \rightarrow E$ isomerization rate constant k_{iso} of 4-(phenylamino)-4′-nitro-azobenzene in acetone/H_2O (1:1, v:v) vs. pH, established by addition of concentrated HCl (the line is a guide for the eye; $pK_S \approx 4.2$ can be estimated).

In aqueous solutions, protonation of one of the nitrogen atoms — preferably at the N = N double bond — causes a considerable reduction in the activation barrier.[32] Inversely, hydroxide ions decrease the reaction rate.[33] To study thermal $Z \rightarrow E$ isomerization rates of unprotonated azobenzenes in aqueous solutions, the pH of the solution should be clearly above the threshold where protonation influences the rate. The dependence of k_{iso} of 4-(phenylamino)-4′-nitroazobenzene on H_3O^+ concentration in acetone/water (1:1, v/v) mixtures corresponds to a titration curve (see Figure 89.6).[9,34] The flash-photolytic preparation of thermally unstable *Z*-isomers offers the interesting possibility of determining their pK_S-data by means of kinetic experiments.

In aqueous solutions, λ_{max} of the *E*-isomer is strongly influenced by hydrogen bonding. Despite decreasing λ_{max}, indicating apparently lower polarity (see 89-3), the rate constants k_{iso} of the *Z*-isomer continuously increase with increasing water content in poly(ethylene oxide)/water solutions. This is only in part due to the concomitantly decreasing bulk viscosity. By comparing H_2O and D_2O solutions, separating the solvent isotope viscosity effect, there is a significantly higher isomerization rate in H_2O. A dynamic hydrogen-bonding effect was postulated, assuming that the higher frequency in hydrogen-bond making and breaking in H_2O compared to D_2O increases the frequency of electron density fluctuations, which are favorable for approaching the bipolar transition state.[11]

This strong solvent dependence of the absorption maximum λ_{max} and the thermal $Z \rightarrow E$ isomerization rate constants k_{iso} of "push-pull" azobenzenes were used as "spectroscopic" and "kinetic" probes to study aqueous microheterogeneous solutions of surfactants and lipids.[9,11,31,35] The λ_{max} of the stable *E*-isomer indicates that it is solubilized at the head group/water interface, probably more or less aligned with the nitro group to the water side. It was shown that the isomerization rates in solutions of increasing surfactant concentrations decrease with increasing micelle size.[9] The decreasing and vanishing kinetic solvent isotope effect $k_{iso,H_2O}/k_{iso,D_2O}$ (KSIE) indicates decreased accessibility of water to the probe molecules.[9] Interesting non-Arrhenius behavior of k_{iso} of "push-pull" azo dyes was observed in aqueous solutions of triblock copolymers of the poly(ethylene oxide)–poly(propylene oxide)–poly(ethylene oxide) type, which behave as non-ionic surfactants with strong temperature-dominated aggregation behavior. With increasing temperatures, S-shaped Arrhenius plots were obtained, which give decreasing rate constants with increasing temperature due to micelle formation in an intermediate temperature range[11,35] (Figure 89.7).

On structure changes, these "kinetic probes" sensitively reflect the increasing microviscosity and decreasing water content in the microenvironment of the probe molecules, as indicated by decreasing KSIE. In some cases, critical micellization temperatures (cmt) can be derived from these plots. Such systems can be considered as models for the interplay of reaction rates and structure changes in biology.

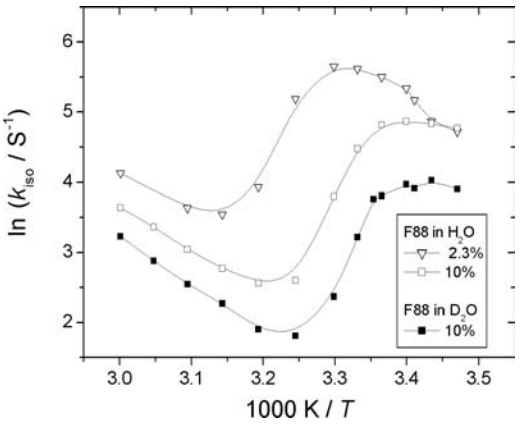

FIGURE 89.7 Arrhenius plots of thermal $Z \rightarrow E$ isomerization rate constants k_{iso} of 4-(phenylamino)-4′-nitroazobenzene in aqueous solutions of the triblock copolymer F88 (poly(ethylene oxide)$_{96}$–poly(propylene oxide)$_{39}$–poly(ethylene oxide)$_{96}$), reflecting micelle formation on increasing temperature. Lines are guides for the eye.

Calculations on transition states of the thermal $Z \rightarrow E$ isomerizations of "push-pull" azobenzenes also became available. *Ab initio* methods, including solvent effects based on continuum models, were applied to 4-(amino)-4′-nitroazobenzene and 4-(dimethylamino)-4′-nitroazobenzene.[36,37] These calculations showed that the transition-state structure of the rotation path was stabilized by the solvent. However, the transition state of the inversion path of the "pull" group is lower in energy than the transition state for the rotation path. Moreover, for 4-(dimethylamino)-4′-nitroazobenzene, the authors concluded that the reaction proceeds by a mechanism of a mixture of the two limiting cases: inversion and rotation.[37] The expected specific solvent interaction with a dipolar transition state, however, cannot be treated with continuum models.

Asano and co-workers studied the effect of pressure on the thermal $Z \rightarrow E$ isomerization of 4-(dimethylamino)-4′-nitroazobenzene in an effort to test the effect of bulk viscosity of the medium on isomerization reactions with respect to reaction rate theories.[38]

Semi-empirical ZINDO calculations showed that the HOMO of 4-phenylaminoazobenzene and 4-(phenylamino)-4′-nitroazobenzene is mainly at the amino nitrogen and the LUMO is localized at the nitrobenzene moiety, confirming the charge-transfer character of the $\pi \rightarrow \pi^*$ absorption band. Protonation at the azo nitrogen leads to a LUMO that is mainly localized at the azo nitrogens. Protonation appears to stabilize the LUMO in accordance with the observed bathochromic shift.[10]

89.6 Applications of the Photoisomerization of Azobenzenes

The change in the absorption spectrum and the molecular structure on photoisomerization of azobenzenes can be used for practical applications. The literature on possible applications in photoresponsive materials was reviewed up to 1988 by Rau.[2] Important contributions by Japanese workers, for example, on light-driven potassium ion transport through membranes by means of crown ethers with a photofunctional azobenzene cap, were recently summarized by Shinkai.[39] Moreover, light-manipulation of other super molecules based on azobenzene photoisomerization is described in the book by Feringa.[40] The $E \rightarrow Z$ *p*hotoisomerization for the preparation of thermally unstable *Z*-isomers for use as "kinetic probes" in microheterogeneous media was described in Section 89.5.

Many studies have been directed toward utilizing azobenzene photochromism in optical data storage devices. However, thermal $Z \rightarrow E$ isomerization limits the stability of the *Z*-isomer and causes information loss. Application of low temperatures is not an alternative for practical reasons. Embedding the photoactive molecules into more rigid matrices improves the stability of such photoswitches. Azobenzene included in microporous zeolites of different structures, such as $AlPO_4$-5 and ZSM-5, shows reversible

photoswitching behavior between the *E* and *Z* states, which is indicated by a remarkable refractive index change for use in all-optical microswitches.[41] Azobenzene-containing melamine resins turned out to be materials with high thermal, optical, and mechanical stability for holographic information storage.[42] First attempts to use thin films of azobenzene-functionalized dendrimers with 32 azobenzene groups in the periphery for holographic materials yielded diffraction efficiencies up to about 20%. The quantum yield of each photoactive unit was not dependent on the total number of azobenzene units present.[43] Other authors studied the light orientation of the azobenzene groups of dendrimers under the action of linearly polarized light.[44,45]

All-optical switching of selectively reflected colors based on isomerization of an azobenzene compound and subsequent change in transmittance were investigated by Ikeda et al.[46] It was found that small amounts of achiral photochromic dopants, as 4,4′-di-n-alkylazobenzenes in cholesteric liquid crystals, accomplished a photo-rewritable, full-color image recording.[47] Molecular switches based on stereoisomers of chiral photoresponsive molecules have the advantage over photochromic systems. The feasibility of nondestructive readout of an optical recording system was demonstrated by monitoring the optical rotation at wavelengths remote from the wavelengths of the actinic light necessary for switching. Azobenzene containing peptide oligomers was used for this purpose.[48]

Liquid crystal forming molecules with donor/acceptor azobenzene units induced and increased the rate of thermal isotropic→nematic phase transition by several orders of magnitude compared to alkoxyl-type azobenzene liquid crystals. These materials suggest their prospective application in real-time holographic materials.[49]

In another field of current activity, the aggregation behavior of amphiphile molecules is modified and controlled by photoswitching of azobenzenes that are covalently linked as a component of some part or all the amphiphilic molecules. Japanese workers collected a large amount of data on photosensitive artificial membranes based on azobenzene derivatives.[50]

Fast osmotic shrinkage of lipid membranes after photoisomerization of azobenzene derivatives and subsequent structure ordering have been demonstrated.[51] Depending on the ratio of azobenzene units containing amphiphiles to other amphiphiles, H-aggregate formation of the azobenzene moieties can occur. The *E*→*Z* isomerization by UV irradiation leads to "catastrophic" destruction of vesicles in the case of azobenzene aggregate or cluster formation.[52] Photochemical switching of vesicle formation in a mixture of an azobenzene-modified cationic surfactant and sodium dodecylbenzenesulfate brought about disruption of the vesicles into larger aggregates on *E*→*Z* isomerization.[53] Wavelength-programmed solute release from photosensitive liposomes based on the photochromism of azobenzene containing lipids was shown by Bisby et al.[54] An azobenzene containing cationic surfactant increased its critical micellization concentration (cmc) from 2.7 m*M* in the *E*-form to 8.2 m*M* in the *Z*-form. In this way, oily substances could be released or up taken by switching between the *E*- and *Z*-forms. The solubilizing capacity could also be varied.[55] Another azobenzene–surfactant also shows the expected increase in the cmc (0.13 m*M* compared to 0.34 m*M*) and of the average area per molecule on the surface (0.60 compared to 0.74 nm^2 per molecule) on switching from pure *E*-isomer to a *Z*-rich mixture on irradiation.[56]

Light control of dynamic surface tension was demonstrated in a mixture of sodium dodecylsulfate and 4,4′-bis(trimethylammonium)hexyloxyazobenzene bromide. A decrease of 25 mN/m was determined on *E*→*Z* isomerization by UV irradiation. Aggregation in the bulk and mass transport of the surfactant to the surface of the solution differ between the isomers. This phenomenon can be used to trigger the release of droplets of aqueous solutions from capillaries.[57] Calix[4]resocinarene derivatives substituted with azobenzenes exhibited reversible precipitation/dissolution in dilute methanol solution upon alternate UV and VIS light irradiation due to the low solubility of the all-*trans* isomer.[58]

The photoisomerism of azobenzenes is one working principle in the regulation of structure and function of biomolecules by light as, for example, the binding of proteins and stimulation of enzyme activity.[59] Photoisomerism of azobenzenes has also been applied to the regulation of bioreactions. By photoregulation of a template-dependent DNA polymerase reaction using photoresponsive oligonucleotides as modulators, DNA of predetermined length is selectively produced from one template DNA.[60]

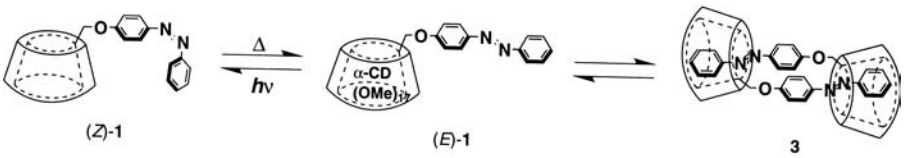

FIGURE 89.8 Monomer(*E*)-1/dimer(3) equilibrium of a permethylated α-cyclodextrin-azobenzene dyad. The equilibrium is disturbed by (*E*)-1→(*Z*)-1 photoisomerization and may be reformed after thermal (*Z*)-1→(*E*)-1 isomerization. (From Fujimoto, T., Nakamura, A. Inoue, Y., Sakata, Y., and Kaneda, T., *Tetrahedron Lett.*, 42(45), 7987, 2001. Reprinted with permission from Elsevier Science. Copyright 2001.)

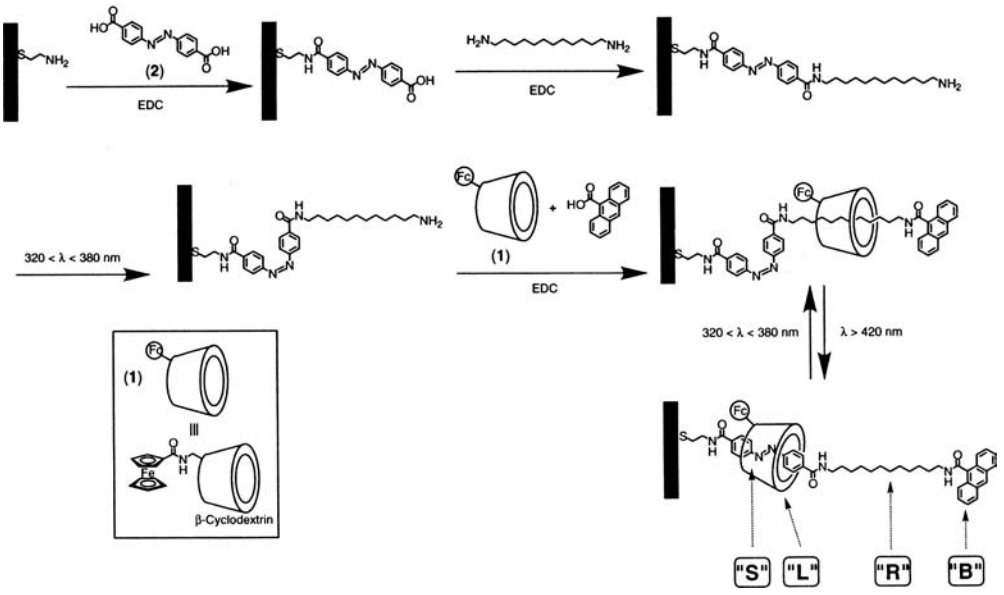

FIGURE 89.9 Organization of the "molecular train" (MT) assembly on a gold electrode and its photoinduced translocation. The MT assembly consists of a station S, a railway R, a locomotive L, and a barrier B (see text). (From Willner, I., Pardo-Yissar, V., Katz, E., and Ranjit, K., *J. Electroanalytical Chemistry,* 497, 172, 2001. Reprinted with permission from Elsevier Science. Copyright 2001.)

The *Z*→*E* isomerization of an azobenzene moiety in the side chain of oligonucleotides reversibly photoregulates the formation and dissociation of the duplex, which is destabilized after switching into the *Z*-form.[61]

Molecular opto-electronic assemblies, which consist of a functionalized gold electrode with a photoisomerizable redox-activated monolayer, enables amperometric transduction of the photonic information recorded by the interface.[62] On-off operation of superstructure formation of hermaphroditic cyclodextrin derivatives is brought about by disturbing the monomer/dimer equilibrium of *E*-azobenzene structures by photoisomerization. When the structures have the *Z*-form, the dimer dissociates. The thermal *Z*→*E* isomerization can be enhanced by heating in favor of the dimer formation (Figure 89.8).[63]

An impressive example of a "molecular machine" was presented by Willner et al.[64] (Figure 89.9). Using the base 1-ethyl-3(3-dimethylaminopropyl)carbodiimide (EDC), a super molecule attached at a gold electrode was synthesized in a stepwise fashion. Here *E*→*Z* photoisomerization of the azobenzene moiety is a necessary step already in the synthetic procedure. By switching photolytic wavelengths between 320–380 and >420 nm, respectively, the movement of the shuttle is activated between the *E*-azobenzene "station" site and an alkyl-chain "railway" component. The distance between the redox active ferrocene label from the electrode is indicated by a chronoamperic response.

All these examples demonstrate the possibility of manipulating self-assembling structures of amphiphiles and artificial supramolecular structures, respectively, by reversible photoswitching between *E*- and *Z*-azobenzene structures. Advancements in the direction of real practical applications will depend on demonstrating the usefulness and stability of such systems.

90.1 Introduction and Applications of α-Diazocarbonyl Compounds

The chemistry of α-diazocarbonyl compounds is closely associated with the Wolff rearrangement[1–5] (see Scheme 1), a versatile reaction that has found wide application in diverse areas of research and technology ranging from long-standing use in organic synthesis[6] to recent examples in surface science.[7] The Arndt-Eistert synthesis utilizes the Wolff rearrangement of α-diazoketones to ketenes in the homologation of carboxylic acids.[6] Wolff rearrangement of cyclic diazoketones leading to ring contraction has been particularly useful in the synthesis of strained small-ring compounds,[8] including four- and six-membered heterocycles.[9] The synthetic applications of ketene nucleophilic[10,11] and electrophilic reactions[12] have also been extensively studied. Ketene radical addition,[5,13–20] bisketene reactions,[5,21] and the chemistry of highly stable silyl-substituted ketenes[22,23] are also active areas of research.

The most extensive application of α-diazocarbonyl compounds is in the lithographic production of integrated circuits used by the computer industry. The majority of photoresist materials involved in this process are α-diazoketone derivatives.[24,25] Upon photolysis, these compounds form ketenes that subsequently react with water to produce carboxylic acids. The difference in carboxylic acid and diazoketone solubility is then utilized to pattern electronic devices.

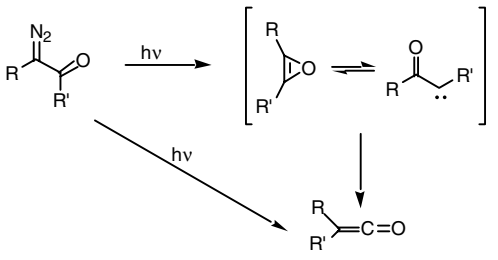


SCHEME 1

Recently, photoinduced Wolff rearrangements have been explored as potential methods of generating DNA cleavage reagents.[26–28] α-Diazoketones absorb UVA (320 to 400 nm) light to produce highly electrophilic ketenes that have intrinsic reaction selectivity toward nucleophilic nucleobases such as guanine and adenine.

As a result of the wide applicability of α-diazoketones, much effort has been applied to understanding the mechanistic pathways available to this class of compounds. Several possible intermediates (e.g., α-carbonylcarbenes, oxirenes, and excited-state species) have played a central role in the proposed mechanisms of the Wolff rearrangement. This chapter examines both experimental and theoretical work that has furthered our understanding of the mechanisms underlying the complex reactivities of these systems.

90.2 Reactive Species Involved in the Wolff Rearrangement

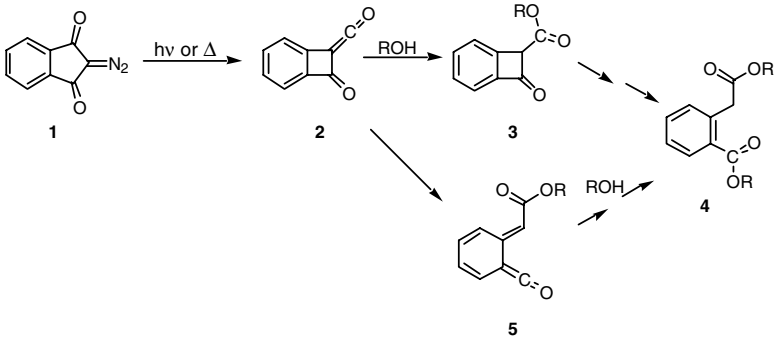
The mechanism of the Wolff rearrangement has been proposed as either the concerted loss of nitrogen and rearrangement to a ketene, or the stepwise loss of nitrogen to give an intermediate carbene (or oxirene) that then rearranges to give ketene (Scheme 1). Carbenes have been detected both directly and indirectly, but the oxirene intermediate has been much more elusive and only indirect evidence is available.

The ketene products of the Wolff rearrangement are by far the most thoroughly characterized and well understood of the reactive species involved.[29] Ketenes are known to undergo both nucleophilic and electrophilic addition reactions, as well as various types of cycloaddition reactions. Of particular interest are the reactions of ketenes with water, alcohols, and amines.

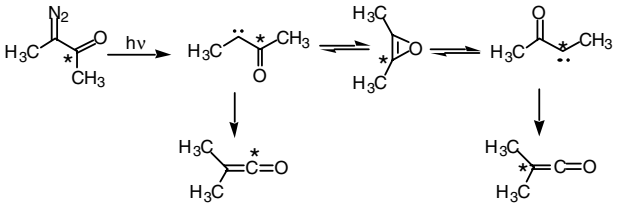
The ketene hydration reaction has been examined recently by time-resolved spectroscopic techniques.[30–34] Intermediate enols have been directly observed in solution,[35–38] although this is not generally the case because ketene hydration is usually slower than enol tautomerization. The hydration rate constants of representative groups of ketenes[30–34,39–41] in aqueous solutions have been obtained and their reactivities rationalized.

The mechanism of the ketene-alcohol addition reaction[30,38,42] depends on the reaction conditions. A time-resolved UV-VIS (TRUV-VIS) study has shown that, under normal photolysis conditions, 2-diazo-1,3-indandione (**1**)[43] in alcohols forms diester **4** via the secondary photolysis of ester **3**. However, under laser drop photolysis conditions,[44] where the laser intensity is very high, the formation of diester **4** occurs via intermediate **5** (Scheme 2).

Spectroscopic methodologies have provided a wealth of information concerning the amination of ketenes.[45,46] Scaiano and co-workers have measured rate constants for ketene reactions with various classes of amines in acetonitrile.[46] The reaction rate is influenced by the basicity of the amine as well as by steric factors in both the ketene and the amine. Ketene amination has also been studied by time-resolved infrared (TRIR) spectroscopy.[47,48] The strong ketene IR band near 2100 cm^{-1} makes it an excellent candidate for study by this spectroscopic technique. Scaiano, Wagner, Lusztyk, and co-workers provided evidence[47] for the first nucleophilic attack being rate determining and that the transition state involves an enol amide. They further found that the asymmetric stretching IR band of substituted ketenes



SCHEME 2



SCHEME 3

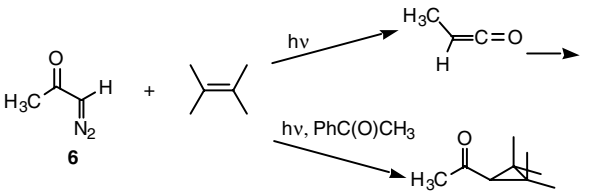
correlates with the inductive parameter of the substituent, but not field or resonance effect parameters. For more stable ketenes, such as $PhMe_2SiCH{=}C{=}O$, the rate of amination is found to be second or third order in amine concentration, by both calculation[49,50] and experiment.[51] Cyclic intermediates have therefore been proposed for these cases.

Recently, other photochemical and thermal retro-Wolff rearrangements have been examined by several researchers.[52–55] Under flash vacuum and pulsed pyrolysis conditions, Wentrup and co-workers observed the formation of (cyanovinyl)ketenes from aza fulvenones.[56] Additionally, Moore and co-workers have done extensive work on the gas-phase photochemistry and molecular dynamics on the C_2H_2O surface using state-resolved spectroscopic methods.[57]

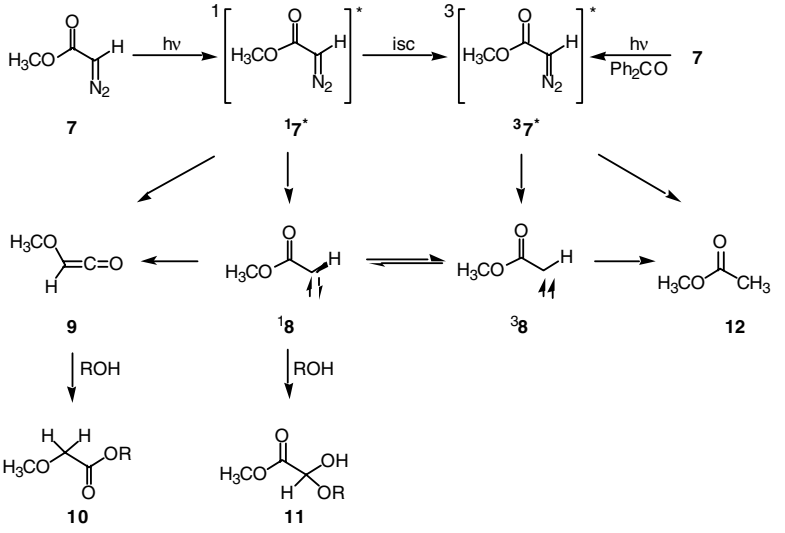
A persistent question concerning the Wolff rearrangement is whether or not an alternate intermediate, such as an excited state of the diazo precursor[58–61] or an oxirene,[62,63] is involved. Carbonylcarbenes have been detected in low-temperature matrices by electron spin resonance (ESR)[64–70] and FTIR[71–75] spectroscopies. Evidence for the participation of oxirenes[62,63] comes from experiments[76–79] in which diazoketones labeled at the carbonyl carbon rearrange to form ketenes that possess a label at both carbon atoms (Scheme 3). Similar results were obtained in studies of unsymmetrically substituted diazoketones.[80,81] The direct observation of oxirene intermediates, however, has been more elusive. Initial reports of oxirene detection[82,83] were later called into question.[84,85] Bodot and co-workers have advanced evidence for the existence of dimethyloxirene and its deuterated analogue by low-temperature FTIR methods.[86,87]

90.3 Singlet vs. Triplet Reactivity

Previous classical studies have clearly indicated that the Wolff rearrangement takes place in the singlet rather than triplet manifold.[88,89] For example, Jones and Ando found that the photolysis of diazoacetone **6** in olefin solution leads only to Wolff rearrangement products (Scheme 4). Carbene adducts, however, were isolated upon triplet-sensitized photolysis, demonstrating that the singlet state of either the diazo precursor or the carbene is involved in the Wolff rearrangement.



SCHEME 4



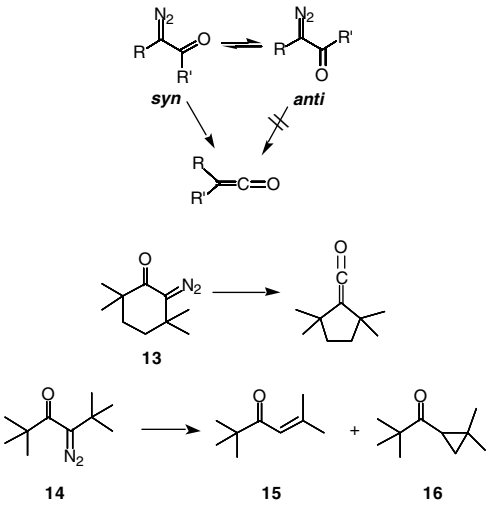
SCHEME 5

Further insight into the multiplicity of the species involved was obtained by Tomioka and co-workers in their thorough study of the photochemistry of methyl diazoacetate **7** (Scheme 5). They demonstrated that direct photolysis of **7** produces an excited singlet state (^{1}**7***) that may suffer Wolff rearrangement concurrent with nitrogen extrusion to yield ketene **9**, lose nitrogen to form the singlet carbene ^{1}**8,** or intersystem cross to give the triplet diazoester ^{3}**7***. The ketene and singlet carbene intermediates are both trapped by alcohol, but give different products, **10** and **11**, respectively. Reduction product **12** is clearly derived from a triplet species, ^{3}**7***, ^{3}**8**, or both, because its yield is enhanced upon triplet-sensitized photolysis but is suppressed by the triplet quencher piperylene, following direct photolysis.

The alcohol insertion product **11** is still formed upon sensitized photolysis of **7**, demonstrating that the triplet carbene ^{3}**8** can interconvert to the singlet carbene ^{1}**8**. Hutton and Roth previously demonstrated, by low-temperature ESR spectroscopy, that ^{3}**8** is the ground state of the carbene.[67] Thus, Tomioka's results show that the more reactive singlet carbene is close in energy to the triplet ground state. In addition, because formation of ketene **9** is suppressed upon triplet sensitization of **7** in neat alcohol, any singlet carbene that is formed must react with neat alcohol faster than it can undergo Wolff rearrangement.

90.4 Role of Conformation

Several studies have indicated that the conformation of the diazo precursor plays a critical role in the pathway of the Wolff rearrangement. Kaplan and co-workers were the first to demonstrate that diazocarbonyl compounds exist as an equilibrium mixture of *syn* and *anti* forms and that concerted rearrangement

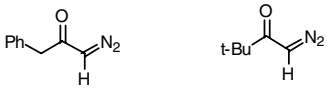


SCHEME 6

is facile from the *syn* conformation, but less likely in the *anti* form (Scheme 6).[90,91] They found that photolysis of 3,3,6,6-tetramethyl-2-diazocyclo-1-hexanone (**13**), which is locked in the *syn* conformation, leads almost exclusively to the Wolff rearrangement product. On the other hand, photolysis of 2,2,5,5-tetramethyl-4-diazo-3-hexanone (**14**), which exists predominantly in the *anti* conformation, produces no ketene.[92] Instead, only carbene derived products, mainly **15** and **16**, are obtained (Scheme 6)

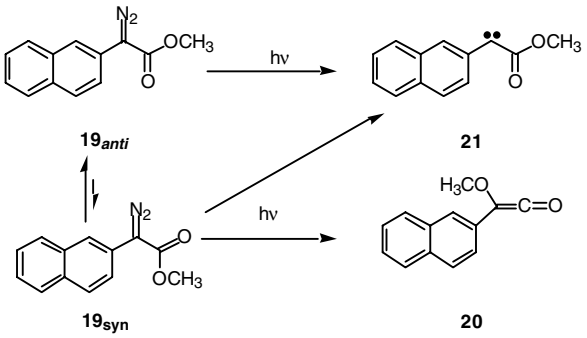
In general, Kaplan and co-workers found that the *syn* form is highly preferred in alkyl diazoketones, but that the *syn* and *anti* forms are present in approximately equal amounts in the case of diazoacetic esters.[90,91] These conformational preferences might be the underlying reason that intermolecular carbene chemistry is much more prevalent in carbene esters than in simple ketocarbenes.[1–5,93]

Tomioka and co-workers expanded on Kaplan's work in their investigation of a series of compounds, including diazoketones **17** and **18**, which exist predominantly in the *syn* conformation.[94] Direct photolysis of these compounds in methanol results almost exclusively in Wolff rearrangement-derived products. However, triplet-sensitized photolysis results in a significant decrease in Wolff rearrangement along with the appearance of carbene-derived products. These results support Kaplan's hypothesis that diazocarbonyl conformation is preserved in the singlet excited state and that rearrangement occurs in concert with nitrogen loss from the *syn* conformer.



90.5 Spectroscopic Studies of Intermediates Involved in the Wolff Rearrangement

TRUV-VIS spectroscopy is an established method that has been routinely applied to the study of carbene chemistry.[95–100] Obviously, to study an intermediate of interest by absorption spectroscopy, it must possess a useful chromophore in the UV-VIS region. To study spectroscopically "invisible" carbenes, Platz and co-workers introduced the pyridine-ylide probe methodology.[48,101] Here, carbenes without useful absorptions react with probes such as pyridine to form strongly absorbing ylides from which kinetic data can be derived.[48,100,101]



SCHEME 7

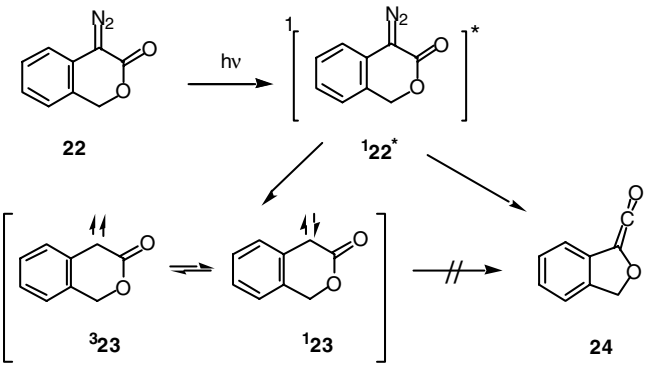
Recently, TRUV-VIS studies have made significant contributions to understanding the chemistry of carbonylcarbenes and to clarifying the mechanism of the Wolff rearrangement.[93] Aromatic substituents adjacent to the carbene center significantly prolong the carbene lifetime. For example, phenylcarbomethoxycarbene[102] has a lifetime of 461 ns and 2-naphthyl(carbomethoxy)carbene[103] has a lifetime of 2.2 μs in Freon-113 (1,1,2-tricloroflurоethane). On the other hand, non-aryl carbenes, such as carboethoxycarbene,[104] dicarbomethoxycarbene[105] and its mono- and di-sulfur analogues,[106] and simple ketocarbenes,[107] have lifetimes of only several nanoseconds in the same solvent.

TRUV-VIS studies have also provided evidence to support the role of conformation in the rearrangement reaction.[93] For example, a series of simple diazoketones $RCON_2H$, where R = H, Me, *i*-Pr, and *t*-Bu, has been examined by laser flash photolysis methods[107] and also by picosecond transient grating spectroscopy.[108] Within this series, as the steric bulk of R increases, the extent of the *anti* diazoketone conformer present at equilibrium decreases relative to the *syn* conformer. Consistent with a direct rearrangement pathway leading to ketene via only the *syn* conformer, the amount of trappable carbene intermediate decreases as R becomes more bulky.

The role of diazocarbonyl precursor conformation has also been addressed recently by nanosecond TRIR methods with which the kinetics of the rearrangement process can be monitored directly.[109,110] When excited-state contributions are important, the ketene growth rate will be unresolvable on the nanosecond timescale (assuming a diazocarbonyl excited-state lifetime beyond the time resolution [50 ns] of the TRIR experiments performed). Thus, ketene production from only an excited state is indicated by a fast, unresolvable increase in ketene IR absorbance following laser photolysis. Production only from a relaxed carbene intermediate, on the other hand, would be revealed by a rate of ketene growth equal to that of carbene decay. For diazoester **19**, the observed rate of ketene growth is equal to the rate of carbene decay, clearly demonstrating that ketene **20** arises entirely from carbene **21** (Scheme 7).

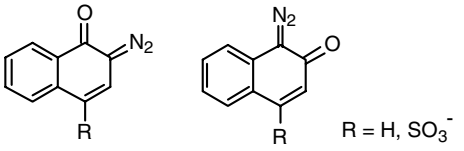
This result is in excellent agreement with the alcohol-trapping experiments of Platz and co-workers,[103] who isolated essentially only carbene-derived adducts and with the calculations of Zhu et al.[111] Those calculations indicated that diazoester **19** is planar and exists almost entirely (99%) in conformations in which the diazo and carbonyl groups are *anti*. Thus, the preferred conformation of **19** leads to efficient carbene production upon photolysis with very little, if any, direct rearrangement to ketene **20**.

The lack of excited state involvement for **21** is in contrast to the behavior in systems that have substantial equilibrium concentrations of the *syn* conformer. To examine the effect that conformation has on ketene growth kinetics, 4-diazo-3-isochromanone (**22**),[109] a cyclic analogue (phenyl version) of **21** that is locked in the *syn* conformation, was also recently studied by TRIR spectroscopy. In this case, a carbene IR band is observed at 1686 cm^{-1} that decays with a lifetime of 526 ± 50 ns in Freon-113. The ketene IR band at 2116 $cm,^{-1}$ however, in dramatic contrast to the data observed with acyclic diazocarbonyl **21**, is produced faster than the experimental time resolution. Ketene **24,** therefore, is formed entirely from a non-carbene source, presumably the excited state of **22** (Scheme 8). In agreement with this hypothesis, oxygen and methanol quench carbene **23**, but they leave the initial intensity of the ketene IR band unaffected. These



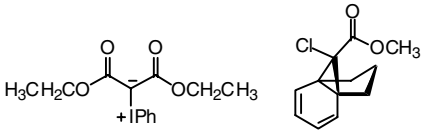
SCHEME 8

results are consistent with other photochemical studies of **19** and the related diazo-naphthoquinones **25**[112,113] and **26.**[114]



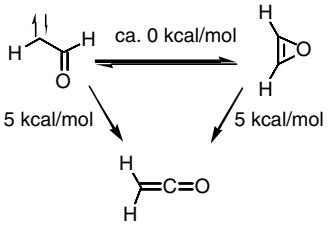
The photoinduced Wolff rearrangement of 5-diazo-1,3-dioxan-4,6-dione has also been examined by TRIR methods.[115] These ultrafast measurements, conducted in a PMMA matrix, revealed that the formation of the ketene rearrangement product was complete within 20 ps; a carbonylcarbene was not detected in this study.

Due to the complication of alternate pathways involved in the photochemistry of diazo compounds or diazirines, new strategies for carbene generation from non-nitrogenous precursors have been studied. Phenyliodonium ylides[116] (**27**) and methyl-8-chloro-3a,7a-methanoindan-8-carboxylates[117] (**28**) are alternative precursors to dicarboethoxycarbene and carbomethoxychlorocarbene, respectively. Photoreactions from these precursors presumably will not be plagued by the excited-state chemistry observed for the diazo compounds and diazirines.

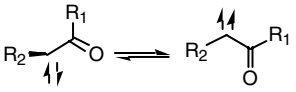


90.6 Computational Studies of the Intermediates Involved in the Wolff Rearrangement

The intermediates involved in the Wolff rearrangement have also been probed computationally. Whether oxirene is a real minimum or a transition state on the potential energy surface is extremely sensitive to the theoretical method used. Schaefer, Radom, and co-workers have calculated the C_2H_2O potential



SCHEME 9



SCHEME 10

energy surface, which includes formylmethylene, oxirene, and ketene, at several levels of *ab initio* theory.[118,119] At their highest level of theory (CCSD(T)/ccpVTZ or CCSD(T)fc/TZ2P(f,d)), they found that there is little or no barrier separating singlet formylmethylene and oxirene, but that both of these intermediates must pass over a 5-kcal mol^{-1} energy barrier to form ketene (Scheme 9). A more recent computational study using density functional theory,[120] on the other hand, predicts oxirene to be a transition state using the B3LYP or the B97-1 hybrid functionals. However, with the B97-2 hybrid functional, oxirene is predicted to be a minimum with formylmethylene 2.1 kcal mol^{-1} lower in energy than oxirene. The Wolff rearrangement barrier is predicted to be 2.9 kcal mol^{-1}.

More recently, Scott, Platz, and Radom have performed *ab initio* calculations on a series of carbonylcarbenes at the G3(MP2)//B3LYP level of theory.[121] In contrast to formylcarbene, carbohydroxycarbene, and carbomethoxycarbene, they predict that chloro- and fluoro-substituted carbonylcarbenes have singlet ground states and that the carbomethoxychlorocarbene will have a singlet-triplet splitting of −3.82 kcal mol^{-1}. (A negative sign indicates that the singlet is of lower energy.) They also predict that the barrier to Wolff rearrangement for the chloro- and fluoro-substituted cases is between 14 and 18 kcal mol^{-1} compared to 2.4 to 7.2 kcal mol^{-1} for the parent carbonylcarbene.

90.7 Solvent and Substituent Effects on the Singlet–Triplet Energy Gap

Calculations[118,119] predict that the triplet states of simple carbonylcarbenes exist in planar conformations while the lowest-lying singlet state is nonplanar with a closed shell configuration (Scheme 10). This orthogonal orientation of the singlet allows donation of the in-plane oxygen lone pair of the carbonyl group to the empty p orbital of the carbene center. In addition, this arrangement also allows the filled σ^2 orbital of the carbene to be in conjugation with the π–system of the carbonyl group. These electron interactions dramatically lower the singlet energy and the singlet–triplet splitting relative to carbenes without adjacent carbonyl groups. Several factors, such as substituent[122–125] and solvent effects,[126] can influence the singlet–triplet splitting and consequently the carbene reactivity.

One complication in the study of carbonylcarbenes is that they generally have a triplet ground state, but the chemistry of the Wolff rearrangement occurs on the singlet surface. As discussed, calculations[121] predict that carbomethoxychlorocarbene possesses a singlet ground state due to the stabilization of the singlet carbene by chlorine subtitution.[127–132] The Wolff rearrangement of this carbene, therefore, is not complicated by the surface crossings required by other triplet ground-state carbonylcarbenes. In agreement with these calculations, carbomethoxychlorocarbene generated in a low-temperature matrix was observed to have a singlet ground state and its rearrangement chemistry has been examined.[117]

Bally, McMahon, and co-workers have recently reported thorough low-temperature spectroscopic and computational studies of the singlet and triplet states of carbene **21**.[111] Very interestingly, they observe reversible interconversion of ^{1}**21** and ^{3}**21** in argon matrices. The barrier between the two spin states is presumably due to the pronounced change in conformation of the carbomethoxy group and may be enhanced in a solid matrix environment.

The solvent dependence of the singlet–triplet energy gap (ΔG_{ST}) for carbene **21** has recently been examined by TRIR spectroscopy and computational methods.[126] The TRIR experiments suggest that ^{3}**21** is favored enthalpically in hexane, but that the singlet is favored in acetonitrile. The preferential stabilization of the singlet carbene is the result of its increased dipole moment in polar solvents and is consistent with the zwitterionic nature of singlet carbenes. The magnitude of the observed solvent effect (approximately 1 kcal mol^{-1}) is comparable to that observed experimentally[133–136] and computationally[137–140] for other carbene systems. Variable-temperature TRIR experiments provide estimates of ΔH_{ST} and ΔS_{ST}, and suggest that solvent and geometrical effects on the entropy of singlet and triplet carbenes can offset the entropic differences arising from spin multiplicity. Density functional calculation using the polarizable continuum solvation model reproduces the general trends in enthalpic differences observed experimentally.[126]

The effects of aromatic substitution on the singlet–triplet gap of substituted phenyl(carbomethoxy)carbene have also been examined by TRIR and computational methods.[123] The *p*-nitro analogue is predicted to have a triplet ground state with a $\Delta G_{ST} = 6.1$ kcal mol^{-1} and the *p*-amino analogue is predicted to have a singlet ground state with $\Delta G_{ST} = -2.8$ kcal mol^{-1}. Predictions of $\Delta G_{ST} = -3.9$ and 1.6 kcal mol^{-1} in the gas phase for the *p*-methoxy and *p*-methyl cases, respectively, have also been made. To model the effects of solvent on the splitting energy, the polarizable continuum model (PCM) was used and predicts ΔG_{ST} of −3.9 and 1.3 kcal mol^{-1}, respectively, in acetonitrile. No solvent perturbations were observed in the TRIR spectra for the parent and *p*-dimethylamino cases, which is consistent with the ground state lying greater than ±2 kcal mol^{-1} from the next electronic state as predicted by the above calculations. Solvent perturbations, however, were observed in the TRIR spectra of the *p*-methoxy and *p*-methyl cases, which is consistent with their ground states lying less than ±1 kcal mol^{-1} away from the next available electronic states. All of these results are consistent with the expected effects of substitution on the benzylic stabilization of carbenes.

90.8 Conclusions

Recent studies of α-diazocarbonyls have helped to clarify their chemistry and have confirmed previous hypotheses concerning the mechanism of the Wolff rearrangement. Clearly, it has been shown that the reaction is mediated in the singlet manifold and that the conformation of the diazocarbonyl precursor has a very significant effect on the resulting photochemistry. It is interesting to note that a reaction discovered at the beginning of the last century is still receiving attention and stimulating new experiments, even at the dawning of a new century.

91.1 Introduction

The chemistry of reactive intermediates has always occupied a significant place in all branches of chemistry. Carbenes, as an example of these intermediates, have been the subject of many interesting studies concerning generation, reaction mechanism, selectivity, multiplicity, and even stability studies. It is no exaggeration to claim a major role for these fascinating species in the modern chemist's armory for the synthesis of a large number of interesting compounds.

In the past decade or so,[1,2] our understanding of carbene chemistry has advanced dramatically with the preparation of persistent triplet diarylcarbenes[3] and the isolation of heteroatom-substituted singlet carbenes.[4] From this and other work it is clear that the common statement that carbenes only occur as reactive intermediates is no longer valid. Stable carbenes have attracted little attention until quite recently, when two groups announced the discovery of phosphinocarbenes as a distillable red oil in 1988[5] and imidazo-2-ylidene as high-melting crystals in 1991.[6] However, these carbenes are stabilized by substituents with a heteroatom connected to the carbenic atom and thus have a singlet ground state.

Surprisingly, except for the article by Zimmerman and Paskovich in 1964 dealing with dimesitylcarbene,[7] no serious attempts to generate stable triplet carbenes appeared in the literature until the account in 1990 by Tomioka.[3]

The correct name of carbenes is obtained by attaching either the prefix "carbena" or the suffix "ylidene" to the name of the skeleton from which it is derived. Carbenes are neutral compounds with a divalent carbon atom with only six electrons in the valence shell and in which the two non-bonded electrons may be either paired (singlet) or unpaired (triplet). Considering the simple carbene –C:–, the carbon atom can be either linear or bent; each geometry is describable by a certain degree of hybridization. The linear geometry implies an sp-hybridized carbene center with two non-bonding degenerate orbitals (p_x and p_y). Bending the molecule breaks this degeneracy and the carbon atom adopts sp^2-hybridization. The p_y orbital (p_π) remains almost unchanged while the p_x orbital is stabilized because it acquires some s character.[1] The influence of substituents on the carbene ground-state multiplicity can easily be analyzed in terms of electronic and steric effects.[1] The multiplicity of the ground state of a carbene is related to the energy of the σ and p orbitals. The singlet ground state is favored by a large σ–p separation. Hoffman found that a value of at least 2 eV is necessary to impose a singlet ground state, whereas a value below 1. 5 eV leads to a triplet ground state.[1,8]

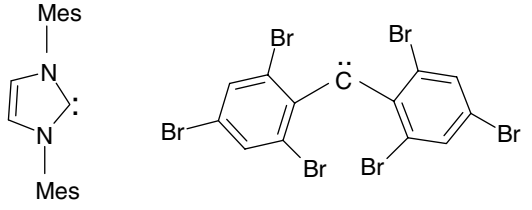
Singlet and triplet carbene

As illustrated above, a carbene can exist, in principle, as a singlet $^1(\sigma^2)$ or as a triplet $^3(\sigma^1 p^1)$ species.[8,9] Higher excited configurations are possible but do not play a major role in preparative experiments. Whereas triplet carbenes exhibit radical-like reactivity, singlet carbenes are expected to show nucleophilic as well as electrophilic behavior because of the lone pair and vacant orbital. Due to their electron deficiency, carbenes, in general, have only fleeting existence and usually behave as transient electrophilic intermediates. However, Wanzlick, after a long debate, was the first one to realize in the early 1960s that electron deficiency of the carbene center can be reduced by electron donation of the appropriate substituent (e.g., amino), resulting in stabilized and less-reactive carbenes with nucleophilic properties.[10] Since the description of stable carbenes by Bertrand and Arduengo, the exploration of their chemical reactivity both experimentally and theoretically has become a major area of current main group chemistry.

In 1991, Arduengo comprehensively characterized a stable, crystalline nucleophilic (singlet) carbene. Since then, numerous derivatives have been reported, including 1. More recently, in 1997, Tomioka isolated the persistent electrophilic triplet carbene 2.[3,11]



1 **2**

Theoretical approaches have been applied to understand the features that are responsible for the stability of imidazole (in)-2-ylidine. Density Functional theory (DFT) was applied in this respect.[12]

Studies examining the relationship between structure and reactivity have shown that thermodynamic stabilization (electronic conjugation effect) usually plays an important role in stabilizing the singlet state and it can become less reactive to such an extent that it can be isolated under ambient conditions.

On the other hand, kinetic stabilization (steric protection) is more effective in stabilizing the triplet counterpart because the introduction of bulky groups around the carbene center results in an increase in the carbene bond angle and therefore must make ΔG_{ST} larger. In this case, the triplet state is thermodynamically stabilized with respect to the singlet.[3,13]

This chapter focuses on the generation of carbenes by extrusion of nitrogen (Tables 91.1 through 91.8). Several other methods are possible, such as the formation from tosylhydrazone salts, oxiranes, aziridines, dioxolanes, and pyrazolenines from cyclopropanes by photocycloelimination, from transition-metal carbene complexes or by α-elimination, from α,α-dihalogen compounds,[14,15] or from base treatment of *N*-nitrosocarbamate.[16]

Carbenes, as reactive species, are detected by flash spectroscopy. This method is also used to directly measure the rate constant of the addition reactions of free carbenes to olefins. UV absorption spectroscopy of chlorophenylcarbene (Figure 91.1) generated from 3-chloro-3-phenyldiazirine (Scheme 1) and its rate of addition to different olefins have been measured (see Table 91.2), for example, at 77K and 293K in isooctane.[17a]

*C-X insertion is not included in this survey, because the emphasis is on the synthetic use of carbene chemistry

SCHEME 4 Intramolecular reactions.

A further method available for the study of triplet carbenes exclusively is ESR spectroscopy. CIDNP experiments are used as well to investigate the spin state of carbenes in solution. Generation of a carbene from 3*H*-diazirine or diazo compounds by thermolysis or photolysis with evolution of nitrogen yields a free carbene (Schemes 1 and 2).

Other methods involving base–-nduced α-elimination from haloalkanes often include the formation of a carbenoid (Scheme 3).

Relative reactivity of olefins with bromophenylcarbene generated either (1) by irradiation of 3-bromo-3-phenyldiazirine or (2) from base-induced α-elimination of α,α-dibromotoluene in the presence and in the absence of 18-crown-6 showed that addition of 18-crown-6 (via the complex of carbene with KCl/KO-*t*-butanolate) as well as photolysis of diazirine afforded the free carbene.[19] α-Elimination normally proceeds via carbenoids (Scheme 3).

The relative reactivities of alkenes with bromophenylcarbene are given in Table 91.3.[19-21]

Carbenes can react either (1) intramolecularly or (2) intermolecularly. The basic reactions are addition and insertion. Triplet carbenes can also react via an abstraction mechanism. As typical examples, the intra- and intermolecular reactions with a double bond are shown in Schemes 4 and 5, respectively.

As a matter of convenience, the generation of each type of carbene will be treated separately.

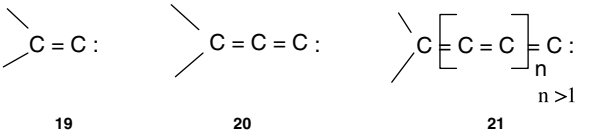
91.2 Formation of Carbenes

Carbene of Coordination Number 1



19 **20** **21**

Alkylidene **Alkenylidene** **Alkpolyenylidene**

Type 1 carbenes $R_2C(=C)_n=C:$ ($n = 0 \rightarrow \infty$) are mainly formed by methods that include α-elimination, although thermal extrusion of nitrogen was reported from tetrazolones[23] and 1-aryl-2-diazo-2-oxo-1-silylethane[24] or from 2,3-bis[*N*-nitrosoacyl-amino]-1,1-diphenylcyclopropane[25] (Scheme 6).

Carbenes of Coordination Number 2

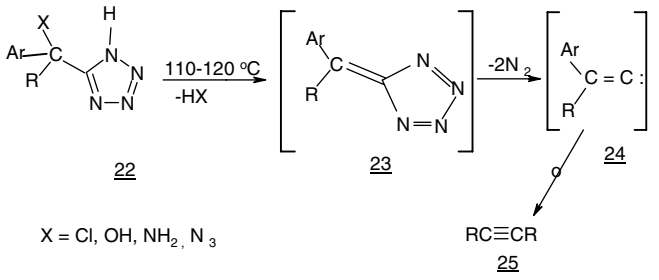
Acyclic Homocarbenes (Methylene, Alkyl-, Dialkyl-, Alkenyl-, and Alkynylcarbenes)

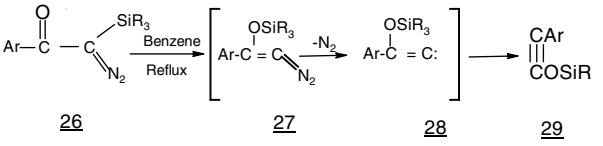
3H-Diazirine.

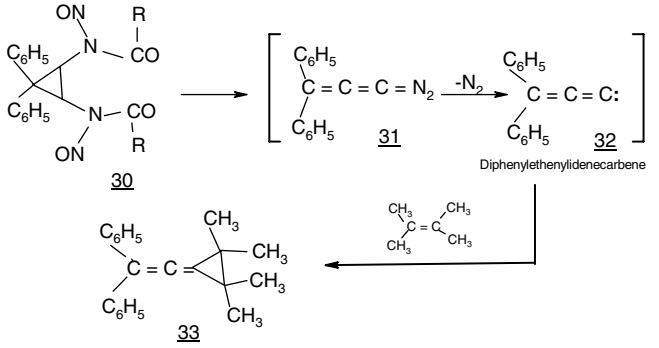
Herzberg and collaborators[26-28] provided the first experimental evidence that a meta-stable, bent singlet was initially produced from diazoalkane and decayed to a ground-state triplet.[29,30] The liquid-phase chemistry of methylene, for example, is simple in comparison with its gas-phase chemistry. However, hot molecules produced by extremely exothermic reactions of methylene play a minor role in the gas phase. Carbenes have been used on countless occasions to make three-membered rings via [1+2]-cycloaddition.

Photolysis and thermolysis of suitably substituted diazirines could be considered an ideal method for the generation of free methylene as well as for alkyl- and dialkylcarbenes. Diazirines are preferred precursors compared to acyclic diazo compounds because of their stability and ease of handling.[31]

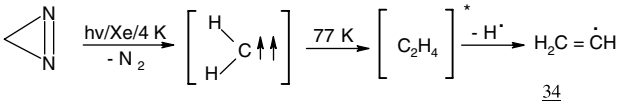
The parent 3*H*-diazirine reveals a weak absorption (ε_{max} = 200) in the range of 280 to 350 nm. Photolysis of 3*H*-diazirine in a xenon matrix at 4 K (Scheme 7) gives triplet ground-state methylene; at 77 K, subsequent dimerization and irradiation afford ethenyl radicals.[32-34]







SCHEME 6

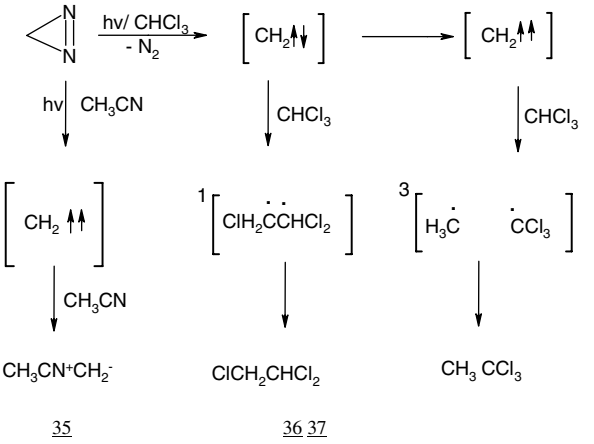


SCHEME 7

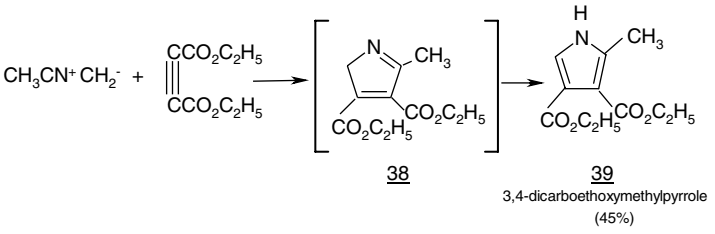
The singlet–triplet energy difference of methylene was found to be about 7.5 kcal.mol^{-1}.[35] Direct photolysis of 3*H*-diazirine in chloroform gives 1,1,2-trichloroethane (92% yield) by carbon chlorine insertion, while in the presence of tetradecane, the carbon-hydrogen insertion product 1,1,1,-trichloroethane is formed. These are illustracted in Scheme 8 and identification was carried out using CIDNP NMR measurements to demonstrate the formation of singlet biradicals.[36,37]

In acetonitrile as solvent, irradiation of diazirine gives a nitrile-ylide as a primary product with an absorption at 280 nm (Scheme 9). The ylide was characterized by Turro[38,39] using the pulsed laser technique. It undergoes 1,3-cycloaddition reactions with diethyl acetylenecarboxylate.[40]

An interesting finding was obtained with 3-isopropyl-, 3-*t*-butyl-, and 3- (1-methyl -1-phenylethyl-3*H*-diazirine (Scheme 10). Sensitized photolysis of **40** gives similar results to those obtained by thermolysis either in the gas phase or in decalin (Table 91.6). However, direct photolysis of **40** in benzene



SCHEME 8



SCHEME 9

leads to similar products but in different ratios. This can be explained by the formation of an electronically excited, less-selective carbene upon direct photolysis, [15,41-44] a result supported by the work of Frey and Stevens.[43]

Diazoalkanes.

As early as 1901, Hantzsch and Lehmann[45] and Staudinger and Kupfer[46] reported on the photochemical and thermal decomposition of diazomethane to afford methylene. Subsequently, Hine[47] and Doering [48] started the **era** of carbene chemistry and excellent reviews were published.[49,50] Compared to other methods, the generation of carbene from diazoalkanes finds wide application despite the toxicity and the tendency of low-molecular-weight diazoalkanes to explode. Diazoalkanes show a weak UV absorption band between 300 and 500 nm, assigned to a forbidden n,π^* transition. Photoexcitation of the long-wavelengh bands of diazo compounds results in an excited singlet state, which may react as shown in Scheme 11.

The rate of disappearance of the diazo compound, that is, the quantum yield of the photolysis, should be independent of the nature and concentration of reactants. This is the criterion for the intermediacy of free radicals. Diazomethane shows a weak UV absorption band between 300 and 500 nm and a sharp band between 200 and 260 nm.[49-52] Photolysis into this band brings about elimination of nitrogen and produces methylene (Scheme 12).

An important new reaction in the chemistry of carbenes is its addition to fullerenes. Addition of CR_2, generated from diazoalkane by the loss of N_2, to pent-hex and hex-hex edges of C_{60}, both with retention and breakage of the carbon-carbon edge bond takes place. The stereochemistries and stabilities of $C_{60}(CR_2)_n$ were investigated.[53]

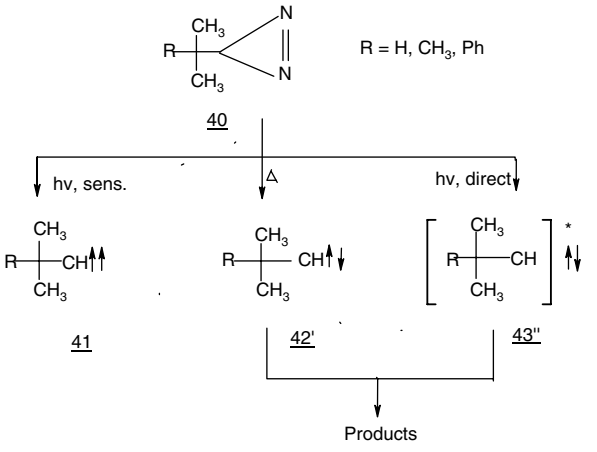

SCHEME 10

Scheme 13 shows the addition of CR_2 to pent-hex and hex-hex edges of C_{60} (46) with retention and breakage of the carbon-carbon edge bond. The movement of the double bond character onto pent-hex edges in the pent-hex bond-intact isomer and the hex-hex bond-broken isomer is indicated.[53]

Evolution of nitrogen from higher diazoalkanes gives the corresponding alkylcarbenes that may undergo (1) intramolecular insertion into β-CH bonds; (2) [1,2]-hydride, alkyl, or aryl shifts; or (3) intramolecular addition in the presence of double bonds as shown in Scheme 14.

By comparison, thermolysis of 1-diazo-2-methylpropane gave only methyl-cyclopropane (33%) and isobutene (67%). Many other carbenes were generated via thermolysis and/or photolysis of the corresponding

diazo precursors (see References 51, 52, 54, and 55). Kirmse and Horn[54] found, in a study of the catalytic, thermal, and photolytic decomposition of diazoalkanes in various solvents, that similar to diazirines, the photodecomposition gave a less-selective intermediate than the thermal reactions. Broadly speaking, it

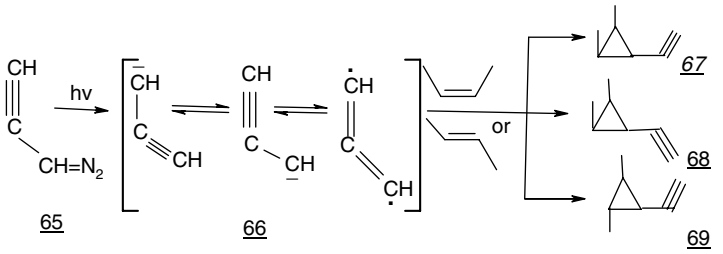
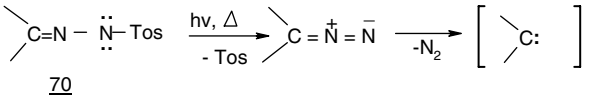
can be said that free carbenes are formed from diazo compounds in photochemical and thermal reactions, whereas all other methods yield carbenoids.

Alkenylcarbenes

The situation completely changes when the intramolecular double bond is α,β to the carbene carbon atom or held in close proximity by steric or structural factors. With few exceptions, it can be stated that if a singlet carbene can undergo internal cycloaddition or insertion, it will not be possible to trap it efficiently with an external reagent.[56] In general, the bicyclo[n.1.0] systems are formed. Some other reaction pathways can predominate, as for example, with 3-diazo-1-propene (Scheme 15).[57] In addition, generation of α-alkenyl carbenes in the absence of nucleophilic reagents leads to the formation of cyclopropenes in high yield[58,59] (Scheme 16).



SCHEME 17



SCHEME 18

Alkynylcarbenes

Skell and Klebe reported in 1960 that photolysis of diazopropyne **65** in *E*- and *Z*-2-butene (Scheme 17) gives a carbene that is slightly nonstereospecific and a mixture of three cyclopropanes (**67**, **68**, and **69**) in the ratios of 4:2.5:1, respectively, with *Z*-2-butene being isolated.[60]

Bamford–Stevens Reaction (Methylene–Alkyl-Dialkylcarbenes).

Thermolysis and/or photolysis of tosylhydrazone salts, accessible by condensation of *p*-toluene-sulfonylhydrazine with aldehydes or ketone, gives rise to elimination of the sulfinate salts and forms the intermediate diazo compound (Scheme 18). Generation of free carbenes by this method is sometimes in doubt and, as a consequence, this method is not included in this chapter except when generation of a carbene from the diazirine or diazo compound is not available.[15,61]

Isocyclic Carbenes

Different cyclopropyl-, cyclobutyl-, cyclopentyl-, cyclohexyl-, cycloheptyl- (or higher) carbenes are known.[56] A survey is provided in the literature.[62] In general, the shift of an alkyl group results in ring expansion (Scheme 19).[56]

Thermolysis or photolysis of cubylphenylcarbene **85** in the presence of ethanol (Scheme 20) affords two isomers of ethoxyhomocubene, **87** and **88**.[65,66] Also, cyclopentyl-,[67] cyclohexyl-.[67] and cycloheptylcarbene[68] are generated, primarily through a Bamford-Stevens reaction to produce a mixture of products (Scheme 21).

Cycloalkenylcarbenes

Cycloalkenylcarbenes are carbenes that contain a cyclic side group. Tolane is the major decomposition product from the decomposition of diphenylcyclopropene diazomethane and a minor product is formed via normal ring expansion[68] (Scheme 22). Cycloheptatrienylcarbene yields only benzene, acetylene, and heptafulvene in addition to cyclooctatetraene[69] (Scheme 23).

Cycloalkylidenecarbene

Optically active cyclopropylidenes afford optically active allenes (Scheme 24).[70,71] Decomposition of diazocyclopentane and diazocyclohexane leads only to cyclopentene and cyclohexene, respectively, but their

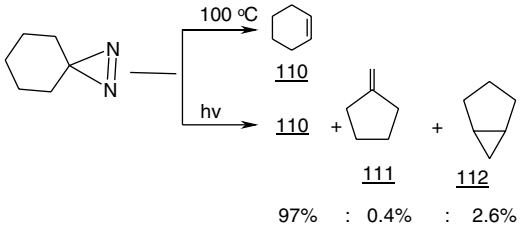
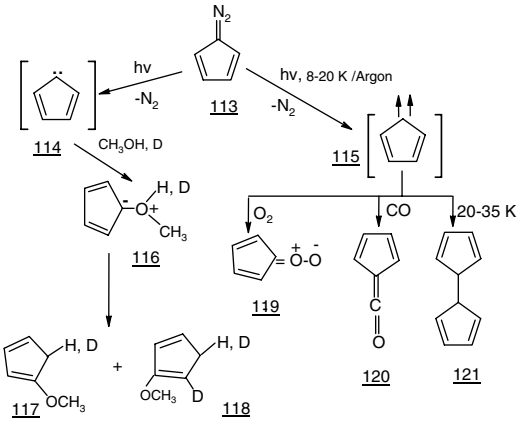


SCHEME 25

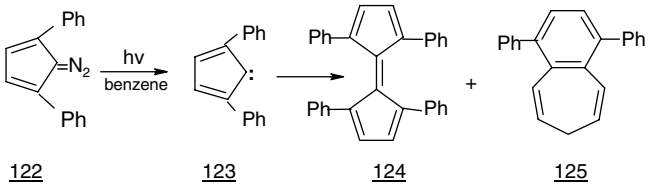
isomers, cyclopentyl- and cyclohexyldiazirine, show different behavior, depending on the method of generation (Scheme 25). However, photolysis is less selective than thermal decomposition.[72,73] Higher cycloalkylidenes have been generated through methods that do not involve free carbenes.[73]

Cycloalkenylidenes

This class of carbenes is of special interest because the carbene carbon is attached to a conjugated α,β-unsaturated system. Within this definition, a different series of cycloakenylidenes can be constructed that

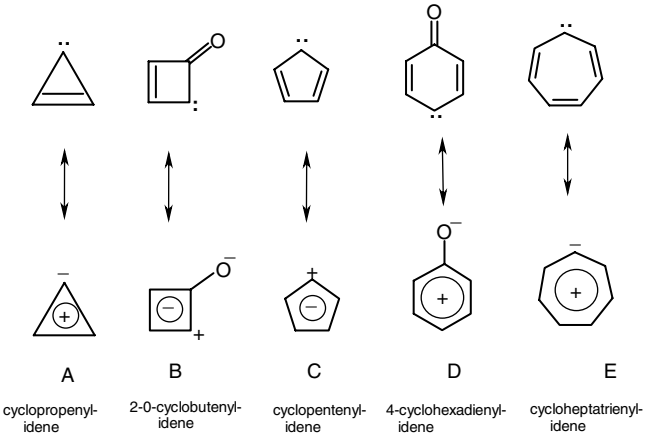


SCHEME 26

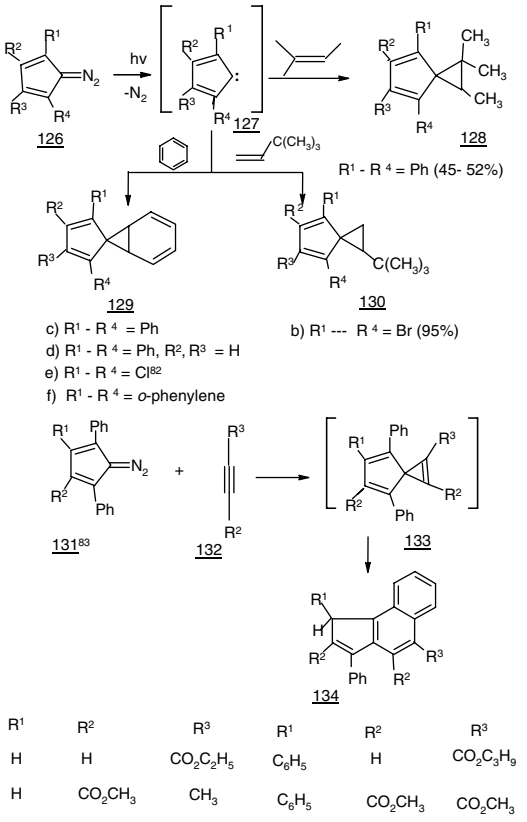


SCHEME 27

contain a total of [4n] or [4n+2] electrons.[74] The resonance structure of these carbenes shows that carbenes A and E have nucleophilic centers and carbenes B, C, and D have electrophilic centers.



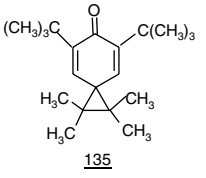
A variety of phenyl-substituted cyclopentadienylidenes have been examined. Irradiation of 5-diazocyclopentadiene at 8 to 20K in argon afforded a triplet carbene,[75,76] while irradiation at 293K in methanol gave a mixture of 1- and 2-methoxy-1,3-cyclopentadiene quantitatively[77] (**117** and **118**, Scheme 26). Irradiation of 5-diazo-1,4-diphenyl-1,3-cyclopentadiene in benzene produced, in addition to the dimer 1,1′-4,4′-tetraphenylfulvene (**124**, 6%); 1,4-diphenyl-7*H* -benzocycloheptatriene (**125,** Scheme 27).[78]



SCHEME 28

Tetrasubstituted 5-diazocyclopentadienes have received attention as a route to spirocyclopropane adducts upon irradiation in alkenes (Scheme 28).[79-81]

Photolysis of 2,5-di-*t*-butyl-3-diazo-6-oxo-1,4-cyclohexadiene at λ = 480 nm (sun lamps) in 2,3-dimethyl-2-butene gave the spiro compound **135** in 80% yield.[84]



135

Interestingly, the catalytic activity of some platinum complexes toward decomposition of diazo compounds is influenced by the oxidation state of the metal and the type of diazo compound under study. For example, 9-diazofluorene is decomposed either catalytically or stoichiometrically, in the presence of the platinum (0) complex [Pt (C_2H_4) $(PPh_3)_2$], to the corresponding azine while the dicationic complex *cis*-[Pt $(PPh_3)_2(CH_2CN)_2$]•$[BF_4]_2$ catalyzes the formation of the corresponding olefin.[85]

Arylcarbenes

Arylcarbenes are probably the most intensively studied carbenes. Arylcarbenes have a triplet ground state, as shown by ESR and/or CIDNP experiments.[86] Singlet ground-state arylcarbenes are also known.[87,88] Arylcarbenes can be subdivided into (1) monoarylcarbenes, (2) diarylcarbenes, and (3) carbenes in which the carbene carbon is a part of the aromatic system (A, B, and C, respectively).

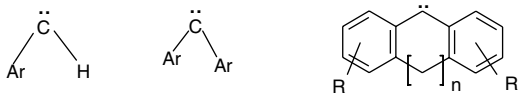
[b] Determination by $\Delta G_{ST} = RT \ln K_{eq}$.
[c] Lifetime (τ) or half-life ($t_{1/2}$) in solution at room temperature.



It has been observed that anthryl groups can act as excellent reservoirs for the unpaired electrons as well as relatively effective kinetic protectors for carbene.

Recent growing interest in triplet carbenes as potential organic ferromagnets[89] adds a practical meaning to this project.

Stabilization of triplet carbenes is shown to be better accomplished by steric protection than by electronic effect. However, the latter strategy can be used to stabilize singlet carbenes.[90]

Diazirines.

Diazirines have been used by many authors for the generation of arylcarbenes. Diazirines can directly be decomposed to give carbenes or rearrange to their diazo isomers, which in turn affords the carbene. Several examples are known and are illustrated in Scheme 29.[91,92]

Cyclopropylmethylchlorocarbene **149** and dicyclopropylmethylchlorocarbene **150** give only [1,2]-hydrogen shift products (**151** and **152**) with K_H (absolute rate constant for the [1,2]-H shifts) = 2.0 x 10^7 and 1.3 x10^7, respectively (Scheme 30).[95]

Photolysis of diazirine **157** (X = MeO) gave alkenes **158** and the [1,2]-carbon shift product **159** in the ratio of 1.67, similar to the product ratio obtained by thermolysis (Scheme 31).[96,97]

Sulfur ylides generated by photolysis or thermolysis of diazirines (Scheme 32) can be utilized for synthesis of β-lactams antibiotics and other natural products.[98,99]

Carbenes generated by irradiation of diazirines containing a photoreactive diazirine and mono- and disaccharides such as **167** were used for photoimmobilization of biomolecules on polystyrene.[100]

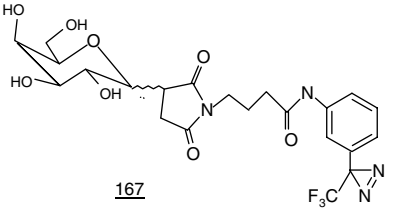
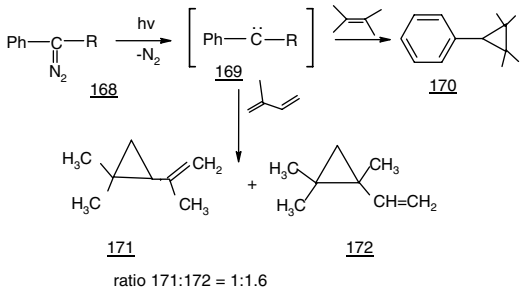
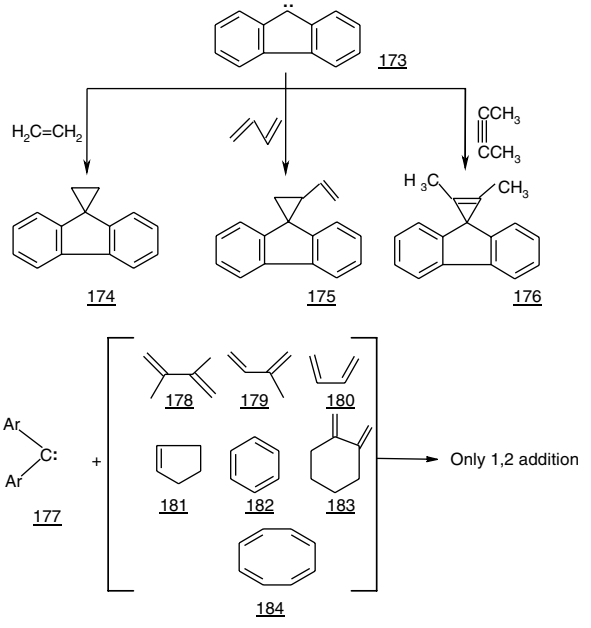
SCHEME 32





SCHEME 33



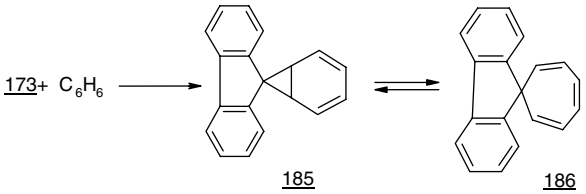
SCHEME 34

Diazo Compounds.

Diazo compounds decompose with extrusion of nitrogen under the effect of light or heat to produce carbenes. Phenylcarbene[101,102] as well as diphenylcarbene[102] possess triplet ground states that are in equilibrium with the singlet configurations.

Decomposition of phenyldiazomethane in olefins (Scheme 33) leads to the formation of cyclopropanes.[28,103] The reaction is largely stereospecific (>96%) and there is only a slight preference for the phenyl group to end up *syn* to the groups attached to the olefins. Fluorenylidenes are of special interest in the field of carbene chemistry. A large number of fluorenylidene derivatives have been prepared and subjected to extensive studies. Diphenylcarbene represents a compound bridged by an infinite chain. Fluorenylidene has two aryl groups connected by a zero bridge. Fluorenylidene seems to be an exceptional carbene (unlike diphenylcarbene) in that it adds easily and without complications to a variety of olefins.[104,105]

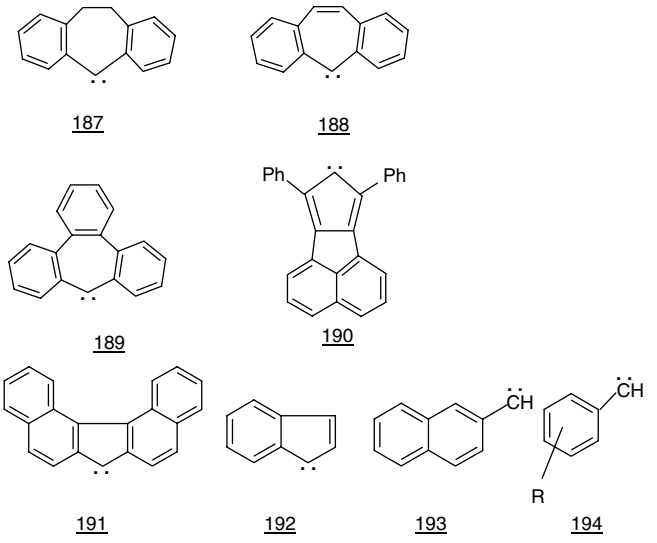
Again, an equilibrium state exists between the triplet and singlet states at ambient temperature. Neither fluorenylidene nor diphenylcarbene can be induced to add in a 1,4 fashion to dienes such as **178** to **184**[106] (Scheme 34).



SCHEME 35

Fluorenylidene attacks benzene to give a mixture of the valence isomers norcaradiene **185** and cycloheptatriene **186** (Scheme 35).[107a]

Other aryl or diarylcarbenes are known, such as **187** through **194**. The carbene **187** is similar to diphenylcarbene in its properties.



Carbene **190** underwent [1+2]- as well as [1+4]-cycloaddition with 2,3-dimethyl-1,3-butadiene (Scheme 36). It was regarded as a nucleophilic singlet carbene in its addition to styrene.[108]

A few di- and polycarbenes are known, and most were studied by spectroscopic techniques. The dicarbenes 201 and 203 are generated by irradiation of the corresponding bisdiazo precursors. Reaction of 201 in toluene with 1,1-diphenylethene gives 202, while 203 undergoes addition to benzene with ring expansion to yield 204 (Scheme 37).[107b,c]

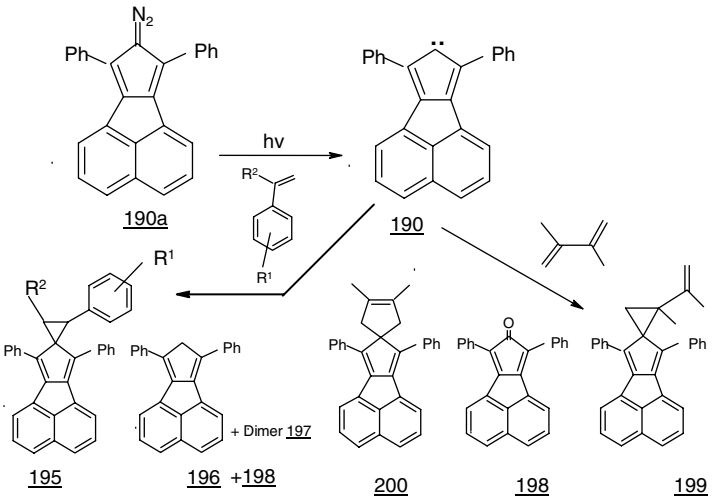
Oxygen-Containing Carbenes

This section includes carboalkoxy- and ketocarbenes. The Wolff rearrangement[2,15,109] is common to both keto- and carboalkoxycarbenes. This intramolecular reaction is of special significance in the Arndt-Eistert synthesis of homologous acids and esters as well as in the synthesis of strained small rings.

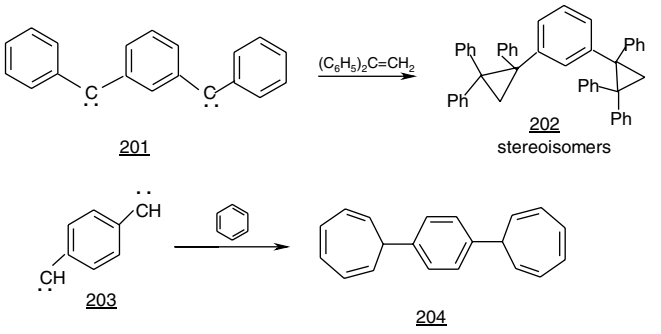
Carboalkoxycarbenes undergo both insertion and cycloaddition. Carbomethoxy-carbene **206** inserts into the α- and β-position of diethyl ether in the ratio of 4:1 to give **207** and **209** in addition to **208**, which may be formed via an ylide[110] (Scheme 38).

Cycloaddition of **206** to olefins has been demonstrated to be stereospecific on addition to cyclic or asymmetric double bonds (Scheme 39) to give mainly the less-hindered *exo*-adduct **210**.[111,112]

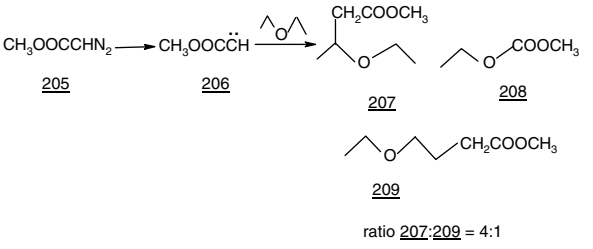
Interestingly, sensitized photolysis of dicyanocarbene in cyclooctatetraene leads to the [1,4]- addition product **212** as well as the major [1,2]-adduct **213** (Scheme 40).[113]



SCHEME 36



SCHEME 37

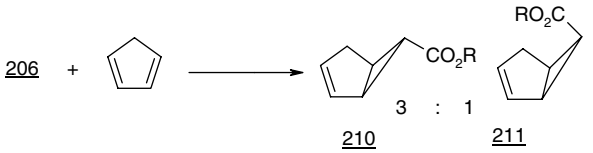


SCHEME 38

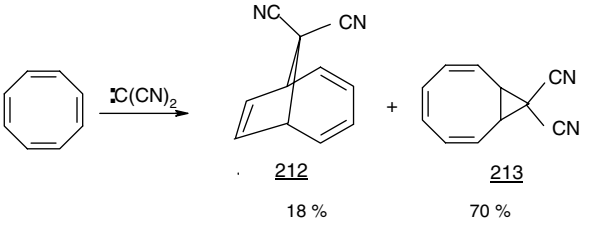
Ketocarbenes are most prone to Wolff rearrangement; for example, **217** is formed as a product of the rearrangement of **216** during photolysis of **214**[114,115] (Scheme 41).

However, photolysis of diazoketone **218** in cyclohexene affords adduct **219,** presumably because of the low mobility of an amide in the Wolff rearrangement (Scheme 41).[116]

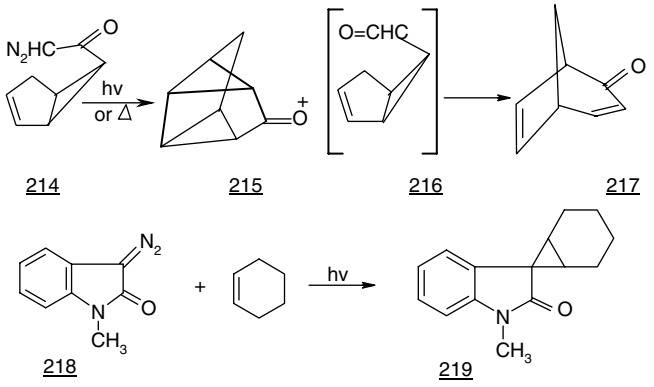
Several other oxygen-containing carbenes are known, such as carbenes **220** through **225**.[110]



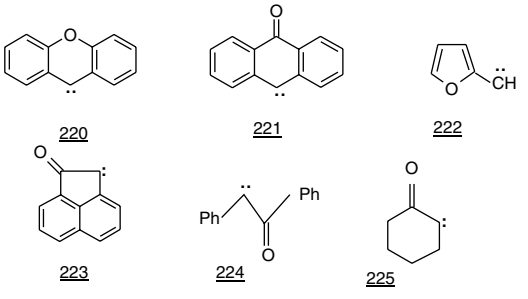
SCHEME 39



SCHEME 40

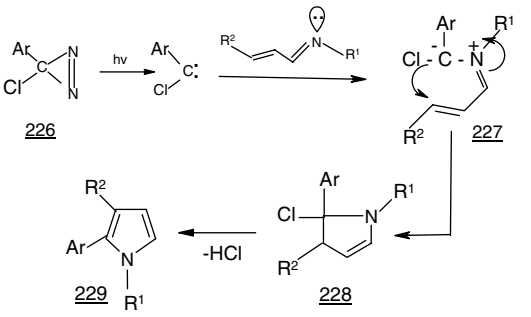


SCHEME 41

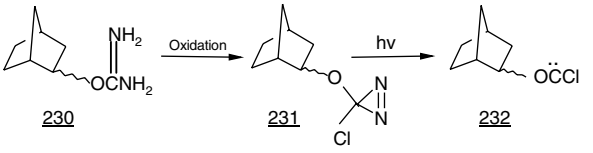


Halogen-Containing Carbenes

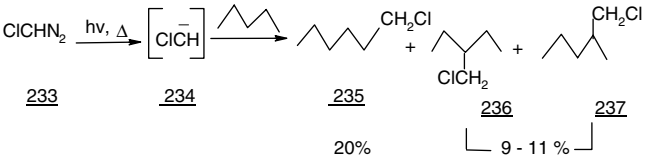
Most of the work on halocarbenes is concerned with carbenoids. Pyrolysis of chlorodiazomethane leads to a less-selective intermediate than its carbenoid counterpart.[117] Addition to 2-butene is stereospecific, but the *syn/anti* ratios in various olefins is markedly different.[117]



SCHEME 42



SCHEME 43



SCHEME 44

The first room-temperature stable triplet carbene 2,2′,4,4′,6,6′-hexabromophenylcarbene was generated from the corresponding diazo derivative, to be a model for chemically stable organic high-spin molecules.[3]

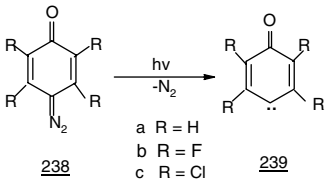
In general, the stable triplet carbene unit is supposed to serve as a useful building block for an extended super-high-spin molecular system and organic super-paramagnets.[118] All arylchlorodiazirines 226 were prepared by oxidation of the corresponding benzamidine hydrochloride with sodium hypochlorite in DMSO. Laser flash photolysis (LFP) of arylchlorodiazirines in the presence of substituted vinylpyridines yield substituted vinylpyridinium ylides (λ = 540 nm), an intermediate 227 of useful synthetic value for a variety of biologically active nitrogen-containing heterocycles (Scheme 42).[119,120]

LFP of arylchlorodiazirine in isooctane in the presence of vinylpyridines yields substituted vinylpyridine ylides that undergo [1,5]-cyclization.

*Ex*o- and *endo*-2-norbornyloxychlorocarbene **232** were generated photochemically from the corresponding diazirine **233** (Scheme 43).[121]

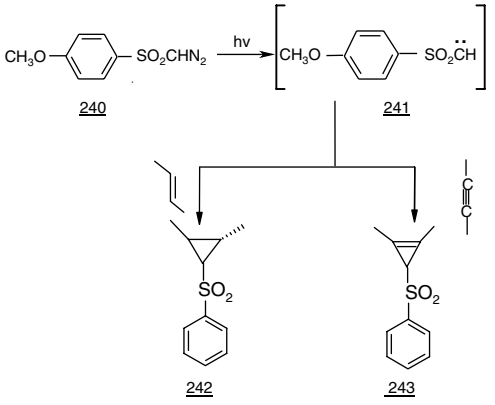
Photochemically or thermally generated carbenes, unlike most carbenoids, undergo the insertion reaction easily. These results are consistent with the involvement of a free halocarbene in its singlet state (Scheme 44).

Difluorocarbene, prepared by thermolysis or photolysis of difluorodiazirine, yields 1,1-difluorocyclopropanes via stereospecific addition to olefins, again consistent with a singlet ground state.[122] The relative reactivities of alkenes with bromophenylcarbene are shown in Table 91.3.



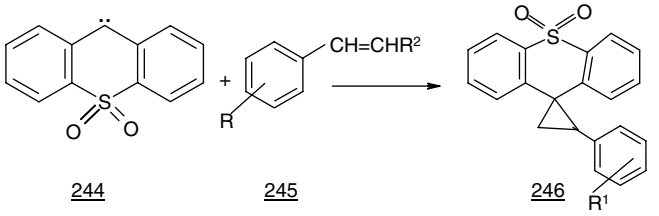
238 239

SCHEME 45



240 241 242 243

SCHEME 46



244 245 246

SCHEME 47

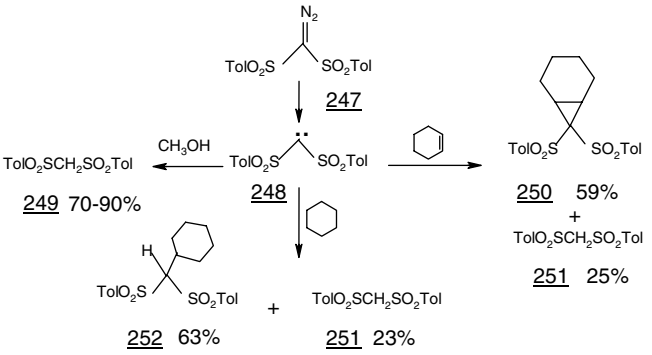
The 4-oxo-2,3,5,6-tetrafluoro- and tetrachloro-cyclohexa-2,5-dienylidenes **239** were prepared and investigated as an interesting class of highly electrophilic carbenes (Scheme 45).[123]

Sulfur-Containing Carbenes

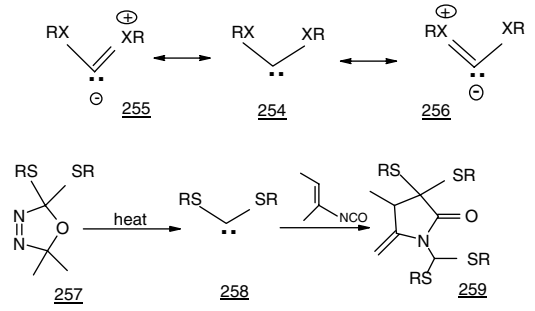
Sulfur-containing carbenes are known and review articles have been published.[124,125] The diazo precursors are prepared either by the action of weak bases on the appropriate *N*-nitrosocompound[126] or by the use of diazo transfer reactions.[127,128] The sulfonylcarbene **241** undergoes an addition reaction to olefins and acetylenes (Scheme 46) to give **242** and **243**, respectively.[14,128,129]

The chemistry of the polynuclear-ring, sulfur-containing carbene thioxathen-ylidene-*S*,*S*-dioxide **244** indicates easy cycloaddition to styrenes.[130] It reacts from its singlet state and behaves as an electrophilic carbene (Scheme 47).

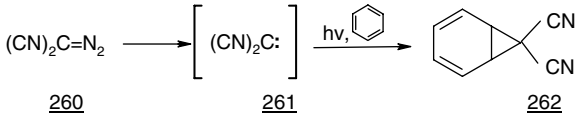
The photochemistry of a series of bis(sulfonyl)diazomethanes was investigated in solution and in low-temperature matrices (Scheme 48).[131]



SCHEME 48



SCHEME 49



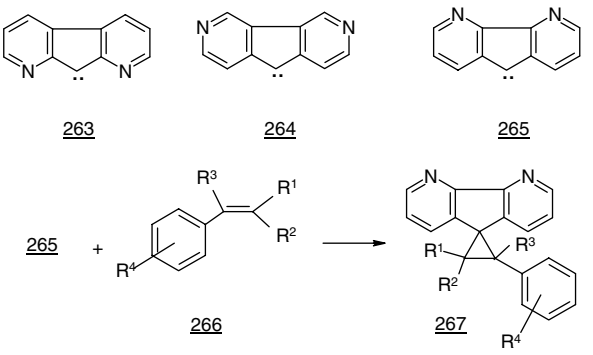
SCHEME 50

Recently, bis(alkylthio)carbenes **258** have been added to the list of nucleophilic carbenes that are useful 1,1-dipole equivalents in reactions with vinyl isocyanates **253**. Substituted hydroindolones, isatins, and hydroquinolines can be prepared by the addition of these carbenes to vinyl isocyanates (Scheme 49).[132,133]

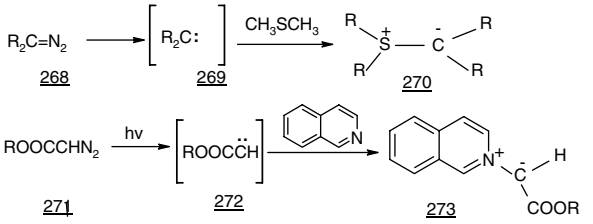
Nitrogen -Containing Carbenes

The unusual stability of imidazolylidene is largely attributed to the accumulated electron density on the nitrogen centers as well as the C4–C5 double bond that surrounds the carbene center, protecting the imidazolylidene from nucleophilic additions and kinetically stabilizing the molecule. Also, imidazolin-2-ylidene (IMH_2) and even bis(diisopropylamino)carbene (IPC) have been isolated as stable crystals. This indicates that unsaturation in the imidazole ring is not required to produce a stable nitrogen-substituted carbene.[3]

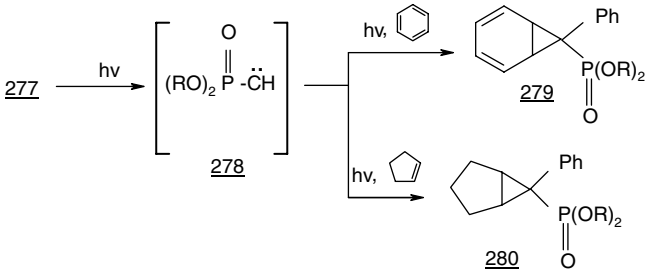
Cyanocarbenes, for example, have a triplet ground state, as confirmed by ESR spectroscopy.[134] Their stereospecific[25] addition to olefins gives cyclopropanes. The benzene adduct is norcaradiene (**262**), not cycloheptatriene (Scheme 50).[135]



SCHEME 51



SCHEME 52



SCHEME 53

Mono- and dinitro-diazomethane are known.[136,137] Diazofluorenylidenes **263** to **265** add to styrenes and other olefins, mainly affording cyclopropanes **267** (Scheme 51).[108,138,139]

Reviews of nitrogen-containing carbenes are available.[1,3,140] Although only a few stable ylides have been made from keto- or carbalkoxycarbenes, **269** and **272** form a stable ylides with alkyl sulfides[141] and isoquinoline,[142] such as **270** and **273**, respectively (Scheme 52).

Phosphorus-Containing Carbenes[143]

Generation of phosphorus-containing carbenes from the corresponding diazo precursors is known. Phosphinocarbene (PC) has been also isolated as distillable oil and shown to react either as a carbene or a phosphaacetylene.[1,3]

Addition to olefins and benzene leads to cyclopropanes **280**, insertion products and norcaradienes **279** (Scheme 53).[144,145]

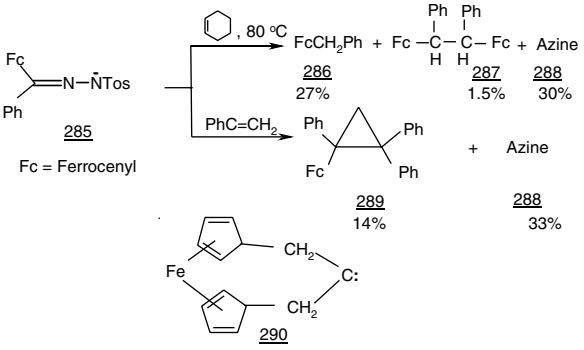
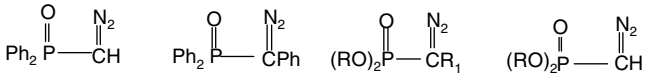
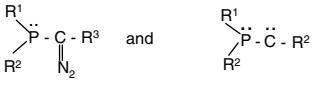


SCHEME 54



Phosphorus-containing carbenes insert into the OH bond of methanol and undergo a Wolff-type rearrangement. The ease of insertion and addition depends on the group attached to the carbene carbon atom.[144]

Bulky substituents kinetically stabilize phosphinocarbenes, but the stability of carbene is often inversely proportional to that of the diazo precursor.

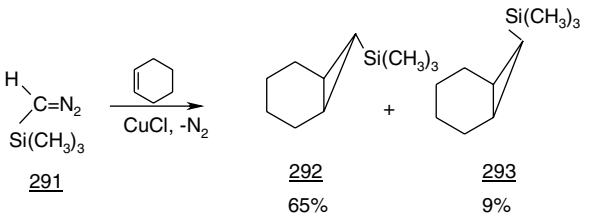


281 and 282 283 and 284

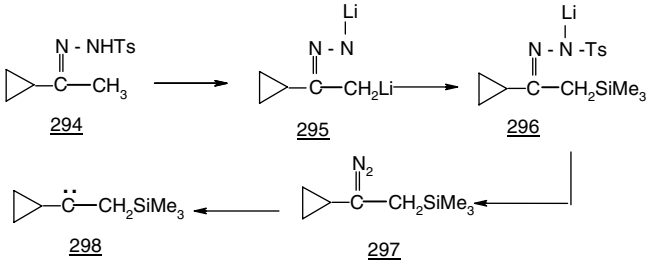
Carbene Containing Other Elements

Several diazo compounds, carbene precursors, containing iron, silicon, cadmium, zinc, germanium, lead, tin, mercury, silver, or lithium are known. Ferrocenylphenylcarbene and ferrocenylmethylcarbene are found to behave similar to diphenylcarbene in their reactions with olefins (Scheme 54).[146-148]

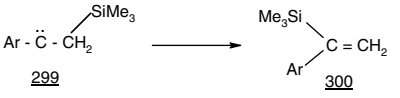
Silicon-containing carbenes, such as trimethylsilydiazomethane (**291**), afforded cyclopropanes **292** and **293** on catalyzed decomposition (Scheme 55).[149]



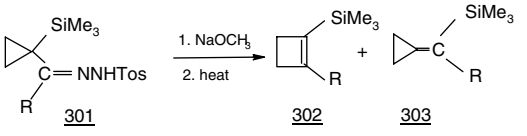
SCHEME 55



SCHEME 56



SCHEME 57



SCHEME 58

The chemistry of carbenes containing trimethylsilyl groups in the vicinity of the carbenic center has great interest.

The tosylhydrazone salt pyrolysis method was used for generation of the diazocompound and carbene (Scheme 56).[150]

Additionally, the trimethyl group is quite prone to migrate to carbon centers or activates hydrogen toward hydride migration to the carbene center (Scheme 57).[151] Computational studies show a substantial interaction of the vaccant carbene orbital with the adjacent C–Si bond (Scheme 58).[151] Concerted loss of molecular nitrogen and rearrangement remains a possibility.[150]

Carbenes containing ferrocenyl substituents $(Fc)_2$ are summarized and the reactivity of these carbenes was explored (Scheme 59).[10]

The Photochemistry of Diazirines

Tevye C. Celius
Johns Hopkins University

John P. Toscano
Johns Hopkins University

92.1 Introduction

Paulsen[1] and Schmitz and Ohme[2] synthesized the first alkyl diazirines independently in 1960. The cyclic structure of diazirines was then determined in 1962.[3,4] Almost immediately after their synthesis, diazirines were recognized as potentially useful photochemical and thermal precursors to carbenes. Unlike their valence isomers (diazo compounds), diazirines are relatively stable to most organic reagents and are reasonably stable in dilute solutions. As a result, the photolysis and thermolysis of diazirines has been studied extensively. Several reviews have been written on earlier experimental work.[5–8] This chapter focuses on recent experimental and theoretical progress.

92.2 Spectral Properties of Diazirines

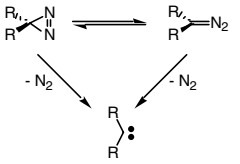
Diazirines contain an N–N double bond constrained in a three-membered ring and have strong absorptions in both the infrared and ultraviolet/visible regions. The N=N stretching vibration of diazirines appears between 1560 and 1630 cm^{-1}.[8] In general, diazirines have an electronic absorption band between 310 and 350 nm ($n\pi^*$), and a second absorption below 200 nm.[8] Associated with the $n\pi^*$ transition is a weak fluorescence.[9,10] The fluorescence lifetime of adamantyldiazirine is on the order of 240 ps with a fluorescence quantum yield of about 0.0012 at ambient temperature.[10] (The lifetime increases with decreasing temperature.)

92.3 General Photoreactions of Diazirines

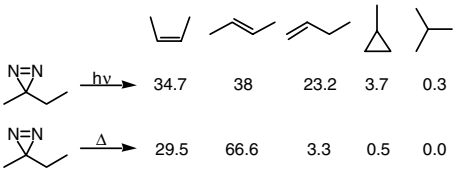
The most important photoreactions of diazirines are the generation of carbenes and the valence isomerization to linear diazo compounds (Scheme 1). At first glance, these appear to be straightforward processes; but under closer scrutiny, several experimental observations introduce complications.

The first indication that the mechanism is not as simple as the one outlined in Scheme 1 is that the product distributions from thermolysis of alkyl diazirines are markedly different from those of photolysis.

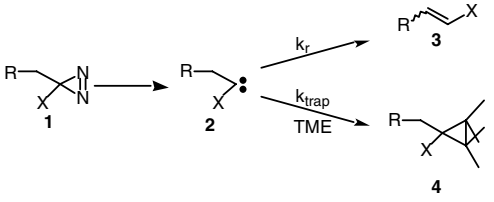
0-8493-1348-1/04/$0.00+$1.50



SCHEME 1



SCHEME 2



SCHEME 3

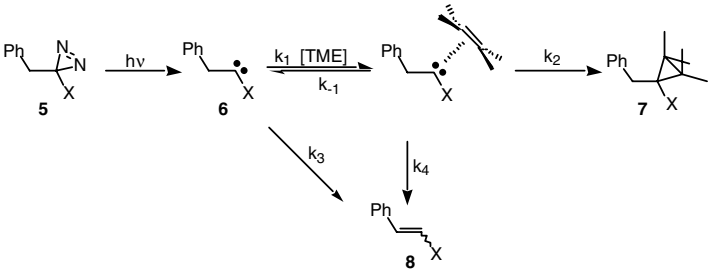
An example of such differences is shown in Scheme 2.[6,11–14] The simplest explanation of these results is that different intermediates are involved in the photolysis and thermolysis reactions. Numerous other examples of such systems have been reported in the literature.[6,11,15–21]

Another experimental observation indicative of the involvement of a second intermediate comes from carbene trapping studies. At high concentrations of carbene trap, apparent intramolecular rearrangements are not completely averted. If intramolecular rearrangement products are derived solely from a carbene intermediate, the ratio of trapped products to rearrangement products should increase linearly with increasing concentrations of carbene trap (Scheme 3). However, such trapping experiments have been carried out on a number of diazirines and show curved relationships between the product ratio and trap concentration.[22–29] Additionally, if trapping experiments are performed on non-nitrogenous precursors such as cyclopropylphenanthrenes, linear relationships are now observed.[18,26,30–35]

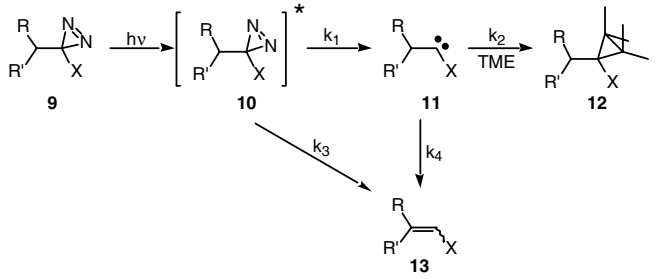
92.4 Mechanisms for the Photochemical Reactions of Diazirines

In light of the above results, the involvement of another intermediate is required but the question of its identity remains. A number of intermediates have been proposed, including a carbene-olefin complex (COC),[22] an excited carbene,[36] a diazo compound,[37] an excited-state diazirine,[9] and a biradical.[38–41] These proposed intermediates are potentially involved in two types of mechanisms: the COC mechanism and the rearrangement in the excited-state (RIES) mechanism.

The COC mechanism was originally proposed to explain the negative activation energies observed for carbene-olefin addition reactions.[42,43] Later, Liu and Tomioka used this mechanism to explain the curved correlations between the ratio of trapping products to rearrangement product and concentration of carbene trap.[22,23,44] They proposed that the second intermediate was a COC in equilibrium with the initially generated carbene intermediate (Scheme 4).



SCHEME 4



SCHEME 5

Application of the steady-state approximation predicts that the ratio of rearrangement to trapping products (**8**:**7**) will be linearly correlated with the inverse of the olefin concentration (Equation 92.1). This correlation is in excellent agreement with the experimental results.[22,44]

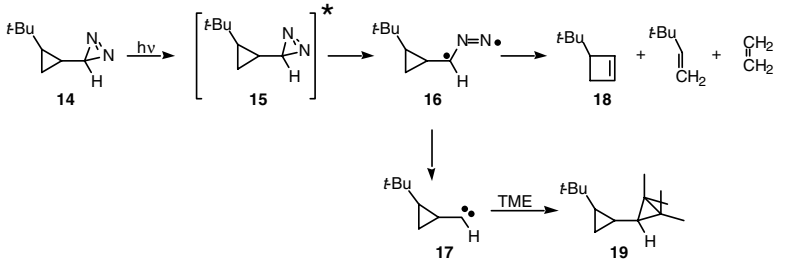
$$\frac{rearrangement}{trapping} = \frac{\mathbf{8}}{\mathbf{7}} = \frac{k_4}{k_2} + \frac{k_3(k_{-1} + k_4 + k_2)}{k_1 k_2 [TME]} \tag{92.1}$$

Although the COC mechanism can explain the experimental observations, there are two problems that have not been resolved. First, a carbene-olefin complex has never been experimentally detected. Second, modern *ab initio* calculations do not predict free energy minima corresponding to COCs in the reaction of chlorocarbenes with olefins.[45–48] They do, however, predict thermally stable π–complexes between benzene and carbenes, indicating that a COC mechanism might be operative if reactions are run in aromatic solvents.[48–51]

The remaining proposed intermediates involve rearrangement from the excited diazirine. This type of explanation was first put forward by Frey[52] and then more recently by Platz and co-workers.[9,10,37,53–55] In this mechanism, an intermediate is formed from the excited diazirine that leads directly to the rearrangement products (Scheme 5). This second intermediate is not defined in the kinetic scheme, but it has been proposed to be an excited carbene,[36] a biradical,[38] a diazo compound,[37] or the excited diazirine itself.[7,27] All of these proposed intermediates are thought to allow for concomitant extrusion of nitrogen and rearrangement.

Again, application of the steady-state approximation predicts that the ratio of rearrangement to trapping products (**13**:**12**) will be linearly correlated with the inverse of the olefin concentration (Equation 92.2).

$$\frac{\mathbf{13}}{\mathbf{12}} = \frac{k_3}{k_1} = \frac{k_4(k_1 + k_3)}{k_1 k_2 [TME]} \tag{92.2}$$



SCHEME 6

Numerous experiments have been performed on different diazirines in search of additional evidence for the RIES mechanism. These have included cyclobutylhalodiazirines,[29] *t*-butylchlorodiazirine,[28] 2,2-dimethylcyclopropylchlorodiazirine,[56] and *trans-t*-butylcyclopropyldiazirnine.[38,57] Of particular interest are the experiments on *t*-butylchlorodiazirine,[28] 2,2-dimethylcyclopropylchlorodiazirine,[56] and *trans-t*-buytlcyclopropyldiazirine.[38,57] When trapping experiments are performed on these systems, it is clearly demonstrated that some of the products are formed exclusively from a second intermediate and therefore lend support to the RIES mechanism.

In the case of *trans-t*-butylcyclopropyldiazirine, Platz and co-workers have proposed an open diazirine biradical (**16**) as the partitioning intermediate (Scheme 6). In the alkene trapping experiments, only a very small change in yield of **18** is observed, indicating that it is derived almost solely from the proposed biradical **16**.[38] Based on theoretical predictions, it is argued that biradical **16** is formed after passage through a conical intersection connecting the first and second singlet excited states. Passage through such an intersection would allow the biradical to be correlated directly with the ground-state products and starting materials.[38]

This scheme is in excellent agreement with the observation that the fluorescence lifetime increases with decreasing temperature,[38] indicative of the fluorescence being in competition with other excited-state processes. This competition in the excited state is further supported by the observation that the fluorescence intensity of diazirines that cannot rearrange, such as adamantyldiazirine and diazirine, fluoresce more strongly than those that can rearrange.[38] Platz and co-workers have performed fluorescence-lifetime measurements on adamantyldiazirine and determined that the barrier to other excited-state processes is between 2.7 and 2.9 kcal mol^{-1}.[10] Additionally, they observed no solvent dependence on the measured fluorescence lifetime, suggesting that the primary nonradiative processes of the first excited singlet state are intramolecular in nature.[10]

92.5 Isomerization of Diazirines to Diazo Compounds

Early experiments on the isomerization of diazirine were controversial. The gas-phase experiments of Amrich and Bell identified diazomethane as a reaction product and concluded that it was formed from isomerization of the starting diazirine.[58] Moore and Pimentel, however, conducted labeling experiments in a solid nitrogen matrix and determined that the diazomethane was formed from recombination of methylene and molecular nitrogen.[59]

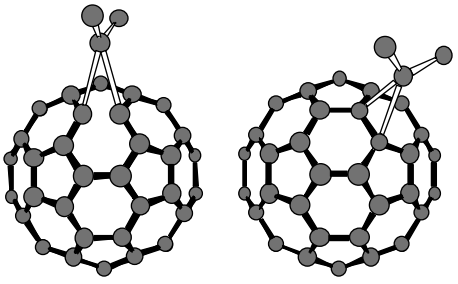
Seburg and McMahon have performed matrix isolation experiments on both 3-methyldiazirine and diazoethane in an attempt to observe ethylidene.[60] They were unsuccessful in detecting the desired carbene but did observe isomerization of diazoethylene to 3-methyldiazirine. When matrix-isolated diazoethylene was photolyzed at 8K, ethene and 3-methyldiazirine were observed as the major products in a ratio of 10:1. Additionally, unlike Moore and Pimentel,[59] Seburg and McMahon did not observe isotopic label scrambling when the photolyses were conducted in an $^{15}N_2$ matrix.

Bonneau and Liu performed time-resolved UV-VIS and standard spectroscopic experiments to determine the quantum yield for formation of carbenes and diazo compounds from several diazirines.[61] In

the case of adamantyldiazirine, the quantum yields for formation of the corresponding carbene and diazo compounds were both 50%. The carbenes and diazo compounds, therefore, are formed in a 1-to-1 ratio. The quantum yields for formation of diazo compounds from isopropylchlorodiazirine and *n*-butylchloroaziridine were measured to be 10 to 13% and 10 to 15%, respectively. Bonneau and Liu used these results to argue that, for the isopropyl and *n*-butyl cases, conversion to the diazo compounds is not efficient enough to be the necessary "second" intermediate in the RIES mechanism.

In further agreement with the above results, the photoisomerization of benzylchlorodiazirine to the corresponding diazo compound has been observed using time-resolved infrared spectroscopy.[26] Additionally, the quantum yield of photoisomerization was determined to be 0.075, indicating that such an inefficient process would not likely be the source of the curvature observed in the olefin trapping experiments.

The partitioning of carbene and diazo formation from the photolysis of adamantyldiazirine has been determined by trapping experiments with C_{60}.[62] C_{60} reacts specifically with diazo compounds to yield fulleroids and with carbenes to form methanofullerenes. Photolysis of adamantyldiazirine in the presence of C_{60} gives carbene- and diazo-derived products in a ratio of 49:51, respectively, in excellent agreement with previous results.[37,61]



Fulleroid **Methanofullerene**

Most recently, this methodology has been extended to the isopropylchlorodiazirine and chloromethylchlorodiazirine systems.[63] For isopropylchlorodiazirine, the carbene, the diazo compound, and the RIES alkene products were formed in 5, 13, and 82% yields, respectively. These results are in excellent agreement with previous laser flash photolysis experiments[61] and quantum yield determinations.[37] For chloromethylchlorodiazirine, carbene and alkene from RIES are formed in 36 and 64% yields, respectively. Additionally, the *E*/*Z* ratio for the alkene is 28:72. Again, these results are in excellent agreement with earlier experiments.[24]

92.6 Computational Investigations

Surprisingly, there have been relatively few theoretical investigations of the photochemistry of diazirines in comparison to the plethora of experimental studies. In 1978, Devaquet[39] and co-workers performed *ab initio* calculations and in 1985 a semiempirical study was reported by Jug and co-workers.[40] Almost a decade later, Olivucci and Robb performed a multi-configuration, self-consistent-field (MC-SCF) study on the reaction mechanism for photolysis of diazirine using the 6-31G* basis set.[41] Using a six electrons in six orbitals active space, they mapped out the potential energy surfaces corresponding to the ground state, the first and second singlet excited states, and the first triplet state. The key features of their calculations are outlined in Figure 92.1.

Photolysis promotes the ground-state diazirine **DZ**(S_0) to the first excited singlet state **DZ**(S_1). A transition state connects **DZ**(S_1) to conical intersection $\mathbf{CI_1}$, leading to ground-state diazomethane **DM**(S_0). Another conical intersection $\mathbf{CI_2}$ connects the first excited-state diazomethane **DM**(S_1) with ground-state carbene and nitrogen. Finally, a third conical intersection $\mathbf{CI_3}$ connects the second excited-state

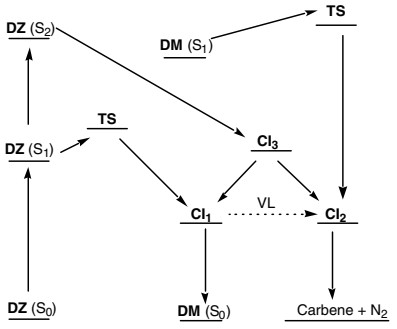


FIGURE 92.1 Schematic of the ground, first excited singlet, and second excited singlet surfaces of diazirine. DZ = diazirine, DM = diazomethane, TS = transition state, CI = conical intersection, and VL = vibrational leakage.

diazirine to the S_1 surface. Diazomethane is proposed to be produced directly from **DZ**(S_1) through $\mathbf{CI_1}$. Formation of methylene and nitrogen comes exclusively from $\mathbf{CI_2}$. Three pathways from **DZ**(S_1) to $\mathbf{CI_2}$ are proposed despite the fact that a transition state connecting them could not be located. The first pathway to $\mathbf{CI_2}$ requires vibrational leakage (VL) from $\mathbf{CI_1}$. The second route requires population of **DZ**(S_2) after promotion to **DZ**(S_1), potentially by passing through $\mathbf{CI_3}$ followed by passage through $\mathbf{CI_2}$. The third route is passage directly from **DZ**(S_1) to $\mathbf{CI_2}$. The barrier separating **DZ**(S_1) and $\mathbf{CI_2}$ is determined to be less than 4 kcal mol^{-1} and might be dynamically preferred over passage through $\mathbf{CI_1}$. Finally, the triplet manifold is concluded not to play a significant role because spin-orbit coupling is very weak.

Hadad, Gustafson, Platz, and co-workers have also performed calculations on the diazirine and adamantyldiazirine systems at the CIS level of theory using a 6-31G* basis set.[10] They arrived at somewhat different conclusions than those described by Olivucci and Robb. First, they were unable to find minima corresponding to diazirine and adamantyldiazirine on the first or second excited singlet surfaces. They also found a point that corresponds to a minimum on both the first and second excited-state surfaces rather than a conical intersection. They suggested that these differences might be the result of the orbitals that were chosen for the active space.

Olivucci and Robb have also performed calculations on the dimethydiazirine system at the CASSCF and CASMP2 levels of theory using the 6-31G* and cc-pVDZ basis sets.[64] They were unable to find any evidence for concerted extrusion of nitrogen and rearrangement on either the ground- or excited-state surfaces. The only reaction path they were able to locate begins on the excited-state surface, passes over a 1.0-kcal mol^{-1} barrier and then through a conical intersection leading to dimethyldiazirine on the ground-state surface. Passage through the conical intersection imparts the molecule with enough energy to pass over the 31.0-kcal mol^{-1} barrier to give ground-state carbene and nitrogen. The carbene can then easily rearrange to propene.

More recently, Arenas and co-workers studied the diazirine system at the complete active space, self-consistent field (CASSCF) level of theory using the cc-pVDZ basis set to map the potential energy surfaces with the critical points recalculated at the CASPT2/cc-pVDZ level.[65] The active space used for these calculations was 12 electrons in 10 orbitals. Additionally, they performed limited direct dynamic trajectory calculations on the S_1 and S_2 surfaces. The key features of the potential energy surfaces are depicted in Figure 92.2.

Two conical intersections $\mathbf{CI}_1$ and $\mathbf{CI}_2$ are located, connecting the three surfaces ($\mathbf{S_0}$, $\mathbf{S_1}$, and $\mathbf{S_2}$). Two transition states are found on the S_0 surface: $\mathbf{TS}_1$ connects the ground-state diazirine **DZ**(S_0) with dissociation products and $\mathbf{TS}_2$ connects **DZ**(S_0) with ground-state diazomethane **DM**(S_0). A transition state connecting **DM**(S_0) with dissociation products is not expected because it requires passage near $\mathbf{CI}_1$, an unfavorable process. Similar to the results obtained by Hadad and co-workers,[10] the stationary points corresponding to diazirine **DZ**(S_1) and diazomethane **DM**(S_1) on the first excited surface are found to be first-order saddle points. Both of these lead directly to $\mathbf{CI}_1$. A molecule that passes through $\mathbf{CI}_1$ would then have enough energy to pass over the barrier to dissociation products. This mechanism is in agreement

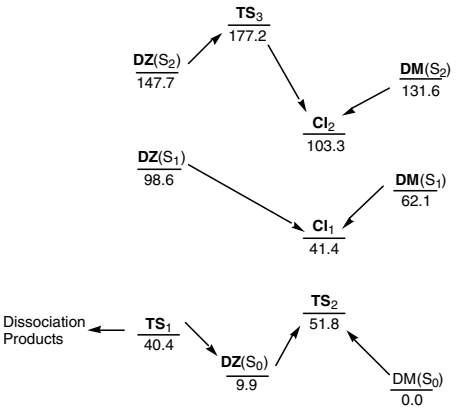

FIGURE 92.2 Schematic of the ground, first excited singlet, and second excited singlet surfaces of diazirine. DZ = diazirine, DM = diazomethane, TS = transition state, and CI = conical intersection. Relative energies are given in kilocalories per mole (kcal mol^{-1}).

with the experimental results of Moore and Pimentel[59] because it requires photochemical generation of diazomethane from diazirine to arise from carbene and molecular nitrogen. Again, on the second excited surface, the stationary points for diazirine **DZ**(S_2) and diazomethane **DM**(S_2) are first-order saddle points. These two saddle points are separated by transition state $\mathbf{TS}_3$ and conical intersection $\mathbf{CI}_2$. Trajectory calculations were performed, starting from various points on the second excited surface. Regardless of the precursor, the observed products were always singlet carbene and molecular nitrogen. The differences in results from earlier work are again suggested to be the result of the orbitals chosen for the active space.

92.7 Conclusion

A great deal of experimental and theoretical effort has gone into understanding the deceptively complicated photochemistry of diazirines. Despite the disagreements between some of the theoretical experimental investigations, most of the evidence points to rearrangement chemistry occurring via the RIES mechanism, with some contribution from carbene complexation possible in aromatic solvents.

Photomechanistic Aspects of Bicyclic Azoalkanes: Triplet States, Photoreduction, and Double Inversion

Waldemar Adam
University of Würzburg

Alexei V. Trofimov
University of Würzburg
and
Russian Academy of Sciences

93.1 Introduction

This contribution is preceded by an earlier chapter, which covered the main topics of the photochemistry of cyclic azoalkanes for over three decades. Herein, we address the following mechanistic aspects of cyclic azoalkane photochemistry: (1) the generation of azoalkane triplet states on direct irradiation and their photochemical transformations, and (2) the double inversion of the molecular skeleton in the formation of housane during photochemical nitrogen extrusion.

The studies reviewed herein have disclosed that the photochemistry of cyclic azoalkanes depends on spin multiplicity. While the singlet excited states of azoalkanes lead exclusively to the cleavage of the α-C–N bond with subsequent nitrogen extrusion and housane formation, their triplet states undergo β-C–C bond rupture followed by azirane formation. Another prominent feature of the triplet-state photochemistry is the photoreduction of bicyclic azoalkanes by hydrogen donors. For this process, direct hydrogen-atom transfer and charge-transfer mechanisms have been documented.

The double inversion of the molecular skeleton upon thermal and photochemical denitrogenation, first observed for the parent 2,3-diazabicyclo[2.2.1]hept-2-ene, DBH (**1**), constitutes a unique stereoselective process, much under mechanistic dispute for almost four decades. The mechanistic alternatives for the denitrogenation process pertain to whether the diazenyl (^{1}**DZ**) or the nitrogen-free cyclopentane-1,3-diyl (^{1}**DR**) biradical intervenes in the product-branching point to afford the diastereomeric housane

products. This long-standing mechanistic query has recently been addressed in terms of medium and substituent effects on the diastereoselectivity in the photochemical denitrogenation. Herein, we consider recent developments, which confirm the intermediacy of the diazenyl biradical ^{1}**DZ** in the photolysis of the DBH-type bicyclic azoalkanes.

93.2 Triplet-State Photochemistry of Bicyclic Azoalkanes

Direct Generation of Triplet-Excited Bicyclic Azoalkanes and Their Photophysical Behavior

The bicyclic derivatives 2,3-diazabicyclo[2.2.1]hept-2-ene, DBH (**1**), and 2,3-diazabicyclo[2.2.2]oct-2-ene, DBO (**2**), serve as instructive probes for the photochemical and photophysical properties of azoalkanes in view of their contrasting behavior. While derivatives of DBH (**1**) readily extrude molecular nitrogen from their excited states with quantum yield close to unity,[a,] DBO (**2**) and most of its derivatives are "photoreluctant," that is, they exhibit very low decomposition yields.[4b,5] With a few exceptions, substituents in the DBH and DBO molecules do not significantly alter the photochemical properties of the parent molecules.[3] Despite the contrasting photochemical reactivity of DBH (**1**) and DBO (**2**), their photophysical characteristics are similar. For both **1** and **2**, the intersystem crossing is inefficient and triplet lifetimes are very short; consequently, these azoalkanes do not phosphoresce, either in solution or even in matrix at 77K.[3b]

DBH (**1**)

DBO (**2**)

The DBH derivative **3a** constitutes the first case for which direct spectroscopic characterization of the *long-lived* (0.63 μs) triplet state was achieved,[3a] in view of the efficient singlet-to-triplet intersystem crossing (Φ_{isc} *ca.* 0.5). This unprecedented finding stimulated further studies on the azoalkanes **3** through **9** in an effort to define the essential structural requirements for the exceptional photophysical features of azoalkane **3a**.[3b] This work[3b] reports, for the first time, the phosphorescence emission spectra of azoalkanes (**3**, **4a**, **6a**, **8**, and *para*-substituted [*p*-F and *p*-Br] derivatives **3c**] at 77K. As representative cases, the photophysical properties of azoalkanes **3a** and **4a** are compared in Table 93.1 with those of

DBH (**1**) and DBO (**2**). It is noteworthy that the lowest triplet states of all azoalkanes **3** through**9** have been found to fall in the narrow range of 62.5 ± 1 kcal mol^{-1}. The n,π* character of the lowest azoalkane triplet state[3b] determines the photochemical reactivity, which is discussed below.

The zeolite environment dramatically alters the photophysical properties of azoalkanes. Thus, the intersystem -crossing efficiency of DBH, negligible in liquid solution and glass matrix, may be significantly enhanced in a zeolite interior through the heavy-atom[7a] or orbital-confinement[7b] effects. A large heavy-atom perturbation, imposed by the Tl^+ cation on $S_1 \rightarrow T_1$ intersystem crossing in the parent DBH, has been recently reported. This was manifested by the phosphorescence emission of DBH in TlY zeolite at 77K, observed for the first time. Recently, the first observation of DBH phosphorescence even at room temperature has been reported in the metal-free theta-1 zeolite.[7b] This was attributed to the orbital confinement, imposed by the spatial constraints of the rigid zeolite cavity, which enhances the intersystem crossing efficiency.

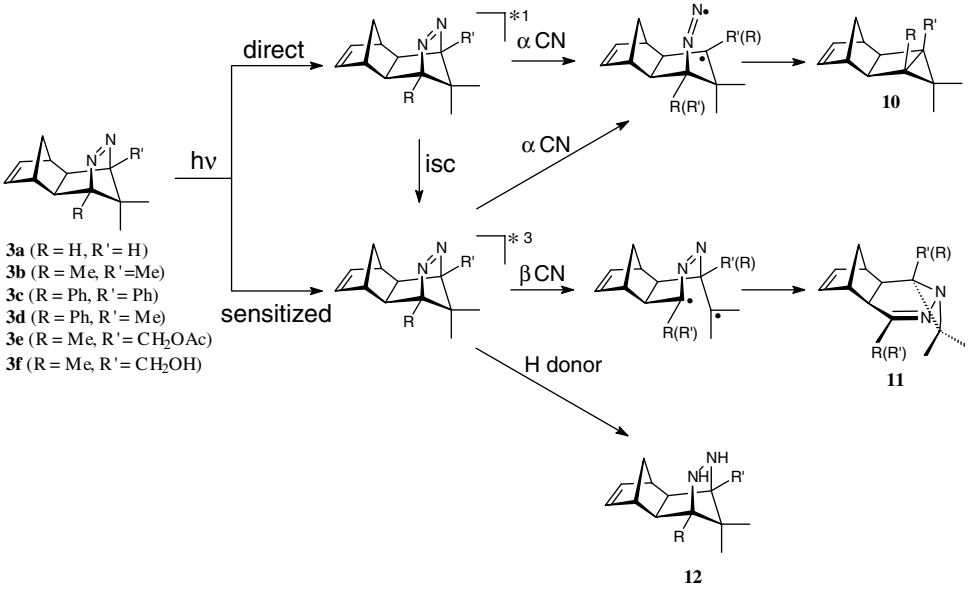
Triplet-State Reactions of Bicyclic Azoalkanes

β-C–C Bond Cleavage

The various photoreactions of the bicyclic azoalkanes **3** are summarized in Scheme 1. On direct irradiation, the azoalkanes **3** do not only afford the housanes **10** through the typical singlet-state α-CN-bond cleavage and subsequent denitrogenation, but also yield the aziranes **11** through β-CC-bond breakage and rearrangement.

The increased formation of the aziranes **11** on triplet sensitization with benzophenone and suppression of these rearrangement products by the triplet quenchers *trans*-piperylene and 1,3-cyclohexadiene show that these photoproducts are derived from the triplet-state azoalkanes ^{3}**3*** on β-CC-bond cleavage.[8a] The larger amount of housanes **10** at higher temperatures[8a] suggests that the intersystem-crossing process ^{1}**3*** $\rightarrow$ ^{3}**3*** competes effectively with denitrogenation in the singlet-excited azoalkanes ^{1}**3***. Because intersystem crossing should not be significantly dependent on temperature, the temperature effect has been rationalized in terms of an activation barrier for α-CN-bond cleavage in the singlet-excited azoalkanes ^{1}**3***.

From the temperature dependence of the direct and sensitized photolysis of azoalkanes **3**, the activation energies were estimated to be ≥3.3 kcal mol^{-1} and ≥10.5 kcal mol^{-1} for α-CN-bond breakage in the singlet and triplet states, and ≥7.9 kcal mol^{-1} for the β-CC-bond cleavage in the triplet state.[8a]



SCHEME 1

Subsequent studies[8b,c] exposed a pronounced medium effect on the product distribution. In the liquid-phase photolysis[8b] of the azoalkanes **3a,b**, for which the triplet channel competes effectively with the singlet-state deazetation, the product distribution depends significantly on the type of solvent. In contrast, the azoalkanes **3c,d**, with efficient denitrogenation in the singlet state, do not display solvent-dependent photobehavior. Thus, the aziranes **11** are produced almost exclusively in polar protic solvents, while housane formation is predominant in nonpolar solvents. It should be noted that the observed solvent dependence derives from bulk medium interactions, as similar product distributions are exhibited by the hydroxy-substituted derivative **3f** and azoalkane **3b** in benzene.[8b] Evidently, the intramolecular hydroxy functionality in the azoalkane **3f** does not influence the photochemistry of the triplet azo chromophore.

Selective formation of the azirane **11** from the triplet-excited azoalkanes **3** in polar media is rationalized in terms of solvent stabilization of the more polar transition state for the β-CC-bond cleavage vs.that for the α-CN-bond scission.[8b] This solvent polarity effect, observed for the liquid-phase photolysis of azoalkanes **3**, is similar to the photochemical behavior of the azoalkane **3a** in the interior of the zeolites.[8c] The polar zeolite environment enhances the formation of azirane **11a** compared to the solution photochemistry in benzene. In contrast to zeolites, the formation of azirane **11a**, a triplet-state product, is completely suppressed in the crystalline state and the housane **10a**, a singlet-state product, is formed selectively.[8c]

Photoreduction

As mentioned, the lowest triplet state of bicyclic azoalkanes is of the n,π* type, similar to that of the carbonyl chromophore. Consequently, the chemical reactivity of the azoalkane triplet state should be characteristic for the n,π* triplets; that is, it should be prone to hydrogen abstraction. Indeed, photoreduction of bicyclic azoalkanes (*cf.* Scheme 1) through intermolecular hydrogen abstraction and charge transfer has been reported.[8b,] As illustrated exemplarily in Table 93.2 for the DBH-type azoalkane 3a,[9] the rate constants for the reaction of the azoalkane ^{3}(n,π*) state with hydrogen donors are rather high. Thus, the formation of azirane **11**, the triplet-state photolysis product, may be almost totally suppressed and hydrazine **12** (*cf.* Scheme 1) is formed in high yields. Noteworthy is the fact that only azoalkanes with high quantum yields of intersystem crossing (Φ_{ISC} *ca.* 0.5) undergo photoreduction,[9c] which implies that the azoalkane triplet states are responsible for this process.

TABLE 93.2 Rate Constants (k_r) and Product Yields for the Reaction of the $^3(n, \pi^*)$-Excited Azoalkane 3a with Hydrogen Donors

Hydrogen Donor	k_q (10^7 $M^{-1}s^{-1}$)	Product yield (%) 10	11	12
None	—	54	46	—
1,4-Cyclohexadiene	2.4	23	3	74
Tributyltin hydride	3.5	<34	—	>66

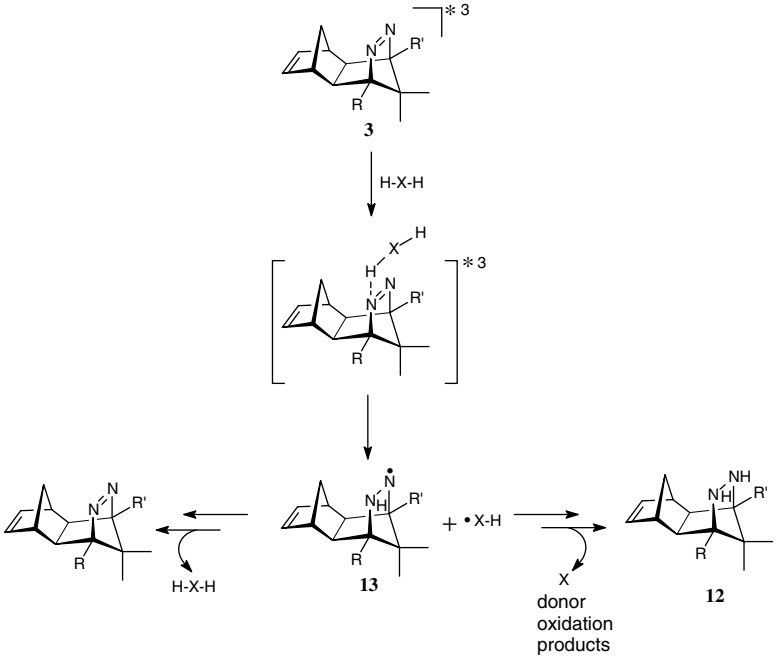
Diethylamine	—	20	—	80
Triethylamine	15	40	—	60
Diphenylamine	130	—	—	—
Triphenylamine	66	—	—	—

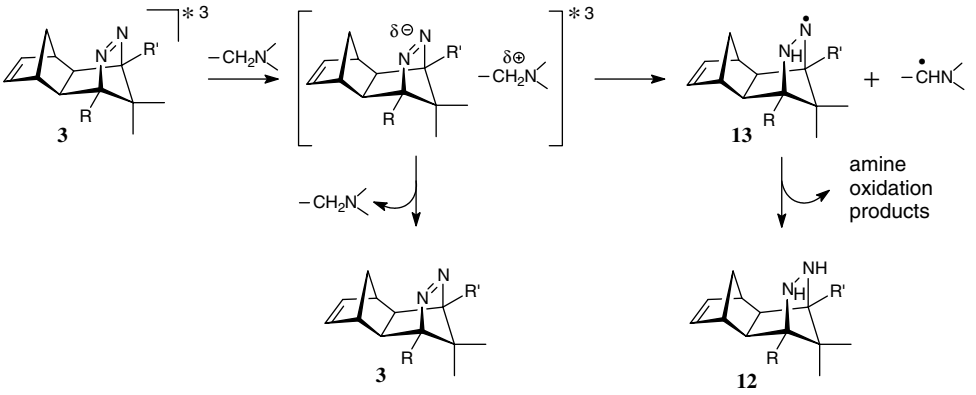
Note: Data taken from Ref. 9.



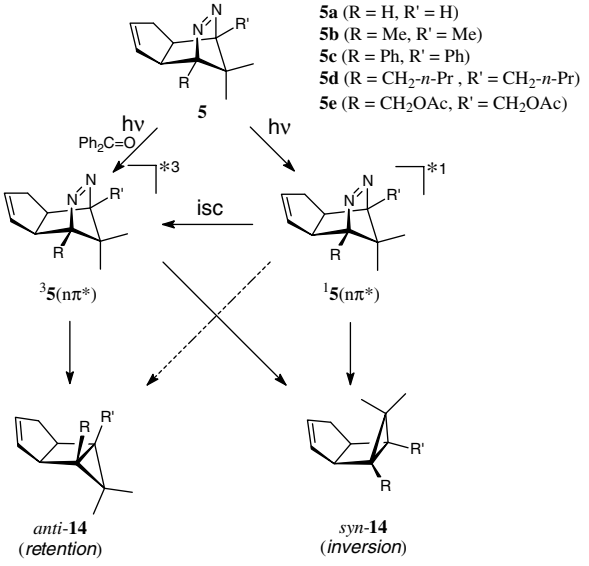
SCHEME 2

Different mechanisms have been proposed for the photoreduction of azoalkanes by a number of hydrogen donors (1,4-cylohexadiene, alcohols, stannanes, and silanes) and amines. While direct hydrogen abstraction operates for the former group of donors,[9b] amines react with the triplet azoalkanes by charge transfer.[9a,c] The mechanistic details of photoreduction by the direct hydrogen donors depend on the donor structure;[9b] however, intervention of the hydrazinyl radical **13** (Scheme 2) is a common feature of these photoreduction processes.

In contrast, photoreduction by amines obeys a general mechanism (Scheme 3) that involves a charge-transfer process.[9c] It should be noted that the azoalkane **3c**, which exhibits a low intersystem crossing (Φ_{ISC} *ca.* 0.1), resists photoreduction.[9c] The efficiencies of photoreduction for the azoalkanes **3** by amines



SCHEME 3

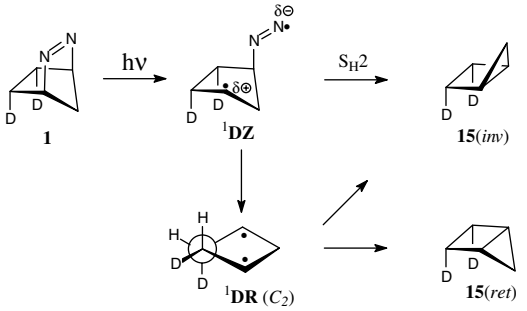


SCHEME 4

follow the same trend (primary ≈ tertiary >> secondary) as observed for benzophenone; the latter also exhibits the lowest photoreduction efficiency with secondary amines. This fact establishes the same general photochemical behavior of the azo and carbonyl n,π* triplet states.

α-CN-Bond Cleavage in Triplet and Singlet States

Definitive for triplet-state photochemistry, the α-CN-bond cleavage has been recently disclosed in the direct irradiation of azoalkanes **5**. A prominent feature of the photolysis of azoalkanes **5** (Scheme 4) is the fact that the *syn*/*anti* product diastereoselectivity depends on temperature and bridgehead substitution. The temperature dependence of the *direct* photolysis of azoalkanes **5** stems from the competition between the singlet and triplet reaction channels (Scheme 4), the latter dominating at low temperature. Mechanistic details of this diastereoselective process is considered below, subsequent to a general discussion on the stereochemical inversion phenomenon in the photochemical nitrogen extrusion.



SCHEME 5

93.3 Stereochemical Double Inversion in Photochemical Nitrogen Extrusion

Liquid-Phase Photolysis of DBH-Type Azoalkanes

The inversion of stereochemistry upon nitrogen extrusion from diazabicyclo[2.2.1]heptenes, DBH (**1**), constitutes an intriguing stereoselective process. More than 30 years ago, it was reported that in the gas-phase thermolysis of *exo*-deuterated diazabicyclo[2.2.1]heptene (*exo*-d_2-**1**), the inverted *exo*-deuterated housane bicyclo[2.1.0]pentane [**15**(*inv*)] was formed as the major product.[2a] Subsequently, it was also shown that, in the liquid-phase photolysis, the inversion dominates.[2b]

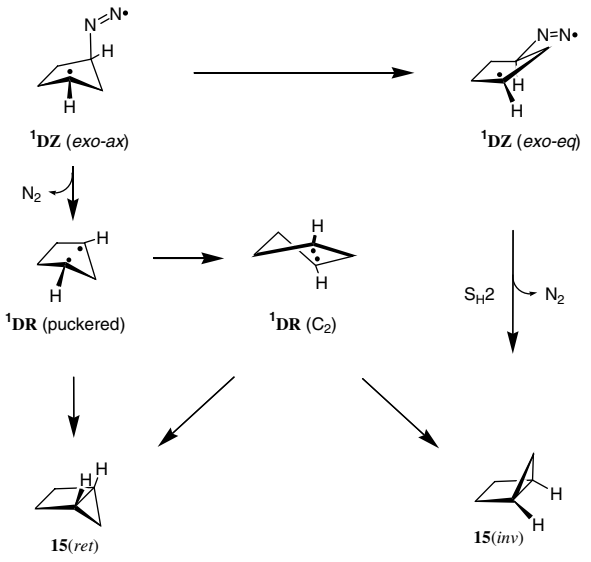
The persisting mechanistic query on this nitrogen extrusion concerns stepwise versus concerted breakage of the two C–N bonds in DBH (**1**): the stepwise CN-bond rupture necessarily implicates a nitrogen-containing intermediate, namely the diazenyl biradical **DZ**, whereas the concerted process passes through the nitrogen-free **DR** species (Scheme 5).

Nitrogen loss from the singlet ^{1}**DZ** biradical along the S_H2 trajectory leads to the inverted housane **15**(*inv*); the N_2 molecule is displaced homolytically through rearside attack by the radical center. Alternatively, the nitrogen-free singlet ^{1}**DR** biradical affords both the inverted and the retained housanes **15**(*inv*) and **15**(*ret*). To account for the loss of stereoselectivity of the ^{1}**DZ** intermediate, a bifurcation in the product-forming step has been proposed (Scheme 5), in which nitrogen extrusion to the singlet ^{1}**DR** biradical competes with the inversion process (S_H2 mechanism).

A recent computational study on the *thermolysis* of the parent DBH has concluded that the lower-energy pathway of deazetation is the concerted expulsion of N_2 directly to the ^{1}**DR** species.[11] The observed stereoselection, namely more **2**(*inv*) than **2**(*ret*), was interpreted in terms of the dynamic effects of the nonstatistical ^{1}**DR** biradical intermediate.

Computational[12] and experimental[13] evidence exist in favor of the stepwise nitrogen elimination in the photolysis of azoalkanes, which implicate the intervention of a diazenyl radical species. Thus, a recent theoretical study on the parent DBH discloses the singlet diazenyl biradical ^{1}**DZ** as the lowest-energy transient on n,π^* excitation.[12] Similarly, computational results on the photolysis of azomethane suggest a stepwise mechanism for the denitrogenation.[14] Indeed, simple symmetry considerations in terms of the Dauben-Salem-Turro theory on photochemical transformations[15] predict a stepwise process.[13c]

The mechanistic implications of the above computational study[12] on the photodenitrogenation of DBH are shown in Scheme 6. Passage of the n,π^*-excited singlet DBH through the conical intersection generates first the ^{1}**DZ**(*exo-ax*) biradical as *bona fide* intermediate, which relaxes to the ^{1}**DZ**(*exo-eq*) species. The latter leads to the inverted housane by means of rearside attack along the S_H2 coordinate. Alternatively, the ^{1}**DZ**(*exo-ax*) intermediate loses N_2 to afford initially the puckered singlet 1,3-cyclopentanediyl biradical ^{1}**DR**(puckered), which is predestined to cyclize into the retained housane (stereochemical memory effect). In competition, the ^{1}**DR**(puckered) transient relaxes to the C_2-symmetric ^{1}**DR**(C_2) biradical, from which the retained and inverted housanes are produced in equal amounts.



SCHEME 6

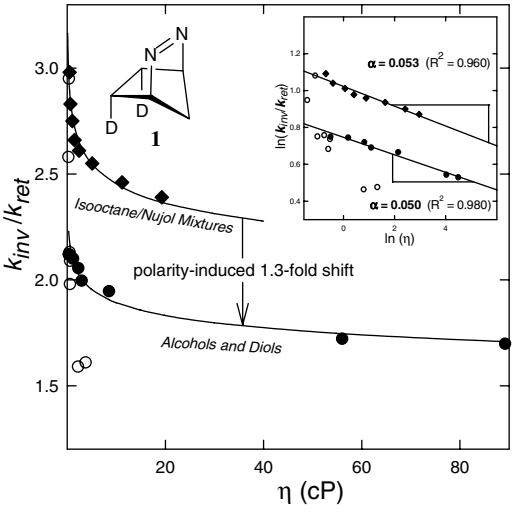


FIGURE 93.1 Viscosity dependence of the k_{inv}/k_{ret} ratio in the DBH (**1**) photolysis (λ = 333 nm) as a function of solvent at 20°C and 1 atm for alcohols and diols {●}, isooctane/nujol mixtures {◆}, and aprotic solvents of different polarity {○} (for details, *cf.* ref 16c); the insert displays the double-logarithmic plots of the viscosity *versus* k_{inv}/k_{ret} data (η expressed in cP).

The stepwise mechanism with the unsymmetrical singlet diazenyl biradical ^{1}**DZ** as pivotal intermediate is corroborated by the viscosity effects observed for the inversion (k_{inv}) and retention (k_{ret}) channels in liquid-phase DBH photolysis. In a more viscous solvent, the inversion process along the S_H2 trajectory is slowed down due to frictional impediment on the inversion motion (flap mode) of the methylene bridge, which is manifested by the decrease of the inversion/retention ratio i.e., k_{inv}/k_{ret} (*cf.* Figure 93.1). Conversely, for the concerted denitrogenation process, no viscosity effect on the k_{inv}/k_{ret} ratio should be expected, because similar motions of the methylene bridge to form the inverted [**15**(*inv*)] and retained

[**15**(*ret*)] housanes from the C_2-symmetric[17] ^{1}**DR** biradical would experience the same frictional impediment in the liquid medium.[16]

As is evident from Figure 93.1, the $\boldsymbol{k}_{inv}/\boldsymbol{k}_{ret}$ ratio exhibits the same viscosity profiles in polar protic (alcohols and diols) and nonpolar aprotic (Nujol/isooctane mixtures) media, but the two curves are shifted relative to one another by a constant factor of *ca.* 1.3. This becomes especially evident from the linear double-logarithmic plots of $\ln(\boldsymbol{k}_{inv}/\boldsymbol{k}_{ret})$ vs. $\ln(\eta)$ [*cf.* insert in Figure 93.1]. In both cases, the $\boldsymbol{k}_{inv}/\boldsymbol{k}_{ret}$ ratio depends on the viscosity to the same fractional power, *i. e.*, $\boldsymbol{k}_{inv}/\boldsymbol{k}_{ret} = const x \eta^{-\alpha}$; α takes the value 0.050 ± 0.002 for both solvent series (*cf.* insert in Figure 93.1).[16c] This viscosity behavior has been rationalized in terms of the free-volume model for the molecular reorganization,[16] in which the α value constitutes a characteristic parameter of the chemical transformation, namely the fraction of molecular volume involved in the rearrangement process.

The similar viscosity profiles of the $\boldsymbol{k}_{inv}/\boldsymbol{k}_{ret}$ ratio in protic and aprotic solvents (Figure 93.1) manifest the same free-volume requirements (the same α) and thereby reflect similar frictional impositions on the stereoselective inversion in the DBH photolysis in these media. The 1.3-fold shift of the $\boldsymbol{k}_{inv}/\boldsymbol{k}_{ret}$ curve for the alcohols and diols relative to that for the isooctane/Nujol mixtures is due to bulk polarity rather than hydrogen-bonding effects.[16c] The decrease in the $\boldsymbol{k}_{inv}/\boldsymbol{k}_{ret}$ ratio in polar media is accounted for by the lower dipole moment of the transition state for denitrogenation compared to that of the diazenyl biradical ^{1}**DZ**.[16c]

Clearly, the α value depends primarily on substituents in the molecule that suffer major displacement during the reaction, while substituents distant from the reaction center should have little effect. Hence, the dependence of the α value on substitution in various parts of the molecule should provide pertinent information on the motion of substituents during the chemical transformation and thereby offer valuable mechanistic details.

Table 93.3 compiles the experimental α data for the photolysis of azoalkanes **1, 16, 5b**, and 17.[16] As expected, the lowest α value (0.050 ± 0.003) is observed for the unsubstituted (parent) DBH **1**. As is evident from Table 93.3, dimethyl substitution in the methylene bridge (azoalkane **16**) increases the α value *ca.* threefold (0.146 ± 0.005) compared to the parent **1**. This is also expected because in a more viscous solvent, the inversion process (k_{inv}) along the S_H2 trajectory should be slowed down mainly due to frictional impediment on the inversion motion (flap mode) of the methylene bridge. Substitution in the methylene bridge should enhance the frictional imposition by the liquid medium on the flap mode of the skeletal inversion.

Furthermore, inspection of Table 93.3 reveals the following mechanistically important fact: bridgehead substitution (azoalkane **17**) leads to an additional increase of α, which takes the value 0.27 ± 0.01, the latter value is *ca.* two times higher than that of the merely methylene-bridge-substituted azoalkane **16** and *ca.* five times higher compared to parent DBH **1**. This observation shows that, in addition to the flap motion of the methylene bridge, the displacements of the bridgehead substituents are also of importance for the skeletal inversion during nitrogen extrusion.

Interesting is the finding that the cyclopentene annelation does not cause a large difference in the α values for azoalkane **5b** compared to **17** (*cf.* Table 93.2). Evidently, the annelated cyclopentene ring in the bicyclic **5d** is sufficiently distant from the reaction site such that it exercises little influence on the skeletal inversion process.

DBH Photolysis in Supercritical Fluids: Pressure Dependence of the Diastereoselectivity

As seen from Figure 93.2, the diastereoselectivity in the DBH photolysis in supercritical fluids (sc-CO_2 and sc-C_2H_6) depends on pressure.[18]The increase of pressure up to 200 bar leads to a *ca.* 2.3-fold decrease of the stereoselectivity (k_{inv}/k_{ret} ratio) in sc-CO_2 and sc-C_2H_6. Analysis of the observed pressure dependence in terms of collisional (self-diffusion coefficient) and frictional (viscosity) effects discloses that frictional impositions by the fluid media account best for the experimental observations. This is consistent with the experimental observations on solvent effects for liquid-phase DBH photolysis.[16]

TABLE 93.3 The α Values for the Photochemical Skeletal Inversion

Reactant	α [a]
 **1**	0.050 ± 0.003 (Refs 16a,c)
 **16**	0.146 ± 0.005 (Ref 16e)
 **5b**	0.20 ± 0.01 (Ref 16d)
 **17**	0.27 ± 0.01 (Ref 16b)

[a] The α value refers to the fraction of molecular volume involved in the rearrangement process (for details, cf. text).

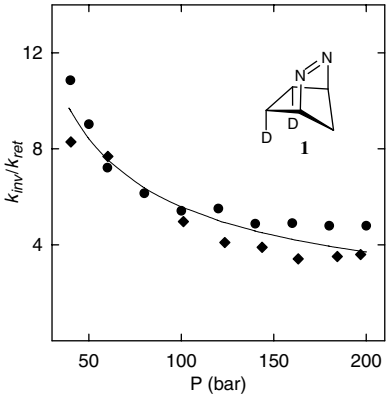

FIGURE 93.2 Pressure dependence of the k_{inv}/k_{ret} ratio (data taken from ref 18) for the photolysis (λ = 333 nm) of DBH (**1**) in supercritical carbon dioxide (◆) and ethane (●) at 50 °C.

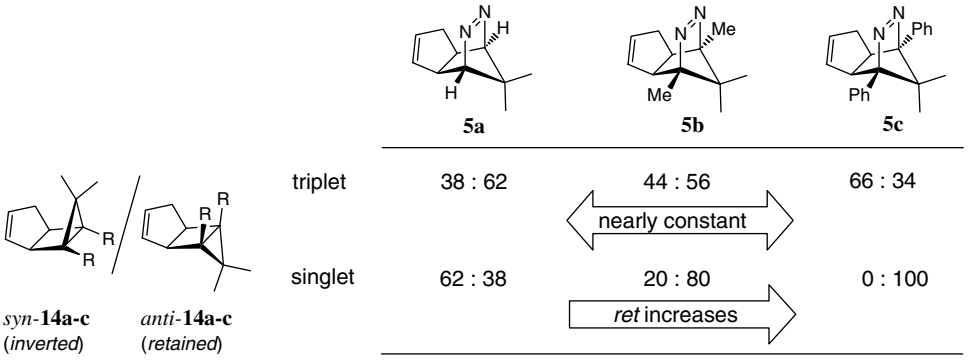


SCHEME 7

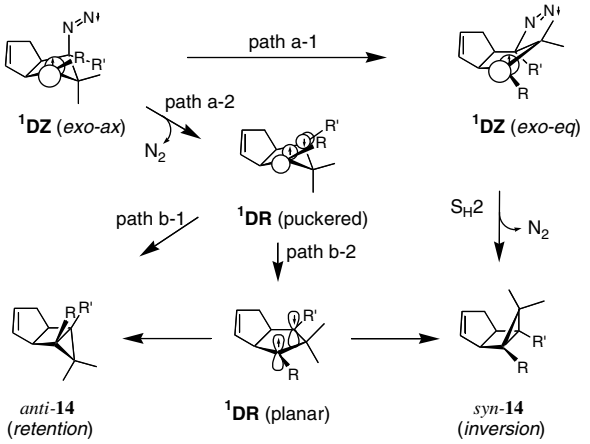
Temperature and Substitution Effects

The dependence of the diastereoselectivity on spin multiplicity exhibits different structural effects for the rotationally symmetric (azoalkanes **5a,b,c**) and rotationally unsymmetric (azoalkanes **5d,e**) bridgehead substitutions.[10b,c] The bridgehead substituents in azoalkanes **5a,b,c** are *rotationally symmetric* in the sense that both sides of the 1,3-cyclopentanediyl ring are equally sterically shielded on rotation of the substituents about the bridgehead position; conversely, the *n*-propyl and the acetoxymethyl groups at the bridgehead positions of the azoalkanes **5d** and **5e** are rotationally unsymmetric. Furthermore, the effect of long-range steric interactions between the annellated ring and the *gem*-dimethyl-substituted methylene bridge has been recently exposed.[10c]

Rotationally Symmetric Bridgehead Substitution

As mentioned, the temperature dependence of the diastereoselectivity (*syn*/*anti* ratio) in the photodenitrogenation of azolkanes **5** (*cf.* Scheme 4) manifests a competition between the singlet (high temperature) and triplet (low temperature) reaction channels in the direct photolysis. More explicitly, the observed change-over in the reaction path with temperature stems from the temperature dependence of the α-CN-bond cleavage in the singlet-excited azoalkanes **5**: at high temperatures (20 to 40°C), α scission is efficient, whereas at low temperatures (−20 to −75°C), it no longer competes effectively with the essentially temperature-independent (barrierless) intersystem crossing (Scheme 4).[10] The triplet pathway of the photodenitrogenation at low temperatures is evidenced by the same product distribution for the direct and benzophenone-sensitized photolysis under the same temperature conditions.[10]

Scheme 7 summarizes the results on the product distribution for the triplet and singlet photolysis channels of the azoalkanes **5a,b,c**. For the triplet reaction path, two characteristic features are evident from Scheme 7: the low diastereoselectivity and the small substituent effect on the latter. Thus, for **5a**, merely a small preference for the retained product has been found, whereas for **5c** an inverted housane is slightly favored (Scheme 7). The low stereoselectivity suggests the intervention of a thermally equilibrated *planar* biradical **DR** in the triplet process, which affords similar amounts of the inverted (*syn*) and retained (*anti*) housanes **14** upon ring closure.[10] Expectedly, for the planar **DR** intermediate, the substituent effects on the inversion and retention channels should be similar. In contrast, the singlet reaction channel exhibits a pronounced dependence on bridgehead substitution. In the latter case, the amount of the *anti* diastereomer (retention) follows the order Ph > Me > H (Scheme 7); that is, the larger the substituents, the more retained housane is formed. This stereochemical memory is interpreted in terms of the inertia (mass) effect of the substituents and steric interaction (size) between the substituents at the bridgehead and the methylene bridge during the deazetation step of the *exo-axial* [^{1}**DZ**(*exo-ax*)] and *exo-equatorial* [^{1}**DZ**(*exo-eq*)] conformations of the diazenyl biradical **DZ** (Scheme 8).[10,12b] The larger mass imparts a drag (inertia) on the bridgehead substituent during the inversion, whereas the larger size imposes a higher steric barrier in moving the bridgehead substituents past the *gem*-dimethyl



SCHEME 8

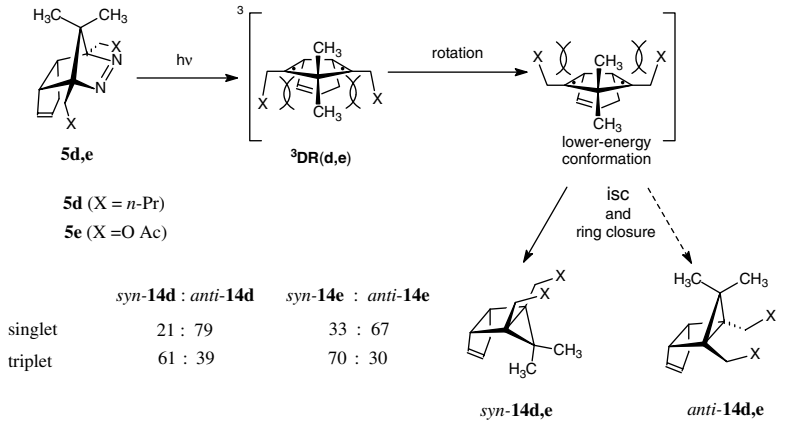
bridge; both expectedly slow down the conformational changes and promote nitrogen loss from the original geometry.

To qualitatively rationalize the bridgehead-substituent effect, it suffices to consider the two extreme cases, which are the unsubstituted derivative **5a** and the diphenyl case **5c**. Scheme 8 displays two bifurcation steps, namely, path a-1/a-2 and path b-1/b-2. For **5a**(H/H), both the mass drag and the steric hindrance are minimal on the conformational change along path a-1 and most of the singlet-state denitrogenation proceeds by the S_H2 mechanism to afford mainly inverted housane *syn*-**14a**(*inv*). Because substantial amounts of retained housane *anti*-**14a**(*ret*) are produced, denitrogenation along path a-2 must compete, but beyond this point it is difficult to assess even qualitatively what happens stereochemically because no information is available on the relative importance of the path b-1 vs. path b-2 in the subsequent bifurcation step. If one assumes that all of the ^{1}**DR**(puckered) relaxes to ^{1}**DR**(planar) along path b-2 (no memory effect), on the basis of the observed product ratios,[10b] *ca.* one third of the direct photolysis goes through the S_H2 process and the remaining two thirds through the thermally equilibrated ^{1}**DR**(planar) biradical. In contrast, the stereochemical analysis of the **5c**(Ph/Ph) case is straightforward because only the retained housane *anti*-**14c**(*ret*) is obtained; that is, complete stereochemical memory. In this case, both the mass and steric factors operate so efficiently that only the a-2 and b-1 paths are pursued by the respective biradicals ^{1}**DZ**(*exo-ax*) and ^{1}**DR**(puckered); the conformational changes in the a-1 and b-2 steps are too slow to compete with the a-2 and b-1 paths.

Rotationally Unsymmetric Bridgehead Substitution

Contrary to the rotationally symmetric bridgehead substitution (azoalkanes **5a,b,c**), which leads to the unselective triplet reaction channel and selective formation of *anti*-configured (retained) housanes (Scheme 7), the direct photolysis of the rotationally unsymmetric bridgehead-substituted azoalkanes **5d,e** is moderately diastereoselective for *both* the singlet and triplet modes of photolysis (Scheme 9), as evidenced by the *syn*/*anti* (inversion/retention) ratio. Thus, the photolysis of **5d,e** affords under singlet conditions (high-temperature direct photolysis) predominantly the retained housanes *anti*-**14d,e** (*syn*/*anti* 21:79 for housane **14d** and 33:67 for **14e**); while under triplet conditions (low-temperature direct or benzophenone-sensitized photolysis), the inverted diastereomer *syn*-**14d,e** is favored (*syn*/*anti* 61:39 for **14d** and 70:30 **14e**).

This unprecedented inversion for the triplet pathway is rationalized in terms of the unsymmetric nature of the *n*-propyl and acetoxymethyl substituents in regard to rotation about the bridgehead position of the planar cyclopentane-1,3-diyl triplet biradicals ^{3}**DR**(**d,e**); *cf.* Scheme 9. For the lower-energy conformation of the ^{3}**DR**(**d,e**) biradical, the X fragments of the bridgehead substituents points, for steric reasons, away from the annellated cyclopentene ring and are preferably located on the upper side of the



SCHEME 9

diyl ring. After intersystem crossing (ISC) of the triplet biradicals ^{3}**DR**(**d,e**) to the singlet biradicals ^{1}**DR**(**d,e**), the *gem*-dimethyl-substituted methylene bridge may tilt either downward or upward, too close to the respective diastereomeric *syn* and *anti* housanes (Scheme 9). The preference for the *syn* housane comes from the steric interactions of the upper methyl group on the methylene bridge with the two bridgehead substituents in their lower-energy conformation (located above the diyl plane), which directs the tilting motion of the methylene bridge downward in favor of the *syn* housane.

Long-Range Steric Effects

Usually the triplet photolysis mode of azoalkanes **5a,b,c** affords poor product selectivity with a slight preference for the retained housane *anti*-**14a** (H/H in bridgehead), for which the *syn*/*anti* ratio is 38:62. This slight preference for retention has recently[10c] been mechanistically attributed to the steric interactions between the annellated cyclopentene ring and the *gem*-dimethyl-substituted methylene bridge during the ring closure of the planar nitrogen-free triplet biradical ^{3}**DR**. It may be anticipated that an increase in the steric interactions between the remote annellated ring and the *gem*-dimethyl-substituted methylene bridge should raise the energy barrier of the ^{3}**DR** → *syn*-**14a** cyclization and, consequently, the formation of *anti* housane should be enhanced. That this is actually the case has been demonstrated[10c] for the photodenitrogenation of the saturated azoalkane derivative **18** (Scheme 10). Whereas in the direct photolysis (singlet-excited process), the *syn/anti*-**19** housane ratio (*syn/anti* 53:47 for **19** vs. 62:38 for **14**) is nominally affected by this structural change, for the benzophenone-sensitized photolysis (triplet-excited process), essentially exclusively (*syn/anti* 6:94 for **19** vs.38:62 for **14**) the *anti*-**19** housane is observed.

Scheme 10 provides a pictorial rationale for the essentially exclusive *anti* stereoselectivity in the photolysis of azoalkane **18** under triplet conditions. After intersystem crossing (ISC) to the singlet biradical ^{1}**DR**, the direction of the ring closure to the diastereomeric housanes **19** is controlled by steric effects between the *gem*-dimethyl-substituted methylene bridge and the annellated ring. This steric interaction is more effective for the bulkier annellated cyclopentane ring during the puckering motion of the ring closure in the resulting ^{1}**DR**(**18**) biradical, such that the *anti*-**19** (path a) rather than *syn*-**19** (path b) is pursued in high preference (Scheme 10).

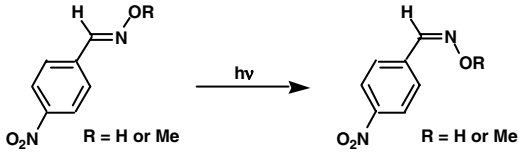
94.1 Brief Historical Background

Oximes, nitrones, hydrazones, imines, and azo compounds having either a nitrogen–carbon or nitrogen–nitrogen double bond in the *Z* or *E* configuration exhibit a wide variety of photochemical reactions. In particular, the reversible *E,Z*-photoisomerization of azobenzene and its derivatives has recently attracted considerable attention by virtue of their potential for technological applications. This chapter briefly presents an overview of the *E,Z*-photointerconversions that are the primary photoreactions of these groups of compounds. The accompanying diverse photochemical reactions are also described.

The first recorded example of the *E,Z*-isomerization of a CN double bond was that of oximes by Hantzsch in Zürich, who reported in 1890 that *E,Z*-isomerization took place when the tolylphenyl ketone oxime or α-anisylphenyl ketone oxime was irradiated.[1] Subsequent to this study, Ciamician and Silber at Bologna reported that when *E-o-* and *p*-nitrobenzaldehyde oximes, as suspensions in benzene, were exposed to sunlight, they were converted to the corresponding *Z*-nitrobenzaldehyde oximes.[2] This report was confirmed and extended to O-methyloximes by Brady and Dunn in London (Scheme 1).[3] Stoermer also found a similar photochemical *E,Z*-photoisomerization with certain ketoximes.[4]

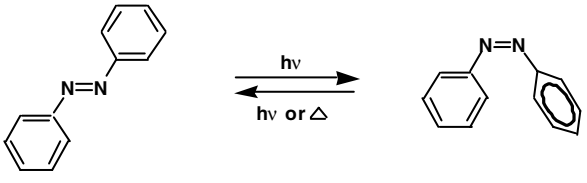


SCHEME 1

Subsequent to Thiele's preparation of azomethane, the first azoalkane, and the observation on its thermal decomposition to give ethane and nitrogen in 1909,[5] Ramsperger first reported in 1928 that azomethane similarly decomposed to ethane and nitrogen upon irradiation with monochromatic light.[6] Studies on the photochemistry of azoalkanes since then, especially those by Ausloos,[7] Bartlett,[8] and Steel[9] and their colleagues between 1950 and the 1960s were primarily concerned with the mechanistic aspects of nitrogen elimination in connection with the behavior of the generated biradicals.

Sophisticated mechanistic details concerning the elimination of the nitrogen from azoalkanes are still being reported to this day.[10]

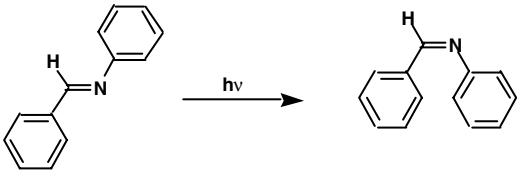
The first report concerning the photochemical *E,Z*-isomerization of the NN double bond was made by Hartley in 1937.[11] His work dealt with azobenzene and its derivatives because these compounds have greater stability than azoalkanes. The possibility of isomerism in azobenzenes had been discussed for many years prior to this report. He thus succeeded in isolating *Z*-azobenzene, w;hich thermally reverted to *E*-azobenzene. The physical and chemical properties of the *Z*-isomer were measured (Scheme 2). In subsequent years, the photoisomerization was found to be general for azobenzenes and their naphthalene or heterocyclic derivatives. Some 25 years later, Hutton and Steel found that *E,Z*-photoisomerization was a general reaction of even the simple azoalkanes.[12]



SCHEME 2

The photochemical *E,Z*-isomerization of imines carrying alkyl, aryl, or acyl substituents at the nitrogen of their CN group, on the other hand, was reported much later. This was due to the fact that the energy

barrier to interconversion was normally small for imines and that, at ambient temperatures, a thermal reversion from the *Z*-form to the more stable *E*-form readily takes place. Fischer and Frei thus reported in 1957 that the irradiation of some diarylimines in solution at −100°C induced a change in the UV spectrum and led to photoequilibrium.[13] The spectrum of the starting solution was restored by allowing the solution to warm up to ambient temperature. They correctly interpreted this change in the spectra as being due to *E,Z*-interconversions of the imines (Scheme 3).



SCHEME 3

Since the 1960s, numerous investigations have been carried out on the nature of the CN and NN double bond photoisomerization and the competitive nature of the *E,Z*-isomerization with other processes, such as photocyclization, photoreduction and photorearrangement. The variety of substrates studied included oxime, oxime ethers, aliphatic and aromatic azo compounds, azoxy compounds, hydrazones, and Schiff bases. The accumulated results were the subjects of several comprehensive and thorough review articles by Wettermark,[14] Padwa,[15] Pratt,[16] Griffiths,[17] Engel,[9] Dürr,[18] and Taylor.[92]

A notable application of *E,Z*-photoisomerization of azobenzene since the late 1960s involves the construction of a great number of photoresponsive molecules, including polymers, peptides, and crown ethers. The most impressive developments in the past 10 years involved the constructions of new photoresponsive molecules containing azobenzene units, including photoresponsive dendrimers and liquid crystals for technological devices such as optical switching as well as new photoreactions of imines and oximes. The irradiation of complex molecules carrying an azobenzene function is accompanied by profound reversible conformational changes; these photoresponsive molecules have great potential for application to a number of technological problems related to photocontrol.

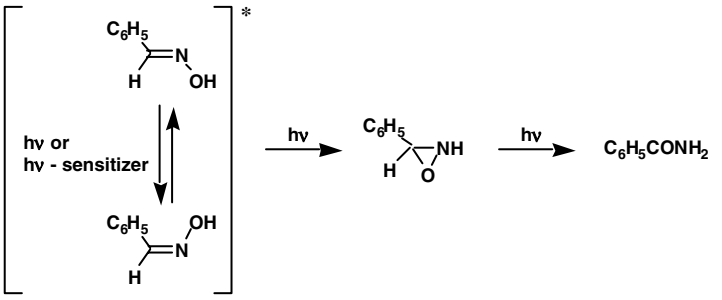
94.2 *E,Z*-Photoisomerization and the Accompanying Reactions of Oximes, Oxime Ethers, Nitrones, and Hydrazones

Oximes and Oxime Ethers

An isolated -C=N-OH group in saturated oximes in a hydrocarbon solvent gives rise to a band at 192–200 nm (ε; 7800–9440),[19] which has been assigned to the $\pi\pi^*$ transition.[19] The corresponding O-methyl oxime also revealed absorption at a similar wavelength and with a similar intensity (cyclohexanone O-methyl oxime; 201 nm; ε; 7000).[20] No distinct low-intensity band or shoulder attributable to a $n\pi^*$ transition has been observed, and any weak $n\pi^*$ band occurring near 190 nm should be submerged in the $\pi\pi^*$ band.

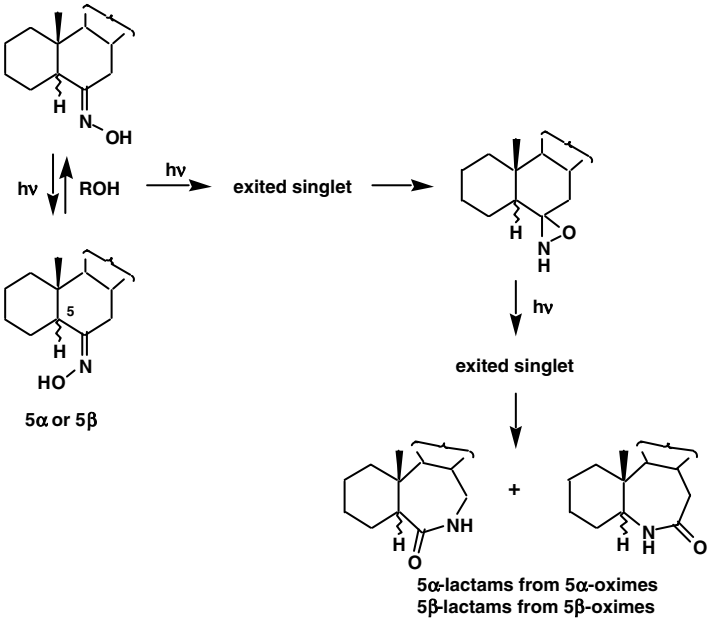
In 1963, de Mayo and colleagues found that arylaldoximes, such as benzaldoxime in protic solvents, undergo a Beckmann-type photorearrangement to give the corresponding amide upon irradiation through quartz.[20] The major reaction for energy dissipation was, however, *E,Z*-photoisomerization. They suggested, based on a variety of experimental evidence, that the amides are produced from an oxaziridine intermediate formed from an excited oxime as outlined in Scheme 4. The intermediacy of the oxaziridine in this rearrangement was subsequently confirmed by de Mayo[20] as well as by Oine and Mukai.[21]

Subsequent to this discovery, the formation of amides and lactams was found to be the major competing photoreaction of oximes; Just and colleagues found that the irradiation of a methanolic solution of cyclohexanone oxime gave caprolactam.[22] We found that the chirality of the migrating carbon center α to the hydroxyimino group in the formation of lactams in the photo-Beckmann rearrangement is



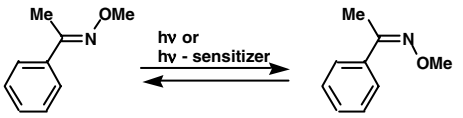
SCHEME 4

retained[23a–j] with one exception;[23k] typically, 5α-cholestan-6-one oxime gives a 1:1 ratio of the two corresponding 5α-lactam isomers, while 5β-cholestan-6-one oxime gives a 1:1 ratio of two 5β-lactam isomers in the photo-Beckmann rearrangement. Based on this and other evidence, we have proposed the path of the photo-Beckmann rearrangement in terms of a simple scheme (Scheme 5) involving photochemical *E,Z*-isomerization, followed by transformations of the excited singlet *E*- and *Z*-oximes into oxaziridine intermediates, and reorganization of the resulting singlet excited oxaziridines to the lactams in a fully concerted manner.[23a–c] A number of five- to eight-membered steroidal lactams were subsequently synthesized by photo-Beckmann rearrangements.[23d–j]



SCHEME 5

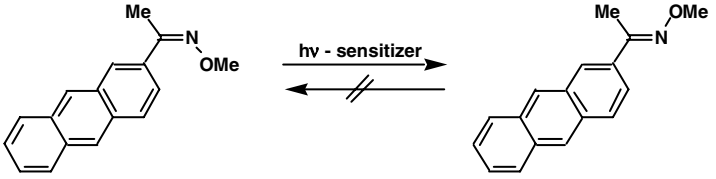
The oxime ethers (such as outlined in Scheme 6) are attractive candidates for mechanistic studies concerning the *E,Z*-photoisomerization of imines *(vide infra)* because the presence of the alkoxyl group drastically reduces the rates of thermal interconversion ($K \times 10^{-3}$ at 60°C) and allows mechanistic studies to be carried out at ambient temperatures.[24] Padwa and Albrecht studied photochemical *E,Z*-isomerization regarding the carbon-nitrogen bond of O-methyl oxime ethers in some detail.[24] They found that upon direct irradiation of the O-methyl oximes of acetophenone, a photostationary state *Z*:*E* ratio of



SCHEME 6

2.20 can be achieved. Photoisomerization about the CN double bond of the oxime ethers could also be induced by triplet excitation. A photostationary state vs. the triplet energy of the sensitizer plot indicates: (1) a high-energy region in which the stationary state ratio is *ca*. 1.5; (2) a gradual increase in the *Z:E* ratio from 72 down to 59 kcal of the triplet energy; and (3) a sharp decrease from 59 to 54 kcal. The latter two observations are explained by a non-vertical excitation of the acceptor, as in the case of stilbene photochemistry. Because direct irradiation could not be quenched with a high concentration of piperylene, an electronically excited singlet appears to be the reactive state in direct irradiation. The O-methyl oxime ether of 2-acetophenone has also been reported to undergo facile *Z,E*-photoisomerisation.[24b] The composition of the photostationary state appears to be concentration dependent, with the *Z*-isomer predominating at low concentration. Fluorescence quenching studies and photosensitization experiments gave evidence for the involvement of a singlet state.[24b] The photoisomerization of some α-oxo-oxime ethers was also investigated in some detail.[25]

More recently, Tokumaru and collaborators found that the O-methyl ether of an aromatic ketone oxime, 2-acetylanthracene oxime O-methyl ether, upon irradiation in benzene underwent one-way *Z,E*-isomerization through a quantum chain process in the triplet state[26a] (Scheme 7). The kinetics of the triplet-state isomerization and the potential energy surface of the triplet state were studied by transient spectroscopy. A quantum yield as high as 22 at a concentration of 1.35×10^{-3} *M* was obtained. According to their calculation, the T_1 potential-energy curves of the substrate are in agreement with the rotation mechanism for one-way isomerization.[26b]



SCHEME 7

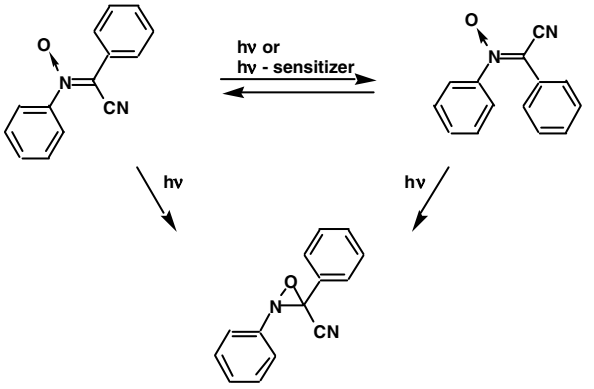
The photochemical reactions of some acyclic β,γ-unsaturated oxime O-methyl ethers, such as 2,2,4-trimethyl-1-phenylpent-3-en-1-one oxime O-methyl ether, were found to undergo only *E,Z*-isomerization and no ADPM rearrangement was observed.[27]

Nitrones

Koyano and Tanaka found that *E*-to-*Z*- and *Z*-to-*E*-photoisomerization takes place upon the irradiation of a solution of α-cyano-α,*N*-diphenylnitrone in the presence of a triplet sensitizer, while the irradiation of *E*- or *Z*-forms of the nitrone in the absence of a sensitizer resulted in the formation of the corresponding oxaziridine.[28] These results indicated that photochemical $E \rightarrow Z$ and $Z \rightarrow E$ isomerization take place from the triplet-excited nitrone, while the photochemical formation of the oxaziridine takes place from a singlet-excited nitrone (Scheme 8).

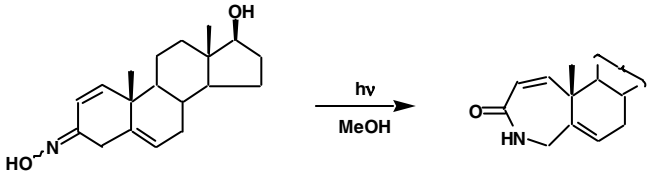
α,β-Unsaturated Oximes

Conjugation of the hydroxyimino group with a CC double bond results in the appearance of a highly intense absorption near 236–260 nm ($\varepsilon = 1.1–2.6 \times 10^4$),[19,29] probably assignable to $\pi\pi^*$ transitions.



SCHEME 8

Subsequent to some early studies concerning the photoreactions of α,β-unsaturated ketone oximes, Bonet and collaborators reported that the photolysis of 17β-hydroxyandrost-1,5-dien-3-one oxime in methanol gave the corresponding lactam arising from a photo-Beckmann rearrangement as outlined in Scheme 9.[30]

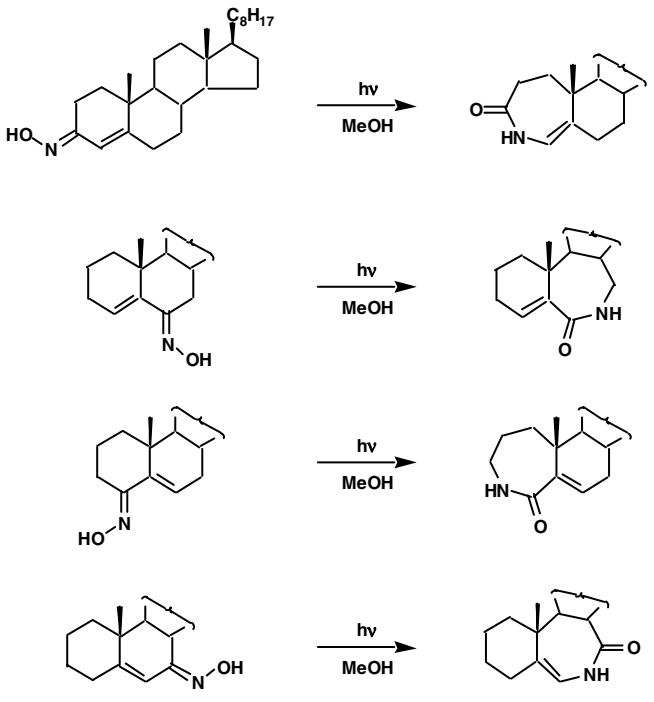


SCHEME 9

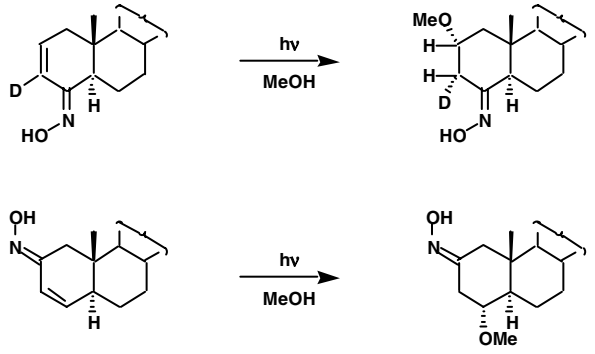
A more systematic investigation on the photoreactions of steroidal α,β-unsaturated cyclic ketone oximes as model substrates was carried out by Suginome and collaborators.[31–34] The steroidal substrates studied included the oximes of steroidal 1-en-3-one, 2-en-1-one, 2-en-4-one, 3-en-2-one, 4-en-3-one, 5-en-4-one, and 5-en-6-one. These oximes were found to react in the following ways on irradiation in protic solvents: (1) *E,Z*-isomerization of the hydroxyimino group, (2) a photo-Beckmann rearrangement to give lactams (Scheme 10), (3) an addition to the α, β-double bond, and (4) a new rearrangement to isoxazoline derivatives, although this was restricted to a single example.

Thus, while the excited oximes, such as those of steroidal-4-en-3-one, 4-en-6-one, 5-en-4-one, and 5-en-7-one, having a constrained CC double bond at a ring junction, lead to a photo-Beckmann rearrangement to give either the corresponding enamine-type lactam or enamide (Scheme 10),[31] the excited oximes with more flexible CC double bonds at a non-ring junction (such as the oximes of 5α-cholest-1-en-3-one, 2-en-3-one, and 3-en-2-one) dissipate the excited energy by photoisomerization in preference to the photo-Beckmann rearrangement. This yields transient *trans*-isomers from which stereospecific additions of protons or methanol to the *trans*-CC double bonds take place (Scheme 11).

While the factor that controlled the regioselectivity of the photo-Beckmann rearrangement of steroidal α,β-unsaturated oximes remains obscure, the different regioselectivity in the lactam formation may originate from a stereoelectronic effect — the relative geometry between a lone pair on the nitrogen and the migrating CC bond in the oxaziridine intermediate.

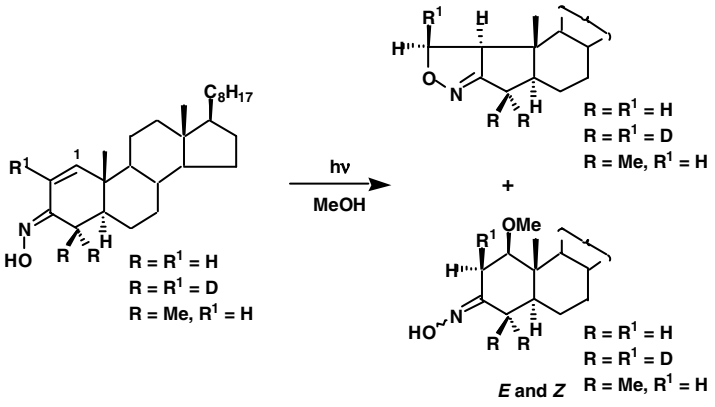


SCHEME 10



SCHEME 11

5α-Cholest-1-en-3-one oxime and its 4,4-dimethyl derivative behaved differently upon irradiation.[32] Thus, the irradiation of 5α-cholest-1-en-3-one oxime or its 4,4-dimethyl derivative in a protic or an aprotic solvent gave isoxazole derivatives (determined by x-ray), arising from an unprecedented rearrangement. These products were accompanied by 1β-methoxy-oximes arising from stereospecific addition of methanol (Scheme 12).



SCHEME 12

The pathway leading to the isoxazoles from the excited enone oximes, based on the results of deuterium labeling, is outlined in Scheme 13;[32] excited oximes generate a twisted ground-state intermediate in which the CC bond is twisted by more than 90°. Stereospecific protonation by either the hydroxyimino proton or by a protic solvent then takes place at C2 of the reactive twisted intermediate from the rear side to give carbocation, since the front side is blocked by the ring. A significant portion of the proton bonded to C2 would be the hydroxyimino proton because the isoxazoline is formed even in dry hexadeuteriobenzene. A carbocation in which the nitrogen lone pair on the C2–C3 bond is oriented in an appropriate geometry for fragmentation may immediately give a nitrile oxide by cleavage of the C2–C3 bond. An intramolecular stereospecific 1,3-dipolar addition of nitrile oxide may give the isoxazoline.

The stereochemistry of the photoaddition of methanol to the cycloalkenone oximes, as disclosed by deuterium labeling, indicates that the adducts are formed by a *syn*-addition to the twisted double bond of the ground-state intermediate from the rear side, as outlined in Scheme 13. The carbocation D fragments to give nitrile oxide E before it is trapped by methanol to give the adduct. The effect of the alkyl group attached to C1 is profound. The irradiation of the 1-methyl derivative of 5α-cholest-1-en-3-one oxime in either a protic or aprotic solvent gave 1-methylene-5α-cholestan-3-one oxime arising from an unprecedented photodeconjugation of α,β–enone oximes into the β,γ -isomers, as outlined in Scheme 14.[33] Neither the expected isoxazole derivative (Scheme 13) nor the unsaturated lactam that arises

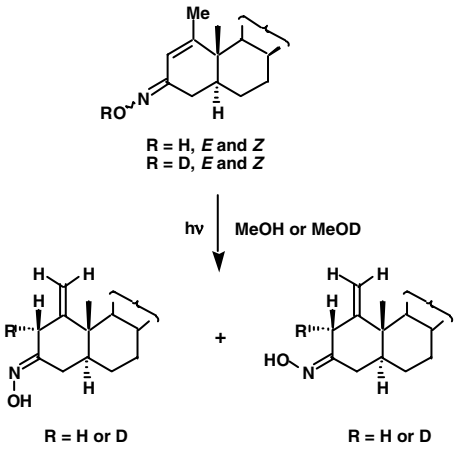
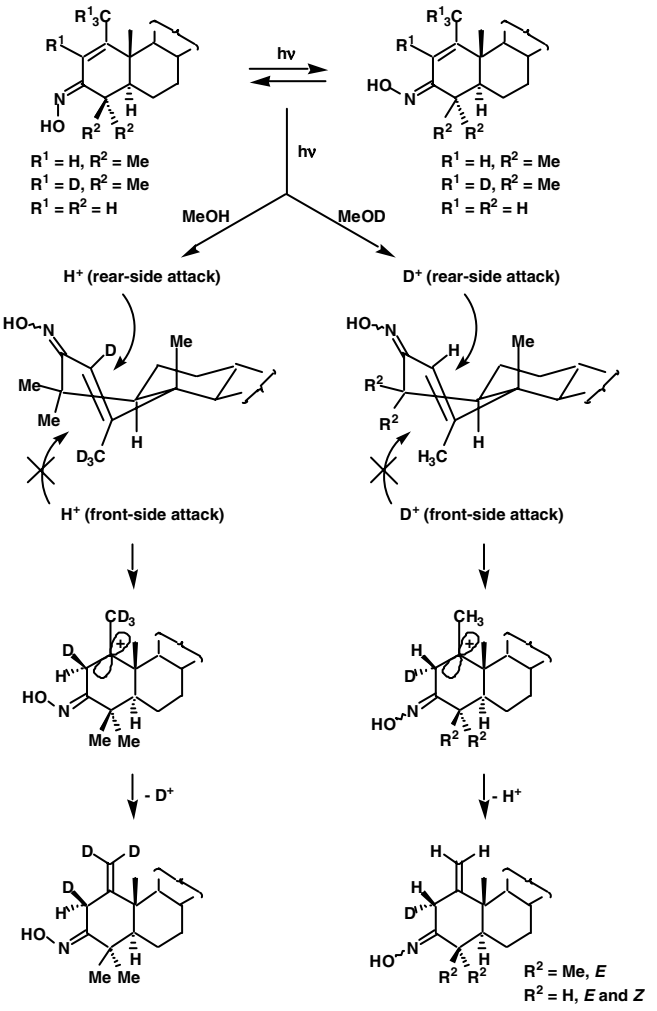
SCHEME 13



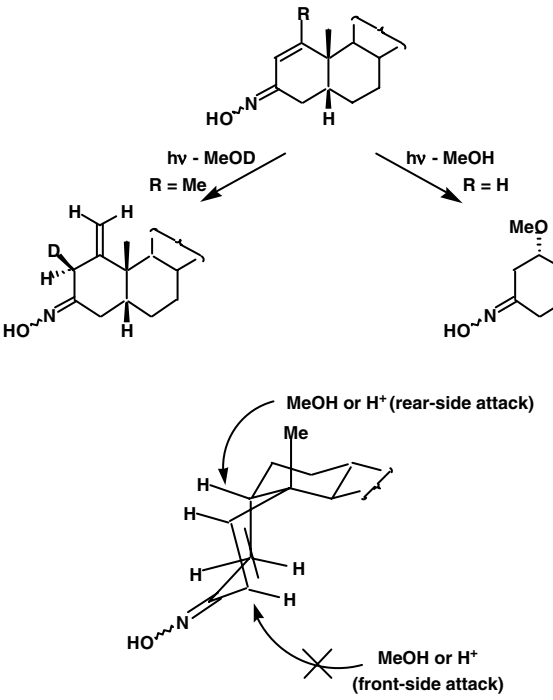
SCHEME 14

from a photo-Beckmann rearrangement was formed. Deuterium labeling studies on the photoreactions of 1-methyl-5α-cholest-1-en-3-one oxime established that either a proton or a deuteron is stereospecifically introduced at the 2α-position of the steroidal oxime in this photodeconjugation. A pathway to the 1-methylene derivative that involves the stereospecific addition of either a proton or deuteron to the photogenerated, twisted double bond of the oximes from the rear side of the steroidal framework, followed by the loss of a proton or deuteron from the 1-methyl group of the resulting carbocation intermediate, is outlined in Scheme 15.



SCHEME 15

The irradiation of 5β-cholest-1-en-3-one in methanol gave 1α-methoxy-5β-cholestan-3-one arising from the photoaddition of methanol, accompanied by the corresponding ketone and a product derived from a skeletal rearrangement of the ketone.[34] Deuterium labeling studies confirmed that the formation of the methanol adduct again involves a stereospecific *syn*-addition of methanol to the photogenerated, twisted, ground-state double bond of the oxime from the rear side of the steroid framework, as indicated by the formation of the 1α-methoxy-steroid (Scheme 16).

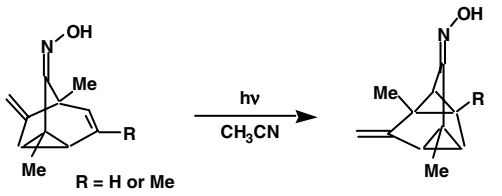


SCHEME 16

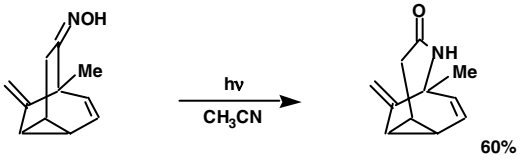
The irradiation of 1-methyl-5β-cholest-1-en-3-one oxime in methanol gave almost exclusively 1-methylene-5β-cholestan-3-one oxime, arising from photodeconjugation.[34] A deuterium labeling study established that deuterium is stereospecifically introduced at the 2β-position of the oxime in the photodeconjugation in deuteriomethanol, while deuterium is stereospecifically introduced at the 2α-position in the photodeconjugation of its 5α-isomer, as mentioned above (Scheme 16). The results are fully parallel with the pathway concerning the above-mentioned photodeconjugation of the 5α-isomer. Neither the isoxazole derivative nor the unsaturated lactam is formed in these photoreactions.

β,γ-Unsaturated Oximes

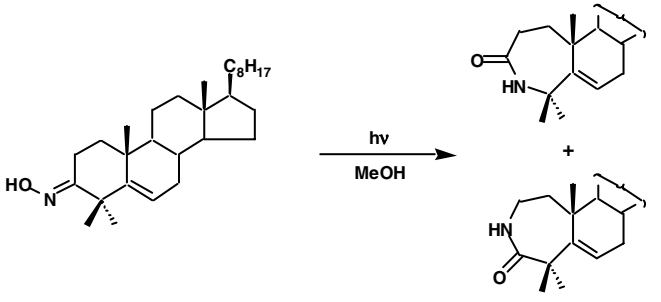
The photoreaction of β,γ-unsaturated oximes was first reported in 1977 by Nitta and collaborators.[35] They found that a highly constrained cyclic β,γ–unsaturated ketone oximes, such as substituted tricyclo[3.2,1.$0^{2,7}$]oct-3-en-8-one oxime in acetonitrile upon irradiation with 254-nm light, resulted in an aza-di-π-methane (ADPM) rearrangement involving the hydroxyimino group to give tetracyclo[3.3.0.$0^{2,8}$ $0^{4,6}$]octane-3-one skeleton, as outlined in Scheme 17.[35a] They also reported that a less-constrained substituted tricyclo[3.3.1.$0^{2,8}$]nona-3-en-6-one oxime with a hydroxyimino group in a larger ring failed to give any product arising from an ADPM rearrangement, but gave the corresponding lactam arising from a photo-Beckmann rearrangement, as outlined in Scheme 18.[35b] Steroidal β,γ-unsaturated ketone oximes, such as 4,4-dimethylcholest-5-en-3-one oxime, behave like saturated cyclic ketone oximes, as expected by the photoreaction of the parent ketone (Scheme 19).[36] Apart from the photoreaction of the constrained oximes, the only photoreaction of acyclic β,γ-unsaturated systems found until the middle of the 1990s



SCHEME 17



SCHEME 18



SCHEME 19

was *E,Z*-isomerization;[27] the oximes usually showed no ADPM reactivity. However, in 1994, Armesto, Horspool, and collaborators found that while direct or sensitized irradiation of acyclic oximes, such as the 2,2-dimethyl-4,4-diphenyl-but-3-enal oxime and its methyl ether (Scheme 20, **1** and **2**), showed no ADPM reactivity, the acetate of the oxime **2** and oximes, such as 2-methyl-4,4-diphenyl-2-vinylbut-3-enal oximes and its methyl ether (Scheme 20, **3** and **4**), underwent the ADPM rearrangement to give the corresponding cyclopropyl derivatives upon direct or sensitized irradiation.[37]

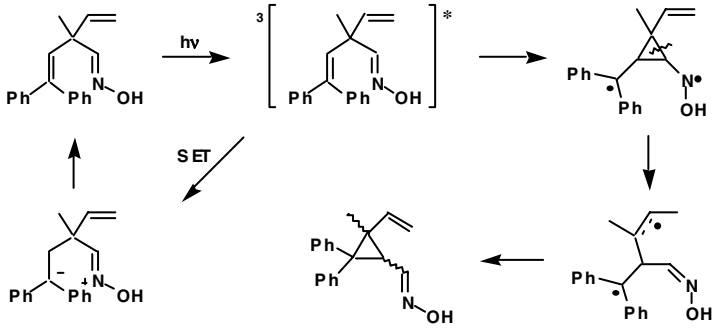
2; R = R^1 = R^2 = Me
3; R = Me, R^1 = -CH=CH_2; R^2 = H
4; R = R^2 = Me, R^1 = -CH=CH_2
5; R = R^1 = Ph, R^2 = H

SCHEME 20

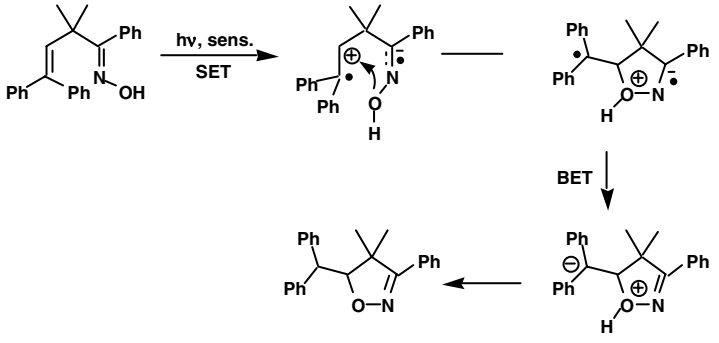
In contrast to the acyclic DPM process, which occurs from the singlet state in most cases, these ADPM rearrangements of the oximes take place from their excited triplet state.



SCHEME 21

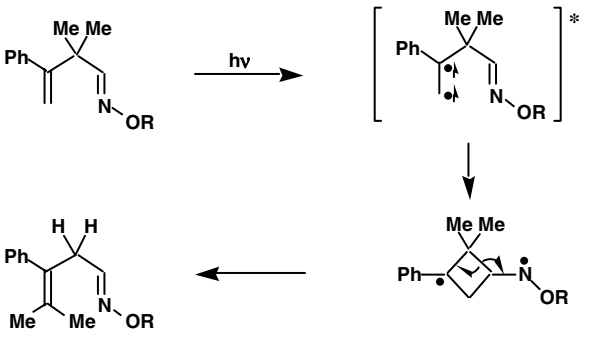
The mechanism for the ADPM rearrangement of the oximes proposed by the authors is outlined in Scheme 21. Thus, the ADPM rearrangement from an excited triplet of the oxime to the cyclopropyl derivative via a 1,3-biradical competes with the SET process, leading back to the starting material. If the energy barrier for the conversion of the excited state to the 1,3-biradical is lower than that for the SET process by virtue of its sufficient stabilization, the ADPM process dominates to give cyclopropyl products. The stability of the intermediate 1,3-biradical is crucial to allow the ADPM rearrangement to compete with the SET process that reverts to the starting material. The replacement of the methyl group attached to the central carbon of the oximes by substituents, such as a vinyl or a phenyl group (Scheme 20, **5**), provides stability for the 1,3-biradical.

Armesto and collaborators also reported that the irradiation of ketoximes, such as (*E*)-2,2-dimethyl-1,4,4-triphenylbut-3-en-1-one oxime, resulted in the formation of the new dihydroisoxazoles.[38,39] According to the authors, this cyclization is controlled by a SET process from the alkene moiety to the hydroxyimino group, as outlined in Scheme 22. Cyclization within the zwitterionic biradical, followed by back electron transfer and hydrogen migration affords the final product.



SCHEME 22

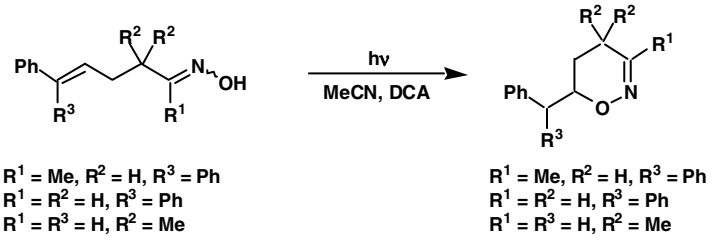
Armesto, Horspool, and co-workers also found a new photochemical 1,3-migration of the hydroxyimino groups in β,γ-unsaturated oximes, although it is restricted to a very limited number of the oximes with all of the correct parameters;[40] acetophenone-sensitized irradiation of the oxime acetate of 2,2-dimethyl-3-phenylbut-3-enal brought about an efficient conversion (81%) to 4-methyl-3-phenylpent-3-enal oxime acetate, as outlined in Scheme 23. This rearrangement is the first example of a 1,3-migration of a C=N group in a 1-aza-diene system. In this rearrangement, one of the radical centers in the intermediate 1,4-biradical is stabilized by conjugation with a phenyl ring.



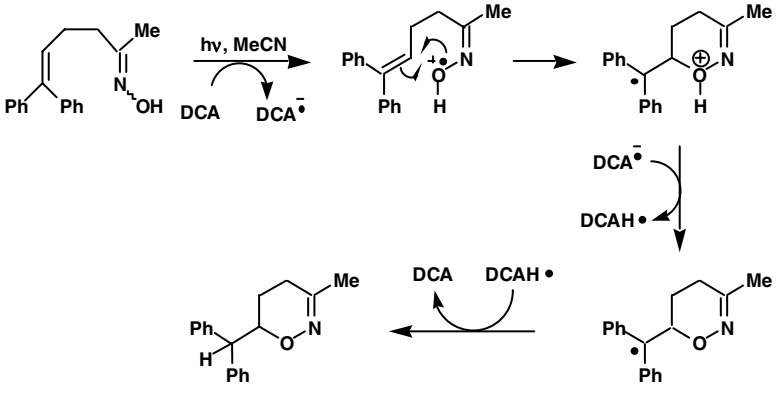
SCHEME 23

γ,δ-Unsaturated Oximes

Armesto, Horspool, and collaborators reported in 1996 that the 9,10-dicyanoanthracene (DCA)-sensitized irradiation of acyclic γ,δ-unsaturated oxime, such as 6,6-diphenylhex-5-en-2-one oxime, underwent a novel photochemical cyclization, yielding the corresponding 5,6-dihydro-4*H*-2,2-oxazine, as outlined in Scheme 24.[41] The mechanism proposed to account for this cyclization by the authors is outlined in Scheme 25. The excitation of DCA, followed by SET from the hydroxyimino group to the sensitizer, generates the radical cation intermediate. The cyclization affords a new radical cation. Proton transfer from the cation to the DCA radical anion, followed by hydrogen abstraction, forms the observed product.



SCHEME 24

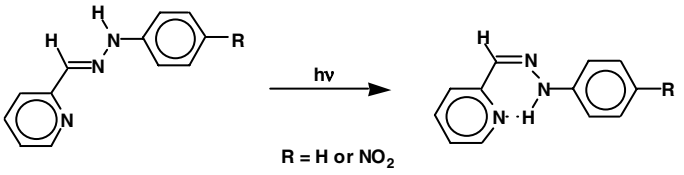


SCHEME 25

The photocyclization of γ,δ-unsaturated oximes enlarges the synthetic utility of the photochemical reaction of oximes.

Hydrazones

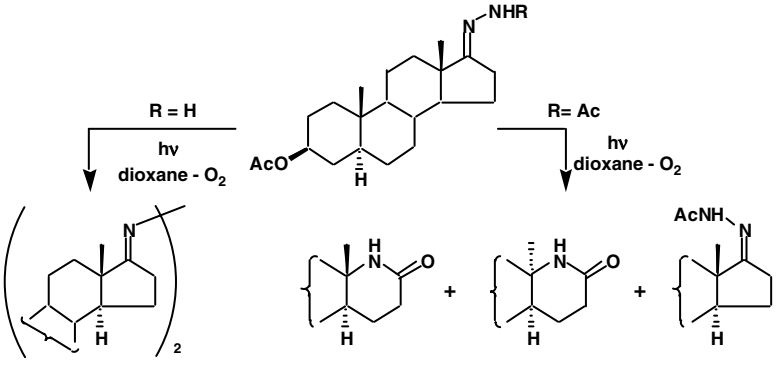
The photochemical *E,Z*-isomerization of phenylhydrazones has also been investigated.[42–46] The introduction of a nitro group to the *N*-aryl group of pyridine-2-aldehyde phenylhydrazone[44] enhances the quantum yield of the photoisomerization of the *E*-isomer to the *Z*-isomer in benzene, but decreases the quantum yield to zero for the reverse process.[44,45] Thus, a direct irradiation of the *E*-isomer of pyridine-2-aldehyde 4-nitrophenylhydrazone in benzene resulted in a complete one-way isomerization to the *Z*-form, the stability of which apparently arises from an intramolecular hydrogen bond between the nitrogen of the pyridine ring and NH (Scheme 26).[44,45]



SCHEME 26

Meanwhile, the photoreactions of some alicyclic and aromatic hydrazones and their acetyl derivatives were investigated by Suginome and Uchida, disclosing photochemical reactions other than the *E,Z*-isomerization.[47–49]

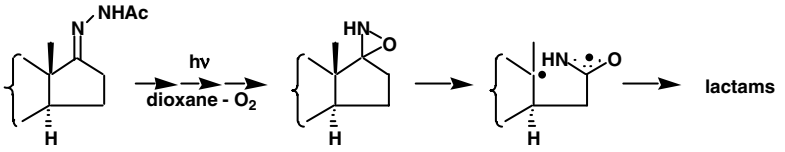
An isolated –C=N-NH_2 group of hydrazones in the UV spectrum gives rise to a band at 198 nm (ε = 3900) in methanol, assignable to the $\pi\pi^*$ transition.[47] The photolysis of an alicyclic ketone, 3β-acetoxy-5α-androstan-17-one hydrazine, was found to lead to NN-bond homolysis to give rise to the corresponding azines in the presence or absence of oxygen (Scheme 27).[47] Thus, *E,Z*-isomerization and NN-bond homolysis are the major photoreactions of excited alicyclic ketone hydrazones.



SCHEME 27

Steroidal cyclic ketone acetyl hydrazones, on the other hand, behaved differently upon photolysis; an unprecedented formation of lactams was found in the photolysis of some steroidal acetylhydrazones in the presence of oxygen.[47,48] The irradiation of 3β-acetoxy-5α-androstan-17-one acetyl hydrazone in dioxan in the presence of oxygen afforded 17-oxo-17α-aza-D-homosteroid and its 13α-isomer in low yields, while if oxygen was excluded, none of these lactams were formed (Scheme 27).[47] A pair of γ-lactams is also formed from its D-nor homologue.[48] Although the details of the multistep process for the lactam

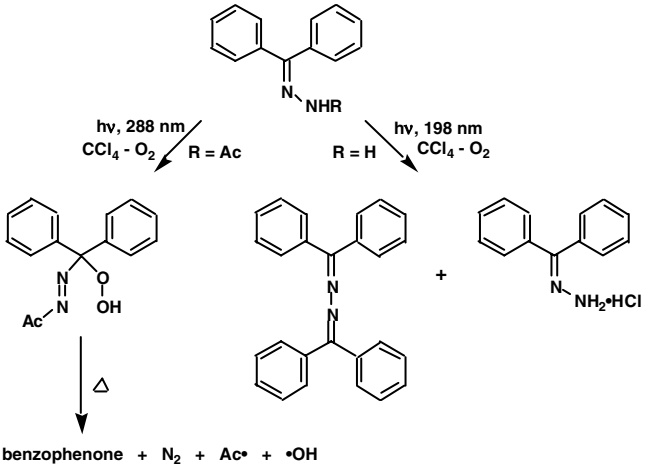
formation were not defined, the path most probably involves the formation of an oxaziridine intermediate, followed by rearrangement to the lactams, as outlined in Scheme 28,[47] since the corresponding oxime yields the same lactam pair arising from the photo-Beckmann rearrangement.[23k]



SCHEME 28

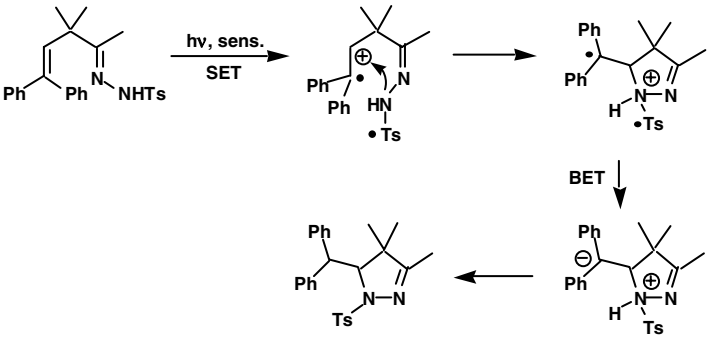
Monochromatic light-induced reactions of aromatic ketone hydrazones and acetyl derivatives were also investigated in an effort to compare with those of the alicyclic ketone hydrazones.[49] Benzophenone hydrazone and its 4-substituted derivatives exhibit two strong absorption maxima due to $\pi\pi^*$ transitions in dioxan, one at 277 nm and the other at 223–234 nm. The acetyl derivative also exhibited two absorption maxima due to $\pi\pi^*$ transitions, which are stronger than the hydrazones.

The irradiation of the hydrazone of benzophenone in carbon tetrachloride in the presence of oxygen with 273-nm monochromatic light generated from a grating spectro-irradiator gave rise to the corresponding azine arising from NN-bond homolysis. On the other hand, the irradiation of the acetylhydrazone of benzophenone in the presence of oxygen gave rise to the corresponding hydroperoxide, which was transformed spontaneously into benzophenone upon isolation (Scheme 29). 4-Substituted derivatives of benzophenone hydrazone and the acetyl derivatives behaved similarly.[49]



SCHEME 29

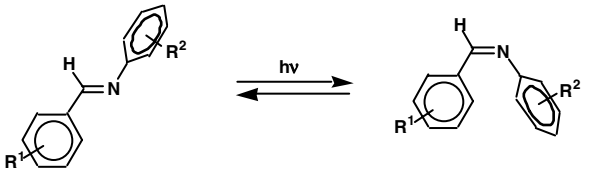
Recently, Armesto, Horspool, and collaborators reported a novel photochemical cyclization of acyclic β,γ-unsaturated tosylhydrazone leading to dihydropyrazoles.[39] The acetophenone-sensitized irradiation of the 3,3-dimethyl-5.5-diphenylpent-4-en-2-one tosylhydrazone yielded the dihydropyrazole in 75% yield. The reaction path, analogous to the oxime cyclization mentioned above, involves SET from the alkene moiety to the substituent on the terminal nitrogen as outlined in Scheme 30.[39]



SCHEME 30

94.3 *E,Z*-Photoisomerization and the Accompanying Reactions of Imines

An isolated azomethine chromophore in alkylimines gives rise to two absorption bands in the UV region of the spectrum at about 230–260 nm ($\varepsilon \approx ca.\ 2 \times 10^2$) and at 170–180 nm ($\varepsilon \approx 10^4$). The former was assigned to the $n\pi^*$ transition band and the latter to the $\pi\pi^*$ transition.[14] Aryl substituted imines absorb at longer wavelength.[50] They exhibit a number of bands; band positions depend on the substituents on the aromatic ring. These bands have been interpreted as being of $\pi\pi^*$ and charge-transfer type;[50] benzylideneaniline exhibits an intense absorption maximum at 252 nm and a shoulder at 315 nm. The absorption attributable to the $n\pi^*$ transition has not been unambiguously assigned and may be submerged in the $\pi\pi^*$ band. It was shown that the absorption spectrum of benzylideneaniline is distinctly different from that of stilbene and azobenzene. It was proved that *E*-benzylideneaniline exists in a conformation in which the PhC=N moiety is planar, but the plane of the *N*-phenyl ring makes an angle with the rest of the molecule. This allows conjugation with the lone-pair electron on the nitrogen atom, but reduces the conjugation between the phenyl rings through the CN double bond. The angle of rotation in the *E*-isomer in the gas, solution, and solid phases was estimated by various techniques to be in the 30 to 55°.[51] It seems to be generally agreed that the aniline ring of the *Z*-form is also rotated.



SCHEME 31

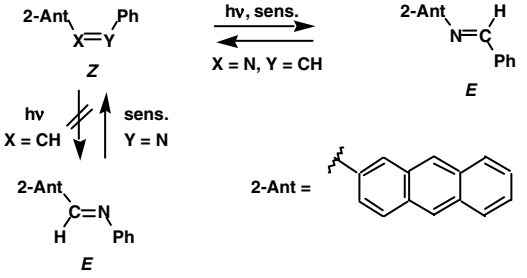
In 1957, Fischer and Frei found that the irradiation of some diarylamines in solution at −100°C induced distinct changes in the UV spectra of the solutions, with the changes leading to an equilibrium.[13] Allowing the solutions to warm up to room temperature restored the spectrum of the original isomer. This report was the first spectroscopic observation of the *E,Z*-photoisomerization of imines. They estimated the thermal relaxation to have an activation energy of 16 to 17 kcal mol^{-1}, which was appreciably lower than those of azobenzene and stilbene (23 and 42 kcal mol^{-1}, respectively). Later, Wettermark and co-workers demonstrated that *E,Z*-isomerism of *N*-benzylideneaniline and related compounds can take place even at room temperature (Scheme 31).[52] At this temperature, thermal relaxation proceeds with a half-life of about one second. They obtained the range of activation energies of $Z \rightarrow E$ thermal relaxation for a number of derivatives of *p*-substituted *N*-benzylideneaniline.

The formation of the *Z*-forms of benzylideneaniline and its derivatives was also observed in matrices at 77K by ^{1}H-NMR,[53a] ^{13}C-NMR,[53b] UV spectroscopy, and IR spectroscopy in Nujol at 77K[53c] and in solution at room temperature by flash photolysis.[53d]

The photochemistry of salicylideneanilines suffers from competing reversible photoreactions involving transfer of the phenolic proton to the imino nitrogen, along with the formation of the corresponding *o*-quinoid forms (photochromism)[52a,54a–d] or a zwitterion.[54e]

Many simple imines are susceptible to facile hydrolysis to give their parent ketones in the presence of even a trace of moisture. The small amount of ketones generated affects the results of the photoreaction of imines. Thus, a major activity in investigating the photochemical behavior of imines has been on imine derivatives, such as O-alkyl oximes and hydrazones, which are less susceptible to hydrolysis. Extensive studies were thus carried out on the *E,Z*-photoisomerization of the configurationally stable oxime ethers, which have already been described (*vide supra)*.[24–27]

A 2-anthryl substituent attached to an imine double bond, as in the case of the corresponding oxime O-methyl ether, was found to affect the photostationary *E*:*Z*-ratio upon low-temperature, triplet-sensitized irradiation. Thus, while *Z*-2-anthrylmethylidene aniline undergoes one-way $Z \rightarrow E$ isomerization upon triplet-sensitized irradiation, the triplet-sensitized irradiation of benzylidene-2-aminoanthracene in an EPA matrix affords a photostationary *E,Z*-mixture rich in the *E* isomer under the same reaction conditions (Scheme 32).[26,55]



SCHEME 32

Comprehensive reviews concerning the photochemistry of the carbon–nitrogen double bond were published in the mid 1970s.[15,16]

Two decades ago, Armesto, Horspool, and collaborators demonstrated that acyclic 1-aza-1,4-dienes undergo an acetophenone-sensitized aza-di-π-methane (ADPM) rearrangement analogous to the di-π-methane (Zimmerman) rearrangement;[56] the direct irradiation in *t*-butanol or acetophenone-sensitized irradiation in benzene of moisture-sensitive imines of 2,2-dimethyl-4,4-diphenylbut-3-enal with UV light resulted in the formation of a cyclopropyl imine as a single product arising from an ADPM rearrangement, as outlined in Scheme 33. In contrast to the DPM rearrangement, which takes place from the excited singlet in most cases, the ADPM reaction takes place from the excited triplet state with a quantum yield of 2.6×10^{-3} in a typical example.

SCHEME 34

Since the discovery of the reaction, extensive investigations have disclosed that the photorearrangement is very general in acyclic 1-aza-1,4-dienes (Scheme 34).[57] The reaction was recently extended to β,γ-oximes.[37]

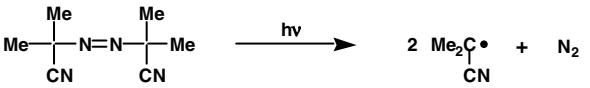
Thus, the scope of this reaction for the synthetic utility has been considerably expanded.

94.4 *E-Z* Isomerization of Azo Compounds

Azoalkanes

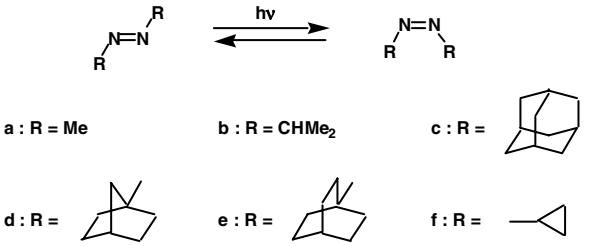
Azoalkanes exhibit absorption bands in two regions: one in the 320–380 nm (ε = 10–150) region and other in the 200-nm region (ε = 1000).[9a,58] The weak, longer wavelength band has been assigned to the nπ* transition and the stronger, shorter wavelength band to the nσ* transition. Bathochromic and hypsochromic effects of the nπ* band are observed in going from *E*-azoalkanes to the *Z*-isomer; *E*-azoisopropane exhibits the nπ* band at 360 nm with ε = 14.5, while the *Z*-isomer exhibits the corresponding absorption at 380 nm with ε = 140 in nonpolar solvents.[9a,59]

The principal reactions of azo compounds upon irradiation with UV light are either the elimination of nitrogen to give alkyl radicals or *E,Z*-isomerization. Until the 1950s, studies on the photoreaction of aliphatic azo compounds largely focused on the elimination of nitrogen in the gas phase.[17,60] For example, the photolysis of azoisopropane in the gas phase generates isopropyl radicals and nitrogen with unit quantum efficiency (Scheme 35).[61] Many aliphatic azo compounds, such as 2,2′-azoisobutyronitrile,[62] that readily generate alkyl radicals upon irradiation or pyrolysis have been used as initiators of such radical reactions as polymerization and radical cyclization in organic syntheses.



SCHEME 35

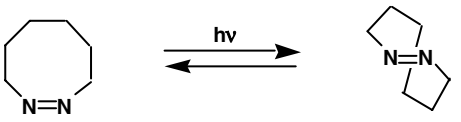
However, in 1964, Hutton and Steel found that irradiation into the nπ* band of *E*-azomethane in solution at room temperature caused a decrease in the quantum yield of nitrogen formation to 0.17 and led to *E,Z*-photoisomerization, as detected by UV and ^{1}H-NMR spectroscopy (Scheme 36).[12] More energetic irradiation into the nπ* band of aliphatic *E*-azoalkanes, such as azoisopropane, using UV light in the 200-nm region led to the elimination of nitrogen along with the formation of vibrationally excited alkyl radicals.[63]



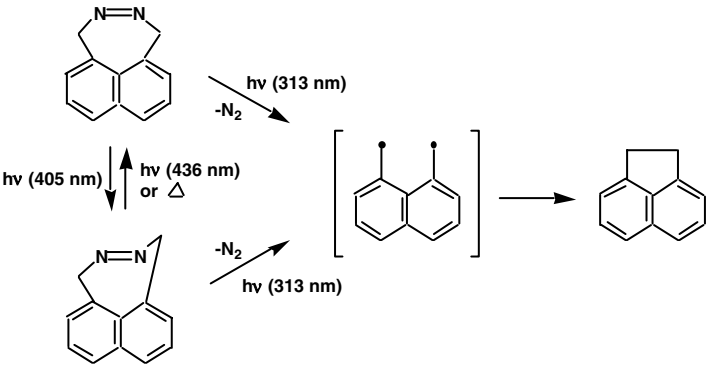
SCHEME 36

Subsequently, Arin and Steel as well as Mill and Stringham found that *E,Z*-isomerization is an important general process competing with dissociation and that many of the photogenerated *Z*-isomers undergo remarkably facile thermal decomposition to give nitrogen and alkyl radicals.[63,64] The irradiation of *E*-azomethane at 25°C in benzene gives the *Z*-isomer with a quantum yield $\Phi_{E\rightarrow Z}$ of 0.42.; the quantum yield $\Phi_{Z\rightarrow E}$ of the reverse reaction was found to be 0.45.[65] The steric effect and the nature of the incipient radical largely govern the stability of *Z*-azoalkenes. *Z*-Azo-2-methyl-2-propane decomposes with an activation energy of 23 kcal mol^{-1}, some 20 kcal mol^{-1} less than that of the *E*-isomers.[64a] The activation energy of the thermal decomposition of *Z*-azoisopropane[64b] is 41 kcal mol^{-1}, which is only about 8 kcal mol^{-1} less than that of the *E*-isomer, while the *Z*-isomer of azobis(1,1-dimethyl-2-propene) decomposes at −120°C.[9a,64c] This mechanism, *E,Z*-isomerization followed by thermal decomposition of the unstable *Z*-isomer to give alkyl radicals, was found to be general for symmetric[66] and unsymmetric azo compounds.[67]

The *Z*-isomer, having considerable steric bulk and a high energy of decomposition due to the generation of high-energy radicals, is expected to be stable and can be thermally isomerized to the *E*-form without the loss of nitrogen. Thus, Engel and colleagues synthesized *Z*-di-1-adamantyldiazene and *Z*-di-1-norbornyldiazene by UV irradiation of the corresponding *E*-isomers in toluene at 0°C (Scheme 36).[68] The quantum yields of nitrogen eliminationin these *E,Z*-isomerizations were extremely low. Engel and Gerth also synthesized *Z*-azacyclopropane via irradiation of the corresponding *E*-isomer with 313-nm light (Scheme 36). It exhibited extraordinary thermal stability toward elimination of nitrogen.[69] Similarly, an eight-membered cyclic *E*-azoalkane was synthesized by Overberger and colleagues, as outlined in Scheme 37.[70] The formation of a seven-membered cyclic *E*-azoalkane has been reported;[71] the direct irradiation (403 nm, nπ* band) or the triplet-sensitized irradiation of 1,4-dihydronaphtho [1,8-de][1,2]-diazepine resulted in a smooth isomerization to the *E*-isomer, while irradiation of either the *E*- or *Z*-isomer with 313-nm light (ππ* band) induced a clear removal of nitrogen to give acenaphthene via a biradical, as outlined in Scheme 38.



SCHEME 37



SCHEME 38

The mechanism by which *E*- and *Z*-azo compounds are interconverted remains unclarified. $\Phi_{E,Z}$ for *E*-azopropane and *E*-azocumene over the +20 to −190°C temperature range indicated no significant barriers to isomerization.[9] Theoretical studies indicated that the mechanism involving rotation about the NN double bond is the preferred pathway for the $n\pi^*$ state, whereas that involving in-plane motion of the substituent group is the preferred one for the $^3\pi\pi^*$ state.[72]

The investigation of *E,Z*-isomerization of azo compounds by triplet sensitization up to the 1980s has been summarized by Engel.[9b]

Azoarenes

E- and *Z*-azobenzenes exhibit three absorptions at longer wavelength.[17,58,73] The lowest-energy bands assignable to their $n\pi^*$ transitions occur at approximately 440 nm ($\varepsilon = 500$) in the *E*-isomer and at 430 nm ($\varepsilon = 1500$) in the *Z*-isomer, respectively. Their second absorption bands occur at 314 nm ($\varepsilon = 17000$) in the *E*-isomer and at 280 nm ($\varepsilon = 5100$) in the *Z*-form. The highest-energy absorption band occurs in the 230–240-nm region for both isomers. The marked hypsochromic shift of the absorption band in the *Z*-isomer is due to the nonplanar conformation of the *Z*-isomer in solution.[17,58] The introduction of an electron-donating substituent to the azobenzene system results in the appearance of the absorption bands in the visible region (azo dyes).

The direct irradiation of aromatic azo compounds in solution brings about *E,Z*-isomerization; but, in contrast to azoalkanes, the elimination of nitrogen to give aryl radicals is negligible (see Scheme 2). This is due to the stronger CN-bond and lower excited-state energy. A full understanding of the nature of the excited state associated with the photoisomerization of azobenzene is more difficult than hydrocarbon analogues, such as stilbene, because of the involvement of an additional $n\pi^*$ state. (Readers should refer to a review article with regard to this aspect.[17])

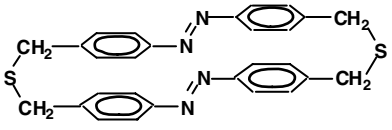
Subsequent to the discovery and identification of the thermally unstable *Z*-isomer of azobenzene by Hartley (see Scheme 2),[11] the crystal structures of the *E*- and *Z*-isomers were determined by Robertson.[74] The benzene ring of the *Z*-isomer of azobenzene is rotated by 56° from the planar position and the distance between the 4 and 4′-carbons is shortened from 9.0 Å in the *E*-isomer to 5.5 Å in the *Z*-isomer. Since then, the generality of the photoisomerization reaction has been demonstrated with a variety of

azobenzene derivatives.[75] A convenient isolation procedure of *Z*-azobenzene, *Z*-2,2′-azopyridine and azonaphthalenes using column chromatography has been described.[76]

The proportion of the *Z*-isomer at the photostationary state is increased if the wavelength of light applied is not absorbed by the *Z*-isomer. Fischer and colleagues showed that the proportion of *Z*-azobenzene at the photostationary state increased to 91% with 365-nm light, while it was only 37% with unfiltered UV light, because the *E*-isomer has a much higher extinction coefficient than the *Z*-isomer.[77]

The quantum efficiency of *E,Z*-isomerization was studied by several investigators.[77,78] Among them, the quantum yields determined by Zimmerman are: for the ultraviolet band, $\Phi_{Z,E} = 0.42$, $\Phi_{E,Z} = 0.11$; for the visible band, $\Phi_{Z,E} = 0.4.8$; $\Phi_{E,Z} = 0.24$.[78]

Although the mechanism of the photoisomerization of azobenzene may involve either twisting around the central NN double bond in the excited state (rotation mechanism) or inversion at one of the nitrogen atoms (inversion mechanism), this has been a subject of debate.[79] Evidence has recently been reported for the involvement of an inversion mechanism for $n\pi^*$ excitations.[80] An *E,Z*-photoisomerization took place when *E*-2,19-dithia[3,3](4,4′)-*trans*-diphenyldiazeno(4)phane 1 in benzene was irradiated. This



1

was taken as unequivocal proof for an inversion mechanism of azobenzene because a planar inversion in this molecule is possible while rotation should be severely hindered. The quantum yields were found to be wavelength independent, in contrast to those of the parent azobenzene. Further evidence was reported[80b] that normal azobenzenes isomerize via an inversion from the $n\pi^*$ state, but that upon $\pi\pi^*$ excitation a rotational feature becomes important. Evidence for the involvement of an inversion mechanism has also been obtained from a study of a substituted azobenzene.[80c]

The activation energy of the thermal reversion of *Z*-azobenzenes to their *E*-forms has been shown to be *ca*. 24 kcal mol^{-1} for a wide range of derivatives. This value is some 13 kcal mol^{-1} lower than that observed for the isomerization of stilbene, thus suggesting an inversion mechanism.[81]

More recently, it was shown that the thermal $Z \rightarrow E$ isomerization of a *Z*-isomer of azobenzene-bridged azacrown ether (**5** *Z*, Scheme 53) took place via an inversion mechanism[82] because the isomerization via rotation was severely hindered in this molecule.

A fundamental study of the sensitized photochemical *E,Z*-isomerization of azobenzene in solution was again carried out.[83]

The photochemistry of 4-diethylamino- and 4-diethylamino-4′-methoxyazobenzene was studied as reasonable models for commercially useful mono-azo dyes.[84] It was concluded that the lowest singlet and triplet states of these azobenzene derivatives are only capable of geometrical isomerization, whereas hydrogen abstraction takes place from the high-lying triplet state of both the *E*- and *Z*-forms of these dyes.[84]

Karatsu and co-workers recently reported that, like the corresponding oxime O-methyl ether and imine,[26] a 2-anthryl group attached to an azo group appreciably influenced the *Z*:*E* ratio, rich in the *E*-isomer, at the photostationary state; 2-phenylazoanthracene in an EPA matrix in the presence of eosin as a triplet sensitizer upon irradiation at 273K with 520-nm light resulted in a 9:1 *E*:*Z*-mixture of the isomers.[55]

94.5 *E,Z*-Isomerization of Azoxy Compounds and Nitrosoalkane Dimers

Like azo compounds, aromatic aliphatic or mixed azoxy compounds, represented by the general formula $R\text{-}N^+(\text{-}O^-)\text{=}N\text{-}R'$ (R, R′ = alkyl or aryl), exist in *E*- and *Z*-forms. Nitrosoalkane dimers, represented by

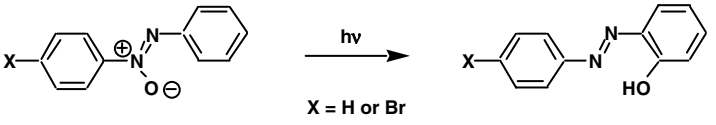
the general formula R-$N^+(-O^-)$=$N^+(-O^-)$-R (R = alkyl) are also able to exist in two interconvertible *E*- and *Z*-geometrical forms.

Although studies of the action of light on azoxy compounds were initiated at the turn of the last century, little attention was paid to the photochemical *E,Z* isomerization for the initial 60 years.

Azoxyarenes

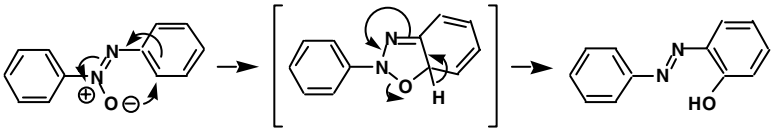
Since the discovery of azoxybenzene by Zinin,[85] which dates back to as early as 1841, *E*-azoxybenzene was prepared either by the reduction of nitrobenzene[86] or by the oxidation of *E*-azobenzene[87] with peracetic acid.

Wacker was the first to report that paper impregnated with 1,1′-azoxynaphthalene turned red upon exposure to sunlight and to propose the formation of an "oxy-azo" compound.[88] Subsequently, Knipscheer reported that azoxybenzene, impregnated in sheets of filter paper, rearranged to 2-hydroxyazobenzene upon exposure to sunlight (Scheme 39; X = H).[89] Cumming and co-workers subsequently found that this rearrangement also took place when azoxybenzenes in various solvents were irradiated with ultraviolet light.[90] Bigelow[91] has reviewed the early development of the chemistry of azoxybenzene, including the action of light. The development of the photochemical reactions including *E,Z*-isomerizations until the late 1960s has been summarized by Spence, Taylor, and Buchardt.[92]

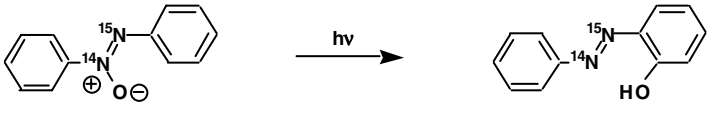


SCHEME 39

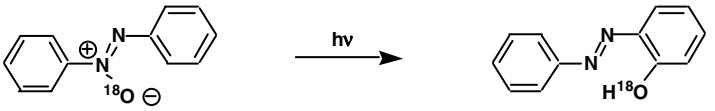
Badger and Buttery then demonstrated that unsymmetrical azoxybenzene and azoxynaphthalene derivatives rearranged (5 to 15% yields) to the corresponding *o*-hydroxyazo compounds, the oxygen atom migrating from nitrogen to the remote aromatic nucleus, upon exposure to sunlight for 1 month; α-4-bromoazoxybenzene rearranged to give 4-bromo-2-hydroxyazobenzene (Scheme 39; X = Br).[93] This result suggested the process outlined in Scheme 40 involving an intramolecular transfer of oxygen. The intramolecularity was further proved by ^{15}N or ^{18}O labeling studies (Scheme 41 and Scheme 42)[94,95] and by a study using azoxybenzene substituted with alkyl groups (Scheme 43).[96]



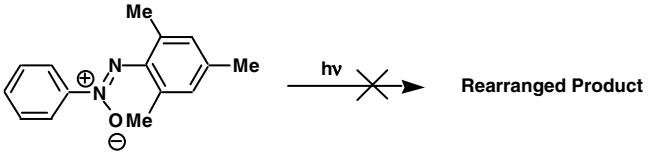
SCHEME 40



SCHEME 41



SCHEME 42



SCHEME 43

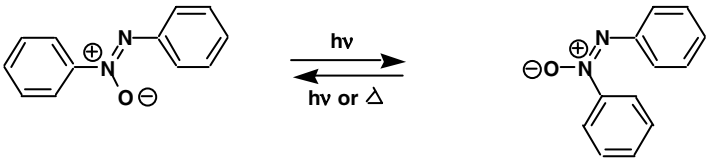
Like azo compounds, *E,Z*-isomerization should have taken place in the photoirradiation of the azoxy compounds. However, the reported formation of 2-hydroxyazobenzene mentioned above required either prolonged sunlight irradiation or UV light irradiation at a temperature of 150 to 200°C, although the inefficiency of the rearrangement suggested some other competitive energy dissipation process. In fact, a paper published by Müller in 1932 reported that isoazoxybenzene in alcohol was transformed into normal azoxybenzene upon UV irradiation at 0°C.[97]

An excited state leading to oxygen transfer and *E,Z*-isomerization of azoxybenzene was first reported by Tanikaga.[98] The UV spectrum of azoxybenzene in ethanol shows an absorption maximum at 323 nm ($\varepsilon = 14700$) assignable to the $\pi\pi^*$ band, but the $n\pi^*$ band is submerged under the $\pi\pi^*$ band. The direct irradiation of *E*-azoxybenzene with light longer than 300 nm resulted in the formation of 2-hydroxyazobenzene, together with *E*- and *Z*-azoxybenzenes, while the irradiation in ethanol in the presence of benzophenone as a triplet sensitizer resulted in the formation of azobenzene. Based on these results, Tanikaga concluded that the formation of 2-hydroxyazobenzene and *E*- and *Z*-azoxybenzene takes place from the excited $\pi\pi^*$ singlet state of azoxybenzene.

The mechanism of the photoreduction of azoxybenzene to azobenzene in the presence of benzophenone was rationalized by Monroe and Wamser to involve the transfer of a proton from the ketyl radical, generated from excited benzophenone via hydrogen abstraction from the solvent to azoxybenzene, followed by dehydration (chemical sensitization).[99]

Mauser and collaborators then proved spectrophotometrically that *E*- azoxybenzene in methanol isomerises to *Z*-azoxybenzene upon irradiation with 313 nm light and the *Z*-form is converted back to the *E*-form under the action of light or in the dark. The *E*-isomer rearranged to 2-hydroxyazobenzene in a parallel reaction.[100]

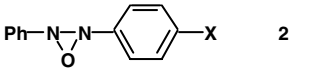
In 1964, Webb and Jaffe found that the irradiation of a substituted *E*-azoxybenzene at low temperature resulted in an *E,Z*-equilibrium mixture from which the corresponding *Z*-isomer was isolated by adsorption chromatography for the first time.[101] Thermal *Z,E*-isomerization seems to be suppressed at this low temperature. Rhee and Jaffe then made a photo- and thermochemical study of the *E,Z*-isomerization of azoxybenzene. They reported that the activation energy of the *E,Z*-isomerization of azoxybenzene was 25 kcal mol^{-1} in 95% ethanol and 19 kcal mol^{-1} in heptane (Scheme 44). The quantum yields for the photoisomerization in heptane or ethanol were 0.11 for $E \rightarrow Z$ and 0.60 for $Z \rightarrow E$ and were independent of the wavelength of irradiation in the 330- to 370-nm range.[102]



SCHEME 44

Among several studies made from the 1970s to the 1980s on the mechanistic details of the photorearrangement,[103–108] Bunce and collaborators[106] concluded that the rearrangement involves an intermediate formed by an intramolecular electrophilic substitution by the azoxy oxygen, originally proposed by Badger and Buttery.[93] They also argued,[101,106] based on their quenching experiment and INDO calculations, that the excited state responsible for the azoxybenzene rearrangement is the $n\pi^*$ singlet and not the $\pi\pi^*$ singlet assumed by Tanikaga.

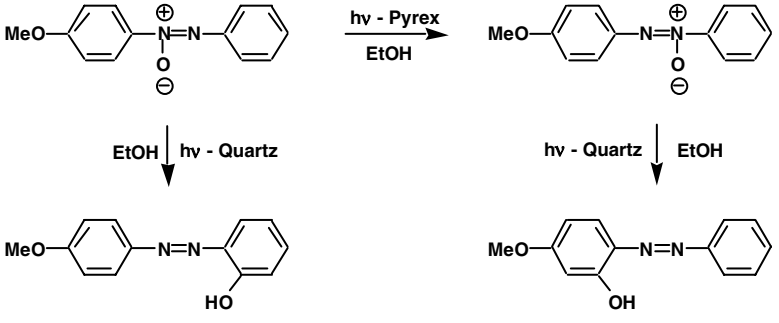
More recently, Albini and collaborators took up the problem.[108] They investigated the photoreactions in alcohol and in benzene of six azobenzenes bearing methoxy or dimethylamino group(s) at the *para*- and/or *para′*- positions. They found significant solvent and wavelength effects for the rearrangement, which occurred for all except the disubstituted derivatives (Scheme 45). The process involves a Badger intermediate, which either reverts to the starting material or is transformed into the final *o*-hydroxyazobenzene via a diazonium ion that can be trapped with 2-naphthol (Scheme 46). The effect of wavelength of irradiation also seems to be significant in those azoxybenzenes having electron-donating group(s); 1,2-oxygen shift from (4-methoxyphenyl)phenyldiazene-2-oxide to the isomeric 1-oxide in ethanol upon Pyrex-filtered light irradiation is general for the azoxybenzenes bearing an electron-donating group (Scheme 45). The oxygen transfer, which probably involves an oxadiazirine intermediate 2, is a one-way



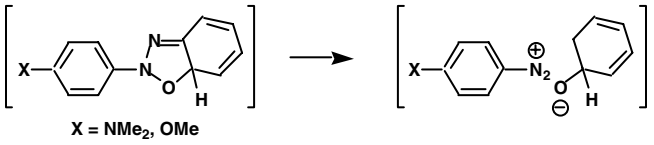
2

X = NMe_2, OMe

process in every case, transferring the oxygen atom distant from the ring bearing the electron-donating group. On the other hand, the photorearrangement to 2-hydroxyazobenzene in ethanol takes place upon irradiation with quartz-filtered light (Scheme 45).



SCHEME 45

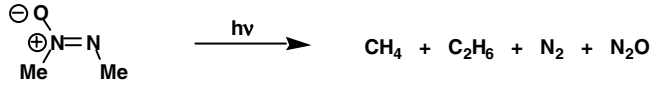


SCHEME 46

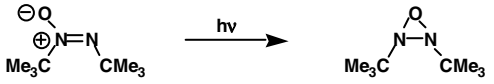
Based on the solvent and substituent effects on the electronic spectra, the quantum yields, and the product distribution, it was concluded that the azoxy rearrangement takes place from a $\pi\pi^*$ CT (charge-transfer) state rather than the $n\pi^*$ state as suggested by Bunce.

Azoxyalkanes

Lythgoe and co-workers synthesized azoxymethane and other azoxyalkanes.[109] The photolysis of azoxymethane led to a decomposition to give nitrogen, nitrous oxide, methane, and ethane (Scheme 47).[110] Azoxy-*t*-butane stabilized by *t*-butyl groups, however, resulted in the formation of 1,3-di-*t*-butyloxadiaziridine upon UV irradiation at 10°C (Scheme 48).[111]



SCHEME 47



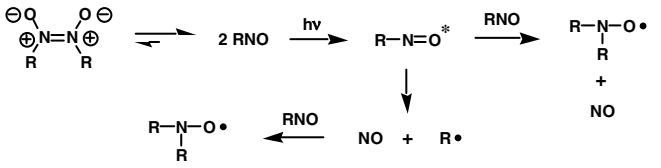
SCHEME 48

Nitrosoalkane Dimers

Many nitrosoalkanes and nitrosoarenes exist as dimers at room temperature. In 1976, Gowenlock and Trotman carried out a unique investigation on the isolation of *E*- and *Z*-isomers of the nitrosoalkane dimer.[112] They prepared two isomers, A and B, of dimeric nitrosomethane generated by the photolysis and pyrolysis of *t*-butyl nitrite vapor by trapping them on the surface of the apparatus. The less-stable isomer A was transformed into isomer B upon heating or by dissolving it in a solvent. They formulated the A and B forms as *Z*- and *E*-isomers of diazine dioxides **3**. The diazine dioxide structure for the nitroso dimers was later confirmed by NMR spectroscopy by Freeman.[113]

3*E* **3*Z***

Many nitrosoalkane dimers in solution are in equilibrium with nitrosoalkane monomers at room temperature. De Boer and collaborators demonstrated that the photolysis of nitrosoalkane dimers in solution results in the formation of the corresponding nitroxides, as proved by ESR spectroscopy (Scheme 49).[114] The formation involves a combination of alkyl radicals generated from excited nitrosoalkanes with ground-state nitrosoalkanes.

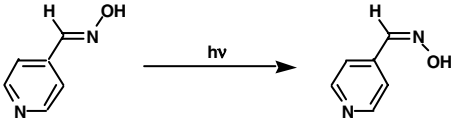


SCHEME 49

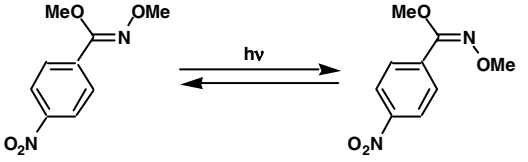
94.6 Applications

Synthesis

The ground-state synthesis of imines, oximes, and azo compounds invariably produces the more stable *E*-isomers and photochemical isomerization is practically the only means for preparing their less-stable *Z*-isomers,[76] as in the case of olefins such as stilbene. For example, the pharmacologically active *Z*-isomer of isonicotinaldehyde was prepared by photoisomerization (Scheme 50).[115] A less stable *E*-isomer of methyl *p*-nitrophenylhydroximate O-methyl ether can be isolated in 38% yield by UV irradiation of the *Z*-isomer in benzene, followed by preparative TLC (Scheme 51).[116]



SCHEME 50

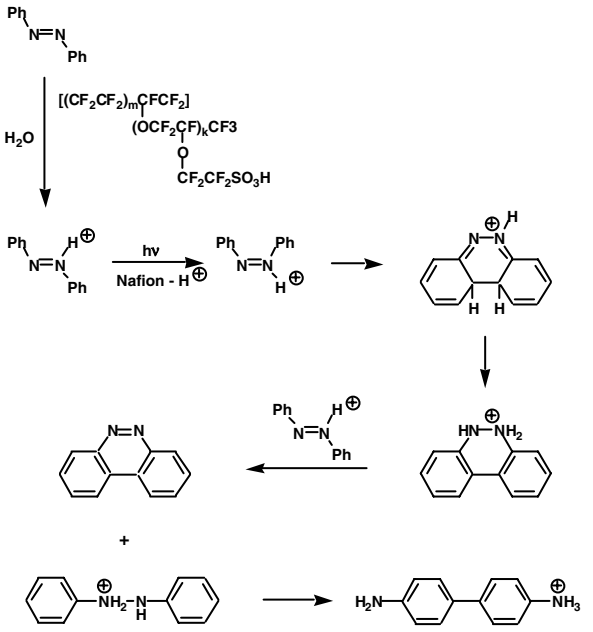


SCHEME 51

The *E,Z*-photostationary ratio is largely governed by the relative extinction coefficient of the absorptions of the two isomxxsers at the wavelength used for direct irradiation.[24,77] Isomerization can also be achieved by triplet sensitization, in which the relative values of the triplet energies are important in governing the ratio of the isomers.[24]

Photoreactions of Azobenzenes Adsorbed on Polymer or Silica Film

The photochemical and photophysical behavior of azobenzene adsorbed on polymer or silica films has been reported recently;[117] azobenzene adsorbed in water-swollen Nafion-H^+ (Nafion is a polymer consisting of a perfluorinated backbone and short pendant chains terminated by sulfonic acid groups) exhibited strong fluorescence. The irradiation resulted in the formation of benzo[*c*]cinnoline and benzidine in quantitative yield, while azobenzene incorporated into a methanol-swollen Nafion-H^+ membrane did not emit fluorescence but merely underwent *E,Z*-isomerization. Thus, solvent–swollen Nafion is useful in the selective phototransformation of azobenzene. According to the authors, protonated azobenzene molecules are located at the fluorocarbon/water interface in water-swollen Nafion-H^+ *Z*-Azobenzene formed on these membranes resulted in cyclization to give the observed products (Scheme 52).



SCHEME 52

On the other hand, an azobenzene derivative was recently used as a photoresponsive probe to examine photoreactions in constrained media.[118] *E,Z*-photoisomerization was observed over the temperature range of 80 to 300K when a cationic azobenzene derivative, *p*-(ω-dimethylhydroxyethylammonioethoxy)-azobenzene, adsorbed on an aluminum-containing mesoporous silica film as a nano-reactor for photoreactions, was irradiated with 350-nm light. The results indicated that mesoporous silica films can be exploited as a nano-reaction vessel over a wide temperature range for photochemical reactions.

Photoresponsive Molecules Containing an Azobenzene Unit

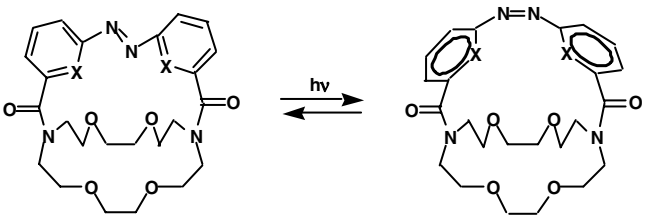
The photoinduced *E,Z*-isomerization of azobenzene, which is a typical photochromic molecule,[119] has attracted considerable attention of chemists since the 1970s when several research groups recognized the usefulness of photoinduced *E,Z*-isomerization of azobenzene as a new tool to enforce reversible changes in the conformation of a lamellar multibilayer,[120] a synthetic bilayer membrane,[121] cyclodextrins,[123] crown ethers,[124–129] gelators,[135,136] enzyme regulators,[139,151] dendrimers,[141–145] polypeptides,[122,146–153] and polymers[154–157] with a variety of intentions. The applications have recently expanded from the field of molecular recognition to that of bio- and material sciences and technology such as liquid crystal displays and devices, reversible optical data storage systems, holographic gratings, etc. Thus, considerable efforts have been devoted to investigations concerning the constructions and properties of photoresponsive molecular systems having azobenzene units, especially in the past two decades.

Photoresponsive Crown Ethers

Shinkai and colleagues have synthesized a number of photoresponsive azobenzene-bridged crown ethers and studied their functions. In general, 70 to 80% of the photoresponsive molecules containing the *E*-azobenzene unit can be converted to the *Z*-isomer upon irradiation with UV light ($330 < \lambda < 380$ nm). The *E*-isomer is quantitatively regenerated, either thermally or upon irradiation with visible light ($\lambda >$ 420 nm). Because of space limitations, only a few of the results in this area are highlighted in this review.

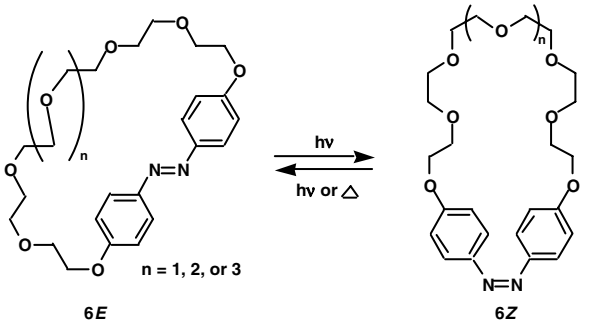
Thus, in their first study, Shinkai and colleagues prepared the azobenzene-bridged azacrown ether **4** and found that the binding efficiency of **4** for alkali-metal ions can be modified by *E,Z*-photoisomerization (Scheme 53). The result was rationalized in terms of a photoinduced expansion of the azacrown ether

size.[124a] Similarly, they prepared the *E*-isomer of a new photoresponsive cryptand **5** containing a 2,2′-azopyridine bridge that can bind heavy-metal ions such as Cu^{2+}, Ni^{2+}, Co^{2+}, and Hg^{2+} from aqueous solution into the organic phase, whereas the photo-generated *Z*-isomer is unable to bind such ions (Scheme 53).[125]



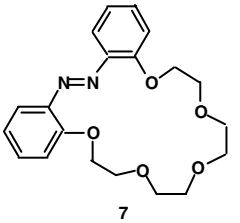
SCHEME 53

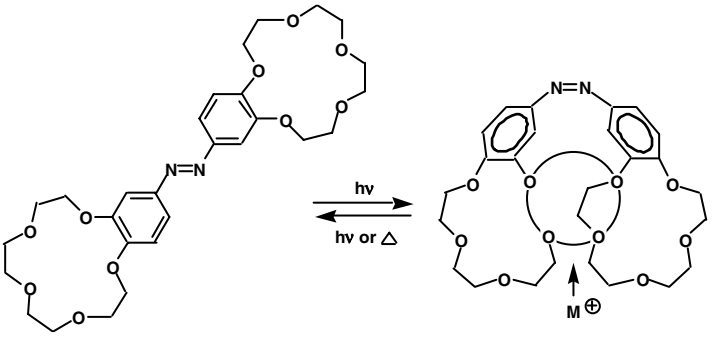
In contrast, the *E*-isomer of azobenzenophane crown ether **6** totally lacks the ability to extract metal ions, whereas the *Z*-isomer is able to bind alkali-metal cations (Scheme 54).[126]



SCHEME 54

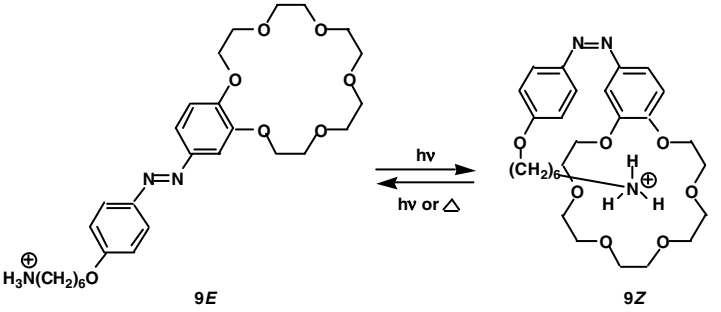
The *Z*-form of the photoresponsive crown ether **7**, prepared by Shiga and colleagues, lacks affinity for alkali-metal ions, whereas the *E*-form is reactive in this process.[124b] The *E*-isomer of a bis-crown ether **8** and the photoisomerized *Z*-isomer (Scheme 55) exhibit a contrasting ion-extraction ability;[127] the ratio (*E*:*Z*) of extractability for Na^+ against that for K^+ is 238-fold. Rb^+ and Cs^+ are also extracted by **8*Z*** more efficiently that by **8*E***.





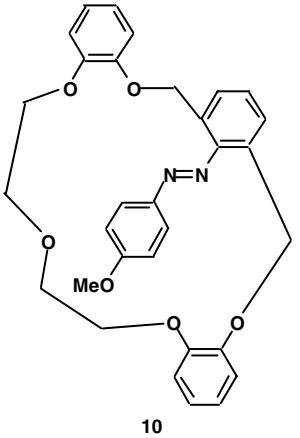
SCHEME 55

Moreover, the rate of the K^+ transport across a liquid (*o*-dichlorobenzene) membrane was found to be suppressed by light when a hydrophobic counterion was used, whereas it was accelerated by light when a relatively hydrophilic counterion was used. The ion-binding ability of the *E*-form of the photoresponsive crown ether **9** changes upon irradiation as a consequence of an intramolecular interaction between the ammonium group and the crown ether in the *Z*-isomer, as outlined in Scheme 56.[128]

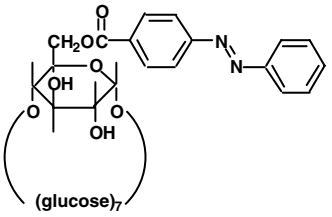


SCHEME 56

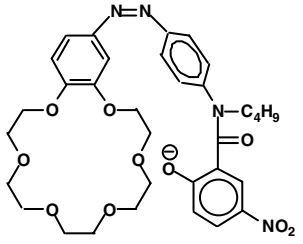
Similarly, the ion-binding properties of the crown ether **10** are appreciably altered upon *E,Z*-photoisomerization.[129]



In another attempt, azobenzene-appended γ-cyclodextrin **11** was prepared. Upon the irradiation with 320- to 390-nm light, 70% of the *E*-isomer in water isomerized to the *Z*-isomer, which exhibited an enhanced binding ability for (−)-borneol and (+)-fenchone.[130] Benzo-18-crown-6 **12** linked to a phenol was synthesized. Upon irradiation by UV light, the azo linkage isomerized to the *Z*-isomer. It slowly reverted to the *E*-form in the dark and rapidly upon irradiation with visible light. An enhanced extraction of Ca^{2+} by the *Z*-isomer has been observed. The *Z* structure constitutes a "photoresponsive anion cap."[131]

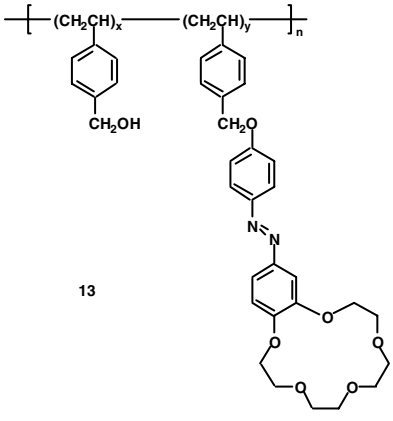


11



12

A polymer-bearing pendant photoresponsive crown ether **13** was prepared and the effects of photoirradiation on metal ion extraction was examined. There was little effect on the extractability for Na^+ and K^+ but a significant decrease for Rb^+ and Cd^+.[132]



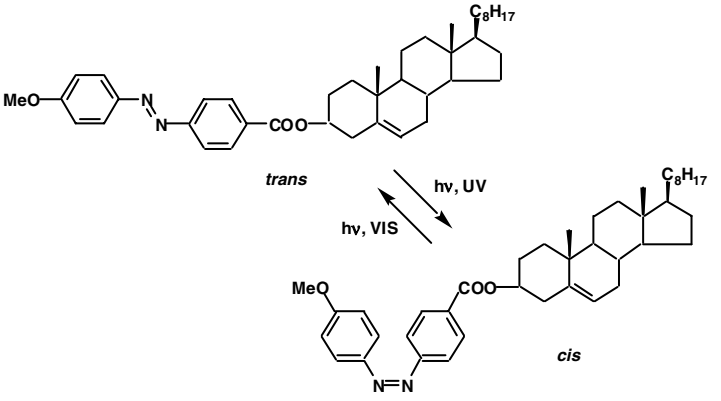
13

Readers interested in this application of the photoisomerization of azo compounds should refer to the review articles[133] and the original papers.[134]

Photoresponsive Gelators

Photoresponsive steroids containing an azobenzene moiety were synthesized and their functions as a gelator[135] were studied by Shinkai and collaborators.[136a] The sol–gel transition of the steroidal gelator– butanol system could be controlled by UV and visible light irradiation, which induced the reversible *E,Z*-isomerization of

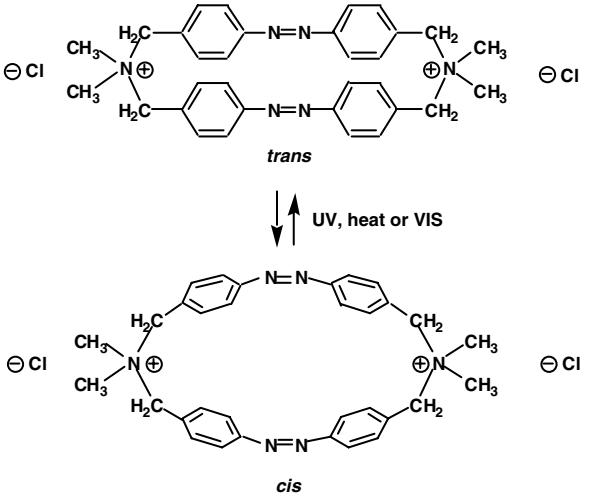
the azo unit (Scheme 57). Shinkai and collaborators then prepared more than 19 cholesterol derivatives containing a variety of azobenzene moieties coupled to a steroidal structure through an ester linkage.[136b] Among them, cholesterol derivatives bearing a *p*-alkoxyazobenzene group acted as gelators of various organic fluids. The gel formed from the *E*-isomer was found to be converted to the sol when *E,Z*-isomerization was brought about on irradiation. This process could be repeated reversibly.



SCHEME 57

Photoresponsive Cyclophane

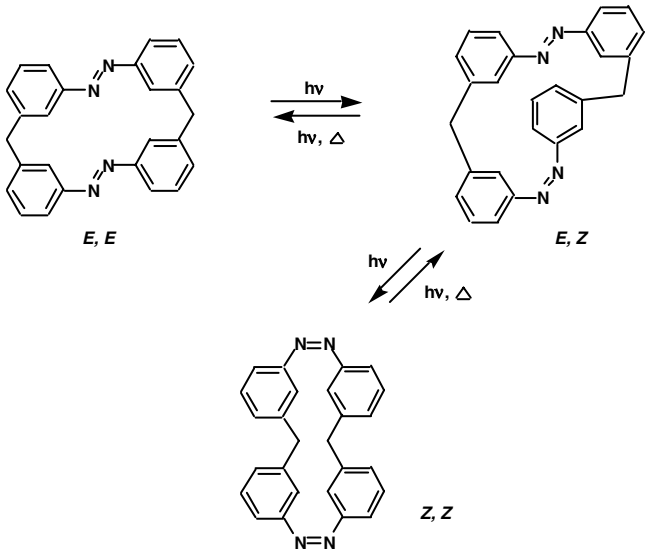
The synthesis of a photoresponsive, water-soluble azobenzenophane and the photoresponsive association properties for mono- and dicarboxylate guest molecules were studied by Shinkai and collaborators.[137] It was found that the guest recognition ability of the cyclophane was affected by photo-irradiation, which induced a change in its cavity shape generated by *E,Z*-isomerism of the azobenzene moieties (Scheme 58).



SCHEME 58

Tamaoki and co-workers have reported the synthesis of several azobenzenophanes, and their most recent work includes the synthesis of [1,1]-(3,3′)–azobenzenophane, in which two azobenzene units are connected by $-CH_2-$ chains at the *meta* positions.[138] They isolated the three isomers, *EE*, *EZ*, and *ZZ*, (Scheme 59) and determined the crystal structures. The x-ray crystal structures disclosed slightly and

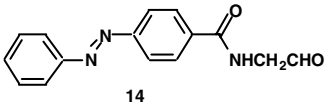
highly distorted conformations for the *EE* and *EZ* isomers, respectively. The *ZZ* isomer, however, is not strained and this is in agreement with the thermal stability of the isomers in solution.



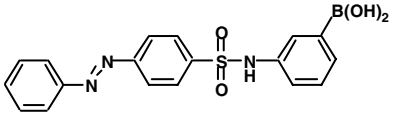
SCHEME 59

Photochromic Enzyme Inhibitors

Photocontrol of enzyme functions is an important area of current research. The aldehyde **14** and the boronic acid **15,** both bearing an azobenzene group, were designed.[139] In these molecules, the head consists of a primary recognition moiety for reversible binding in the enzyme active site. The tail is a photochromic moiety for controlling enzyme functions in a photoswitchable manner. These photochromic molecules were shown to be reversible, photoregulatable inhibitors of several enzymes such as cysteine and serine proteases; the irradiation of a solution containing papain and *trans*-**15** with $300 > \lambda > 370$-nm light resulted in a photostationary state of 83% of *cis*-**15** and a 5 times increase in the enzyme activity. The original activity level was subsequently restored by irradiation with visible light that converted the *cis*-isomer back to its *trans*-configuration.



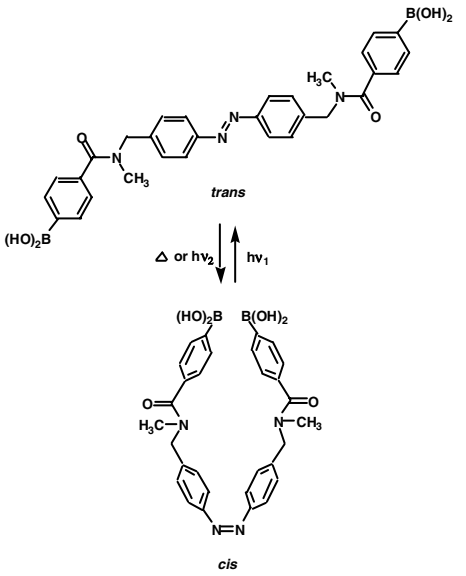
14



15

Light-Gated Receptor

A bis(boronic acid)-based receptor bearing an azobenzene moiety has been synthesized. The photocontrol of the saccharide-binding properties by the change of distance between two boronic acid groups was found to be possible by *E,Z*-photoisomerization of the azobenzene unit[140] (Scheme 60).



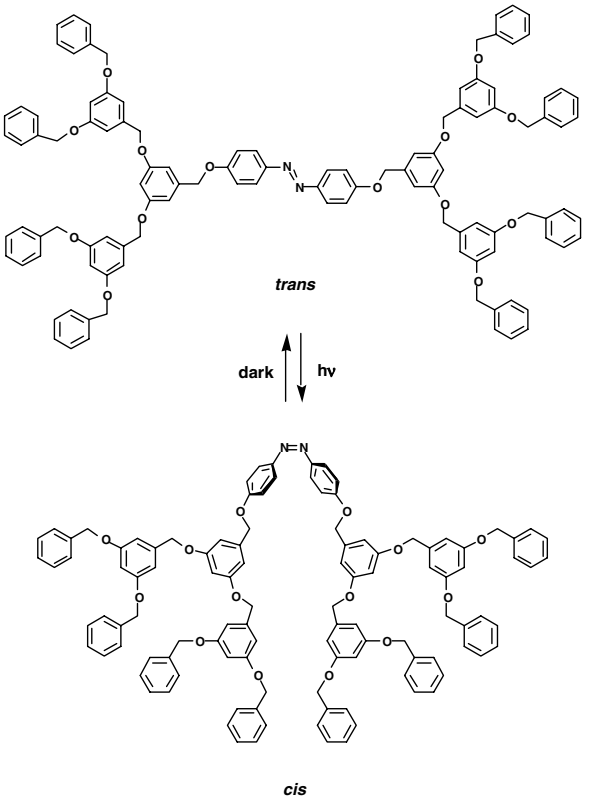
SCHEME 60

Photoresponsive Dendrimers

Dendrimers belong to a new class of multi-branched macromolecules[141] and have attracted much attention in recent years as photoresponsive molecules. This interest stems from the fact that the precise placement of a photoactive group in a well-defined macromolecule is possible, and predictable control of the reversible photoinduced molecular change for altering their function can be expected for these molecules.

Thus, a number of photoresponsive dendrimers with photochromic azobenzene units in the exterior,[142] interior,[143] periphery,[144] or whole[145] of the structure have been designed and prepared with different intentions.

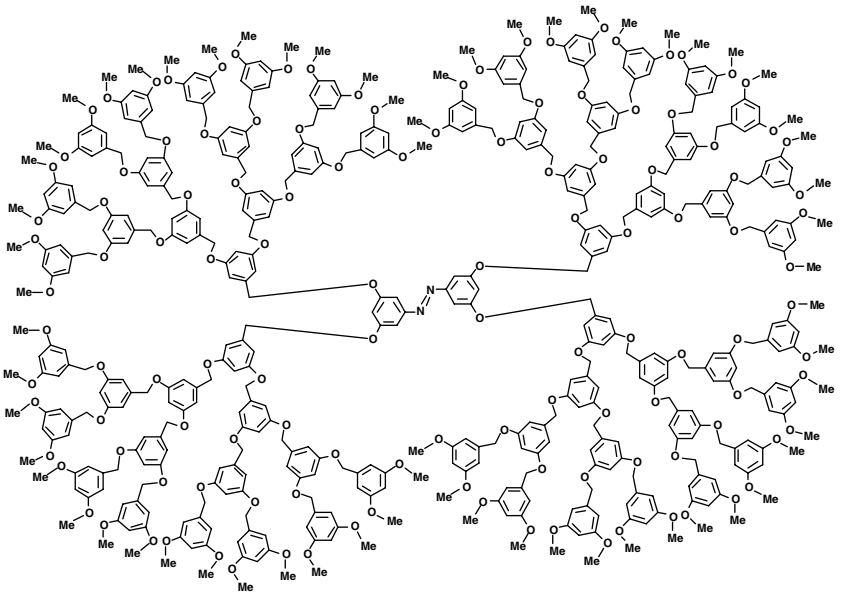
Junge and MacGrath synthesized benzyl aryl ether dendrimers with azobenzene central linkers.[143a] The irradiation of the *E*-dendrimers in dichloromethane with 350-nm light resulted in clean isomerization to *Z*-isomers, which reverted to *E*-isomers upon exposure to bright sunlight for a period of only several seconds (Scheme 61).



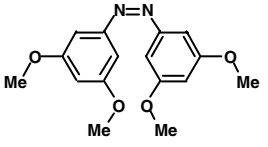
Scheme 61

SCHEME 61

Jiang and Aida reported on the synthesis of even more highly branched aryl ether dendrimers (*trans*-LnAZO, where n denotes the number of aromatic layers, 1, 3–5) with azobenzene in the center of the molecules.[143b] Upon UV irradiation at 21°C, these *E*-dendrimers isomerized to *Z*-isomers, which slowly reverted to the *E*-form in the dark. Remarkably, IR irradiation appreciably accelerated reversion to the *E*-form, and this reversion depended on the size of the dendrimers; the rate of the isomerization of *Z*-L5AZO to the *E*-form **16** was 260 times faster than that of thermal isomerization at 21°C in the dark, while, in sharp contrast, no effects were observed upon IR irradiation for the isomerization of smaller homologues, such as *Z*-L1AZO,**17** and *Z*-L3AZO.



16

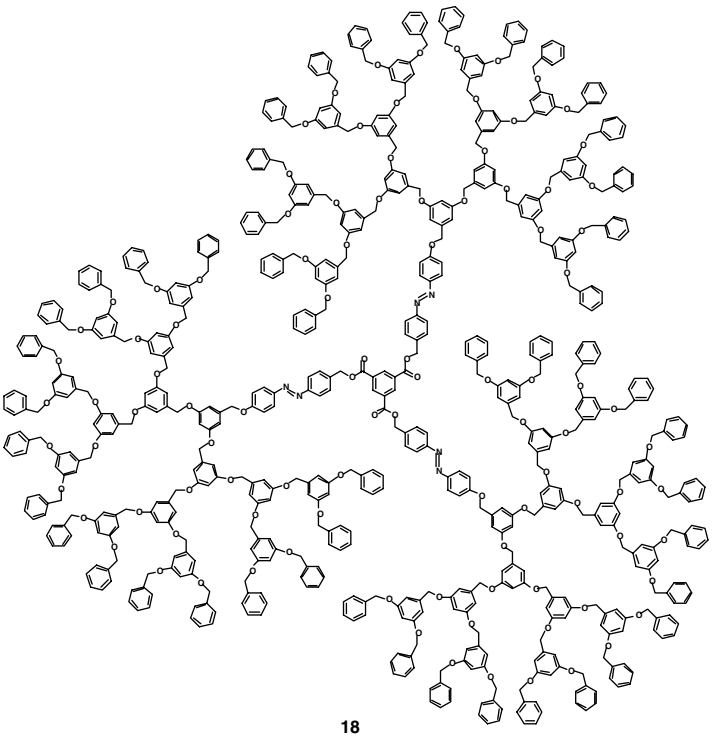


***cis*-L*1*AZO**

17

According to the authors, intramolecular energy transfer from the aromatic rings of the dendrimer matrix, which absorbed the infrared energy, excites the central azobenzene chromophore and accelerates the *Z,E*-isomerization. Thus, low-energy photons may serve for the chemical transformation of molecules such as dendrimers with the azobenzene unit in the center.

More recently, the preparation of dendrimer **18**, which contains three interior azobenzene units radially configured about the core unit, was reported.[143c] All four possible states (*EEE, EEZ, EZZ*, and *ZZZ)* with regard to the azobenzene chromophore were detected in solution and exhibited different physical properties. Thus, the dendrimer undergoes multiple discrete property changes upon an external stimulus of the interior groups.[143c]



18

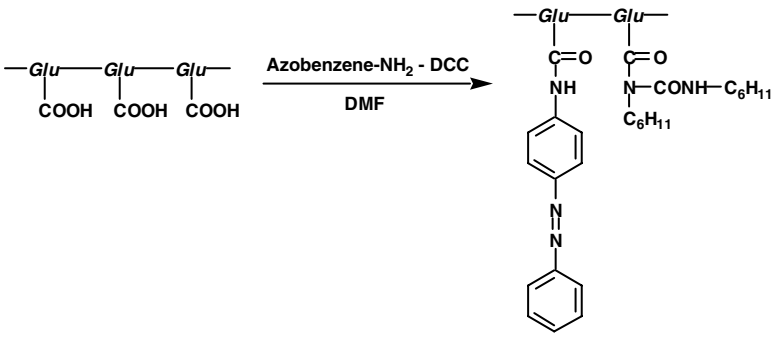
Photoresponsive Polypeptides

Polypeptides can exist in disordered or regularly folded structures, such as α-helix and β-structures. Among photoresponsive polymers, chiral polypeptides bearing photochromic units, such as an azobenzene or spiropyran group in their side chain, occupy a special position, because the change of the chiroptical properties in their photoisomerisation upon irradiation can be correlated with their conformational changes involving their backbone secondary structure and their conformation of the side chain bearing the photochromic groups. Any study on the behavior of these photoresponsive polypeptides should be of considerable value for a deeper understanding of some important biological processes and for the development of devices, such as chiroptical switches and sensors.

The exploitation of the *E,Z*-isomerization of the azoaromatic group for conformational problems was first studied in the 1960s. Goodman and Falxa synthesized copolypeptides of L-*p*-(phenylazo)phenylalanine with γ-benzyl-*L*-glutamate. They found that photoisomerization of the azobenzene group in synthetic polypeptides resulted in changes in the ORD spectra due to changes in the conformation.[-146]

A decade later, Ueno and collaborators synthesized a number of copolymers, such as those of *p*-phenylazobenzyl-*L*-aspartate and β-benzyl-*L*-aspartate and studied their conformational change by means of CD spectrometry.[147]

Ciardelli and co-workers, on the other hand, synthesized polymers of *L*-glutamic acid containing azobenzene or stilbene groups in the side chain (Scheme 62) and studied the relationship between their secondary structure and the photochromic behavior.[148,149]



SCHEME 62

Subsequent to these investigations, many investigations on the synthesis of polypeptides bearing azobenzene groups in their side chain and correlations between their photoisomerization and the change of the chiroptical properties associated with their conformation were carried out by several groups of investigators. Italian investigators reviewed these investigations, carried out until the 1980s,; any readers interested in this subject are advised to refer to the available review articles.[150,153] A few recent examples are mentioned below.

Photoregulation of the hydrolysis activity of a modified enzyme-containing azobenzene group was recently reported. Thus, Imanishi and collaborators prepared a semi synthetic mutant, phospholipase A_2, which replaced Trip[3] with nonnatural aromatic amino acids, such as *p*-phenylazo-*L*-phenylalanine, by a semi synthetic method.[151] While a modified AzoF-AMPA having an *E*-configuration of the azophenylalanine unit lost hydrolysis activity for phospholipid membranes, AzoF-AMPA with a *Z*-configuration generated by UV light irradiation recovered hydrolytic activity. The change in the enzyme activity is ascribed to a conformational change of the mutant proteins.[151]

Fissi and colleagues recently reported the preparation of a new azo-modified poly(*L*-lysine) **19,** in which the azobenzene units are linked to the Lys side chains by means of a sulfonamide function.[152] In contrast to azo-modified poly(*L*-lysine) containing azobenzene units linked to the Lys side chains by means of an amide function, **20**, the new polypeptide, in hexafluoro-2-propanol, adopted a random-coil conformation, irrelevant of the configuration of the azobenzene units. However, the addition of co-solvents, such as methanol, to the solution resulted in the system being able to respond to light, giving rise to reversible photoinduced random coil/α-helix conformational transitions. Thus, poly{N^{ε}–[(phenylazophenyl)sulfonyl]-*L*-lysine} may have potential as a material for designing sensors, optical and chiroptical switches and devices that can be photomodulated.

Readers interested in more detailed aspects of work in this area are referred to a recent comprehensive review article.[153]

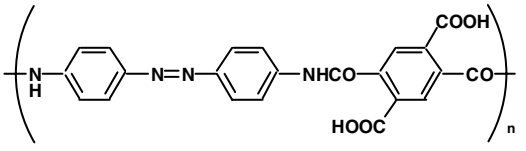
Photoresponsive Polymers

In 1966, Lovrien was the first to propose photoresponsive polymers in which photochromic units, such as azobenzene chromophores, are parts of the polymers.[154] He envisioned that isomerization of the photoresponsive units in the polymer by light energy may influence the conformation of the polymers, thereby resulting in a reversible change of the polymers in solution. He found that the viscosity of an aqueous solution of copolymers of methacrylic acid and *N*-(2,2′-dimethoxyazobenzene)acrylamide increased upon UV light irradiation. The photoisomerization of the azobenzene units to the *Z*-configuration led the polymer coil to expand due to a decrease in the hydrophobic interaction between the azobenzene chromophores.

Since the 1970s a great number of photoresponsive polymers have been designed and prepared. The physical and chemical properties of these polymers in conjunction with their reversible conformational change upon photoirradiation have been examined. This work was aimed at the reversible control of their properties.

Among various photoisomeric units, azobenzene has been most widely used to construct photoresponsive polymers, as is apparent in applications to the field of polypeptides, already separately discussed in the previous section.

Concerning the polymers, Irie and collaborators prepared a number of polyamides with azobenzene groups in the backbone (e.g., **21**).[155] The viscosity of the polyamides in a polar solvent decreased upon irradiation and returned to the initial value in the dark.

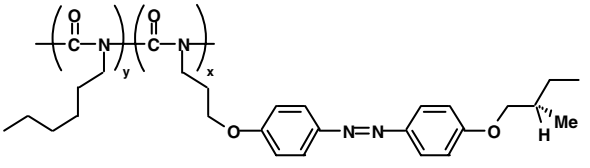


21

The development of some fundamental and practical aspects of the area until the 1990s has been summarized in several comprehensive review articles.[156,157]

Some examples of the recent progress in this area are discussed below.

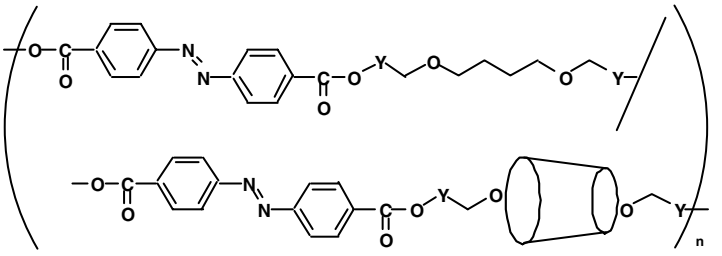
Müller and Zentel prepared several copolymers by copolymerization of hexylisocyanate with seven new chiral azo chromophores with an isocyano functionality (e.g., **22**). The co-polyisocyanates with the azo side chains possess a helical conformation. The interplay of the chiral side chains and the helical main chains in the polymers were studied by chiroptical methods.[158]



22

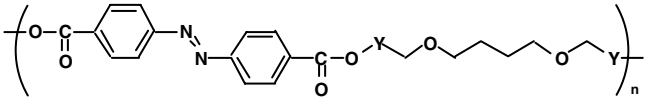
Yamamoto and co-workers recently prepared a polyrotaxane **23** composed of an azobenzene-containing polyester and γ-cyclodextrin. While a DMSO solution of the polymer underwent *E,Z*-photoisomerization upon UV irradiation, the reverse *Z,E*-photoisomerization did not take place upon irradiation with visible light under ordinary conditions. In contrast, cyclodextrin-free polyester **24** having azobenzene groups, prepared in a similar manner, underwent *E,Z*-photoisomerization with UV light and reverse

Z,E-photoisomerization with visible light.[159] According to the authors, intramolecular N····H-O- hydrogen bonds between a *Z*-azo group and a hydroxyl group of the isomerized polyrotaxane molecules retarded the photoinduced *Z,E*-photoisomerization.



Y = $-CH(CH_2OH)-$ (0.79 : $-CH_2-CH(OH)-$ 0.21)

23



Y = $-CH(CH_2OH)-$ (0.62 : $-CH_2-CH(OH)-$ 0.38)

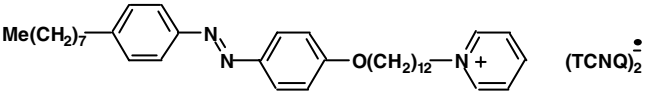
24

Preparation of hydrogen-bonded complexes, composed of poly(4-vinylpyridine-co-styrene and 4-[(4-octylphenylazo)phenoxy]butanoic or hexanoic acid, has been reported by Kato and colleagues.[160] The polymeric complexes behave like side-chain liquid-crystalline polymers and caused reversible photoinduced phase transitions due to *E,Z*-isomerization of an azobenzene moiety in the guest molecules.

Materials for Optical Devices and SAM-Modified Electrodes, etc.

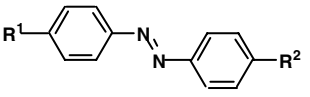
A potential technological exploitation of the reversible *E,Z*-isomerization of materials containing azo units has attracted growing attention over the past decade and the subject was reviewed in 1993.[163] A variety of the attempts include liquid-crystal displays and devices,[161] nonlinear optics,[162] optical switching and data storage,[163–168] holographic grating, etc.

Tachibana designed a molecule **25** that functions as an organic switching device by a photoinduced change in the conductivity of a Langmuir-Blodgett (LB) film composed of a charge-transfer complex between TCNQ and the pyridinium cation bearing an azobenzene unit.[164] About 25% of the *E*-isomer isomerized to the *Z*-form upon 356-nm light irradiation, and the *E*-isomer reverted to the *Z*-isomer upon 436-nm light irradiation. The measured conductivity of the LB film increased by aproximately 30% for a 25:75 *Z/E* mixture, compared to the pure *E*-isomer.



25

Ikeda and Tsutsumi synthesized three azobenzene derivatives **26**. Liquid-crystal films formed from these azobenzenes exhibited a nematic phase in the *E*-isomer and no LC (liquid crystal) phase in the *Z*-isomers. *E,Z*-photoisomerization of these azobenzenes with a laser pulse resulted in a nematic-to-isotropic phase transition with a rapid optical response of 200 microseconds.[165]

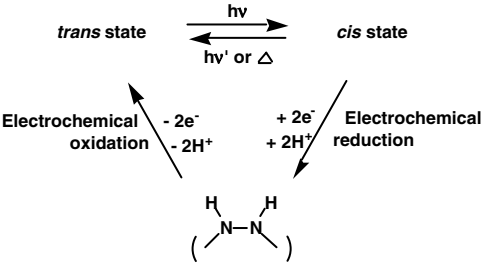


$R^1 = n\text{-}C_4H_9$; R^2 = MeO-
$R^1 = R^2 = n\text{-}C_8H_{17}O$-
$R^1 = -(CH_2\text{-}CH)_n-$; $R^2 = C_2H_5O$-
C=O
$O(CH_2)_6O$-

26

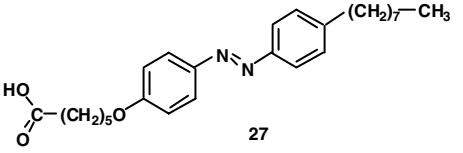
Öge and Zentel designed a ferroelectric LC side-chain copolymer containing both azo and mesogenic units. A change in the ferroelectricity in the LC polymer was observed upon UV irradiation.[166]

Fujishima and collaborators have devised an information storage system using Langmuir-Blodgett films containing an azobenzene unit.[167a] The LB film was prepared by depositing 4-octyl-4′(5-carboxy-pentamethyleneoxy)azobenzene **27** onto SiO_2 glass. Scheme 63 outlines the data-storage system based on



SCHEME 63

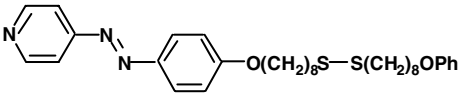
the combination of photochemical isomerization and electrochemical reduction — oxidation processes. Irradiation of *trans*-state LB films in aqueous solution by a He-Cd laser (325 nm) induced *E,Z*-isomerization. The potential of the film was then switched to a voltage where only the *cis*-azobenzene unit was reduced to the hydrazobenzene derivative. This was converted electrochemically back to the original *trans*-state. The stored data could be detected by the difference in the UV absorption. The advantage of this system is to remove the possibility of any undesirable thermal re-isomerization of the *Z*-isomer in the photoprocess. The authors also investigated the structures and properties of several related SAM and LB films.[167b–d]



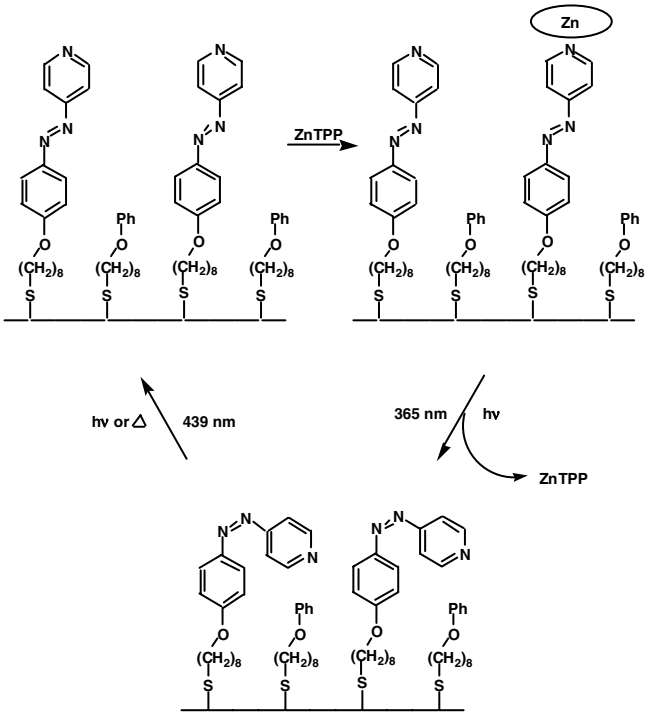
27

The design of a system for photoswitching 'on' and 'off' coordination sites in a self-assembled monolayer (SAM) containing an azopyridine unit has recently been reported by Cook and co-workers.[168] The required SAM was prepared by depositing an unsymmetrical disulfide **28** having 4-(arylazo)pyridine and phenoxy moieties onto an 8-nm-thick film of gold supported on a quartz glass slide. Scheme 64 outlines the system for the evanescent field-driven SAM photoswitch. Zinc tetraphenylporphyrin (ZnTPP) was

then coordinated to the pyridine nitrogen atom in the *trans*-form film. Direct or 365-nm waveguided-light illumination of the coordinated SAM films resulted in photoisomerization to the *cis*-form film, releasing the coordinated ZnTPP. Further irradiation with 439-nm light effected the *Z,E*-isomerization. Thus, a three-step cycle involving the waveguided, light-induced release of metallomacrocycles within a SAM was achieved.

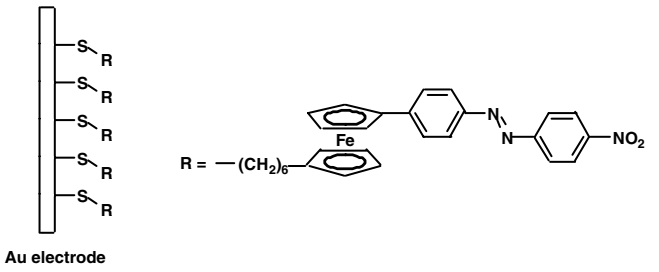


28



SCHEME 64

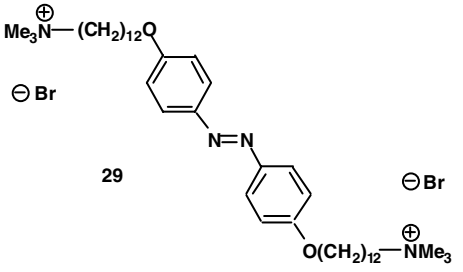
SAMs containing an azobenzene moiety have also been used to modify the electrochemical properties of electrodes by several investigators.[169] Thus, Uosaki and collaborators constructed a SAM by depositing an alkyl thiol molecule containing ferrocene and azobenzene moieties on gold electrode surface (Scheme 65).[169] They found that the charge-transfer rate of the ferrocene group in the SAM could be reversibly controlled by electro- and photochemical isomerization between *E,Z*-forms of the azobenzene moiety in the SAM.



SCHEME 65

Various LB and SAM films and vesicles containing an azobenzene unit have been prepared, and their structures and functions have been investigated to seek new functional materials.[170]

Meanwhile, a self-assembled alternating multilayer film, composed of a bipolar amphiphile, 4,4′-bis[(12-(trimethylammonio)dodecyl)oxy]azobenzene dibromide **29** and an anionic polyelectrolyte poly(vinyl sulfate, potassium salt) on a pre-coated fused silica substrate, was prepared. The effects of added salt on the photochemical isomerization of the azobenzene unit in the self-assembled multilayer films were investigated.[171]



Acknowledgments

The author wishes to thank Dr. Hisanori Senboku for his kind assistance in preparing the diagrams.

Novel Di-π-methane Rearrangements Promoted by Photoelectron Transfer and Triplet Sensitization

Diego Armesto
Universidad Complutense of Madrid

Maria J. Ortiz
Universidad Complutense of Madrid

Antonia R. Agarrabeitia
Universidad Complutense of Madrid

95.1 Introduction

The di-π-methane (DPM) reaction of 1,4-alkenes and its counterpart (the oxa-di-π-methane [ODPM] rearrangement of β,γ-unsaturated ketones) have been known for more than 30 years.[1a–i,1l] The large number of studies devoted to these two reactions by different research groups during three decades show that these reactions are very general and usually take place with high chemical and quantum yields, affording cyclopropane derivatives that, in many instances, are difficult to obtain, or not available, by alternative routes. Both reactions show a high degree of diastereoselectivity, or even enantioselectivity in some instances. Therefore, it is not surprising that these rearrangements have been applied in the synthesis of complicated molecules that are difficult to prepare by alternative reaction paths. In particular, the ODPM reaction has been applied as the key step in the synthesis of some natural products by routes that compete with conventional alternatives.[1g,1i,1l,2] Some comprehensive reviews of this subject have been published in the past 25 years or so, summarizing the mechanistic aspects, scope, and synthetic applications of these rearrangements.[1a–i,1l]

Despite the large number of studies carried out on the DPM and ODPM rearrangements since the discovery of the DPM reaction in 1967 by Zimmerman et al.,[5] it was necessary to wait 10 years before the reaction was extended to other 1,4-unsaturated systems, particularly to CN double bond derivatives. The first example of a 1-aza-di-π-methane rearrangement (1-ADPM) was reported by Nitta et al.[6] in a study of the photoreactivity of highly constrained tricyclic oximes. However, the reaction was limited to

0-8493-1348-1/04/$0.00+$1.50

a few compounds, and attempts to extend the rearrangement to other related systems were unsuccessful. The first examples of 1-ADPM reactions in acyclic CN double bond derivatives were reported by Armesto et al.[7] in 1982 in the triplet-sensitized irradiation of a series of β,γ-unsaturated imines that yielded the corresponding cyclopropyl imines regioselectively. The studies in this area have demonstrated that the 1-ADPM rearrangement is as general as the DPM and ODPM counterparts.[1j-n] The reaction has been extended to different CN double bond derivatives, such as oxime esters, semicarbazones, and hydrazones.[1j-m]

As a result of the studies carried out by different research groups worldwide on these three types of di-π-methane reactions, the majority of organic photochemists considered that the photoreactivity of 1,4-unsaturated systems was well established and totally predictable in most cases and, therefore, there was very little to uncover in this area of research.

However, studies recently carried out in our laboratory have demonstrated that some of the ideas firmly established about the photoreactivity of these compounds are incorrect. Thus, the normal photochemical reactivity of β,γ-unsaturated aldehydes reported in books and monographs is decarbonylation.[1c,1i,8] However, our results demonstrate that many β,γ-unsaturated aldehydes undergo the oxa-di-π-methane rearrangement even more efficiently than the corresponding methyl ketones, which is contrary to popular belief.[9] Alternative reaction modes, such as 1,3-formyl migration and decarbonylation, that take place via the T_1 excited state and, therefore, are not Norrish Type I processes, have also been uncovered.[9c] These novel photoreactions of aldehydes are discussed in a separate chapter.

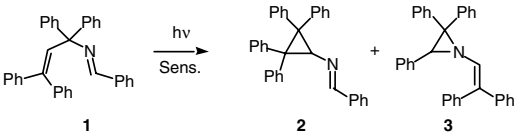
On the other hand, di-π-methane rearrangements have been considered the paradigm of reactions that take place exclusively in the excited state.[1a-l] Concerted or biradical mechanisms were postulated to justify these rearrangements in all the cases studied.[1a-l] There were no data that suggested the involvement of other intermediates in these processes. However, our results on the photoreactivity of 1-aza- and 2-aza-1,4-dienes, using electron-acceptor sensitizers, demonstrate that the 1-ADPM and 2-aza-di-π-methane (2-ADPM) rearrangements can occur via radical-cation intermediates in the ground state. Under these conditions, 2-aza-1,4-dienes rearrange to *N*-vinylaziridines in the first example of a reaction of the di-π-methane type that yields heterocyclic products. Finally, recent studies demonstrate that DPM and 1-ADPM rearrangements also occur in the ground state of radical-anion intermediates.

In our opinion, these results have modified some of the ideas firmly established for many years on the photoreactivity of β,γ-unsaturated systems and demonstrate that a considerable research effort remains necessary in order to rationalize the photo-behavior of these compounds. The following sections summarize our findings in the area of SET-sensitized di-π-methane reactions.

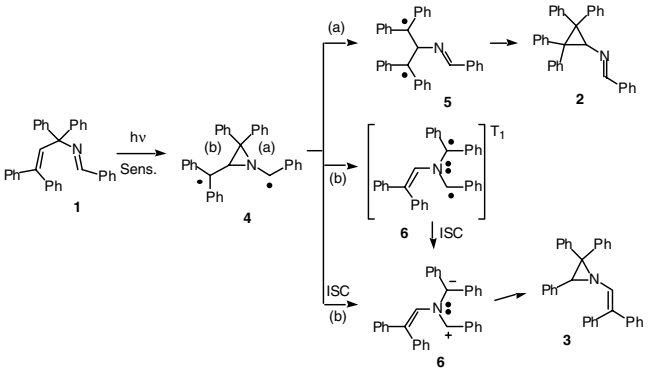
95.2 The 2-Aza-di-π-methane Rearrangement

As mentioned, the large number of studies on the photochemical reactivity of β,γ-unsaturated compounds, carried out by many different research groups worldwide, demonstrated that DPM rearrangements are very general for a variety of 1,4-unsaturated systems, such as, 1,4-dienes, β,γ-unsaturated aldehydes and ketones, and different 1-aza-1,4-diene derivatives.[1] However, up to 1997, the literature was devoid of studies describing the photoreactivity of the closely related 2-aza-1,4-diene derivatives. This was somewhat surprising considering that Mariano and co-workers had previously documented the interesting SET-promoted photocyclization reactions of iminium salts derived from 2-aza-1,4-dienes.[10] The interesting results obtained in our studies on the 1-ADPM rearrangement and also Mariano's precedents prompted us to explore the photoreactivity of 2-aza-1,4-dienes.

The first compound selected for this study was the azadiene **1**. Previous studies demonstrated that tetraphenyl-substitution in positions 3 and 5 of the β,γ-unsaturated system promotes efficient DPM, ODPM, and 1-ADPM reactions in acyclic 1,4-dienes,[11] β,γ-unsaturated aldehydes,[9b] and 1-aza-1,4-dienes,[12] respectively. Based on these precedents, the 2-azadiene **1** was considered to be a suitable candidate to undergo rearrangement of the di-π-methane type. Triplet-sensitized irradiation of azadiene **1**, using acetophenone, for 25 min, afforded two new products that were identified as the cyclopropyl imine **2** (11%) and the vinylaziridine **3** (3%) (Scheme 1). Compound **2** hydrolyzes to the corresponding cyclopropyl amine during isolation.[13]



SCHEME 1



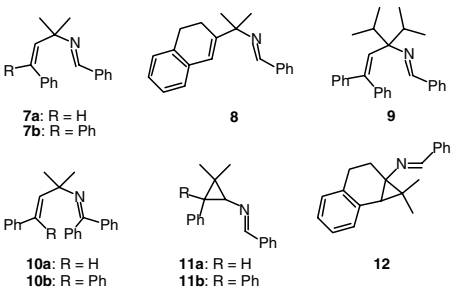
SCHEME 2

Direct irradiation of **1**, for 10 h, also afforded the cyclopropyl imine **2** (4%). Qualitatively, the direct irradiation reaction is less efficient than the triplet-sensitized process. In addition, the direct irradiation photoreaction of **1** is quenched by 1,3-cyclooctadiene, suggesting that the rearrangement occurs via the triplet excited state.

The formation of **2** and **3** can be justified by a conventional biradical mechanism similar to those normally used to rationalize the previously reported di-π-methane processes, as shown in Scheme 2. This involves generation of the aziridinyl-dicarbinyl biradical **4**. Cleavage of the CN bond labeled (a) in **4** affords the highly stabilized 1,3-biradical **5**, which yields the major product **2** (path a). The alternative fragmentation of the C–C bond in **4** generates the intermediate **6**, the precursor of the *N*-vinylaziridine **3** (path b). It is interesting to note at this point that intermediate **6** could be either a triplet 1,3-biradical or a singlet azomethine ylide, depending on whether or not ISC (intersytem crossing) occurs prior to bond cleavage in **4**. Only the singlet azomethine ylide is capable of undergoing cyclization to form **3**. As far as we are aware, this is the case in a di-π-methane reaction where a zwitterion can be postulated as a possible intermediate.[13b-c] The photoreaction of **1** represents the first example of a 2-aza-di-π-methane rearrangement (2-ADPM) that takes place via a three-membered ring heterocyclic biradical and brings about the formation of a heterocyclic product. This result is of importance because previous attempts to observe the formation of oxiranes by the ODPM rearrangement were unsuccessful.[14]

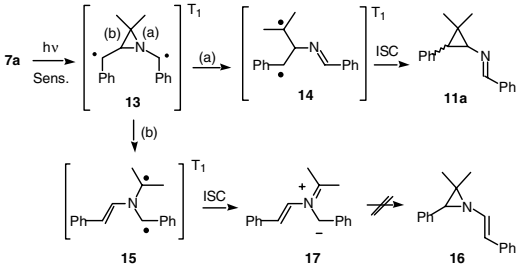
The study was extended to azadienes **7a,7b**, **8**, **9**, and **10a,10b**. Triplet-sensitized irradiation of compounds **7a**, **7b**, and **8** afforded the corresponding cyclopropyl imines **11a**, **11b**, and **12**, respectively, in low yield. In these instances, the corresponding *N*-vinylaziridines were not formed.[13b]

The results obtained in the triplet-sensitized irradiation of compounds **1**, **7a**, **7b**, and **8** indicate that the 2-ADPM rearrangement takes place in 2-aza-1,4-dienes with different substitution patterns, affording cyclopropyl imines in low isolated yields. Attempts to increase product yields resulted in destruction of the starting material. In one case only (compound **1**), the corresponding regioisomer, the *N*-vinylaziridine **3**, has been obtained. The reasons for this regioselectivity remain unclear but it is obvious that methyl substitution at the methane carbon in the 2-aza-1,4-diene system suppresses the formation of the corresponding *N*-vinylaziridines.



The absence of the heterocyclic regioisomer in these reactions is particularly surprising in the case of azadiene **7a**. According to the mechanism postulated for the 2-ADPM rearrangement (Scheme 2), the ring opening of the aziridinyl-dicarbinyl biradical intermediate **13** should afford the 1,3-biradicals **14** and **15** of comparable stability, the precursors of **11a** and the aziridine **16**, respectively (Scheme 3).[13b]

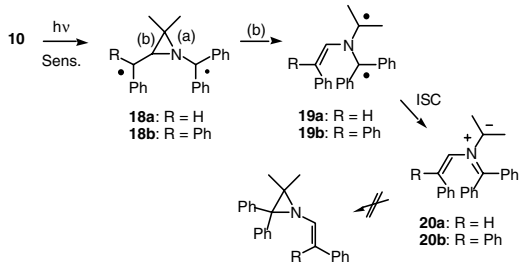
A possible explanation for the absence of **16** could be found by considering that intermediates **14** and **15** should be triplet biradicals. Intersystem crossing in **14** would afford a singlet biradical that cyclizes to the cyclopropyl imine **11a**. However, intersystem crossing within biradical **15** would yield the zwitterionic intermediate **17**, which is not stabilized by phenyl substitution, as in the case of **6** (Scheme 2). Literature precedents[15] show that nonstabilized 1,3-dipolar intermediates similar to **17** do not cyclize to three-membered heterocycles but undergo different reactions yielding a complex mixture of products. This interpretation is speculative at this point and it will be necessary to carry out additional studies to establish the accuracy of this proposal.



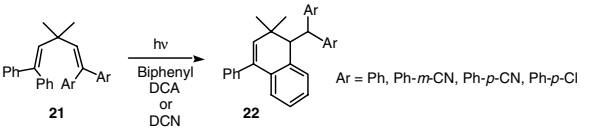
SCHEME 3

Azadienes **9**, **10a**, and **10b** have substitution patterns that promote DPM rearrangements efficiently.[11] However, triplet-sensitized irradiation of these compounds afforded recovered starting material and a complex mixture of products in which the corresponding cyclopropyl imines or *N*-vinylaziridines were not present. These results demonstrate that the 2-ADPM reaction has features that make it different from other versions of the rearrangement studied previously. In particular, the lack of reactivity of ketoimines **10** is surprising because the stability of biradical intermediates **18** should be comparable to, or even greater than, the corresponding intermediates derived from aldimines **7**. The absence of 2-ADPM products in the irradiation of azadienes **10** could be due to the presence of two phenyl rings at C1 of the azadiene system that would favor the preferential ring opening of the aziridinyl intermediates **18** by breaking bond (b) to afford the 1,3-biradicals **19** (Scheme 4). Intersystem crossing in **19** would give the zwitterionic intermediates **20**, which could decompose to a mixture of products instead of undergoing cyclization to the corresponding vinylaziridines (Scheme 4).

In summary, our results on the triplet-sensitized photochemistry of a series of 2-aza-1,4-dienes have uncovered the first examples of 2-ADPM rearrangements yielding cyclopropyl imines. In the case of azadiene **1**, the *N*-vinylaziridine **3** was also obtained in the first example of a di-π-methane rearrangement



SCHEME 4



SCHEME 5

that yields a heterocyclic product. However, the 2-ADPM reaction presents special features that make it different from other versions of the rearrangement previously described. Further studies will be necessary to understand the mechanistic aspects of the 2-ADPM rearrangement and the factors that control the influence of substitution on the outcome of the reaction.

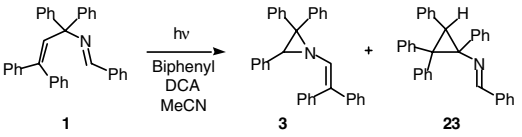
95.3 Di-π-methane Rearrangements *via* Radical-cation Intermediates

The studies carried out on di-π-methane for many years involved the direct or triplet-sensitized irradiation of 1,4-unsaturated systems. The results obtained show that, in general terms, acyclic 1,4-dienes undergo the DPM reaction in the singlet excited state while cyclic and polycyclic dienes are reactive as triplets.[1a,1d,1f,1h,1l] The ODPM, 1-ADPM, and 2-ADPM counterparts only occur in the triplet excited state of β,γ-unsaturated carbonyl compounds,[1a-c,1e,1g,1i,1l] 1-aza-1,4-dienes,[1j-n] and 2-aza-1,4-dienes,[1m,1n,13] respectively. An attempt to observe di-π-methane reactions promoted by SET sensitization was unsuccessful. Thus, Zimmerman and Hoffacker[16] carried out a study on the photoreactivity of 1,4-dienes **21** using 9,10-dicyanoanthrathene (DCA) or 1,4-dicyanonaphthalene (DCN) as electron-acceptor sensitizers. The results obtained show that these compounds undergo intramolecular cyclization to yield dihydronaphthalenes **22** (Scheme 5). The corresponding DPM products are not produced in these photoreactions.

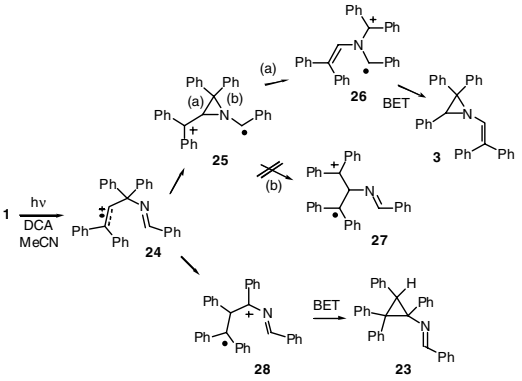
2-ADPM Rearrangements via Radical-cation Intermediates

Based on the above precedent, we were interested in carrying out a study on the DCA-sensitized reactivity of 2-aza-1,4-dienes **1**, **7a,7b**, **8**, **9**, and **10a,10b** to determine whether these compounds would behave similarly to the 1,4-dienes reported by Zimmerman or undergo alternative reactions. The results obtained were unexpected and have opened novel and very interesting lines of research.

DCA-sensitized irradiation of **1**, in acetonitrile for 25 min, using biphenyl as co-sensitizer, afforded the *N*-vinylaziridine **3** (11%) and the cyclopropyl imine **23** (19%), as shown in Scheme 6.[13] This result was very surprising because it represents the first examples of SET-promoted di-π-methane reactions (a 2-ADPM rearrangement generating **3** and an aryl-di-π-methane reaction affording **23**) that take place



SCHEME 6

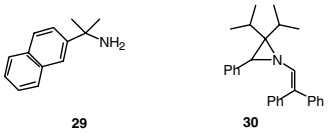


SCHEME 7

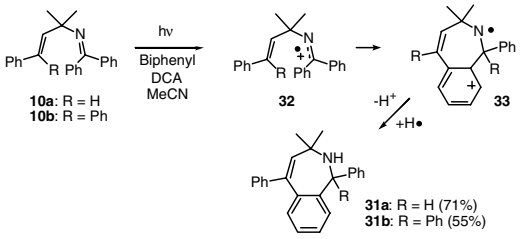
via radical-cation intermediates in the ground state. As mentioned previously, di-π-methane reactions were considered the paradigm of processes that took place in the excited state only.[1] In addition, it is also worth noting that the vinylaziridine **3** is formed in both the triplet- and DCA-sensitized irradiations of **1**.

The mechanism shown in Scheme 7 was proposed to account for the formation of these two products. This involves the generation of an olefin-localized cation-radical intermediate **24** that bridges by CN bond formation to give the aziridinyl cation-radical **25**. Ring opening in **25** by path (a) generates **26**, which by back electron transfer and biradical cyclization yields **3**. The alternative ring opening of **25** by path (b), which would have produced the corresponding cyclopropyl imine, does not occur probably because the intermediate radical-cation **27** is less stable than **26**. A competitive route, involving phenyl migration in **24**, generates the cation-radical **28**, the precursor of **23** (Scheme 7).

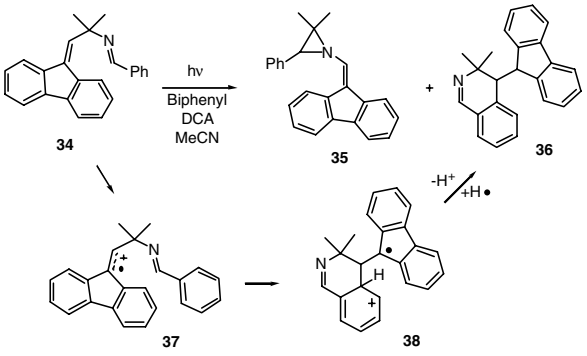
The study was extended to azadienes **7a,7b**, **8**, **9**, and **10a,10b**.[13b] DCA-sensitized irradiation of **7a** yielded the corresponding vinylaziridine **16**, exclusively, in low yield. However, azadiene **7b** gave a complex mixture of products in which the corresponding aziridine was not present. The lack of 2-ADPM reactivity of **7b** is difficult to explain at this point.



Compound **8** is also unreactive in the 2-ADPM mode. DCA-sensitized irradiation of **8** afforded the naphthalene derivative **29**, resulting from aromatization of the dihydronaphthalene unit and hydrolysis of the CN double bond. This result shows, under these conditions, that oxidation of the cyclohexene moiety takes preference over the 2-ADPM rearrangement. Despite these negative results, compound **9** yielded the aziridine **30** in 14% yield after only 15 min of irradiation.



SCHEME 8



SCHEME 9

DCA-sensitized irradiation of compounds **10a** and **10b** for short periods of time afforded the corresponding dihydrobenzoazepines **31a** and **31b**, respectively, in high isolated yields (Scheme 8). The corresponding *N*-vinylaziridines are not generated in these processes, showing that diphenyl substitution at C1 in ketoimines **10** allows an alternative cyclization route to form dihydrobenzoazepines to take place in preference to 2-ADPM rearrangement. The formation of **31** is consistent with a mechanism involving the generation of an imine-localized radical-cation **32** that, by electrophilic attack on the phenyl ring at C5, yields intermediate **33**, the precursor of **31** (Scheme 8). The high yields of products obtained in the DCA-sensitized irradiation of **10** suggest that this methodology might be applicable to the synthesis of dihydrobenzoazepines from β,γ-unsaturated ketoimines.

Finally, the study was extended to azadiene **34**.[13] Irradiation of **34** under the above conditions, for 1 h, yielded the vinylaziridine **35** (24%) and the dihydroisoquinoline **36** (16%), as shown in Scheme 9. The formation of **36** can be explained by a pathway in which a cation-radical **37**, centered on the olefin unit, undergoes electrophilic attack on the phenyl ring at C1, affording intermediate **38**, the precursor of **36** (Scheme 9).

The results summarized above demonstrate that the novel 2-ADPM rearrangement of 2-aza-1,4-dienes to form *N*-vinylaziridines via radical-cation intermediates is not restricted to compound **1** but can be extended to azadienes **7a**, **9**, and **34**. The SET-sensitized irradiation of azadienes **10a,10b** and **34** afford dihydrobenzoazepines **31a,31b** and dihydroisoquinoline **36**, respectively, showing that alternative cyclization paths are open to the radical-cation intermediates, in addition to the 2-ADPM reaction. Something worth noting regarding the formation of compounds **23**, **31a,31b**, and **36** is that, while compounds **31a,31b** result from radical-cations centered in the imine moiety, the aryl-di-π-methane product **23** and the dihydroisoquinoline **36** are formed from radical-cations centered in the alkene unit. This is somewhat surprising and demonstrates that two different radical-cation intermediates can be generated from the alkene and imine functional groups, which have different ionization potentials.

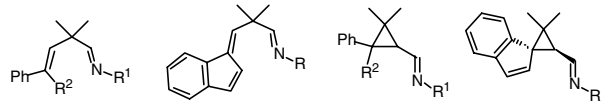
The comparison between the results obtained in the triplet-sensitized and the SET-sensitized irradiation of 2-aza-1,4-dienes shows that there are clear differences between these two reactions. Probably the most significant of these is the observed regiochemistry. Thus, while the triplet reaction yields cyclopropyl imines, SET-promoted rearrangement affords the corresponding *N*-vinylaziridines. Although the reasons for the triplet regioselectivity are still unclear, formation of the vinylaziridines can be easily explained based on the differences in stability between the two possible radical-cation intermediates resulting from ring opening of the intermediate aziridinyl radical-cation (Scheme 7). Another important difference has been observed in the reactions of **7b** and **9**. Thus, while **7b** undergoes the triplet 2-ADPM rearrangement in low yield, the corresponding aziridine is not formed via radical-cation intermediates. On the other hand, azadiene **9** yields the aziridine **30** in the SET-sensitized reaction but does not rearrange under triplet sensitization. These results are difficult to interpret at this point, but they clearly show that the structural factors that control these two reactions are very different.

In summary, our studies of the triplet-sensitized photoreactions of 2-aza-1,4-dienes have allowed us to uncover the first examples of 2-ADPM rearrangements that yield cyclopropyl imines. In the case of azadiene **1**, the reaction also affords the *N*-vinylaziridine **3**. This is the first example of a di-π-methane rearrangement that yields a three-membered ring heterocyclic photoproduct. However, azadienes with substitution patterns that promote efficient DPM, ODPM, and 1-ADPM reactions do not undergo the 2-ADPM rearrangement. A possible reason for this difference might be due to the unique involvement of azomethine ylides in the 2-ADPM rearrangement.

A more significant conclusion of this study is that 2-ADPM rearrangements can also take place under SET-sensitized irradiation conditions to generate *N*-vinylaziridines regioselectively. In the case of azadiene **1**, cyclopropyl imine **23**, resulting from an aryl-di-π-methane reaction via a radical-cation intermediate, is observed. This result demonstrates that DPM processes can also occur by way of radical-cation intermediates. Alternative cyclization modes have been detected, in some instances yielding dihydrobenzoazepines and dihydroisoquinolines. It is our belief that the results coming from these studies have led to new views of an old but still important photochemical rearrangement process.

1-ADPM Rearrangements via Radical-cation Intermediates

The results obtained in the SET-sensitized irradiation of 2-aza-1,4-dienes using DCA as an electron-acceptor sensitizer suggested that other β,γ-unsaturated compounds could also participate in di-π-methane type rearrangements via radical-cation intermediates. To test this proposal, we have carried out a study on a series of 1-substituted-1-aza-1,4-dienes. The compounds selected for this study were the β,γ-unsaturated imines **39a**, **39b**, and **40a**. DCA-sensitized irradiation of these imines in acetonitrile, using biphenyl as co-sensitizer, yielded the corresponding cyclopropyl imines **41a**, **41b**, and **42a**, which hydrolyze to the corresponding cyclopropane carbaldehydes during isolation.[17]



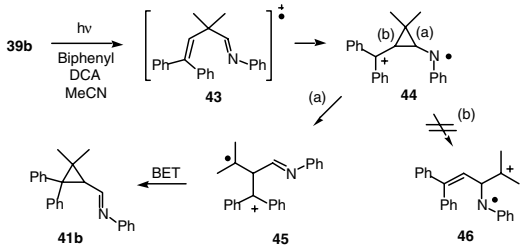
39a: R^1 = Ph, R^2 = H
39b: $R^1 = R^2$ = Ph
39c: R^1 = OAc, R^2 = H
39d: R^1 = OAc, R^2 = Ph
39e: R^1 = OMe, R^2 = H
39f: R^1 = OMe, R^2 = Ph

40a: R = Ph
40b: R = OAc
40c: R = OMe

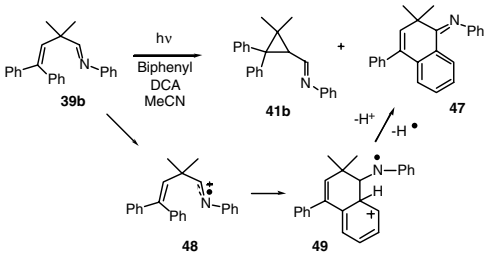
41a: R^1 = Ph, R^2 = H
41b: $R^1 = R^2$ = Ph
41c: R^1 = OAc, R^2 = H
41d: R^1 = OAc, R^2 = Ph
41e: R^1 = OMe, R^2 = H

42a: R = Ph
42b: R = OAc
42c: R = OMe

These results clearly demonstrate that di-π-methane rearrangements via radical-cation intermediates are not restricted to 2-aza-1,4-dienes but can be extended to 1-aza-1,4-dienes. The mechanism shown in Scheme 10 is proposed to account for the formation of **41b**. This involves the generation of radical-cation **43**, which bridges to afford the cyclopropyl cation-radical **44**. Ring opening by bond (a) cleavage generates **45**. Back electron transfer in **45**, followed by biradical cyclization, yields **41b**. The alternative



SCHEME 10



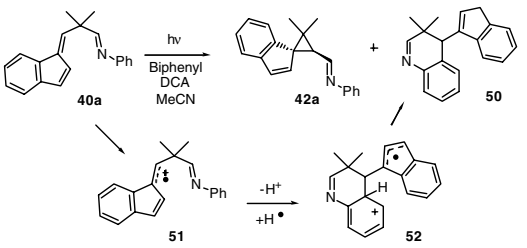
SCHEME 11

cleavage of bond (b), which would have yielded the corresponding aziridine, is not observed, probably due to the fact that the resulting radical-cation **46** is less stable than **45**.

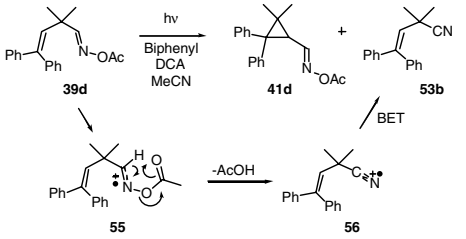
Irradiation of imine **39b** afforded, in addition to the cyclopropyl imine **41b**, the dihydronaphthalene derivative **47** (Scheme 11). This result shows that two different reaction paths are open to the radical-cation intermediate derived from **39b**. The first involves 1-ADPM rearrangement leading to **41b** and the other is the intramolecular cyclization affording **47**. A possible mechanism to justify the formation of **47** involves electrophilic attack of a radical-cation centered in the CN double bond **48** to one of the phenyl ring at C5, affording the intermediate **49**, which loses a proton and a hydrogen radical to yield **47** (Scheme 11). The formation of **47** is similar to the reaction described in the study of the electron-acceptor sensitized photoreactions of 1,4-dienes **21**, which yield dihydronaphthalenes **22**.[16] However, dienes **21** do not undergo radical-cation rearrangements of the di-π-methane type.

An alternative cyclization of the radical-cation intermediate has been observed in the irradiation of **40a** that affords, in addition to the cyclopropane **42a**, the dihydroquinoline **50**.[17b] The formation of **50** is in agreement with a mechanism involving the generation of the radical-cation centered in the CC double bond **51**. Intramolecular cyclization in **51**, by electrophilic attack on the phenyl ring attached to the nitrogen atom, generates the intermediate **52**, which by aromatization and hydrogen abstraction yields **50** (Scheme 12).

The study was extended to β,γ-unsaturated oxime acetates and oxime ethers that do not hydrolyze to the corresponding aldehydes during isolation. Previous studies on the triplet photoreactivity of 1-substituted 1-aza-1,4-diene derivatives have demonstrated that oxime acetates undergo the 1-ADPM rearrangement more efficiently than the corresponding imines.[12] However, oxime ethers do not rearrange on triplet-sensitized irradiation.[18] Therefore, it was considered of interest to explore the photoreactivity of these compounds under DCA-sensitized conditions to determine possible analogies or differences between the triplet- and DCA-sensitized reactivity of these substrates. The compounds selected for this study were the oxime acetates **39c**, **39d**, **40b**, and the oxime ethers 3**9e**, **39f**, **40c**, structurally related to the imines **39a,39b** and **40a**. DCA-sensitized irradiation of oxime acetates **39c**, **39d**, and **40b** for variable times afforded the corresponding cyclopropanes **41c**, **41d**, and **42b**, respectively, resulting from 1-ADPM

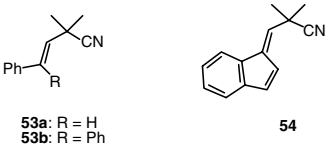


SCHEME 12



SCHEME 13

rearrangements.[17] The qualitative efficiencies of the reactions of oxime acetates and the yields of products are clearly higher than those for the corresponding imines.

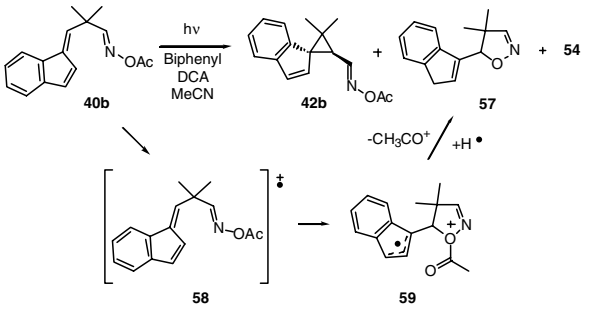


SET-sensitized irradiations of **39c, 39d**, and **40b** also afforded, in addition to the corresponding cyclopropanes, the nitriles **53a**, **53b**, and **54**, respectively, resulting from elimination of acetic acid.[17b]

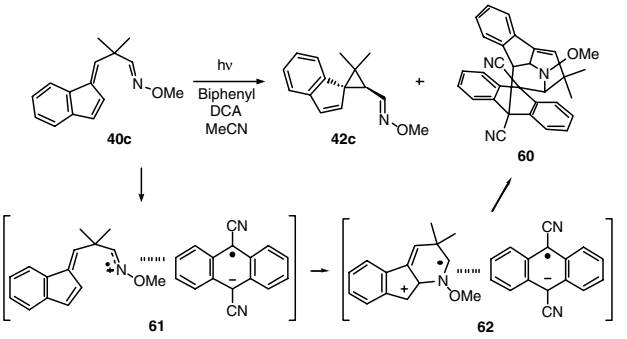
This elimination reaction cannot be considered a thermal process because it does not occur in the triplet-sensitized irradiation of oxime acetates. The mechanism shown in Scheme 13 for compound **39d** is proposed to account for the formation of these nitriles. It involves the generation of a radical-cation centered on the CN double bond **55**, followed by elimination of acetic acid to afford the radical-cation **56**, which yields the nitrile **53b** by back electron transfer (Scheme 13).

In the case of oxime acetate **40b**, the dihydroisoxazole **57** was obtained in addition to the cyclopropane **42b** and the nitrile **54**. A possible mechanism to justify the formation of **57** is shown in Scheme 14. This involves the generation of the radical-cation **58** that by intramolecular cyclization affords the radical-cation **59**. Elimination of acetic acid in **59** yields **57**.

DCA-sensitized irradiation of oxime ethers **39e** and **40c** afforded the corresponding cyclopropanes **41e** and **42c** in low yield.[17] However, for unknown reasons, irradiation of compound **39f** under these conditions gave a complex mixture of products in which the corresponding 1-ADPM product was not present. Irradiation of oxime ether **40c** also afforded the [4+4]-cycloadduct **60**.[17b] The mechanism shown in Scheme 15 could justify the formation of **60**. This involves the generation of a radical-cation/radical-anion pair **61**. Intramolecular cyclization of the radical-cation within the solvent cage generates the intermediate **62**, which undergoes intermolecular cyclization, to yield the observed product (Scheme 15).



SCHEME 14

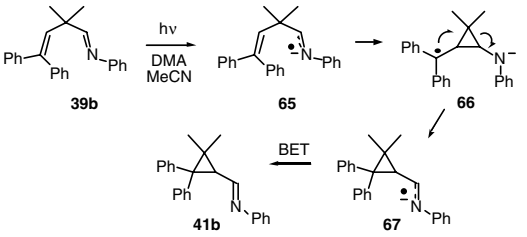


SCHEME 15

The results obtained in the DCA-sensitized irradiation of β,γ-unsaturated oxime acetates and oxime ethers show that the 1-ADPM rearrangement via radical-cation intermediates is not limited to β,γ-unsaturated imines but can be extended to hydrolytically stable CN double bond derivatives. Something worth mentioning in this study is that a previous report showed that β,γ-unsaturated oxime ethers do not undergo the 1-ADPM rearrangement on direct or triplet-sensitized irradiations,[18] but compounds **39e** and **40c** rearrange via radical-cation intermediates, although in low yields. Finally, alternative reactions of the radical-cation intermediates, affording nitriles, dihydroquinolines, dihydronaphthalenes, dihydroisoxazoles, and [4+4]-cycloadducts, have been observed in some instances.

Another interesting observation in this study is that, while the dihydronaphthalene derivative **47** and the nitriles **53a**, **53b**, and **54** are formed from radical-cations centered in the CN double bond, the dihydroquinoline **50** results from a radical-cation centered in the alkene unit. These observations are in agreement with similar results obtained in the study of the photochemical reactivity of 2-aza-1,4-dienes under SET-sensitized conditions and suggest that two different radical-cations intermediates can be generated from functional groups with different ionization potentials.

The 1-ADPM rearrangement and the alternative reaction modes of 1-substituted-1,4-dienes via radical-cation intermediates described above have an obvious mechanistic interest. However, the yield of products in these reactions is considerably lower than in the triplet-sensitized photoreactions of these compounds, with the exception of oxime ethers **39e** and 4**0c**; therefore, the synthetic utility of these reactions is limited. However, this inconvenience can be overcome using alternative electron-acceptor sensitizers. Recent results show that replacing DCA by dicyanodurene (DCD) as an electron-acceptor sensitizer and biphenyl as a co-sensitizer, results in a considerable increase in the yields of 1-ADPM photoproducts.[17b] Thus, for example, DCA-sensitized irradiation of **39c**, for 2.5 h, affords cyclopropane **41c** in 15% yield, whereas using DCD as the sensitizer, this compound is obtained in 60% yield after



SCHEME 16

only 1 h of irradiation. Similar enhancements in the yield of 1-ADPM photoproducts have been observed in most of the cases studied.[17b] Furthermore, the nitriles **53a**, **53b**, and **54**, obtained in the DCA-sensitized irradiation of oxime acetates **39c**, **39d**, and **40b**, are not obtained under DCD-sensitization conditions.

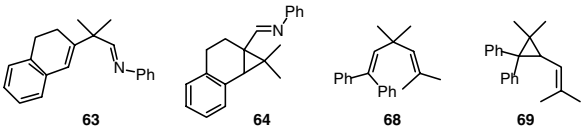
In summary, our investigations on the photochemical reactivity of β,γ-unsaturated imines, oxime acetates, and oxime ethers using electron-acceptor sensitizers have allowed us to describe the second example of di-π-methane rearrangements that take place via radical-cation intermediates in the ground state. In some instances, alternative reactions of these intermediates have been observed, yielding nitriles, dihydroquinolines, dihydronaphthalenes, dihydroisoxazoles, and cycloaddition products. Some of the products obtained in these SET-promoted reactions arise from radical-cations centered in the alkene unit while others are formed from radical-cations centered in the CN double bond. The yield of 1-ADPM photoproducts increases considerable when DCD is used as electron-acceptor sensitizer instead of DCA. Finally, the reactions of the di-π-methane type observed in the SET-sensitized irradiations of 1-aza- and 2-aza-1,4-dienes are important because these rearrangements have been considered for many years as the paradigm of processes that took place in the excited state only. Our results show that these rearrangements can also occur in the ground state of radical-cation intermediates. In our opinion, the studies summarized above have opened new lines of research in the area of di-π-methane reactions.

95.4 Di-π-methane Rearrangements *via* Radical-Anion Intermediates

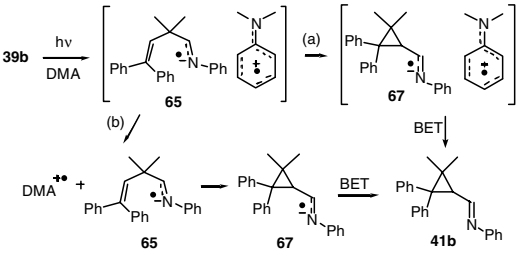
The aryl-di-π-methane, 1-ADPM, and 2-ADPM rearrangements via radical-cation intermediates observed in the DCA-sensitized irradiations of 1-aza- and 2-aza-1,4-dienes suggested the possibility that these reactions could also occur via radical-anion intermediates. To test this proposal we have carried out a study on the photoreactivity of 1-aza-1,4-dienes **39a**, **39b**, **40a**, and **63** using *N*,*N*-dimethylaniline (DMA) as electron-donor sensitizer. Irradiation of **39a**, **39b**, **40a**, and **63**, in acetonitrile, under these conditions, afforded the corresponding cyclopropyl imines **41a** (21%), **41b** (15%), **42a** (11%), and **64** (15%), respectively, that hydrolyzed to the corresponding aldehydes during isolation.[19] These results demonstrate that the 1-ADPM rearrangement of azadienes **39a**, **39b**, **40a**, and **63** can be promoted by DMA, a well-known electron-donor sensitizer.[20] A possible mechanism to account for the formation of the cyclopropyl imines is shown in Scheme 16 for compound **39b**. It involves generation of the radical-anion **65** that bridges to form the cyclopropyl radical-anion **66**. The rearrangement in **66** generates **67**, which, by back electron transfer, yields **41b** (Scheme 16).

However, previous studies show that compound **39b** undergoes 1-ADPM rearrangement very efficiently in the triplet excited state.[7b] Because DMA has a triplet energy of 68.4 kcal mol^{-1},[20] efficient triplet energy transfer to the alkene unit is a possibility to take into account in these reactions. Therefore, the question that arises is whether the 1-ADPM rearrangements of compounds **39a**, **39b**, **40a**, and **63** occur by triplet energy transfer or by SET via radical-anions. To answer this question, the DCA-sensitized irradiation of compounds **39a**, **39b**, and **40a** was carried out in hexane, a nonpolar solvent that should not favor the generation of radical-anions. Under these conditions, the corresponding cyclopropanes **41a** (2%), **41b** (2%), and **42a** (4%) were also obtained but the yields of products were considerably lower

than in the runs carried out in acetonitrile.[19] This result support the involvement of radical-anions in these rearrangements when the reaction is carried out in acetonitrile. However, in the case of compound **63**, the yield of cyclopropane **64** in hexane and acetonitrile were comparable, thus casting doubt on whether or not these reactions are taking place via triplet sensitization or SET.



Trying to arrive at a definitive answer to this question, the study was extended to the 1,4-diene **68**. In a previous study, Zimmerman and Pratt[21] reported the efficient DPM rearrangement of **68** on direct irradiation to give cyclopropane **69** in good yield. However, the rearrangement was very inefficient when the irradiation was carried out using benzophenone as triplet sensitizer. Therefore, compound **68** was considered to be a perfect candidate to determine whether DMA was acting as a triplet energy donor or as an electron donor. DMA-sensitized irradiation of **68**, in acetonitrile, afforded **69** in 34% yield. When the reaction was carried out in hexane, **69** was obtained in 22% yield. However, benzophenone-sensitized irradiation of **68**, in hexane, for the same period of time gave **69** in 5% yield only, in agreement with the earlier results. The drastic decrease in the yield of product in the reactions run in hexane caused by changing the sensitizer from DMA to benzophenone cannot by explained by less efficient triplet energy transfer from the benzophenone to the diene **68** because the triplet energy of benzophenone (69.2 kcal mol^{-1})[20] is comparable to the value reported for the DMA (68.4 kcal mol^{-1}).[20] Therefore, the results obtained in the study of the photoreactivity of diene **68** clearly support the involvement of radical-anions in the DMA-sensitized irradiation. Considering that the CN double bond in compounds **39a**, **39b**, **40a**, and **63** should be a better electron acceptor than the diphenylvinyl unit in **68**, it is logical to assume that the rearrangement of **39a**, **39b**, **40a**, and **63** also occurs via similar radical-anion intermediates. However, the absence of a solvent polarity effect on the efficiency of photoreactions of **63** and **68** is surprising. A possible explanation for the strong influence of the solvent polarity in the case of compounds **39a**, **39b**, and **40a** and the small influence of this effect for compounds **63** and **68** is shown in Scheme 17 for compound **39b**.



SCHEME 17

Thus, the very fast rearrangement of the radical-anion **65** within solvent cages (Scheme 17, path a) could justify the absence of solvent polarity effect. In cases in which this intermediate escapes from the cage before rearrangement occurs (Scheme 17, path b), a significant influence of the polarity of the solvent would have been observed. This is the situation in DMA-sensitized reactions of **39a**, **39b**, and **40a**.[19]

The results summarized above demonstrate that 1-ADPM, 2ADPM, and DPM reactions can take place via radical-cation and radical-anion intermediates. These observations have modified some of the ideas firmly established for many years on the photoreactivity of β,γ-unsaturated systems, opening new lines of research in an area in which, due to the large number of studies carried out for more than 30 years,

apparently there were very few things to uncover. Further studies are underway to determine the scope and possible synthetic applications of these novel reactions and to rationalize the photo-behavior of these compounds.

96.1 Introduction and Definition

Photochromism is an exemplary field of photochemistry that deals with photochemical reactions that are reversibly thermally or photoinduced. This term is made up of two parts — photo (light) and chroma (color) — and the suffix "ism" indicates the phenomenon. Photochromism literally means coloration by light. It has received considerable attention ever since its discovery toward the end of the 19th century, both for organic or inorganic substances, and is still an active field of research, primarily because of its actual and potential applications and for its paramount importance in biological phenomena.[1–6]

Photochromism[7–11] is a reversible transformation of a single chemical species between two states, whose absorption spectra are recognizably different, brought about, in at least one direction, by electromagnetic radiation (Equation 96.1).

$$A\,(\lambda_1) \underset{\Delta \text{ or } h\nu_2}{\overset{h\nu_1}{\rightleftharpoons}} B(\lambda_2) \quad \text{(unimolecular process)} \tag{96.1}$$

Species A is transformed into the higher-energy form B as a result of irradiation with light. The reverse reaction to reform A usually occurs as a spontaneous thermal process, but may also be light induced. Equation 96.1 holds only for unimolecular reactions. More recently, bimolecular photochromic systems, based on a cycloaddition or cycloreversion,[12–14] have also been discovered.

$$A\,(\lambda_1) + B(\lambda_2) \underset{\Delta \text{ or } h\nu_2}{\overset{h\nu_1}{\rightleftharpoons}} C(\lambda_3) \quad \text{(bimolecular process)} \tag{96.2}$$

1 E **2** Z

SCHEME 1

The photochromic[1–7,15] systems illustrated in Equation 96.1 can be classified into several groups on the basis of a photochemically induced primary step:

1. *Z,E*-(*cis,trans*)-isomerization
2. Tautomerism
3. Pericyclic reactions
4. Homolytic bond cleavage
5. Electron transfer reactions

This chapter discusses only *N*-containing photochromic molecules. However, it covers many classes of photochromic systems. Therefore, photochromism based on triplet-triplet absorption of stilbenes, thioindigo, bianthrylidenes, fulgides, and salicylates (only briefly) is not discussed. Nitrogen-containing photochromic systems are dealt with if the reacting fragment of the molecule contains nitrogen. One exception is made for the very important spiropyrans (*vide infra*).

96.2 *Z,E*-(*cis-trans*)-Isomerization

Azobenzenes

When the double bond of azo compounds is excited either directly or via sensitizers, a reversible *Z,E*-isomerization is observed.[16–18]

Azobenzene isomerization normally is a very clean reaction (Scheme 1). In the presence of oxygen, slow photooxidation to azobenzene occurs.[16]

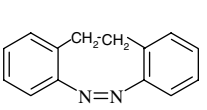
E,Z-isomerization can be induced by a direct (singlet) or sensitized (triplet) route from the n,π^* or π,π^* state. The thermal back-reaction from the *Z*-isomer is slow in azobenzene and fast in amino- or aminonitro-substituted azobenzenes (pseudo-stilbenes). The color change is more in intensity than in wavelength.[16–18] In geometrically locked azobenzene (i.e., in **3**, **4**, and **5**), the *Z*-form might be stable and cannot isomerize (Scheme 2).[18]

Compounds of type 4 show identical quantum yields $\phi_{E,Z}$ when excited either in the n,π^* or π,π^* state.

More recently, so-called photoresponsive crown ethers have also been prepared and, in these too, the light-sensitive behavior is based on *Z,E*-isomerization.[17,18] The study of azo-groups in polymers[18b-d] has been undertaken recently. Switching processes have been an intensively studied domain in recent years as show in some recent papers.[18e,18f] *Z,E*-isomerization also plays an important role in simpler compounds such as benzylidene anilines[17b] and azomethines. The latter are of importance in biological systems such as rhodopsin in the human eye.[1–5]

96.3 Pericyclic Reactions

Pericyclic reactions are among the most important processes that allow for the design and construction of photochromic systems, and a large number of photochromic organic molecules utilize pericyclic reactions as the bases for photochromic materials.



3

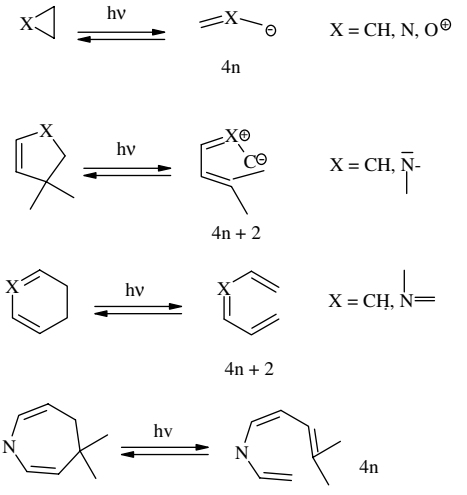
5

SCHEME 2



SCHEME 3

Electrocyclization

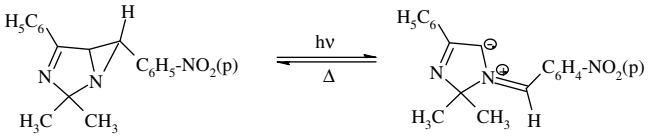
Electrocyclic reactions have proved especially suitable as a structural unit for photochromic systems. Scheme 3 shows four different types of ring-opening reactions. However, only a few of the many possible electrocyclizations are important with regard to application.

4n-System

Here, the three-membered heterocycles have an outstanding role. Griffin and co-workers prepared a new class of stable carbonyl ylides from epoxydiphenylsuccinimde **6** and diphenylepoxymaleic anhydride **7**.[19] Colors are generated when the bicyclic oxides **6** and **7** are irradiated at 77K. In rigid matrices (2-methyltetrahydrofuran), ring opening affords the ylides **8** and **9.** The colors of **8** and **9** persist after the matrix is warmed, softens, and appears to become fluid (130 to 140K).

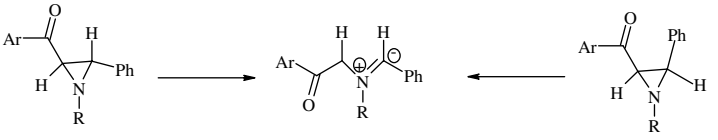
10 **11**

SCHEME 4



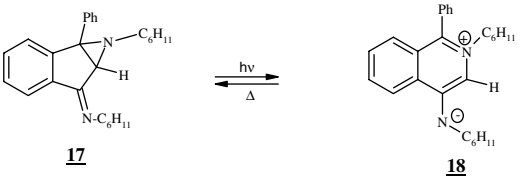
12 **13**

SCHEME 5



14 **15** **16**

SCHEME 6



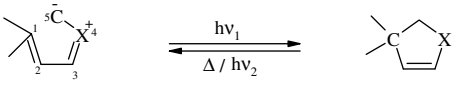
17 **18**

SCHEME 7

8 **9**

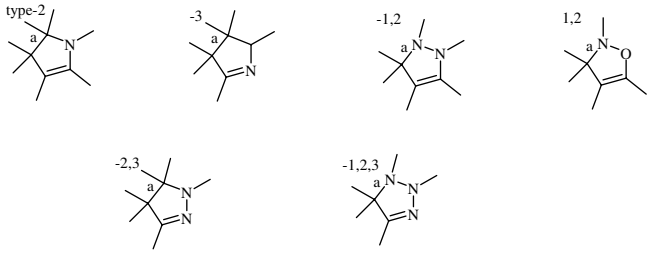
Color is not visible at ambient temperature in fluid 2-methyltetrahydrofuran; however, **8** and **9** are stable in the solid state even at room temperature.

In the analogous way, the nitrones **10** can be converted by irradiation into the oxaziridines **11** (Scheme 4). The latter are powerful oxidizing agents, highly reactive, and in most cases they cannot be isolated. The reverse reaction takes place upon heating. Here, the open form **10** is more stable. Interesting photochromic molecules of the aziridine type have been found by Cromwell[20] and Tap Do Minh and Trozzolo et al.[21–23] Aziridines show photochromic behavior in the crystalline state although some systems



19 **20**

SCHEME 8



SCHEME 9 The numbers show the positions of the heteroatoms in aza-pentadiene, thus classifying the molecule as type 2-system etc.

are also photochromic in solution. An especially efficient photochromic system is found in the bicyclic aziridine **12**, which undergoes a light-induced reaction according to Scheme 5 to give monocyclic **13.**[21–23]

Cromwell and co-workers[20] discovered the photochromism of arylaziridines some time ago. Padwa and Hamilton[24] investigated the photochromism of glasses at 77K in the arylaziridine system **14**, **16**. On warming slowly, the colors fade and the aziridine is regenerated.

All attempts to obtain colored species by carrying out the irradiation in solution failed. Lown and Matsumoto[25] as well as Padwa and Vega[26] investigated another class of photochromic aziridines based on 1,3-electrocyclization.

4n+2 Systems (5 Atoms, 6 Electrons n = 1)

A very efficient photochromic system was discovered in 1979 by Dürr and Hauck.[27,28] It is based on the electrocyclic ring closure of azapentadienes to azacyclopentenes.

Nitrogen or oxygen can be in different positions (1 to 5) of the azapentadiene system. Thus, a great versatility is available as far as different classes of five-membered heterocycles are concerned. The different photochromic compounds based on this intercoversion are given in Scheme 9.

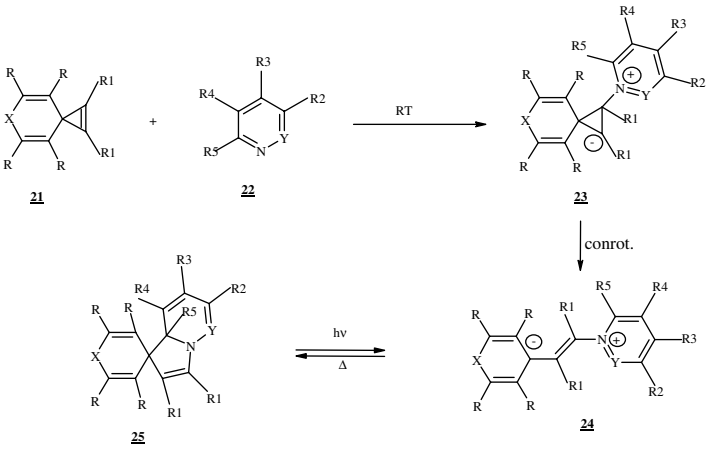
This scheme shows the classification (types) and characteristic structural features of the new photochromic system (a: σ-bond formed upon 1,5-electrocyclization). According to the position of the heteroatom in the aza-pentadiene, fragments are classified as type 2, etc.[7,27,28]

Type 2 System

Systems of type 2 can be regarded as "1,3-dipoles of an allylic type."[28] The organic chemist's entire armory has been brought to bear on the study of 1,3-dipolar cycloadditions[29] but despite this, it is only quite recently that the reaction has been successfully used in an effective photochromic system.

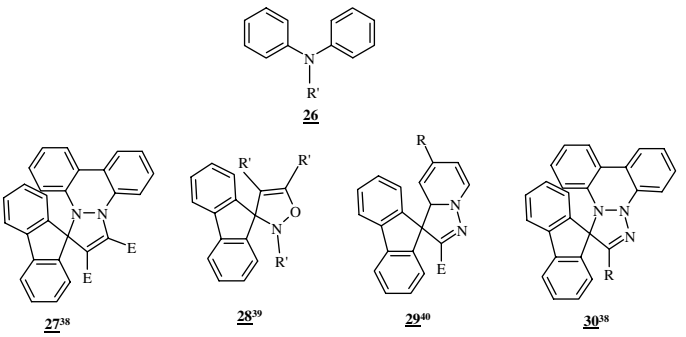
A new photochromic system whose structural basis are the spiro-dihydroindolizines[27] was found and studied intensively.[27,28,30–33] It can be prepared easily by different routes[30–33] and a typical path is shown in Scheme 10. When spirocyclopropenes with the general structure **21**[30] are allowed to react with pyridine or pyridazine derivatives, photochromic [1,8-a]dihydroindolizines **25** (Y = CH or Y = N, respectively) are formed.[34–36]

Compounds with a very wide range of absorption wavelength can be synthesized using this "cyclopropene route." The photochromic properties are not linked, however, to spiro-dihydroindolizines; simpler systems (diphenyl derivatives) can also be prepared easily. Thus, by introducing a variety of



21 + **22** → **23** (RT); **23** → **24** (conrot.); **24** ⇌ **25** (hν / Δ)

SCHEME 10 Cyclopropene route to **24** and **25**. Solvent: CH_2Cl_2/ether; temperature: 25°C; yield: 12 to 89%.



26

27[38] **28**[39] **29**[40] **30**[38]

SCHEME 11

different substituents in all positions of **25**, molecules with tailor-made properties are accessible. Crown ether-linked dihydroindolizines can be made that allow special effects due to host, guest, or supramolecular assemblies.[34]

Type 3 System

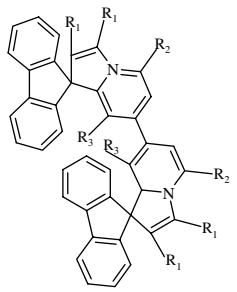
On irradiation, systems of the type such as **20** in the presence of oxygen give indoles. However, owing to subsequent thermal reactions, such as sigmatropic H-shifts (and possibly oxidation) at moderate or high temperature, irreversible secondary reactions occur to yield di-and tetrahydroindolizines and the system therefore cannot be regarded as being reversibly photochromic.[37]

Mixed systems (1,2; 2,3-; 1,2,3.)

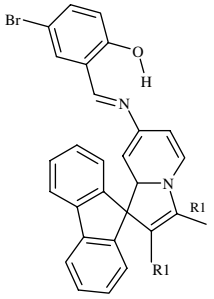
Mixed photochromic systems such as **27** through **30** can be synthesized as well. A survey of typical examples is given below.

Biphotochromic systems containing (1) two DHI-molecules,[41] (2) a DHI- and a salicylideneanil,[42] and (3) DHI-spirooxazine have also been prepared.

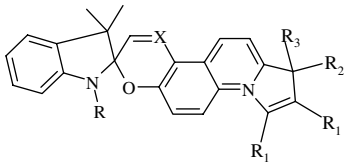
Applying one of the above four synthetic routes in combination with the same or a second approach can lead to biphotochromic systems.[41,42] In principle, these are symmetrical systems such as DHI-DHI **31** and unsymmetrical systems such as DHI_a-DHI_b, photochromic systems(**32** or **33**) are possible (see Scheme 12).



31

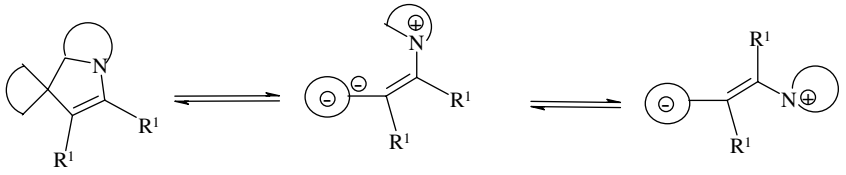


32



33

SCHEME 12



25 *E*-**24** *Z*-**24**

SCHEME 13

A typical system for an unsymmetrical photochromic compound is molecule **32**. It is prepared by reaction of **21** with pyridosalicylidenanil.[42] Recently, unsymmetrical biphotochromic molecules combining spiroxazine-and spirodihydroindolizine structures have been prepared.[43]

1,5-Electrocyclization

The UV spectra of the dihydroindolizines **25**, X = CH, and dihydropyrrolo[1,2-b]pyridazine **25**, X = N, usually have absorption maxima in the near-UV between 360 and 410 nm. The betaines **35** produced by photochemical ring opening absorb at about 505 to 726 nm.

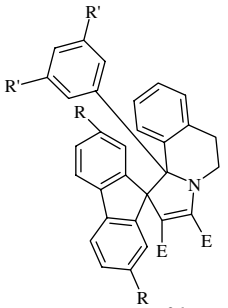
The σ-bonds in the various azoheterocycles that undergo photochemical cleavage are marked in Scheme 9. These cases differ significantly from the ring opening of the cyclopentenyl anion because, in previous molecules, no anion is formed. The photoproduced compounds from these electroneutral, five-membered heterocycles are zwitterions or betaines in all cases.

The ring opening of **25** occurs easily in solution, in polymers, and in rigid matrices at room temperature. In some cases, ring opening was also observed in the crystalline state.

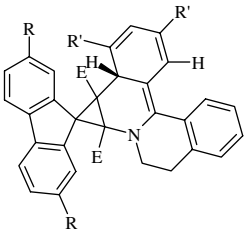
Dürr and co-workers[35b] recently discovered the first intramolecular trapping of the key intermediate in the formation of indolizine photochromic compounds. Therefore, the reaction of substituted spirocyclopropenes with 1-(3,5-dinitrophenyl)-3,4-dihydroisoquinolines afforded not only the expected tetrahydroindolizines (THI) **26** but also novel fluorenespiroazanorcaradiene dyes **27,** which were proved to be formed via 1,6-electrocyclization as shown in Scheme 14.

Multiplicity of the Photochemical Reaction 25 → 24

The photochemical reaction for the ring opening of **25** to **24** was demonstrated to proceed via an excited singlet or a fast-reacting triplet state that does not undergo bimolecular quenching (for details, see Ref. 36 and 44a). The determination of the quantum yield for ring opening **25** → **24** was carried out using nonlinear optimization methods (details in Reference 45). The values for ϕ_R are on the order of 0.4 to

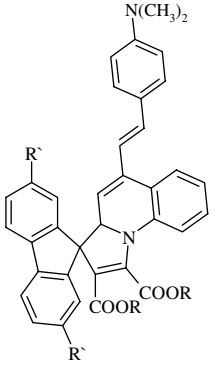


26

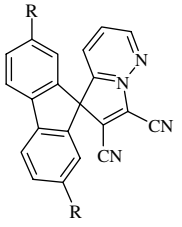


27

SCHEME 14



25A



25B

SCHEME 15 Structure of the P_r chromophore of phytochrome.

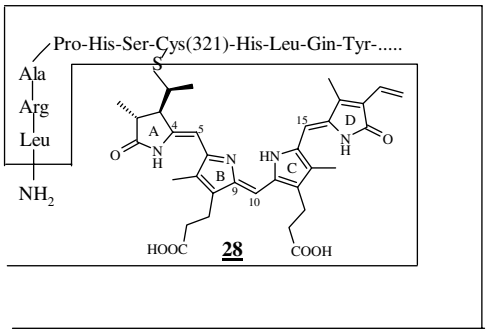
0.8 for the forward reaction and 0.1 for the back reaction. The quantum yields are also wavelength dependent.

We have also shown that the amino-styryl –DHI **25A** undergoes ring opening to a blue betaine **25A′** showing for the first time fluorescence from the colored form. This has been used to develop *destruction*-free, dual-mode storage systems or switches.[44] Using films of **25A** in PMMA, a single molecule fluorescence was detected.[44] The use of the long-lived colored form, produced by irradiation of **25B** allowed the development of a holographic data storage system.[44] The photochemical switch based on the DHIs **25** is now well established.

An important system belonging to the class of five-membered heterocyclic interconversions are the phytochromes (P_R), which have been studied by Schaffner and Braslavsky et al.[46] These systems play an important biochemical role in regulating plant growth.[46]

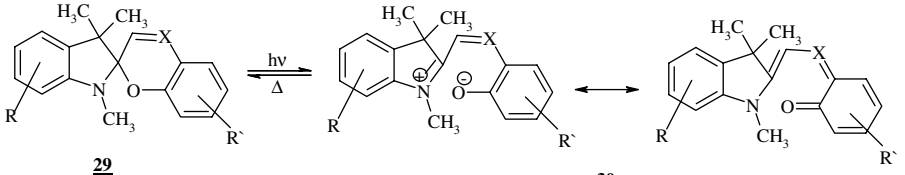
4n + 2 System: (6 Atoms, 6 Electrons)

An electrocyclic (4n + 2)-reaction (n = 1) is also found in the spiropyrans **29**[47–50] as shown in Scheme 15. UV irradiation of the colorless or slightly yellow spiro compounds **29** leads to cleavage of the CO bond to give the open-chain molecule **30** that absorbs strongly in the visible region. These highly interesting photochromic spiropyrans have been studied very intensively.[1,50] This system has also led to a number of practical applications. Braeuchle et al., among others, have shown that an unstable intermediate with an orthogonally bridged structure is formed during ring opening of nitrobenzo-spiran at 4.2K.[51]



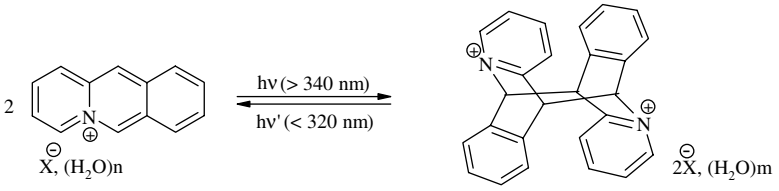
28

SCHEME 16



29 **30**

SCHEME 17 R and R′ can be a large number of organic groups; each ring can also contain several substituents.



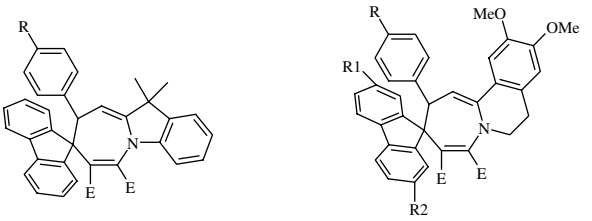
37 **38**

SCHEME 18

If in Scheme 17 X is N, the molecules **29** belong to the class of spirooxazines.[52–58] This photochromic system undergoes very fast ring opening to the colored form **30** with good quantum yield ($\phi_{R=}$ 0.2 to 0.8) in solution and in films. The color rapidly fades thermally. No photochromism is observed in the crystalline state. The spiroxazines have recently been studied with regard to solvatochromism,[58d] sol-gel inclusion,[58c] and semiempirical caclulations.[58a] In connection with good, long-term photostability, spirooxazines are of great commercial value. They belong to the best N-containing photochromic systems used today.[57] Recently, a series of spirooxazines has been investigated and their photochemical[58] properties have been discussed in detail. Related electrocyclizations were also studied with 1-nitro-2-aryl-alkenes.[59]

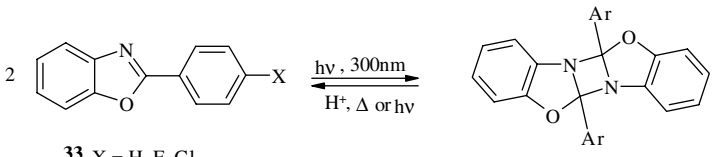
1,7-Electrocyclization

Recently, Dürr and co-workers[36,60] reported a new photochromic 8π-process based on an azaheptatriene 1,7-electrocyclization **31, 32**. This type of photochromic systems is formed by a pericyclic process. Other



31 **32**

SCHEME 19



33 X = H, F, Cl **34** "ht"

SCHEME 20

reports on 8π-seven-atom photochromic systems (4n) are rare.[60] Only a very few molecules have been described and the reversibility of the processes involved has been established.[2]

Cycloadditions

[2 + 2]-Cycloadditions

The photodimerization of 2-phenylbenzooxazole **33** produces a head-tail photodimer **34** involving two carbon-nitrogen double bonds.[61]

The photodimer **34** is labile in fluid solution but thermally stable in the solid state at room temperature. This system has been proposed as a system for light-energy conversion, because the thermal reversion of the photodimer to the starting material **33** releases 116 kJ mol.$^{-1}$ A similar reversible [2+2]-cycloaddition has been reported for 1,1′-polymethylene-bisthymines (n = 2 to 6). The dimerization (λ = 300 nm) can be reversed by irradiation with 254-nm light.[62]

[4 + 4]-Cycloaddition

2-Aminopyridine as the HCl-salt can undergo a [4+4]-photodimerization.[63] The diphosphate or dimethanesulfate of the dimer **36** can be cleaved by short wavelength irradiation. Chandross has used this reversible photoreaction, employing crystals of the dimer, to write holographic gratings.[64] In a [4+4]-cycloaddition, acridinium bromide **37** gave **38**.[65] Related studies were carried out with polymethylene-linked acrizidinium salts.[66]

SCHEME 23

96.4 Tautomerism

Light-induced tautomerism can occur within the salicylidene-anilines in the form of prototropic rearrangements such as **39** → **40.**[67–72]

These molecules are photochromic in the crystalline state (α and β modification) and in rigid glasses. The large Stokes shift (F-spectrum) is explained by proton transfer in the excited state. The mechanism has been studied in great detail.[73]

Similar behavior is found in 2-, 3-, or 4-(salicylideneamino) pyridines.[73,74] However, compounds **41a,b,c** show only thermochromism in the crystalline state. In rigid glasses at low temperature, salicylideneanilines **41** are also photochromic.

Some theoretical studies,[74e] photochromism in sol-gel systems, and photochromic switching of salicylideneanils were reported recently.[67–74]

A related tautomerization occurs in aromatic nitro compounds **42.** It is designated as an acid/nitro phototautomerization (Scheme 24).[73]

An interesting tautomerism occurs in benzotriazoles (TINUVIN)* that are used as light filters in dye protection.[75] The tautomerism processes in porphyrins are the basis of a photochromic reaction used in hole burning.[76a] This process has been used for making a molecular computer. Dithizonates were used as photochromic materials in ophthalmic lenses.[76b]

*TINUVIN is the commercial name for benzotriazoles, which are used as light stabilizers in polymers and dyes.

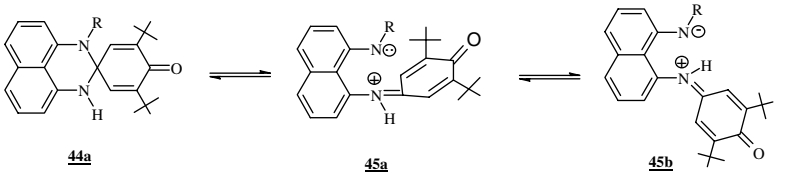
SCHEME 25



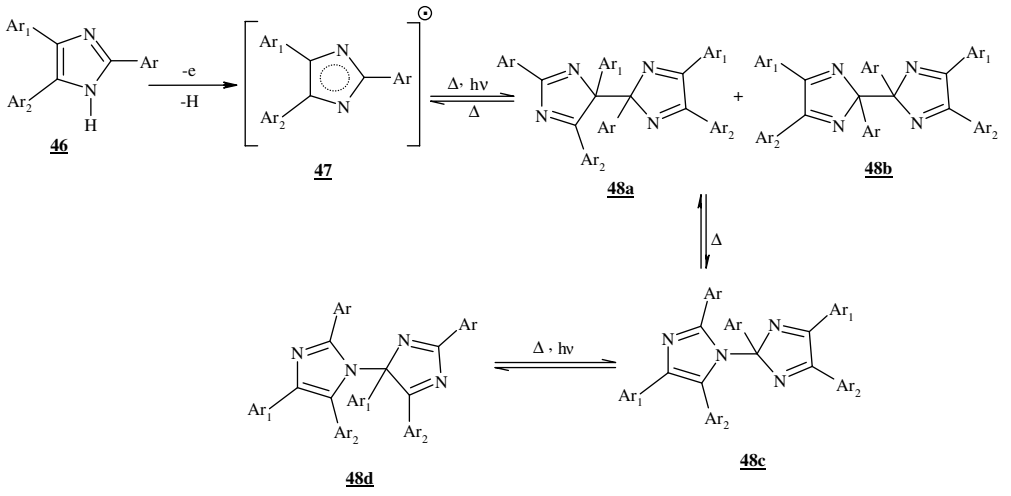
44a **45a** **45b**

SCHEME 26

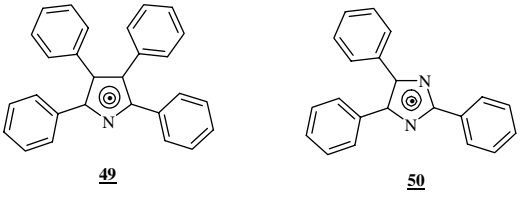
Valence and prototropic tautomeric reactions are among the most important mechanisms that govern transformations of a broad variety of photochromic organic systems.[3,4] Until recently, no examples of photochromic compounds have been reported whose photochromic behavior was due to a combination of these two tautomeric reactions. Such a combination, which is characteristic of ring-chain/tautomerism,[77] a sigmatropic reaction, has been implemented in the photochromic and thermochromic rearrangements of a novel type of heterocyclic photochromes, derivatives of 2,3-dihydro-2-spiro-4′-(di-*tert*-butylcyclohexadien-one)perimidine **44a** and its analogues.[78] The occurrence of a proton transfer step is in accord with the fact that the *N,N′*-dimethyl derivative of **44a** exhibits no photochromic properties.

UV irradiation of an octane solution of **44a** (R = H or alkyl) changes its color from yellowish to deep blue. The initial spectrum is slowly restored at room temperature (the effective lifetime of the colored form at room temperature is about 10^4 s). The mechanism of the photochromic reaction involves cleavage of a C-N bond in the first singlet excited state of **45a**, followed by the conformational rearrangement of the resultant zwitterionic (biradical) intermediate **45b** that precedes the final step of the intramolecular proton transfer (Scheme 26).

It has, therefore, been concluded that any further modification of the photochromic compound **44a** should be associated with structural variations in its 2,3-dihydroperimidine moiety. In the course of subsequent studies, the spirocyclohexadienones **44a** have been found to display photo-and thermochromic properties.[77]



SCHEME 27



SCHEME 28

96.5 Dissociation/Homolytic Cleavage of Bonds

Homolytic and heterolytic dissociation processes play a role in the field of reactions responsible for the photochromic properties of various chemical compounds.[79]

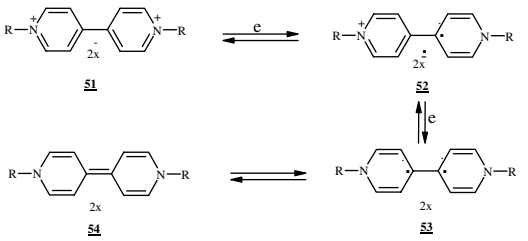
Imidazoles **46** under oxidative condition form dimers **48** that are photochromic both in the crystalline state and in solution.[80] A long-lived intermediate **47** was assumed to be responsible for the observed purple color and the radical nature was proved by ESR methods.[80]

Typical examples of this type include the cleavage reactions of octaphenyl-1,1′-bipyrrolyl and of hexaphenyl-1,1′-biimidazolyl, which on exposure to light yield the colored free radicals **49** and **50**, respectively. These reactions form the basis of a photochromic system.[81] Photochromism is observed both in the crystalline state and in solution.

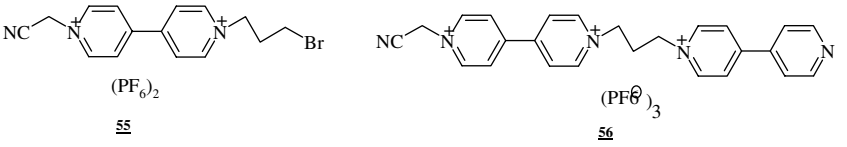
96.6 Electron Transfer/Redox Photochromism

The best photochromic system based on an electron transfer reaction is undoubtedly that of AgCl, which is decomposed by light according to Equation 963.[82]

$$\mathrm{AgCl} \xrightarrow{h\nu} \mathrm{Ag} + \dot{\mathrm{Cl}} \qquad (96.3)$$



SCHEME 29



SCHEME 30

The photochromic mechanisms of redox-photochromic compounds are usually difficult to determine because they are often multicomponent systems. However, the methylene blue/iron sulfate system [83] is relatively well understood.

Nanasawa[84] has reported studies on new photochromic viologens such as 4,4′-bipyridine **51**, 2,2′-bipyridine, and 1,10-phenanthroline based on electron transfer. The colorless viologens composed of diquaternary salts turn into a violet-blue radical-anion **52** by one-electron reduction[81–86] and are further reduced to the yellowish quinonoid **54** via the biradical **53**. New results in crown ether containing viologenes,[84e] in the crystalline state[84c] as well as in polymer[84a,b,d,] were reported recently.

We have demonstrtaed that viologen dications **55** and bisviologen trications **56** (X = PF_6^-) in polyvinylpyrrolidone films give blue radical-cations on irradiation being thermally reversible, thus showing clear photochromism of this system.[87]

96.7 Application of Photochromic Materials

The inherent properties of photochromic systems make them suitable for use in many different areas. Thus, applications are directly dependent upon the color change caused by the molecular and electronic structures of the two species (A, B) and their corresponding absorption or emission spectra.

Typical applications include:

- Variable-transmission optical materials such as the photochromic ophthalmic lenses
- Camera filters
- Fluid flow visualization
- Optical information storage
- Novelty items (toys, T-shirts, etc.)
- Authentication systems (security printing inks)
- Cosmetics

Properties such as conductivity, refractive index, electrical moment, dielectric constant, chelate formation, ion dissociation, phase transitions, solubility, and viscosity can be changed as well. Certain physical changes that occur when the photochromic entity is chemically attached to the macromolecular backbone of polymers are of special interest. Some examples of possible applications utilizing these physical or chemical changes that accompany the observed shift in the absorption maxima are given below:

TABLE 96.1 Applications of Photochromic Materials

Control and Measurements of Radiation Intensities	Contrast Effects	Recording and Storage of Information
Optical filters	Masks for contrast equalization in photography	Imaging
Lenses	Film material	Instantaneous imaging material
Glasses		Office copying materials
Cuvettes	Amplifying contrast in projected images	Microfilm
	Projection screens	
Radiation protection equipment	Projection walls	Microfilm copying materials
Glasses		Sprays
Spectacles	Production of printing plates and circuit boards	Digital information
Films	Photoresists	Slow storage
Containers	Photopolymers	Bulk data storage (archives, etc.)
Protection from sun	Solar energy conversion	Holography
Protection from flash exposure, lasers, etc.	Energy storage	Storage disks
		Storage films
Document preservation		Crystals
Temperature indicators		Data display system
		Display screens (image screens)
Actinometry, dosimetry		Molecular computers
Actinometer		Q-switches (for lasers)
Dosimeter		Molecular electronics

- Optoelectronic systems (semi-conductor modulated by photochromic pigments).
- Reversible holographic systems.
- Photochemically switchable enzymatic systems.
- Nonlinear optical devices

The use of photochromic molecules such as spirooxazines in combination with chromenes in ophthalmic plastic lenses has been a major commercial breakthrough for photochromic molecules. Thus, these molecules are manufactured worldwide; leading firms include Ttransitions, Rodenstock, and Essilor (see Tables 96.1, 96.2, and 96.3). Practical use in dental materials has been reported as well.

Some commercial applications as well as potential applications of simple and very sophisticated applications are collected in Table 96.1 while some selected properties of commercially interesting molecules are given in Tables 96.2 and 96.3.

TABLE 96.3 Kinetic and Photochemical Parameters of NOSI Compounds at 352 nm in Toluene at 294K

Compound	ϕ_B/ϕ_A	$\phi_A + \phi_B = \phi_A$	$k(s^{-1})$
NOSI1	NA	0.23 ± 0.10	0.270 ± 0.010

The application of photochromics in data storage, information recording, and holographic data storage is very promising and commercial applications in this field are anticipated in the near future.

Optical computers using photochromes are under active study. So, the field is moving forward and promises a series of applications to be marketed in the near future.

Photoisomerization of Some Nitrogen-Containing Hetero-Aromatic Compounds

James W. Pavlik
Worcester Polytechnic Institute

This chapter deals with the photoisomerization reactions of pyrazoles, 1,2,4-oxadiazoles, pyridine, and its simple derivatives and pyridinium cations. The photochemistry of nitrogen-containing heteroaromatic compounds that also contain sulfur are considered in another chapter.

97.1 Pyrazole Photochemistry

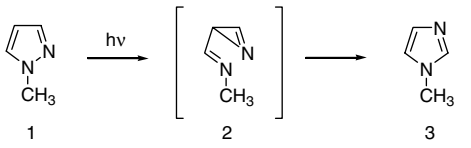
The photochemistry of 1-methylpyrazoles has been of considerable interest since it was reported that 1-methylpyrazole **1** undergoes photoconversion to 1-methylimidazole **3**. This transposition was rationalized in terms of a ring contraction ring-expansion mechanism shown in Scheme 1 involving the intermediacy of 2-(*N*-methylimino)-2*H*-azirine **2** formed by cyclization of a photochemically generated biradical species. This mechanism would result in a transposition pathway involving interchange of only the N2 and C3 atoms of the pyrazole ring as shown in Scheme 2. The ring-scrambling pattern resulting from the N2–C3 interchange shown in Scheme 2 has been referred to as the P_4 pattern.[2]

Although the intermediacy of acylazirines has been demonstrated in the analogous isoxazole-oxazole phototransposition,[3] iminoazirines such as **2** have not been detected in a pyrazole→imidazole reaction and thus this mechanistic suggestion has never been confirmed.

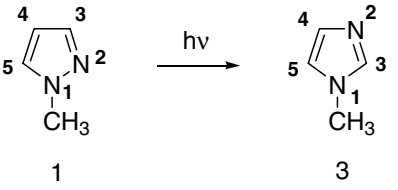
The existence of an additional reaction pathway was confirmed by Beak and co-workers, who reported (see Scheme 3) that 1,3,5-trimethylpyrazole **5** phototransposes to 1,2,5-trimethylimidazole **6**, a product that can result from the 2,3-interchange pathway and 1,2,4-trimethylimidazole **7**, a product which cannot be formed by this pathway.[4,5] The formation of the latter product was suggested to occur (Scheme 4) by a pathway involving initial electrocyclic ring closure, heteroatom migration via [1,3]-sigmatropic shift of nitrogen, and rearomatization of the resulting 2,5-diazabicyclo[2.10]pentene to provide **7**.

Barltrop and colleagues[6] also observed that 3-cyano-1,5-dimethylpyrazole **8** undergoes photoisomerization to yield **9** and **10** (Scheme 5), which can be formed by the 2,3-interchange pathway and the one-step nitrogen

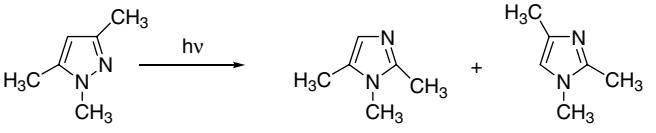
0-8493-1348-1/04/$0.00+$1.50



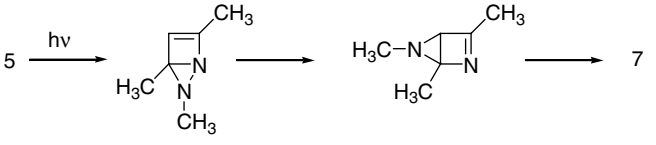
SCHEME 1



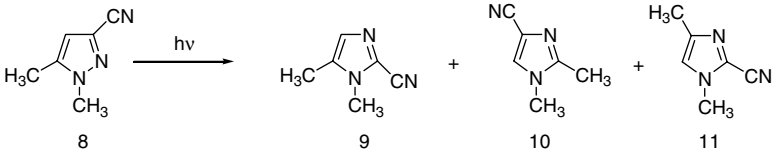
SCHEME 2



SCHEME 3



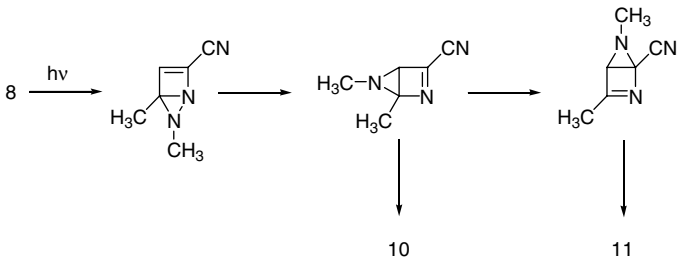
SCHEME 4



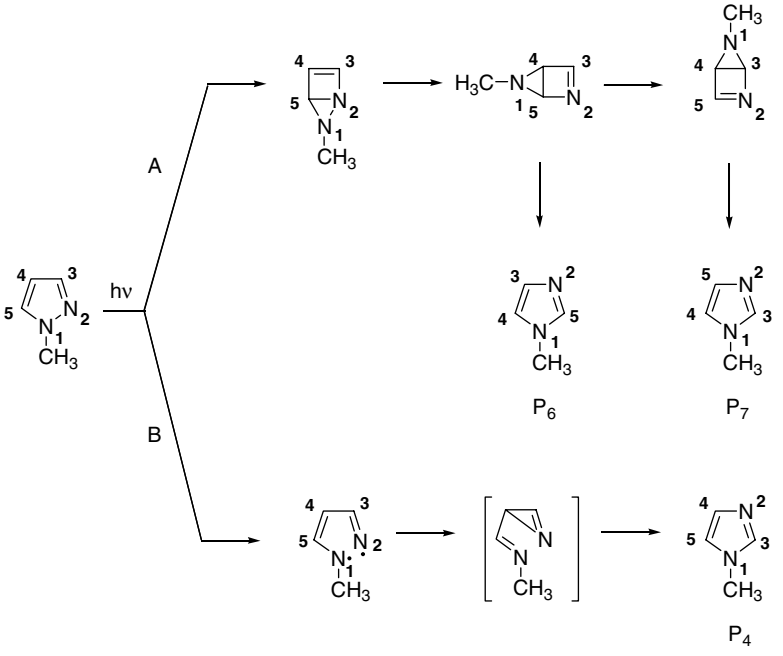
SCHEME 5

walk mechanism, respectively, and **11,** which cannot be formed by either of these pathways but was suggested to arise by the double nitrogen walk mechanism shown in Scheme 6. Such a double walk process has also been observed in the photochemistry of cyanothiophenes[7] and cyanopyrroles.[2b,8]

The mechanistic pathways implicated by these reactions are shown in Scheme 7, which shows how the ring atoms transpose by each pathway.



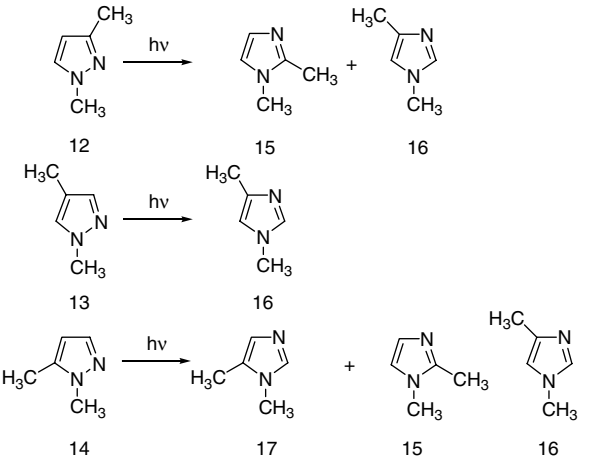
SCHEME 6



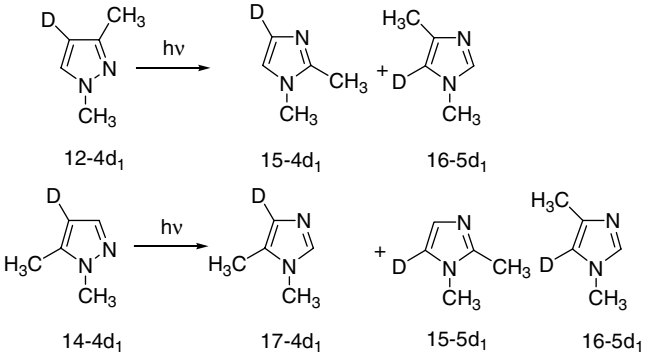
SCHEME 7

According to this interpretation, the photochemistry of 1-methylpyrazoles involves competition between electrocyclic ring closure (path A, Scheme 7) and cleavage of the N1–N2 bond (path B, Scheme 7). Path A results in the formation of a 1,5-diazabicyclo[2.1.0]pentene intermediate that undergoes one or two sigmatropic shifts of nitrogen, followed by rearomatization of the two isomeric 2,5-diazabicyclo[2.1.0]pentene species to yield 1-methylimidazoles with two different ring scrambling patterns referred to as P_6 and P_7.[2] It is interesting to note that because only pyrazole-to-imidazole transpositions have been observed, the [1,3] sigmatropic shift of nitrogen must take place away from the azetine nitrogen to form a 2,5-diazabicyclo species but not in the opposite direction toward the azetine nitrogen to yield an isomeric 1,5-diazabicyclic species and eventually a pyrazole-to-pyrazole transformation. Alternatively, path B leads to a species that can be viewed as a biradical that is the precursor of the 1-methylimidazole in which the P_4 scrambling pattern involves only interchange of the N2 and C3 atoms.

The photochemistry of 1-methylpyrazoles **12** through **14**, in which the various ring carbons are systematically labeled with a second methyl group, has also been studied.[9] The primary products shown in Scheme 8, and the results of deuterium labeling studies shown in Scheme 9 confirm that these dimethylpyrazoles undergo only pyrazole-to-imidazole phototransposition by as many as three distinct pathways.



SCHEME 8



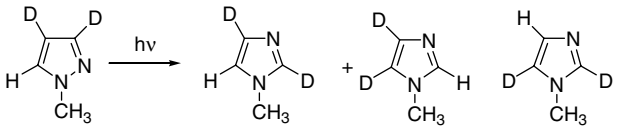
SCHEME 9

Thus, whereas 1,5-dimethylpyrazole **14** transposes by the P_4, P_6, and P_7 pathways to yield 1,5-, 1,2-, and 1,4-dimethylimidazoles **17**, **15**, and **16**, respectively, 1,3-dimethylpyrazole **12** transposes only via the P_4 and P_6 pathways to form 1,2- and 1,4-dimethylimidazoles **15** and **16**, respectively. Finally, 1,4-dimethylpyrazole **13** transposes to a single product, 1,4-dimethylimidazole **16**, presumably via the P_4 N2–C3 interchange pathway.

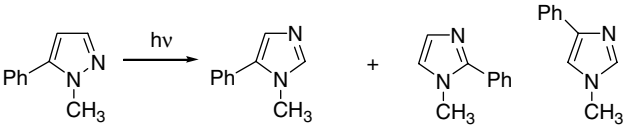
To study the phototransposition with minimum substituent perturbation, the phototransposition chemistry of 3,4-dideuterio-1-methylpyrazole **1-3,4d$_2$** was also studied.[9] This labeling pattern allows distinction between the three pathways because Scheme 7 shows that conversion of **1**→**2** via the P_4, P_6, or P_7 pathways is accompanied by transposition of C5 of the reactant to ring position 5, 2, or 4 in the product.

After less than 10% photoconversion of **1-3,4d$_2$**, ^{1}H NMR analysis revealed that the product consisted of a mixture of **2-2,4d$_2$**, **2-4,5d$_2$,** and **2-2,5d$_2$,** confirming that **1-3,4d$_2$** undergoes phototransposition via the P_4, P_6, and P_7 pathways in a ratio of 4.8:6.5:1.0. Thus, the phototransposition of 1-methylpyrazole **1** to 1-methylimidazole **2** is considerably more complicated than originally suggested.

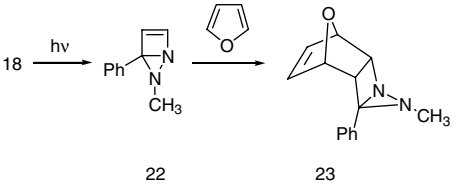
A key mechanistic step in the formation of the P_6 and P_7 imidazoles is electrocyclic ring closure leading to a transient 1,5-diazabicyclo[2.1.0]pentene. Convincing evidence for the existence of this species is available. Thus, whereas irradiation of 1-methyl-5-phenylpyrazole **18** in methanol results in the formation



SCHEME 10



SCHEME 11



SCHEME 12

of the anticipated P_4, P_6 and P_7 imidazoles **19** through **21** in the chemical and quantum yields shown in Scheme 11, irradiation of **18** in neat furan led only to the pyrazole-furan [4+2] adduct **23**.[10] The formation of this product is consistent with furan trapping of a photochemically generated 1,5-diazabicyclopentene species **22** as shown in Scheme 12.

In addition to phototransposition, *N*-substituted pyrazoles have also been observed to undergo two photocleavage reactions to yield enaminonitrile and enaminoisocyanide photoproducts. Thus, 1-methyl-4-phenylpyrazole **24** phototransposes regiospecifically to the P_4 product 1-methyl-4-phenylimidazole **25** and to the two photocleavage products (*E,Z*)-3-(*N*-methylamino)-2-phenylpropenenitrile **26** and (*E,Z*)-2-(*N*-methylamino)-1-phenylethenylisocyanide **27** in the chemical and quantum yields shown in Scheme 13.[10,11] Furthermore, these photocleavage pathways are not limited to the reactions of **24**, they are involved in all other pyrazole to imidazole photoreactions investigated.

Direct irradiation of *Z*-enaminonitrile **26** and *Z*-enaminoisocyanide **27** shows (Scheme 14) that both undergo *Z*→*E* isomerization and photocyclization to 1-methyl-4-phenylimidazole **25**, the P_4 transposition product. In addition, cyclization of **27** to **25** was observed when the former was heated to 80°C. Although the quantum yields shown in Scheme 14 reveal that the photocyclization of enaminonitrile **26** to imidazole **25** is a very inefficient reaction, chemical and quantum yields show that the photocleavage-photocyclization pathway via an isocyanide intermediate is a major route for the P_4 phototransposition reaction.[10] Furthermore, it has been shown that this pathway is general for a variety of other pyrazoles that bear hydrogen at the C3 ring position.

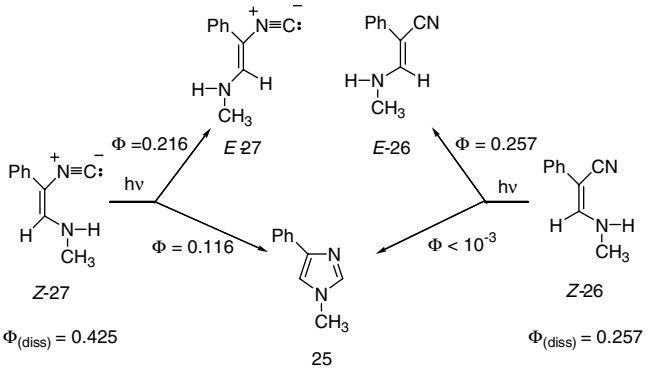
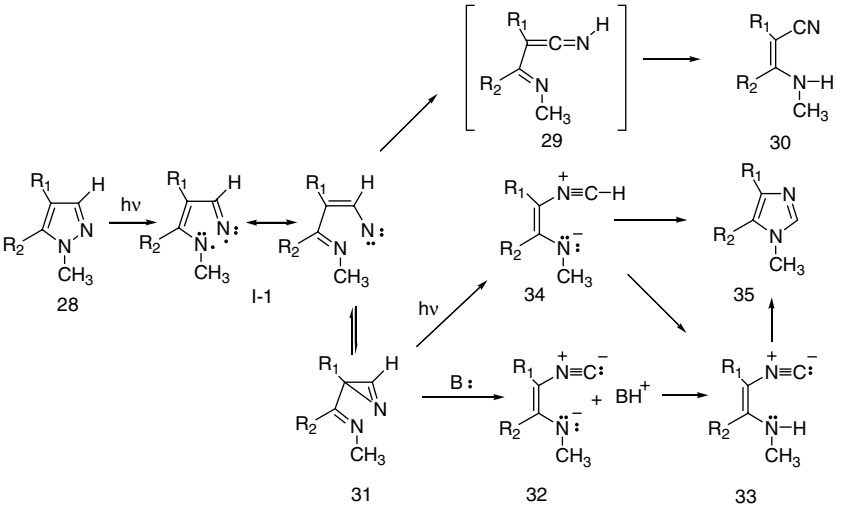
SCHEME 13

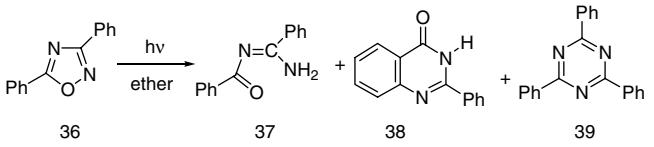


SCHEME 14



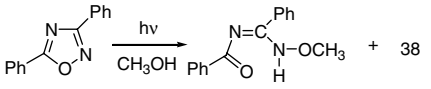
SCHEME 15

From these studies, a general mechanistic scheme for the P_4 N2–C3 interchange pathway is emerging. As shown in Scheme 15, photocleavage of the N1–N2 bond in **28** is suggested to result in the formation of a species I-1 that was described as either a biradical or as a β-iminovinyl nitrene. The isomerization of terminal vinyl nitrenes to nitriles is a well-documented reaction.[12] Accordingly, nitrene I-1 would be



36 37 38 39

SCHEME 16



36 40

SCHEME 17

expected to rearrange as shown in Scheme 15 to the enaminonitrile photocleavage product **30**, plausibly by way of iminoketeneimine **29**. In addition, vinyl nitrene I-1 would also be expected to be in equilibrium with the isomeric iminoazirine **31**,[13] which could isomerize to the enaminoisocyanide **33**, a known precursor of imidazole **35**, the P_4 phototransposition product. This reaction requires proton transfer from carbon in **31** to nitrogen in **33**. Although in the case of acylazirines[14] and thioformylazirines[15] this proton transfer requires an added base, pyrazoles and certainly imidazoles are sufficiently basic to act in this capacity. Alternatively, electrocyclic ring opening of azirine **31** would be expected to yield nitrile ylide **34**,[16] which could undergo direct cyclization to the P_4 imidazole **35** or proton transfer resulting in the formation of the isocyanide **33**. If azirine **31** is formed in the ground state, calculations suggest that in the absence of deprotonation by a base, the most likely reaction pathway is back to the pyrazole. Calculations also reveal that excitation to the S_1 surface is accompanied by an increase in the carbon-carbon bond length from 1.49 to 1.74Å. Accordingly, if an azirine-like structure is reached on the reaction coordinate before crossing to the S_0 surface, the excited species would be expected to undergo facile conversion to the nitrile ylide rather than resulting in an isolable product.

97.2 1,2,4-Oxadiazole Photochemistry

Irradiation of an ethereal solution of diphenyl-1,2,4-oxadiazole **36** with quartz-filtered light from a medium-pressure Hg lamp was reported to result (Scheme 16) in the formation of a photoreduced product **37** in 31% yield, a photoisomerization product **38** in 5% yield, and an interesting ring-expansion product **39** in 0.5% yield.[17] When the irradiation was carried out in methanol solvent, the major product (Scheme 17) was identified as the 1:1 methanol adduct **40** (or its tautomer) in 40% yield and **38** in 7.5% yield.[18] Thus, irradiation of **36** results in homolysis or heterolysis of the O–N bond in the oxadiazole.

Cleavage of the O–N bond also dominates the photochemistry of isoxazoles.[3] In this case (Scheme 18), cleavage of isoxazole **41** is followed by ring contraction to the acylazirine **42** and subsequent ring expansion to the oxazole **43** in which the N2 and C3 atoms of the isoxazole ring have been interchanged.

By analogy with isoxazole chemistry, 1,2,4-oxadiazoles **44** might also be expected to undergo phototransposition by the ring contraction–ring expansion pathway shown in Scheme 19 leading to the formation of 1,3,4-oxadiazole **46** via diazirine **45**. This reaction has been studied in detail by Vivona[19] and colleagues and found to occur in greater than trace quantities only when a tautomerizable group (NH_2, $NHCH_3$, NHPh, or OH) is present at the C3 position of the 1,2,4-oxadiazole ring, as shown in Scheme 20.[20–22] Thus, direct excitation of 1,2,4-oxadiazoles **47** through **55** at 254 nm in methanol solution led to the formation of 1,3,4-oxadiazoles **56** through **64** in yields of approximately 10%. The phototransposition of **47** through **56** could not be quenched with added penta-1,3-diene (E_T = 62.5 kcal mol^{-1}) or

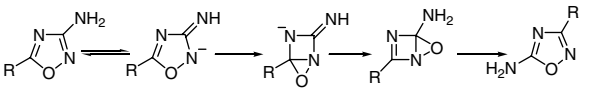
65 66 67 68 69 70

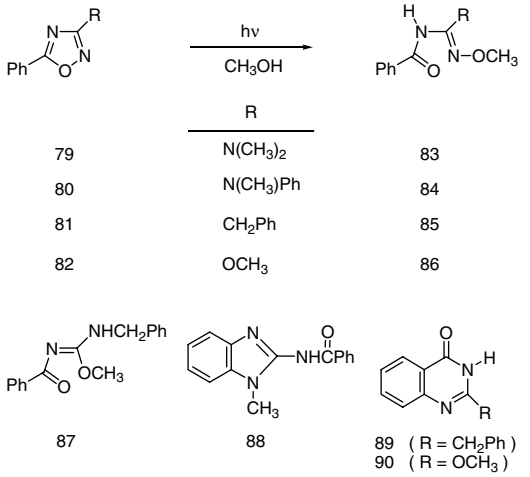
SCHEME 21

sensitized by diphenylacetylene (E_T = 62.5 kcal mol^{-1}) and thus presumably does not involve the triplet state of the reactant.

Because of the necessity of the tautomerizable group at C3 of the reactant, it was suggested that a tautomeric form **66** of the oxadiazole **65** or intermediate **67** (Scheme 21) might be involved in this phototransposition.[21] The photoconversion of 2-methyl-5-phenyl-f^4-1,2,4-oxadiazolin-3-one **69** to 3-methyl-5-phenyl-f^4-1,3,4-oxadiazolin-2-one **70** is consistent with this suggestion.



SCHEME 22



SCHEME 23

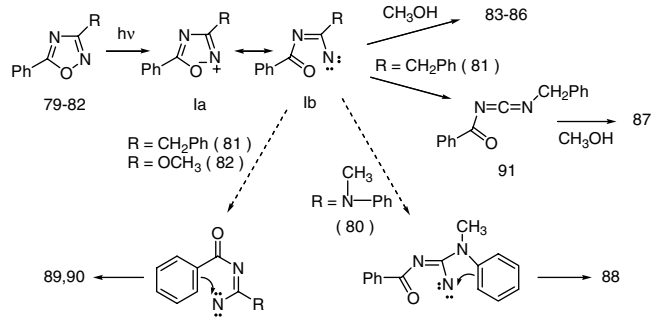
Interestingly, irradiation of 3-amino-5-alkyl-1,2,4-oxadiazoles **53** or **54** at 254 nm in methanol containing a small quantity of base such as triethylamine (TEA) or aqueous sodium bicarbonate leads to the formation of 1,3,4-oxadiazoles **62** or **63** and also to 5-amino-3-alkyl-1,2,4-oxadiazoles **77** and **78**, respectively, as shown in Scheme 22.[22]

It has been suggested that photochemically excited **53** or **54** is deprotonated by the base, resulting in the formation of the anionic species **71** or **72**, respectively, which undergo electrocyclic ring closure between N2 and C5 to give the stabilized anions **73** and **74**, respectively. Oxygen migration and reprotonation then provides **75** and **76**, from which the observed phototransposition products **77** or **78** arise by rearomatization.

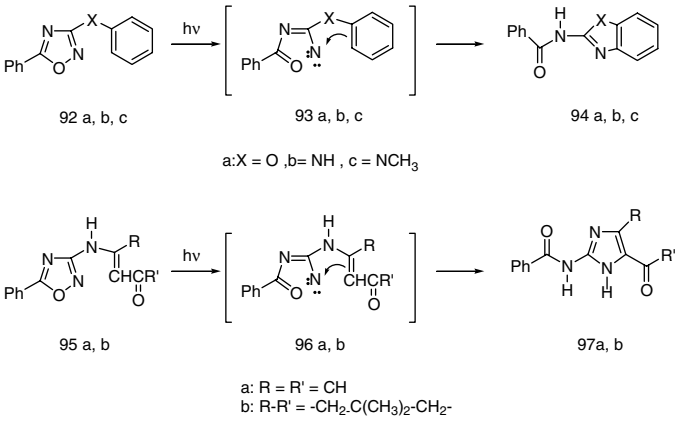
In contrast, when the C3 substituent is not tautomerizable, as in the case of **79** through **82** in Scheme 23, irradiation at 254 nm in methanol solvent led to the solvent adducts **83** through **86**, respectively; and in the case of **81**, to a second adduct **87**. In addition, irradiation of **80–82** also resulted in the formation of the cyclized products **88–90**, respectively.[20]

The products shown in Scheme 23 can be rationalized in terms of photocleavage of the O–N bond in **79** through **82**, resulting in a species that can be viewed as a zwitterion **Ia** or as a β-acyliminonitrene **Ib** (Scheme 9). The observed products then result from reactions typical of an electrophilic nitrogen.[20] Thus, reaction with the nucleophilic solvent (Scheme 24) leads to **83** through **86**; a 1,2-shift of the benzyl group from carbon to nitrogen in the nitrene formed from **81** would provide the carbodiimide **91**, which would react with methanol to form **87**; electrophilic attack on the phenyl ring in the C3 substituent of **80** results in the benzimidazole **88**; or electrophilic attack on the C5 phenyl group in **81** or **82** would provide quinazolines **89** or **90**.

When the substituent at C3 of the 1,2,4-oxadiazole ring is a participating three-atom side chain, new reaction pathways become available.[23–27] Thus, irradiation of 1,2,4-oxadiazoles **92a,b,-c** at 254 nm in methanol solvent also resulted in the formation of benzimidazoles **94a,b** or benzoxazole **94c** (Scheme 25).



SCHEME 24



SCHEME 25

Similarly, enanimoketones **95a,b** photoisomerize to imidazoles **97a,b**.[23] These reactions can also be rationalized by photocleavage of the O–N bond of the oxadiazole ring and electrophilic attack by the electron deficient nitrogen in **93a,b,c** or **96a,b**.

The photochemistry of 3-benzoylamino-5-methyl-1,2,4-oxadizole **98** and 3-acetylamino-5-phenyl-1,2,4-oxadiazole **99** has also been investigated (Scheme 26).[24–27]

Upon direct excitation at 254 nm, **98** gave quinazolinone derivative **101**, which was suggested to result from initial hetero-electrocyclic ring closure to yield **100** followed by ring opening. This reaction can be quenched by added penta-1,3-diene and was suggested to involve the triplet state of the aroylamino group. Direct irradiation of 3-acetylamino **99** at 254 nm gave the 3-benzoylamino isomer **98**, which was converted to **101** under the conditions of the irradiation. The photoconversion of **99** could not be quenched by added penta-1,3-diene, and its conversion to **98** was assumed to involve the intermediacy of singlet nitrene **102**. Interestingly, triplet-sensitized excitation of **99** using phenylacetylene or diphenylacetylene led to the direct formation of quinazolinone **101** without the intermediacy of **98**. This conversion was suggested to involve the intermediacy of the triplet nitrene **102**. The triplet-sensitized irradiation of 5-phenyl-1,2,4-oxadiazoles can be used as a synthetic route to various 2-substituted quinazolin-2-ones.[27]

The conversion of oxadiazoles to quinazolin-4-ones can also be achieved by electron-transfer sensitization.[28] For example, 9,10-diphenylanthracene (DAN)-sensitized irradiation at 313 nm of 5-aroyl-3-methoxy-1,2,4-oxadiazoles **103ab,c,d** and 5-aroyl-3-phenyl-1,2,4-oxadiazoles **106a,b,c,d** resulted in the formation of quinazolin-4-ones **104a,b,c,d** and **107a,b,c,d**, respectively, and photoreduced products **105a,b,c,d** and **108a,b,c,d**, respectively. In these reactions, neither singlet nor triplet sensitization is

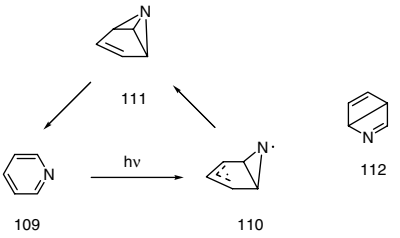
feasible. These reactions can also be achieved by direct excitation of **103a,b,c** at 313 nm in methanol solvent containing an excess of triethylamine (TEA).[28] Under these conditions, **103a,b,c** gave **104a,b,c** in yields of 50 to 60% and photoreduced products **105a,b,c** in approximately 30% yield. Similarly, **106a** provided quinazolin-4-one **107a** in 36% yield, along with a trace quantity of the photoreduced product **108a**. These reactions are envisioned to occur by cleavage of the N–O bond in the 1,2,4-oxadiazole radical anion formed either by electron transfer from the excited sensitized (DAN) to the ground state of the 1,2,4-oxadiazole or from TEA to the excited singlet state of the 1,2,4-oxadiazole.

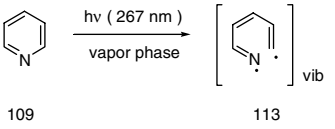
97.3 Pyridine Photochemistry

Introduction and Background

The photochemistry of six-membered aromatic compounds has been of considerable interest since it was shown that benzene and its simple derivatives undergo photo-valence isomerization and phototransposition.[29–32] The photochemistry of the important heteroaromatic compound pyridine **109** is of interest because it has an $S_2(\pi, \pi^*)$ state similar to benzene and a lower-lying $S_1(n, \pi^*)$ state not available to benzene. Accordingly, pulsed excitation of pyridine in neutral solution led to the observation of two transients with decay components of 2.2 ps, assigned to motion along the π,π^* reaction pathway, and 23 ps that represents the nonradiative, nonreactive decay pathway of S_1 leading to intersystem crossing to the $T(\pi,\pi^*)$ state or to chemical reaction.[33]



SCHEME 28



SCHEME 29

Excitation of aromatic molecules such as benzene or pyridine with excess energy results in a dramatic decrease in their fluorescence yields due to the availability of an extremely rapid nonradiative deactivation pathway.[34] This phenomenon has been termed the "channel three" process. For pyridine **109**, the onset of channel three deactivation occurs at ~1600 cm^{-1} above the S_1 origin.[35] This deactivation was originally thought to involve a concerted pathway, originating from a vibrationally excited S_1 aromatic molecule, leading to the ground state of a bicyclic prefulvene biradical. In the case of pyridine **109** (Scheme 28), this species would be azaprefulvene **110,** which could rearomatize to pyridine **109,** either directly or via azabenzvalene **111** in an energy wasting process. More recently, it has been proposed that channel three deactivation might involve direct S_1–S_0 internal conversion resulting in a vibrationally excited ground-state species geometrically disposed to undergo isomerization to the prefulvene isomer.

Time-Resolved Studies

The nonradiative transitions in pyridine vapor have been studied using femtosecond, time-resolved mass spectroscopy.[36] In these experiments, pyridine vapor was excited with a femtosecond light pulse of 277 nm, which is below (~300 cm^{-1}) the channel three threshold. Time-resolved mass spectroscopy revealed a fast decay component of 400 fs, which describes the initial motion on the pyridine potential surface and shows components of 3.5 and 15 ps, which were assigned to the formation of Dewar-pyridine **112** and azabenzvalene **111**, respectively (Scheme 28).[36]

These processes have also been studied using ultra-fast electron diffraction.[37] In this case, a femtosecond light pulse of 267 nm was used to excite pyridine **109** vapor into the S_1 (n, π^*) state with an excess energy of ~2700 cm^{-1}, well above the ~1600 cm^{-1} threshold for channel three behavior. Sequentially delayed ultra-short electron pulses were then used to probe the ensuing structural dynamics.

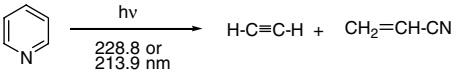
Interestingly, the results were not consistent with either direct $S_1 \rightarrow S_0$ internal conversion to a vibrationally excited ground-state molecule or with valence isomerization-mediated internal conversion. Instead, surprisingly, the results indicate that the primary product is a hot ring-opened biradical **113** (Scheme 29) formed via cleavage of a CN bond.

The deactivation pathway for excited pyridine **109** in solution phase has been studied using femtosecond transient absorption spectroscopy.[33] According to these studies, excitation of pyridine **109** in acetonitrile with a femtosecond pulse of 266 nm results in the population of vibrationally excited $S_1(n,\pi^*)$ and $S_2(\pi,\pi^*)$ molecules. The S_2 $(\pi,\pi^*)_{vib}$ relaxes to its equilibrium geometry in less than 100 fs. This vibrationally relaxed $S_2(\pi,\pi^*)$ molecule can either undergo internal conversion to the S_1 (n,π^*) state in

109
S_2 (π,π*)

110

SCHEME 30



109 114 115

SCHEME 31

greater than 10ps or, more rapidly (~2.2 ps), can isomerize to the azaprefulvene **110** (Scheme 30) by passing over the barrier in the S_2 state and crossing the conical intersection. Previous calculations on pyridine also suggest the existence of an azaprefulvene structure formed from the $S_2(\pi,\pi^*)$ excited state.[38] This prefulvene species **110** can revert to the ground state of pyridine **109** in greater than 2 ns by passing over the barrier and crossing over to the ground state of pyridine **109**. These studies also conclude that $S_1(n,\pi^*)$ pyridine can decay via intersystem crossing to the $T_1(\pi,\pi^*)$ triplet state and by interconversion to other isomers. Although earlier theoretical studies indicated that the potential energy surfaces of both $S_1(n,\pi^*)$ and $S_2(\pi,\pi^*)$ have a crossing point along the isomerization coordinate to the azaprefulvene, these studies show that the barrier from the $S_1(n,\pi^*)$ surface is too high for this isomerization to occur. It was concluded, however, that $S_1(n,\pi^*)$ pyridine can interconvert to other isomers.

Continuous Excitation Studies

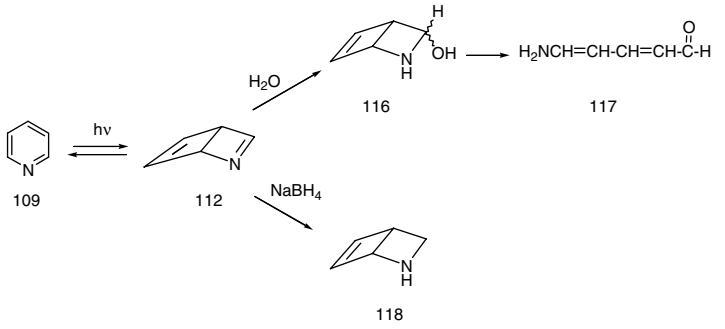
The vapor-phase photochemistry of pyridine **109** under conditions of continuous irradiation has been studied at various wavelengths. Little or no decomposition of pyridine was observed upon irradiation at 254 nm and no gaseous products were detected after irradiation at 265 or 248 nm.[39] Upon irradiation at 228.8 or 213.9 nm, however, pyridine **109** was converted to acetylene **114** and acrylonitrile **115** (Scheme 31).

Irradiation of pyridine **109** in butane solution at −15°C with light of 254 nm has been shown to result in the formation of Dewar-pyridine **112,** which was characterized and observed to have a half-life of 36 minutes at 0°C and 2 minutes at ambient temperatures.[41] Alternatively, if pyridine is irradiated in water[42,43] or in aqueous sodium borohydride, the initially formed **112** undergoes hydration to **116** and ring opening to form 5-amino-2,4-pentadienal **117** or reduction to provide 2-azabicyclo[2.2.0]hex-5-ene **118**, respectively (Scheme 32).

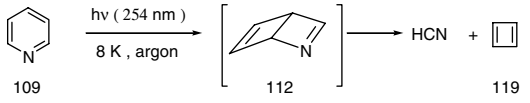
Irradiation of pyridine **109** matrix isolated in argon at 8K gave rise to hydrogen cyanide and cyclobutadiene **119** as secondary photoproducts.[44] It was assumed that these products arise from photofragmentation of the initially formed Dewar-pyridine **112** (Scheme 33).

Irradiation of 2-methylpyridine **120** vapor (10 to 15 Torr) led to the formation (Scheme 34) of both 3-methylpyridine **121** and 4-methylpyridine **122** in a ratio of 10:1.[45]

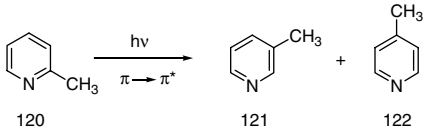
Within the $\pi\rightarrow\pi^*$ transition absorption band, the quantum yields for the formation of **121** and **122** increased by a factor of 6 when the excitation wavelength is decreased from 266 nm (0–0) to 238 nm.[45] These results are typical for channel three behavior. No conversion of 2-methylpyridine **120** was observed upon irradiation in the $n\rightarrow\pi^*$ transition at either 280 or 290 nm. It was suggested that the conversion of **120** to **121** and **122** proceeds via an azaprismane intermediate.[45]



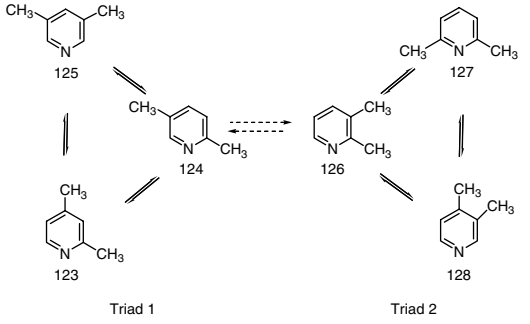
SCHEME 32



SCHEME 33



SCHEME 34

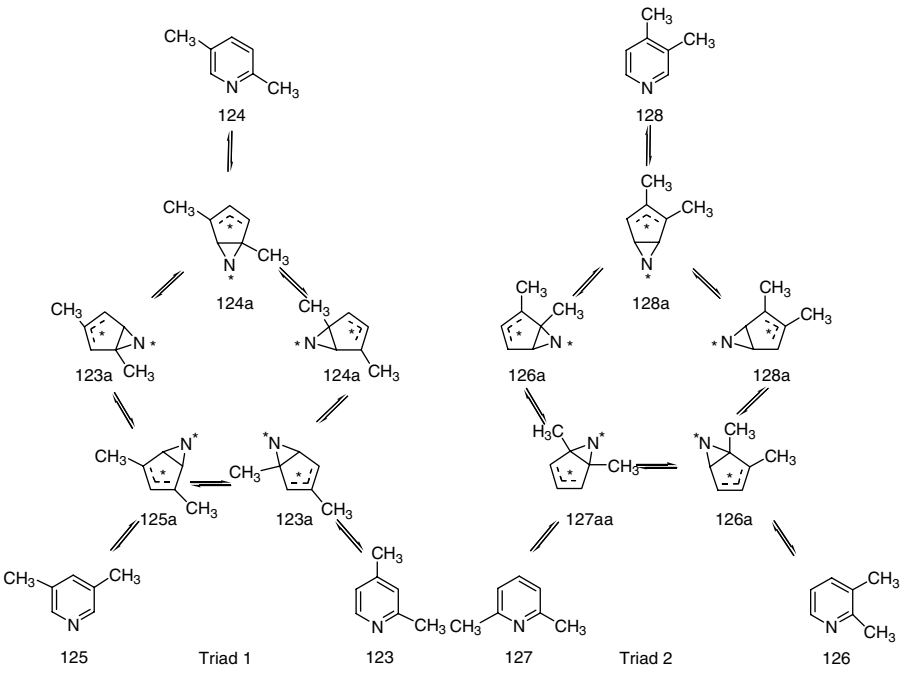


SCHEME 35

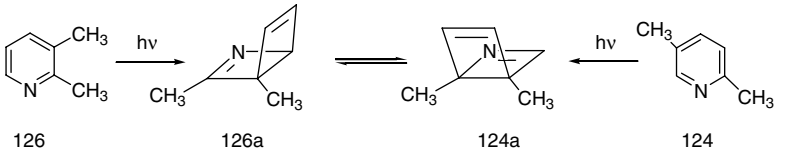
Dimethylpyridines were also reported to undergo phototransposition in the gas phase. These reactions were also suggested to occur by way of azaprismane intermediates.[46]

The photochemistry of dimethylpyridines in the vapor phase has been reinvestigated with substantially different results and conclusions.[47] According to these studies, irradiation of the six dimethylpyridines **123** through **128** at 254 nm in the vapor phase results in phototransposition and photodemethylation or, in one case, photomethylation of a dimethylpyridine to a trimethylpyridine.

Based on the major transposition products observed, the six isomers can be divided into the two triads shown in Scheme 35. The first triad consists of 2,4-dimethyl-**123**, 2,5-dimethyl-**124**, and 3,5-dimethyl-**125**,



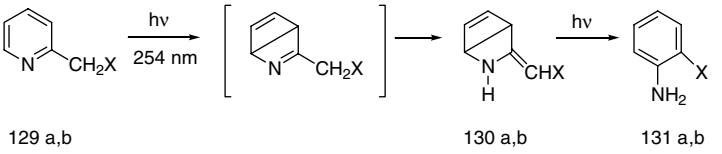
SCHEME 36



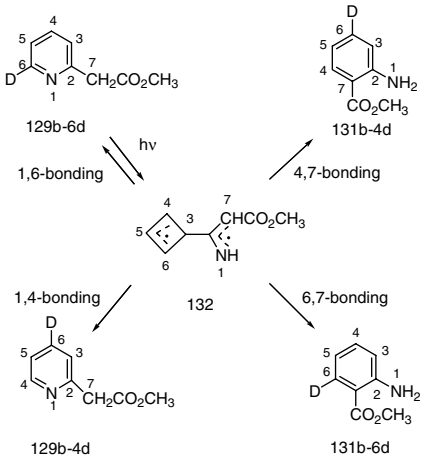
SCHEME 37

while the second triad includes 2,3-dimethyl-**126**, 2,6-dimethyl-**127**, and 3,4-dimethylpyridine **128**. These intra-triad interconversions were suggested to occur (Scheme 36) via 2,6-bonding, originating from a vibrationally excited $S_2(\pi,\pi^*)$ state of the dimethylpyridine, resulting in the formation of the dimethyl-azafulvene intermediates shown in Scheme 36. Subsequent nitrogen migration and rearomatization then allows interconversion of the three members of each triad. The unsubstituted azaprefulvene **110** was also suggested to result from the $S_2(\pi,\pi^*)$ state of pyridine generated by pulsed excitation.[33] In that case, sigmatropic nitrogen migration would not lead to a distinguishable product after rearomatization.

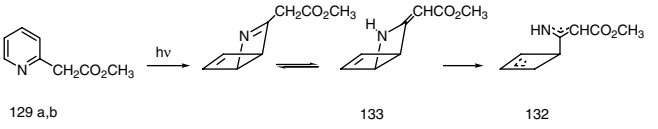
In addition to these intra-triad reactions, 2,5-dimethylpyridine **124**, a member of triad 1, was observed to interconvert with 2,3-dmethylpyridine **126**, a member of triad 2 (Scheme 35). As illustrated in Scheme 37, these inter-triad interconversions were shown to occur via interconverting Dewar-pyridine intermediates **124a** and **126a**, which were detected by ^{1}H-NMR spectroscopy after irradiation of the dimethylpyridines in CD_3CN at −30°C. These inter-triad reactions involving Dewar-pyridine intermediates were enhanced by dilution of the dimethylpyridine vapor with nitrogen, by irradiation with light of wavelength >290 nm, and took place in the condensed phase at low temperature. These facts indicate that Dewar-pyridine formation occurs from an excited state of lower energy than the first excited singlet (π,π^*) state. These observations do not seem to be consistent with the suggestion based on calculations that isomerization to the Dewar-pyridine can involve a Möbius-pyridine on the higher-energy π,π^* potential energy surface.[48]



SCHEME 38



SCHEME 39

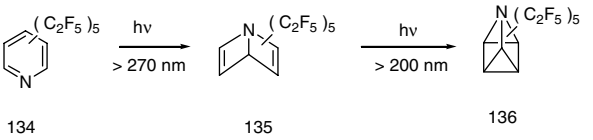


SCHEME 40

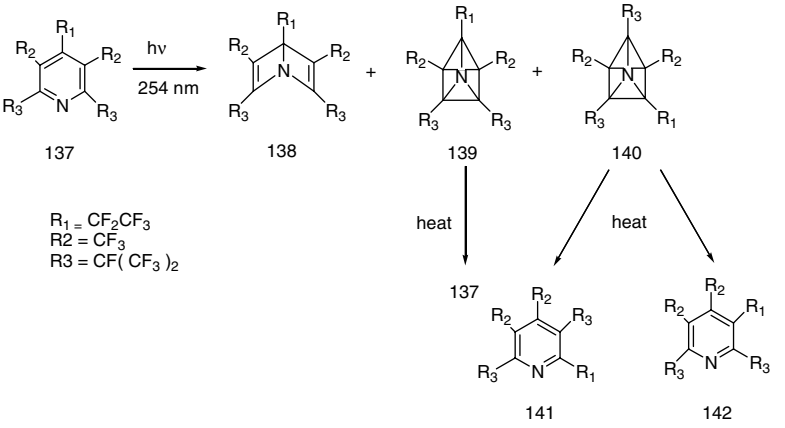
Dewar-pyridine derivatives have been implicated as intermediates or isolated as products in other photoreactions of pyridine derivatives in solution phase. Irradiation of pyridine derivatives **129a,b** (Scheme 38) at 254 nm in ether/*t*-butyl alcohol solvent led to the formation of aniline derivatives **131a,b** via Dewar-pyridine tautomers **130a,b**.[49] The tautomer **130b** was isolated when **129b** was irradiated in aqueous sodium hydroxide and was shown to be photochemically converted to **131b** upon irradiation in diethyl ether solution.[50]

The photochemistry of **129b-6d** was also studied.[51] After 80% conversion of the reactant (Scheme 39), the rearranged product was shown to consist of equal amounts of **131b-4d** and **131b-6d** (Scheme 39) while the unconverted reactant consists of the original **129b-6d** and 10% of the rearranged reactant **129b-4d**. The mechanism suggested to account for the conversion of the 2-substituted pyridine **129b** to the methylanthranilate product **131b** and to explain the observed deuterium scrambling (Scheme 39) involves formation and cyclization of intermediate **132**. Presumably, **132** is not formed directly from the pyridine reactant **129b** but from the Dewar-pyridine tautomer **133** as shown in Scheme 40.

Polyperfluoroalkyl substitution greatly stabilizes both Dewar-pyridine and azaprismane valence isomers. Irradiation of pentakis(pentafluoroethyl)pyridine **134** in perfluoro-n-pentane with light of $\lambda >$



SCHEME 41



SCHEME 42

270 nm (Scheme 41) gave the 1,4-bonded Dewar isomer **135** in 95% yield. Irradiation with light of $\lambda >$ 220 nm led to the formation of the azaprismane **136**, pentakis(pentafluoroethyl)-1-azatetracyclo[2,2,0,0,$^{2}0^{3,5}$]hexane in 91% yield, apparently by way of the Dewar-isomer **135**. Both isomers are thermally quite stable with boiling points of 176°C and 184°C, respectively. Indeed, **135** was reported to have a half-life, $t_{1/2}$ = 104 h at 170°C.[52,53]

The perfluoroalkyl-substituted pyridine **137** (Scheme 42) contains four different ring labels, provided nitrogen is included. Irradiation of this compound at 254 nm resulted in the formation of a small yield of the 1,4-bonded Dewar-pyridine **138** and larger yields of the azaprismane derivatives **139** and **140**, which were thermally converted back to **137** or to pyridines **141** and **142**, respectively. The conversion of **137** $\rightarrow$ **138** $\rightarrow$ **139** is straightforward; the formation of **140** from **137** requires rearrangement. The pathway suggested, as shown in Scheme 43, involves initial formation of the 2,5-bonded Dewar-pyridine **143**, which isomerizes to the 1,4-bonded isomer **144** via a 1,3-shift. Ring closure then leads to the observed azaprismane **140**.[54,55]

It is interesting to note that these conversions indicate a strong preference for formation of the 1,4-bonded Dewar-pyridine isomer despite the prediction that the 2,5-isomer is the more stable isomer. The conversion of pyridine **145** (Scheme 44) to the 1,4-bonded Dewar-pyridine **146** is another example of this preference.[56]

When pyridine derivatives **147**, **148**, and **149** (Scheme 45) were irradiated at 254 nm using a slow transference technique, however, the 2,5-bonded Dewar-pyridines were the major or only valence isomers formed.[57] All of these Dewar-pyridine isomers rearrange at 160°C to the corresponding pyridine. Preference for 2,5-bonding was also observed in the photoisomerizations of tri-*t*-butylpyridines **155**, **156**, and **157** to the Dewar-pyridine **158**, **159**, and **160** shown in Scheme 46. As expected, preference is for the 2,5-bonded Dewar isomers, in which steric interference of the three adjacent t-butyl groups is minimized.

97.4 Pyridinium Cation Photochemistry

Some years ago it was shown that *N*-methlypyridinium chloride **161** undergoes photohydration to yield 6-methylazabicyclo[3.1.0]hex-3-en-2-0l **162** (Scheme 47). This product appeared to result from formation and hydration of an azabicyclohexenyl cation.

Labeling experiments, however, revealed that, in some cases, 1,2-shifts of nitrogen precede nucleophilic capture of the bicyclic cation. These shifts are consistent with formation and statistical opening of a 1-methylazoniabenzvalene **163**, resulting in the formation of unrearranged and rearranged azabicyclohexenyl cations **163a** and **163b**, respectively, which are both captured by water.[58]

Recent experimental and theoretical studies indicate that 2,6-bridging is the primary photochemical event and that azabicyclohexenyl cation **163b** can be captured by solvent or be converted to the azoniabenzvalene cation **163**. In addition to opening to **163b** as previously suggested, it also appears that **163** can be intercepted directly by nucleophilic attack at its allylic bridgehead positions.[59]

2,6-Bridging, which must arise via the π,π^* state of the pyridinium ring, is quite different from Dewar-pyridine formation observed upon irradiation of neutral pyridine, in which the lower-energy n,π^* state is also accessible. Indeed, transient absorption spectroscopy following pulsed excitation of the pyridinium cation in acetonitrile revealed that the slower decay component, associated with decay of the n,π^* state is totally missing while the first component due to motion along the π,π^* reaction pathway remains practically unchanged.[33] Taken together, these results suggest that the $S_2(\pi,\pi^*)$ state of pyridine leads to the 2,6-bridged isomer while the $S_1(n,\pi^*)$ state or some state derived from it, gives rise to the Dewar-valence isomer. It is interesting to note that in the case of benzene, Dewar-benzene formation requires excitation to a state of higher energy (i.e., $S_2(\pi,\pi^*)$,[60] while in the case of pyridine and its dimethyl derivatives, Dewar formation is enhanced by population of an excited state that is of lower energy than the first (π,π^*) state.[47]

In addition to the mechanistic interest of the photoreactions of pyridinium cations, the bicyclic products have several interesting features. Both the *N*-alkyl group and OH group adopt the *exo* orientation with respect to the bicyclic skeleton. Furthermore, the photochemical step fixes the relative configuration of the three new stereogenic carbon atoms. It is now recognized that photohydration of *N*-substituted pyridinium cations provides a powerful approach to a variety of synthetically useful materials.[61–65]

Photochemistry of Thiazoles, Isothiazoles, and 1,2,4-Thiadiazoles

James W. Pavlik
Worcester Polytechnic Institute

98.1 Introduction and Historical Review

The photochemistry of five-membered heteroaromatic compounds containing two heteroatoms has been of interest[1] since the first report that *N*-methylpyrazole **1** (Scheme 1) undergoes photoconversion to *N*-methylimidazole **2**.[2] Subsequent mechanistic studies revealed that this formally simple isomerization is mechanistically quite complex,[3–8] involving competition between the two pathways shown in Scheme 2. These include the electrocyclic ring closure–heteroatom migration pathway (A) that leads to imidazole **2a**, with interchange of the N2 and C4 ring atoms, and **2b**, with interchange of both N2–C3 and C4–C5. Alternatively, photocleavage of the N1–N2 bond initiates a second primary pathway (B) that leads to imidazole **2c** with interchange of the N2 and C3 atoms of the pyrazole ring. This pathway, which is enhanced by substitution at C4 of the pyrazole ring, is known to involve enaminonitrile **3** and enaminoisonitrile **4** intermediates.

The photoisomerization of isothiazole **5** to thiazole **6** (Scheme 3) was the first reported phototransposition in the isothiazole-thiazole heterocyclic system.[9] Later work published during the period 1971 to 1978 by Lablache-Combier and co-workers,[10] by Vernin and colleagues,[11–17] and by Maeda and Kojima[18–21] also showed that methylisothiazoles phototranspose to methylthiazoles and that phenyl-substituted isothiazoles and thiazoles also undergo phototransposition reactions. A surprising finding, however, was that phenylisothiazoles were not observed to react via the N2–C3 interchange pathway, an important pathway in pyrazole photochemistry. Furthermore, a common conclusion of these studies was that these photoisomerizations proceed by way of tricyclic zwitterionic intermediates, which had no counterparts in pyrazole photochemistry.

98.2 Mechanistic Studies

Methylisothiazoles and Methylthiazoles

Reinvestigation showed that methylisothiazoles **7**, **8**, and **9** (Table 98.1) undergo phototransposition in ethanol solvent to yield methylthiazoles **10, 11,** and **12** in the yields shown in Scheme 4.[22] Thus, although 5-methylisothiazole had been previously reported to transpose to 5-methylthiazole **12**, 3-methylisothiazole

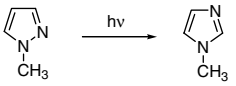
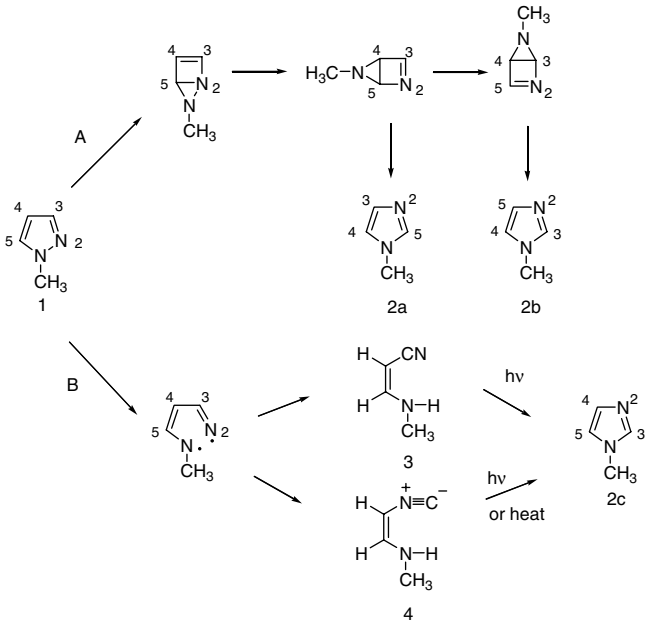
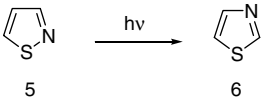


SCHEME 1



SCHEME 2



SCHEME 3

7, and 4-methylthiazole **2**,[10] the latter two products could not be detected in the reaction mixture. All of the products formed (Scheme 4) can be viewed as the result of N2–C3 interchange reactions. This indicates that the methylisothiazole-to-methylthiazole transposition is mechanistically analogous to the N2–C3 interchange reaction observed for pyrazole-to-imidazole photoisomerization. Accordingly, it is not necessary to invoke the intermediacy of tricyclic zwitterions as intermediates in these reactions.[22]

Although methylthiazoles do not undergo phototransposition in a variety of neutral solvents, methylthiazolium cations **10H**$^+$ through **12H**$^+$, formed by dissolving methyl-thiazoles **10** through **12** in trifluoroacetic acid (TFA), do undergo phototransposition (Scheme 5) to methylisothiazolium ions **9H**$^+$, **7H**$^+$, and **8H**$^+$, respectively. These N2–C4 interchange reactions are consistent with the electrocyclic ring closure–heteroatom migration mechanism (Scheme 6) in which the heteroatom migrates regiospecifically toward the positively charged azetine nitrogen. This regiospecificity is in contrast to that observed in the neutral 1-methylimidazoles, in which the heteroatom only migrates away from the azetine ring nitrogen to give only imidazole-to-imidazole transpositions.

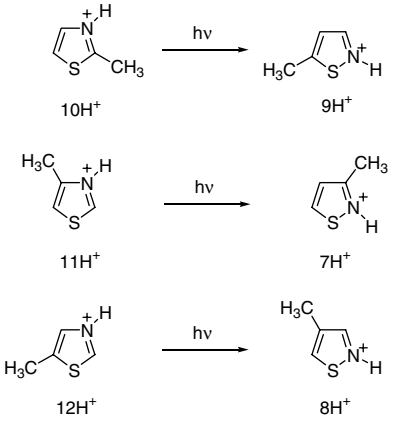
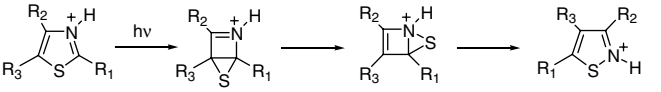
Phenylisothiazoles and Phenylthiazoles

Interconversions in Benzene Solution

Vernin and colleagues conducted extensive studies of the phototransposition chemistry of phenylisothiazoles **13**, **14**, and **15** and phenylthiazoles **16**, **17**, and **18** in benzene solution (see also Table 98.2).[12–17]



SCHEME 5



SCHEME 6

From these studies, they concluded that although most of the products observed could be explained by the electrocyclic ring closure–heteroatom migration mechanism, the apparent conversion of 5-phenylthiazole **18** to 5-phenylisothiazole **15** and 3-phenylisothiazole **13** could not occur by this mechanistic pathway. Accordingly, Vernin et al. concluded that one mechanistic pathway could not account for the formation of all products and suggested that phenylisothiazoles **13**, **14**, and **15** and phenylthiazoles **16**, **17**, and **18** react by the electrocyclic ring closure–heteroatom migration mechanism and by the mechanism postulated by Kellog[23] to account for the interchange of any two ring atoms in the 5-membered ring.

Later work, however, showed that 5-phenylthiazole **18** transposes to 4-phenylisothiazole **14** but that 5-phenylisothiazole **15** and 3-phenylisothiazole **13** are not formed in this reaction. As a consequence, it is not necessary to invoke the Kellogg mechanism to explain the formation of any products in the photoreactions of phenylthiazoles or phenylisothiazoles.[24]

According to the observed photochemical products and the results of deuterium labeling studies, the six isomeric phenylisothiazoles **13**, **14**, and **15** and phenylthiazoles **16**, **17**, and **18** can be organized into a tetrad of four photochemically interconverting isomers and a dyad in which 5-phenylthiazole **18** phototransposes to 4-phenylisothiazole **14** (Scheme 7), the only isomer that did not yield a transposition product upon irradiation in benzene solution. In addition to transposing to members of the tetrad, the transposition of 5-phenylisothiazole **15** to 5-phenylthiazole **18**, the first member of the dyad, in less than 1% yield, was the only observed conversion between the tetrad and dyad. This conversion was assumed to occur via the N2–C3 interchange reaction pathway.[24]

The photoisomerizations within the tetrad are consistent with the electrocyclic ring closure–heteroatom migration mechanistic pathway shown in Scheme 8. According to this mechanism, photochemical excitation of any member of the tetrad is predicted to result in electrocyclic ring closure, leading to the formation of azathiabicyclo[2.1.0] pentene intermediates. The four bicyclic intermediates, and hence the four members of the tetrad, are interconvertible via 1,3-sigmatropic shifts of sulfur around the four sides of the azetine ring. Thus, sulfur migration followed by rearomatization allows sulfur insertion into the four different sites in the carbon–nitrogen sequence.

TABLE 98.2 UV Absorption Maxima for Phenylisothiazoles and Phenylthiazoles

Compound	λ max (nm)	ε max	Solvent

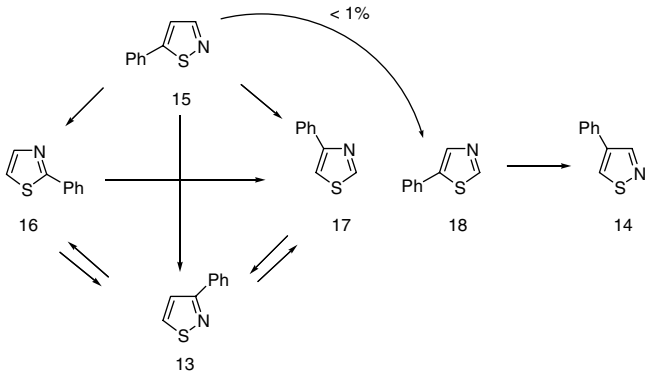
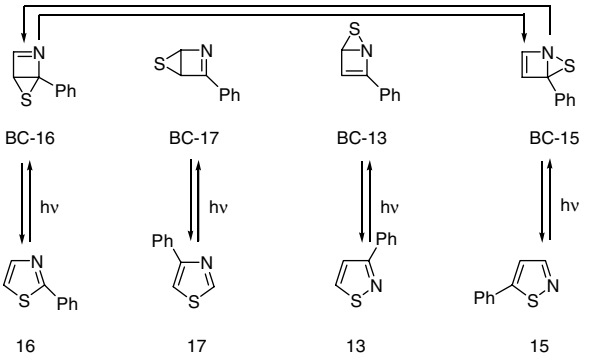
 18	274	13,309	cyclohexane

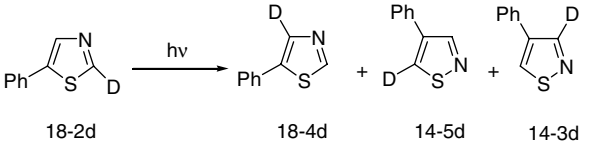


SCHEME 7

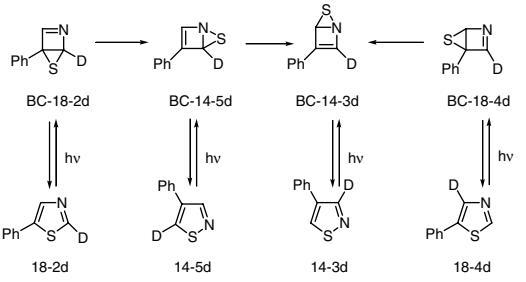
Insertion of sulfur between ring positions C1 and C4, or betweem C1 and C2 of the 3-phenylazetine ring leads to the same compound, 5-phenylthiazole **18**. Similarly, insertion of a sulfur atom between N3 and C4, or between N3 and C2, leads to 4-phenylisothiazole **14**. Accordingly, because of the symmetry of the 3-phenylazetine ring, only a dyad results. This symmetry is removed, however, in the case of



SCHEME 8



SCHEME 9

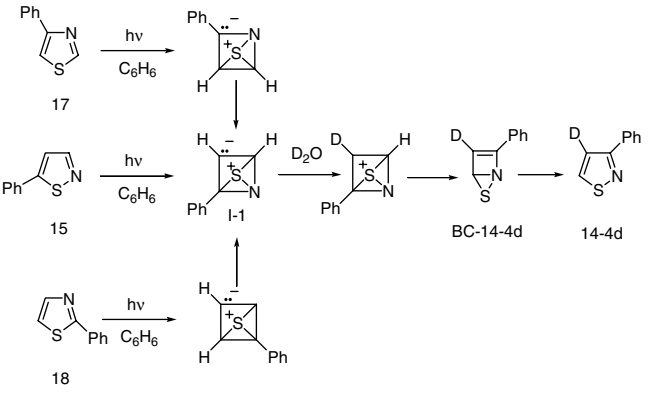


SCHEME 10

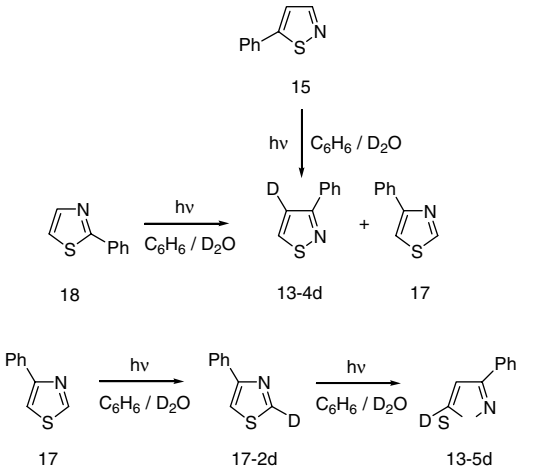
2-deuterio-5-phenylthiazole **18-2d**. Hence, deuterium labeling expands the dyad into a tetrad. As expected, irradiation of 2-deuterio-5-phenylthiazole **18-2d** resulted in the formation of three isomeric products (i.e., 4-deuterio-5-phenylthiazole **18-4d**, 5-deuterio-4-phenylisothiazole **14-5d,** and 3-deuterio-4-phenylisothiazole **14-3d** (Scheme 9). These deuterium-labeling results are entirely consistent with the electrocyclic ring closure-heteroatom migration mechanism shown in Scheme 10.

Photodeuteration Studies

Maeda and Kojima studied the photochemistry of phenylisothiazoles **13**, **14**, and **15** and phenylthiazoles **16**, **17**, and **18** in benzene or ether saturated with D_2O.[18–21] They reported that 2-phenylthiazole **16**, 4-phenylthiazole **17**, and 5-phenylisothiazole **15** each phototranspose under these conditions to 3-phenylisothiazole **13** with deuterium incorporation at ring position 4. Irradiation of 2-phenylthiazole **16** also led to the formation of 4-phenylthiazole **17** but without deuterium incorporation. Finally, they reported that none of the reactants undergo photodeuteration prior to transposition.



SCHEME 11

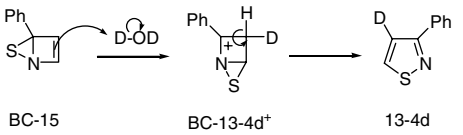


SCHEME 12

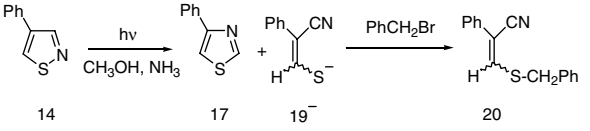
Maeda and Kojima argued that deuterium incorporation demands a carbanion intermediate. They, therefore, rejected the electrocyclic ring closure–heteroatom migration mechanism and concluded that all three reactants isomerize to 3-phenylisothiazole **13** via a common tricyclic zwitterionic intermediate I-1 (Scheme 11) that reacts with D_2O with deuterium incorporation. Thus, according to these workers, the carbanion intermediate responsible for deuterium incorporation is on the reaction pathway leading from 4-phenylthiazole **17**, 5-phenylisothiazole **15**, and 2-phenylthiazole **18** to 3-phenylisothiazole **14**.

Later work,[24] shown in Scheme 12, confirmed that 3-phenylisothiazole **13** is formed with deuterium incorporation at C4 upon irradiation of either 2-phenylthiazole **18** or 5-phenylisothiazole **15** in benzene/D_2O but revealed that **13** is formed with approximately twice the extent of deuterium incorporation from the latter reactant. Furthermore, it was also shown that 4-phenylthiazole **17** undergoes photodeuteration at C_2 when irradiated in benzene/D_2O more rapidly than it transposes to 3-phenylisothiazole **13**. Upon further irradiation, the initially formed 2-deuterio-4-phenylthiazole **17-2** transposes to 5-deuterio-3-phenyl-isothiazole **13-5d** without additional incorporation of deuterium.

These results show that, within the tetrad (Scheme 8), the intermediate that incorporates deuterium is on the reaction pathway leading from 2-phenylthiazole **16** and 5-phenylthiazole **15** to 3-phenylisothiazole **13** but is not on the pathway leading from 4-phenylthiazole **17** to 3-phenylisothiazole **13.** Accordingly,



SCHEME 13



SCHEME 14

although Maeda and Kojima concluded that the photodeuteration reactions demanded the intermediacy of tricyclic zwitterionic intermediates, these results actually preclude their involvement in the phototransposition pathway.

These results can be rationalized by the electrocyclic ring closure–heteroatom migration mechanism (Scheme 8) by assuming that **BC-15** (Scheme 13), formed by electrocyclic ring closure of 5-phenylisothiazole **15,** undergoes deuteration with simultaneous sulfur migration to yield **BC-13–4d**$^+$. This accounts for the greater deuterium incorporation when 3-phenylisothiazole **13** is formed from 5-phenylisothiazole **15** than from 2-phenylthiazole **16**. From 5-phenylisothiazole **15**, all molecules of 3-phenylisothiazole **13** must arise via **BC-15**; (i.e., **15** + hν → **BC-15** → **BC-13** → **13** with deuterium incorporation. From 2-phenylthiazole **16**, however, 3-phenylisothiazole **13** may be formed by the pathway **16** + hυ → **BC-16** → **BC-15** → **BC-13** → **13** with deuterium incorporation or by the pathway **16** + hυ → **BC-16** → **BC-17** → **BC-13** → **13** without passing through **BC-15** and, hence, without deuterium incorporation.

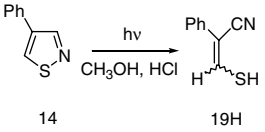
These results reveal that both isothiazoles and pyrazoles phototranspose by the electrocyclic ring closure–heteroatom migration mechanism and that tricyclic zwitterionic intermediates, once thought to be important in thiazole and isothiazole photochemistry, need not be invoked.

The N2-C3 Interchange Pathway: The Effect of Added Base

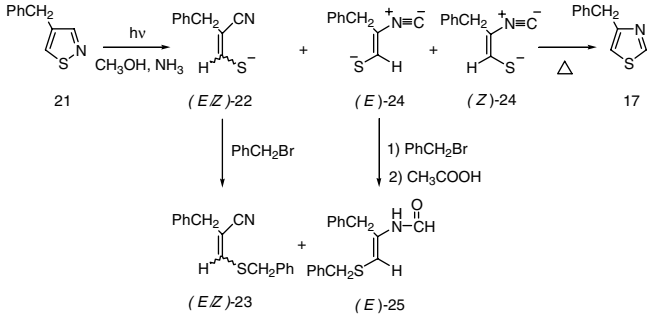
A significant difference between the photochemistry of pyrazoles and the photoreactions of phenylisothiazoles in benzene solutions is the almost complete absence of transposition of the latter via the N2-C3 interchange reaction pathway. Indeed, although 4-phenylisothiazole **14** is expected to be the most reactive isomer by this pathway, it is the only isomer that was not observed to yield a phototransposition product upon irradiation in benzene solution. This is not due to the low reactivity of the isomer because the quantum yield for disappearance of this compound ($\Phi = 0.41$) indicates that it is the most reactive of the phenylisothiazole isomers.

In contrast to the reactivity in benzene solution, when 4-phenylisothiazole **14** was irradiated in methanol containing a small quantity of base such as aqueous NH_3 or triethylamine (TEA),[24] the N2-C3 interchange product, 4-phenylthiazole **17**, was obtained in 90% yield (Scheme 14), with a small amount of the deprotonated photocleavage product **19**$^-$ that was trapped by reaction with benzylbromide to yield the (*E/Z*)-benzylthioether **20**. Conversion of **14-5d** to **17-5d** under these conditions confirmed that the transposition occurs via the N2-C3 interchange pathway. Although phototransposition is enhanced by the addition of base to the reaction medium, if the reaction is carried out in methanol containing HCl, phototransposition is completely quenched, and the only product observed is a large yield of the photocleavage product **19H** (Scheme 15).

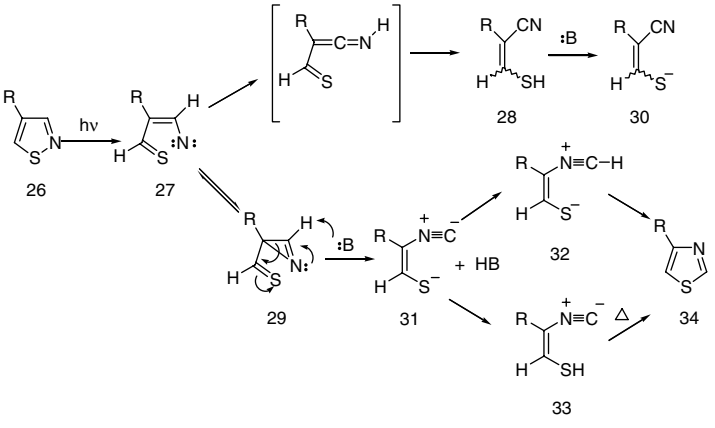
Convincing evidence for the intermediacy of an isocyanide cleavage product in the N2-C3 interchange transposition was obtained by studying the photochemistry of 4-benzylisothiazole **21**



SCHEME 15



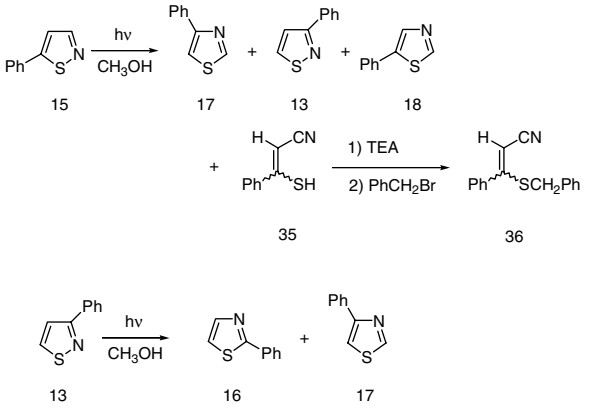
SCHEME 16



SCHEME 17

(Scheme 16). Irradiation in methanol-NH_3 led to the formation of 4-benzylthiazole **17**, the N2-C3 interchange product, and to the nitrile photocleavage product **22**, which was trapped as the benzylthioether **23**, and to the formation of the (*E*) isocyanide photocleavage product (*E*)-**24**, which was trapped by reaction with benzylbromide followed by hydrolysis to yield (*E*)-formamide (*E*)-**25** and the (*Z*)-isocyanide photocleavage product (*Z*)-**24**, which was thermally converted to the observed phototransposition product **17**.

Mechanistically, it was suggested that the N2-C3 interchange reaction was initiated by photocleavage of the S–N bond in **26,** resulting (Scheme 17) in the formation of β-thioformylvinyl nitrene **27** that is expected to rearrange to the cyanothiol photocleavage product **28** and also to be in equilibrium with an undetected thioformylazirine **29**. In the absence of an external base, β-thioformylvinyl nitrene **27** is thus converted totally to cyanothiol **28**. As a result, upon irradiation in benzene or methanol containing HCl, 4-substituted isothiazoles only undergo photocleavage to cyanothiols. In the presence of NH_3 or TEA,



SCHEME 18

the base converts cyanothiol **28** to cyanosulfide **30** and, more importantly, the base can also deprotonate azirine **29**, resulting in its conversion to isocyanide **31**.

The fate of the isocyanide was suggested to depend on the nature of the substituent originally at C4 of the isothiazole ring. If the substituent is aromatic, the isocyanide is reprotonated at the isocyanide carbon to yield **32**, which spontaneously cyclizes to the 4-subsituted thiazole **34**, the observed N2-C3 interchange transposition product. If the substituent is not aromatic, **31** is reprotonated at sulfur to provide **33**, which has a higher energy barrier to cyclization. In these cases, the isocyanosulfides can be observed spectroscopically and can be trapped as their *N*-formylaminobenzyl thioether derivatives.

Although the photochemistry of 4-substituted isothiazoles is dominated by reactions initiated by cleavage of the S–N bond, as shown in Scheme 17, 5-phenyl- and 3-phenylisothiazoles **15** and **13**, react by competing photochemical pathways.[26] As shown in Scheme 18, 5-phenylisothiazole **15** undergoes phototransposition in methanol by the electrocyclic ring closure–heteroatom migration pathway to yield 4-phenylthiazole **17** in 6% yield and 3-phenylisothiazole **13** in 2% yield, and by the N2-C3 interchange pathway to yield 5-phenylthiazole **18** in 23%. The yield of **18**, the N2-C3 interchange product, was increased to 34% upon addition of TEA to the reaction medium, and to 42% when the irradiation of **15** was carried out in the more polar solvent, 2,2,2,-trifluoroethanol containing TEA. In addition to phototransposition, 5-phenylisothiazole **15** was also reported to undergo photocleavage to cyanothiol **35** that was trapped as its benzylthioether **36**. 3-Phenylisothiazole **13** also phototransposes by both reaction pathways; but without hydrogen at C3, the N2-C3 interchange pathway is not enhanced by the addition of a base.

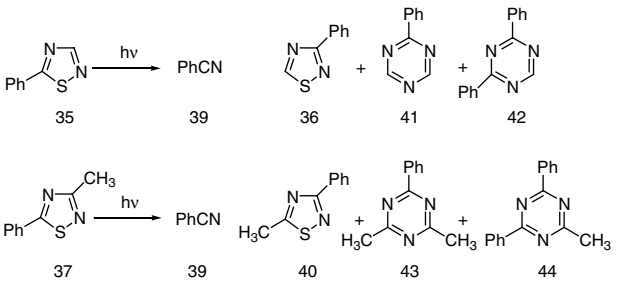
These results indicate that the photochemistry of pyrazoles and isothiazoles can be understood in terms of one general mechanistic scheme involving competition between the electrocyclic ring closure–heteroatom migration and the N2-C3 interchange pathways. Although in the case of isothiazoles the addition of a base substantially alters the competition between these pathways, similar effects are not observed in pyrazole photochemistry. Presumably this is because pyrazoles and imidazoles are already sufficiently basic to deprotonate the azirine as shown in Scheme 17.

Phenyl-1,2,4-Thiadiazoles

Phenyl-substituted 1,2,4-thiadiazoles (see Table 98.3) undergo a variety of photoreactions, including photofragmentation, phototransposition, and a unique photo-ring expansion reaction.[26] As shown in Scheme 19, irradiation of 5-phenyl-1,2,4-thiadiazole **35** in acetonitrile solvent with light of Î > 290 nm results in the formation of benzonitrile **39**, the photofragmentation product, 3-phenyl-1,2,4-thiadiazole **36**, the phototransposition product, and phenyl-1,3,5-triazine **41** and diphenyl-1,3,5-triazine **42**, the two photo-ring expansion products. 3-Methyl-5-phenyl-1,2,4-thiadiazole **37** reacted similarly to yield

TABLE 98.3 UV Absorption Maxima for Phenyl Substituted 1,2,4-Thiadiazoles

Compound	λ max (nm)	ε max	Solvent
 35	273 273	13,880 13,870	cyclohexane acetonitrile
 36	264	10,200	cyclohexane
 37	278	14,100	acetonitrile
 38	255	6190	cyclohexane

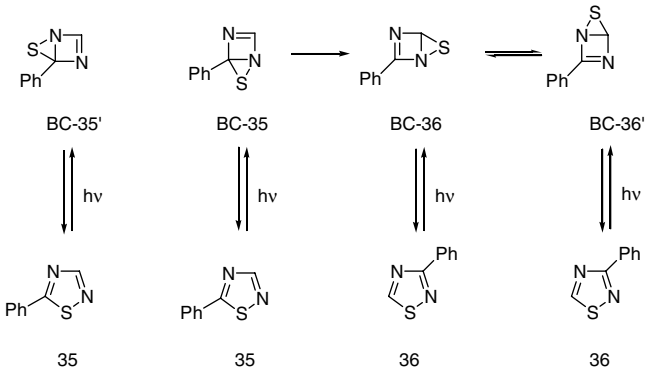


SCHEME 19

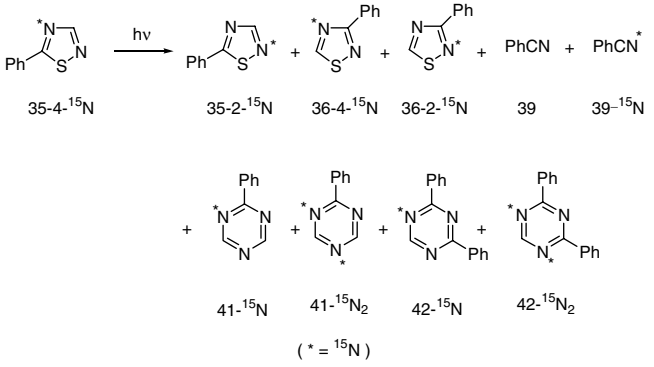
benzonitrile **39**, 5-methyl-3-phenyl-1,2,4-thiadiazole **40**, dimethylphenyl-1,3,5-triazine **43**, and methyldiphenyl-1,3,5-triazine **44**.

The phototransposition of **35** to **36** (and of **37** to **40**) can be explained by the electrocyclic ring closure-heteroatom migration mechanism shown in Scheme 20. Thus, photoexcitation of **35** is predicted to result in electrocyclic ring closure resulting in the formation of bicyclic species **BC-35**. 3-Phenyl-1,2,4-thiadiazole **36** can be formed by one or two sigmatropic shifts of sulfur, followed by aromatization. Reaction in the opposite direction would lead back to **35** via the intermediacy of **BC-35′**. Experiments using ^{15}N-labeling confirmed that sulfur can undergo sigmatropic shifts around all four sides of the diazetine ring in this bicyclic species. Thus (Scheme 21), irradiation of 5-phenyl-1,2,4-thiadiazole-4-^{15}N (**35-4-^{15}N**) led to the formation of 5-phenyl-1,2,4-thiadiazole-2-^{15}N (**35-2-^{15}N**), 3-phenyl-1,2,4-thiadiazole-4-^{15}N (**36-4-^{15}N**), and 3-phenyl-1,2,4-thiadiazole-2-^{15}N (**36-2-^{15}N**).

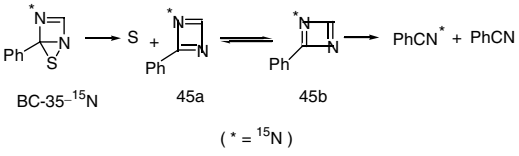
Bicyclic species **BC-35** was also suggested to undergo sulfur elimination. As shown in Scheme 22, sulfur elimination from ^{15}N-labeled **BC-35** would provide an equilibrium mixture of **45a** and **45b,** which could undergo complete fragmentation to a 1:1 mixture of benzonitrile-^{14}N (**39-^{14}N**) and benzonitrile-^{15}N (**39-^{15}N**). Alternatively, it was also suggested that **45a** and **45b** could undergo [4 + 2]-cycloaddition



SCHEME 20



SCHEME 21



SCHEME 22

(Scheme 23), leading to unstable tricyclic adducts **46** and **47**, the suggested precursors of the 1,3,5-triazine ring expansion products. The tricyclic adducts **46** and **47** can eliminate benzonitrile-^{15}N (**39-^{14}N**), leading to a 1:1 mixture of mono- and di-^{15}N-labeled phenyl-1,3,5-triazine **41-^{15}N** and **42-^{15}N$_2$**. These predicted 1:1 ratios are very close to the experimentally determined ratios.[26]

3-Phenyl-1,2,4-thiadiazole **37** was found to react exclusively by the photofragmentation pathway, leading to benzonitrile. Experiments using ^{15}N-labeling showed that irradiation of 3-phenyl-1,2,4-thiadiazole-2-^{15}N (**37-2-^{15}N**) results in the formation of only benzonitrile-^{15}N **39-^{15}N** without transposition to 3-phenyl-1,2,4-thiadiazole-4-^{15}N (**37-4-^{15}N**). This led to the conclusion that photochemically excited 3-phenyl-1,2,4-thiadiazole **39** does not undergo electrocyclic ring closure but reacts only by the more efficient photofragmentation pathway.

Photochemistry of *N*-Oxides

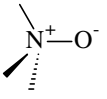
Angelo Albini
University of Pavia

Maurizio Fagnoni
University of Pavia

99.1 Introduction

The large class of *N*-oxides includes the nitrogen-containing compounds formally obtained by adding an oxygen atom forming a covalent bond with the nitrogen lone pair. Since the electron pair is donated by the nitrogen atom, charges are indicated in the *N*-oxide functionality, N^+ -O^- (or, in the older literature, the donative bond is indicated by an arrow directed toward the electron-receiving oxygen, N→O), although this does not necessarily means that *N*-oxides have a zwitterionic character.[1]

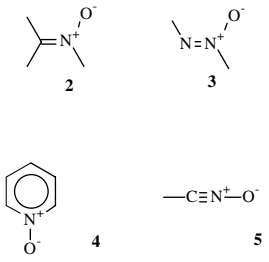
Indeed, (formal) *N*-oxidation does not affect different classes of nitrogen-containing compounds in the same way, and it is important to distinguish different classes of such compounds. This can be conveniently done by making reference to the hybridization of the nitrogen atom before oxidation, although some confusion in the nomenclature can be found in the literature and leads to the following classification. Amines (nitrogen sp^3-hybridized) form amine *N*-oxides (only in the case of the trialkyl derivatives, see formula **1** in Equation 99.1).



1 (99.1)

Imines, azo derivatives, and heteroaromatic compounds (nitrogen sp^2–hybridized) form nitrones (**2**), azoxy derivatives (**3**), and heteroaromatic *N*-oxides (**4**), respectively. Nitriles (nitrogen *sp*-hybridized) form nitrile *N*-oxides (**5**, Equation 99.2).

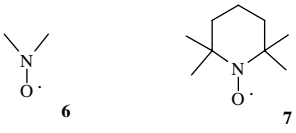
0-8493-1348-1/04/$0.00+$1.50



2 **3** **4** **5** (99.2)

These compounds differ greatly in their chemical and physical properties, including, as discussed below, the structure of their electronic excited states, but interestingly share the characteristic of exhibiting a photochemistry different from that of the corresponding non-oxidized derivatives. Such photochemistry is often, although by no means necessarily, more efficient than that of the non-oxidized compounds and usually consists of the cleavage or some transformation of the *N*-oxide function itself, involving either the N^+-O^- bond or a C–N bond α to the *N*-oxide group or both of them. Indeed, the *N*-oxide function is one of the few to which monomolecular photochemistry is quite generally associated, making this class of compounds one of those for which photoreactivity was noticed early (more than a century ago)[2] and to which a large and continuing interest has been devoted.[1,3-6]

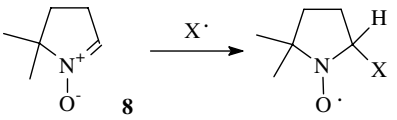
All of the compounds considered above are obviously closed-shell species, as is every organic molecule. It is important to distinguish such compounds, to which the name of *N*-oxide applies, from *N*-oxyl radicals (or "nitroxides", **6**, see Equation 99.3), that is, the products formally resulting from the homolysis of the OH bond in dialkylhydroxylamines.



6 **7** (99.3)

Although there is some confusion in the literature about the nomenclature, these are odd-electron species unrelated to the above *N*-oxides. Some of these radicals are endowed with an uncommon persistence, such as shown in the indefinite stability of many 2,2,6,6-tetramethylpiperidine *N*-oxyl (TEMPO, **7**) derivatives.[7,8] This has led to their widespread use as radical traps, particularly for carbon-centered radicals generated in thermal and photochemical reactions.[9,10] *N*-oxyl radicals and their photochemical reactions are not discussed in this chapter.

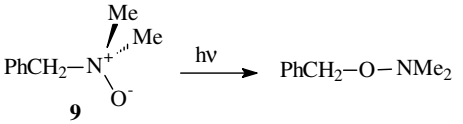
Likewise, photochemical reactions of *N*-oxides are considered in the following, not the use of *N*-oxides in photochemistry. Therefore, the use of nitrones, in particular of cyclic polysubstituted cyclic nitrones such as 5,5-dimethylpyrroline *N*-oxide (DMPO, **8**, see Equation 99.4), as radical traps for oxygen-centered radicals, in particular the hydroxyl radical or the superoxide anion,[11-13] is not discussed here. In fact, these nitrones are used for determining the mechanism of photoinduced oxidation reactions, for example, in lipid photooxidation[14] or in oxidative DNA damage[15,16] but are not undergoing a photochemical reaction under such circumstances.



8 (99.4)

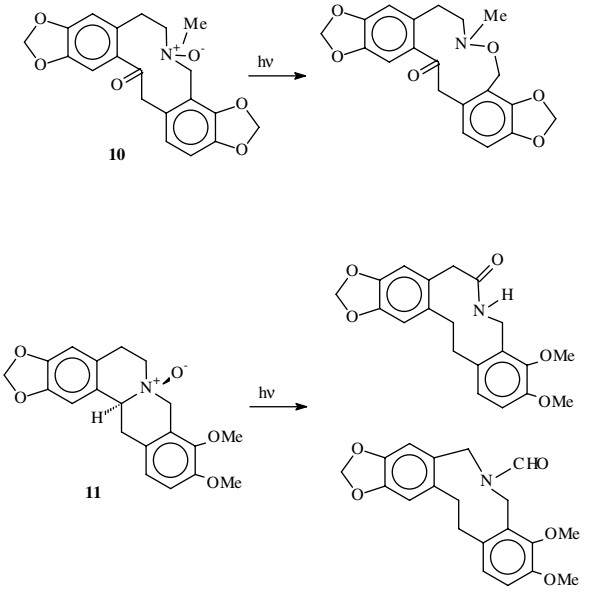
99.2 Tertiary Amine *N*-Oxides

Aliphatic tertiary amines easily give the corresponding *N*-oxides. These derivatives, just like aliphatic amines, do not absorb above 200 nm and their photochemical properties have not been investigated, at least in solution. When a different light-absorbing moiety is present in the molecule, a reaction can take place at the *N*-oxide function, even if this is not directly involved in light absorption. A typical case is that of benzyldimethylamine *N*-oxide (**9**, Equation 99.5), which has been found to undergo the Meisenheimer rearrangement to the corresponding *O*-benzylhydroxylamine, not only thermally but also photochemically, a result that has been taken as support of the radical mechanism of the rearrangement.[17]



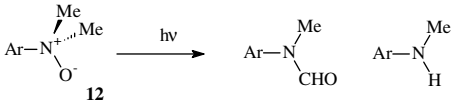
9 (99.5)

Some alkaloid *N*-oxides have been found to react photochemically, either with rearrangement to hydroxylamines, as with protopine (**10**) and allocryptopine *N*-oxides,[18] or with conversion to amides, as with canadine (**11**) and xylopine *N*-oxides (see Equation 99.6).[19]



(99.6)

N-Oxidation has an important effect on the absorption spectrum of *N,N*-dialkylanilines (e.g., **12**, see Equation 99.7). The substituent is no longer an electron-donating group and both a hypso- and a hypochromic shift take place.[20] In this case, irradiation causes hydrogen transfer to the solvent, as well as attack on the side chain leading to amides and dealkylated anilines.[21]



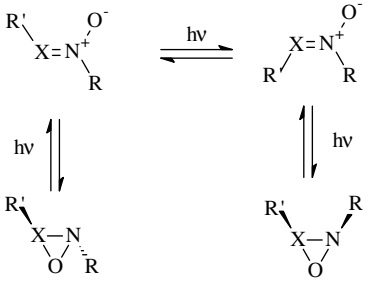
12 (99.7)

This has been observed with dialkylaminoazobenzenes *N*-oxides, that, when irradiated in 11*M* sulfuric acid, cyclize to the corresponding benzo[*c*]cinnoline, the *N*-oxide group in this case serving as an oxidant of the dihydrobenzophenanthrene intermediate.[22]

99.3 Nitrones and Azoxy Compounds

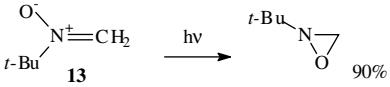
Different from the case of tetrahedral amine *N*-oxides, linking an oxygen atom to the sp^2-hybridized nitrogen, pertaining to the planar moiety of imines, azo compounds, and heterocycles completely changes the electronic structure with the introduction of a further conjugated *p* electron pair. In these compounds, the lowest-energy absorption band is thus a $\pi\pi^*$ transition with strong internal charge-transfer character. In general, this band is red shifted with respect to the corresponding imine, although it is not always distinguishable, particularly in compounds containing further conjugation. Due to the charge-transfer nature, the band is blue-shifted in polar and protic solvents.[23,24]

Two main classes of photoreactions have been observed with such compounds, *E,Z*-isomerization, ubiquitous with open-chain derivatives, rearrangement (typically cyclization) (see Equation 99.8); photocycloaddition occurs rarely. It has been demonstrated in some cases and is probably generally valid that *E,Z*-isomerization occurs via the triplet, cyclization via the singlet excited state.[25]



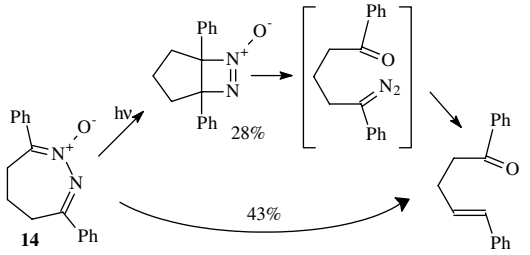
X = CR", N (99.8)

[π^4]-Electrocyclic ring closure would be the expected reaction for such derivatives. Indeed, both aliphatic[26] and aromatic nitrones[27-29] undergo cyclization to oxaziridines. The quantum yield is approximately 0.5.[30] This is, in fact, a useful entry for such three-membered heterocycles, provided that the short-wavelength component is removed from the irradiation source by filters, as the oxazirine is itself photolabile (see, for example, the aliphatic nitrone **13**, Equation 99.9).



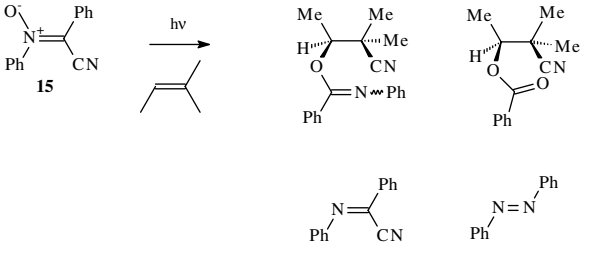
(99.9)

Starting from cyclic nitrones, bicyclic oxaziridines,[31,32] as well as spiro-oxaziridines[33,34] have been obtained. Some examples of stereospecific rearrangement have been reported,[31,35] although this is not always the case. The result may be altered both by photoisomerization of the nitrone (for open-chain derivatives)[27] and by isomerization of the oxaziridine,[26] the latter process occurring also via reversible photoisomerization to the nitrone.[36] Furthermore, an enantiomeric excess has been obtained upon photocyclization of some nitrones in chiral solvents at −78°C.[37] Likewise, irradiation of some azine *N*-oxides has been studied. As an example, cyclic azine *N*-oxide **14** undergoes firstly π^4 electrocyclic ring closure and the resulting diazetine *N*-oxide fragments, possibly via rearrangement to the oxaziaziridine and cleavage to a diazoketone (see Equation 99.10).[38]



(99.10)

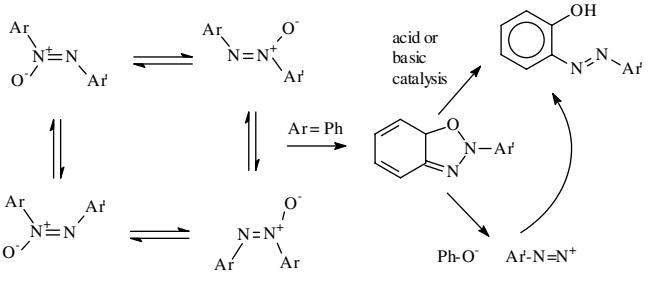
As mentioned, the oxaziridines are, in turn, photolabile and when products such as amides are obtained, these are often rationalized as being formed via such three-membered heterocycles, even if these are not directly observed. Such reactions may involve cleavage of the NO bond to give a biradical and in this connection it should be mentioned that addition of 2-methyl-2-butene to a diphenylcyanonitrone (**15**) has been found to occur through such a mechanism (see Equation 99.11).[39]



(99.11)

In a similar way, azoxy derivatives cyclize to oxadiaziridines (see Equation 99. 8, X = N). Here, however, the reaction is limited to aliphatic derivatives, both open chain[40,41] and cyclic,[42-44] even if the resulting fused oxadiaziridines may have limited stability. At any rate, cyclization is usually thermally and/or photochemically reversible and the transient formation of oxadiaziridines may be also involved when either *E,Z*- or positional isomerizations of the azoxy derivatives are the observed final result. Likewise, products from further photochemical rearrangement or fragmentation of oxadiaziridines may be obtained.

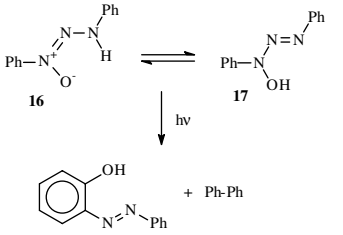
Diarylazoxy[45-49] as well as arylalkylazoxy[50] derivatives, on the other hand, undergo a different photorearrangement. In this case, 2-hydroxyazobenzenes are formed, a reaction that bears a loose likeness to the (thermal) Wallach rearrangement to 4-hydroxyazobenzenes (see Equation 99.12). The photorearrangement involves exclusively attack of the oxygen atom to the *ortho* position in the aromatic ring far from the *N*-oxide function (when such positions bear a substituent, the reaction fails) and occurs via an intermediate, apparently a dihydrobenzooxadiazole. This either reverts back to the azoxy compound, or gives the final hydroxyazobenzene, either via a hydrogen shift, subject to both acid and basic catalysis, or via a fragmentation-recombination mechanism where an aryldiazonium cation (which can be trapped) is formed.



(99.12)

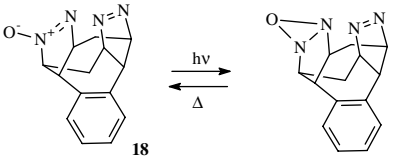
Due to the reversibility of the first step of the rearrangement, the overall yield of the hydroxyazo compound undergoes a marked solvent effect and, likewise, the proportion of the paths followed in the second part of rearrangement depend on solvent polarity. This rearrangement has also been observed upon irradiation in the solid state of a tetra-(*t*-butyl)-substituted azoxybenzene and apparently then mainly proceeds via a diazonium cation.[51] Substituents with a strong electron-withdrawing or electron-donating effect (e.g., 4-dimethylamino) slow the above reaction and a different process, positional isomerization reasonably via an oxadiaziridine, becomes more important. The latter process shows little solvent dependence.

1,3-Diaryltriazene 1-oxides (**16**, Equation 99.13; tautomeric with 3-hydroxytriazenes **17**) are photochemically cleaved, giving finally the products from fragment recombination, *viz.* biphenyls and azoxybenzenes, as well as the products from the secondary photolysis of the latter derivatives.[52]



(99.13)

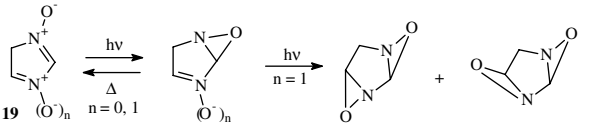
$[\pi^2+\pi^2]$-Cycloaddition would appear a further possibility for nitrones or azoxy derivatives, at least in suitable intramolecular models. However, methathesis and no cycloaddition was observed with proximate, *syn*-periplanar bis-diazene *N,N*-dioxides (in the mono *N*-oxides elimination predominates).[53-55] Interestingly, cyclization to an oxadiazirine occurred in preference to cycloaddition in other rigid systems possessing a geometry seemingly favorable to addition, such as azoxy **18** (see Equation 99.14).[56] Finally, nitrones can be prepared photochemically. Arylbenzyl nitrones have been prepared through the photosensitized (with cyanoanthracene or 10-methylacridinium perchlorate) oxidation of dibenzylhydroxylamines, the active species being the superoxide anion.[57,58] as well as by the photoreaction of nitro(hetero)aromatics with styrene.[59]



(99.14)

99.4 Five- and Seven-Membered Heterocyclic *N*-Oxides

The photochemistry of five- and seven-membered heterocyclic *N*-oxides is most often related to that observed with nitrones. Thus, rearrangement to bicyclic oxaziridines has been documented in a number of cases. Both with 2*H*- and with 4*H*-imidazole *N*-oxides, rearrangement to the corresponding oxaziridines has been reported.[60,61] The *N,N*-dioxide of the latter heterocycle (**19**, n = 1, see Equation 99.15) undergoes two consecutive photorearrangements to give the *cis*- and *trans*-isomers of the tricyclic derivative.

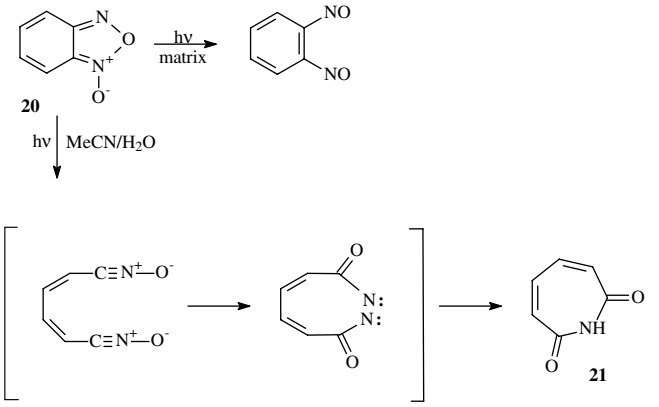


(99.15)

More often, products that can be envisioned as resulting from further reaction of oxaziridines are isolated. As an example, lactams are obtained from 1-alkyl-1,2,4-triazole 4-oxides,[62] 1-alkylbenzimidazole 3-oxides (in protic medium)[63] or 3*H*-indole 1-oxides.[64] Alternatively, ring-cleaved lactams are obtained from 1-alkylbenzimidazole 3-oxides in aprotic solvents,[63] and from 1*H*-tetraarylimidazole 3-oxides.[65]

With polyaza heterocycles, positional isomerism of the *N*-oxide function is often observed, as is the case with (benzo)thiadiazoles,[66,67] benzofuroxans,[68] and benzotriazoles.[69] There are indications that such reactions involve a ring-opening/ring-closure mechanism. In particular, with benzofuroxan (**20**, Equation

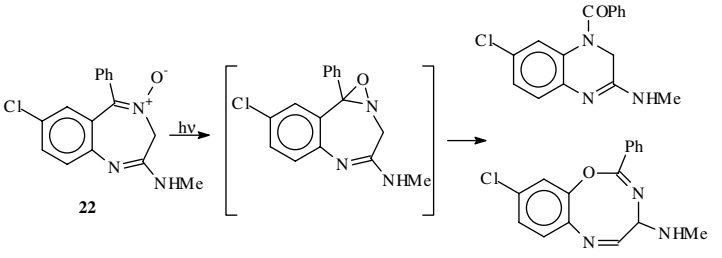
99.16), 1,2-dinitrosobenzene has been directly observed by irradiation in Ar or Xe matrices.[70,71] Noteworthy, photolysis of benzofuroxan in wet acetonitrile gives 1*H*-azepine-2,7-dione (**21**), a reaction that has been rationalized as involving cleavage to a bis-nitrile oxide.[72]



(99.16)

3,5-Diaryl-1,2,4-oxadiazole 4-oxides undergo photochemical cleavage to give, in addition to an arylnitrile, a nitrosocarbonyl intermediate that can be trapped by dienes[73] and 2,2-dimethyl-2*H*-benzimidazole 1,3-dioxide cleaves to *O*-(2-nitrosophenyl)acetone oxime.[74]

An example of the complex chemistry occurring upon irradiation of a seven-membered heterocycle is shown below for the case of the sedative chlordiazepoxide **22** (see Equation 99.17), where both ring contraction and expansion occur.[75]



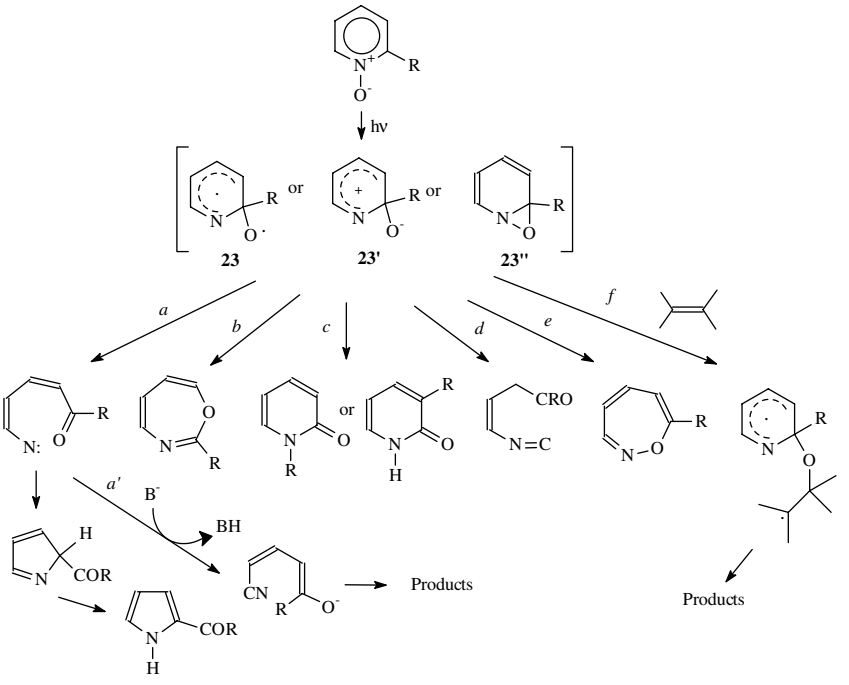
(99.17)

On the other hand, some photochemical syntheses of heterocyclic *N*-oxides exists, typical being the cyclization of *o*-nitrophenylazo dyes to give 2-aryl-2*H*-benzotriazoles under basic conditions.[76]

99.5 Photorearrangement of Six-Membered Heterocyclic *N*-Oxides

Six-membered heterocyclic *N*-oxides depart more strongly in their photochemical behavior from that observed with nitrones. Also in this case, the lowest excited singlet state is a $\pi\pi^*$ state with internal charge-transfer character from an essentially oxygen-centered *p* orbital to the ring.[77,78] With pyridine 1-oxide and other monocyclic *N*-oxides, the transition is clearly discernible as a weak band that shows a marked blue shift in polar and protic solvents. With azanaphthalene and azaanthracene *N*-oxide, the transition is strong, tends to become blurred with the following bands, and shows decreased solvatochromism. Azaanthracene *N*-oxides and derivatives containing further fused rings fluoresce and in general show photophysical properties increasingly similar to that of carbocyclic aromatics, while maintaining a photochemical reactivity centered on the *N*-oxide group. The quantum yield of reaction is largely dependent on structure and conditions, typically ranging between 0.05 and 0.5.[3] Two kinds of photoprocesses occur,

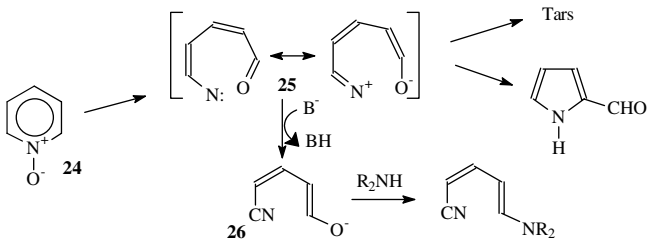
rearrangement (proceeding only from the singlet) and deoxygenation, which proceeds at least in some cases via the triplet. The latter reaction will be discussed in a following section in connection with the use of *N*-oxides as oxidizing species. The observed reactions are, in part, related to those occurring with nitrones, in the sense that most of the processes occurring can be envisaged as arising from further evolution of a primarily formed oxaziridine. However, the situation is profoundly different. With nitrones, oxaziridines have been actually isolated in a large number of cases and their further thermal or photochemical transformation has been demonstrated. With heterocyclic *N*-oxides, on the contrary, oxaziridines have never been isolated. The reactions are surely monophotonic and in most cases no intermediate is detected. Thus, although a high-quality computational study on the subject is still lacking, it appears that the oxaziridine structure (**23″** in Equation 99.18) corresponds to no minimum of the potential energy surface connecting the excited state to the final products, in all of which, however, the oxygen atom becomes bonded to the carbon atom in α (or to carbon atoms further away). Therefore, the rearrangement is expected to proceed over some biradical (**23**) or zwitterionic (**23′**) structure, which however represents no minimum. The main paths identified in simple *N*-oxides is indicated in Equation 99.18.



(99.18)

This includes cleavage of the CN bond (path *a*), insertion of the oxygen atom between C_α and C_β with expansion to an oxazepine ring (*b*), formation of a lactam (*c*), cleavage of the CC bond (path *d*), and insertion of the oxygen atom between the nitrogen atom and the vicinal carbon (path *e*, not observed with monocyclic *N*-oxides). Trapping reactions with evidence of the biradical or zwitterionic nature of the intermediate have been also obtained in some cases (see path *f*).

Irradiation of the parent of the series, pyridine 1-oxide (**24**, see Equation 99.19), gives only a tiny amount of an isolable product, 2-formylpyrrole, while intractable tars account for the major part of the converted reagent. Similar results are obtained with alkyl-substituted derivatives.[79,80] This has been attributed to the formation of nitrene **25** (compare path *a* in Equation 99.18), which readily polymerizes. In accord with this hypothesis, carrying out the irradiation in basic aqueous solution, the nitrene is deprotonated to give a conjugate anion (**26**), which can be detected by flash photolysis or trapped by amines to give an unsaturated aminonitrile (path *a′*).[81,82]

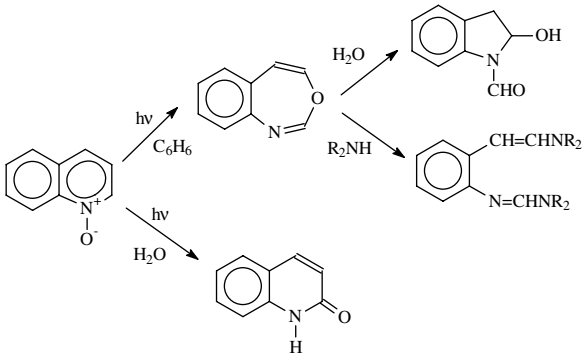


(99.19)

A different ring cleavage occurs with pentachloropyridine 1-oxides, which give pentachlorobutadienylisocyanate.[83] Rearranged heterocycles are obtained in medium to high yield from pyridine 1-oxide bearing conjugating substituents, such as cyano or phenyl. The main processes are ring contraction to 2-acylpyrroles and ring expansion to 1,3-oxazepines.[84,85] The latter products (≥80% with tetra- and pentaphenylpyridine 1-oxides) undergo thermal or acid-catalyzed rearrangement to 1-acylpyrroles and 3-hydroxypyridines, which are in some cases the products obtained from the work-up of the raw photolysate.

As for diazine *N*-oxides, pyridazine 1-oxides cleave in a way formally analogous to that of pyridine 1-oxide, to yield 4-diazobut-2-en-1-ones identified by flash photolysis and from these intermediates both nitrogen-conserving products (5-acylpyrazoles) and products resulting from the corresponding carbene (cyclopentylketones and furans).[86,87] On the other hand, pyridazine 1,2-dioxide undergoes cleavage of the NN bond and rearrangement to finally give 3,4-dihydroisoxazolo[4,5-*d*]isoxazole and isoxazole.[88] With pyrimidine 1-oxides, both ring contraction to 4-acylimidazoles[89] and ring cleavage to acylaminoacrylonitriles[90] have been observed. 1,2,4-Triazine 4-oxide follows the first path, giving 1,2,4-triazoles.[91] 4-Acylimidazoles are often formed form pyrazine-1-oxides,[92] while 1,4-pyrazine 1,4-dioxide (in aqueous solution) gives 2,5-dihydroxypyrazine.[93]

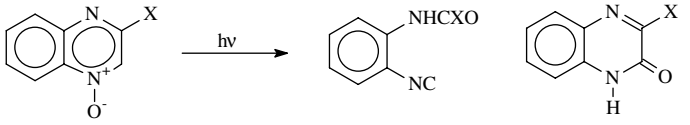
With azanaphthalene *N*-oxides, the photochemistry becomes simpler and is dominated by two processes, *viz.* ring enlargement to benzoxazepines in aprotic solvents (compare path *b* in Eq. 99.18) and rearrangement to lactams (path *c*) in protic solvents. Thus, the parent quinoline 1-oxide and many derivatives give 3,1-benzoxazepines (Equation 99.20),[94-98] and, likewise, isoquinoline 2-oxides give 1,3-benzoxazepines (too sensitive to be isolated from the parent system).[94,98-100]



(99.20)

Several substituted quinoxaline 1-oxides give 3,5,1-benzoxadiazepine[101,102] and 4-phenylquinazoline 3-oxide gives the corresponding 1,3,5-benzoxadiazepine in aprotic media.[103] The photoproducts are moisture sensitive and easily add nucleophiles, and their isolation requires careful work-up. As an example,

parent 3,1-benzoxadiazepine can be obtained by bulb-to-bulb distillation of the photolysate from quinoline 1-oxide in benzene and easily adds water and amines,[94] (and ring-contracted derivatives are often directly obtained)[104] while isomeric 1,3-benzoxapine has not been obtained in the pure state, but only as the adduct with amines.[94] The presence of some substituents such as phenyl, cyano, methoxy, and trifluoromethyl at the iminoether moiety makes the benzoxapines much more stable and allows easier isolation. Ring fragmentation is less often observed than with azabenzene *N*-oxides. However, examples of this are the formation of an open-chain isocyanide from parent quinoxaline 1-oxide (**27**, X = H, Equation 99.21) as well as its 3-methoxy derivative (**27**, X = OMe) [101] and the 3-carbamate,[105,106] and likewise from 3-methoxyquinoline 1-oxide (compare path *d* in Eq. 99.18).[97]



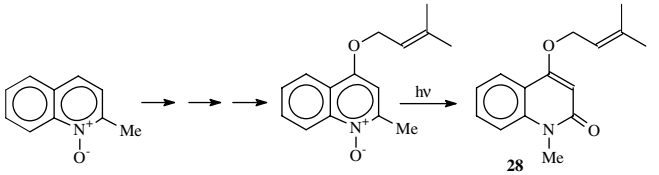
27

in C_6H_{12}	X = H	65%	27%
	X = OMe	80%	
in H_2O	X = H		90%
	X = OMe		95%

(99.21)

Another fragmentation reaction leads to the formation of diazoketones from 1,4-diphenylphthalazine 2-oxide.[86] Benzo-1,2,3-triazine 3-oxide[107] and cinnoline 2-oxide[108] also undergo ring fragmentation.

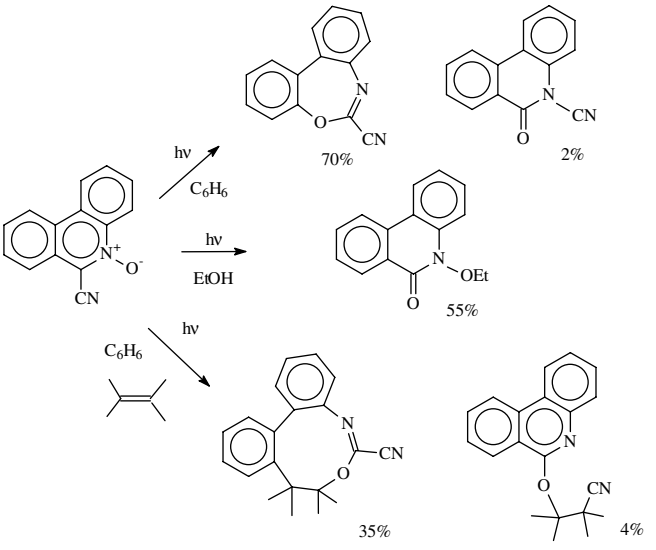
On the other hand, rearrangement to lactams is generally observed in a good yield in protic solvents, for example, carbostyril from quinoline[3] and isocarbostyril from isoquinoline[109] *N*-oxides. Exceptions are the above-mentioned *N*-oxides containing a conjugating substituent in the α position; in that case, ring enlargement remains the main process and the final products result from solvent addition to such derivatives. When the substituent in the α position is an alkyl group, however, the rearrangement to lactams occurs and the alkyl group migrates either to the nitrogen atom or to the β position (as does a deuterium atom in α).[110] An application of such a rearrangement is the preparation of the alkaloid ravenine (**28**, see Equation 99.22), a *N*-methyl-4-alkoxycarbostyril from the corresponding 2-methylquinoline 1-oxide.[111]



28

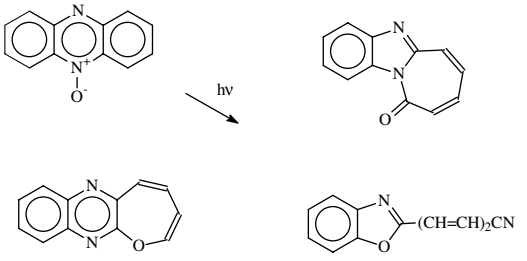
(99.22)

The solvent dependent photochemistry extends also to the phenanthrene and anthracene series, with some interesting variations. In apolar solvents, both 1- and 4-azaphenanthrene *N*-oxides rearrange to the corresponding naphthoxazepines, while phenanthridine gives only phenanthridone.[112] However, 6-aryl- and 6-cyanophenanthridine 5-oxides do undergo ring enlargement to dibenzoxazepines (see Equation 99.23).[113-115] In polar solvents, all of these *N*-oxides rearrange to lactams. Noteworthy is that with 6-alkylphenanthridine 5-oxides, 5-alkylphenanthridones are formed, except when a strongly stabilized group such as a benzyl is the substituent; in that case, the group is eliminated in the rearrangement.[113,116] This is an indication of the development of biradical/zwitterionic character during the rearrangement (compare formulae **23**, **23′** in Equation 99.18), which has been also evidenced through various reactions of 6-cyanophenanthridine 5-oxide. This adds ethanol when this is the solvent and alkenes when these are present (see Equation 99.23, compare path *t* in Equation 99.18).[114,117]



(99.23)

Among azaanthracene *N*-oxides, acridine and phenazine derivatives have been extensively investigated. Some acridine 10-oxides, such as the 9-chloro- and 9-cyano-substituted derivatives, give the corresponding dibenzo-1,2-oxazepines and it may be that products of similar structure are formed and then further converted with other derivatives.[118] Parent acridine 10-oxide gives a mixture of cycloheptatrienoindoles in apolar solvents and 11-methoxy-5,11-dihydrodibenzo[*b,e*]-1,4-oxazepine, which could arise by addition of the alcohol to a primarily formed dibenzo-1,2-oxazepine, in methanol (compare path *e* in Equation 99.18). Furthermore, oxepinoquinoline, with migration of the oxygen atom to the neighboring ring, are found in acetonitrile-water.[119] Phenazine 5-oxides tend to give azepinonbenzimidazoles and minor amounts of 5-(2-benzoxazolyl)pentadienenitrile in aprotic media, with a larger proportion of oxepinoquinoxalines in protic solvents (Equation 99.24).[120]



(99.24)

The study of several substituted derivatives has shown that the rearrangement to acylbenzimidazoles involves rotation of the carbocyclic ring, as if the intermediate were a *spiro*-oxocyclohexadienylbenzimidazole; whereas in the rearrangement to the oxepine, no rotation occurs and the oxygen atom inserts between the close-lying atoms.[121,122]

With both benzo[*a*]acridine[123] and benzo[*a*]phenazine 7-oxides,[124] a photorearrangement occurs and the oxygen atom migrates toward the naphthalene ring, forming annulenes with two fused seven-membered rings. Benzo[*a*]phenazine 12-oxide in part gives the same product as the 7-oxide, along with a larger amount of naphthoimidazoloazepinones where the oxygen atom has migrated toward the 7-oxide

ring. Some *N*-oxides of important polyazaheteroaromatics, such as purine and pteridine, have also been studied photochemically, usually in water, where tautomerism with the *N*-hydroxy form is important. Deoxygenation tends to predominate under such conditions (see below), but some of the rearrangements discussed above have also been observed, such as positional isomerism of the *N*-oxide function (with purines),[125] rearrangement to lactams (with purines[126,127] and pteridines),[128] and cleavage of the pyrimidine ring (with some purines[129] and a pyrazolopyrimidine).[130]

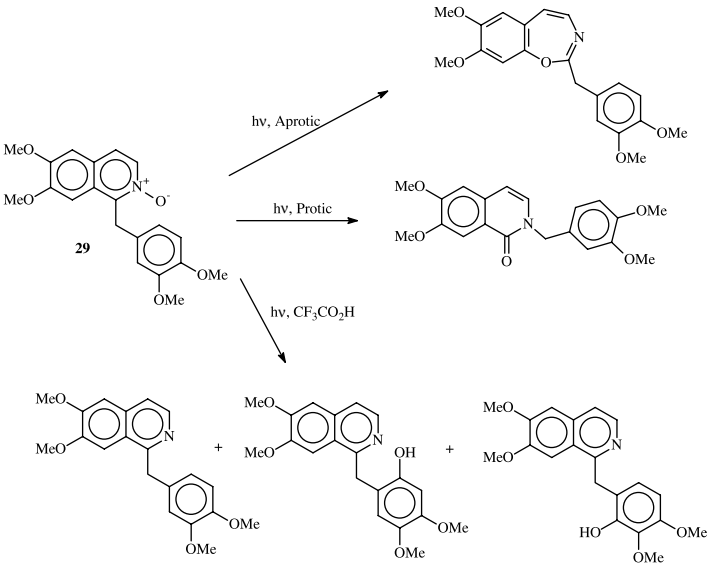
A photochemical synthesis of *N*-oxides, that of phenazine *N*-oxides from acylated *o*-nitrodiphenylamines, has also been reported.[131]

99.6 Photoinduced Deoxygenation of Heterocyclic *N*-Oxides

As mentioned, reduction to the corresponding heterocycle occurs along with the various rearrangements upon irradiation of *N*-oxides. The role of this reaction changes greatly, from practically negligible to quantitative, depending on both structure and conditions. As one might expect, the fraction of the deoxygenation process with respect to the overall photoreaction increases in more easily reduced substrates, *viz.* in polycyclic vs. monocyclic *N*-oxides, in polyaza *N*-(poly)oxides, and in electron-withdrawing substituted *N*-oxides.[3] Thus, deoxygenation is, as a rule, more important (20 to 50%) with pyridazine and pyrazine than with pyridine (≤5%) *N*-oxides and tends to become the only photoreaction with *N*-oxides such as those of benzoylpyridine,[132] benzo[*c*]cinnoline,[133] and nitrophenazine.[134] Likewise, using a good hydrogen donor as the solvent favors deoxygenation: phenazine *N*-oxide rearranges in most solvents but is mainly reduced in methanol.[120] Tautomerism to the *N*-hydroxy form, as observed in 2-pyridone[135,136] and 2-thiopyridone 1-oxide[137,138] or in purine and alloxazine *N*-oxides,[139] also favors deoxygenation. The photodeoxygenation of 1-deazapurine 3-oxide has been proposed as an actinometer in view of the expeditious fluorimetric determination of the heterocyclic compound in the presence of the *N*-oxide.[140] There has been some discussion about the mechanism involved in deoxygenation or oxygen transfer to an acceptor, be it the medium or a specifically added reagent. Probably, there is no uniform answer and different mechanisms operate. A rationalization that has been considered is that rearrangement occurs from the singlet and deoxygenation occurs from the triplet. A triplet reaction involving hydrogen abstraction from the solvent appears to operate in the photodeoxygenation of benzoylpyridine 1-oxides[132] as well as of some diazine *N,N′*-dioxides (see below)[3] and triplet-sensitized *N*-deoxygenations have been documented.[141] A second mechanism involves electron transfer to the excited *N*-oxide, followed by proton transfer; this appears to operate in the photoreduction of 2-nitrophenazine 10-oxide by amine (in this case via the singlet).[134] A third possibility envisages oxygen transfer as occurring on the same path as rearrangement, *viz.* as involving a rearranged intermediate such as an oxaziridine; this route has been followed particularly in the case of 6-cyanophenanthridine 5-oxide.[115]

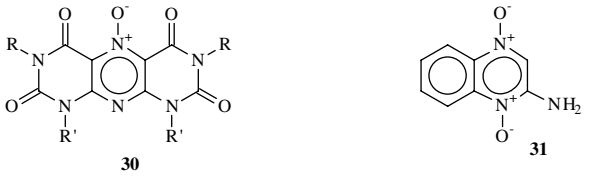
Obtaining a selective and effective *N*-deoxygenation is susceptible to two kinds of applications. The first is the use of photochemistry for deoxygenating *N*-oxides, a process that is efficient in the presence of suitable oxygen acceptors such as boron trifluoride,[142] triphenylphosphine,[143] triphenylphosphite,[144] or amines,[134] and is synthetically useful when occurring selectively, leaving unaffected other potentially reducible moieties such as a nitro group (as is well known, nitration of the *N*-oxides is usually much more expeditious than that of the corresponding heterocycles).

Second, heterocyclic *N*-oxides (typically benzodiazine of polycyclic polyazine *N*-oxides) can be used as mild photochemical oxidants. Under these conditions, reactions such as the hydroxylation of aromatics[145-147] but also of alkanes,[148] the epoxidation of alkenes,[146] the oxidation of epoxides to ketones,[149] of phosphine sulfides to phosphine oxides,[150] as well as the oxidative dealkylation of amines[151] can be carried out. Intramolecular variations have been found in the photochemistry of papaverine *N*-oxide (**29**, see Equation 99.25), which gives the typical medium-dependent rearrangements in neat organic solvents but intramolecular hydroxylation of the benzyl group in the presence of trifluoroacetic acid,[152,153] and in the case of some nucleoside derivatives, which upon irradiation in the presence of a *N*-oxide gives the radical cation, in turn attacked by the hydroxyl group of the sugar moiety to form a cyclonucleoside.[154,155]



(99.25)

The use of the *N*-oxides as oxidizing agents obviously reiterates the question of the mechanism. Apart from the electron-transfer path that is operative when using *N*-oxides that are very good acceptors, such as pyrimido[5,4-*g*]pteridinetetraone *N*-oxides (**30**, see Equation 99.26)[154] or tirazapamine (**31**),[156] with good donors such as amines and nucleosides, the oxidation is probably the result of the generation of some "activated" oxygen species.



(99.26)

The fact that alkanes are oxidized suggested that atomic oxygen is liberated[157] and also the attack on aromatic hydrocarbons[158-160] seems to differ from reaction via hydroxyl radicals. Actually, the hydroxylation of aromatics by this path has been considered as a model for biochemical oxidation.

Recently, however, there has been increased interest in *N*-oxides for the generation of hydroxyl radicals in aqueous solution. This process has been reported for some nitrated *N*-oxides[161] but is most often observed for tautomeric *N*-oxides, where the *N*-hydroxy form is significant.[135-140] The main application is in photobiology, as specific sources of hydroxyl radicals for DNA damage, both strand break and base modifications. *N*-Hydroxy-2-pyridone and 2-pyridinethione,[162] *N*-hydroxy-4-(4-chlorophenyl)thiazole-2(3*H*)-thione,[163] and pyrimido[5,4-*g*]pteridinetetraone *N*-oxide (for which the path followed depends on conditions)[164] and related *N*-oxides[165] have been used for this purpose.

An oxygen transfer reaction is presumably the origin of the successful photo-cross-linking of several polymers containing heterocyclic *N*-oxide moieties in the backbone or with *N*-oxides as additives[166-168] as well as for photolithography.[169]

99.7 Nitrile *N*-Oxides

Nitrile *N*-oxides are reactive intermediates that are usually generated *in situ* through an elimination reaction. These are rarely stable enough to allow the study of their photochemical behavior. When this

is possible, as with sterically hindered arylnitriloxides, irradiation has been found to cause rearrangement to either acylnitrenes or isocyanates, both of which can be characterized via adducts to suitable traps.[170] Acetonitrile oxide has been generated by means of photolysis of an aziridine, addition of oxygen, and fragmentation of the resulting 5*H*-dioxazole.[171]

A New Look at Pyridinium Salt Photochemistry

Patrick S. Mariano
University of New Mexico

100.1 Overview

Interest in the area of pyridinium salt photochemistry dates back to the 1960s, a time when intense efforts were underway to probe the mechanistic details of photoinduced, benzene valence bond isomerization reactions. Amid this flurry of activity is found a single report in 1972 by Kaplan, Pavlik, and Wilzbach[4], describing the novel, bicyclic aziridine forming, photohydration reaction of N-methylpyridinium chloride. Many years passed before another study, in 1983 and focused on pyridinium salt single electron transfer photochemistry, led to the tangential observation that the bicyclic aziridines, arising by excited-state cyclizations of pyridinium salts, participate in acid catalyzed ring opening reactions to produce functionalized aminocyclopentenes. This area again remained uncultivated for many years until the pyridinium salt photocyclization and bicyclic aziridine ring-opening processes were finally investigated in a more thorough manner. The more recent efforts, starting in the mid-1990s, have finally uncovered the unique synthetic value of this chemistry.

In this review, the results of early studies in this area will be presented first in order to establish the background and context of the recent studies of pyridinium salt photocyclization and bicyclic aziridine ring-opening reactions. The overall aim of the presentation is to show how these processes can be used as key steps in synthetic routes to simple, yet interesting natural and non-natural products.

100.2 Early Studies of Pyridinium and Pyrylium Salt Photochemistry

An intense series of highly competitive investigations in the 1960s led to a comprehensive picture of excited state valence bond isomerization reactions of benzene and its substituted derivatives.[1] The principal products of the generally inefficient benzene photoreactions are benzvalene, Dewar-benzene and

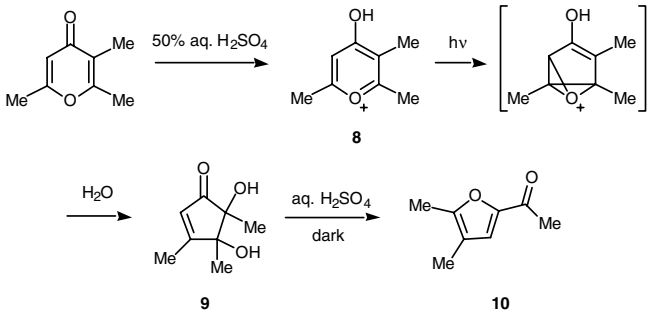
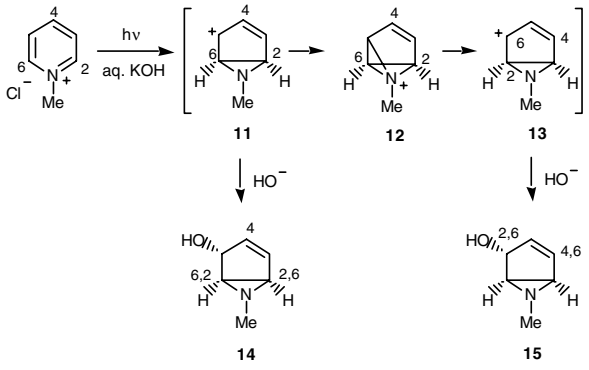
fulvene (Scheme 1). Stimulated by these observations, studies were initiated in the early 1970s to probe the photochemical properties of heteroatom analogs of benzene. Early independent investigations by Baltrop[2] and Pavlik[3] and their co-workers demonstrated that pyrylium salts undergo photoinduced ring isomerization and ring-opening reactions. For example, irradiation of 2,4,6-trimethylpyrylium perchlorate (**1**) was found to result in the formation of its 2,3,5-trimethyl isomer **3** along with the unsaturated keto-aldehyde **4** when water is present in the reaction mixtures (Scheme 2). In a similar vein, the cyclopentenetriol **7** was observed as the major primary product formed upon irradiation of an aqueous solution of the *t*-butyl-pyrylium salt **5** (Scheme 3). Both of these processes were proposed to involve the intermediary of oxabenzvalene cations **2** and **6**. Ring opening of these intermediates would form isomerized pyrylium salts while their hydrolytic cleavage would lead to the triol. 4-Hydroxypyrylium salts, formed by *in situ* protonation of 4-pyranones, have similar excited-state reactivity profiles. This is exemplified by the photochemical conversion of the 2,3,6-trimethyl-4-hydroxypyrylium salt **8** to the cyclopentenediol **9** by irradiation at 0°C in 50% aq. H_2SO_4 (Scheme 4). At elevated temperature, **9** undergoes a dark, acid-catalyzed reaction to produce the furfuryl ketone **10**.

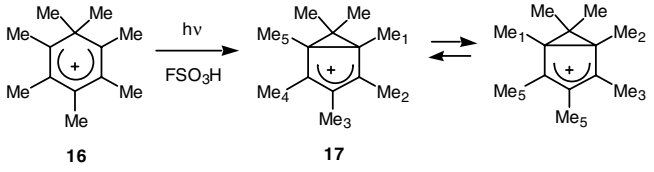
Of comparable interest, yet receiving much less attention, was the early report by Kaplan, Pavlik and Wilzbach[4] that N-methylpyridinium chloride undergoes photoinduced cyclization to produce the bicyclic aziridine **14** upon irradiation in aqueous base solution (Scheme 5). The structure and stereochemistry of the product of this reaction, along with those generated by irradiation of ring-deuteriated and methyl-substituted analogs, led these workers to propose that the process is initiated by excited-state electrocyclization. The bicyclic-aziridine cation **11** formed in this manner undergoes least-hindered addition of hydroxide (Scheme 5). To account for partial scrambling of the carbon skeleton in these photoreactions, Kaplan and co-workers suggested that the initially formed cation **11** undergoes competitive isomerization (**11** → **13**) via the azabenzvalene cation **12**. As a consequence, it was proposed that product distributions from photoreactions of ring-deuteriated and methylated pyridinium salts are governed by the relative rates of hydroxide capture and 1,5-migrations of the key cation intermediates (e.g., **11** and **13**).



SCHEME 4



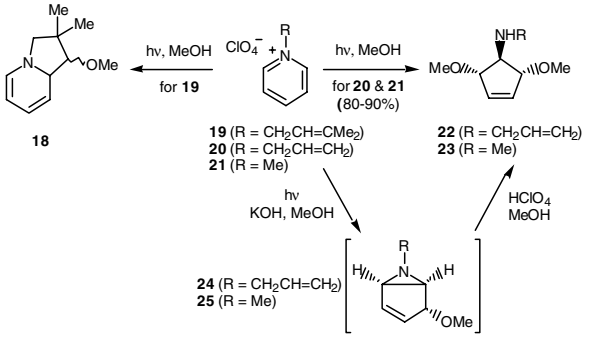
SCHEME 5



SCHEME 6

The photocyclization reactions of pyridinium and pyrylium salts are initiated by excited-state 2,6-bonding. These processes are analogous to 1,3-diradical forming photocyclization reactions of benzenes.[1] Also, these pyridinium and pyrylium excited-state processes can be visualized as photo-Nazarov cyclizations of cyclohexadienyl cations, which result in the formation of heteroatom substituted bicyclo[3.1.0]hexenyl cations.[5]

In the early investigations summarized above, benzvalene oxonium and ammonium ion intermediates were invoked to explain how ring carbon scrambling occurs in the initially formed bicyclic allyl cation intermediates. Although reasonable, rationalizations for these skeletal rearrangements do not necessarily require the intermediacy of benzvalene-like onium ions. Winstein,[6] in his early studies of carbocation photochemistry, showed that the heptamethyl bicyclo[3.1.0]hexenyl cation **17** (Scheme 6), generated by photocyclization of the corresponding cyclohexadienyl cation **16**, undergoes exceptionally rapid ($\Delta G^{\pm}$ = 9 kcal mol^{-1}) ring isomerization. The NMR-detected, fivefold degenerate rearrangement of this cation, occurring even at low temperatures, suggests that the suprafacial 1,5-migration with inversions at the



SCHEME 7

migrating carbon is an exceedingly facile process. Thus, similar pathways not involving the intermediacy of benzvalene onium ions might be responsible for isomerization reactions of the initially formed bicyclic allyl cations in the photochemistry of pyrylium and pyridinium salts.

A number of years passed, following the first report describing the photocyclization reaction of N-methylpyridinium chloride, before this process was again investigated. In the interim, interest in the general field of photochemistry shifted away from benzene valence bond isomerizations to other synthetically relevant processes. During this time, numerous efforts focused on photochemical reactions that are driven by excited-state singlet electron transfer (SET). Owing to the large excited-state reduction potentials of pyridinium and related N-heteroaromatic salts, these substances readily participate in SET-photochemical reactions with suitable electron donors.[7] Another perspective of pyridinium salt photocyclization processes was opened by observations made in a 1983 study by Mariano and co-workers[8] of SET-promoted photoreactions of N-heteroaromatic salts. An example of this is found in the photochemistry of N-prenylpyridinium perchlorate **19**, which undergoes smooth SET-promoted cyclization to form indolizidine **18**. In contrast, the N-allyl derivative **20** is efficiently transformed to the aminocyclopentene **22** upon irradiation in MeOH (Scheme 7). In a similar fashion, the aminocyclopentene **23** is produced by irradiation of N-methylpyridinium perchlorate **21** in MeOH.

The aminocyclopentene products of these pyridinium salt photoreactions were shown to arise by acid-catalyzed methanolytic aziridine ring opening of bicyclic aziridine intermediates. Accordingly, treatment of the bicyclic aziridines **24** and **25**, produced by irradiation of basic MeOH solutions of the salts **20** and **21**, with catalytic quantities of $HClO_4$ in MeOH led to smooth formation of the respective aminocyclopentenes **22** and **23**. Thus, when base is not included in pyridinium salt photoreaction mixtures, the initially formed photocyclization products are N-protonated bicyclic aziridines, which are subject to nucleophile-induced cleavage at their allylic aziridine centers.

100.3 Recent Studies of Pyridinium Salt Photocyclization: Bicyclic Aziridine Ring-Opening Processes

As has become the pattern in this area, it took a decade before the synthetic significance of the pyridinium salt photocyclization–aziridine ring opening sequence was finally recognized. As pointed out in the 1996 publication by Mariano and co-workers,[9] a two-step methodology (Scheme 8) can be employed in the stereocontrolled preparation of a variety of symmetric and differentially functionalized aminocyclopentenes. For example, these workers found that irradiation of the N-substituted pyridinium perchlorates **26** in aqueous or methanolic base solutions leads to efficient formation of the bicyclic-aziridinyl alcohols or ethers **27** (Scheme 9). Acid-catalyzed ring opening of the photoproducts, using a number of different nucleophiles, results in production of the *trans,trans*-aminocyclopentenes **28**.

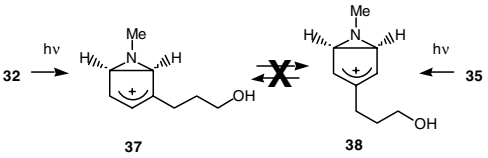
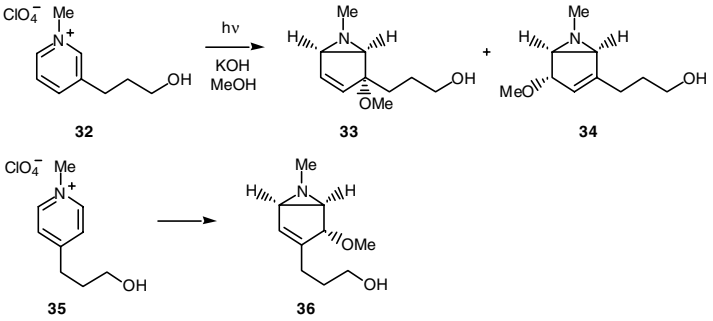
SCHEME 11

Very similar (in some cases, identical) observations were reported in a 1998 publication by Burger and co-workers.[10] More novel are the recent findings by Penkett and Simpson[11] that irradiation of 3-alkoxypyridinium salts in aqueous alcohol solutions gives rise to bicyclic ketals. As depicted in Scheme 10, irradiation of the 3-methoxy salts **30** gives use to ketals **29** in yields that are highly dependent on the nature of the C6 substituent. In addition, β-hydroxyketones **31** are produced when the corresponding methoxy-substituted pyridinium salts are irradiated in aqueous base solutions (Scheme 10). Penkett and Simpson have also demonstrated the bicyclic ketal photoproducts participate in anti-S_N2' reactions with organocopper reagents to afford novel aminocyclopentene adducts (Scheme 11).[12]

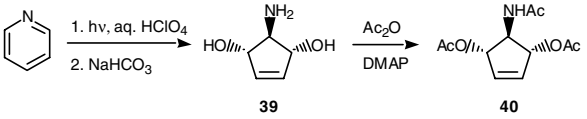
Another interesting feature of the pyridinium salt photocyclization reactions is pointed out by the observation made by Mariano and his co-workers[9] that products resulting from intramolecular nucleophilic



SCHEME 13



SCHEME 12

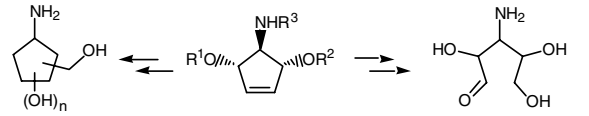


SCHEME 14

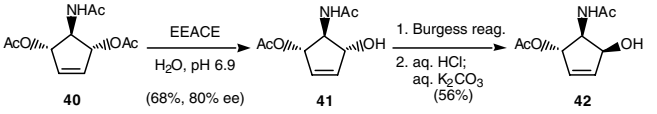
capture of intermediate azabicyclic allyl cations, are not formed in these processes. This feature is exemplified by photoreactions of N-tethered alcohol and amide substrates **26** (Scheme 9) which only yield products arising by addition of the external nucleophiles (MeOH and H_2O) to the cation intermediates formed by excited state 2,4-bonding. This trend extends to substrates that possess hydroxyalkyl side chains appended to C3 or C4 of the N-heteroaromatic nucleus. For example, the bicyclic alcohols **33** and **34** are the sole products formed when a basic MeOH solution of 1-methyl-3-hydroxypropylpyridinium perchlorate (**33**) is irradiated (Scheme 12). Similarly, the 4-hydroxypropyl analog **35** is transformed to the solvent incorporation adduct **36** exclusively under these photoreaction conditions.

It is interesting to note as an aside that the above photocyclization reactions are not attended by ring reorganization (i.e., no crossover formation of **36** from **32** or **33** + **34** from **35**). This result contrasts with the early observations of Kaplan and co-workers[4] and suggests that the initially formed bicyclic allyl cation intermediates **37** and **38** (Scheme 13) do not interconvert by 1,5-nitrogen migration on the intermolecular methanol addition time scale.

Another significant and synthetically relevant observation was made in studies probing the photochemical reactivity of N-protonated pyridines. Mariano and co-workers[9] have demonstrated that irradiation of a solution of pyridine in aqueous perchloric acid at 45 to 70°C results in clean generation of the cyclopentene aminodiol **39**, isolated as its triacetyl derivative **40** (Scheme 14). Despite the fact that the quantum efficiency of this reaction is low, the process can be used to prepare 1–2 g quantities of 40 following 1–2 day irradiation periods.



SCHEME 15



SCHEME 16

100.4 Applications of Pyridinium Salt Photochemistry to the Synthesis of Biomedically Relevant Targets

The pyridinium salt photocyclization–aziridine ring opening reactions described above introduce remarkably high levels of molecular, functional, and stereochemical complexity into the reacting substances. As a consequence of this characteristic, a number of synthetic applications of this chemistry can be envisaged. For example, the aminocyclopentene formed by these sequences contain functionality at each of the five contiguous ring carbons. Consequently, these substances are ideal intermediates in synthetic routes targeted at the biomedically interesting aminocyclopentitol class of natural and non-natural products (Scheme 15). In addition, the $\Delta^{1,2}$-alkene moiety and differentiable C3 and C5 substituents make the aminocyclopentenes suitably disposed for ring-opening reactions, which can be used to elaborate stereochemically defined, terminally differentiated five-carbon acyclic arrays. In this way, pyridinium salt photochemistry can be employed as key steps in concise sequences for the preparation of aminoaldopentoses and higher amino-sugar analogs (Scheme 15).

Studies conducted thus far to develop synthetic applications of this chemistry have relied heavily on the earlier finding that the *trans,trans*-amidocyclopentenyl acetate **40** can be prepared readily by irradiation of pyridine in aqueous acid solution (Scheme 14).[9] This substance is functionally similar to compounds that have been converted to non-racemic mono-alcohols by enzymatic desymmetrization processes. Thus, treatment of diacetate **40** with the electric eel acetylcholinesterase (EEACE) was found to generate the mono-ester **41** in a 68% yield and 80% ee (Scheme 16).[13] In addition, Mariano and co-workers have demonstrated that stereochemical diversity can be introduced into the aminocyclopentene ring system using hydroxyl inversion procedures.[9,13] An example of this is found in the conversion of **41** to its *cis-trans*-diastereomer **42**[13] by employment of the amide directed inversion method developed by Wipf and co-workers[14] (Scheme 16). These observations have established the foundation for applications of pyridinium salt photochemistry to the synthesis of the biomedically important aminocyclopentitols and aminoaldopentoses shown in Schemes 17, 18 and 19.[13,15–17]

100.5 Summary

Without doubt, it is possible to characterize the developments made in the area of pyridinium salt photochemistry as slow and "far between." More recent investigations of this chemistry have begun to uncover its synthetic significance. However, a number of questions pertaining to the mechanism of the photocyclization process, the factors governing the rates of ring isomerization, and the regiocontrol of nucleophilic addition to the unsymmetrically substituted cation intermediates still need to be answered before the full potential of this unique excited-state process can be elaborated.

101.1 Overview

Single electron transfer (SET) is now recognized as a key mechanistic event in a wide variety of ground- and excited-state chemical and biochemical processes.[1–5] Organic photochemistry is one discipline where this recognition has profoundly impacted the understanding of mechanistic pathways and the development of new reactions.[6] Owing to the large driving force for SET in the electronic excited states vs. ground states, radical ion formation is often one of the most efficient pathways for excited-state deactivation.

Consequently, in contrast to classical photochemical reactions, SET-promoted excited-state processes are controlled by the nature and rates of secondary reactions of charged radical intermediates.

α-Heterolytic fragmentation reactions are the most common types of decay pathways open to ion radicals. These fragmentation reactions play a pivotal role in SET photochemistry. Departure of an electrofugal or nucleofugal group from a respective cation or anion radical often competes with back electron transfer or alternative reaction modes to generate a carbon-centered radical intermediate in routes for product formation. Therefore, knowledge about the dynamics of ion radical fragmentation reactions and their dependence on structure, substituents, and the reaction medium is crucial for the design of new and efficient SET photochemical processes.

This review[7–9] focuses on α-heterolytic fragmentation reactions of aminium radicals (Scheme 1), which are derived by one-electron oxidation of amines. In these fragmentation processes, electrofugal groups are transferred to either Lowry-Brønsted or Lewis bases to produce α-amino radicals. The review concentrates on the results of investigations that have provided information about the dynamics of important aminium radical fragmentation reactions, including deprotonation, demetallation, retro-Aldol fragmentation and decarboxylation. Included in the discussion are examples that show how the rates of aminium radical cleavage influence the nature and efficiencies of photochemical reactions involving amine substrates.

101.2 Redox Properties of Amines

Amines are among the most easily oxidized classes of neutral organic substances. This is reflected by their low oxidation potentials (Table 101.1). As expected, oxidation potentials of amines are significantly altered by N-substituents. Accordingly, amines bearing N-substituents that are capable of stabilizing the formed aminium radicals have lower oxidation potentials as compared to those with N-electron-withdrawing substituents. Resonance stabilization caused by N-aryl substituents lowers the oxidation potential of amines by nearly 0.4 V while alkoxycarbonyl or acyl substitution raises the oxidation potential by *ca.* 0.9 to 1 V. A less dramatic effect is seen for substituents that inductively stabilize the aminium radical. This is exemplified by the only slight decrease in the oxidation potential of tertiary amines caused by α-alkyl substitution (e.g., Me_3N, +0.82 V; Et_3N, +0.79 V; nBu_3N, +0.62 V).

In contrast, other types of α–substituents can lead to large stabilization of amine cation radicals. For example, Yoshida[10] and Cooper[11] have demonstrated that α–trialkylsilylamines and α–trialkylsilylcarbamates have significantly lower oxidation potentials than their non-silicon substituted counterparts.

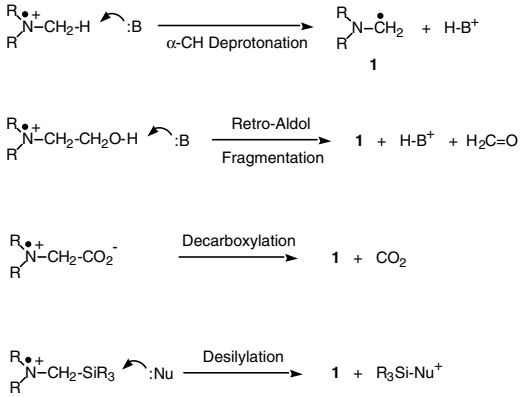
This phenomenon, observed also for allyl- and benzylsilanes,[12,13] is attributed to hyperconjugative stabilization of the aminium radicals by interaction of the half-vacant nitrogen nonbonding *p*-orbital with the carbon-silicon σ–orbital.[14] α–Silyl substitution also causes a significant decrease in the oxidation potentials of ethers by as much as 0.9 eV.[15,16] This effect is strongly dependent on molecular geometry, being larger in cases where the C–Si bond is oriented to overlap well with the half-vacant oxygen orbital.

101.3 Photochemical Generation of Aminium Radicals

Owing to their low oxidation potentials, amines serve as potent electron donors in photoinduced SET processes. SET occurs at near diffusion controlled rates from amines to acceptors, which have excited-state reduction potentials that are higher than the oxidation potential of the amines. Three common methods have been used to promote excited state SET oxidation of amines. These include (1) SET to the excited state of acceptors, which participate as substrates in photochemical reactions with the amine (e.g., α,β-unsaturated ketones); (2) SET to the excited-state acceptors, which serve as sensitizers (e.g., cyanoarenes) for photochemical reactions occurring between amines and other substrates; and (3) SET to preformed radical cations. The third method, in which amines are converted to aminium radicals without simultaneous in-cage generation of substrate or sensitizer anion radicals, is known as redox photosensitization.[19] In contrast, the former two methods lead to direct formation of contact ion radical pairs (CIRP) or solvent-separated ion radical pairs (SSIRP), whose lifetimes and behavior depend on the polarity of the medium. Polar solvents facilitate cage escape of the ion radicals, leading to generation of fully solvated free ion radical intermediates.

101.4 Chemical Reactions of Aminium Radicals

Aminium radicals have a rich history as reactive intermediates in organic chemistry. The nature and rates of aminium radical reactions play a major role in governing the chemoselectivities, regioselectivities, and efficiencies of a wide variety of amine oxidation processes. Perhaps the most common reaction mode open to tertiary aminium radicals is α-CH deprotonation, which results in the production of neutral α-amino radicals (Scheme 2). Closely related to α-CH deprotonation are other α-heterolytic fragmentation reactions in which electrofugal groups are lost to Lowry-Brønsted or Lewis bases. One example of this reaction type is base-induced retro-Aldol cleavage of cation radicals derived from tertiary β-aminoalcohols. Decarboxylation, with or without simultaneous deprotonation, is another common reaction of aminium radicals derived from SET oxidation of α-amino acids or their carboxylates. Finally, silophile-promoted α-desilylation of α-trialkylsilylaminium radicals is the last type of reaction pathway commonly



SCHEME 2

observed for these reactive intermediates. In all cases, the driving force for fragmentation of the aminium radical is provided by a combination of factors, including (1) delocalization of the N-centered positive charge density into the α-C-H, α-C-C, or α-C-SiR_3 σ-bonds, and (2) the thermodynamics associated with formation of carbonyl π-bonds or silicon-silophile σ-bonds.

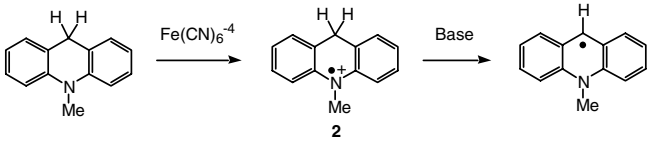
101.5 α-CH Deprotonation of Aminium Radicals

Direct Measurement of Deprotonation Rates

Studies probing the structural, spectroscopic, and chemical characteristics of aminium radicals have been discussed in a thorough earlier review by Nelsen and co-workers.[20] The cationic and radical nature of these intermediates combine to define their chemical properties. The N-H protons of primary and secondary aminium radicals generally are more acidic (pKa *ca.* 7) than their neutral amine (pK_a *ca.* 35) or charged ammonium ion (pKa *ca.* 11) counterparts.[21] Consequently, cation radicals derived from SET oxidations of primary and secondary amines typically undergo rapid N-H-deprotonation to generate neutral aminyl radicals. By employing kinetic ESR techniques, Ingold[22] has determined that the rate constants for N-H proton transfer from the Me_2NH cation radical to solvents varies from 10^5 to 10^6 M^{-1} s^{-1}.

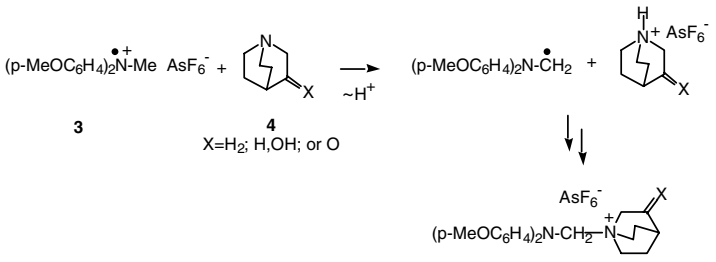
Tertiary aminium radicals also are acidic, owing to the presence of α-CH protons. As a result, the most common reaction mode open to these charged radicals is α-CH deprotonation, leading to generation of α-amino radicals (Scheme 2). The importance of this process in electrochemical and SET photoinduced oxidation reactions of amines has stimulated a number of detailed studies aimed at elucidating the kinetics of base-promoted α-CH deprotonation of tertiary aminium radicals. In an early investigation, Das and Von Sonntag[23] used pulse radiolysis methods to determine that the pKa of the N-centered radical cation derived from trimethylamine is *ca.* 8 in H_2O (Scheme 3). In addition, this effort established that the bimolecular rate constant for proton transfer from this aminium radical to Me_3N is 7×10^8 M^{-1} s^{-1}. Equally informative results have come from another early kinetic investigation of ferricyanide oxidation reactions of 1,4-dihydropyridines and N-methylacridanes by Bruice and co-workers.[24,25] Kinetic analysis of these reactions demonstrated that rate-limiting deprotonation of the aminium radical intermediates **2,** with imidazole and acetate as bases, occurs with rate constants in the 1×10^7 M^{-1} s^{-1} range (Scheme 4). The primary kinetic isotope effect of 4.4 and Brønsted β-value of 0.2 measured for this process suggest that the transition states for proton transfer in these processes lie close to the aminium radical reactants rather than the α-amino radical products.

SCHEME 3



SCHEME 4

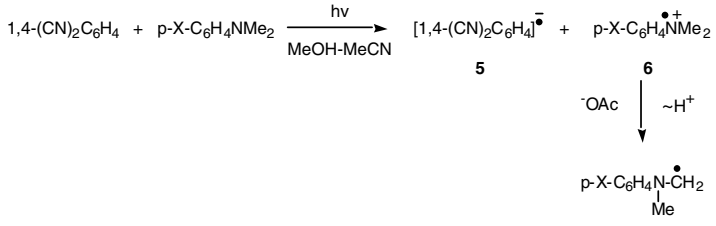
A more thorough evaluation of the dynamics of tertiary aminium radical α-CH deprotonation reactions has come from relatively recent studies employing stopped-flow, time-resolved laser flash photolysis, and electrochemical techniques. In one effort, Dinnocenzo and Banach[26] examined acid-base reactions of the stable aminium radical **3**, prepared by SET oxidation of N,N-dianisyl-N-methylamine (Scheme 5). Using stopped-flow kinetic methods, these workers showed that the bimolecular rate constants for α-deprotonation of **3** by four quinuclidine bases **4** in MeCN are (1) in the range of 1×10^2 to 6×10^4 M^{-1}



SCHEME 5

s^{-1} and (2) associated with a primary deuterium isotope effect (NCH_3 vs. NCD_3) of 6 to 7.8. Also, the rate constants were found to be linearly dependent on the pKa values of the quinuclidines, providing a Brønsted β-value of 0.63. Thus, the rates of α-CH deprotonation of **3** parallel the thermodynamic driving force associated with base strength.

More typically, aminium radicals are unstable species that can be detected and studied only by using ultra-fast kinetic methods. An example of this is found in the time-resolved laser spectroscopic investigation of anilinium radicals conducted by Mariano, Falvey, and co-workers.[27] Laser flash photolysis (LFP) of a solution of N,N-dimethylaniline (DMA) and 1,4-dicyanobenzene (DCB) leads to generation of the respective free ion radical intermediates **5** and **6** (X = H). In the absence of added bases, these free ion radical transients undergo diffusion-controlled, second-order decay by back electron transfer (Scheme 6). α-CH deprotonation of anilinium radical **6** (R = H) by the weak bases n-Bu_4NOAc and n-$Bu_4NO_2CCF_3$ occurs with respective second-order rate constants of 3.1×10^5 and 8×10^4 M^{-1} s^{-1} and a deuterium isotope effect (NCH_3 vs. NCD_3) of 3.6 (for n Bu_4NOAc). To probe the driving force dependence of the rates of this process, *p*-OMe, *p*-Me, *p*-CF_3-substituted dimethylanilines were subjected to LFP studies. The substituents were found to have a pronounced effect on the rates of n-Bu_4NOAc-induced deprotonation (k(*p*-OMe) = 2.0×10^4 M^{-1} s^{-1}, k(*p*-Me) = 1.1×10^5 M^{-1} s^{-1}, k(*p*-CF_3) = 2.5×10^6 M^{-1} s^{-1}). These effects are well correlated with the control of the oxidation potentials of the aniline derivatives by groups at the *para*-position. A cyclic voltammetry study of *p*-substituted N,N-dimethylanilines by Parker and Tilset[28] led to the same general conclusions about the substituent dependence of α-CH deprotonation rates.



SCHEME 6

Substituents located on the α-carbon center can also influence the rates of aminium radical α-CH deprotonation through a combination of steric and electronic effects. This issue was probed by Mariano, Falvey, and co-workers[27] in studies with N-substituted-N,N-diphenylamines **7** (Scheme 7, Table 101.2). Aminium radicals **8**, produced by photoinduced SET from the amines **7** to DCB, undergo deprotonation by n-Bu_4NOAc with rate constants in the region of *ca.* 1×10^6 M^{-1} s^{-1}. Interestingly, alkyl substitution at the α-carbon retards deprotonation while conjugating substituents at this position bring about an acceleration in the rate of deprotonation.

Studies by Saveant and co-workers[29] provide a more comprehensive picture of how steric and electronic effects govern the rates of aminium radical α-CH deprotonation. In this account, a combination of double potential step chronoamperometry, cyclic voltammetry, and laser flash photolysis methods were used to measure the rates of 9-CH deprotonation of aminium radicals **9**, produced by SET oxidation of 9-substituted-N-methylacridanes (Scheme 8). Amines with differing base strength and steric constraints were employed as bases. The data (Table 101.3) clearly show that the deprotonation rate constants are significantly reduced when sterically encumbering substituents are present at C-9 of the acridanium

radical or on the base. In addition, the rates correlate closely with the pKa values of both the bases and amine cation radicals.

The results emanating from the studies described above have demonstrated that nitrogen and α-carbon substituents control the kinetic α-CH acidities of aminium radicals. It is clear that the kinetic acidities of these reactive intermediates, like those of other CH-proton donors, parallel thermodynamic acidities as reflected by their pKa values. As the empirical relationship developed by Nicholas and Arnold[30] shows, the pKa of an aminium radical is determined by both the oxidation potentials (E^o) of the parent amine (a measure of the aminium radical stability) and the bond dissociation energy (BDE) of the cleaved α-CH bond in the amine (a measure of the stability of the α-amino radical formed by deprotonation). In line with this formulation, electron-donating groups on nitrogen lower acidity by decreasing the energy of the aminium radical. The electronic effects of α-substituents on acidity operate through their control of α-amino radical stability.

Another important feature of aminium radical deprotonation reactions is revealed by comparing the results from independent investigations by Saveant[31] and Peters[32–35] of N-methylacridane cation radical deprotonation reactions. Under the conditions used in the electrochemical and laser flash photolysis experiments carried out by Saveant, the free N-methylacridanium radical is observed. This species undergoes deprotonation by base in a diffusion-governed encounter process. Using d-isotope effects, Saveant showed that deprotonation of this free aminium radical occurs preferentially at C9 of the acridane ring. Earlier picosecond LFP studies by Peters revealed that proton transfer between the SET-photogenerated N-methylacridanium radical and arylketone anion radicals can also occur in contact ion radical pairs (CIRP). Interestingly, Peters found that in the CIRP generated by photoinduced SET between benzophenone and N-methylacridane, proton transfer occurs selectively from the N-methyl position of the acridanium radical. These contrasting observations suggest that the site of deprotonation in aminium radicals can be strongly influenced by the environment in which the deprotonation process occurs, that is, whether it takes place in a diffusion encounter manner or within a highly organized ion radical pair. In the latter case, the lowest energy orientation of the charged radical partners can influence deprotonation regioselectivities.

Relative Rates of Aminium Radical α-CH Deprotonation Based on Photoproduct Distributions

Information about the relative kinetic acidities of aminium radicals has also come from a number of studies probing product distributions of SET-promoted photochemical reactions. One of the earliest investigation in this area was conducted by Cohen and co-workers,[36] in which product distributions of SET-induced photoreactions of unsymmetrically substituted tertiary amines were used to gain information about how alkyl substituents affect the rates of aminium radical α-CH deprotonation. Irradiation of solutions of 4-benzoylbenzoic acid containing a variety of tertiary amines leads to formation of dealkylation products (Scheme 9). In these processes, the initially formed aminium radical **10** transfer a proton to the 4-benzoylbenzoic acid anion radical to generate an α-amino radical, which then donates an electron to another 4-benzoylbenzoic acid molecule. Hydrolysis of iminium ions **11**, formed in this manner, then gives carbonyl and secondary amine products. The results of these studies qualitatively indicate that dealkylation occurs preferentially at the less alkyl-substituted α-carbon.

From Lewis, F.D. and Ho, T.L., *J. Am. Chem. Soc.,* **102**, 1751, 1980; Lewis, F.D., Ho, T.L., and Simpson, J.T., *J. Org. Chem.,* **46**, 1077, 1981; Lewis, F.D., Ho, T.I., and Simpson, J.T., *J. Am. Chem. Soc.*, **104**, 1924, 1982.

Detailed investigations of the SET photochemistry of tertiary amine–stilbene systems by Lewis and co-workers[37–39] have elucidated a number of factors that govern the relative rates of α–deprotonation reactions of aminium radicals. As shown in Scheme 10, photoreactions of stilbene with unsymmetrically substituted tertiary amines in acetonitrile proceed via pathways in which contact ion radical pairs (CIRP), generated by excited-state SET, undergo proton transfer to yield radical pair precursors of stilbene–amine photoadducts. By careful analysis of the product distributions, Lewis has determined the relative kinetic α-CH acidities of the intermediate aminium radicals (Table 101.4).

These data show that both steric and electronic factors contribute in determining the kinetic acidities of tertiary aminium radicals. Proton transfer in the stilbene-amine CIRP requires that the α-CH bond be aligned parallel to the half-vacant *p*-orbital on nitrogen in the aminium radical. Lewis has proposed that the energy of the transition state for proton transfer in the CIRP is influenced by steric strain associated with internal interactions between alkyl groups in the amine cation radical component.[37–38] In addition, the energies of transition states for proton transfer in these CIRPs should be governed by steric interactions between the tightly aligned ion radical partners. As a result, transition state energies should vary with the nature of the α–carbon in the following manner: methyl < primary < secondary. Importantly, steric effects of alkyl substituents appear to be more important than electronic effects in controlling the rates of proton transfer from aminium radicals in contact ion radical pairs.

The influence of electronic effects on aminium radical α-CH kinetic acidities has been observed in product distribution studies of Mariano and co-workers.[40–41] These workers found that irradiation of β-aminoethyl-substituted cyclohexenones **12** leads to formation of mixtures of regioisomeric products **14**. The SET promoted photocyclization reactions proceed via the intermediacy of zwitterionic biradicals **13.** Intramolecular proton transfer between the aminium and enone anion radical moieties in **13** is followed by radical coupling to give spirocyclic aminoketones **14** (Scheme 11). The relative rates of aminium radical

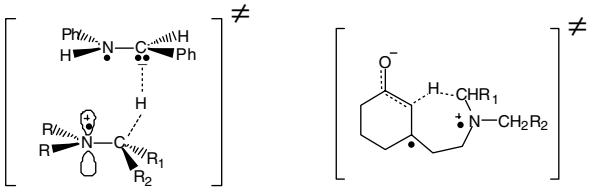
α-deprotonation (Table 101.5), obtained from analysis of the product ratios, indicate that the radical stabilizing ability of α–substituents (C≡CH > CH = CH_2 > Ph > CO_2Me > TMS > Me > H) plays a key role in determining the aminium radical kinetic acidities in these cases.

A comparison of the product distribution results obtained from studies of the stilbene–amine and aminoethylcyclohexenone photoreactions shows that steric and electronic effects contribute differently in determining aminium radical kinetic acidities. Product distribution analysis of SET-induced stilbene–tertiary amine photoadditions suggests that alkyl substitution leads to decreased rates of α-CH proton transfer from the tertiary aminium radicals to the stilbene anion radical within contact ion radical pairs. As mentioned, this effect is likely due to steric hindrance that raises the energy of early transition states for proton transfer when the stilbene anion radical is tightly associated with the aminium radical. In this pair, the aminium radical exists in a stereoelectronically preferred conformation **16** (Figure 101.1), having good overlap between the half-vacant nitrogen *p*-orbital and filled α-CH σ–orbital. The fact that proton transfer in the stilbene–amine photoreaction occurs in a contact ion radical pair, whose rigid structure (i.e., relative orientation of negative and positive radical partners) is governed by the need for maximum charge neutralization,[42,43] could cause kinetic acidities to be more sensitive to steric factors.

In contrast, α-CH proton transfer in SET-promoted photoreactions of tethered amino-enones occurs in an intramolecular fashion. The proton transfer transition states **17** (Figure 101.1) are significantly different from those involved in the stilbene–amine CIRP. The intramolecular nature of proton transfer in the enone–amine zwitterionic biradicals disfavors coplanar alignment of the aminium radical α–CH σ–orbital and nitrogen *p*-orbital. This conformational requirement could very well lead to a minimization



16 **17**

FIGURE 101.1 Proton transfer transition states involved in stilbene–amine and tethered amino–enone photoreaction pathways.

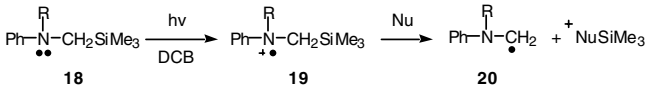
of steric effects on the proton transfer process. Also, proton transfer in this case occurs to a less basic anion radical than in the stilbene–amine system and this may translate into a later, more α–amino-radical-like transition state for proton transfer. As a result, electronic (radical stabilizing) properties of substituents may be more dominant in governing the relatives rates of proton transfer in amino–enone zwitterionic biradicals. Consistent with this proposal is the observation that kinetic acidities observed for intramolecular proton transfer in the amine–enone derived zwitterionic biradicals closely parallel thermodynamic acidities as judged by estimated relative pKa values.[30]

101.6 Desilylation Reactions of α-Trialkylsilylaminium Radicals

Laser Flash Photolysis Measurements of Desilylation Rates

α-Silylamines are more easily oxidized than their non-silicon-containing counterparts (Table 101.1). This is attributable to an aminium radical stabilizing interaction between a high-energy α-CSi orbital and the half filled *p*-orbital on nitrogen. This effect also results in kinetic instabilty because the α-CSi bond is weakened and the silicon is made more electropositive by the orbital interaction. As a consequence, silophiles promote C–Si bond cleavage in α-silylaminum radicals, resulting in the formation of carbon centered α-amino radicals.

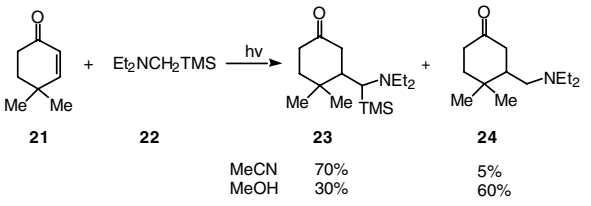
Mariano, Falvey, Yoon, and Su[27,44] probed the dynamics of aminium radical desilylation using time-resolved laser flash photolysis studies of SET photoreactions of 1,4-dicyanobenzene (DCB) and N-silylmethylanilines **18** (Scheme 12). Interestingly, the rate of desilylation of the anilinium radical **19** (R = Me), formed by SET from the corresponding aniline to DCB, is slow and not competitive with back-SET (BSET) when weak silophiles such as MeCN are present. However, in the presence of good silophiles, such as MeOH or water, desilylation of **19** (R = Me) occurs more rapidly than either BSET or α-deprotonation. Second-order rate constants for the desilylation processes are found to parallel the silophilicity of the silophile (e.g., 8.9×10^5 M^{-1} s^{-1} for MeOH and 1.3×10^6 M^{-1} s^{-1} for H_2O, and 3.1×10^9 M^{-1} s^{-1} for fluoride ion in MeCN).



18 **19** **20**

SCHEME 12

In a fashion similar to amine cation radical α-CH-deprotonation reactions, the presence of electron-withdrawing substituents on nitrogen results in a significant enhancement of the rates of desilylation of α-silylaminium radicals. This is seen in comparisons of the second-order rate constants for methanol-promoted desilylation of anilinium radicals **19** having N-methyl (R = Me, 9×10^5 M^{-1} s^{-1}), N-ethoxycarbonyl



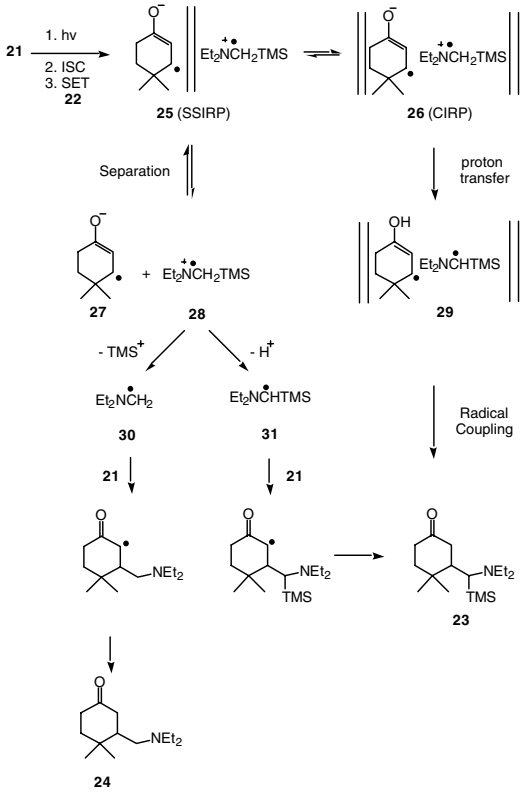
SCHEME 13

(R = CO_2Et, 2×10^7 M^{-1} s^{-1}), and N-acetyl (R = COMe, 6×10^7 M^{-1} s^{-1}) substituents. Because an N-electron-withdrawing group pronouncedly increases the oxidation potential of the silylaniline **19** while having little effect on the stability of the resulting α-amino radical **20**, the rate acceleration is attributable to destabilization of the amine cation radical.

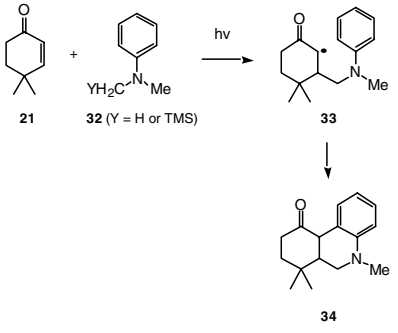
The Influence of Desilylation Rates on SET Photoreactions of α–Silylamines

The results of early studies by Mariano, Yoon, and co-workers[45,46] demonstrated that SET-promoted photoreactions of α-silylamines are governed in unique ways by the relative rates of aminium radical desilylation and deprotonation. An example is found in the photoaddition reactions of silylamine **22** and cyclohexenone **21** (Scheme 13). The polarity and protic nature of solvents used for this process govern the relative efficiencies for formation of the TMS and non-TMS photoadducts **23** and **24**. Production of the TMS-adduct **23** is favored when the photoreaction is conducted in low-polarity aprotic solvents (e.g., MeCN) while the non-TMS-adduct **24** predominates in processes occurring in high-polarity protic media (e.g., MeOH). A more detailed study of this phenomenon demonstrates that the non-TMS to TMS adduct ratio (**24**:**23**) increases as the polarity of the solvent increases. This trend is even more pronounced when the solvents are comprised of a series of alcohols of varying nucleophilicity (MeOH > EtOH > n-PrOH > *t*-BuOH). Finally, this effort shows that salts also exhibit a similar effect on the non-TMS to TMS adduct ratio. For example, the **24**:**23** ratio from photoreactions of enone **21** with silylamine **22** in MeCN increases significantly as the concentration of $LiClO_4$ is increased. On the other hand, increasing the concentration of amine **22** results in decrease of the adduct ratio (**24**:**23**).

These observations suggest that the nature of photoreactions of cyclohexenone-silylamine systems is controlled by factors that govern the chemical reactivity of the intermediate aminium radicals. A reaction sequence involving the intermediacy of different types of enone anion and amine cation radical pairs is proposed to account for these results (Scheme 14). The reaction is initiated by SET from the silylamine **22** to triplet excited state of **21**, generating a solvent-separated ion radical pair (SSIRP) **25**. Proton transfer in one route to the TMS–adduct **23** requires that a contact ion radical pair (CIRP) **26** form first. In aprotic solvents of low polarity, formation of the CIRP would be favored, owing to the fact that stabilization between the oppositely charged radicals is more effective than with the solvent. α-Proton transfer from the most kinetically acidic site (see above) in the aminium radical to the enone anion radical occurs in the CIRP to generate the caged radical pair **29,** which undergoes radical coupling to give the TMS–adduct **23**. In polar protic solvents (MeOH), transformation of SSIRP to free radical ions (**27** and **28**) would be more facile due to strong solvation of the radical ions by H-bonding and dipole interactions. Salts, especially those that contain an oxophilic metal cation (Li^+), have a similar effect on enhancing free radical ion formation. Two possible reaction pathways are available to the solvated free α–silylaminium radical **28**. When the concentration of amine **22** (a base) is low and the solvent is highly silophilic, desilylation of **28** is expected to predominate over deprotonation. This yields the α-amino radical **30**. On the other hand, when the amine concentration is high, deprotonation of **28** becomes competitive with desilylation and a mixture of **30** and the TMS-containing radical **31** is produced**.** Conjugated addition of **30** or **31** to the ground state of enone **21** then gives rise to the respective non-TMS or TMS–adduct **24** or **23**.



SCHEME 14



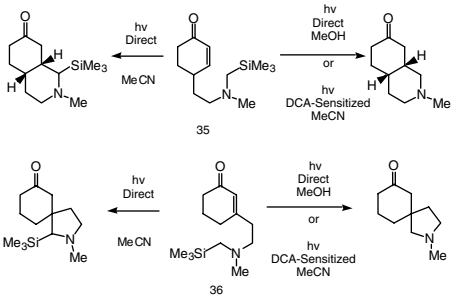
SCHEME 15

To further investigate the modes of C–C bond formation (specifically the competition between radical coupling and radical conjugate addition routes) in the SET-promoted photoaddition of amines to conjugated enones, Mariano and co-workers[47] designed a system in which intramolecular trapping of the putative α-ketoradical would reveal the operation of the radical conjugate addition mechanism (Scheme 15). For this purpose, photoaddition reactions of N,N-dimethylaniline and its silyl analog **32** (Y = H or TMS) were investigated. The observed formation of the tricyclic adduct **34** in photoreactions of the silyl-aniline in polar silophilic solvents indicates that the keto-radical **33** is an intermediate in this

process. Also, it shows that the radical conjugate addition pathway is a competitive, if not exclusive, pathway followed in photoreactions proceeding through the intermediacy of free ion radical intermediates.

That base strength of the enone anion radical **27** is an important factor governing the relative rates of deprotonation, and desilylation of the silylaminium radical **28** is further evidenced by additional observations made in related photochemical studies. For example, 9,10-dicyanoanthracene (DCA) SET-sensitized photoaddition reaction of silylaniline **32** (R = TMS) and cyclohexenone **21** in MeCN leads to near-exclusive production of the non-TMS-containing tricyclic ketone **34**. In this case, desilylation of the intermediate anilinium radical predominates over deprotonation even when the solvent is not highly silophilic because the DCA anion radical is a very weak base. In addition, non-TMS-containing adducts are generated exclusively in direct SET-promoted photoaddition reactions of silylamine **22** in the weakly silophilic solvent MeCN with a variety of acceptors, including DCA,[48] acenaphthenoquinone,[49] and N-methylphthalimide.[50] Thus, unlike the anion radicals of conjugated enones, which have a pKa value of *ca.* 10 (H_2O),[51,52] those of DCA (pKa < 0),[53,54] α-diketones (pKa *ca.* 5),[51] and phthalimides (pKa < 7)[52] are much less basic.

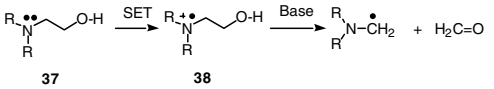
The ability to control the nature and regiochemistry of fragmentation reactions of silylamine cation radicals by the choice of solvent has served as a key component in the design of new and highly efficient SET-promoted photocyclization reactions. This is demonstrated by observations made in studies of photochemical transformations of the silylaminoethyl-cyclohexenones **35** and **36** (Scheme 16), where cyclizations occur to give non-TMS products cleanly on direct irradiation in MeOH or DCA-sensitized irradiation in MeCN. In contrast, TMS-containing spirocyclic products are formed exclusively when MeCN is used as solvent for the direct irradiation reactions.[40,55] The much higher degrees of chemoselectivity in these processes as compared to their intermolecular counterparts are presumably due to the fact that low amino–enone concentrations of *ca.* 1×10^{-3} *M* are used in the intramolecular systems. Consequently, amine induced deprotonation of the intermediate amine cation radical is less favorable.



SCHEME 16

101.7 Heterolytic Cleavage of Aminium Radicals Derived from β-Aminoalcohols

Davidson and co-workers[56] were the first to observe that aminium radicals, derived by SET oxidation of β-aminoalcohols, undergo C–C bond-cleaving fragmentation by a pathway that is analogous to a retro-Aldol process (Scheme 17). Both the mechanistic features and chemical and biochemical applications of this process have received much attention. An analysis[57–61] of the thermochemical and electrochemical properties of β-aminoalcohols indicates that the bond dissociation energy of the cleaving C–C bond in the aminium radical **38** is much lower than that in the parent neutral molecule **37**. Thus, retro-Aldol-like fragmentations have high thermodynamic driving forces. In a related manner, thermochemical calculations suggest that the corresponding C–C bond in the 1,2-diamine radical cation is slightly weaker than that in amino alcohol derived aminium radicals.[62,63]

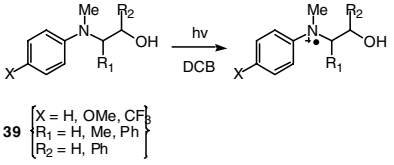


SCHEME 17

Base-Induced Retro-Aldol Cleavage of β-Aminoalcohol Derived Aminium Radicals

Investigations by Schanze[64,65] have demonstrated that retro-Aldol fragmentation of β-aminoalcohol-derived aminium radicals takes place relatively slowly in the absence of base and that this process is accelerated by the addition of bases. Schanze and co-workers observed that the rate constants for deprotonation of aminium radicals, derived from the β-hydroxyanilines $ArNHCH_2CH(Ph)OH$, by pyridine fall in the range of 10^5 to 10^7 M^{-1} s.$^{-1}$ When the hydroxyl hydrogen in these cation radicals is replaced by deuterium, kinetic isotope effects in the range of 1.3 to 4 are observed, and the magnitude of these effects is inversely related to the basicity of the proton acceptor. Furthermore, rate data for deprotonation reactions of these aminium radicals with substituted pyridines can be fitted to the Brønsted relationship. Thus, the mechanism for retro-Aldol fragmentation of β-aminoalcohol cation radicals most likely involves base-induced deprotonation in concert with C–C bond cleavage.

Similar results have come from laser flash photolysis studies by Su and co-workers.[44] This effort probed the kinetics of acetate-induced fragmentation reactions of cation radicals derived by photoinduced SET from a variety of β-anilinoethanols **39** (Scheme 18) to 1,4-dicyanobenzene. The data demonstrate that, like in related α-CH deprotonation and desilylation reactions, substituents that destabilize the β-hydroxyanilinium radical enhance the rates of retro-Aldol cleavage. (e.g., **39** ($R_1 = R_2 = H$) (X = OMe), k = 2.8×10^4 $M^{-1}s^{-1}$; (X = H), k = 4.1×10^4 $M^{-1}s^{-1}$; (X = CF_3), k = 3.1×10^5 $M^{-1}s^{-1}$). In addition, alkyl substitution at the R_1 position slows fragmentation (e.g., **39** (R_1 = Me, R_2 = H, X = H), k = 3.3×10^4 $M^{-1}s^{-1}$) and phenyl substitution at the R_2 position accelerates the process (e.g., **39** (R_1 = H, R_2 = Ph, X = H), k = 3.1×10^5 $M^{-1}s^{-1}$).



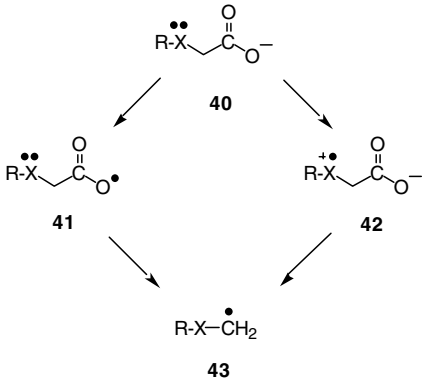
SCHEME 18

A comparison of the rate constants for acetate-induced α-CH deprotonation of anilinium radicals (**6**, Scheme 6) with those for retro-Aldol fragmentation of related β-hydroxyanilinium radicals promoted by the same base gives rise to a perplexing conclusion. Specifically, the α-CH deprotonation rates are larger than those for retro-Aldol cleavage in comparably substituted anilinium radicals. Yet, retro-Aldol fragmentation is the predominant pathway followed. This finding suggests that β-hydroxyanilinium radicals are inherently less reactive than related anilinium radicals, which do not have β-hydroxy substitution. A possible source for this effect might be a through-space interaction of the filled oxygen sp^3-orbital and half filled nitrogen *p*-orbital, which would stabilize the hydroxyl-substituted charged radical intermediates.

101.8 Decarboxylation Reactions of Aminium Radicals Derived from α-Amino Carboxylates

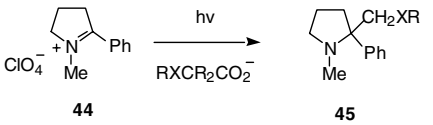
SET Pathways in the Photoinduced Decarboxylation of α-Heteroatom Substituted Carboxylates

Early investigations of the photochemistry of α-heteroatom substituted carboxylates **40** (Scheme 19) concentrated on the operation of SET processes. These substances possess two potential electron donor sites. SET from the carboxylate moiety leads to formation of an acyloxy radical **41** while SET from the heteroatom center gives rise to a zwitterionic radical **42**. Subsequent loss of carbon dioxide from either of these intermediates yields the same carbon-centered, heteroatom-stabilized radical **43**. The critical factors determining which of these pathways is responsible for the SET-promoted decarboxylation reactions of substrates in this family is (1) the relative oxidation potentials of the two potential donor moieties and (2) the relative rates of decarboxylation of intermediates **41** and **42**. Redox potential data indicate that electron transfer from sulfur (E(+) = *ca.* 0.4 V) and nitrogen (E(+) = ca. 0.7 V) centers to acceptors should be thermodynamically more favorable than from carboxylate groups (E(+) = *ca.* 1.4 V).



SCHEME 19

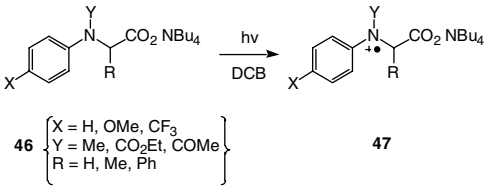
Ohga and co-workers[66,67] carried out an interesting study that provides important information about the nature of decarboxylation reactions of α-heteroatom-substituted carboxylates. It is known that the singlet excited state of N-methyl-2-phenyl-1-pyrrolinium perchlorate (**44**) (Scheme 20) participates as an acceptor in SET-promoted photochemical reactions.[67–69] As expected, irradiation of this salt in the presence of a variety of α-heteroatom substituted carboxylates leads to efficient formation of substituted pyrrolidines **45**. The adducts are generated by sequential SET, decarboxylation, radical coupling pathways. Moreover, Stern-Volmer analysis of data obtained from fluorescence quenching of **44** by reversible SET from α-heteroatom-substituted and simple carboxylates clearly shows that SET is more favorable from nitrogen and sulfur centers than from the carboxylate grouping. For example, near-diffusion-limited fluorescence quenching is observed for $HSCHMeCO_2$ and $H_2NCH_2CO_2$, whereas quenching by acetate occurs an order of magnitude more slowly.



SCHEME 20

Stern-Volmer analysis of excited-state emission quenching data has also been used by Davidson and co-workers[70,71] to probe SET pathways involved in photoinduced decarboxylation reactions of α-thio- and α-amino-substituted carboxylic acids. In this study, Davidson compared k_q values for benzophenone triplet excited state quenching by the substituted carboxylic acids with those for quenching by related heteroatom electron donors not containing the carboxylic acid function. The data obtained reveal a striking similarity between these rate constants, strongly suggesting that SET from the heteroatom is the predominant mode of triplet benzophenone quenching by the α-thio- and α-amino-substituted carboxylic acids.

Laser flash photolysis techniques have been employed to evaluate the dynamics of decarboxylation reactions of cation radicals derived from α–aminocarboxylates.[44,72] In one report,[44] variously substituted aminium radicals **47** were generated by laser flash excitation of anilinocarboxylates **46** (Scheme 21) in MeCN solutions containing the acceptor, 1,4-dicyanobenzene. These transients undergo fast, first-order decay by a pathway involving loss of carbon dioxide. The rate constants for decarboxylation were found to be in the range of 8×10^5 to 4×10^6 s^{-1}. In addition, the rates show the same dependence on nitrogen, α-alkyl and α-phenyl substituents, as do the related α-CH deprotonation, α-desilylation, and retro-Aldol cleavage reactions.

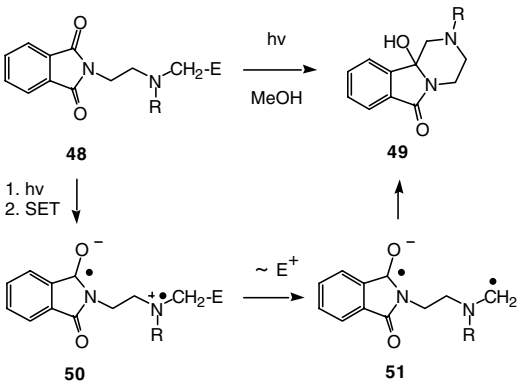


SCHEME 21

The nature and concentration of added metal cations play a major role in governing the rates of decarboxylation of anilinocarboxylate-derived aminium radicals. For example, the rate of decarboxylation of the tetrabutylammonium derivative of **47** (X = R = H, Y = Me) decreases from 4.1×10^6 s^{-1} to 3×10^5 s^{-1} when the concentration of added $CsClO_4$ is increased from 1 to 100 m*M*. Also, $LiClO_4$ has a greater effect on lowering the decarboxylation rate than does $CsClO_4$ (1.1×10^6 s^{-1} vs. 2.9×10^6 s^{-1} at 10 m*M*, respectively) and $Ca(ClO_4)_2$ greatly retards this process (8×10^4 s^{-1}at 10 m*M*). These observations suggest that the aminium carboxylate decarboxylation reaction is dependent in a predictable manner on the oxophilic nature of metal cations and that free carboxylates lose carbon dioxide faster than do their metal cation-ligated analogs.

The Influence of Decarboxylation Rates on SET-Photoreactions of α–Amino Carboxylates

The data presented above demonstrate that the rates of α-heterolytic fragmentation reactions of aminium radicals are principally governed by the nature of the leaving electrofugal group. In addition, nitrogen and side-chain substituents in these reactive intermediates also contribute in governing the rates of these processes. The speed with which aminium radical α-heterolytic cleavage occurs plays a significant role in determining the chemical yields (see above) and quantum efficiencies of SET-promoted photoaddition and photocyclization reactions of amine substrates. In these excited-state reactions, fragmentation in the direction of product formation competes with photon wasting, back electron transfer to generate ground states of the amine reactants. As a consequence of this competition, the quantum efficiencies of reactions of structurally related amines should correlate with the rates of α-heterolytic cleavage. A demonstrative example of this relationship is found in the photochemistry of the N-(aminoethyl)phthalimides **48** (Scheme 22).[44] Irradiation of these substrates in MeOH solutions containing either 0.3 *M* n-Bu_4NOAc or n-Bu_4NClO_4 results in production of the corresponding tricyclic-amidols **49**. These products arise by pathways involving initial intramolecular SET from the amine to the excited phthalimide. This is followed



SCHEME 22

by fragmentation of aminium radical **50** and C–C bond formation in the resulting biradical **51**. The quantum yields of these cyclization reactions display a dramatic dependence on the nature of the electrofugal group in a manner that parallels aminium radical fragmentation rates (e.g., for **48** (R = Me, E = H, with 0.3 *M* n-Bu_4NOAc) $\phi = 0.003$, for **48** (R = Me, E = TMS, 0.3 *M* n-Bu_4NClO_4) $\phi = 0.039$, and for **48** (R = Me, E = CO_2NBu_4, 0.3 *M* n-Bu_4NClO_4) $\phi = 0.32$).

Acknowledgments

The authors express their deep appreciation to their enthusiastic, hard-working, and productive coworkers whose studies in the area of amine electron transfer photochemistry established the basis for the results presented in this review. Also, the generous financial support given to the PSM research group by the National Institutes of Health and the National Science Foundation and to the UCY research group by the Korea Science and Engineering Foundation (Basic Research Program 2001-1-12300-006-3, International Cooperative Research Program, and CBM of POSTECH) is acknowledged.

Remote Functionalization by Alkoxyl Radicals Generated by the Photolysis of Nitrite Esters: The Barton Reaction and Related Reactions of Nitrite Esters

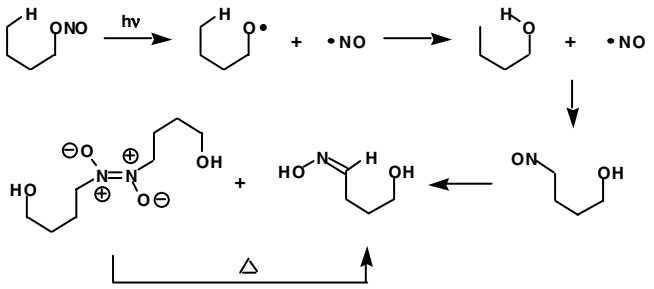
Hiroshi Suginome
Hokkaido University

102.1 Definition of the Reaction and a Short Historical Background

The photolysis of organic nitrites of appropriate constitution and conformation in solvents such as benzene, toluene, or acetonitrile transforms them into δ-nitroso alcohols via a homolytic fission of the O–N bond of their nitrosoxy group, followed by an intramolecular δ-hydrogen abstraction of the resulting alkoxyl radicals to generate a δ-carbon radical that combines with the generated nitric oxide. The nitroso alcohols are isolated as δ-hydroxyimino alcohols via a spontaneous thermal isomerization or the nitroso-dimers[1] (Scheme 1). This transformation has been named the "Barton reaction."[2]

Thompson and colleagues initiated spectroscopic as well as photochemical investigations of organic nitrites in the vapor phase during the 1930s at Oxford.[3] The interpretation of the primary mode of the photochemical decomposition of nitrite esters by Thompson, however, differed from what has now become established as the primary process for nitrite photolysis. Subsequent to Thompson's study, Coe

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1

and Doumani reinvestigated the vapor-phase photolysis of *t*-butyl nitrite, confirming that the products of photolysis were acetone and nitrosomethane[4] (Scheme 2). They interpreted the results in terms of a concerted photochemical molecular rearrangement of *t*-butyl nitrite because no ethane was detected in this photolysis.

SCHEME 2

Gray and Style proposed, for the first time, that the primary step of nitrite photolysis is the homolysis of the ONO bond, based on their study on the photolysis of methyl nitrite.[5] The process was entirely analogous to a mechanism that had already been proposed for the gas-phase pyrolysis of organic nitrites by Steacie.[6] Tarte then undertook an extensive investigation of the photolysis of primary, secondary, and tertiary alkyl nitrites, believing that his results could be accommodated by either of the two possible mechanisms,[7] depending on the wavelength of the incident light and the structure of the alkyl nitrite.

Since these early studies on nitrite photolysis, a number of extensive synthetic and physicochemical studies on the photodissociation of steroidal alcohol nitrite esters and simple alkyl nitrites, such as *t*-butyl nitrite (as summarized by Calvert and Pitts, Jr.[8]), established that the primary reaction of the photolysis of nitrite esters in solution is the homolysis of the ONO bond of their nitrosoxy groups to give alkoxyl radicals and nitric oxide (Scheme 3).

SCHEME 3

The sophistication of the physicochemical details of the photodissociation process of the ONO bond of prototype alkyl nitrites, such as methyl, ethyl, and *t*-butyl nitrites,[9a] (and the SNO bond of thionitrites[10]) in the gas phase,[9b] in matrix isolated states,[11] in adsorbed states[9a] and at a shorter wavelength band (S_2 state),[12] etc. is continuing today through newer techniques. These aspects are beyond the present discussion.

The photochemistry of nitrite esters, however, became the subject of considerable attention by organic chemists when Barton ingeniously showed its usefulness for organic synthesis in the beginning of the 1960s.[1] He and his colleagues showed that the photolysis of suitably constituted steroidal alcohol nitrites provoked an intramolecular exchange of the NO of the nitrite group with a hydrogen atom attached to a carbon atom in the δ-position, as mentioned above. This reaction has been shown not only to be one of the most useful photochemical processes for the selective functionalization of an unactivated carbon atom in organic synthesis, but has also led to a renaissance of the concept of remote functionalization

by an intramolecular reaction, such as the Hofmann-Löffler-Freytag reaction.[13] This led to the general recognition of the utility of photochemical and radical reactions in organic synthesis.

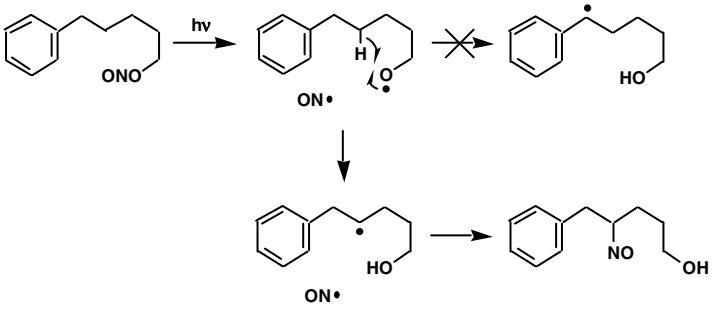
The historical and mechanistic aspects and the synthetic applications of the reaction have been the subject of a number of comprehensive review articles by Barton[14] himself, as well as his pupils.[2,15]

102.2 Mechanism of the Barton Reaction

Alkyl nitrites, which can readily be prepared either by reactions of the corresponding alcohols with nitrosyl chloride in pyridine[1] or by an exchange reaction between the alcohols and *t*-butyl nitrite,[16] exhibits UV absorptions in two regions: a broad, unstructured band centered at ca. 210 nm (ε = 1000 to 1700) and a structured band at ca. 360 to 380 nm (ε = ca. 80).[8,17] The absorption at the longer wavelength band (S_1) is assigned to the ($n\pi^*$) transition; that at the shorter wavelength band (S_2) is assigned as being due to a $\pi\pi^*$ transition and possibly higher excited states.[8,9b,18] The irradiation of the weak $n\pi^*$ band causes a homolysis of the ONO bond to give the corresponding alkoxyl radicals and nitric oxide with a quantum yield of 0.7, as proved by the photolysis of steroidal nitrite esters in methanol with 365-nm monochromatic light.[17] A quantum yield of 0.76 was also reported for the photolysis of octyl nitrite in heptane.[19] A quantum yield less than unity in the solution photolysis of the nitrites may indicate the reversibility of the primary process of the dissociation. The photodissociation of *t*-butyl nitrite at 193 nm using a newer technique has recently been reported.[12]

The thermolysis of nitrite esters in solution, on the other hand, resulted in the decomposition of nitrite esters and did not lead to any homolysis of the ONO bond. This was attributed to ionic decomposition due to protonation of the ONO group with adventitious protons as an impurity in the solution.[20]

Alkoxyl radicals thus generated intramolecularly abstract a hydrogen that is appropriately located. A number of experiments with a variety of cyclic and acyclic systems[2,15,21,22] have established that hydrogen abstraction involving a six-membered cyclic transition state is preferred over that involving five- or seven-(and more) membered cyclic transition states; the alkoxyl radical generated by the photolysis of the nitrite of 5-phenylpentanol abstracts a hydrogen attached to the δ-carbon, but not a hydrogen attached to the ε-carbon, to generate stabilized benzyl radicals[21] (Scheme 4). On the basis of a number of results in the steroid field, together with an inspection of Dreiding models, the most appropriate distances between an alkoxy radical and a carbon bearing a hydrogen atom to be abstracted have been estimated to be in the 2.5 to 2.7 Å range.[23]

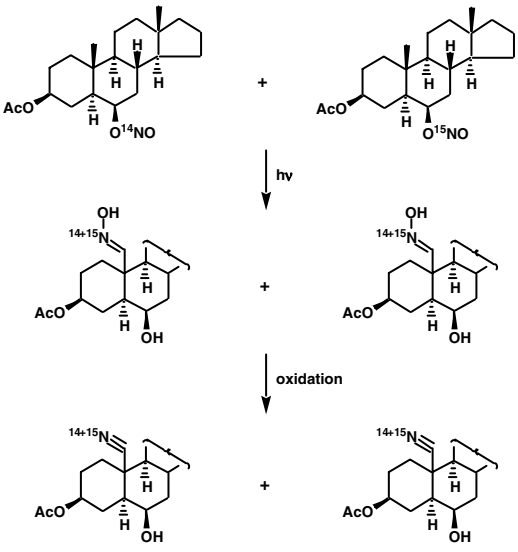


SCHEME 4

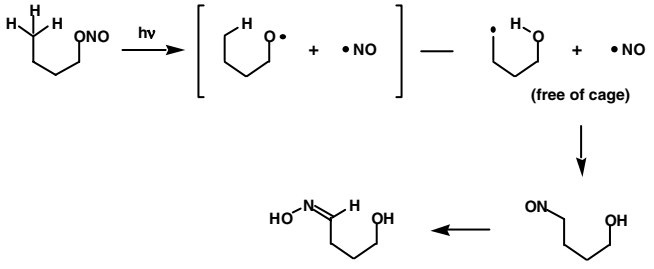
Carbon-centered radicals thus generated then combine with nitric oxide to form nitroso compounds, which readily isomerize to afford the corresponding oximes (or nitrosodimers[24]). Quantum-yield studies of the overall process cited above[8,17] indicated that this free radical reaction is not a chain process. The behaviors of the nitric oxide generated in the solution was studied by using labeled nitrites;[25,26] the photolysis of an equimolecular mixture of ^{15}N nitrite A and ^{14}N nitrite B gave a mixture of two products (arising from intramolecular hydrogen abstraction) in which ^{15}N and ^{14}N were completely scrambled

in the two products[25,26] (Scheme 5). It was thus concluded that a cage structure in which NO is kept in the solvent cage during the entire process does not exist. A similar mass spectrometric determination on the nitrite recovered after partial completion of the photolysis showed that no scrambling took place at this stage. These experiments indicated that non-cage combinations take place after hydrogen abstraction, although the primary homolysis step is a cage process, as outlined in Scheme 6.[25]

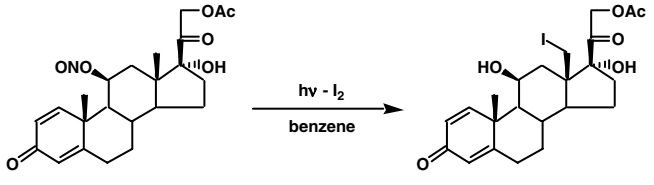
In agreement with this mechanism, 18-iodopredonisolone 21-acetate, but not the 18-oxime, is obtained when predonisolone 11β-nitrite 21-acetate in benzene is photolyzed in the presence of iodine (Scheme 7).[27]



SCHEME 5



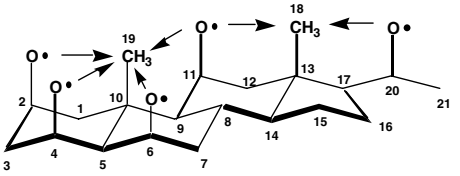
SCHEME 6



SCHEME 7

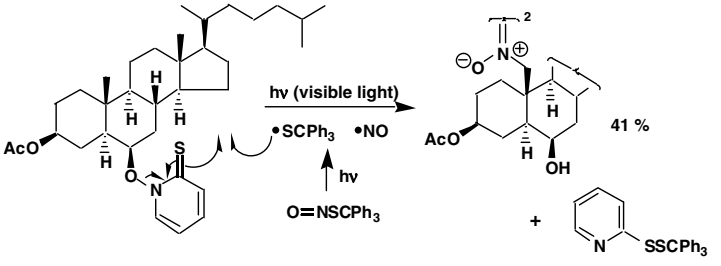
102.3 Synthetic Applications

Because angular methyl groups and alkoxyl radicals with a 1,3-diaxial relationship in a rigid steroid and some terpenoid molecules ideally satisfy hydrogen abstraction through a 6-membered cyclic transition state, the Barton reaction has most successfully been applied to the field of steroids and some di- and triterpenoids. By this reaction, functional groups can, in principle, be introduced into the unactivated angular 10β- or 13β-methyl groups of steroids. As shown in Scheme 8, a hydrogen attached to the 13β-carbon can be abstracted by an alkoxyl radical at C11, C15, or C20 and a hydrogen attached to the 10β-carbon from an alkoxyl radical at C2, C4, C6, or C11. Thus, a one-step introduction of functionality into an unactivated position can be achieved.



SCHEME 8

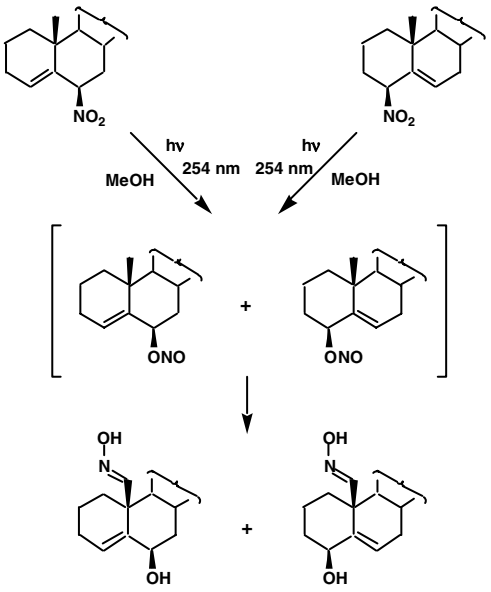
Potier, Motherwell, and their colleagues[28] recently devised a new version of the Barton reaction in which the functionalisation of the10b-methyl of steroids can be achieved by irradiating a solution with visible light instead of ultraviolet light. The method employs O-alkylthiohydroxamates,[29] which have also been proved to be efficient precursors for the generation of alkoxyl radicals. Thus, the irradiation of 6-O-acylthiohydroxamate in benzene containing an equimolecular amount of thionitrite as a donor of NO with a 250-W tungsten lamp gave the nitroso dimer corresponding to the product obtainable by the photolysis of 6β-ol nitrite, in 41% yield (Scheme 9).



SCHEME 9

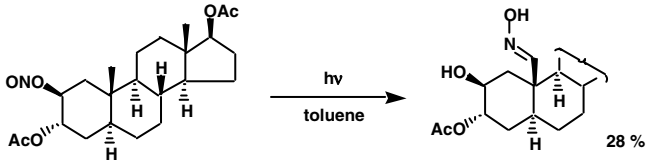
Suginome and collaborators have discovered a tandem Barton-remote-functionalization through the photochemical nitro-nitrosoxy rearrangement.[30] Thus, photolysis of 6β-nitrocholest-4-ene in methanol with 254-nm light gave 19-hydroxyiminocholest-4-en-6β-ol and its 5-ene-4β-ol isomer, along with accompanying formations of cholest-4-en-6-one and cholest-4-en-6β-ol. The isomeric 4β-nitrocholest-5-ene reacted in an entirely analogous manner, as outlined in Scheme 10. The products are formed via successive reactions; homolysis of CN, recombination of generated NO_2 to give nitrites, and the Barton reaction.

In the following, some representative examples among the numerous applications of this reaction found over four decades are presented. For more details of each example of functionalization, readers should consult the review articles and original papers cited:[2,15]



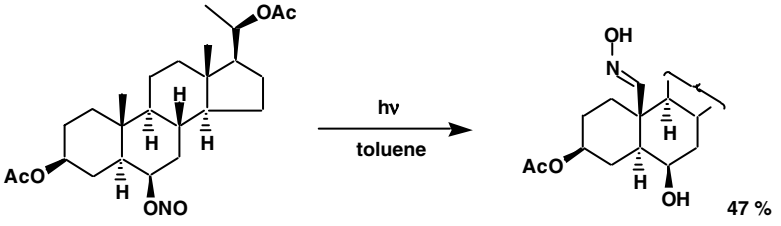
SCHEME 10

1. Functionalization of 10β-Me of a steroid from the 2β-ol nitrite[31] (Scheme 11)



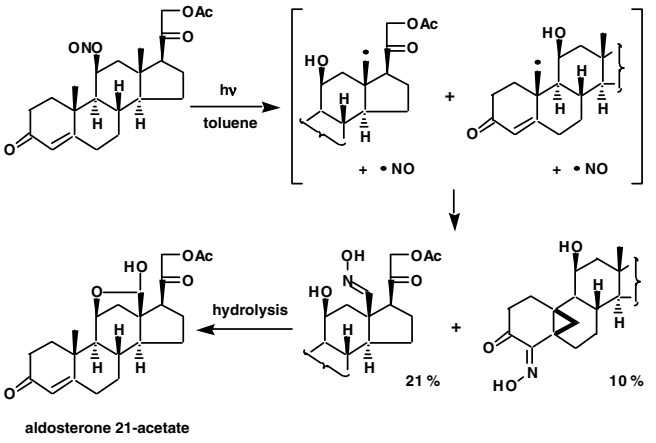
SCHEME 11

2. Functionalization of 10β-Me of a steroid from the 6β-ol nitrite[1,28] (Schemes 9 and 12)

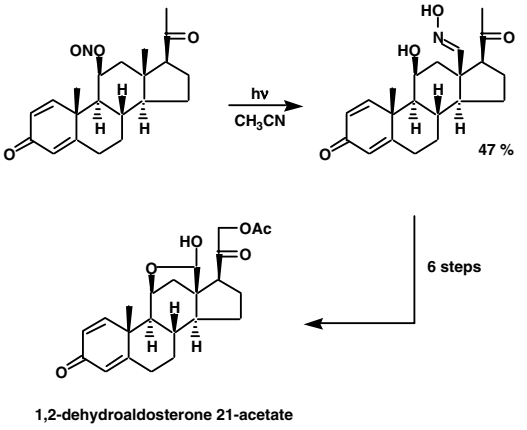


SCHEME 12

3. Functionalization of 10β- and 13β-Me of steroids from the 10β-ol nitrite: synthesis of aldosterone acetate[32,33] (Schemes 13 and 14)



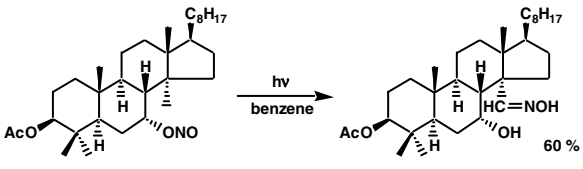
SCHEME 13



SCHEME 14

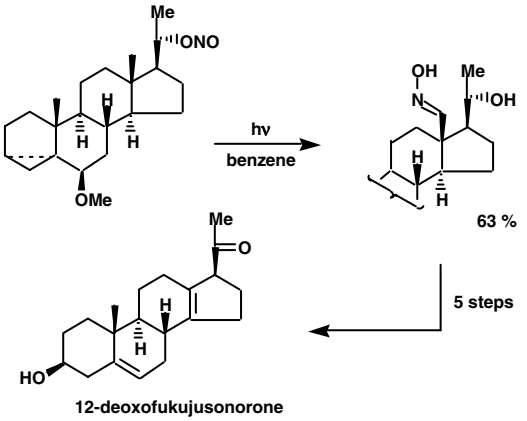
These examples are the most well-known applications of the reaction found by Barton as well as by his colleagues. The irradiation of corticosterone acetate nitrite affords aldosterone acetate oxime, which with nitrous acid gives aldosterone 12-acetate (Scheme 13). The overall yield, however, is rather low (15%) because an attack by the 11β-alkoxyl radical on C19 competes with the desired attack on C18. The incorporation of the 1,2-double bond into the nitrite could avoid an undesired C19 attack by the radical; a far better yield (47%) of 19-oxime was achieved, as shown in Scheme 14. These examples of the functionalization may indicate that the Barton reaction is sensitive to structural changes and that the distance and conformation requirements between the alkoxyl radical and the methyl group, which are in a 1,3-diaxial relationship, is rather strict (Scheme 14).

4. Functionalisation of 14α-Me of a steroid from steroidal 7α-ol nitrite[34] (Scheme 15)



SCHEME 15

5. Functionalization of 13α-Me from steroidal 20α-ol nitrite: synthesis of deoxofukujusonorone[35] (Scheme 16)



SCHEME 16

6. Functionalization of an angular methyl of terpenoid[36] (Scheme 17)

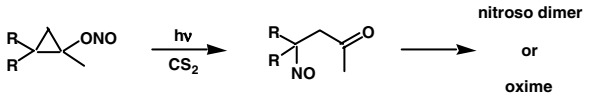
102.4 Accompanying Reactions to the Barton Reaction in the Photolysis of Nitrite Esters

The reactions described here compete with the Barton reaction in the photolysis of nitrites when the alkoxyl radical and the hydrogen to be abstracted are not ideally disposed for the Barton reaction. Representative examples, including the formation paths in each competing reaction, are shown in the schemes below. The fundamental nature of these competitive reactions of alkoxyl radicals generated from simple alcohols has been extensively investigated.[37] The competing reactions occasionally predominate over the Barton reaction (Scheme 24) or comprise an exclusive reaction (Schemes 18 through 23 and 26), which can be used for synthetic purposes. Among these reactions, the β-cleavage is frequently the predominant reaction. Since the 1970s, we have found a variety of new processes in which the β-cleavage of alkoxyl radicals takes place in a highly selective manner. We obtained the first concrete evidence for the reversibility of β-fragmentation.[38] Although little attention was drawn to its potential in synthesis until the 1970s, we recognized that the β-cleavage of alkoxyl radicals is as useful as intramolecular hydrogen abstraction in organic synthesis and have shown the usefulness by synthesizing a variety of natural products using β-cleavage of alkoxyl radicals (generated from alkyl hypoiodites) as the key step. This topic is dealt with in a separate chapter.[39]

β-Fragmentation and Epimerization of Alkoxyl Radicals

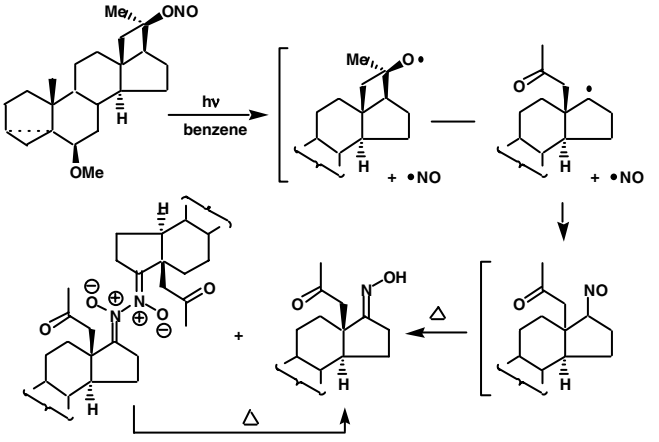
β-Cleavage takes place especially readily when the cleavage relieves some strain, such as cyclopropanoxyl and cyclobutanoxyl radicals, or provides stabilized carbon-centered radicals, such as those conjugated with a heteroatom or tertiary and allyl radicals, as outlined in the following examples.

1. β-Fragmentation of cyclopropanol nitrites[40,41] (Scheme 18)



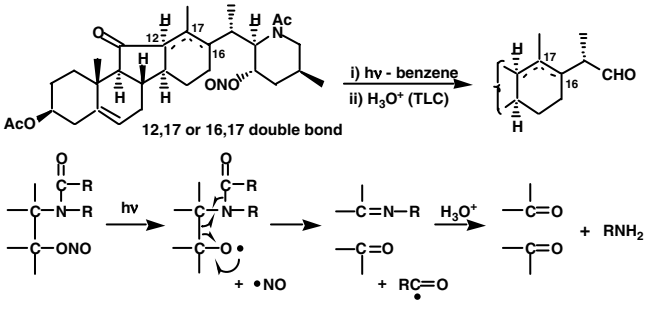
SCHEME 18

2. β-Fragmentation of cyclobutanol nitrite[42] (Scheme 19)



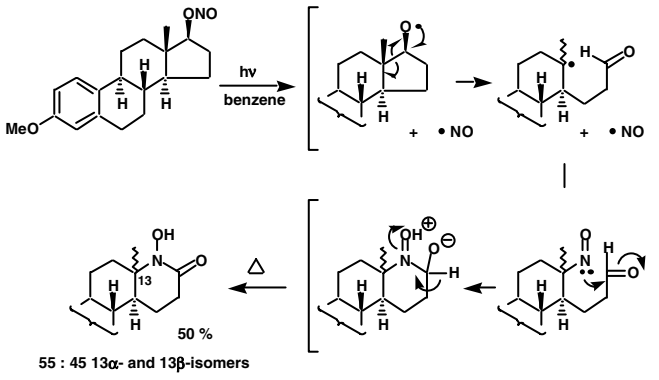
SCHEME 19

3. β-Fragmentation of N-acyl-3-nitrosoxypiperidine ring[43] (Scheme 20)



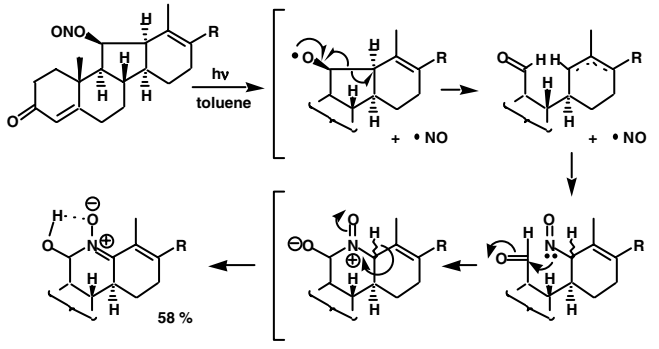
SCHEME 20

4. Formation of cyclic hydroxamic acids[42b,44] (Scheme 21)



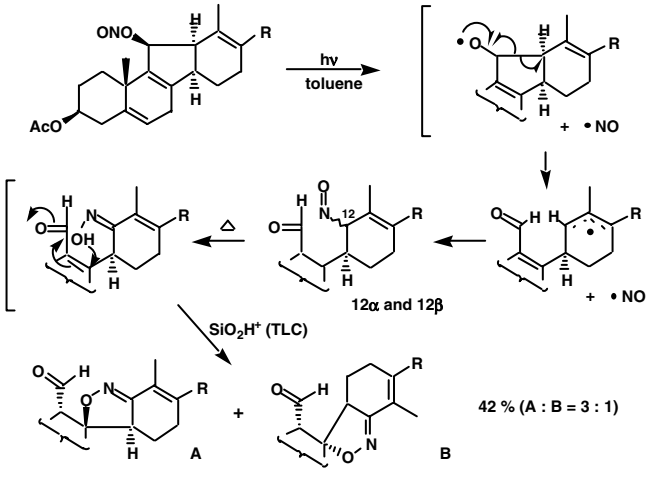
SCHEME 21

5. Formation of cyclic nitrone[17,45] (Scheme 22)



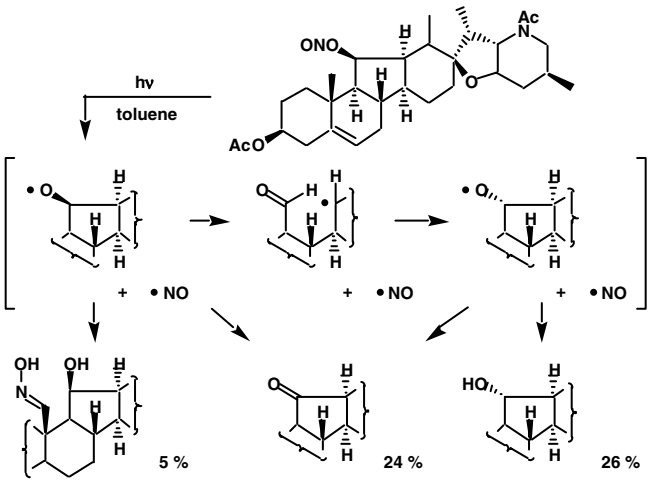
SCHEME 22

6. Formation of spiroisoxazolines[46] (Scheme 23)

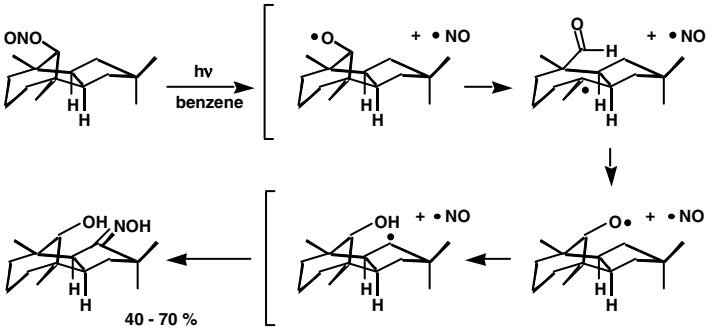


SCHEME 23

7. Epimerization of alkoxyl radicals[38,47] (Schemes 24 and 25)

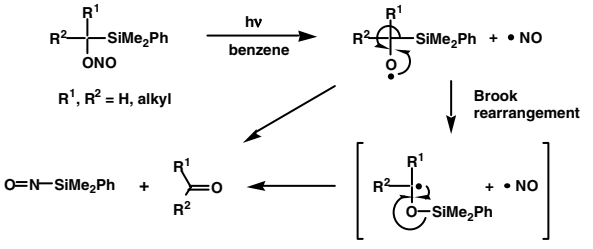


SCHEME 24



SCHEME 25

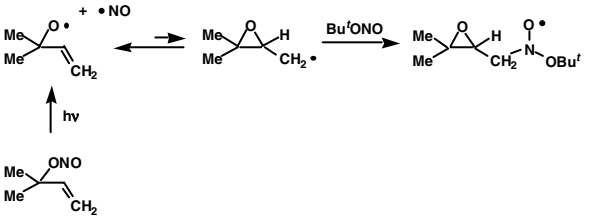
8. β-Fragmentation of β-silyl alkoxyl radicals[48] (Scheme 26)



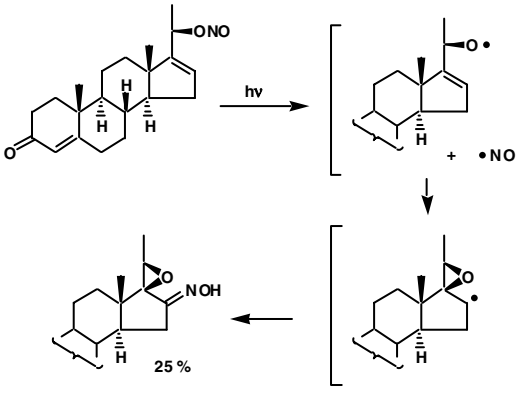
SCHEME 26

Intramolecular Addition of the Alkoxyl Radicals to the CC Double Bond[49]

1. The formation of oxirane[50,51] (Schemes 27 and 28)

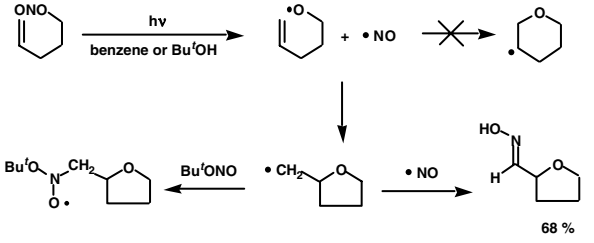


SCHEME 27



SCHEME 28

2. The formation of a tetrahydrofuran ring[51,52] (Scheme 29).



SCHEME 29

Disproportionation or α-Hydrogen Fission

The photolysis of cyclic secondary alcohol nitrites is sometimes accompanied by the formation of the corresponding cyclic ketones via loss of the α-hydrogen of the alkoxyl radicals arising from either disproportionation or, less likely, α-hydrogen fission.

Intermolecular Hydrogen Abstraction

The parent alcohols are formed as a by-product via hydrogen abstraction from another molecule when the above-mentioned reactions are inefficient.

The untimely death in 1998 of Derek Barton, the inventor of the reaction, is a great loss to organic photochemistry and radical chemistry.

The Barton reaction is considered to be one of the classics of the photo- and radical reactions in organic chemistry. Although its application to synthesis is rather limited today, the reaction has had a great impact on organic chemists in general and has aroused the interest and imagination of synthetic organic chemists for photo- and radical reactions, in particular. It has contributed to the considerable development of these research fields, as we see today.

Acknowledgments

The author thanks Dr. H. Senboku for his assistance in preparing the diagrams.
