
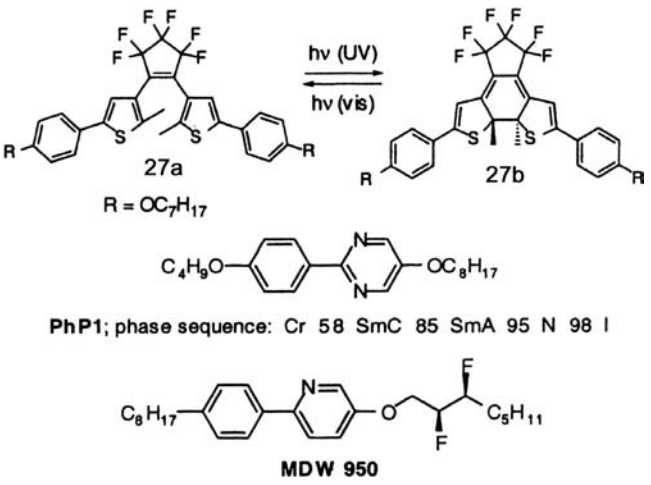

FIGURE 35.15 Structures of doped diarylethene and liquid crystal molecules.

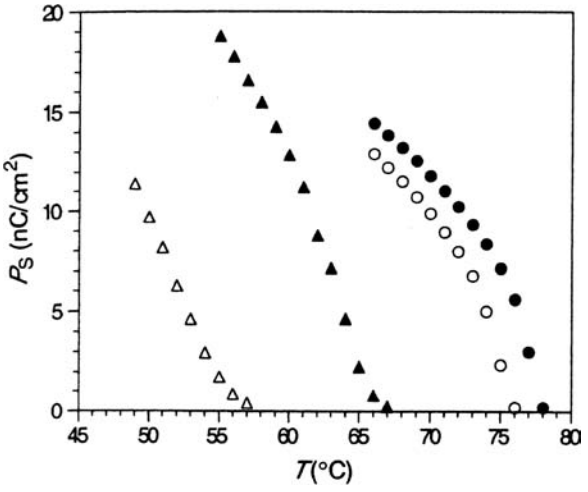

FIGURE 35.16 Spontaneous polarization P_s as a function of temperature T for FLC mixtures doped with **27a** at 1.0 mol % (circles) and 3.0 mol % (triangles) before and after irradiation with UV light (filled and open symbols, respectively).

Spontaneous electric polarization (*Ps*) of ferroelectric liquid crystal (FLC) can be modulated reversibly via photoisomerization of the dithienylethene dopant **27a**.[25] Compound **27a** was doped in a FLC host containing a 10 mol% mixture of the displaytech compound (*S,S*)-5-(2,3-difluorooctyl)-2-(4-octylphenyl)pyridine (**MDW950**) in the achiral SmC liquid crystal 2-(4-butyloxyphenyl)-5-octyloxypyrimidine (**PhP1**). *Ps* was measured as a function of temperature before and after irradiation of the FLC films with 365 nm light for a period of 3 min. As shown in Figure 35.16, photocyclization of the dopant causes the *Ps* vs. *T* plots to shift to lower temperatures. The shift indicates destabilization of the SmA* phase. The SmC*–SmA* transition temperature decreases by 2 K upon irradiation of the 1 mol% mixture and by 10 K upon irradiation of 3 mol% mixture. The spontaneous polarization can be fully restored by reversing the photocyclization by using visible light $\lambda > 455$ nm. The *Ps* photomodulation cycle can be repeated many times without any sign of photochemical degradation.

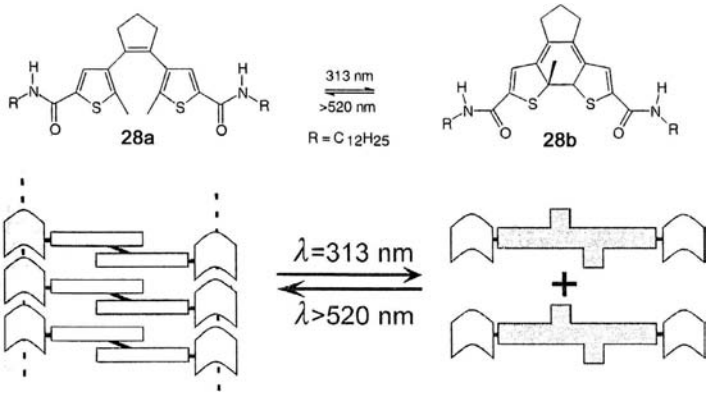

FIGURE 35.17 Photoswitching of diarylethene **28a** and **28b** and thereby controlling the extent of self-assembly of **28** by photochemical switching.

35.7 Self-Assembly

Feringa et al. reported the photocontrolled self-assembly of molecular switches using a diarylethene derivative. As shown in the Figure 35.17, the intermolecular interaction was found to change upon photoirradiation.[26] In the open-ring form **28a**, the two thienyl moieties can rotate along the bond connecting them to the ethene moiety, whereas in the closed-ring isomer **28b** the rotational freedom is lost and the molecule becomes planar. The geometrical change along with the photochemical transformation is expected to change the self-assembling properties of **28**. These researchers observed the viscosity change of the benzene solution containing **28** by alternative UV and visible light irradiation.

35.8 Conclusion

In this chapter we have described various types of diarylethene derivatives with different functionalities. The characteristic features of the photochromic reactions, such as switch of π-conjugation length, geometrical structure changes, and electric as well as vibrational structure changes, can find applications in various molecular photonics devices.

Alexander K. Chibisov
Russian Academy of Sciences

36.1 Introduction

Linear polyenes with push–pull groups are important synthetic organic dyes.[1] Their photophysics and photochemistry have attracted much attention and are the subject of many publications. The influence of the polymethine structure on the spectral-luminescent properties has been described elsewhere.[2–4] Recent work with polymethine dyes, carried out through the 1990s, has been reviewed by Mishra et al.[5] Among the various symmetric cyanine dyes, the classes of indocarbocyanine (**In**), thiacarbocyanine (**Tn**), oxacarbocyanine (**On**), and benzoimidocarbocyanine (**Bn**) in organic and aqueous solution have been intensively investigated. 1,3,3,1′,3′,3′-Hexaalkylindocarbocyanine (**I2**, n = 2), 3,3′-dialkylthiacarbocyanine (**T2**, n = 2), 3,3′-dialkyloxacarbocyanine (**O2**, n = 2) and 1,1′-dialkyl-2,2′-carbocyanine (**B2**, n = 2) are frequently used examples.

[a] All data in the chapter refer to room temperature unless otherwise indicated.
[b] Depending on the counterion.

Here we focus on the literature of photophysical processes and photochemical reactions of cyanine and merocyanine dyes in solution at ambient temperatures. Besides pioneering and fundamental articles,[6–15] mainly recent publications are discussed. This chapter does not include stilbazolium-type dyes and their crown ethers,[5] and data concerning films or adsorbed dyes[16,17] are not covered.

36.2 Photoprocesses of Cyanine Dyes in Organic Solvents

Polymethine dyes, unless they are sterically hindered, are generally present in their all-*trans* form.[18–43] The primary photoprocesses in nonaqueous fluid solution are fluorescence and rotation about a polymethine C-C bond prior to population of a *cis*-photoisomer.

Singlet and Triplet State Properties and *trans*→ *cis* Photoisomerization

The excited singlet state (S_1) of many cyanine dyes at room temperature is characterized by a relatively short lifetime (τ_f) and a low or moderate quantum yield of fluorescence (Φ_f).[2,11] A rather high quantum yield of *trans* → *cis* photoisomerization ($\Phi_{t\text{-}c}$) (Table 36.1) and a large rate constant for rotation about polymethine C-C bonds (k_{rot}) are typical for cyanine monomers.

The temperature dependence of fluorescence shows that *trans* → *cis* photoisomerization as a competing path is activated; the activation energy (E_{rot}) lies in the 15–30 kJ mol^{-1} range (Table 36.2). The viscosity dependence of k_{rot} was intensively studied by picosecond laser spectroscopy.[10,12–14] The relaxation rates of **I2** dyes were interpreted by assuming a viscosity dependence of E_{rot}.[33] The effect of viscosity on nonradiative processes in fluid solution was extended to high pressure.[22] For a homologous series of **T1–T4** dyes, k_{rot} increases with the chain length.[30] The quantum yield, $\Phi_{t\text{-}c,}$ is largest for n = 2 and decreases with increasing chain length. For 1,1′-diethyl-2,2′-dicarbocyanine (**B3**), $\Phi_{t\text{-}c}$ is 2×10^{-4}.[44] Upon high intensity excitation, another isomer becomes detectable for **T3**.[37]

The triplet lifetime (τ_T) of **T2** or **I2** in deoxygenated solution is in the 0.1–100 msec range; the triplet state is quenched by oxygen and the quenching rate constant is up to $3 \times 10^9 M^{-1}\text{sec}^{-1}$.[2,17,28,29] A low quantum yield of intersystem crossing (Φ_{isc}), $<5 \times 10^{-3}$ for several cases (Table 36.1), and a small rate constant (k_{isc}) are typical for monomeric dyes. A long-lived transient is often detected in addition to the triplet state. Its absorption difference spectrum is characteristic for a *cis*-isomer; the decay is temperature dependent and insensitive towards oxygen. The overlapping triplet and isomer spectra can be separated by appropriate conditions.

A frequently examined dye is 3,3′-diethyloxadicarbocyanine (**O3**); the iodide is commonly denoted as DODCI.[8] The activation energy ($E_{c\text{-}t}$) of the thermal *cis* → *trans* isomerization of cyanine dyes lies in the

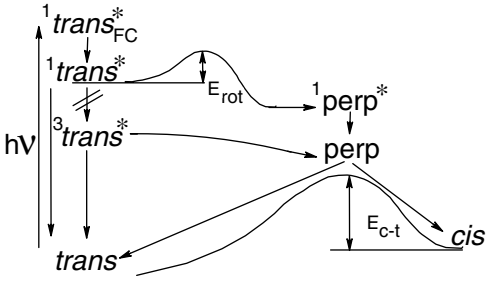

SCHEME 1

50–80 kJ mol^{-1} range (Table 36.2). The influence of the viscosity of the medium and molecular structure on the isomerization dynamics in several cyanines was investigated by Aramendía and co-workers.[26,27] For symmetric carbocyanines the experimental and theoretical data of the ground-state potential energy surface are in agreement.[38] In laser-induced optoacoustic spectroscopy studies, Braslavsky and her group found that the molecular volume change due to photoisomerization of **T2** in ethanol–water is 52 ml mol^{-1} and that of **O2** (iodide) is zero.[18,19] A combination with semiempirical calculations indicates mainly rearrangement of solvent molecules.[19]

There is agreement that the *trans* → *cis* photoisomerization in polymethine cyanines takes place via the S_1 state. The fluorescing ^{1}*trans** state is populated via the Franck Condon (FC) precursor and decays via the perpendicular state (^{1}*perp**) into *trans*- and *cis*-isomers (Scheme 1). The potential energies of the ground and excited singlet states as a function of the angle of rotation about polymethine C-C bonds have a respective maximum and minimum at about 90°.[8,13,14,38] Two theoretical models were presented for **O3** and **T3**; the experimental check reveals a common intermediate in the *cis* $\rightleftharpoons$ *trans* photoisomerization routes.[23,24] The deactivation routes were discussed for **I2**,[28,33,36] **I3**,[29,31,35,36] **T2**,[23,28] **T3**,[34,37] **O2**,[23] and **O3**.[6,32,34] For asymmetric **I2** and **I3** related dyes, *trans* → *cis* photoisomerization occurs about those bonds that have the highest bond order in S_0.[36] Isomerization dynamics of 1,1′-diethyl-4,4′-cyanine were studied by third-order nonlinear spectroscopy.[40] Photoisomerization via higher excited-state and intersystem crossing to T_1 was observed for **T3**.[32] To induce *trans* → *cis* isomerization via T_1, a sensitizer can be applied.[29]

Substituent Effects

Variations of the conjugated polymethine chain and the unconjugated alkyl chains have been examined. For **T2** and derivatives with a long chain (up to $C_{18}H_{37}$), the Φ_f, Φ_{isc}, and $\Phi_{t\text{-}c}$ values are rather similar.[25] Linking of two chromophores by one or two chains has substantial influences on the absorption, fluorescence, and other photorelaxation processes. The fluorescence decay of a bis-**T3** (two covalently linked

TABLE 36.3 Quantum Yields of **I2** and **T2** and bis-Cyanine Dyes

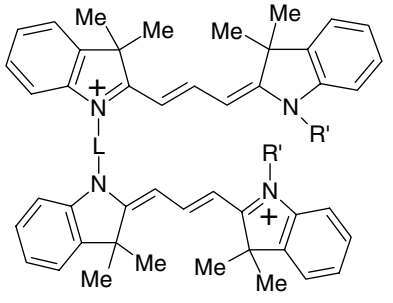
chains) has three fluorescence lifetime components, which originate from different structures.[39] The data for bis-**I2** (one link, L = C_2H_4), bis-**I2′** (two links, L = C_4H_8) and bis-**T2** (one link, L = C_5H_{10}) dyes show that Φ_{isc} is enhanced in ethanol at the expense of $\Phi_{t\text{-}c}$ (Table 36.3), while $E_{c\text{-}t}$ (47–64) kJ mol^{-1} remains essentially unchanged.[28] For bis-**I2** Φ_f is reduced and Φ_{isc} enhanced.[42]



bis-**I2**

The effects of 9-substituents in the polymethine chain on the photoprocesses of **I3** in ethanol are compiled in Table 36.4. The quantum yield Φ_{isc} is largest when R is bromo, while $\Phi_{t\text{-}c}$ depends on charge-transfer and $E_{c\text{-}t}$ (47–64 kJ mol^{-1}) remains essentially unchanged. Bulky substituents in **I2**[43] or a 9-R-**T2**[45,46] force the molecule in organic solvents to adopt a sterically less hindered mono-*cis* form.

Source: Khimenko, V., Chibisov, A.K., and Görner, H., *J. Phys. Chem. A,* 101, 7304, 1997.

For **T2a–c** containing alkyl substituents in the polymethine chain, the equilibrium between two isomers is shifted from the all-*trans*-isomer in nonpolar media towards the mono-*cis*-isomer in polar media, thereby reducing Φ_f and $\Phi_{t\text{-}c}$ (Table 36.5).[47] The photophysics and subnanosecond relaxation dynamics of **T3** and its 9-Me derivative were studied.[48] Implications for the design of near-IR fluorochromes with high fluorescence efficiencies were found from steady-state and picosecond laser studies of a **I4** (IR 125) dye.[49]

Photoinduced Electron Transfer

The photochemistry of **I2** type ion-pairs in nonpolar solution was intensively studied by the group of Schuster.[20] Evidence was given for electronic and steric control of the rate for rotation about polymethine C-C bonds k_{rot} in the relaxation of **I2** in benzene.[20] For some salts, k_{rot} and τ_f or Φ_f are sensitive to the substitution on the aryl rings.[21] For **I2** alkyltriphenylborate salts, intra-ion-pair electron transfer occurs, a locally excited singlet state is formed, and boranyl radicals are involved; the relationship between the rate constant (k_{et}) and the free energy change (ΔG_{et}) has been outlined.[50] An influence over the k_{isc} value of iodide ion pairs and the external iodine atom was registered.[51] Bulky borate anions distort the structure of bis-**I2** (two links) and influences the deactivation processes.[52]

For **I2** and **I3** type dyes with various counterions in nonpolar media, electron transfers via singlet and triplet states were distinguished by flash photolysis.[53] The rate constant for electron transfer from the first excited singlet state of **O2** in methanol to benzoquinone and other suitable acceptors is $k_{et} = (1\text{–}3) \times 10^{10}$ $M^{-1}sec^{-1}$.[54] Electron transfer, involving the triplet state of **T2–T4**, was performed with benzoquinone and ascorbic acid in alcohols.[17] ESR results with various cyanine dyes were interpreted by electron transfer involving the superoxide radical anion.[55] Electron transfer competes with delayed fluorescence and *trans→cis* isomerization when induced by energy transfer from triplet anthracene to **I3** dyes.[56] Charge-transfer states were reported for cyanine–oxonol ion pairs.[57]

36.3 Merocyanines

Some properties of excited merocyanine dyes are compiled in Table 36.6. The most frequently studied is merocyanine 540 (**M1**). **M1** is readily soluble in alcohols and lipid membranes, making it attractive for many technical applications and biological activity studies.[58–66] The solvent polarity has a significant influence on τ_f and the related quantum yields.[59,60] An intrinsic barrier height of E_{rot} = 3 kJ mol^{-1} for isomerization in S_1 was determined from dynamical solvation effects on the rate k_{rot} of **M1** in polar solvents.[59] Environmental effects on radiative and nonradiative transitions have been studied for merocyanines in homogeneous and microheterogeneous systems.[67]

TABLE 36.6 Fluorescence Lifetime and Quantum Yields of Merocyanines

Structural modifications have implications on photophysical properties and biological activity. A correlation between Φ_{isc} and quantum yield of formation of molecular singlet oxygen (Φ_Δ) has been found.[61] Harriman and his group studied the photoisomerization of derivatives, e.g., with two sulfur (**M3**) and two selenium (**M5**) atoms; for **M5** Φ_{isc} is strongly enhanced (Table 36.6). The spin-orbital coupling for sterically hindered dyes is unaffected by substitution.[63] The role of a zwitterionic resonance form, where the barbiturate unit acts as an electron acceptor, was discussed.[64] Intersystem crossing from upper triplet levels was reported for parent **M1**.[65] Whitten and his group found for bis-**M6** type dyes with methylene spacers that exciton and charge-transfer interactions in nonconjugated merocyanine dye dimers cause novel solvatochromic behaviour for tethered bichromophores and excimers.[66] In liposomes, **M1** is incorporated into the lipid bilayer as monomer and Φ_{isc} is a few percent.[58] The parent **M1** has a high recognition potential for leukemia cells, but optimized photophysical and photochemical properties do not necessarily go along with therapeutic improvements. The phototoxicity was examined with Daudi cells[62] or clonogenic assays on L1210 cells.[61]

36.4 Cyanine Dyes in Aqueous Solution

The properties of dimers and aggregates have been discussed for various cyanine dyes in aqueous solution.[68–88] Aggregated cyanine dyes play a key role in spectral sensitization.[16,68,69] With increasing dye concentration, monomers are converted into dimers before higher aggregates are formed.[70] The equilibria depend also on the dye structure and the medium. J(Jelly)-aggregates and H-aggregates (H for hypsochromic) exhibit generally short- and long-wavelength peaks, respectively. Dimerization can be enhanced in the presence of salts or by the association with hydrophobic (borate) anions, thereby changing the luminescence features.[16] A face-to-face alignment was suggested for the non-fluorescent dimers of **T2d–g**.[72]

Ground State Equilibria

Self-association of dyes in solution is caused by van der Waals forces, hydrophobic interaction, and hydrogen bonding with the solvent or intermolecularly. For 4,5-benzo- (**T1a**) and 5,5′-dichlorothia-monomethincyaninebetaine, the thermodynamic parameters of photographic dimerization have been studied.[75] The monomethine dyes **T1a–d** were applied for spectral sensitization of emulsions, since the intrinsic sensitivity of AgCl grains is very low at 400–500 nm. They are mainly present as dimers in aqueous solution and as monomers in ethanol (Table 36.7). The dimerization constant is $K_D = 7 \times 10^5$ M^{-1} for **T1b** in water and lower in the presence of ethanol or in the case of **T1c**.[74] Pseudoisocyanine (**B1**, n = 1) is a frequently used water-soluble dye, denoted as PIC.[70,77,81]

Formation of dimers in water, due to hydrophobic interaction and hydrogen bonding, can be facilitated by the reduction of repulsion between similarly charged ions. In contrast, the dyes in alcohols, due to high solubility, are present as monomers. Moreover, dimer formation reduces hydrophobic interactions with water. Hydrogen bonding with water is the main driving force for dimerization of xanthene dyes, where the enthalpy (ΔH_D) and enthropy (ΔS_D) dimerization values are negative. The thermodynamic parameters for **T1a** in aqueous methanol are $\Delta H_D = -54$ kJ mol^{-1} and $\Delta S_D = -97$ J mol^{-1}K^{-1}.[74] Dimerization is characterized by an intense band at shorter and a weak band at longer wavelengths (Table 36.7), by the effects of temperature or concentration, and by an aggregation number of two. A distance of 1.0 nm between the centers of gravity of the two molecules and an angle of 55° between the polarization axes of the monomers in the dimer were estimated. The J-aggregate of **T1b** is formed in the presence of KCl and in heavy water. Anisotropic structures of aggregated dyes were found for pseudoisocyanine.[76] H- and J-Aggregates are formed when cyanine dyes are bound to DNA templates.[77]

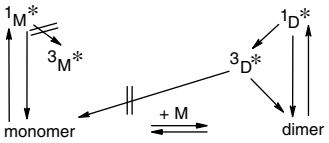

SCHEME 2

Photoprocesses of Dimers and Aggregates

The photoprocesses are determined by the state of aggregation. Aggregated molecules play an important role in photosynthesis in green plants and photosynthetic bacteria.[89,90] The dimers of **T1a–d** exhibit fluorescence with a yield 10–20 times larger than that of the monomers (Table 36.7). Lower Φ_f and Φ_{isc} values with respect to the dimers indicate efficient internal rotation of the naphthothiazolium residue about the monomethine chain. Φ_{isc} decreases with increasing temperature, supporting the hypothesis that the observed triplet state originates from the excited dimer (Scheme 2). Subnanosecond relaxation dynamics in monomers, dimers, and H- and J-aggregates were observed for **B1**[80] and **T2**.[82]

Fluorescence was observed for dimers of acridine orange and rhodamine 6G; whereas dimers of squaraine, Zn-phthalocyanine, and certain xanthene dyes do not fluoresce at ambient temperature.[74] Two aggregates were postulated on the basis of a fluorescence study of PIC.[78] $\Phi_f = 4 \times 10^{-4}$ was reported for J-aggregates from indocyanine green (**I4** type) in aqueous solution.[83] The dimers of **T2d–f** exhibit a lower Φ_f value than the monomers do (Table 36.7). This results from different orientations; i.e., an alignment other than face-to-face may be the reason for the fluorescence of the dimer of **T1**. Shifting the monomer–dimer equilibrium also changes Φ_{isc}. Triplet states of dimers were observed for methylene blue, acridine orange, rose bengal, triarylmethane dyes, triarylpyrylium salts, phthalocyanines, porphyrines, and **T2**, cf.[74] Photoinduced electron transfer takes place in J-aggregates when the dyes are adsorbed to a surface of an appropriate semiconductor, e.g., silver halide microcrystals.[17,69]

Surfactants

In the presence of surfactants, dyes can deaggregate. On the other hand, surfactants can influence aggregation, and ion-pairing is a prerequisite for this process. Dyes in microheterogeneous media, such as micelles, reveal a strong enhancement of Φ_f, e.g., for cyanine dyes (Table 36.7), and a higher photostability, e.g., for rose bengal, methyl orange, or **M1** cf.[74] These processes were studied using sodium dodecyl sulfate (SDS), cetyltrimethylammonium bromide (CTAB), or Triton X-100 as anionic, cationic, and nonionic surfactants, respectively. For similarly charged reactants and with increasing surfactant concentration, the monomer and dimer absorptions of **T2d–f** reach half of their maximum values ($conc_{1/2}$) at the critical micelle concentration (cmc).[73] This is in contrast to oppositely charged reactants, where aggregates appear at $conc_{1/2}$ values much smaller than the cmc (Table 36.8). Φ_f reflects the behavior of the monomer, whereas Φ_{isc} reflects that of the dimer.

For the cationic CTAB, the hydrophobic interaction between the monomer and the surfactant, which causes the deaggregation, is enhanced by the attracting Coulombic forces. The J-aggregates of **T2f**, due to association of the dye with the micelle in the cmc region and above, are converted into monomers. This system is characterized by three regimes, which are separated by the formation of ion pairs, formation of J-aggregates, and their conversion into solubilized monomers. For those dyes where J-aggregates are not formed, the $[CTAB]_{1/2}$ values in Table 36.8 refer to dimer splitting. Conversion into solubilized **T2d–f** monomers was suggested for [CTAB] higher than the cmc. Photoisomerization and fluorescence in micelles have also been studied for **O2** (iodide) and **T2d,g**.[87]

Polyanions

Aggregation phenomena are observable when cationic dyes are bound to anionic polyelectrolytes, such as polyacrylic acid (PAA), polymethacrylic acid (PMA), or polystyrene sulfonate (PSS).[91–98] Φ_f is strongly

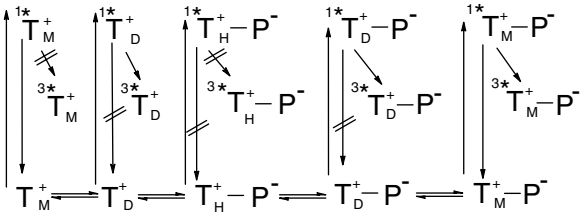

SCHEME 3

reduced when dimers and aggregates of **T2′a–c** are present (high dye loading conditions) and enhanced for bound monomers (low dye loading, Table 36.9). The ground state properties, the decay kinetics, and the Φ_f and Φ_{isc} values depend in specific manners on the ratio of polyanion residue to dye concentrations (r). **T2′a–c** in aqueous solution are present as cationic monomer and dimer (T_M^+ and T_D^+, respectively), and the amount of dimers is strongly enhanced with respect to organic solvents. The dye properties are changed by polyanions (P^-) due to their interactions. Higher aggregates (T_H^{+-} P^-) are formed at high dye loading, whereas dimers (T_D $^{+-}P^-$) are formed on increasing the concentration of polyanion residues, and at an even higher r monomers (T_M $^{+-}P^-$) are present (Scheme 3).

36.5 Spiropyran-Derived Merocyanines

Another class of merocyanines consists of ring-opened spiropyrans, such as spiro[2*H*-1-benzopyran-2,2′-indolines] (BIPS), especially of 6-nitro-substituted derivatives (NO_2BIPS). The photochromism of spiro

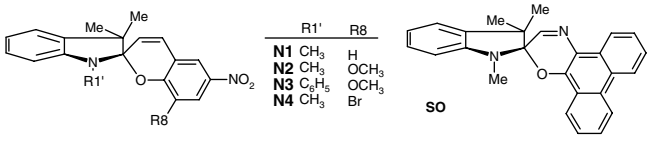
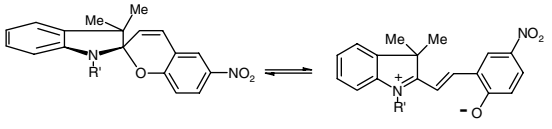
compounds has been the subject of fundamental investigations,[99–102] and various features were reviewed by Bertelson[103] and Guglielmetti.[104,105] The spiropyrans and spirooxazines are versatile molecules widely used for technical[106,107] and biological[108] applications. Here, four NO_2BIPS (**N1–N4**)[109–127] and a spirooxazine (**SO**) were chosen as examples, and certain aspects are discussed.



Photochromism of Spiropyrans

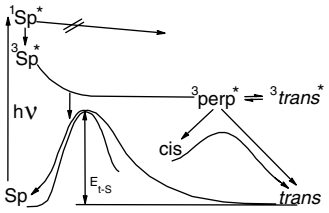
UV irradiation of spiropyrans enhances the coloration with maxima in the UV and in the red spectral range (λ_t). The major photoprocess at ambient temperature is ring opening, which takes place in the psec domain.[115–117] The eight possible merocyanines have a zwitterionic or quinoid character; four conformers with the central transoid segment can be expected after photochemical cleavage of the C-O bond (quantum yield: Φ_{col}); the most stable merocyanine isomer is indicated as *trans*.

When the light is removed, the absorbance in the red spectral range decreases and reaches its original stationary value. This rearrangement defines the thermal relaxation time ($\tau_{t\text{-}S}$), which depends on structure, solvent, and temperature.[113,114] In polar solvents generally a minor part of the *trans*-isomer remains after thermal relaxation, whereas in solvents of low polarity equilibrium (1) is completely shifted toward the Sp side. Indoline spiropyrans and their photomerocyanines are separated by an energy barrier, and the activation energy ($E_{t\text{-}S}$) lies in the 80–90 kJ mol^{-1} range (Table 36.10). The thermal relaxation of **N1** occurs also in polymer matrices.[123]



(1)

For NO_2BIPS, in contrast to BIPS and spirooxazines, intersystem crossing is dominant. In particular, a triplet state and a *cis*-isomer are involved in the photocoloration of **N1–N4**.[109–114] The triplet state with a typical τ_T of 10 μsec originates from an equilibrium between the perpendicular (^{3}perp*) and ^{3}*trans**



SCHEME 4

Sources: Chibisov, A.K. and Görner, H., *J. Phys. Chem. A,* 101, 4305, 1997; Görner, H., *Chem. Phys.,* 222, 315, 1997.

forms (Scheme 4). This is concluded from the independence of the *cis*-isomer yield of oxygen.[109–114] Fluorescence from the $^1Sp^*$ state plays no role, but phosphorescence (Φ_p) is observable in rigid media; the energy level is E_T = 238 kJ mol^{-1} for **N2**.[118] The three yields Φ_{col}, Φ_{isc}, and Φ_Δ have rather large values in nonpolar media at room temperature and exhibit the same decrease with increasing solvent polarity (Table 36.10). In polar solvents, the major deactivation step of $^1Sp^*$ is internal conversion rather than reaction to *trans*-***N***. Significant spectral changes take place for **N1** in water, where the phenoxide moiety is sensitive to pH.[119] High switching reversibilities were found for **N1** in zeolites.[127]

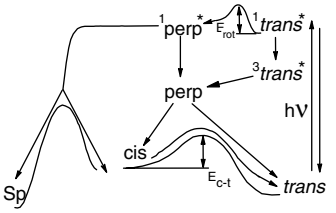
The potential energy surface of the ground state along the reaction coordinate should have one major maximum with the activation barrier $E_{t\text{-}S}$ and at least one minor barrier. The potential energy surfaces of S_0 and S_1 have been calculated for BIPS[128] and NO_2BIPS.[129,130] MO calculations indicate that the dipole moment of the open form of **N1** is twice as large as for Sp.[130] A strong decrease of the potential energy of the relevant S_1 and T_1 states is expected on going from the Sp form via the *cis-cis-cis* (CCC) geometry to the TTC isomer or the most stable merocyanine. The mechanism for photochemical ring opening in BIPS and NO_2BIPS has also been interpreted on the basis of calculations.[128]

Photoprocesses of Spiropyran-Derived Merocyanines

The photoprocesses from *trans*-***N*** are weak fluorescence and weak intersystem crossing, i.e., the major path is internal conversion.[110,131–134] In particular, *trans* → *cis* photoisomerization takes place followed by thermal *cis* → *trans* isomerization (Table 36.11). In specific cases, such as **N2** in ethanol, a route into the Sp form is also opened.[131] The above-mentioned triplet state of **N1–N3** is likewise involved upon population of the ^{1}*trans** state (Scheme 5). The low values of Φ_f and Φ_{isc} at room temperature are in line with the 50- to 100-fold increase of both, when the viscosity is enhanced, e.g., at 77 K.[111] The activation energy, obtained from plots of Φ_f vs. 1/T, is $E_{rot} \approx 10$ kJ mol^{-1}; that for *cis* → *trans* isomerization is $E_{c\text{-}t} \approx 35$ kJ mol^{-1}.

Photoprocesses of Spiropyran Complexes with Metal Ions

In the presence of the metal salts (M^{n+} X^-, n = 2,3) the ground state equilibrium has to be extended towards complexes, *trans*-***N***-M^{n+} (Scheme 6), giving rise to modified spectroscopic and photophysical



SCHEME 5

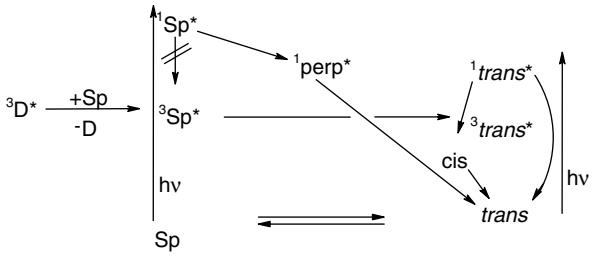
features.[133–138] The absorption and fluorescence maxima are blue-shifted from 580–600 nm to 480–500 nm and from 660 nm to 580–640 nm, respectively, and the thermal relaxation times become longer. Photocolouration of Sp **N1–N3** yields the complexes via the above mentioned (noncomplexed) triplet state.[133,134] The photoprocesses of *trans-**N***-M^{n+} are fluorescence and intersystem crossing in modified yields; the latter initiates *trans* → *cis* photoisomerization. In addition, a photosubstitution of the ligand by solvent plays a role. Data in Table 36.12 show that Φ_{isc} and $\Phi_{t\text{-}c}$ are largest and smallest for complexes in acetone with Pb^{3+} and Ni^{2+}, respectively.

Photoprocesses of Spirooxazines

The photochromism of spirooxazines has been investigated by Chu,[139] Schneider,[140] and many other researchers.[141–151] Their application potential seems to be very powerful.[104–107] Ring opening of the Sp form of **SO** occurs via the S_1 state[105,144] and takes place in the psec domain.[150,151] The quantum yield Φ_{col} is rather large in solvents of either low or large polarity.[143,144] A biexponential thermal decoloration was observed, which is consistent with fully established equilibria between the Sp form and two photoisomers.[141] Therefore, two separate steps leading to the ring-closure were considered for **SO**. In addition, a more twisted isomer was spectroscopically and kinetically observed upon irradiation of the most stable



SCHEME 7

photomerocyanine in several solvents at lower temperatures.[142, 146] A triplet route (Scheme 7) can be initiated by energy transfer from an appropriate donor (D) to the Sp form.

To account for the finding that Φ_{col} is well below unity, there should be a deactivation pathway left of the maximum of the barrier in S_0, i.e., efficient internal conversion at the Sp geometry competes with ring opening via the singlet mechanism. From calculations of the energy levels of the stereoisomers, TTC was found to be the most stable form.[149] Whether or not the potential energy surface at the position of the CCC isomer has a minimum remains open as yet. The degree of zwitterionic and quinoid character in BIPS and spirooxazines is also an open question.[148]

Photochemical Aromatic Substitution

37.1 Introduction and Mechanism

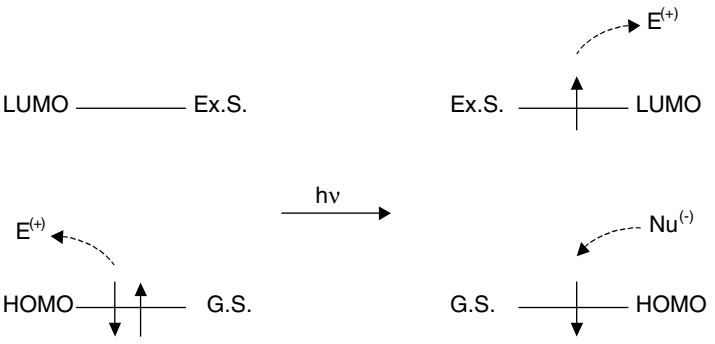
The photochemical aromatic substitution reactions described within this article are mainly devoted to homocyclic aromatic compounds. The work described is focused on the mechanism of the various reactions described. An outstanding mechanistic feature of photochemical aromatic substitution is that, in contrast to thermal reactions, photochemical substitutions take place by nucleophilic paths.[1,2] There are numerous examples of photonucleophilic aromatic substitutions in the literature.[3] The aromatic nucleus is electron rich; therefore, electrophilic aromatic substitution is dominant in thermal reactions via the formation of an arenium σ-complex intermediate. Electrophilic aromatic substitution reactions are governed by thermodynamic factors rather than kinetic factors in ground-state chemistry, whereas the energetic nature of the photo-excited state of aromatic molecules brings about the different reaction paths seen in photochemical substitution reactions. Epiotis and Shaik[4] have shown that the regiochemistry of electrophilic and photonucleophilic substitution is controlled by the electron density of the highest occupied MO (molecular orbital) of the aromatic substrate, and the regiochemistry of nucleophilic and photoelectrophilic aromatic substitutions is controlled by the electron density of the lowest unoccupied MO of the aromatic substrate.[4] An electron is raised from the ground state HOMO to an excited state LUMO. This creates a susceptibility to nucleophilic attack on the half-filled HOMO level, and the electron in the half-filled LUMO level can undergo attack at an electrophile (Scheme 1).

Photosubstitution may proceed by direct attack of the nucleophile on the triplet (or singlet) excited state of the aromatic molecule with the formation of a σ-complex, S_N2Ar^* (Scheme 2).

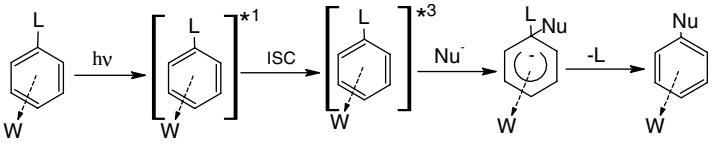
Kuzmič and Souček proposed that the differences in the position of the photonucleophilic substitution of a methoxy group in 3,4-dimethoxybenzene and 3,4-dimethoxyacetophenone by cyano or hydroxide anion is due to the fact that the cyanide anion interacts with the singlet excited state of the aromatic ring (shown from fluorescence quenching studies) whereas hydroxyl anion does not.[5] Further evidence regarding the mechanism of photonucleophilic substitution is obtained from the fact that the reaction of 4,5-dinitroveratrole with amines also brings about photoreduction. This is the result of an electron transfer from the amine to the triplet state excited aromatic ring.[6–9]

Marquet et al. confirmed that differing photoreactivity is dependent on the excited state (singlet or triplet) involved. Thus, the photosubstitution of 4-nitroveratrole takes place through a singlet $S_N2^1Ar^*$ mechanism by elimination of a methoxy group, whereas 4,5-di-nitroanisole involves the triplet $S_N2^3Ar^*$ mechanism. This brings about the elimination of a nitro group in the presence of the amines as the

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1



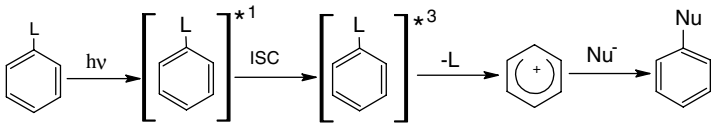
SCHEME 2

nucleophiles.[10] Marquet and co-workers have also compared the photochemistry of 4-nitroveratrole and 2-fluoro-4-anisole in polar solvents with nucleophiles such as cresol, sulfides, amines, and carboxylic acids. The reaction was also studied in aqueous methanol containing pancreatic bovine ribonuclease A. This particular study was designed to examine the applicability of nucleophilic aromatic substitution, S_N2Ar^*, as a method for labelling an enzyme. This would make use of nucleophilic centers within the peptide chain.[11] The nucleophilic aromatic substitution of 3-nitroanisole, 4-nitroanisole, and 4-nitroveratrole in the presence of phenethylamine was investigated in aqueous solution and in the solid state in a β-cyclodextrin complex.[12] In an aqueous solution of 4-nitroveratrole, the major product is 2-methoxy-5-nitrophenol, which arises from regioselective substitution of a methoxyl group. However, in the confined environment of β-cyclodextrin with phenethylamine as the nucleophile, the only product was identified as 4-nitrosoveratrole.

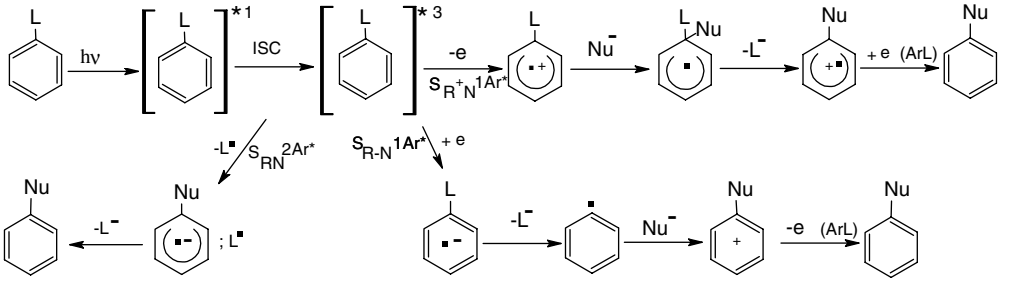
Bonilha et al. have studied the photonucleophilic substitution reaction between nitroaryl–alkyl ethers and hydroxide anions in water. The investigations of the quenching of nitroaryl ethers by anions led to the conclusion that the mechanism is a direct displacement within the triplet state, $S_N2^3Ar^*$.[13] Arnold and Snow [14] showed that in the photonucleophilic S_N2Ar^* aromatic substitution reaction, dicyanobenzene and a methanol–olefin combination are more efficient in the presence of an electron donor photosensitizer. Photochemical nucleophilic substitution with acenaphthylene and dicyanonaphthalene is found to be more complicated than with dicyanobenzene and tetracyanobenzene. In this system, photoelectron-transfer from a singlet exciplex resulted in the formation of numerous products.[15] Boggeri et al. have shown that aromatic nitriles can undergo photochemical nucleophilic substitution with acenaphthylene via electron-transfer in the singlet exciplex. This is evidence for the operation of a S_N2Ar^* mechanism.[16]

In the S_N1Ar^* mechanism, which is found in rare cases, a strong electron withdrawing group leaves the triplet excited state to form the cation of the aromatic moiety, This is followed by the addition of a nucleophile (Scheme 3). Havinga and Cornelisse and Spillane have recognized, in the photosubstitution of 2-nitrofurane with cyanide and water nucleophiles, that the quantum yield for the reaction is independent of the concentration of the nucleophile; a photodissociation (photoionization) to give an ion pair has been suggested.[17,18]

The photoionization of excited aromatic molecules would lead to $S_{RN}1Ar^*$ mechanisms by an electron-transfer from the nucleophile to the excited aromatic substrate with formation of the radical-anion



SCHEME 3



SCHEME 4

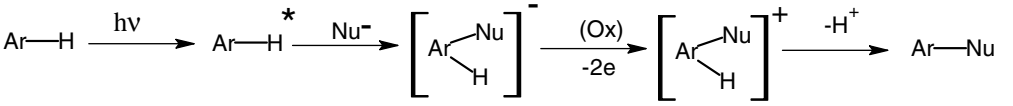
intermediate, $S_R{-}_N1Ar^*$, or by an electron-transfer from the excited aromatic substrate to an appropriate electron acceptor. This would be followed by the attack of the nucleophile on the resultant aromatic-cation, $S_R{+}_N1Ar^*$.[19] The radical cation intermediate within the $S_R{+}_N1Ar^*$ mechanism is formed only when an electron donating group is present on the aromatic substrate (Scheme 4). This $S_{RN}1Ar^*$ type of reaction was first reported by Kim and Bunnet[20] in the nucleophilic substitution of phenyl iodide by potassium iodide. The reactions of aryl halides with phosphonate anion,[21] carbanions,[22] aryl amides,[23] and phenoxide anions[24] have been studied extensively.[25] Photoreduction and nucleophilic photosubstitution of 4-bromonitrobenzene have been proven to be catalyzed by HCl in aqueous propanol solutions and involve radical intermediates.[26] The formation of a bimolecular exciplex via electron transfer from chloride anion to the $^3(n\text{-}\pi)^*$ state, following the protonation of the exciplex, proceeds by the $S_{RN}1Ar^*$ mechanism.

Photonucleophilic aromatic substitution reactions of phenyl selenide and telluride with haloarenes have also been proven to involve the $S_{RN}1Ar^*$ mechanism, with the formation of anion radical intermediates.[27] Another photonucleophilic substitution, cyanomethylation, proves the presence of radical cations in the reaction mechanism.[28] Liu and Weiss have reported that hydroxy and cyano substitution competes with photo substitution of fluorinated anisoles in aqueous solutions, where cation and anion radical intermediates have been shown to be the key factors for the nucleophilic substitution type.[29] Rossi et al. have proposed the $S_{RN}1Ar^*$ mechanism for photonucleophilic substitution of carbanions and naphthoxides to halo anisoles and 1-iodonaphthalene.[30,31] An anion radical intermediate photonucleophilic substitution mechanism has been shown for the reactions of triphenyl(methyl)stannyl anion with halo arenes in liquid ammonia.[32] Trimethylstannyl anion has been found to be more reactive than triphenylstannyl anion in the photostimulated electron- transfer initiation step.

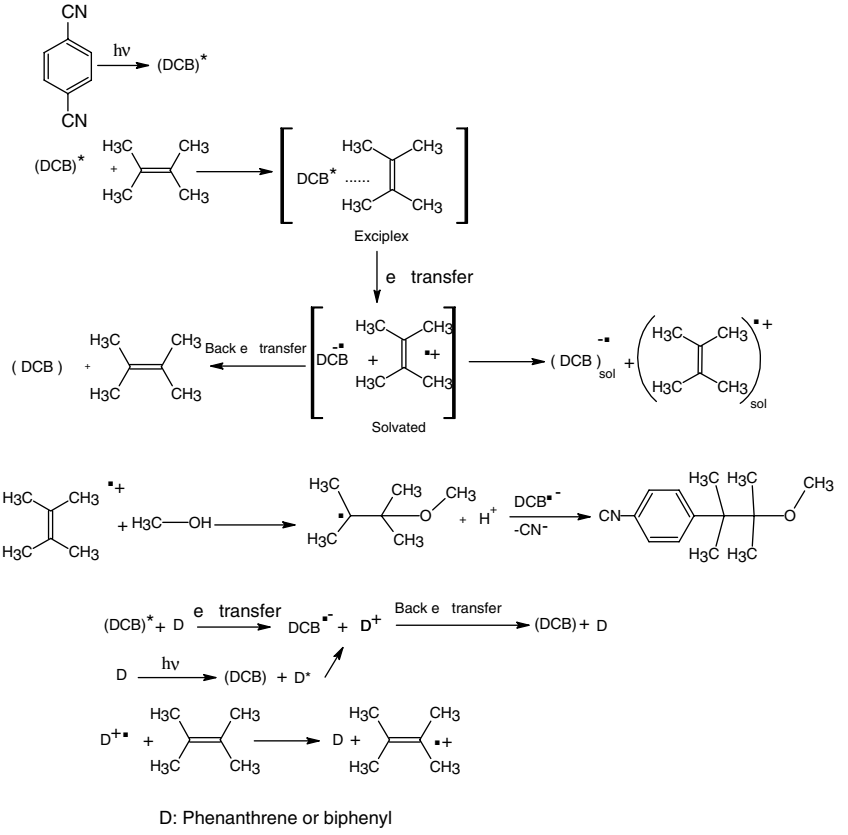
37.2 Recent Studies on Photochemical Aromatic Substitutions

S_N2Ar^* Reactions

Photocyanation of deuterium-labelled 1-nitronaphthalenes with cyanide nucleophile has been proven to involve primarily an ipso attack followed by isomerizations.[33] The reaction of nucleophiles with halogenated aromatics proceeds via attack of the nucleophile on the nitroarene, generating an anionic σ-complex. This is followed by departure of the leaving group and rearomatization. Cervera et al. and Huertas et al. have shown a direct coupling of carbon nucleophiles with *m*-dinitrobenzene via fluoride promoted nucleophilic aromatic substitution (Scheme 5).[34,35] Amines, amides, ethyl acetate, acetonitrile, and acetone



SCHEME 5

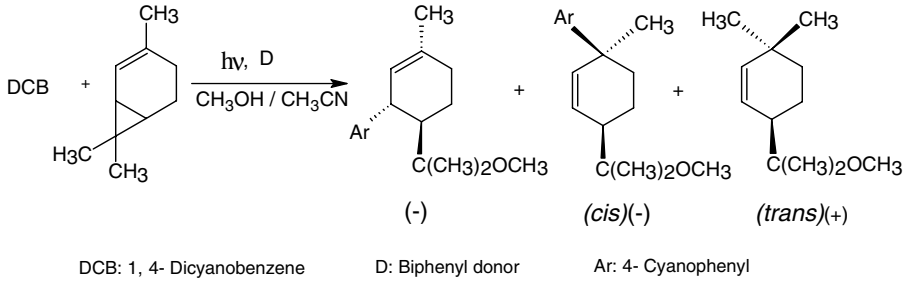


SCHEME 6

were used as nucleophiles to bring about regioselective nucleophilic substitution in the presence of *m*-dinitrobenzene and tetrabutylammonium fluoride in THF or DMF solutions.

The photo-NOCAS reaction was first described by McMahon and Arnold[15] and is a photonucleophilic S_N2Ar^* aromatic substitution between dicyanobenzene and an olefin in the presence of electron donor photosensitizers (phenanthrene or biphenyl) in acetonitrile–methanol solutions. This reaction system has been researched extensively in recent times. As shown in Scheme 6, the single electron transfer from olefin to photo-excited electron-deficient dicyanobenzene forms the cation radical of the olefin, which initiates a quenching reaction with nucleophile solvent methanol molecules and forms the methoxyalkyl radical. Addition of an electron transfer photosensitizer (phenanthrene or biphenyl) to the reaction mixture increases the efficiency of the reaction simply by absorbing more light. The excited state of the photosensitizer donates an electron to dicyanobenzene to give the photosensitizer radical cation and dicyanobenzene radical anion. The photosensitizer radical cation then oxidizes the olefin.

The reaction system discussed above was applied to optically pure α-pinene, β-pinene, tricyclene, and nopol.[36] 4-Cyanophenyl and/or methoxy substituted derivatives in optically pure or racemic mixture forms were isolated as products. Nucleophile-assisted cleavage of the radical cation has been proposed



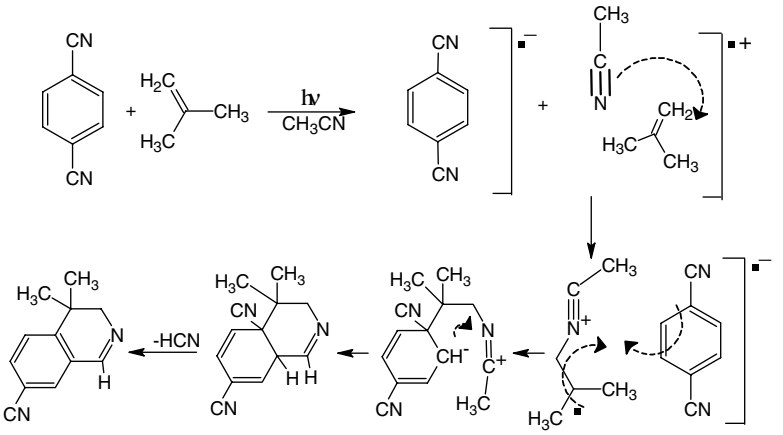
SCHEME 7

as the mechanism for the nucleophilic selectivity and the regio- and stereochemistry of the adducts. 1,5-Hexadiene and 2-methyl-1,5-hexadiene olefins also react with 1,4-dicyanobenzene under the same reaction conditions illustrated in Scheme 6. The photo-NOCAS products were also formed using 2-methyl-1,5-hexadiene as the alkene component. However, 1,5-hexadiene gave only *ortho* and *meta* cyclic adducts, and no photo-NOCAS products were found.[37] This result can be explained on the basis of the high oxidation potential of 1,5-hexadiene (>3 V vs. SCE), which precludes the single electron transfer from olefin to the 1,4-dicyanobenzene. The conjugated dienes, 1,3-butadiene, 2-methyl-1,3-butadiene, 2,3-dimethyl-1,3-butadiene, and 2,5-dimethyl-2,4-hexadiene, do not suffer this problem and yielded the regio- and stereoselective aryl and methoxy adduct products of the photo-NOCAS process.[38] High yields (80%) of the usual products were obtained with (+)-2-carene under the usual conditions (Scheme 7).[39] The oxidation potential of the (+)-2-carene was determined to be low, 1.39 V vs. SCE, and the calculated free energy change (ΔG_{ET} = –119.5 kJ mol^{-1}) for the electron transfer to the singlet excited state of dicyanobenzene was highest compared to the oxidation potentials and free energy change values of α-pinene, β-pinene, and 1-methylcyclohexene, respectively. The outcome of the reaction is illustrated in Scheme 7.

The photo-NOCAS reaction with 2,6-dimethyl-1,6-heptadiene gave two major cyclic aryl–methoxy adducts (a cyclohexane and a cycloheptane) as well as an acyclic heptene adduct.[40] Variation in concentration of the nucleophile, methanol, and co-donor, biphenyl, has been shown to affect the product ratios. Further applications of the photo-NOCAS S_N2Ar^* reactions with the alkyl-4-enols, α-terpineol, limonene, 2-methyl-2-butene, 2,3-dimethyl-2-butene, β-myrcene, and 1,4-bis (methylene) cyclohexene have been reported.[41–48] The aryl–methoxy adduct product ratios have been investigated and discussed in terms of the stability of radical intermediates and the factors controlling the regiochemistry of reaction with the nucleophiles alcohols, cyanide, and fluoride; attempts to justify the results by *ab initio* molecular orbital calculations have been made. The photo-NOCAS reaction with 2-methylpropene in the absence of methanol and a donor molecule has shown that solvent acetonitrile can act as a nucleophile. Under these conditions a tetrahydroisoquinoline product is formed, prior to HCN elimination, in high yield as illustrated in Scheme 8.[49] The adduct product formation was rationalized on the basis of the relatively high oxidation potential of the olefin.

Tetrahydroisoquinoline formation was reported earlier by Vanossi et al. following the S_N2Ar^* reaction of 1,2,4,5-tetracyanobenzene and 1-hexene in acetonitrile.[50] Photo-NOCAS mechanistic pathways were also operative when 1,4-dicyanobenzene was replaced with 1,2,4,5-tetracyanobenzene, 4-halobenzonitriles, 4-haloanisoles, and 1,4-dicyanonaphthalene as the electron acceptors.[51,52] A singlet excited state electron transfer reaction leading to nucleophilic aromatic substitution has been reported by Torriani et al. in the photolysis of 1,4-dicyanobenzene and 2,3-dimethyl-2-butene in the presence of CH_3OH, H_2O, and CF_3CH_2OH as the nucleophiles. These reactions gave adducts analogous to the previous examples discussed.[53] The quantum yields are in the range of 0.006–0.020 and reach the upper limit only in the presence of nucleophiles.

When nucleophilic aromatic substitution reactions of the S_N2Ar^* type are carried out in a protic solvent (i.e., water), the oxygen effect is neglected. Marquet has proven that aromatic radical anion intermediates



SCHEME 8

can form reactive superoxide anion radical via electron transfer, which then can form cyanide anion from acetonitrile and ethoxide anion from ethyl acetate. Hence it is proposed that the presence of oxygen in polar aprotic solvents should be avoided in nucleophilic aromatic photosubstitution reactions.[54]

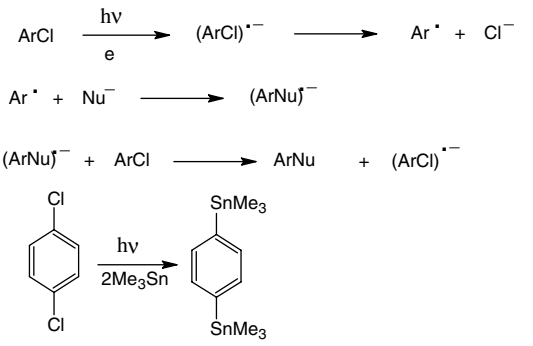
Tedesco et al. have reported the nucleophilic aromatic substitution reactions of nitroaryl ethers with sodium hydroxide in aqueous solution contained in cationic micelles.[55] Quantum yields of the reactions were found to be dependent on the length of the *n*-alkyl chain of micelle (maximum for methyl, minimum for decyl). The dependence on surfactant concentration was in accord with the mechanistic model for aromatic nucleophilic photosubstitution. Intramolecular photoreactions were investigated with the bichromophoric *p*-nitroarylethers, $p\text{-}O_2NC_6H_4O(CH_2)_nNHC_6H_5$.[56] The lower homologues ($n \leq 6$) are found to undergo aromatic photochemical nucleophilic substitution of the S_N2Ar^*, which can be classified as a Smiles-type rearrangement. When the chain is sufficiently long ($n \geq 8$, i.e., $p\text{-}O_2NC_6H_4O(CH_2)_8NHC_6H_5$), the photorearrangement and the nucleophilic substitution are forbidden; instead, a photoredox reaction (reduction of nitro to nitroso and the oxidation of nitrogen bonded methylene to aldehyde) and the cleavage of the aniline molecule take place. Nakagaki and Mutai[56] have proposed that the photoredox reactions are the only accessible reaction processes for the higher homologues. The magnetic field effects on the end product distribution are due to changes in the intersystem crossings rate induced by hyperfine interaction within biradical intermediates.

$S_{RN}1Ar^*$ Reactions

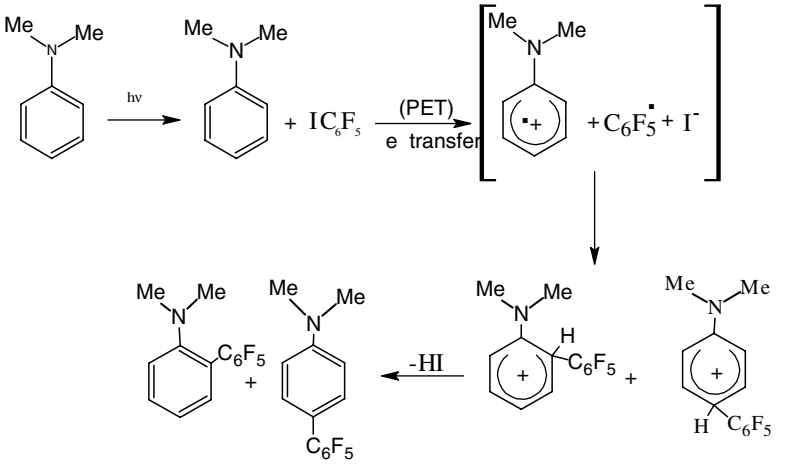
Galli et al. have reported the calculation of the LUMO energy of the substitution product of the aromatic $S_{RN}1Ar^*$ reaction.[57] It is suggested that $S_{RN}1Ar^*$ reactivity can be predicted for structurally homogeneous compounds by calculation of the LUMO energy of the substituted product in relation to the MO energy of the aromatic radical anion intermediate. The photohydrolysis quantum yields were analyzed by the partial least square method, and it is predicted that the photohydrolysis quantum yields of substituted aromatic halides are dependent on the characters of the CX bonds being broken and the character of the halogen bonds to be replaced during photolysis.[58]

Almost quantitative radical nucleophilic aromatic substitution reactions were reported by Córsico and Rossi from the reaction of nucleophile trimethylstannyl ions with mono-, di- and trichloro-substituted aromatic substrates in liquid ammonia.[59] The chain process shown in Scheme 9 requires an initiation step, and it can be either light induced or be a spontaneous electron transfer from the nucleophile to the aromatic substrate.

Chen and Li have studied the photoinduced electron transfer reactions of perfluoroalkyl iodides both with a variety of nucleophiles and with electron-rich aromatic compounds.[60,61] A photoinduced electron



SCHEME 9

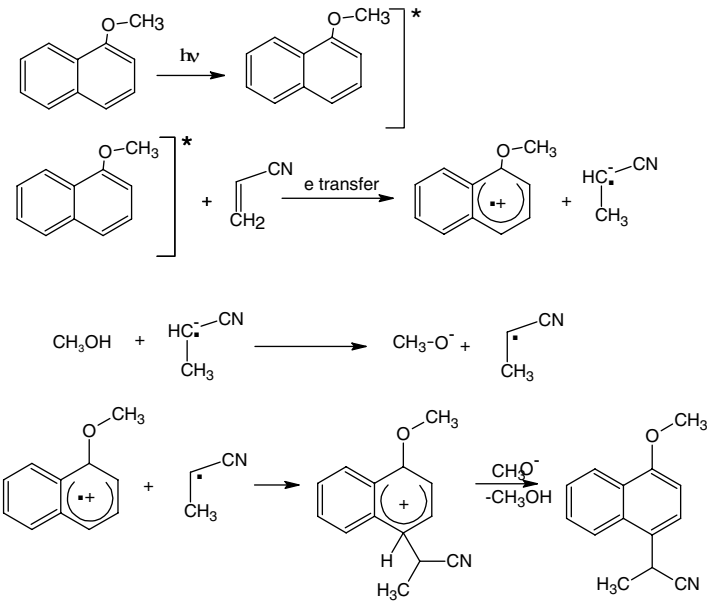


SCHEME 10

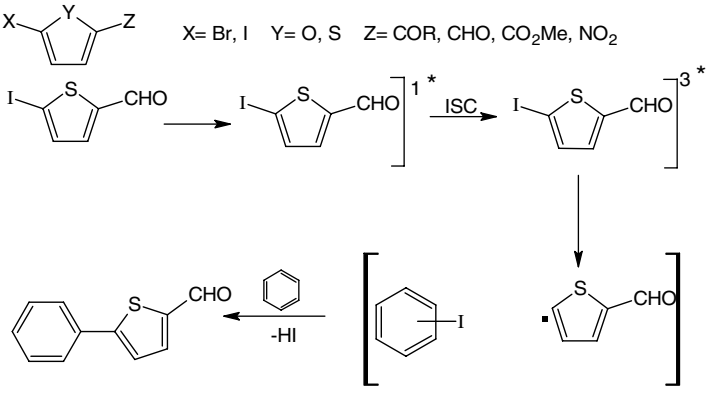
transfer (PET) mechanism was proposed for the photochemical reactivity of pentafluoroiodobenzene with anilines, pyrroles, indoles, aromatic ethers, and phenols (Scheme 10).[62]

Photobromination of naphthalene using molecular bromine gives tetrabromo-tetrahydronaphthalene as the only stereoisomer. This reaction is followed by dehydrobromination to give 1,3-dibromonaphthalene in high yield.[63] In a recent study by Mangion et al., the reaction of 1-methoxynaphthalene, 1,8-dimethoxynaphthalene, or 1,4-dimethoxynaphthalene with acrylonitrile in acetonitrile and methanol was found to have a distinct $S_R+_N1Ar^*$ mechanistic pathway. This has been called a photochemical electrophile-olefin combination, aromatic substitution abbreviated to a photo-EOCAS reaction.[64] The methoxynaphthalene forms a radical cation intermediate by the photoinduced electron transfer. This couples with the acrylonitrile radical (Scheme 11). The $S_R+_N1Ar^*$ reaction mode has been proposed to account for the nucleophilic photosubstitution of 1,4-dicyanobenzene with isobutylene in acetonitrile/methanol solutions.[65] A similar but reverse $S_R-_N1Ar^*$ reaction path, was suggested by Vanossi et al. for photoreactions of 1,2,4,5-benzenetetracarbonitrile with 1-hexene in acetonitrile.[66] The formation of aromatic anion radicals and allyl cation radicals were suggested,m and the allyl cation radical is trapped by methanol.

Nucleophilic aromatic photosubstitution reactions of furans and thiophenes substituted with iodo or bromo and electron withdrawing groups in the presence of aromatic compounds have been studied extensively.[67–71] The aryl nucleophilic substitution reaction mechanism of these compounds is illustrated in Scheme 12.

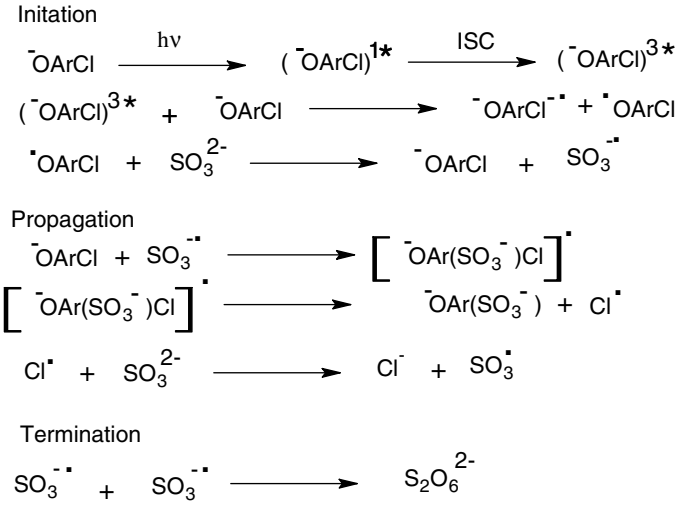


SCHEME 11



SCHEME 12

D'Auria proposes that the triplet n-π* excited state of furan and thiophene does not cleave the CI bond. The cleavage reaction would require a higher excited triplet state (π-σ*, n-σ*, or σ-σ*) mainly localized on the carbon–iodine bond. The interaction between this triplet state of the substrate and the aromatic compounds would lead to homolytic cleavage of the CI bond and the formation of a thienyl radical and a complex between the aromatic compound and the iodine atom. The formation of this complex was identified by the presence of a short-lived transient with $\lambda_{max} = 510$ nm, showing second order kinetics, $\tau \approx 0.4$ μsec, in laser flash photolysis. The thienyl radical then reacts rapidly with the aromatic compound to give the corresponding arylation product.[72] A recent study has proven that a similar $S_{RN}1Ar^*$ reaction mechanism is involved with mono and diiodopyrroles in the presence of various aromatic and heteroaromatic compounds.[73] The photochemical reaction between benzenecarbothioamide and substituted furans is reported to bring about β-benzoylation as a major reaction path. The mechanism appears to be more complex in this regioselective reaction.[74]



SCHEME 13

Photolysis of 4-chloro-1-hydoxynaphthalene in an aqueous solution of sodium sulfite results in replacement of chloride with sulfite. This is an example of an $S_{RN}1Ar^*$ mechanism. The chain reaction process is illustrated in Scheme 13.[75]

The presence of high concentrations of KI has been found to enhance the quantum yield of photosubstitution of chloride by sulfo groups on irradiation in the 313–365 nm band. The yields of aryl and heteroaryl products obtained by reactions of aryl and heteroaryl halides with a ketone enolate ion in Me_2SO are enhanced by catalysis with ferrous ion.[76] Photo-$S_{RN}1Ar^*$ reactions of chloro substituted *N*-methylpyridones with phenoxide have been reported.[77]

Photolysis of arylated digermanes is reported to involve germanium–germanium bond homolysis. This gives a pair of germyl radicals that abstract a hydrogen atom from a suitable source and either yield the corresponding hydromonogermanes or couple to afford digermanes as the main products. Irradiation of 1-(pentamethyldigerman)naphthalene yields 1-(dimethylgermyl)-8-(trimethylgermyl)naphthalene via the photochemical formation of a trimethylgermyl radical and a naphthyldimethylgermyl radical. Recombination at the 8 position of the latter followed by an intramolecular 1,4-hydrogen shift affords the final product.[78] Homolytic Ge-Ge bond scission within the singlet excited state is responsible for the germyl substitution on the naphthalene ring (Scheme 14).

$S_{RN}2Ar^*$ Reactions

Marquet et al. have proposed that if there is a direct reaction of the nucleophile on the aromatic substrate radical anion, an $S_{RN}2Ar^*$ mechanism is operative.[79] Such a mechanism was postulated by Hoz et al.[21,80] but was later rejected on experimental grounds. A few examples have appeared in the recent literature and have stimulated a reinvestigation of such a mechanism, which is shown in Scheme 15.[81,82]

The photoinduced photochemical substitution reactions of pentafluoronitrobenzene with several nucleophiles in aqueous media and the electrochemical detection of aromatic radical anions are taken as evidence for the presence of radical anion intermediates within the radical chain reaction steps.[79,83]

Photodehalogenation of Aryl Halides

Leah Schutt
University of Guelph

Nigel J. Bunce
University of Guelph

38.1 Introduction

The photochemistry of aryl halides (Ar-X) has been studied since the 1960s, and a very large number of citations is available. Previous reviews include Sammes,[1] Grimshaw and de Silva,[2] Lodder,[3] Davidson et al.,[4] Choudhry et al.,[5] and Burrows et al.[6] The examples reviewed in this chapter concern solution phase chemistry, unless noted otherwise.

Photochemical C-X fission in aryl halides may be defined as any photochemical process leading to cleavage of a carbon-to-halogen bond. The emphasis in this review is on mechanisms of C-X bond fission, of which three mechanistic reaction types may be identified.

1. Homolysis $\quad Ar\text{-}X^* \rightarrow Ar^\bullet + X^\bullet$
2. Electron transfer $\quad Ar\text{-}X^* \rightarrow (Ar\text{-}X)^{\bullet -} \rightarrow Ar^\bullet + X^-$
3. Photonucleophilic substitution $\quad Ar\text{-}X^* + Nu:^- \rightarrow Ar\text{-}Nu + X^-$

Aryl halides tend to be chemically unreactive and include persistent environmental pollutants such as dichloro-diphenyl-trichloroethane (DDT), polychlorinated biphenyls (PCBs), dibenzo-*p*-dioxins (PCDDs), dibenzofurans (PCDFs), and polybrominated diphenyl ethers (PBDEs). Many studies of the photochemistry of halogenated aromatic compounds have been stimulated by environmental concerns, the goal often being to understand whether photolysis is an important sink for these compounds in natural waters[7–9] or in the atmosphere.[10] The photochemistry of aryl halides causes problems in this context because many aryl halides have minimal absorption in the region of the tropospheric solar spectrum (>295 nm), and experiments at environmentally irrelevant wavelengths such as 254 nm are

0-8493-1348-1/04/$0.00+$1.50

TABLE 38.1 Energetics (kJ mol^{-1}) of CX Homolysis

Arene System	Triplet Energy	X	D(C_6H_5–X)
Benzene	360	F	520
Naphthalene	255	Cl	350–390
Biphenyl (no *o*-X)	275	Br	335
Biphenyl (one *o*-X)	>285	I	270
Anthracene	180	—	—
Pyrene	200	—	—

often more feasible. In addition, most halogenated aromatic compounds have very low solubility in water, necessitating the use of model solvents such as methanol or aqueous acetonitrile. Both the quantum yield of photoreaction (and hence estimates of environmental persistence) and the reaction products may be solvent dependent. These considerations make it difficult to extrapolate the photochemical behavior observed in the laboratory to natural systems. For this reason, many recent investigations of the photochemistry of aryl halides, in particular those considered to be environmental pollutants, have focused on elucidation of the photodegradative processes that do occur under environmental conditions and identification of systems that can be employed to increase their efficiency.

38.2 Reactions Proceeding Via Homolysis

Homolytic cleavage of the aryl carbon–halogen bond affords aryl free radicals, which can either arylate a suitable aromatic reaction partner or abstract hydrogen from a hydrogen atom donor (reductive dehalogenation), as first reported over 35 years ago. A recent example is the report by Meunier et al.[11] that photolysis of 1,4-dichlorobenzene in the absence of oxygen yielded 4,4′-dichlorobiphenyl and 2,4′,5-trichlorobiphenyl as reaction products. The general reaction mechanism proceeds as follows:

$$\mathrm{Ar - X^{*}} \longrightarrow \mathrm{Ar^{\bullet} + X^{\bullet}}$$

$$\mathrm{Ar^{\bullet} + R - H} \longrightarrow \mathrm{Ar - H + R^{\bullet}}$$

or

$$\mathrm{Ar^{\bullet} + Ar'H} \longrightarrow \mathrm{(ArHAr')^{\bullet}} \xrightarrow{-\mathrm{H}} \mathrm{Ar - Ar'}$$

However, because arylation and dehalogenation may occur by other mechanisms, product studies alone cannot be used to infer that homolysis has occurred.

Homolysis of photoexcited aryl iodides and bromides has been exploited as a means of producing aryl radicals; in some cases, these reactions have synthetic potential for the formation of biaryls, including the use of intramolecular arylation in order to construct polycyclic systems.[2] Reductive dehalogenation has been suggested as a synthetic route to specifically deuterated aromatic compounds by photolysis of aryl halides in solvents containing abstractable deuterium atoms.[12]

The energetics of homolysis is straightforward, requiring the energy of the reactive excited state (usually T_1) to be greater than the CX bond dissociation energy (Table 38.1). Homolysis is thermodynamically unfavorable (and is not seen) for aryl fluorides, in either singlet or triplet π,π^* states. As an example, 1,2,3-trifluorobenzene is unaffected by irradiation at 254 nm for 3 days.[13] 1-Chloropyrene (monomer) and 9,10-dibromoanthracene are unaffected by lengthy photolysis in alkane solvents. If the aromatic nucleus contains more than one type of halogen, the weakest C-X bond is cleaved preferentially. The rate of dechlorination of chlorobenzenes must be very fast, as shown by 1-bromo-3-*p*-chlorophenoxypropane,[4] which loses Cl exclusively upon photoexcitation even though the side chain contains the weaker C-Br bond (i.e., the excitation energy is not transferred to the weaker bond).

The data in Table 38.1 show that homolysis is exothermic for triplet iodo- and bromo-benzenes and probably for chlorobenzenes, although the correct value of the C_6H_5–Cl bond dissociation energy has

been the subject of controversy. In hydrogen-donating solvents, many chlorinated, brominated, and iodinated benzenes exhibit high quantum yields of both intersystem crossing $S_1 \rightarrow T_1$ and dehalogenation, and when $\Phi_{ISC} + \Phi_r$ significantly exceeds 1.0, the reactive excited state can be concluded to be T_1.

Halophenyl ketones have been studied from the point of view of the competition between C-X cleavage and pinacol formation from the ketone functionality. In cyclopentane solution, *m*- and *p*-bromobenzophenones reacted almost exclusively at the carbonyl group; conversely, the corresponding iodobenzophenones and bromoacetophenones gave near-quantitative yields of dehalogenated ketones.[14] These results were explained in terms of the relative ordering of n,π^* and π,π^* triplet excited states. It is suggested that C-X bond cleavage from the lowest π,π^* triplet excited state of halobenzenes involves an endothermic C-X bond stretching until the $^3\pi,\pi^*$ becomes co-energetic with a dissociative state. A follow-up study of the two iodobenzophenones indicated that the quantum inefficiency of deiodination is due to in-cage radical recombination, as shown by severely decreasing quantum yields of dehalogenation with increased solvent viscosity.[15] At some point, interaction between the carbonyl *n* orbital and the CI σ^* is necessary in order to facilitate bond cleavage.[14,15] In π,π^* triplets, it is suggested that the partial positive charge on a *meta* halide close to the negative carbonyl counteracts the normal higher *para* π^* electron density.[14]

In chlorophenols, homolytic C-Cl cleavage is usually a minor pathway compared with heterolysis,[16] but the relative quantum yields depend on the positions and numbers of chlorine atoms on the benzene ring.[6]

Studies have also been conducted on halobenzenes in the gas phase. Quantum yields of homolysis are high.[3,17] Ichimura et al.[17] photolyzed dichlorobenzenes and chlorotoluenes at 193 nm and proposed three different channels for the rupture of the C-Cl bond:

1. A very fast predissociation and/or direct dissociation channel
2. A predissociation channel via vibrationally excited triplet levels
3. A predissociation channel via highly excited vibrational levels of the ground electronic state

In chlorobenzene and dichlorobenzenes, the three pathways have equal probabilities; however, the addition of a methyl group, as in chlorotoluene, greatly increases the flow through the second channel, probably due to enhanced intersystem crossing by the methyl group. Studies with iodo- and bromobenzene suggest that only two dissociation pathways exist for these compounds, due to the presence of the π,π^* electronic system in the phenyl ring in addition to the n,σ^* electronic system in the C-X bond. The first is an instantaneous direct dissociation leading to the formation of photofragments, and the second involves a slower cleavage from the π,π^* triplet state, followed by predissociation via the repulsive n,σ^* state.[18,19] Only two pathways are proposed for *p*- and *o*-bromotoluene: a direct dissociation and a fast predissociation involving fast intersystem crossing.[18,20]

In the presence of hydrogen donors such as ethane,[21] reductive dehalogenation occurs as in solution. The situation is different upon photolysis in air, when little of the starting material has been accounted for. Low yields of phenols were identified, presumably the result of trapping aryl radicals by O_2; the remainder of the starting material is assumed to have been mineralized.[10] The atmospheric chemistry of PCBs, PCDDs, and PCDFs in the gaseous phase has been extensively reviewed by Atkinson.[22]

The regiospecificity of homolysis generally favors relief of steric strain. For example, photolysis of 1,2,3,5-tetrachlorobenzene in hydrogen-donating media gives predominantly 1,3,5-trichlorobenzene and 1,2,4-trichlorobenzene rather than 1,2,3-trichlorobenzene.[5] Halobiphenyls substituted at an *ortho* and another position cleave the *ortho* halogen preferentially,[4] both because loss of an *ortho* chlorine relieves steric strain and because *ortho* substitution raises the energy of the excited state due to partial deconjugation of the biphenyl chromophore, which shifts the absorption spectrum toward the blue. Among simple chlorobiphenyls containing only one to three chlorine substituents, those containing *ortho* chlorines have markedly larger quantum yields of homolysis than those without.[3] This was exemplified in the recent work of Masuzaki et al.,[23] who investigated the photodegradation of mono-, di-, and trichlorobiphenyls in decane at 254 nm. One apparent exception to these generalizations is 2,2′,5,5′-tetrachlorobiphenyl,[24] which is reported to lose both *ortho* and *meta* chlorines with comparable efficiency and which also gave small amounts of chlorobenzenes upon irradiation with a xenon lamp in hexane solution. In the environmental context, the efficiency of photolysis of PCBs is determined both by their intrinsic

photolability (Φ_r) and by the overlap of their absorption spectra with the tropospheric solar spectrum, the *o*-chlorobiphenyls having less spectral overlap but higher quantum yields of homolysis.[9] The photohomolysis of polybrominated biphenyls,[25] polybrominated diphenyl ethers,[26] and polybrominated dibenzofurans[27] has also been described. In the majority of cases, photodegradation in organic solvents by ultraviolet (UV) radiation results in the formation of lower brominated congeners.

Various surfactant solutions have been employed[28,29] to increase the extraction of PCBs from soil matrices and to increase the quantum yield of PCB photodegradation by transferring the PCBs into an alkane-like environment. The problem that remains is that at doses high enough to form micelles the aqueous phase of the soil may be colored due to the solubilization of humic material and hence inhibit the penetration of light into the solution. Chu et al.[29] found sixfold faster degradation of Aroclor 1254 and 2,3,4,5-tetrachlorobiphenyl in 0.5-m*M* Brij 58 micellar solutions than in water alone upon irradiation at 253.7 nm. The major initial product of 2,3,4,5-tetrachlorobiphenyl photodegradation was 3,4,5-trichlorobiphenyl. Two possible pathways were postulated for its formation: (1) by homolysis, forming a biphenyl radical that may abstract a hydrogen from the surfactant hydrocarbon, or (2) by the triplet state of 2,3,4,5-tetrachlorobiphenyl abstracting a hydrogen from the surfactant hydrocarbon. An overall 1,4-shift isomerization reaction was observed, with a high production of 2′,3,4,5-tetrachlorobiphenyl, as a result of the second postulated pathway.

Polychlorinated dibenzo-*p*-dioxins are reported to lose lateral (2, 3, 7, 8) in preference to apical (1, 4, 5, 9) chlorines upon photolysis in solution,[30,31] but in the gas phase photodechlorination occurs preferentially from the *peri* positions, based on relative rates of disappearance of starting material and product studies.[32] In solution, PCDDs give very low yields of dechlorination products under both direct homolysis and amine-assisted photolysis (Section 3.2).[33] Recently, the missing material has been identified as arising through mechanisms involving C-O rather than C-Cl cleavage to afford both polychlorinated hydroxydiphenyl ethers and polychlorinated 2,2′-dihydroxybiphenyls.[34,35]

Under certain conditions, photodegradation of polychlorophenols has been associated with the production of more problematic PCDDs and PCDFs.[36] PCDDs and PCDFs were identified after 5 hours of UV irradiation of pentachlorophenol-containing wastewater using light of wavelength 254 nm. It was noted that complete removal of PCDDs and PCDFs could be achieved by increasing irradiation time or applying high-pressure mercury lamps with higher energy than the low-pressure mercury lamp.

Irradiation of halogenated furans and thiophenes with benzene gives a mixture of arylated and dehalogenated products. It is postulated that excitation of the heterocycle affords a higher excited triplet state (π,σ^*, n,σ^*, or σ,σ^*) localized on the C-X bond and that its reaction with the benzenoid component yields a benzene-complexed halogen atom and a heterocyclic aryl radical that reacts rapidly with the aromatic reagent to give the arylation or dehalogenation products.[37]

38.3 Reactions Proceeding Via Excimers, Exciplexes, and Electron Transfer

These reactions are initiated by the full or partial acquisition of an electron by the aryl halide, affording an excimer, an exciplex, or radical ions, depending upon the electron donor and the solvent. In this review, the term excimer will be used to describe the complexes formed between two arenes, even when they are not identical.

Excimer Reactions

For many aryl halides, a major route of photodehalogenation is via triplet excimer reactions in which the ground state aryl halide absorbs a photon to produce an excited singlet state (S_1). Rapid intersystem crossing affords T_1, usually with high efficiency, due to increased spin-orbit coupling attributed to the "heavy atom effect". The excited triplet interacts with a second ground-state molecule to form a triplet excimer, which leads to dehalogenation products. Deactivation of the triplet monomer by the triplet excimer, returning it to the ground state, is a major cause of quantum inefficiency.[38]

A key mechanistic observation in support of an excimer mechanism is the dependence of the quantum yield of reaction upon the aryl halide concentration: $\Phi_r^{-1}\,\alpha[ArX]^{-1}$. Inferential evidence is provided when an excimer can be detected spectroscopically by fluorescence or flash photolysis.

The photodebromination of 4-bromobiphenyl typifies this mechanism.[39] Biphenyl is the sole product, and the participation of the triplet state is clear in that $\Phi(S_1 \rightarrow T_1) = 0.98$, while $\Phi_r = 0.15$ at high [BpBr]. The involvement of the triplet excimer is shown by the increase of Φ_r with [BpBr]; $\Phi_r^{-1}\,\alpha[BpBr]^{-1}$. The irradiation of 3,4-dibromobiphenyl in acetonitrile afforded 4-bromobiphenyl and 3-bromobiphenyl in a ratio of 7.6 to 1. This reaction also had a linear relationship between Φ_r^{-1} and [3,4-bromobiphenyl]$^{-1}$. AM1 calculations were used to postulate that the products were formed via both excimer and radical anion intermediates.[40] Higher chlorinated biphenyls are also expected to dechlorinate via this mechanism.

Earlier investigations had shown similar increases of Φ_r with concentration in the case of 1-chloronaphthalenes, but a decrease in the case of chlorobenzene,[41] because in the chlorobenzene series the excimer cleaves less efficiently than the monomer ($\Phi_r = 0.54$ in alkanes). Dechlorination via a heteroexcimer is also implicated by studies indicating that benzene "sensitizes" the dechlorination of chlorobenzene.[4]

The reactivity of a heteroexcimer has been exploited as a means of degrading low concentrations of chlorinated pollutants such as polychlorinated biphenyls and polychlorinated benzenes.[42] Copolymers of vinylnaphthalene and styrenesulfonic acid form water-soluble, micellar-like copolymers with a hydrophobic core. When the nonpolar chloro-compounds are dissolved in aqueous solutions containing the water-soluble copolymer, they are scavenged into the core, where they undergo photodehalogenation. In these reactions, essentially all the incident radiation is absorbed by the naphthalene chromophores, which form heteroexcimers with the polychloro-compound. The pattern of dechlorination is characteristic of electron transfer rather than direct homolysis.

The rate of triplet excimer formation appears to be critical in product formation in halogenated benzenes in the presence of oxygen. Recent investigations have revealed a great difference in reactivity upon photolysis of 1,2,4-tribromobenzene, 1,2,3,5-tetrabromobenzene, and pentachlorobenzene in air under natural light.[37] The brominated compounds debrominated readily, but pentachlorobenzene was unreactive. The following kinetic relationship was found for the quantum yield of debromination under direct photolysis:

$$1/\Phi = 1/(\Phi_{ISC}F) + \{(k_q[O_2] + k_{td})/(k_2\Phi_{ISC}F) * (1/[ArX])\}$$

where Φ_{ISC} is the quantum yield of intersystem crossing, which for these compounds is high; F is the efficiency of product formation; k_q is the rate of oxygen quenching of the triplet state (estimated to be 3×10^9 L mol^{-1} s^{-1} for all three compounds); k_{td} is the rate constant for C-X bond cleavage in the triplet excimer; and k_2 is the excimer formation rate constant. In the case of the two brominated benzenes, k_2 is large enough to support dehalogenation, but, in the case of pentachlorobenzene, a smaller value of k_2 leads to total quenching of the triplet by oxygen. In the absence of air, three dechlorination pathways have been deduced for pentachlorobenzene: homolysis from both S_1 and T_1 and fragmentation of a triplet excimer.[43]

The dechlorination of pentachlorobenzene has also been studied in micelles of hexadecyltrimethylammonium bromide in water.[44] The predominant reaction at high [C_6HCl_5] microconcentrations is an excimer-assisted dechlorination, deduced from the relationship $\Phi_r^{-1}\,\alpha[C_6HCl_5]^{-1}$. At low concentrations, a triplet monomer pathway intervenes. Byproducts of the reaction include bromotetrachlorobenzenes, which are postulated to arise through trapping the cationic partner of the excimer by Br^-.

Exciplex Reactions Involving Aliphatic Amines

In these reactions, kinetic evidence for the involvement of the amine is shown by the relationship $\Phi_r^{-1}\,\alpha[\text{amine}]^{-1}$. In cases where the halide has detectable fluorescence, the amine may quench fluorescence according to Stern–Volmer kinetics, and emission from the singlet exciplex is frequently observable in nonpolar solvents.[4] For a predominantly singlet state reaction, concordance is seen between K_{sv} (the Stern–Volmer constant for quenching fluorescence) and K_φ (the parameter intercept/slope from the plot

TABLE 38.2 Photodehalogenation of 9,10-Dihaloanthracenes with Aliphatic Amines

Halogen	Amine	Solvent	K_{SV} (M^{-1})	K_{φ} (M^{-1})

Br	Et_3N	Benzene	23	—
Br	Et_3N	Dioxane	15	—
Br	Et_3N	Methanol	4.5	—

TABLE 38.3 Amine-Assisted Photoreduction of 4-Chlorobiphenyl

Amine	Solvent	K_{SV} (M^{-1})	K_{φ} (M^{-1})
Et_3N	Cyclohexane	11	44
Et_3N	Methanol	2.7	18
Et_3N	Acetonitrile	23	20[a]
Et_3N	Acetonitrile	20	83
Et_3N	Aq. acetonitrile	11	97
Piperidine	Methanol	0.8	2.2
Piperidine	Acetonitrile	13	61

[a] This value is from Ohashi et al.;[48] all others are from Bunce.[49]

of $\Phi_r^{-1}\alpha[\text{amine}]^{-1}$). This kinetic behavior is observed in the diethylamine-assisted photoreduction of 9,10-dihaloanthracenes to 9-haloanthracenes, which are convenient to study because of the lack of an unassisted reaction, as shown[45,46] by the results of Table 38.2, which shows the excellent agreement between K_{sv} and K_{φ}.

Unlike diethylamine, ethylamine failed to quench fluorescence or to induce dehalogenation, while the tertiary alkylamine (Et_3N) quenched fluorescence but induced dehalogenation inefficiently or not at all. The effect on fluorescence is consistent with the order of oxidation potentials of aliphatic amines; the lack of concordance between K_{sv} and K_{φ} in the case of Et_3N suggests a change of mechanism in this case.

These results parallel those obtained upon photolysis of the parent anthracene with amines: neither reaction nor fluorescence quenching with primary alkylamine; fluorescence quenching and photochemical reaction (reductive addition to give a variety of 9,10-dihydroanthracene derivatives) with dialkylamine with transfer of the NH(D) proton; and fluorescence quenching and a less efficient chemical reaction with bonding of the α-carbon of Et_3N to the arene:[47]

$$^1(\text{ArX}^{\delta-}.\text{Et}_2\text{NCH}_2\text{CH}_3{}^{\delta+}) \rightarrow (\text{ArXH.Et}_2\text{NCH}\cdot\text{CH}_3) \rightarrow \text{ArH.CH(CH}_3)\text{NEt}_2$$

In the case of a triplet-state exciplex mechanism, agreement between K_{sv} and K_{φ} will occur only by coincidence, so that $K_{sv} \neq K_{\varphi}$ is compatible with a triplet-state reaction but not with a singlet-state process. This behavior is exemplified by the photodehalogenation of 4-chlorobiphenyl, which is convenient for study because its quantum yield of reduction in the absence of amines is very low ($\Phi < 0.001$). In acetonitrile, the addition of 0.1 *M* amine increased Φ_r to 0.07 (butylamine), 0.25 (dipropylamine), and 0.49 (triethylamine). Initially,[48] the singlet exciplex mechanism was suggested with Et_3N as the amine ($K_{sv} = 23\ M^{-1}$; $K_{\varphi} = 20\ M^{-1}$), but in later work on the same system K_{φ} was consistently found to be greater than K_{sv} (Table 38.3), suggesting a predominantly triplet-state reaction,[49] compatible with a high value of $\Phi(S_1 \rightarrow T_1)$. Furthermore, quenching of the triplet by tertiary amines has been observed experimentally by flash photolysis.[50] Note, however, that even though $K_{sv} \neq K_{\varphi}$, the two parameters follow the same trend with changes in amine and solvent, indicating parallel rates of electron transfer to both singlet and triplet excited states.

Photodechlorination of 4-chlorobiphenyl/Et_3N systems can be carried out using long-wavelength UV, rather than 254-nm, radiation if anthracene is added as the initial light absorber.[51] Besides biphenyl, photoreduction products are formed. The possibility favored by the authors was endothermic electron transfer between anthracene radical anion and 4-chlorobiphenyl.

$$^1C_{14}H_{10} + Et_3N \rightarrow C_{14}H_{10}^{\bullet -} + Et_3N^{\bullet +}$$

$$C_{14}H_{10}^{\bullet -} + C_{12}H_9Cl \rightarrow C_{14}H_{10} + C_{12}H_9Cl^{\bullet -} \rightarrow C_{12}H_9^{\bullet} + Cl^-$$

However, another possibility is the attack of Et_3N on an anthracene-chlorobiphenyl heteroexcimer.

Polychlorinated biphenyls, bromobiphenyls, and 1-bromonaphthalene, all of which undergo efficient $S_1 \rightarrow T_1$ intersystem crossing, show enhanced photodehalogenation in the presence of tertiary aliphatic amines, a reaction consistent with electron transfer to the triplet excited state. An exception is 2,4,6-trichlorobiphenyl, which showed lower photoefficiency in cyclohexane solution when Et_3N was present, a result attributed to its rather efficient photohomolysis ($\Phi = 0.21$); the major effect of Et_3N is, thus, to quench homolysis without providing an alternative efficient reaction channel. In other cases, curved plots of Φ_r vs. [amine] have been interpreted in terms of competing singlet and triplet quenching by the amine.[49] Dechlorination of the higher polychlorinated biphenyl congeners in Aroclor 1254 in natural sunlight is inefficient due to their low absorptivity and lack of short-wavelength radiation but is accelerated in the presence of diethylamine[52,53] and diethyl phenylenediamine;[54] this reaction has been proposed as a method for the destruction of commercial PCB wastes.

Two possible sequences of events follow formation of the exciplex or radical ion:

(A) Loss of halide followed by hydrogen atom abstraction

$$ArX^{\bullet -} \rightarrow Ar^{\bullet} + X^-;\ Ar^{\bullet} + RH \rightarrow Ar - H + R^{\bullet}$$

(B) Protonation followed by loss of a halogen atom

$$ArX^{\bullet -} + H^+ \rightarrow (ArXH)^{\bullet} \rightarrow Ar - H + X^{\bullet}$$

Deuterated solvents have been used to distinguish these possibilities.[49,55] Mechanism A is predicted to give deuterium incorporation using C_6D_{12}, CD_3OH, etc., while Mechanism B should afford deuterium incorporation with CH_3OD, CH_3CN/D_2O, etc.

Mechanism A is implicated by the formation of deuterated product upon photolysis with Et_3N/CD_3OH, and by the failure in other cases to observe deuterium incorporation when CH_3CN/D_2O was used as the solvent. Mechanism B has been suggested for a number of cases (1-chloronaphthalene, 4-chlorobiphenyl, 1-bromonaphthalene, and 9-chloroanthracene), all of which incorporate deuterium into the dehalogenated product when the starting materials are photolyzed with $CH_3CN/Et_3N/D_2O$ or Et_3N/CH_3OD. For example, when Et_2ND was photolyzed with 9,10-dibromoanthracene in heptane, the product 9-bromoanthracene contained deuterium at the *meso* position, indicating that hydrogen was transferred from the amine as a proton rather than as a neutral hydrogen atom:

$$^1(ArBr^{\delta -}.HNEt_2^{\delta +}) \rightarrow (ArBrH.NEt_2) \rightarrow ArH + Br^{\bullet} + Et_2N^{\bullet}$$

Finally, a substantial fraction of the hydrogen always originates from the C-H bonds of the amine, indicating in-cage hydrogen transfer, as shown by the failure to effect complete deuteration with, for example, Et_3N/CD_3OD or Et_3N/C_6D_{12}.

The amine Et_3N also assists the photodechlorination of 1-chloropyrene in acetonitrile, but in this case reduction is further assisted by cyanide ion.[56] Flash photolysis suggests the following sequence of intermediates:

$$PyCl \rightarrow PyCl^{\bullet -} \rightarrow PyClH^{\bullet} \rightarrow PyCNH^{\bullet} \rightarrow PyH$$

TABLE 38.4 Et_3N-Assisted and Unassisted Reactions of Polychlorobenzenes

Products	Unassisted	Et_3N-Assisted
Pentachlorobenzene		
1,2,3,5-Cl_4	67	25
1,2,4,5-Cl_4	26	66
1,2,3,4-Cl_4	7	8
1,2,3,5-Tetrachlorobenzene		
1,3,5-Cl_3	59	22
1,2,4-Cl_3	40	73
1,2,3-Cl_3	<1	5

Singlet 1-chloropyrene gains an electron from Et_3N followed by in-cage proton transfer. Loss of Cl• from this intermediate is very inefficient; however, chloride is displaced by the attack of CN^-. PyCNH• does not go on to give pyrenecarbonitrile, but instead loses CN• to complete the reduction.

Polychlorobenzenes undergo intersystem crossing with high efficiency, thus making T_1 the likely reactive excited state.[57] In these reactions, plots of $\varphi^{-1}\alpha[Et_3N]^{-1}$ are linear at high $[Et_3N]$ but show little Et_3N dependence at low $[Et_3N]$. This suggests the simultaneous involvement of an amine exciplex mechanism and another reaction (excimer or triplet homolysis) that does not involve the amine. Most importantly, the distribution of dechlorinated products is different for the unassisted and Et_3N-assisted reactions in acetonitrile;[58] hence, the regioselectivity of dechlorination may be used as an indicator of the mechanism (Table 38.4). The intermediacy of the polyhalobenzene anion radical in Et_3N-assisted photolyses has been demonstrated unequivocally by the observation of the "assisted" product spread when the radical anion is generated thermally.[59] Furthermore, the "assisted" product distribution is also obtained in Et_3N-assisted reactions sensitized by acetophenone, thus confirming the triplet as the reactive excited state.

The regioselectivity of Cl^- ejection following electron transfer to a polychlorobenzene cannot be interpreted simply in terms of the maximal relief of steric strain[56] but is rationalized instead by considering the stabilization of the radical anion $C_6H_{6-n}Cl_n^{\bullet -}$ by the chlorine substituents. Loss of chlorine is fastest from the position where least delocalization of the negative charge is possible.

Triethylamine also promotes photoreduction of polyfluorobenzenes in both acetonitrile and alkane solvents.[58] In this case, homolysis cannot be a competing reaction, based on energetic arguments. These reactions appear to be entirely parallel to those with polychlorobenzenes, with electron donation to the polyfluorobenzene followed by fluoride loss, together with an excimer component to the reaction. The latter is independent of Et_3N but has $\Phi_r^{-1}\alpha[ArF]^{-1}$. A different product spread is observed in alkanes compared with acetonitrile, consistent with the relative extents of electron transfer in each solvent. Previous to this work, photodehalogenation of fluoroarenes was almost unknown, although photoaddition and photoreduction to dihydro derivatives had been observed with fluorobenzene and aliphatic amines.[60]

Exciplex Reactions Involving Aromatic Amines

These reactions are often mechanistically less clear cut than those with aliphatic amines because both the amine and the aryl halide can potentially absorb light. The reactions of 9,10-dihaloanthracenes with aniline derivative are unambiguous in this respect, as the use of long-wavelength UV radiation ensures light absorption by the haloarene alone. Photoreduction to the 9-haloanthracene is observed for both X = Cl and X = Br, and the excellent agreement between K_{sv} and K_φ for $PhNH_2$, $PhNHCH_3$, $PhN(CH_3)_2$, and $PhNEt_2$ strongly supports reduction through a singlet exciplex.[61]

Dehalogenation of halobenzenes[62,63] and chlorobiphenyls[64] has been studied under conditions where the radiation was initially absorbed by an *N*,*N*-dialkylaniline. The aryl halide quenched the fluorescence of the aniline, and in the halobenzene series reasonable agreement between K_{sv} and K_φ was observed. In

methanolic solution, the halobenzenes yielded benzene and *o*- (and *p*-)phenyl-*N*,*N*-dimethylaniline. Isotopic substitution of the amine ($PhN(CD_3)_2$) afforded benzene-d_1 (66%, X = Cl; 42%, X = Br; 12%, X = I). The d_1 product is the result of proton transfer from $PhN(CD_3)_2$ within the solvent cage. The photoreaction between *m*-chloronitrobenzene and *N*,*N*-dimethylaniline is also an electron transfer process but in this case it is the nitro group that is reduced rather than the chlorine.[65] More recently, the electron donor photosensitizer *N*,*N*,*N*′,*N*′-tetramethylbenzidine (NTMB) has been used to photosensitize the photodehalogenation of chlorobenzenes, resulting in the departure of a chlorine anion.[66]

Miscellaneous Electron Transfer Processes

Like amines, dienes quench many arene singlet and triplet states, a process attributed to the formation of diene/arene exciplexes; these have a much smaller degree of electron transfer than the corresponding arene-amine exciplexes.[67] Ambiguity arises because dienes are commonly used as triplet quenchers and because simple arenes such as benzenes, naphthalenes, and biphenyls absorb at the same wavelengths as dienes.[62]

9,10-Dichloroanthracene absorbs at longer wavelength than simple dienes. It reacts photochemically with 2,5-dimethyl-2,4-hexadiene by two pathways: in nonpolar solvents (benzene) a photocycloadduct forms by way of a singlet exciplex,[64] whereas in polar solvents reduction to 9-chloroanthracene is observed and a triplex ($C_{14}H_8Cl_2$•2DMH) is implicated.[68] Experiments with added D_2O show that in polar solvent the reduction involved transfer of a proton to the exciplex rather than loss of chloride ion.

The dehalogenation of aryl halides is accelerated by aliphatic sulfides,[69] and an electron transfer mechanism is implicated by the incorporation of deuterium in the reduction product when the reaction is carried out in the presence of D_2O.

Radical Anion Chain Reactions

These reactions are relevant to this review in that they may be photoinduced, but as radical chain processes many of them can be initiated in other ways. Radical chain dehalogenation of aryl halides has been reviewed previously.[70] The chain propagation sequence for the deiodination of aryl iodides with CH_3O^-/CH_3OH is shown in Scheme 1. The species $(ArI)^{\bullet -}$ is very short lived and deiodinates efficiently. Reactivity diminishes in the order ArI > ArBr > ArCl and is enhanced in cases where there is relief of steric strain. Photochemical dehalogenations of aryl halides with AlH_4^- and BH_4^- have been proposed to follow similar radical chain mechanisms. Evidence for electron transfer from BH_4^- to ArCl has been present by Freeman and Ramnath.[71]

$$Ar\bullet + CH_3O^- \rightarrow ArH + CH_2O^{\bullet -}$$

$$CH_2O^{\bullet -} + ArI \rightarrow CH_2{=}O + (ArI)^{\bullet -}$$

$$(ArI)^{\bullet -} \rightarrow Ar\bullet + I^-$$

SCHEME 1

Several aryl halides have been reported to dehalogenate efficiently with the combination 2-propanol/OH^-. The proposed mechanism[72] (Scheme 2) is very similar to Scheme 1, with hydroxide ion playing the key role of deprotonating the product of hydrogen abstraction from 2-propanol.

$$ArX^{\bullet -} \rightarrow Ar\bullet + X^-$$

$$Ar\bullet + (CH_3)_2CHOH \rightarrow ArH + (CH_3)_2C^{\bullet}OH$$

$$(CH_3)_2C^{\bullet}OH + OH^- \rightarrow (CH_3)_2CO^{\bullet -} + H_2O$$

$$(CH_3)_2CO^{\bullet -} + ArX \rightarrow ArX^{\bullet -} + (CH_3)_2C{=}O$$

SCHEME 2

Considerable interest has been shown in this reaction as a possible technology for destruction of commercial PCBs. The photolysis of Aroclor 1254 in alkaline 2-propanol at 254 nm had a dechlorination quantum yield of 35, supporting a free-radical chain mechanism.[73] Studies[74–77] elucidating the photodechlorination pathways of 3,3′,4,4′,5,5′-hexachlorobiphenyl, 3,3′,4,4′-tetrachlorobiphenyl, and related lower chlorinated PCB congeners in alkaline 2-propanol reveal that:

1. The more chlorinated congeners are generally more reactive to photodechlorination.
2. Dechlorination occurs mostly on the more substituted ring.
3. Asymmetrical congeners are more readily dechlorinated than more stable symmetrical ones.
4. Dechlorination occurs preferentially at the position that produces a symmetrical product.
5. The π electronic densities of *para* and *meta* chlorines affect their relative reactivities.

Nucleophilic substitution of halogen by the $S_{RN}1$ mechanism follows a related radical chain pathway (Scheme 3), in which the aryl radical Ar• attacks a nucleophile Nu^- rather than abstracting hydrogen. The solvent should not contain easily abstractable hydrogen atoms in order to depress photodehalogenation. Halo-2-pyridones were also found to undergo nucleophilic substitution via an $S_{RN}1$ mechanism when reacted with cesium phenoxides, yielding hydroxyphenyl-2-pyridones.[78]

$$(ArX)^{\bullet -} \rightarrow Ar^{\bullet} + X^-$$

$$Ar^{\bullet} + Nu^- \rightarrow (ArNu)^{\bullet -}$$

$$(ArNu)^{\bullet -} + ArX \rightarrow Ar - Nu + (ArX)^{\bullet -}$$

SCHEME 3

38.4 Heterolytic Mechanisms

Reactions Involving Carbenes

Investigations conducted to elucidate the dechlorination mechanism of 4-chlorophenol have revealed that elimination of HCl via heterolytic C-Cl bond scission from aqueous 4-chlorophenol in the presence of oxygen produces an initial transient carbene, 4-oxocyclohexa-2,5-dienylidene[11,79,80] that has a triplet character and is stable in aqueous solutions. The addition of O_2 to this intermediate affords a benzoquinone-*O*-oxide, from which loss of an oxygen atom yields the major reaction product *p*-benzoquinone. The involvement of a carbene intermediate has also been indicated for 2-chlorophenol.[81]

The role of singlet oxygen in sensitizing the photolysis of chlorophenols has been recently extensively reviewed by Burrows et al.[6] Inhibition of sensitized photodegradation of 2,4,5-trichlorophenol by adding singlet oxygen quenchers supports the participation of singlet oxygen in this process,[16] while the absence of PCDDs and PCDFs among the products of sensitized transformation of 2,4,5-trichlorophenol favors a singlet oxygen mechanism rather than free radical formation. It is believed that singlet oxygen reacts with chlorophenols to produce a $^1O_2$/quencher exciplex via a charge-transfer-induced intersystem crossing process.

Reactions Proceeding Via Nucleophilic Substitution

Photochemical nucleophilic displacements have been studied extensively, and the early work is documented in the exhaustive review by Cornelisse and Havinga.[82] The most detailed studies have been made of methoxynitroarenes rather than halides, and it is well established that nucleophilic displacement occurs most readily *meta* to NO_2. Of the various halide nucleofuges, only fluoride appears to behave analogously to methoxy. Thus, *m*-fluoronitrobenzene reacts photochemically with OH^- to give *m*-nitrophenol, but the reaction is not observed for *m*-chloro- or *m*-bromonitrobenzenes. With oxidizable "nucleophiles" such as secondary amines, photoreduction of the nitro group takes place in preference to substitution

of halide. However, 1-fluoro-3-nitronaphthalene and other "extended *meta*" fluoronitronaphthalenes undergo replacement of fluorine upon irradiation with OH^-, OCH_3^-, CN^-, and CH_3NH_2.[83]

Photoreactions of nitropolychlorinated dibenzo-*p*-dioxins with sodium ethoxide in anhydrous ethanol undergo S_N2Ar^* substitution reactions, yielding ring-opened products.[84] Irradiation of 2,3,4,7,8-pentachloro-1-nitrodibenzo-*p*-dioxin yielded a tetrachloroethoxynitrodibenzo-*p*-dioxin, presumed to be 2,4,7,8-tetrachloro-3-ethoxy-1-nitrodibenzo-*p*-dioxin, based on the *meta* activation of the nitro group. This reaction was associated with a linear relationship between Φ^{-1} and $[Nu^-]^{-1}$. A secondary thermal reaction was also present, yielding a tetrachlorodiethoxyhydroxynitrodiphenyl ether. Irradiation of 1,3,4,7,8-pentachloro-2-nitrodibenzo-*p*-dioxin under the same conditions produced 1,3,7,8-tetrachloro-4-ethoxy-2-nitrodibenzo-*p*-dioxin as a result of the substitution of chlorine *meta* to the nitro group rather than ring opening. A kinetic study suggested that the excited triplet ArX^* undergoes interaction with the nucleophile to give a σ-complex $[ArXNu]^-$ competitively with radiationless decay to the ground state. The σ-complex may then either afford the substitution product or dissociate to ground state reactants.

Photochemical replacement of a substituent by a nucleophile occurs *ortho* and *para* to electron-donating substituents.[85] These reactions are successful for halides as nucleofuges. An example is the conversion of *p*-chloroanisole to *p*-methoxybenzonitrile upon irradiation with cyanide ion. In the case of the isomeric chlorophenols and chloroanisoles, irradiation with alcohols involves a mixture of substitution (replacement by –Cl or –OR) and dehalogenation.[86] The outcomes of these reactions may be highly solvent dependent, as shown by studies on the replacement of fluoride by CN^- and OH^-, when *o*- and *p*-fluoroanisoles are photolyzed with KCN in water/*t*-butyl alcohol mixtures.[87]

Photosubstitution of hexachlorobenzene and other highly chlorinated aromatics by cyanide systems was recently investigated by Konstantinov et al.[88,89] Photolysis of hexachlorobenzene with sodium cyanide resulted in successive photocyanations occurring with a high quantum yield ($\Phi_{diss} = 0.18$) to give the products pentacyanophenol, 4-chloro-2,3,5,6-tetracyanophenol, and a dichlorotricyanophenol. Quantum yields of substrate disappearance increased with the number of chlorine substituents on a substrate and followed the expected relationship $\Phi^{-1}\alpha[CN^-]^{-1}$. The reaction was proposed to proceed via the S_N2Ar^* mechanism. Sensitization and quenching experiments indicated a triplet reactive excited state to be reactive for all substrates tested.

3-Fluoro- and 3-chlorophenol undergo photomethanolysis to yield resorcinol monomethyl ether when irradiated. They also undergo photoamidation by *N*-methylacetamide, a very weak nucleophile, to yield 3-(*N*-methyl-*N*-acetylamino)-phenol together with a small amount of phenol. Photoamidation of *DL*-2-chlorotyrosine methyl ester and *L*-2-fluorotyrosine methyl ester indicated that fluoro compounds are less reactive than chloro compounds in intramolecular amidation. The reactions proceed via a highly reactive electron-deficient intermediate.[90]

Chlorobenzene is converted to phenol in aqueous solution, in quantum yields comparable with that of dehalogenation.[8] Evidence has been presented that the corresponding photohydrolyses of the monochlorobiphenyls involve homolysis, followed immediately by in-cage electron transfer. The aryl cation is trapped by water but can be diverted back to reactant in the presence of added Cl^-:[91]

$$^3Ar\text{-}Cl \rightarrow (Ar\bullet.Cl\bullet) \rightarrow (Ar^+.Cl^-) \rightarrow \rightarrow ArOH$$

Photohydrolysis can therefore be viewed as a variant of photohomolysis. In an organic solvent such as hexane, the radical pair (Ar•.Cl•) separates and then abstracts hydrogen. Abstractable hydrogens are not present in water, and the high dielectric constant permits electron transfer to occur. An exceptional aspect of the reaction is that both 3- and 4-chlorobiphenyls undergo photoisomerization in parallel with photohydrolysis. This is suggested to proceed by way of valence photoisomerization. Related valence photoisomerizations have been observed occasionally upon photolysis of polychlorobenzenes; for example, photolyses of both 1,2,3- and 1,3,5-trichlorobenzenes in aqueous CH_3CN afford up to 10% of 1,2,4-trichlorobenzene in addition to dechlorination products.[5] Modeling studies[92] suggest that the identity of the halogen and the polarizability of the aryl halide are important factors in determining the photohydrolysis quantum yields of substituted aromatic halides.

38.5 Sensitized Reactions of Aryl Halides

In the context of identifying methods for the degradation of aryl halide environmental pollutants in natural waters, solar photodegradation is attractive in terms of "green chemistry" and the economics of using "free"sunlight.[66] A major problem, however, is that haloaromatics do not absorb strongly above 300 nm, and direct photolysis usually proceeds with very low efficiency. The goal is to find a sensitizer that has strong absorption in the solar region of the spectrum and that can transfer energy efficiently to the ground-state target substrate (ArX) to yield an excited triplet substrate state. Because the same excited state of the substrate is produced in both direct and sensitized photolysis, the photoproducts should be similar:

Sensitized route

$$S + h\nu \rightarrow {}^1S^* \rightarrow {}^3S^*$$

$${}^3S^* + ArX \rightarrow S + {}^3ArX^*$$

Direct route

$$ArX + h\nu \rightarrow {}^1ArX^* \rightarrow {}^3ArX^*$$

$${}^3ArX^* \rightarrow \text{products}$$

Occasionally, the products of direct and sensitized photolysis differ, as in the case of acetone sensitization of the dehalogenation of polychlorobenzenes. For example, upon direct photolysis of 1,2,3,5-tetrachlorobenzene in aqueous CH_3CN, 1,2,4-trichlorobenzene was the major product; acetone sensitization of the same reaction gave predominantly the 1,3,5-isomer. The original hypothesis was that the direct reaction involves S_1 and the acetone-sensitized reaction involves T_1.[5] The suggestion that the direct reaction involves S_1 appears untenable given the high value of $\Phi(S_1 \rightarrow T_1)$; in addition, the formation of 1,2,4-trichlorobenzene in the "direct" reaction is reminiscent of the product spread under electron transfer conditions.[56] One possibility is that the acetone-sensitized reaction indeed involves T_1, but that the direct reaction is actually an excimer-mediated reaction.

Various sensitizing chemicals have been investigated in recent years, including hydroquinone and phenol,[93] phenothiazine,[73] hydrogen peroxide,[31] and 2-methoxyphenol.[66]

38.6 Photoinduced Reactions of Aryl Halides

During induced photolysis, a compound added to the solution generates free radicals, which attack the target molecule, producing various types of radicals. Radicals can be formed by either OH-addition or by direct electron transfer, yielding a wide range of possible products. Investigations of the photoinduced degradation of chlorophenols have identified two main pathways of free radical transformation:[6] (1) degradation to nonaromatic compounds, leading to CO_2 and HCl as final products, and (2) condensation, with the formation of phenolic polymers (humic substances). PCDD, PCDF, and PCB products have also been identified during the recombination of phenolic radicals.

38.7 Decomposition of Aryl Halides by Photochemically Produced Hydroxyl Radicals

These reactions do not involve excitation of the aryl halide but are mentioned here because of interest in degrading chlorinated pollutants. Wastewater treatment involving hydroxyl radical production by photolysis of hydrogen peroxide or ozone is a well-known commercial process. Fe^{3+}, H_2O_2, and UV have been used in combination (the photo-Fenton reaction)[28] to enhance the degradation of Aroclor 1242, a mixture of PCBs. The conventional Fenton reaction produces hydroxyl radicals from H_2O_2 and Fe^{2+}:

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^{\cdot} + OH^{-}$$

Under UV irradiation, Fe^{3+} reacts with water to produce more hydroxyl radicals and Fe^{2+}, making the reaction catalytic in iron:

$$Fe^{3+} + H_2O + h\nu \rightarrow Fe^{2+} + OH^{\cdot} + H^{+}$$

The maximum observed PCB removal was 88%, following 20-hr irradiation in water containing 1 m*M* Fe^{3+} and 30 mmol H_2O_2 at 66°C. Hydroxyl radicals reacted at nonchlorinated positions to give hydroxypolychlorobiphenyls. Both *ortho*- and *para*-dihydroxy-substituted rings were readily oxidized to quinones and further oxidation led to ring-opened products that undergo hydrodechlorination rapidly, as shown by the high yield (up to 85%) of chloride ion.

Photolysis of ferric ions (and also nitrate ions) has also been used[11] as a hydroxyl radical source for the degradation of 1,4-dichlorobenzene. The major product, 2,5-dichlorophenol, was formed by hydroxylation at one of the unsubstituted ring positions.

Several studies of photoinduced degradation of aryl halides in recent years have involved the use of semiconductors, particularly TiO_2 and ZnO,[94] as photocatalysts to enhance the degradation of aryl halides,[94–101] the objective being photomineralization to CO_2 and HCl. This chemistry depends on the excitation of the semiconductor with light of energy greater than its optical band gap (3.2 eV or 74 kcal mol^{-1} for TiO_2), whereupon electrons are transferred to the conduction band, thereby leaving an equal number of electron vacancies or "holes" in the valence band. The latter can interact with water to form hydroxyl radicals (although the reaction is inefficient due to competing electron-hole recombination):

$$h^{+} + H_2O \rightarrow H^{+} + OH^{-}$$

Uchida et al.[95] found that the degradation of trichlorobenzene was enhanced by the use of TiO_2 supported on nickel-polytetrafluoroethylene compared with normal TiO_2. This behavior was attributed to Ni/PTFE acting as a sink for conduction band electrons, thereby inhibiting electron-hole recombination.

In TiO_2 aqueous suspensions, the electrons generated in the conduction band can reduce dissolved oxygen to the highly reactive superoxide ion $O_2^{\bullet -}$, which Wang and Hong[101] suggest is the dominant reaction partner in the photochemical ring-opening of 2-chlorobiphenyl/TiO_2. The rate of reaction of 2-chlorobiphenyl was found by Huang et al.[100] to be approximately proportional to the concentration of suspended TiO_2, and is argued to be due to the need for the aryl halide to adsorb to the surface of the photocatalyst.

Pandiyan et al.[96] found that the dehalogenation of chlorophenols using TiO_2 systems is faster for monohalogenated phenols than poly-substituted phenols.[98] Patterns of photocatalytic degradation of polychlorinated biphenyls are similar to those seen in direct photolysis, with lesser and *ortho*-chlorinated congeners being preferentially decomposed. In general, photocatalytic degradation rates increase with increasing degree of *ortho* substitution.[99]

Chiarenzelli et al.[98] suggest that the solubility of PCB congeners controls their rate of decomposition by regulating their transfer to the aqueous phase and thus to the TiO_2 surface. The rate and degree of photodegradation of polychlorinated biphenyls is also enhanced by the use of shorter wavelength UV light, which facilitates hydroxylation reactions, again increasing solubility and accessibility to photocatalytic sites. Solubilization has also been explored by adding the anionic surfactant FC-143 to TiO_2 photocatalytic systems.[102] Enhanced quantum yields of reaction were achieved because the hydrophobic PCBs partitioned into the hydrophobic interior of the micelles, which in turn adsorbed preferentially on to the TiO_2 surface where hydroxyl radicals were being produced.

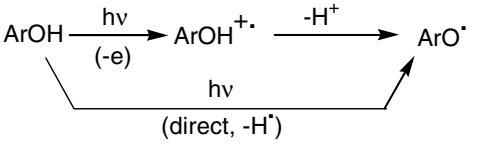
Photochemistry of Hydroxyarenes

Matthew Lukeman
University of Victoria

Peter Wan
University of Victoria

39.1 Introduction

The excited state properties of hydroxyaromatic compounds (phenols, naphthols, etc.) are of interest to a wide audience in chemistry, including those interested in the environmental decomposition of phenols, chemical physicists interested in the very fast dynamics of excited-state proton transfer (ESPT) and excited-state intramolecular proton transfer (ESIPT), physical chemists interested in photoionization and the photochemical pathways for phenoxyl radical formation, and organic photochemists interested in the mechanisms of phenol and hydroxyarene photochemistry. Due to space limitations, this review is restricted to molecular photochemistry of hydroxyaromatic compounds reported during the last three decades that are of primary interest to organic photochemists. It also includes a brief section on the phenomenon of enhanced acidity of phenols and other hydroxyaromatics because this is central to hydroxyarene photochemistry and forms the basis of much of the mechanistic photochemistry to be discussed later on. Several reviews that offer related coverage to this work have also appeared recently.[1] This review does not cover aspects of electron photoejection from phenols or phenolate ions (and related compounds such as tyrosine) or phenol OH homolysis induced photochemically, as shown in Eq. (39.1), as these are adequately covered elsewhere:[2]



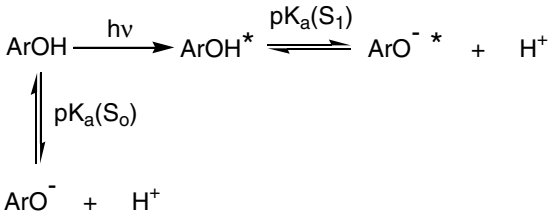
(39.1)

In general, the quantum yields are low (<10%)[2c] and/or arise via two-photon laser excitation. More importantly, to our knowledge, none is known to give rise to well-characterized photoproducts, although the process is important in biological systems.[2d]

0-8493-1348-1/04/$0.00+$1.50

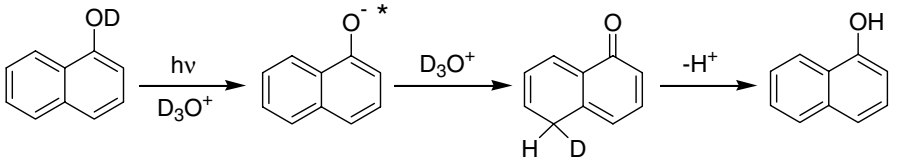
39.2 Enhanced Acidity of Hydroxyaromatic Compounds in the Excited Singlet State

The photoprototopic behavior of phenols and hydroxyarenes in general has been well studied and is based on the enhanced acidity of these types of compounds in S_1 (Scheme 1).[3] For example, the pK_a (S_0)



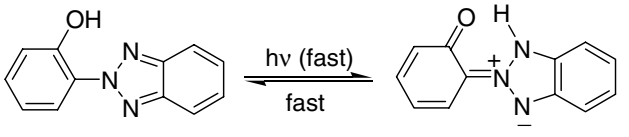
SCHEME 1

of 2-naphthol is 9.5, but its $pK_a(S_1)$ is 2.8, a change in acidity of about 7 orders of magnitude. Even more dramatic is the change in pK_a for 1-naphthol [$pK_a(S_0) = 9.2$; $pK_a(S_1) = 0.4$].[4] The increase in acidity of hydroxyarenes in S_1 is generally believed to be due to the enhanced electron-donating character of the oxygen atom to the benzene π system (more charge transfer character), although other effects such as the symmetry of the lowest singlet also play a role. The enhanced charge transfer character of ArOH* is exemplified by observation of deuterium incorporation of 1-naphthol on photolysis in dilute D_3O^+ where the 5-position is predominately deuterated (Eq. (39.2)), whereas deuterium incorporation in the ground state is observed only on the ring bearing the hydroxyl group:[4,5]



(39.2)

In molecular systems where the phenol or hydroxyarene moiety is in close proximity to a functional group (typically, aromatic ketone or the nitrogen of a heterocycle) that experiences an enhancement in basicity on excitation to S_1, the well-studied phenomenon of excited-state intramolecular proton transfer (ESIPT) is observed.[3] The vast majority of these ESIPT is reversible, some with exceptionally fast rates:[3,6]



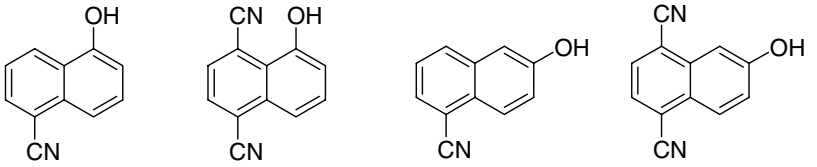
Tinuvin-P

(39.3)

This is a very wide area and is not reviewed in this work except for selected systems that have (or are related to systems that have) net photochemistry and those that are not reversible. These are described in sections to follow.

Simple phenols and naphthols require an aqueous medium for ESPT to take place. The exact role of water in promoting ESPT has been investigated and debated extensively,[5] with the role of water clusters apparently being crucial. Nevertheless, the complete absence of ESPT of simple phenols and naphthols in alcohol (and other organic) solvents is a stark experimental fact. In kinetic terms, the rate of proton dissociation in these solvents cannot compete with other deactivational channels for S_1 of these compounds.

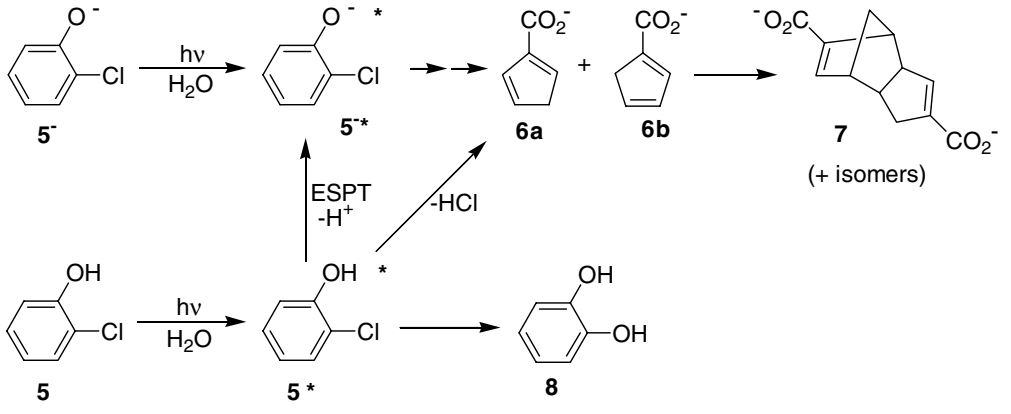
Tolbert and co-workers[5] have carried out extensive studies aimed at enhancing the excited state acidity of naphthols, with the ultimate aim of observing ESPT in organic solvents. Initial work centered on cyano-substituted 1-naphthols **1** and **2**. Both were found to be much more acidic in S_1 and exhibited ESPT in alcohols and DMSO; however, due to the weakness of the fluorescence emission of these naphthols, estimating the $pK_a(S_1)$ was problematic. Fortunately, cyano-substituted 2-naphthols such as **3** and **4** (which have better fluorescence properties) were also stronger acids in S_1. Indeed, the estimated $pK_a(S_1)$ for **4** is –4.5, the most acidic of all the compounds studied to date. Compounds of this type also undergo ESPT in organic solvents such as MeOH, EtOH, DMSO and DMF. These "super photoacids" open up the possibility of carrying out photo-initiated acid-catalyzed reactions in organic solvents.



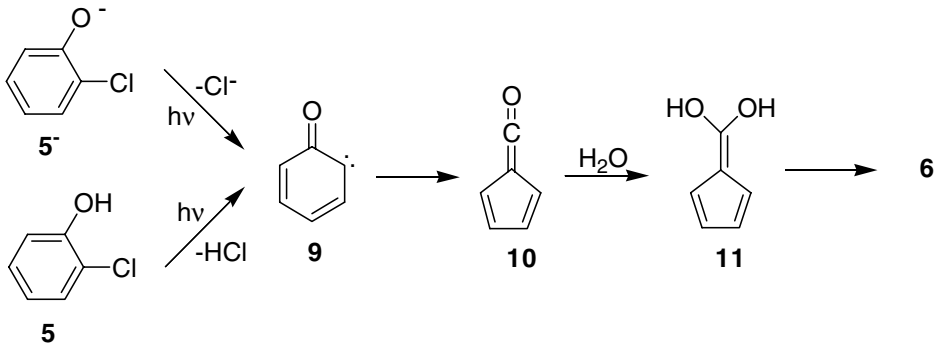
39.3 Photochemistry of Halo and Cyanophenols

The considerable interest in the study of the degradation processes of halophenols is due to their presence as pollutants resulting from pulp and paper processes and from industrial production of herbicides and pesticides.[7] Photochemical methods of breaking down these waste products have received considerable attention, and a detailed mechanistic review of the topic is available.[9] The general mechanisms that govern the photochemical fates of simple (monohalogenated) derivatives are discussed here.

Boule and co-workers[8,11,12] reported very different efficiencies for the phototransformation of 2-chlorophenol (**5**) in neutral (Φ = 0.03) and in alkaline (Φ = 0.32) aqueous media. In alkaline solution, phenolate $\mathbf{5}^-$ gives, upon photolysis, cyclopentadiene carboxylic acids (**6a** and **6b**), which dimerize to **7** in concentrated solution. In neutral solution, this reaction is in competition with the formation of pyrocatechol (**8**) (Scheme 2). Formation of the cyclopentadiene carboxylic acids (**6a** and **6b**) was also observed for 2-fluorophenol and 2-bromophenol. The mechanism shown in Scheme 3 involving a carbene intermediate was proposed as being responsible for the formation of **6**. Although no direct evidence exists for the intermediacy of ketocarbene **9**, more recent studies[10] employing nanosecond laser flash photolysis (LFP) have provided evidence for the presence of ketene **10** and its subsequent conversion to fulvene-6,6-diol (**11**). α-Ketocarbene **9** can quickly undergo a Wolff rearrangement to give **10** and hence is



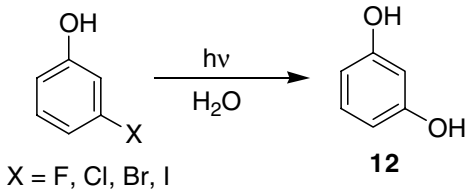
SCHEME 2



SCHEME 3

too short lived to be detected by nanosecond LFP. Not addressed was whether **5** undergoes direct loss of HCl to give **9**, or whether it undergoes ESPT to solvent to give the excited phenolate prior to dechlorination. Similar transients were observed for LFP of 2-bromophenol and 2-fluorophenol, suggesting that they react via a similar pathway. Although the authors did not propose a mechanism for the formation of **8**, a likely mechanism is loss of Cl^- on photolysis to give an aryl cation that is subsequently trapped by water.

The dominant product (>80% yield) resulting from photolysis of 3-halophenols is resorcinol (**12**), with no dependence on the nature of the halogen:[8,10,13,14]

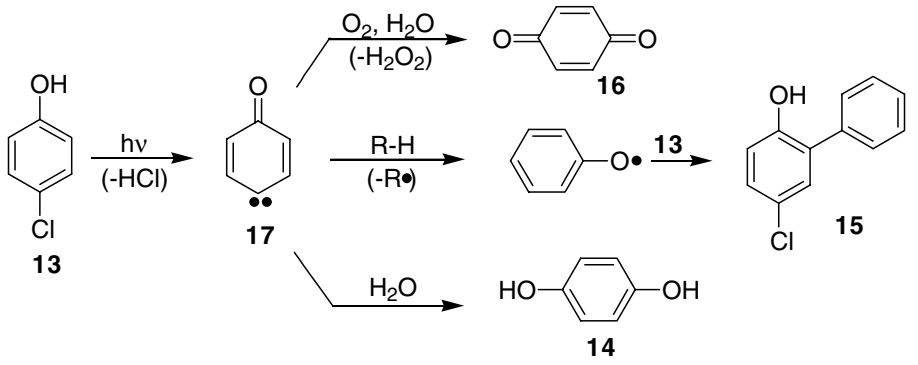


(39.4)

Higher quantum yields were observed on irradiation of the phenolate. The authors[13,14] proposed a mechanism in which a water molecule attacks the ring carbon with concerted loss of Cl^- in an S_N2 fashion, although this mechanism is inconsistent with the higher yields observed on irradiation of the phenolate (the phenolate excited state should be more electron rich than the phenol excited state and thus would be expected to be less reactive toward S_N2 substitutions). Other mechanistic possibilities include ArCl bond heterolysis followed by attack of water on the resultant aryl cation, or initial ESPT to solvent to generate the excited state phenolate, which can then undergo ArCl heterolysis and trapping by solvent. No intermediates were sufficiently long lived to be observed by nanosecond LFP.

4-Chlorophenol (**13**) is perhaps the most studied of the halophenols, as it is a common pollutant found in water that has been treated with chlorine. Early work by Omura and Matsuura[13] revealed that, upon photolysis of concentrated basic solutions, several products are formed, including phenol, hydroquinone (**14**) and the biphenyl based coupling product (**15**). The authors proposed that homolytic cleavage of the ArCl bond is a major pathway from the excited state of **13**, as the formation of aryl radicals would explain the coupling products, although not all observed products could be explained by this pathway. Subsequent studies by Lipczynska–Kochany[14] employing dilute (10^{-4} M) aerated solutions reported that photolysis led to nearly quantitative generation of benzoquinone (**16**). When the solutions were deaerated prior to photolysis, **14** was the major photoproduct recovered, although significant amounts of coupled products were also observed. As the substrate concentration in deaerated solutions was increased, the yield of coupled products also increased, and formation of oligomeric species was detected; in aerated conditions, formation of **16** was still nearly quantitative.

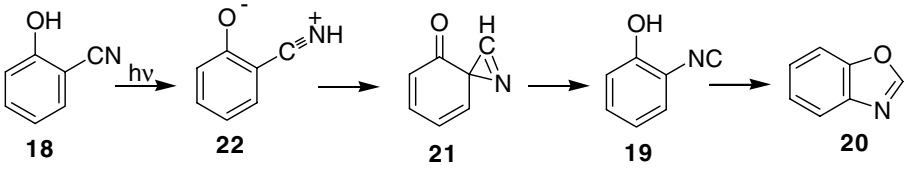
Grabner and co-workers,[15] using nanosecond LFP, were able to observe a transient that they assigned to ketocarbene **17**. This ketocarbene quickly reacts with oxygen, ultimately giving **16** and with H-donating



SCHEME 4

solvents giving the phenoxyl radical (Scheme 4). Ketocarbene **17** also undergoes a slow reaction with water, presumably via insertion into an OH bond, to give hydroquinone (**14**). Subsequent studies[16,17] supported the initial formation of **17**. Grabner and co-workers[15] favored a mechanism of reaction involving initial heterolytic loss of chloride followed by deprotonation over a mechanism involving initial ESPT to solvent followed by loss of chloride, as the efficiency of ketocarbene formation is unaffected by pH in the range of 0 to 7 ($pK_a^* \sim 4$ for **13**). Other studies[14,18] indicated that the fluoro, bromo and iodo analogs reacted via the same pathway.

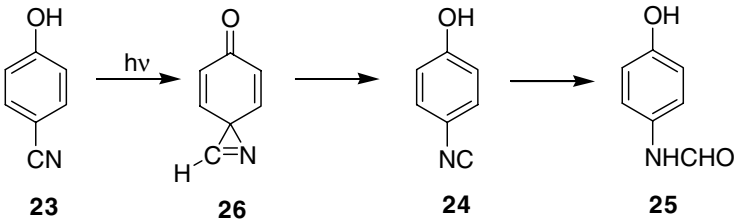
While studying the photochemistry of 2-cyanophenol (**18**), Ferris and Antonucci[19–21] reported that the first formed product of **18** is isonitrile **19**, which then thermally cyclizes to benzoxazole **20** at room temperature:



(39.5)

Isonitrile **19** was detected in ultraviolet (UV) and infrared (IR) studies at low temperatures. They speculated[21] that azirine intermediate **21** may precede the formation of **19** and, indeed, LFP studies on **18** performed by Richard and co-workers[22] allowed observation of an intermediate which was assigned to **21** on the basis of the similarity of its UV absorption spectra to that of the cyclohexadienone chromophore. The reaction was not quenchable by piperylene and is presumed to occur via the singlet manifold. The authors did not put forward a mechanism for the formation of **21**, although it may be formed by initial ESIPT from the phenol to the cyano group to give tautomer **22**, which can then rearrange to give **21**. Similar products (substituted benzoxazoles) were observed via presumed initial ESIPT in structurally related *o*-hydroxy substituted aromatic oximes and oxime ethers.[23]

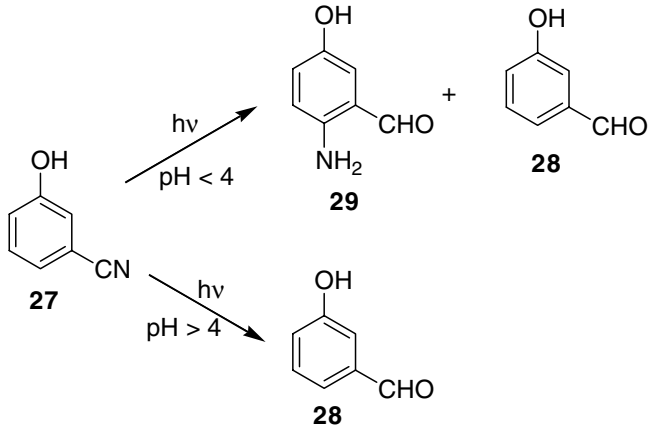
Richard and co-workers[22] observed photoisomerization of 4-cyanophenol (**23**) to 4-hydroxybenzoisonitrile (**24**) in protic solvents:



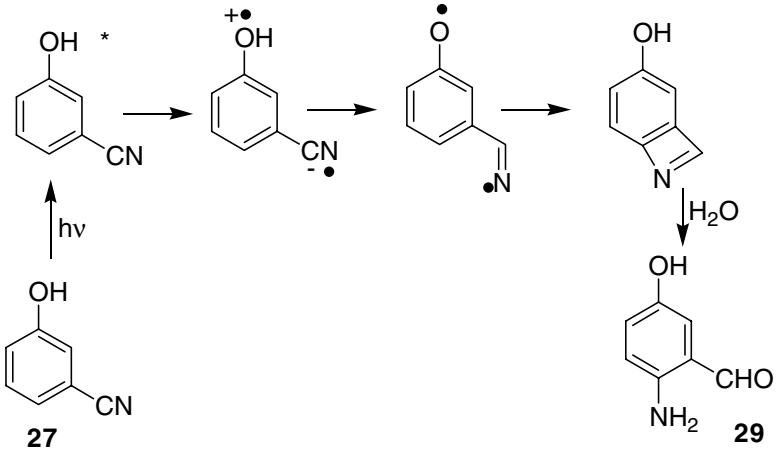
(39.6)

The distal arrangement of the substituents in **24** prevents cyclization to a benzoxazole-type intermediate. While stable in alcohols, this intermediate can undergo hydrolysis (in water) to give hydroxyformanilide (**25**). Further analysis of the reaction revealed that **24** is a secondary photoproduct of the first-formed azirine **26**, in contrast with the thermally induced azirine conversion to isonitrile that is observed for **18**. Triplet quenchers such as oxygen and methyl acrylate quench the reaction efficiently. The authors propose a mechanism for conversion of **23** to **26** that involves a deprotonation–reprotonation sequence preceded by intramolecular electron transfer from the triplet-excited state of **23**.

The interesting photoisomerizations observed for 2- and 4-cyanophenols (**18** and **23**) led Richard and Bonnichon[24] to study the *meta*-isomer **27**. Unlike **18** and **23**, Kekule resonance forms of azirine products stemming from **27** cannot be drawn, suggesting that formation of isonitriles may be an unfavorable pathway for **27**. Photolysis of **27** in deoxygenated aqueous media (pH > 4.0) led to formation of **28** with low yields ($\Phi < 0.001$); for photolyses performed in more acidic media (pH < 4.0), a second photoproduct (**29**) was also formed with quantum yields up to 0.002:



(39.7)

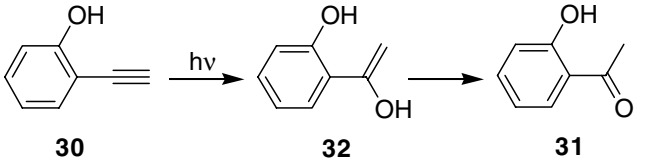


SCHEME 5

Formation of **29** is thought to proceed via the process outlined in Scheme 5. Formation of **28** is poorly understood. The authors[24] proposed a complicated mechanism involving solvated electrons; however, this mechanism is unable to explain the high yields (up to 68%) that were observed. The formation of **28** probably proceeds *via* the triplet state of **27**, as the reaction was efficiently quenched by oxygen and methyl acrylate.

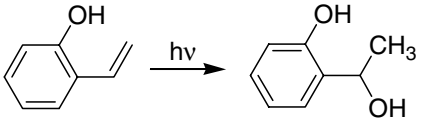
39.4 Photohydration and Photoaddition of Hydroxyarenes

The photohydration of an unsaturated moiety on a phenol ring was first reported by Ferris and Antonucci[20] for *o*-hydroxyphenylacetylene (**30**), which yielded ketone **31**, presumably via initial formation of enol **32**:



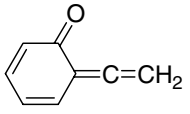
30 **32** **31** (39.8)

Yates and co-workers[25,26] observed a similar reaction for *o*-hydroxystyrene (**33**) (formation of **34**):

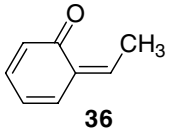


33 **34** (39.9)

Their detailed mechanistic studies revealed that the efficiency of photohydration is independent of the solution pH in the 0 to 7 range. Because the pK_a^* of **30** is expected to lie within this range, it was concluded that the photohydration did not occur via initial protonation of the acetylene by aqueous acid, but instead via initial ESIPT from the phenol to generate quinone methide (**35**) (or **36** from **33**). This quinone methide is trapped by water to give the observed Markovnikov photohydration product. This was the first clear demonstration of ESIPT leading to an irreversible photochemical reaction.

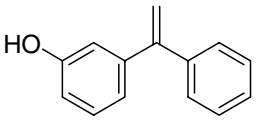


35

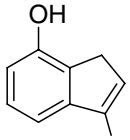


36

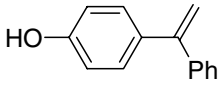
Later work by Fischer and Wan[27,28] demonstrated that *meta* (**37** and **38**) and *para* (**39**) hydroxy-substituted styrenes are also active towards photohydration (Φ = 0.22, 0.24 and 0.1, respectively). Evidence for formation of quinone methide intermediates was provided by nanosecond LFP. Both steady-state and time-resolved fluorescence quenching of **37** by water showed a cubic dependence on water concentration. This was attributed to an initial ESIPT process in which a three-water-molecule "bridge" mediates a proton transfer from the phenol to the basic alkene.



37



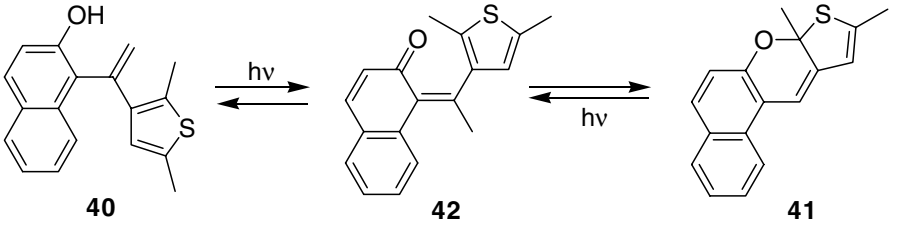
38 Ph



39

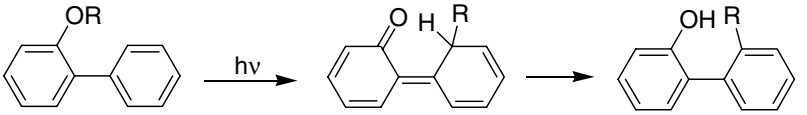
ESIPT to an appended vinyl substituent has been proposed to be the integral step in an interesting photochromic system. Uchida and Irie[29] report that vinylnaphthol derivative **40** gives the closed-ring naphthopyran **41** upon photolysis in hexane (λ = 334 nm, Φ = 0.20). Photolysis of **41** (λ = 400 nm) regenerates **40**. The authors propose an initial ESIPT reaction between the phenol OH and appended

vinyl substituent to generate *o*-quinone methide **42**, which can then undergo thermal electrocyclic ring closure to give **41**:



(39.10)

Recently, Lukeman and Wan[30,31] reported that 2-phenylphenol (**43**) undergoes H-D exchange primarily at the 2′-position when it is photolysed in D_2O solution. The exchange reaction was interpreted as arising from initial ESIPT from the phenol to an aromatic ring carbon to generate *o*-quinone methide (**44**), which then undergoes reverse proton transfer to generate deuterium-labeled starting material:



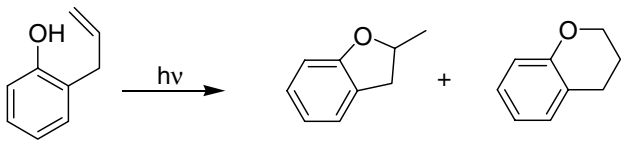
43 R = H
43-*OD* R = D

44

(39.11)

Photolyses of **43**-*OD* in a variety of solvents and in the solid state indicate that the exchange behavior is not water mediated and that the ESIPT process is direct.

Early studies on the photochemistry of *o*-allyl-substituted phenols indicated that photolysis generally gave mixtures of benzofuran and benzopyran cyclization products[32,33] (i.e., **46** and **47** from **45**):

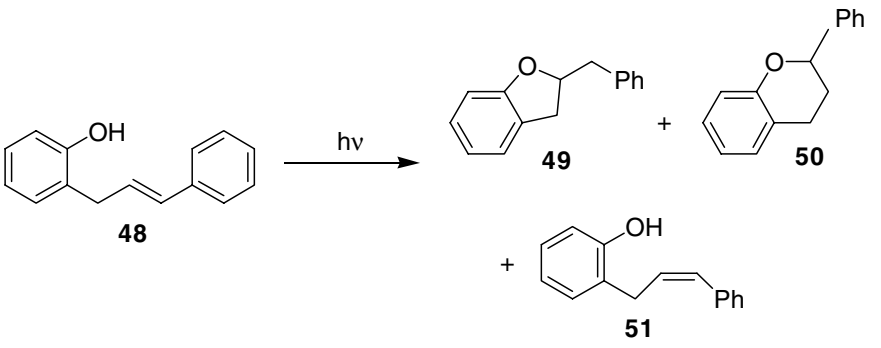


45 **46** **47**

(39.12)

It was proposed that initial ESIPT from the phenol OH to the ground-state alkene gave rise to two possible carbocations, which were then attacked by the phenolate to give the cyclized products; however, it is questionable whether phenols are strong enough acids in S_1 to protonate appended alkenes, as the alkenes are a higher energy chromophore and do not experience enhanced basicity when the phenol is excited. An alternative mechanism has been proposed[34] that involves initial electron transfer between the phenol and alkene, followed by radical ring closure. The work of Shani and co-workers[35] offers support for initial ESIPT. They demonstrated that photocyclization efficiency is reduced when competing hydrogen bond acceptors are available. Recent reports[36,37] showed through product yield and fluorescence quenching studies that the photocyclization of *o*-allyl phenols and naphthols does indeed proceed via ESIPT from S_1 and that a ground-state OH---π interaction is an important prerequisite. The alkene moiety might achieve enhanced basicity through energy transfer from the phenol via an excited-state π-complex.

Phenyl substitution of the alkene in *o*-allylphenols to generate the corresponding cinnamylphenol adds additional mechanistic complexity, as the two chromophores are now of comparable energy. This is evidenced in the photolysis of **48**, as, along with expected ring-closed products **49** and **50**, **51** appears in the product mixture, clearly resulting from *cis/trans* isomerization of the excited styrene chromophore:[38]

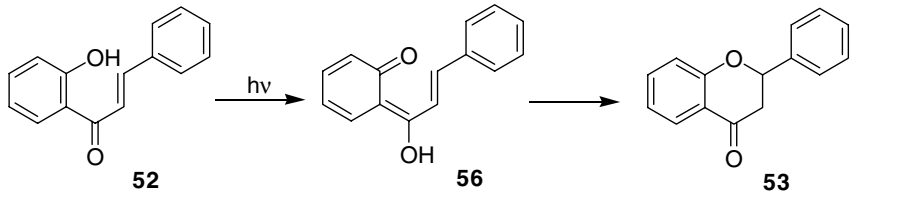


(39.13)

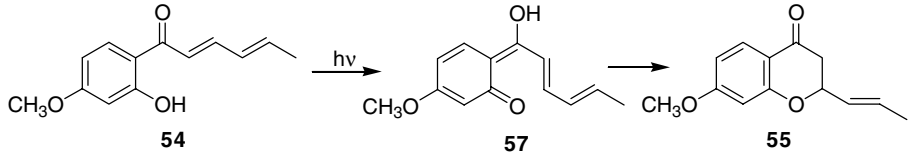
Quenching and sensitization studies indicate that the singlet state of the phenol favors formation of benzofuran **49**, that the styrene singlet state favors the formation of **50**, and that **51** results from the styrene triplet state. The authors invoke an ESIPT mechanism to explain the photocyclization products in this system. Derivitization of the styrenic ring lowers its singlet energy and thus should increase its contribution to the observed photochemistry. Indeed, studies[39] using *trans*-cinnamylphenols substituted with methyl, methoxy, and phenyl groups at the *para* position of the styrenic ring showed that increased proportions of benzopyran and *cis*-isomerized starting material are present in the product mixture. Similar studies in which the phenolic singlet energy is lowered by benzannelation[40] showed that increased proportions of benzopyran products are formed. Although the authors reiterate that ESIPT is responsible for almost all photocyclizations, they do invoke an electron transfer mechanism to explain the very different behavior of a methoxy-substituted derivative.[41]

39.5 Photochemistry of Hydroxyaromatic Ketones

The photogeneration of flavanones **53** and **55** from 2′-hydroxychalcone (**52**) and sorbophenone **54,** respectively, was first reported by Stermitz and co-workers[42]:



(39.14)

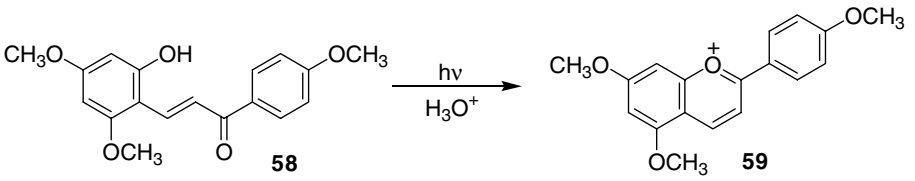


(39.15)

They assumed a mechanism involving ESPT from the phenol to the solvent, followed by attack of the resultant phenolate on the vinyl carbon β to the carbonyl group. Later work by Matsushima and co-workers[43,44] on a number of 2′-hydroxychalcone derivatives demonstrated that triplet quenchers and radical scavengers had no effect on the reaction efficiency, suggesting an ionic singlet-state mechanism. They did notice that the choice of solvent had a dramatic effect; polar aprotic solvents led to the highest efficiencies, polar protic solvents were the least efficient, and nonpolar solvents gave intermediate efficiencies. Such observations led the authors to propose a mechanism involving ESIPT to the carbonyl group to generate an *o*-quinone

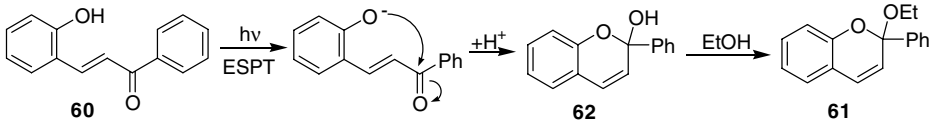
methide (**56** or **57**), which can then undergo electrocyclic ring closure. They proposed that isomerization to the *cisoid o*-quinone methide occurred on the excited-state potential energy surface, as the efficiency of reaction had a dependence on light intensity consistent with a one-photon process.

Jurd[45] reported that the slow thermal conversion of 2-hydroxychalcone (**58**) to the flavylium cation (**59**) was markedly accelerated by photolysis:



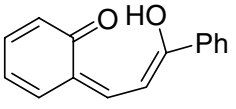
(39.16)

It was assumed that the role of the light was simply to convert the *trans* isomer to the *cis* form and that the cyclization was an acid-catalyzed thermal reaction. The acceleration was realized because the *cis* isomer is in a conformation that is more favorable for cyclization. Later work by Dewar and Sutherland[46] demonstrated that, in neutral ethanol, **60** underwent photocyclization to **61**. They proposed a mechanism involving initial ESPT from the phenol to solvent, followed by attack of the phenolate on the carbonyl to give initially **62** and then **61** (thermal acetal exchange with solvent):



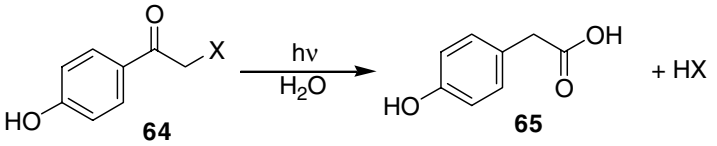
(39.17)

After numerous studies on a variety of 2-hydroxychalcone derivatives, Matsushima and co-workers[47–51] concluded that the reaction is monophotonic and proposed that the reaction proceeds via initial ESIPT from the phenol to the carbonyl group, followed by *cis*/*trans* isomerization (either thermal or adiabatic) to give the *cisoid o*-quinone methide **63**. This intermediate can then undergo electrocyclic ring closure to give the observed products. This interpretation is more realistic than that proposed by Dewar and Sutherland,[46] as few phenols are sufficiently acidic to undergo efficient ESPT to organic solvents.

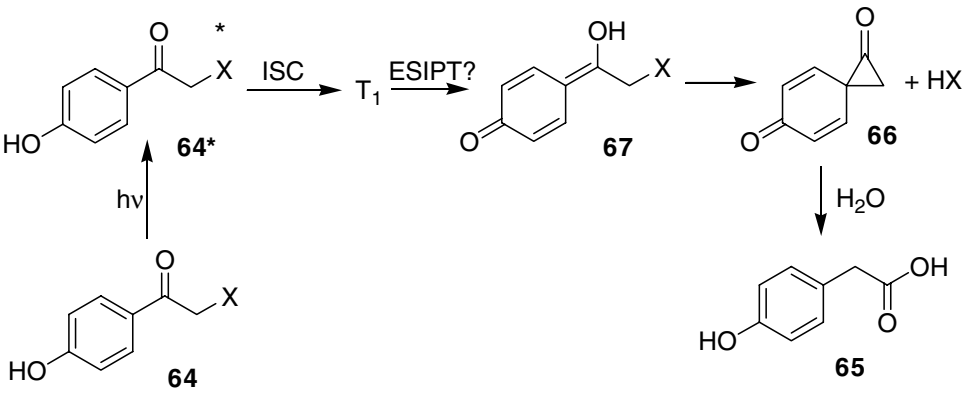


63

Givens and co-workers have reported that the *p*-hydroxyphenacyl chromophore is an effective photocaging group for phosphates (including ATP),[52] amino acids and peptides.[53,54] Photolysis (of **64**) leads to rearrangement of the chromophore to give the non-conjugated acid **65** and heterolytic release of the caged functionality:



(39.18)



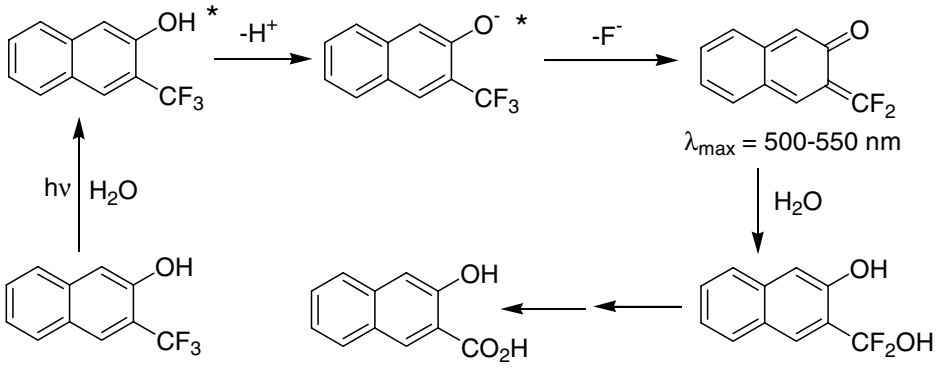
SCHEME 6

The proposed mechanism involves homolytic cleavage of the CX bond from the triplet excited state, followed by rearrangement to cyclopropanone intermediate **66**. Attack on intermediate **66** by water gives **65**. Subsequent studies by Zhang and co-workers[55] resulted in a different mechanism being proposed. Using "radical clock" techniques, they showed that the initial photochemical step is probably not homolytic cleavage. They reported that the reaction is strongly water mediated and proposed ESIPT from the phenol to the carbonyl group as the primary photochemical step, followed by rearrangement to **66** with concerted loss of the caged group. LFP studies allowed identification of tautomer **67**. Furthermore, triplet quenchers had a minimal effect on reaction efficiency, leading the authors to invoke the singlet state as the reactive multiplicity. In later reports, Givens and co-workers[56,57] conceded that the primary photochemical step is probably not CX bond homolysis, but after performing rigorous quenching studies they offered convincing evidence that the reaction proceeds from a short-lived triplet. A mechanistic summary based on what is known to date is provided in Scheme 6.

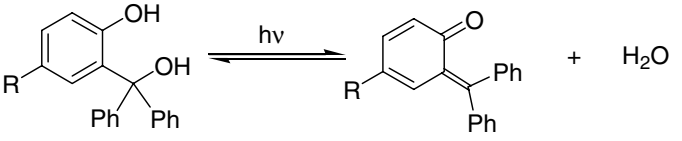
39.6 Photochemistry of Hydroxyarenes with Benzylic Moieties

Seiler and Wirz[58] reported one of the first systematic investigations into the mechanistic photochemistry of phenols and naphthols containing a benzylic-type moiety. They studied the photohydrolysis of eleven trifluoromethyl-substituted phenols and naphthols. Photolysis of these compounds in aqueous solution gave rise to the corresponding carboxylic acids. The mechanism of reaction (common to all of these compounds) involves S_1, with the initial step (in neutral solution) being deprotonation of the phenol (or naphthol) to form the phenolate (naphtholate) ion, which is believed to remain in S_1. This is followed by heterolytic CF bond cleavage to form quinone-methide-type intermediates (observed for selected compounds using flash photolysis) that are subsequently hydrolyzed by water to the carboxylic acids (Scheme 7). This important paper[58] demonstrated the general photochemical reactivity of hydroxyarenes with labile benzylic substituents and that a variety of quinone-methide-type intermediates are accessible from these compounds; however, these aspects of this reaction were not pursued further by the authors, and the paper remained somewhat unrecognized. Indeed, a recent paper[59] on the photochemistry of 2-hydroxy-4-trifluoromethylbenzoic acid (HTB, a trifluoromethyl-substituted phenol and the active form of Triflusal, a platelet antiaggregant drug) failed to cite the earlier work by Seiler and Wirz, although HTB photolysis resulted in hydrolysis of the trifluoromethyl group, analogous to the results initially reported by Seiler and Wirz.[58]

The photochemistry of phenols with the more accessible benzyl alcohol moiety (compared to trifluoromethyl) was reported on several occasions in the 1970s. Hamai and Kokubun[60] documented the photochromic (and thermochromic) behavior of 2-hydroxytriphenylmethanols **68** and **69**. Exposure of these compounds to UV light in *n*-hexane resulted in highly colored solutions due to the formation of fuchsones (which are *o*-quinone methides):



SCHEME 7



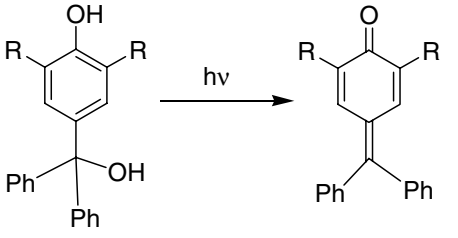
68 R = H
69 R = OCH_3

fuchsones

(39.19)

Addition of water to the organic solvent enhanced the decoloration, an observation that is consistent with the operation of the reverse hydration reaction as responsible for the loss of color.

The mechanism of the photochemical reaction was not investigated. The photochemistry of the closely related *p*-hydroxytriphenylmethanols **70** to **72** has also been studied but only in the solid state. Gomberg[61] first reported that photolysis with sunlight of powdered **70** resulted in the formation of a yellow material only on the top layer of the powder and assigned it to the fuchsone **73**. Lewis et al.[62] have reinvestigated this reaction using additional derivatives **71** and **72**. The x-ray crystal structures of the compounds showed that the phenolic hydrogen is pre-aligned by hydrogen bonding with the triphenylmethyl alcoholic hydroxyl group of an adjacent molecule in a fashion suitable for self-catalyzed dehydration reaction. Indeed, photolysis of these compounds gave highly colored species assignable to **74** and **75**:



70 R = H
71 R = Br
72 R = CH_3

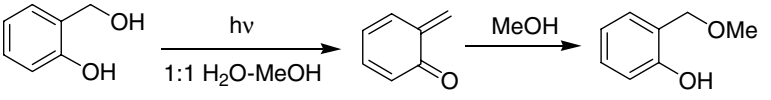
73 R = H
74 R = Br
75 R = CH_3

(39.20)

The authors suggested that one possible pathway of reaction is deprotonation of the photoexcited phenol, which can then catalyze the loss of water from the triphenylmethyl alcohol moiety.

Systematic investigation into the aqueous photochemistry of phenols substituted with benzylic moieties began in Wan's group with a survey of the photosolvolytic efficiencies (in aqueous MeOH) of a variety

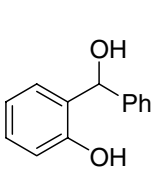
of methoxy-substituted benzyl alcohols.[63] Included along with this group of compounds was *o*-hydroxybenzyl alcohol (**76**), which reacted with one of the highest quantum yields to give methyl ether **78**:



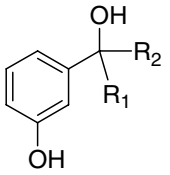
76 **77** **78** (39.21)

It was proposed,[63] at the time, that the propensity to form *o*-quinone methide **77** via a self-catalyzed photoreaction involving ESIPT from the phenol to the benzyl alcohol moiety could account for the enhanced photosolvolytic reactivity. Additional support for the intermediacy of **77** came from photolysis of **76** in basic solution, which gave rise to phenol-formaldehyde-type oligomers.[64] Thus, in the presence of a base, photolysis of the phenolate ion of **76** still gives rise to **77**, but these are now preferentially trapped by the phenolate ion of **76** (via C-alkylation), which is the first step in the formation of phenol-formaldehyde polymers.

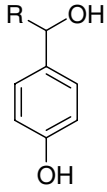
These initial studies reporting the high reactivity of *o*-hydroxybenzyl alcohol (**76**) toward *o*-quinone methide (**77**) formation in aqueous solution led to an exploratory investigation of reactivity all the hydroxybenzyl alcohols isomers, including the hydroxybenzhydrols (compounds **79** to **84**):[65]



79

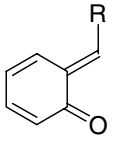


80 $R_1 = R_2 = H$
81 $R_1 = Ph$; $R_2 = H$
82 $R_1 = R_2 = Ph$

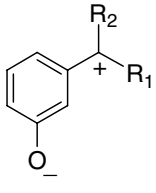


83 R = H
84 R = Ph

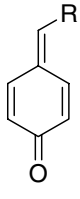
The main finding in this work is that all hydroxybenzyl alcohol and hydroxybenzhydrol isomers are photochemically reactive (the *ortho* and *meta* isomers being the most reactive) in aqueous solution, giving rise to the corresponding quinone methides **85** to **87**, some of which are detectable by LFP and/or standard UV-Vis spectrophotometry (e.g., *o*-quinone methide **85**, R = Ph, has λ_{max} = 350 and 450 nm). *o*-Quinone methides **85** are trappable by externally added electron-rich dienophiles such as ethyl vinyl ether (to give chroman adducts in good yields) or can be trappable intramolecularly in an appropriately designed substrate.[66]



85 R = H or Ph



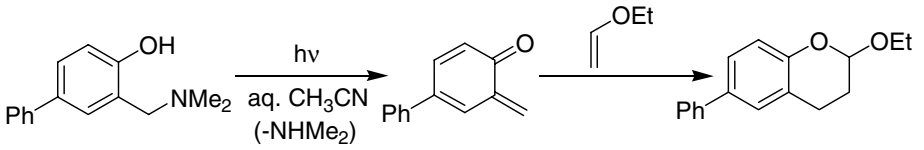
86 R_1, R_2 = H, Ph



87 R = H or Ph

mechanism of reaction was proposed involving initial deprotonation of the phenol in S_1 followed by dehydroxylation from the excited phenolate ion.[65] Initial studies of efficiency of reaction vs. pH are consistent with this mechanism of reaction, although the *o*-isomer may operate via an ESIPT mechanism in which a discrete phenolate ion is not required, at least in neutral or acidic solution.

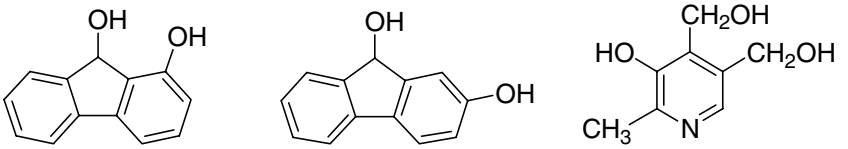
Nakantani et al.[67] have since shown that *o*-quinone methides can also be readily photogenerated from Mannich bases of *o*-substituted phenols; for example,



(39.22)

Photolysis of the phenolate ion (at high pH) failed to cause reaction, indicating that an initial ESIPT from phenol to the Mannich base is required to form the ammonium ion species, which then facilitates its departure as a leaving group.

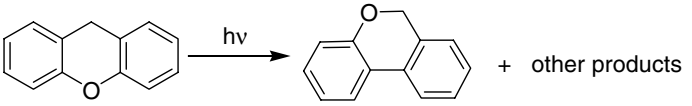
The propensity for hydroxy-substituted benzyl alcohols to react via dehydration on photolysis has now been extended to other chromophores such as fluorenols **88** and **89**[68] and vitamin B_6 (**90**):[69]



88 **89** **90**

Photolysis of these and related compounds in aqueous solution give rise to the corresponding quinone methide intermediate with good to high yields. Some of these are observable by LFP. The *o*-isomers **88** and **90** give rise to *o*-quinone-methide-type intermediates that are trappable by added ethyl vinyl ether. These papers further demonstrate the general utility of the reaction, which appears not to be restricted to benzenoid systems.

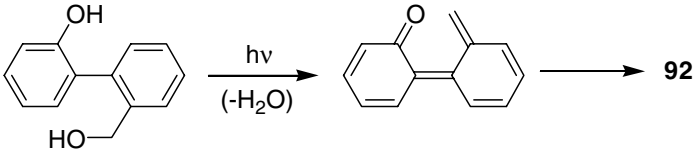
The propensity of hydroxy-substituted biphenyls to undergo photodehydration in a manner like the hydroxybenzyl alcohols above (to give biphenyl-type quinone methides) was discovered during an investigation into the photoisomerization of xanthene (**91**) to 6*H*-dibenzo[*b*,*d*]pyran (**92**):[70]



91 **92**

(39.23)

The proposed mechanism of photoisomerization involves initial CO bond homolysis of **91** to form a biradical, which can subsequently transform to the 2-(2′-hydroxyphenyl)benzyl alcohol (**93**), via a spiroketone intermediate.[70] It was proposed that secondary photolysis of **93** leads to **92** via an initial dehydration reaction to form biphenyl quinone methide **94**:

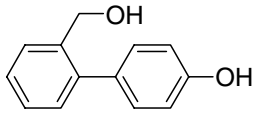


93 **94**

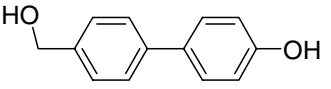
(39.24)

A subsequent study of the photochemistry of **93** and several derivatives[71] confirmed the generality of reaction of these 2,2′-substituted biphenyls to undergo photocyclization via proposed biphenyl quinone methides (e.g., **94**). A particularly novel aspect of this reaction is that the starting alcohols are twisted in the ground state, whereas the pyran products are much more planar. Thus, the photochemical reaction requires a twisting motion to achieve planarity and the enhanced acidity of the phenol moiety, both features apparently available on the S_1 surface. Further studies of this reaction[72] showed that the photocyclization occurs in the solid state and that hydrogen bonding between compounds as observed in the x-ray structure (thereby offering the possibility of intermolecular "acid" catalysis) may be required for reaction.

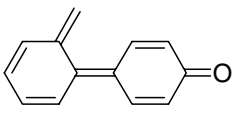
Isomers of 2-(2′-hydroxyphenyl)benzyl alcohol (**93**) that cannot undergo cyclization in a manner shown by Eq. (39.24) (e.g., **95** and **96**) have been studied. These compounds are also reactive: They give the corresponding methyl ether products (at the benzylic position) when photolysed in 1:1 MeOH–H_2O, and LFP studies have showed formation of long-wavelength transients assignable to biphenyl quinone methides **97** and **98**.[73]



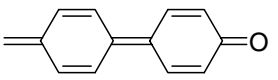
95



96

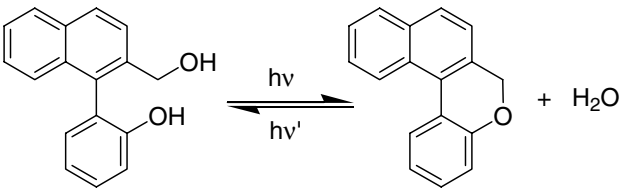


97 (λ_{max} = 570 nm)



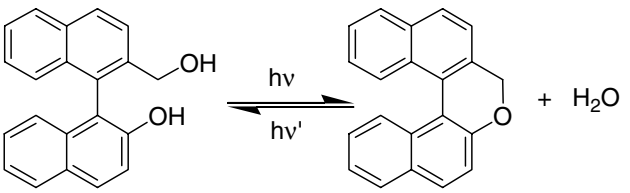
98 (λ_{max} = 525 nm)

Further extension[74] using compounds that are capable of undergoing cyclization (e.g., **99** and **100**; see Eq. (39.25)) showed that the photocyclization occurs even for highly sterically hindered systems such as binaphthyl with respectable quantum yields:



99 **100** (39.25)

In these cases, no transients assignable to biaryl quinone methides were observable by LFP, although Burnham and Schuster[75] have assigned a 560-nm (τ = 5 μs in cyclohexane) transient to the corresponding binaphthyl quinone methide. The photoreversible nature of these reactions (they are photochromic) prompted Burnham and Schuster[75] to investigate the binaphthyl system (Eq. (39.26)) as a possible chiral photochromic optical trigger for liquid crystals:



101 **102** (39.26)

Both **101** and **102** are resolvable into their enantiomeric pairs. Photolysis of optically active **101** resulted in optically active **102** without racemization of **101**; however, photolysis of **102** led to its racemization with formation of optically active **101**.

Dalhousie University

40.1 Introduction

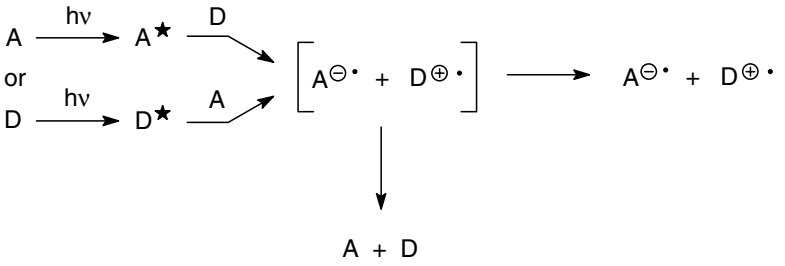
Ever since the pioneering work of Weller,[1] electron transfer photochemistry has received considerable attention, both as a potential synthetic method as well as a convenient technique for generating and studying radical ions in a homogeneous medium.[2] The promotion of an electron from the HOMO to the LUMO of a chemical species enhances both its reducing and oxidizing abilities. This renders electronic excitation a relatively mild and selective way of inducing electron transfer between species that are unreactive toward each other in their ground states.

The change in free energy (ΔG_{PET}) governing the photoinduced electron transfer (PET) process is expressed by means of the Weller equation, Eq. (40.1), an empirical relationship that equates ΔG_{PET} to experimentally measurable terms such as the half-wave redox potentials ($E^{ox}_{1/2}$ and $E^{red}_{1/2}$) of the reactants and the excitation energy ($E_{0,0}$) of the chromophore:

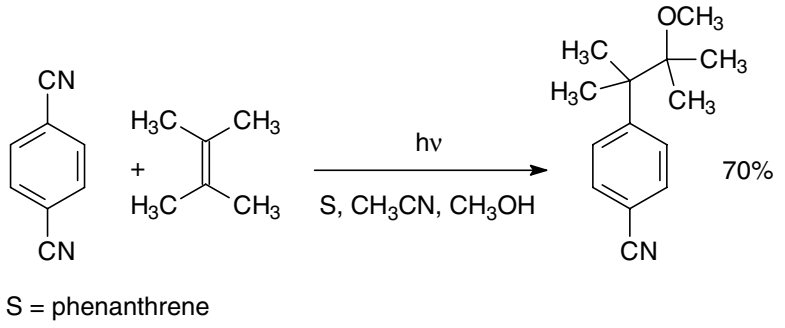
$$\Delta G_{PET} = F\,(E^{ox}_{1/2} - E^{red}_{1/2} - E_{0,0} - e/\varepsilon\alpha) \qquad (40.1)$$

The Coulombic term $e/\varepsilon\alpha$ takes into account the mutual stabilization exerted by the radical ions formed at an encounter distance α. Calculation of ΔG_{PET} is often taken as a preliminary check for assessing the potential of a PET system. Provided that the free energy is exergonic, electron transfer will lead to the formation of the radical cation of the electron donor (D) and the radical anion of the electron acceptor (A) as shown in Scheme 1. These radical ions are typically formed as a contact radical ion pair at an encounter distance of about 7 Å and have the option of either diffusing apart to give free, solvated radical

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1



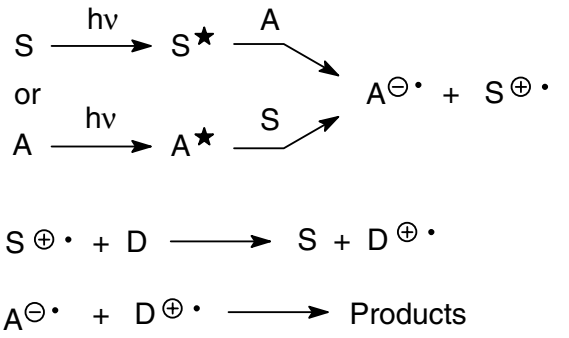
SCHEME 2

ions or reacting with each other within the solvent cage. The course is often dictated by the dielectric constant of the surrounding medium and its ability to solvate the radical ions. In most instances, however, the radical ions undergo back electron transfer (BET), regenerating the ground-state starting materials in what is essentially an energy-wasting process.

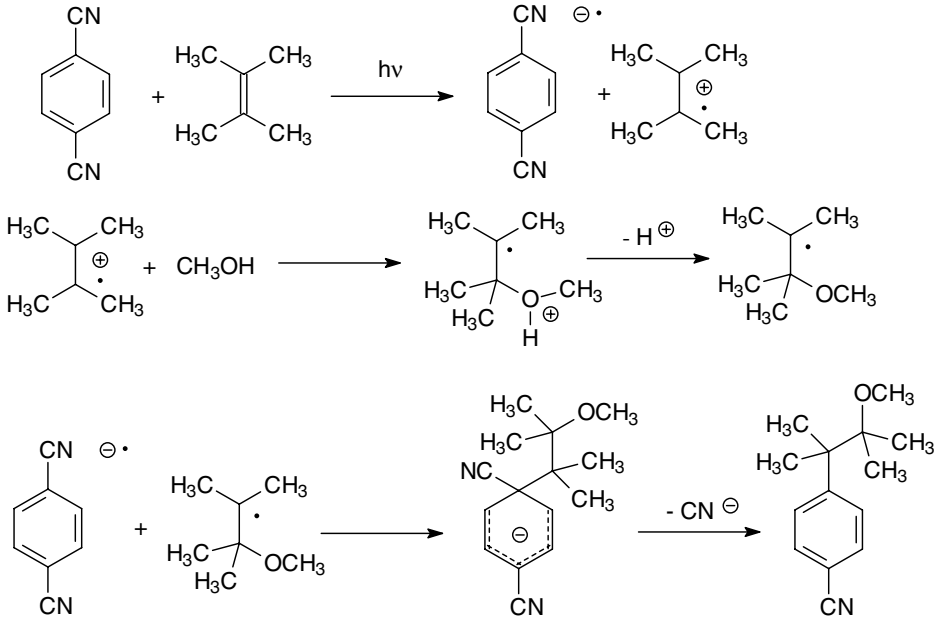
40.2 The Photo-NOCAS Reaction: Establishing the Mechanism

One of the photochemical electron transfer reactions developed quite extensively over the past decades, particularly by our research group, is the photochemical nucleophile–olefin combination, aromatic substitution (photo-NOCAS) reaction.[3] We have used this reaction as a framework in which to investigate the behavior of photogenerated radical ions as well as a well-understood reference against which to compare competing PET reactions.

As the name suggests, the photo-NOCAS reaction involves the regioselective combination of three molecules: an aromatic electron acceptor (typically a cyano-substituted arene), an olefin, and a nucleophile. In the paradigm example, 1,4-dicyanobenzene, 2,3-dimethyl-2-butene, and methanol react to give a single, major photo-NOCAS product in 70% yield (Scheme 2).[4] The reaction is co-sensitized by phenanthrene. A pronounced enhancement in both chemical yield and efficiency is often observed in photo-NOCAS reactions upon co-sensitization by aromatic hydrocarbons such as phenanthrene or biphenyl. The co-sensitizer (S) essentially behaves as an electron relay, generating the reactant radical ions ($A^{-\bullet}$ and $D^{+\bullet}$) in separate stages (Scheme 3). This reduces the opportunity for BET and in-cage reactions between the reactant radical ions. The success of the technique relies on the inertness of the co-sensitizer radical cation as well as on reduced rates of BET between the co-sensitizer radical cation and the reactant radical ions as compared to that between the reactant radical ions themselves.[5] Due to its relatively low half-wave reduction potential ($E^{red}_{1/2} = -1.66$ V vs. SCE, CH_3CN) and the large excitation energy for its $S_0 \rightarrow S_1$ transition ($E^{S}_{0,0} = 4.21$ eV, CH_3CN), 1,4-dicyanobenzene will undergo exergonic PET with potential donors having a $E^{ox}_{1/2} < 2.6$ V. This encompasses most alkenes. Because of this,



SCHEME 3

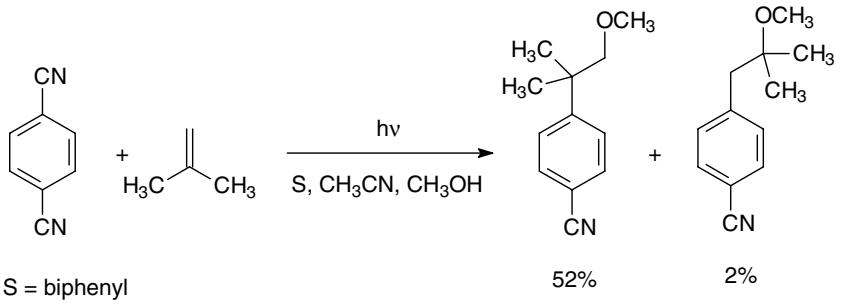


SCHEME 4

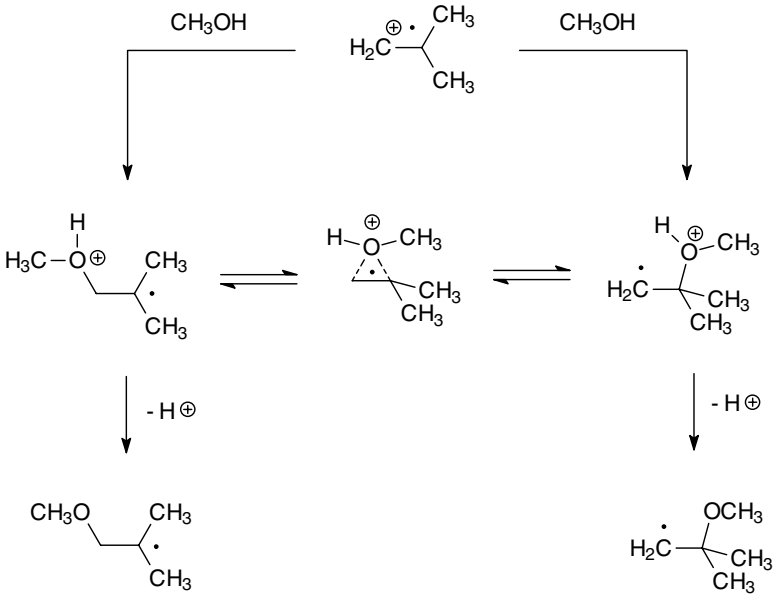
1,4-dicyanobenzene has been the electron acceptor of choice in most of the published photo-NOCAS studies, although other cyanoarenes such as 1,2,4,5-tetracyanobenzene ($E^{red}_{1/2}$ = –0.65 V vs. SCE, $E^{S}_{0,0}$ = 3.83 eV, CH_3CN)[6] and methyl 4-cyanobenzoate ($E^{red}_{1/2}$ = –1.76 V vs. SCE, $E^{S}_{0,0}$ = 4.10 eV, CH_3CN)[7] have been used successfully as well.

The basic mechanism involves the generation of the arene radical anion and the olefin radical cation, directly (Scheme 1) or via a co-sensitized route (Scheme 3). The olefin radical cation is attacked by the nucleophile (methanol) to give a distonic radical cation, which subsequently deprotonates to give the corresponding β-alkoxyalkyl radical (combination step, Scheme 4). This radical then adds to an *ipso*-position of the 1,4-dicyanobenzene radical anion. Semi-empirical calculations clearly show that the cyano-substituted positions on the ring are the sites of highest spin density (for several cyano-substituted arenes). The resulting anionic species extrudes cyanide anion in order to rearomatize, generating the photo-NOCAS product (substitution step, Scheme 4).

An early insight into the regiochemistry of the reaction was achieved by studying reactions involving nonsymmetrical olefins such as 2-methylpropene. In this example, a predominance of the product derived

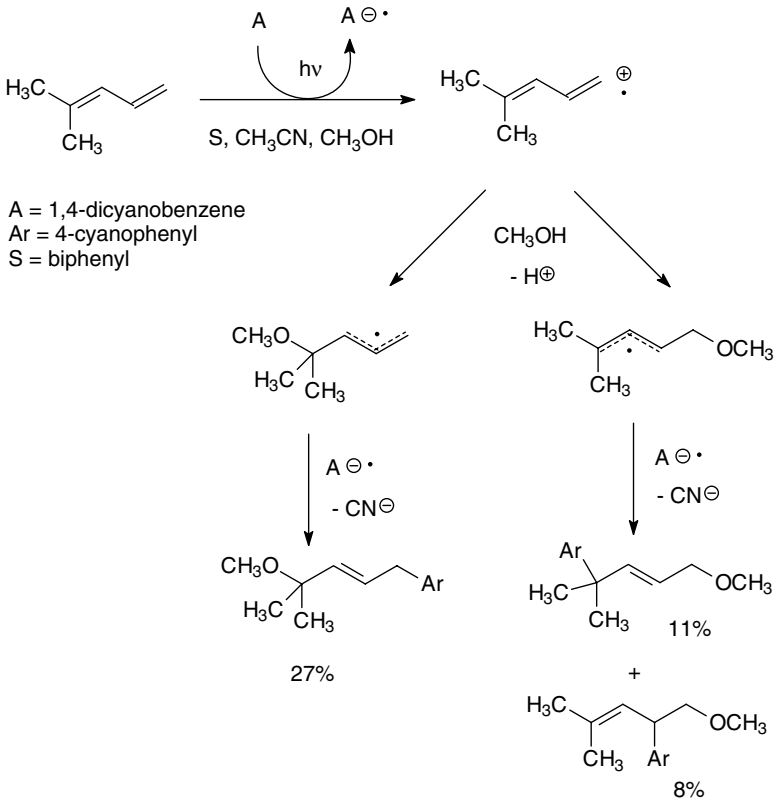


SCHEME 5



SCHEME 6

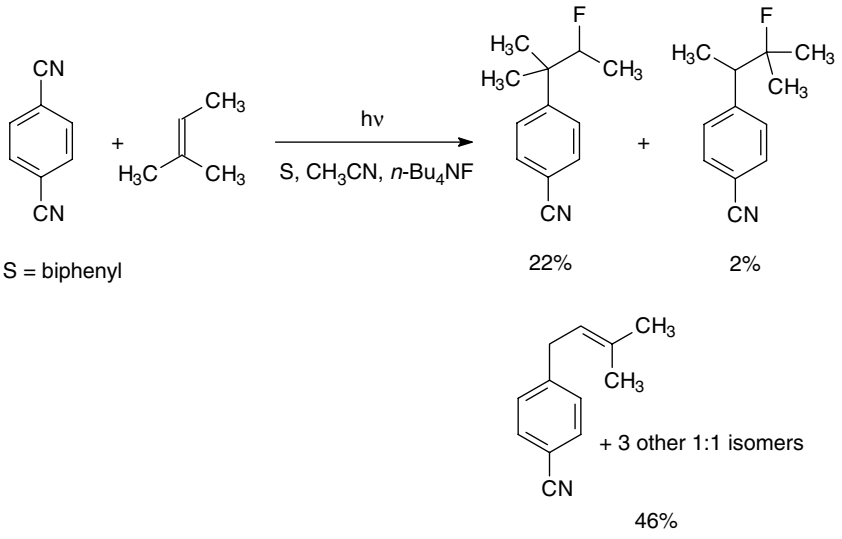
from the more highly substituted β-methoxyalkyl radical was observed (Scheme 5).[4a,8] In this case, the predominant radical is also the more energetically stable of the two possible forms. In fact, it has been proposed that, when a protic nucleophile such as methanol is involved, the regiochemistry of the reaction is thermodynamically controlled and determined by the relative stability of the β-methoxyalkyl radicals (or, possibly, of the distonic radical cations).[9] The possibility of equilibration through a non-classical, bridged species has been suggested (Scheme 6). However, empirically derived heats of formation as well as high-level *ab initio* molecular orbital calculations on the intermediate radicals for a series of alkenes and dienes indicate that the more highly substituted radical is not necessarily the more stable species. Whereas in cases such as 2-methylpropene the greater stability of the tertiary β-alkoxyalkyl radical over the primary radical is straightforward, in other olefins, such as 4-methyl-1,3-pentadiene, the rationalization is more complicated. *Ab initio* calculations indicate that the radical bearing the methyl substituents in the β-position is significantly more stable than the alternative isomer having the methyl substituents attached to the allylic system — the extra stability imparted by the methyl groups attached to the methoxy-bearing carbon outweighs that which would result from the methyl groups being part of the allylic system. These theoretical results are in agreement with experimental observation. The dominant photo-NOCAS product in the reaction involving 4-methyl-1,3-pentadiene arises from the less substituted, but more



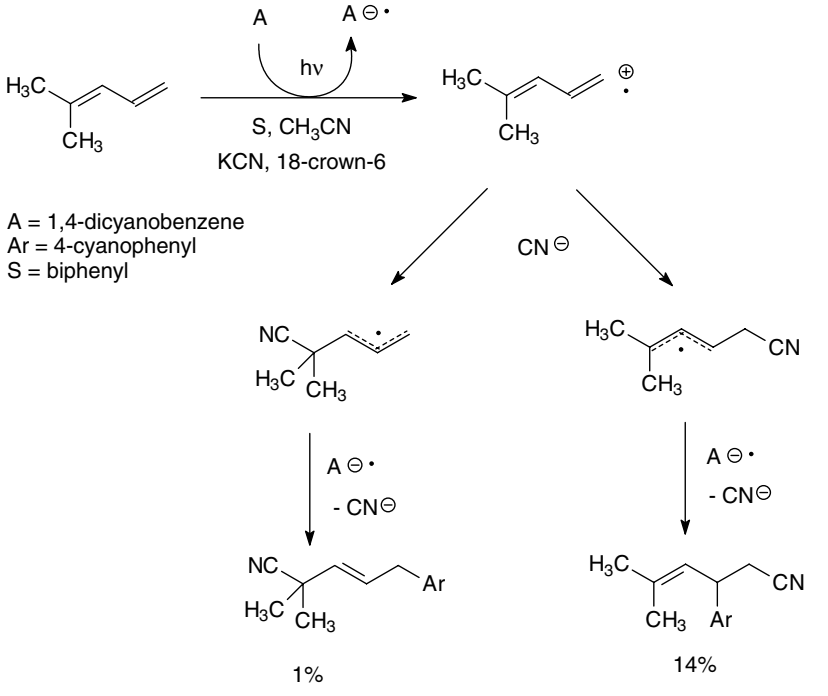
SCHEME 7

stable, β-methoxyallyl radical (Scheme 7).[10] All the alkenes and dienes investigated display a regioselectivity in their photo-NOCAS reactions with methanol that can be rationalized by a thermodynamically controlled mechanism that depends on the relative stability of the intermediate radicals.

The situation changes when non-protic, charged nucleophiles such as cyanide and fluoride anions are involved.[11] In these systems, equilibration between the olefin–nucleophile adducts is not possible; the addition is most likely irreversible, and there is no opportunity for rearrangement through a bridged intermediate. Thus, in contrast with the previous examples, the regioselectivity is now kinetically controlled, with polar and steric factors directing the incoming nucleophile. In the photo-NOCAS reaction involving 2-methyl-2-butene, 1,4-dicyanobenzene, and fluoride anion, the major product arises from the more highly substituted radical (Scheme 8). This might at first appear to be the outcome of thermodynamic control, in which the relative stability of the radicals directs the regiochemistry. However, isodesmic reactions using heats of formation determined by *ab initio* molecular orbital calculations clearly indicate that the more highly substituted β-fluoroalkyl radical derived from trapping by fluoride of the 2-methyl-2-butene radical cation is, in fact, the less stable of the two possible radicals. It is perhaps surprising that the secondary radical is more stable than the tertiary one; however, according to the calculations, the net stabilization gain from an additional methyl group at the fluoro-bearing carbon is greater than that at the radical site. The fact that the reaction actually proceeded via the more highly substituted, and hence less stable, radical intermediate was taken as evidence for a kinetically controlled pathway in which the nucleophile attaches itself predominantly to the less sterically hindered terminus. This is in agreement with the idea that the addition of the nucleophile to the olefin radical cation is irreversible and highly exergonic; the transition state occurs early along the reaction pathway and steric effects control the regioselectivity.

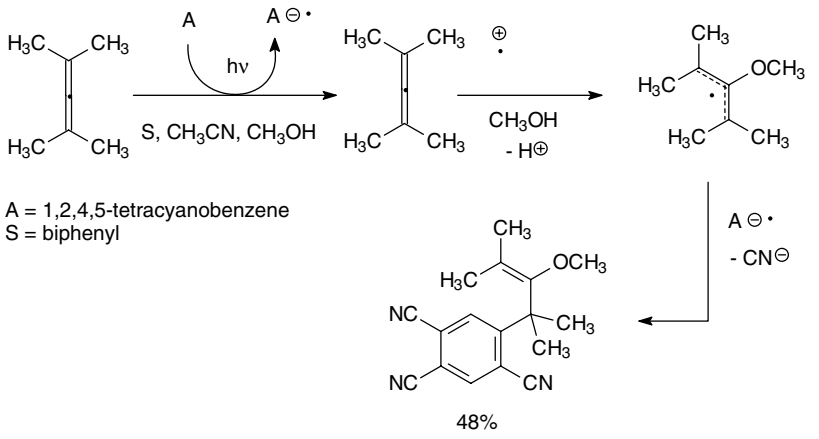


SCHEME 8



SCHEME 9

Similar trends are observed in photo-NOCAS reactions involving cyanide anion. The reaction of 4-methyl-1,3-pentadiene with cyanide anion can be contrasted directly with its equivalent reaction with methanol (Scheme 7). The regiochemistry is reversed, with cyanide attacking the less sterically hindered terminus to give the less stable intermediate radical (Scheme 9).

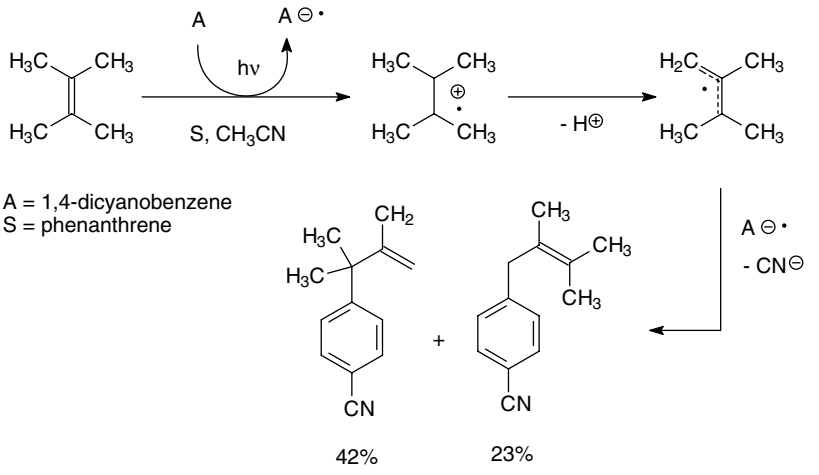


SCHEME 10

The regiochemistry in the reactions involving conjugated dienes has important implications regarding the sequence of events in the photo-NOCAS mechanism, providing us with confirmation that nucleophilic trapping of the olefin radical cation always occurs before association with the arene radical anion. In all the reactions investigated, the nucleophile is exclusively attached to one of the terminal carbons (thereby generating an intermediate allylic radical). The aryl group subsequently adds in a 1,2- or 1,4-fashion, the former placing the aryl group at an internal 2-position. If radical ion coupling occurred before nucleophilic trapping, the aryl group would be attached to a terminal carbon of the diene system. Further verification comes from a study involving allenes. The reaction is again regiospecific, placing the nucleophile exclusively at the central allenyl carbon (Scheme 10). This permits the formation of a relatively stable allylic radical, as opposed to the vinylic radical that would result from addition at a terminal carbon. The absence of any products bearing the aryl group at the central carbon proves that nucleophilic attack always precedes substitution on the arene. In fact, radical ion coupling prior to nucleophilic trapping has only been observed in a few exceptional intramolecular systems.[12]

Olefin radical cations are strongly acidic species. In the absence of a strong nucleophile, deprotonation to give the corresponding allylic radicals will compete with nucleophilic trapping. The formation of olefin–arene substitution products via this deprotonation pathway was observed in the reaction involving 2-methyl-2-butene and fluoride anion shown previously in Scheme 8.[11b] Although these products are negligible in the presence of methanol, the lower nucleophilicity and higher basicity of fluoride anion allow deprotonation to compete successfully with nucleophilic trapping. Deprotonation becomes the sole pathway when the reaction is carried out in pure acetonitrile, in the absence of a formal nucleophile (Scheme 11).[4,13] The allylic radical resulting from deprotonation of the alkene radical cation adds to an *ipso*-position of the arene radical anion from either of its ambident ends to give a mixture of isomeric 1:1 adducts.

In exceptional cases involving highly reactive alkene radical cations, acetonitrile may participate as a nucleophile. One such case is 2-methylpropene, which produces a radical cation exhibiting a localized charge and minimal steric hindrance to the incoming nucleophile.[14] Unlike in the case of methanol, the distonic radical cation resulting from the attack of acetonitrile on the radical cation of 2-methylpropene is incapable of deprotonating (Scheme 12); consequently, coupling with the radical anion of 1,4-dicyanobenzene results in the formation of a zwitterionic species. This species can then cyclize via two possible pathways (A or B) to give the final isoquinoline product. Further insight into the mechanism comes from a study by Albini and co-workers involving 1,2,4,5-tetracyanobenzene and 1-hexene in acetonitrile.[15] Photolysis of this mixture at –40°C led to the formation and isolation of the corresponding non-aromatized isoquinoline precursor, validating pathway B (Scheme 13). These researchers, however, proposed that the reaction proceeds via a termolecular exciplex-mediated pathway that precludes full electron transfer.

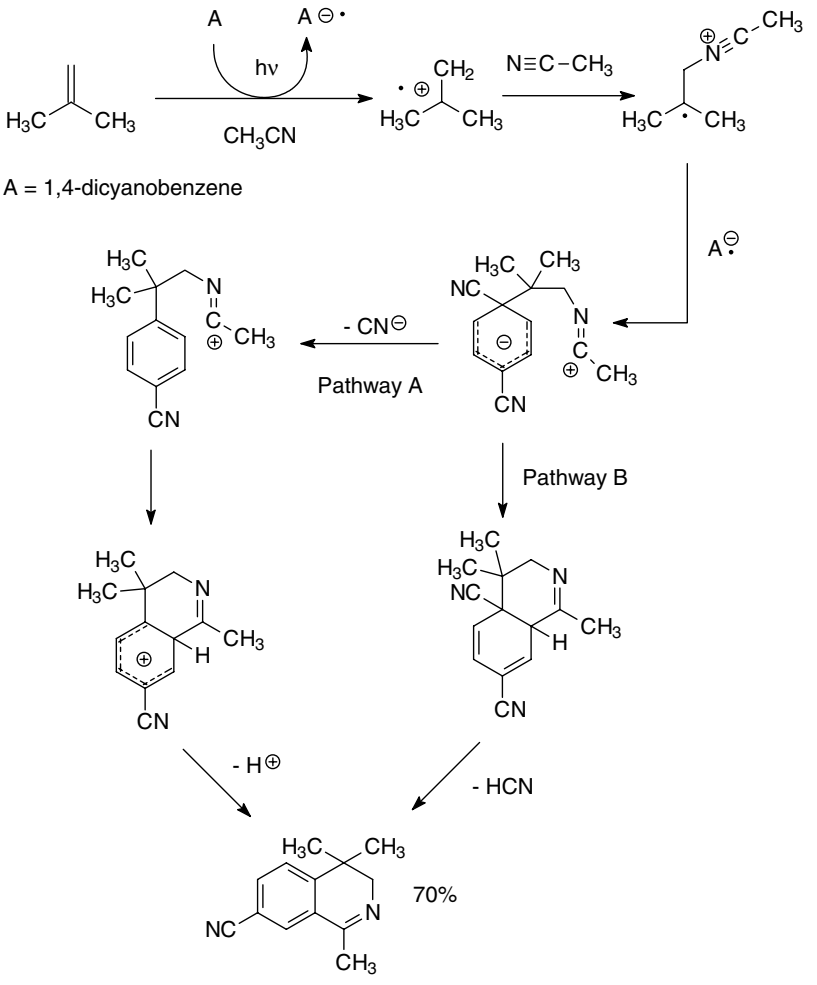


SCHEME 11

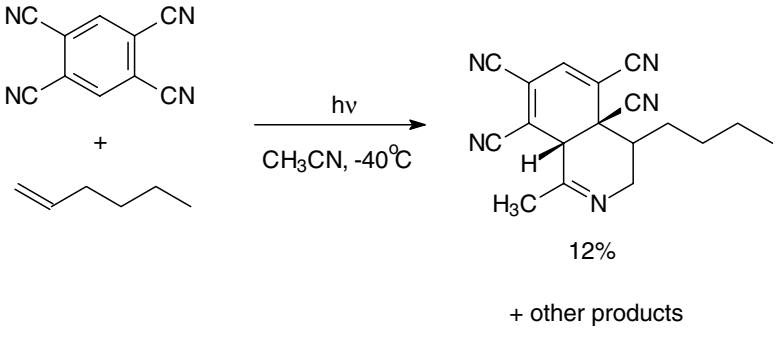
40.3 The Photo-NOCAS Reaction: Extending the Scope

The nucleophile–olefin combination step in the photo-NOCAS mechanism was achieved intramolecularly by using alkenols as both the electron donors and nucleophiles.[16] When generated in the absence of added nucleophiles, the alkenol radical cation is trapped intramolecularly by its own hydroxyl terminus. The alk-4-enols investigated had the option to undergo both 1,5-*exo* and 1,6-*endo*-cyclizations. In agreement with rules developed for carbocation/anion and radical cyclizations, the cyclization of the radical cations of the alk-4-enols showed a distinct preference for 1,5-*exo*-cyclization.[17] The alkenol, 6-methyl-5-hepten-2-ol, underwent 1,5-*exo*-cyclization exclusively (Scheme 14). This might be expected from a purely thermodynamic viewpoint due to the relative stabilities of the radicals involved (1,5-*exo*-cyclization gives a tertiary radical; 1,6-*endo*-cyclization would give a secondary radical). However, intermolecular equivalents such as 2-methyl-2-butene and 1-methylcyclohexene do yield products arising from the secondary radical, albeit in a 1:6 ratio. Therefore, comparison of the inter- and intramolecular cases demonstrates an enhancement in regioselectivity beyond that expected from the relative stabilities of the radicals involved. The preference for 1,5-*exo*-cyclization is even more striking in the case of 5-methyl-5-hexen-2-ol (Scheme 15). In this reaction 1,5-*exo*-cyclization is still preferred over 1,6-*endo*-cyclization, despite the fact that 1,5-*exo*-cyclization proceeds via a primary radical as opposed to a tertiary radical in the 1,6-*endo*-cyclization pathway. This is in sharp contrast to the 26:1 preference for a tertiary radical over a primary one, as observed in simple alkene systems such as 2-methylpropene (Scheme 5).

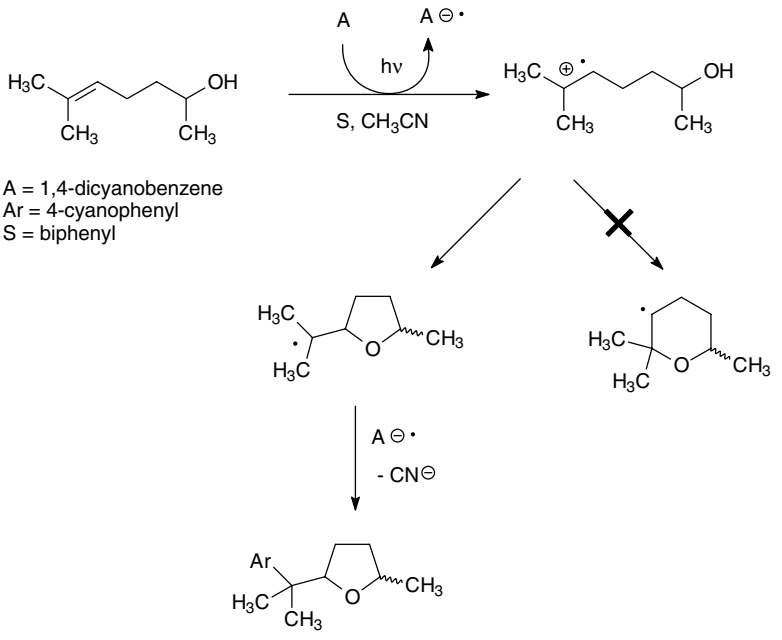
A cyclization step was also introduced into the photo-NOCAS mechanism using nonconjugated dienes as the electron donors.[18] In the reaction of 2,5-dimethyl-1,5-hexadiene, cyclization occurs at the radical cation stage, prior to nucleophilic attack, generating a distonic 1,4-dimethylcyclohexane-1,4-diyl radical cation (Scheme 16). In typical photo-NOCAS fashion, this intermediate is then trapped by methanol to give the corresponding radical, which subsequently substitutes on the arene radical anion. This type of cyclization is dominant at low methanol concentrations and in the presence of co-donors such as biphenyl. Presumably, the co-donor complexes with the initial 1,2-diyl radical cation, thus reducing the availability of its positive charge and decreasing its reactivity towards methanol. Methanol trapping of the 1,2-radical cation is a competing reaction that dominates at high nucleophile concentration. No cyclization occurs at the β-alkoxyalkyl radical stage, however, as 1,4-*exo*-cyclization is thermodynamically unfavorable while 1,5-*endo*-cyclization, usually favored, is now too sterically inhibited. The mechanism becomes more complex when 2,6-dimethyl-1,6-heptadiene is subjected to similar conditions (Scheme 17).[18b] The two pathways rationalized for the hexadiene are active in this reaction as well, but now the formation of the



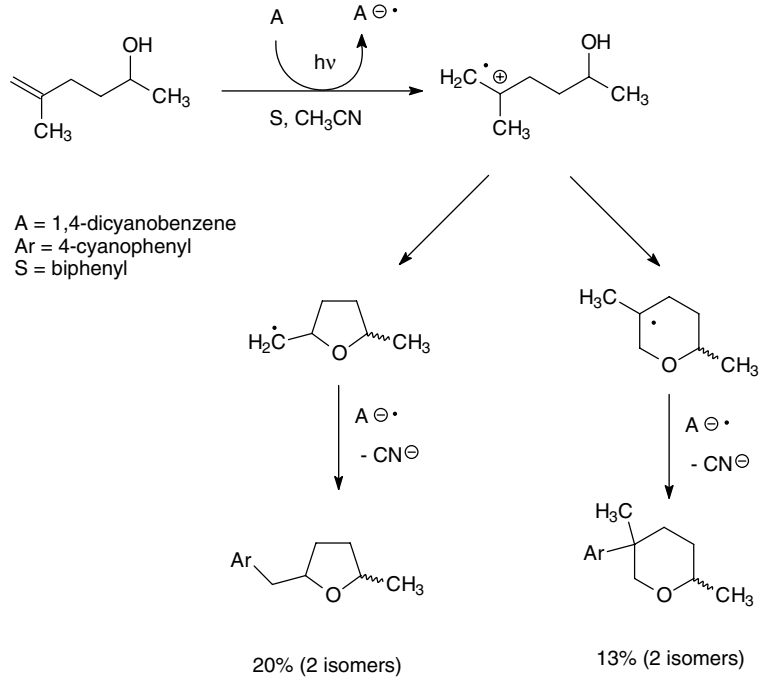
SCHEME 12



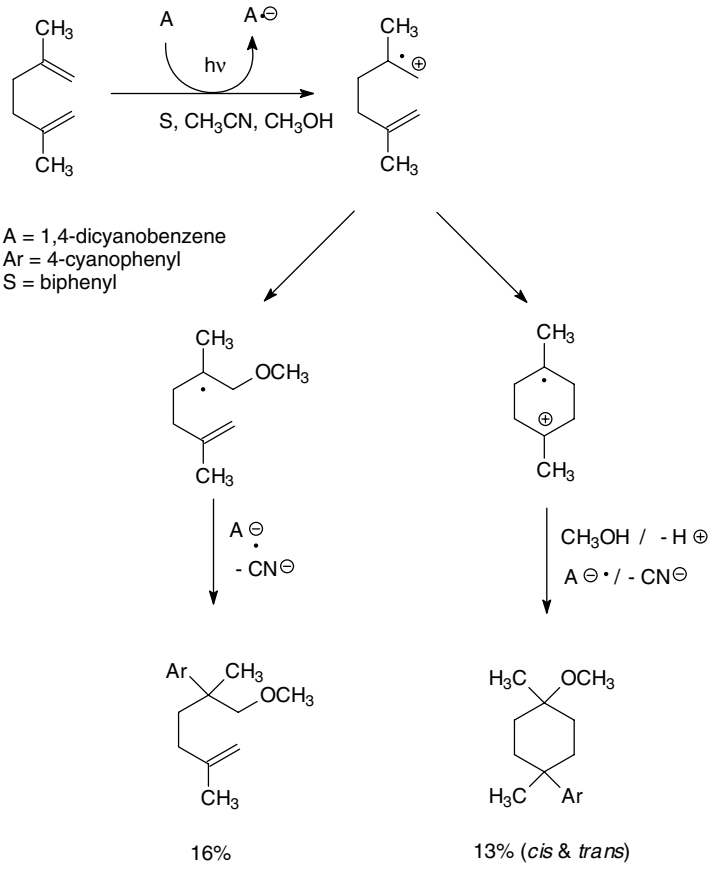
SCHEME 13



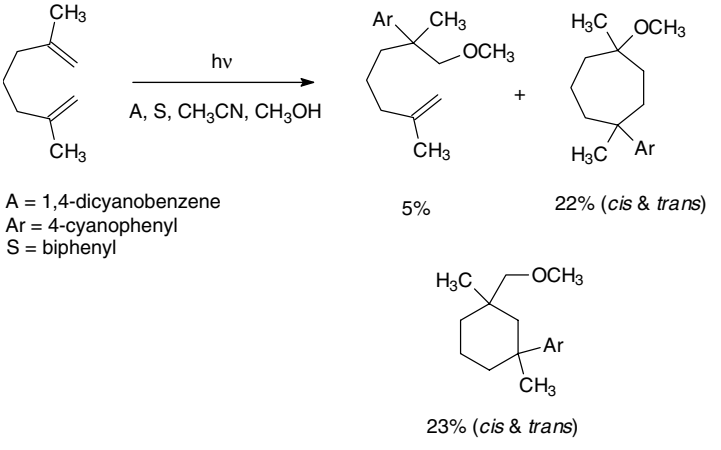
SCHEME 14



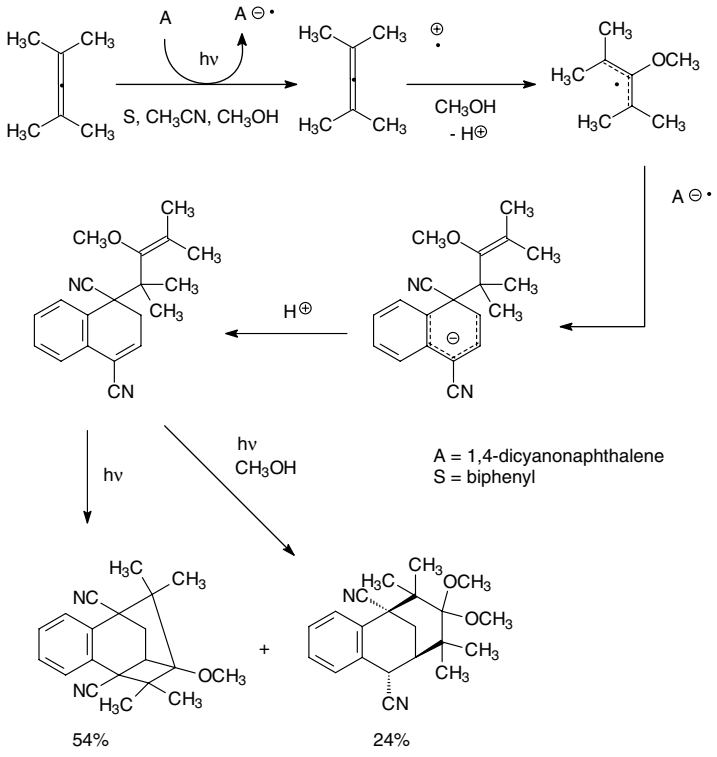
SCHEME 15



SCHEME 16



SCHEME 17



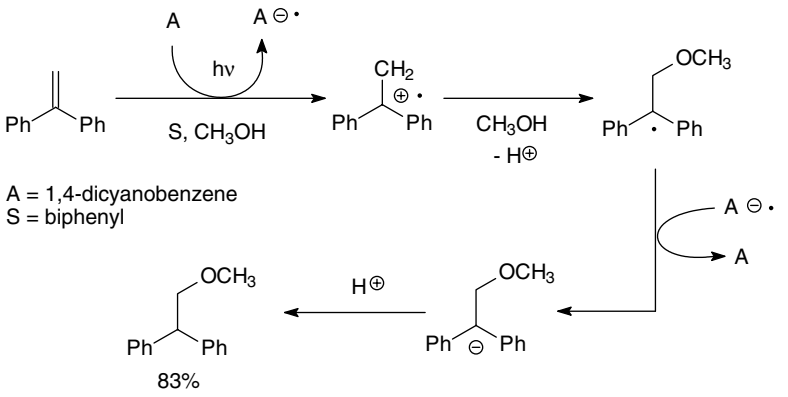
SCHEME 18

β-alkoxyalkyl radical by nucleophilic trapping of the initial 1,2-diyl radical cation provides an additional cyclization route: 1,6-*endo*-cyclization (but not 1,5-*exo*) is a viable pathway. This is in agreement with Beckwith's work on the cyclization of 5-hexenyl radicals.[17c] This work indicated that the preferred mode of cyclization is strongly influenced by the methyl group substitution pattern. Although 1,5-cyclization is typically favored, the directing effects of the 1- and 6-methyl groups in the heptadiene selectively induce a 1,6-*endo*-cyclization. With the basis of the photo-NOCAS mechanism clearly defined, the scope of the reaction was expanded in a series of studies led by the Arnold and Roth research groups.[19] Most of these investigations involve terpenes and related compounds. The radical cations of these substrates underwent a variety of cyclizations, cleavages, and rearrangements, providing a wealth of information on the behavior of radical ions (and their derived radicals and ions) from chemo-, regio-, and stereoselective viewpoints.

40.4 Limitations Due to Competing Pathways

Several potential pathways are available to the olefinic radical cation and the cyanoarene radical anion that will compete with the photo-NOCAS route once certain conditions and structural features in the substrates are altered. It has already been mentioned that deprotonation of the olefinic radical cation and the formation of 1:1 olefin–arene substitution products dominates in the absence of strong nucleophiles.[4a,11b]

The photo-NOCAS reaction is restricted to mononuclear, electron-deficient aromatics as the electron acceptors. Using polynuclear systems such as 1,4-dicyanonaphthalene, for example, leads to the olefin–nucleophile adduct radical adding, rather than substituting, at the *ipso*-position of the arene (Scheme 18). This is most likely due to the reduced rearomatization energy gained in binuclear, as opposed to mononuclear, systems. The photo-NOCAS reaction is limited to aliphatic olefins as electron



SCHEME 19

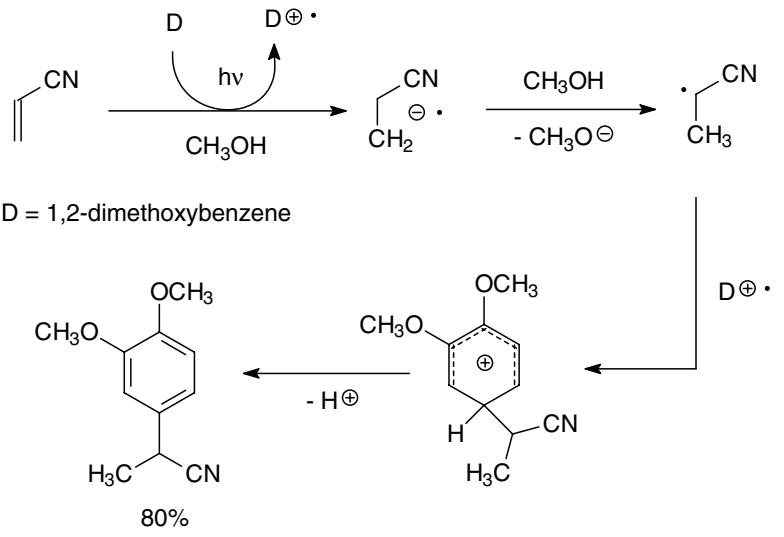
donors. The use of aryl alkenes leads to an alternative pathway in which the β-alkoxyalkyl radical is reduced to the corresponding anion by the arene radical anion instead of undergoing a coupling reaction.[20] This anion is subsequently protonated to yield an olefin–nucleophile adduct (Scheme 19). This alteration in mechanism is a consequence of the increased steric bulk offered by the aryl groups at the radical site and the lower reduction potential of the radicals derived from the aryl olefin as compared to the alkyl olefin ones.[21] In this reaction, the cyanoaromatic is not consumed but acts as an electron transfer photosensitizer.

40.5 The Photo-EOCAS Reaction

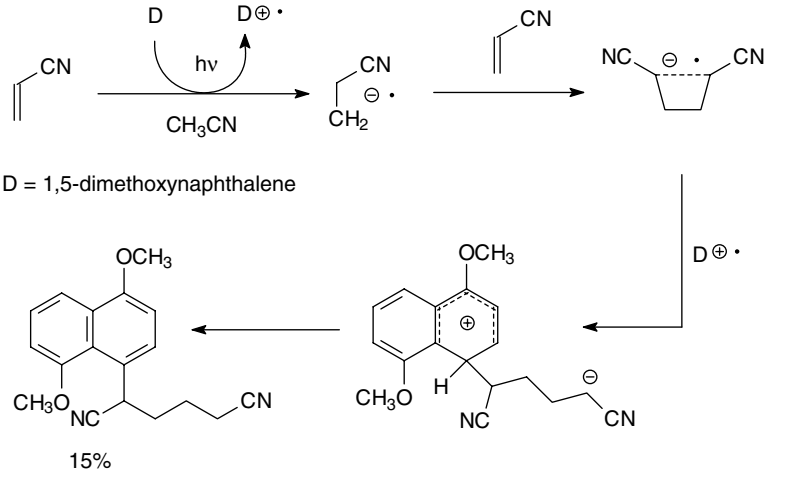
Some variants of the photo-NOCAS reaction have been developed. The photochemical electrophile–olefin combination, aromatic substitution (photo-EOCAS) reaction is complementary to the photo-NOCAS reaction in the sense that the roles of the olefin and the arene are reversed.[22] In this modification, an electron-deficient olefin (e.g., acrylonitrile) and an electron-rich arene (e.g., 1,2-dimethoxybenzene) are employed (Scheme 20). Photoinduced electron transfer generates the olefin radical *anion* and the arene radical *cation*. In the presence of a proton source (the electrophile) such as methanol, the olefin radical anion is protonated to give an α-cyanoethyl radical (from acrylonitrile). This radical adds to the arene radical cation, presumably at the sites of highest spin density. This generates an adduct cation that subsequently deprotonates and rearomatizes. The regiochemistry observed defines the sequence of events, confirming that electrophilic trapping of the alkene radical anion occurs prior to substitution on the arene, in a fashion similar to the photo-NOCAS reaction. In the absence of an added electrophile, acrylonitrile can function as both the electron acceptor as well as the electrophilic trapping agent.[22d] In this situation, the acrylonitrile radical anion is captured by a neutral acrylonitrile molecule to give a dimeric, distonic radical anion. This species can also be envisaged as a long-bond 1,2-dicyanocyclobutane radical anion (Scheme 21). Substitution on the arene radical cation eventually yields a 1:2 arene–olefin product. The reaction has been demonstrated to occur for a wide variety of electron-rich arenes, including binuclear systems such as naphthalene. [2π+2π]-Cycloadditions start competing once ΔG_{PET} becomes weakly exergonic or endergonic.

40.6 The Photo-ROCAS Reaction

Albini and co-workers have developed another pathway that is formally related to the photo-NOCAS reaction.[23] The photochemical radical–olefin combination, aromatic substitution (photo-ROCAS) reaction involves the regioselective combination of a radical, an olefin, and an arene via a PET pathway



SCHEME 20



SCHEME 21

(Scheme 22). The initial photoinduced electron transfer process takes place between a cyanoarene, typically 1,2,4,5-tetracyanobenzene in Albini's studies, as electron acceptor and a radical precursor such as a 2,2-dialkyl-1,3-dioxolane as electron donor. The radical cation of the dioxolane formed upon PET is unstable; it undergoes a rapid fragmentation to generate an alkyl radical. This subsequently couples with a ground-state olefin to generate a second adduct radical. This species attacks an *ipso*-position on the arene radical anion, producing an anion that expels cyanide anion, driven by rearomatization. Because the reaction requires the PET to occur between the arene and the radical precursor, only electron-deficient olefins exhibiting higher oxidation potentials than the radical precursors can be used. Nonetheless, the reaction has been found to occur with various electron-deficient olefins. Furthermore, the versatility of the dioxolane radical cation as alkyl radical precursor extends the reaction to a broad selection of radicals.

SCHEME 22

40.7 Conclusions

The photo-NOCAS reaction has been developed extensively and found to apply to a wide variety of aliphatic olefins. The underlying mechanism has been thoroughly examined and rationalized on the basis of experimental observation in conjunction with detailed, supporting theoretical calculations. Despite minimal optimization from a preparative viewpoint, some of the reactions developed do bear synthetic potential. More importantly, from a more general perspective, the photo-NOCAS reaction serves as a convenient framework in which to investigate how photoinduced radical ions and their derived radicals and ions behave under various competing conditions. The reaction pathway provides the mechanistic chemist with a strict sequence of key steps: photoinduced generation of the radial ions, trapping of the radical cation (nucleophile combination), and trapping of the resultant radical (aromatic substitution). By altering structural features in the substrates and manipulating reaction conditions we have been able to probe and better understand the reactivity and selectivity of radical ions and related transient derivatives.

Intra- and Intermolecular Cycloadditions of Benzene Derivatives

Andrew Gilbert
The University of Reading

41.1 Introduction

As noted by Wender and Dore in the previous edition of this Handbook, "Arene–alkene photocycloadditions are a theoretically intriguing and synthetically unique class of reactions with enormous potential in complex-molecule synthesis."[1] Comprehensive reviews that appeared in the late 1980s and early 1990s have documented the background and mechanistic aspects of intra- and intermolecular photocycloadditions to the benzene ring, including the factors that control selectivites.[1–7] These accounts also outline the numerous examples of the synthetic utility of these processes. By the start of the period of the current review, the photoaddition of ethenes to the benzene ring was already widely acknowledged as a convenient, versatile, and direct access, from simple, readily available starting materials to complex polycyclic systems that are the core architecture of many a synthetic target. The *meta* (1,3-) and *ortho* (1,2-) cycloadditions (Figure 41.1), yielding, respectively, the tricyclo[3.3.0.^{2,8}]oct-3-ene and bicyclo[4.2.0]octa-2,4-diene skeletal, have been well researched and continue to attract appreciable attention. In contrast, the corresponding *para* (1,4-) process remains largely unexplored and exploited mainly because this pathway is seldom observed and also lacks the predictability of the other two modes.

41.2 *meta*-Photocycloaddition

The widely accepted mechanism for the *meta*-photocycloaddition that accounts for essentially all the experimental observations involves initial interaction of the S_0 ethene with the S_1 arene resulting in polarisation of the benzene ring possibly by way of an exciplex intermediate.[1–6] Formation of the *meta* adduct may arise directly from the polarized species or may involve a second intermediate, but evidence for the latter species is lacking. This general mechanism has proved useful not only in providing an understanding of the reactivity and regio- and stereo-selectivities of the process but also in predicting the outcome of the cycloaddition so that it can be applied with confidence as a key step in synthetic sequences. The latter aspect has been particularly well exploited for the intramolecular process, and a number of total syntheses of naturally occurring compounds have thereby been elegantly accomplished

0-8493-1348-1/04/$0.00+$1.50

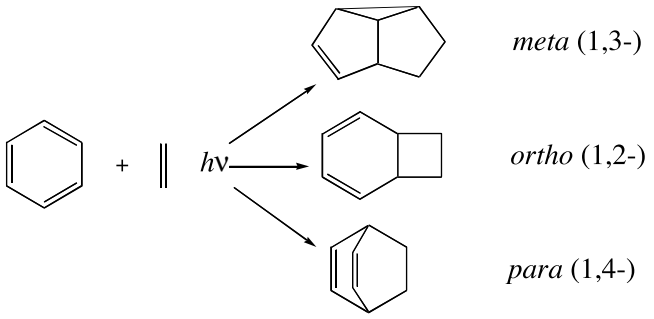

FIGURE 41.1 Modes of photocycloaddition of ethenes to the benzene ring.

in a relatively small number of steps.[2–5] Recent examples of this aspect of the reaction include the use of the intramolecular *meta*-photocycloaddition of **1** to give the angular and linear triquinane adducts **2** and **3**, respectively, the latter of which provides the key framework of (±)-ceratopicanol **4** in five steps with an overall yield of 19%;[8] and the first synthesis of *cis,cis,cis,trans*-[5.5.5.5]-fenestranes **5** from a novel arene–ethene photocycloaddition/radical cyclization sequence from the trichromophore **6** as outlined in Figure 41.2.[9] Furthermore, the angular adduct **7** from the bichromophore **8** has provided the molecular architecture for elaboration to give a formal synthesis of (±)-crinipellin B **9**.[10]

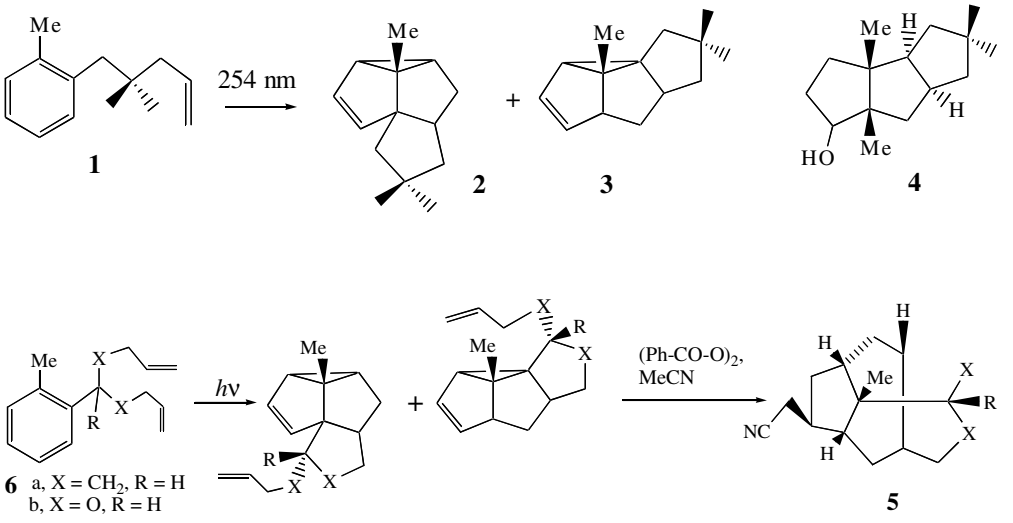

FIGURE 41.2 Synthesis of *cis,cis,cis,trans*[5.5.5.5]fenestranes.

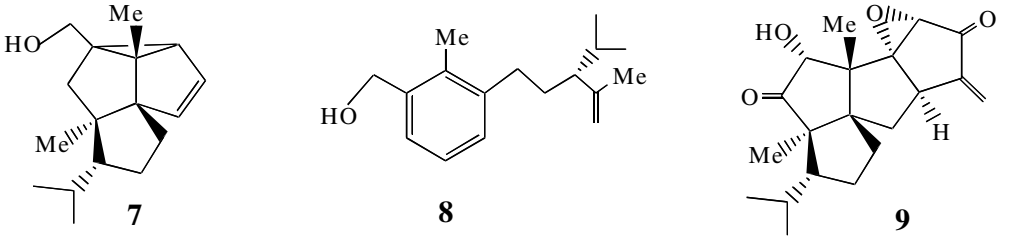
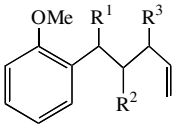
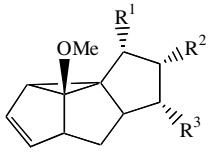


Much recent work on the intramolecular process has been concerned with determining the influence of substituents on the tether between the chromophores and of the presence of heteroatoms in this chain, on the reactivity of the bichromophore and regiochemistry of the addition. Several studies have reported

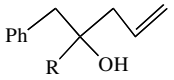
on the photocycloadditions of 5-phenylpent-1-enes having hydroxy,[11–18] methoxy,[12] trimethylsilyloxy,[17] or trifluoroacetate[18] groups at the 3,[11,13,14,17,18] 4-,[12,14,16,17] or 5-[17] positions and with a methoxy group at the 2′-position to direct the attack to the 1′,3′- sites on the benzene ring. All systems undergo *meta*-photocycloaddition with control by both steric and electronic effects. The major observation is that these reactions occur diastereoselectively with the configuration of the mono-substituent, mainly *endo*, as indicated in the conversion of **10** to **11**, and this is considered to be a result of minimization of steric interactions between the substituent and the methoxy group on the arene. For disubstituted compounds such as **12**, the more sterically demanding group has *exo* stereochemistry in the *meta* adduct. Other results suggest that the stereochemistry may be influenced by hydrogen bonding in the conformation prior to addition[12,15,16] and by solvent polarity for certain bichromophores.[12] Incorporation of rigidity into the tether as in **13** and **14** naturally also restricts the conformation of the bichromophore which leads to addition, and this can markedly affect the reaction selectivity.[19] Thus, while the *cis* isomers of these bichromophores undergo addition of the ethene predominantly at the 1,3- positions of the phenyl group, 2,6- addition occurs in high selectivity for the *trans* isomers.



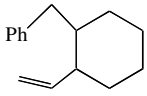
10



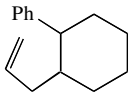
11



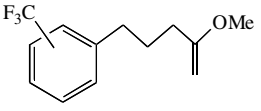
12



13



14



15

It is well known that the pathway discrimination between *meta*- and *ortho*-cycloadditions of ethenes to the benzene ring is dependent upon the electron donor–acceptor relationships between the addends.[6] These relationships can be quantified in terms of the free enthalpy of electron transfer (ΔG^0) given from the Rehm–Weller equation. Not surprisingly, therefore, the reaction mode selectivity of arene–ethene bichromophores is markedly influenced by the position and nature of substituents on the addends and by the presence and position of a heteroatom in the tether between the chromophores. The former effect is illustrated by the photochemistry of 2-methoxy-5-[(trifluoromethyl)phenyl]pent-1-enes **15**, the 3′-isomer of which yields *meta* adducts from 1,3- and 2,6-addition, while the presence of the $-CF_3$ group at the 2′- and 4′- positions results in *ortho*-addition.[20] The latter influence is clearly evident in the differing reaction mode selectivities of 3-benzyloxyprop-1-enes (predominantly *meta*)[21] and 4-phenoxybut-1-enes (both *meta* and *ortho*).[22–26] Furthermore, the 3-benzyloxyprop-1-enes display a marked preference for formation of the linear over the angular isomer following 1,3-addition. This feature in both the oxygen and nitrogen series is rationalized in terms of an unsymmetrical orientation (**16**) in the conformation leading to the adducts, which is considered to result from the smaller bond angle and shorter bond lengths in the $-CH_2-X-CH_2-$ tether compared to the hydrocarbon systems, which generally give approximately equal amounts of the adduct isomers.[27] Bonding between $C_{1'}$ and C_2 then occurs prior to $C_{3'}$ and C_1 in **16**, and closure to give the cyclopropane ring between $C_{2'}$ and $C_{6'}$ is favored by the early attainment of sp^3 hybridization of $C_{1'}$. In support of this proposal, the bichromophore **17** with silicon in the tether preferentially gives the angular isomer **18** because of the longer Si–C bond compared to the C–C bond and this favors $C_{3'}-C_1$ bonding and hence closure between $C_{2'}$ and $C_{4'}$.[28] Diastereofacial differentiation and regiocontrol of the ring closure in the intramolecular process has been achieved with the

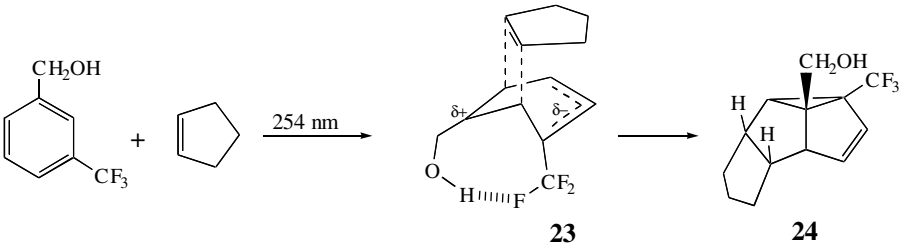


FIGURE 41.3 Control of cyclopropane ring formation by 1,3-substitutents.

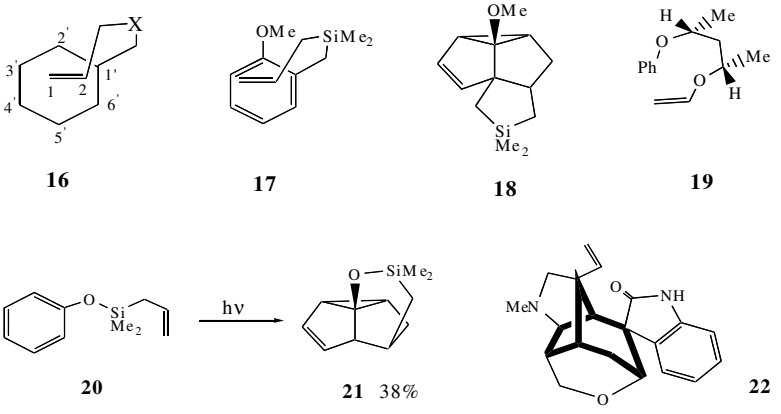
bichromophore **19**, which uses the tether as a chiral auxiliary,[29] and regio and enantioselectivities have been induced in the *meta*-photocycloaddition by irradiation of complexes of phenoxyalkenes with β-cyclodextrin.[26] Irradiation of allylphenoxydimethylsilane **20** gives good yields of the 2,6-addition product **21**,[30,31] which can be readily converted into the core skeleton of the alkaloid gelsemine **22**.[31]



Recent studies of the *meta* process have been mainly concerned with the intramolecular addition and, as outlined above, control over all aspects of the reaction can be achieved including the direction of cyclization to form the cyclopropane ring. In intermolecular reactions of arene–ethene systems, both the reaction mode selectivity and the regiochemistry of the addition can be controlled by the nature of the substituents on the addends.[32] For the *meta* process, the arene substituents may also be used to influence the direction of the formation of the cyclopropane ring in the adduct and so provide specificity in isomer formation. Such specificity has been described for 1,3-additions to 3-trifluormethyl derivatives of phenol, benzyl alcohol, benzyltrimethylsilane, and phenoxytrimethylsilane and is deduced to arise from attractive interactions between the substituents, causing an asymmetric distortion of the C_6 ring in the species (e.g., **23**) immediately prior to addition.[33,34] As outlined in Figure 41.3, cyclization in **23** is favored between C_1 and C_3 to give solely the adduct with the 1,2-disubstitued dihydrosemibullvalene skeleton **24**.

41.3 *ortho*-Photocycloaddition

An excellent review of the *ortho* photocycloaddition of alkenes and alkynes to the benzene ring has recently been published which not only discusses the mechanisms and intermediates of these processes but also presents comprehensive listings of the examples of these reactions which have been reported over the past 40 years or so.[35]

It is common in the intramolecular reaction of arene–ethene nonconjugated bichromophores that, if the molecular architecture allows, the first formed *ortho*-cycloaddition product ring opens thermally to the cyclooctatriene, which then undergoes photochemical electrocyclization to give either or both of the

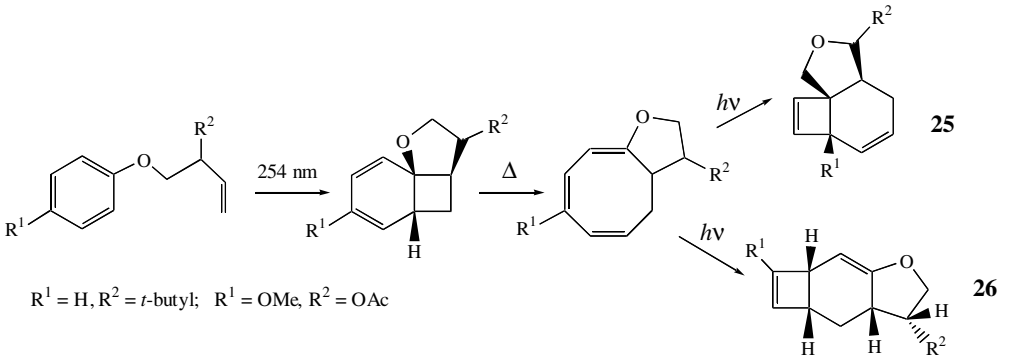


FIGURE 41.4 Intamolecular *ortho* photocycloaddition of 4-phenoxybut-1-enes.

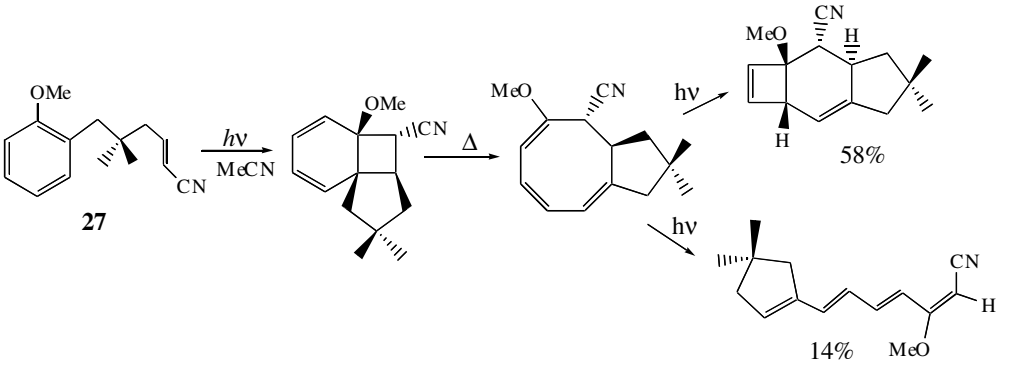

FIGURE 41.5 Intramolecular *ortho* cycloaddition of an electron donor–acceptor bichromophore.

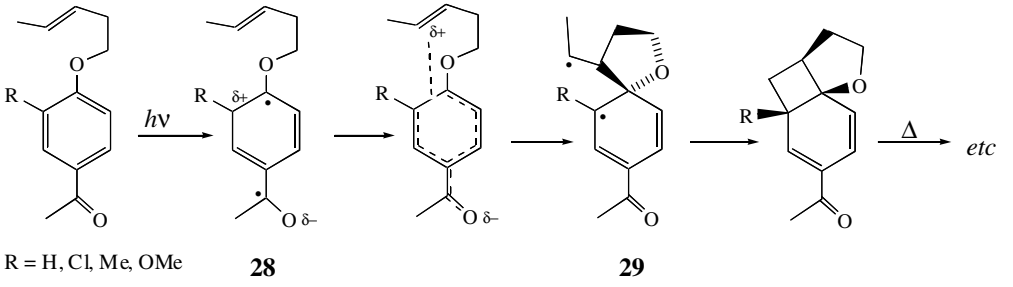

FIGURE 41.6 Mechanism of *ortho* photocycloaddition of alkenylacetophenones.

isomers **25** and **26** as illustrated in Figure 41.4 for the reaction of 4-phenoxybut-1-enes.[25,36] The reaction of these bichromophores may be assumed to arise from the S_1 state of the arene and may also be accompanied by varying amounts of the corresponding *meta*-cycloadducts dependent on the nature and position of substituents. The bichromophore **27,** having an obvious electron donor–acceptor relationship between the addends, undergoes solely *ortho*-cycloaddition (Figure 41.5) from the singlet state as evidenced by the retention of the (*E*) geometry of the ethene unit.[37] However, not surprisingly, the similar reactions reported over the past 15 years for 2- and 4-alkenylacetophenones and related compounds are triplet state processes and are deduced to proceed by charge transfer interaction from the ethene moiety

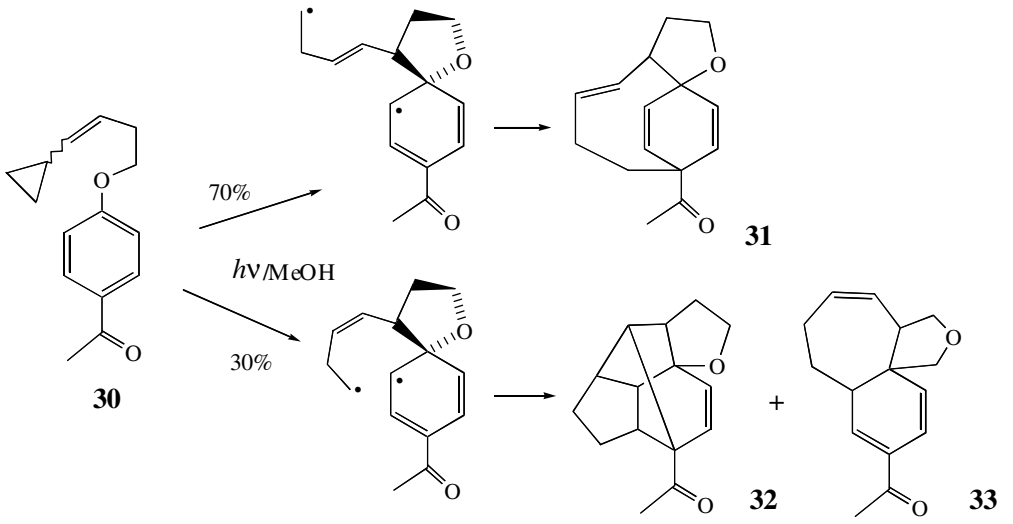

FIGURE 41.7 Evidence for the biradical intermediate **29** using the cyclopropyl compound **30**.

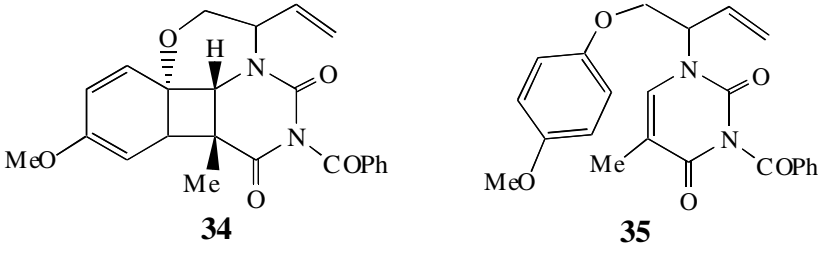
to the T_1 arene and the biradicals **28** and **29** as outlined in Figure 41.6.[38,39] The involvement of the biradical **29** has been proven from a study of the photochemistry of the cyclopropyl-substituted bichromophore **30** which gave none of the *ortho*-cycloaddition-derived products; instead, the three isomers **31**, **32**, and **33** were formed in respective ratios of 5:3:1 by the routes outlined in Figure 41.7.[40] Furthermore, it is deduced that only 30% of the biradicals revert to the starting bichromophore, while 70% undergo rearrangement. In contrast to the 4-phenoxybut-1-enes in Figure 41.4, those having a 2′- or 4′-cyano or 2′-alkoxycarbonyl substituent have been shown by quenching[41] and acetone-sensitization[42] studies to react also from the triplet state, but to yield the same types of product derived exclusively from *ortho*-cycloaddition. Under acid conditions, the photochemistry of 4-phenoxybut-1-enes which are mono- (3′-) or di- (3′,5′-) substituted with hydroxy-,[43–47] methoxy-,[45–47] methoxycarbonyl-,[44,47,48] or cyano-[47] groups provides a convenient access to highly functionalized compounds including cyclobutenes. The reactions proceed by initial intramolecular *ortho*-cycloaddition followed by acid cleavage of the products: typical examples are given in Figures 41.8.[46,47]

Bichromophores of diverse structure undergo intramolecular *ortho*-cycloaddition, and molecular constraints can restrict the ring opening of the initial adduct. Examples of this feature include the formation of **34** by chemo-, regio-, and stereo-selective intramolecular addition of the benzene–thymine bichromophore **35**[49] and the conversion of the chromone **36** in benzene solution to the intramolecular adduct **37**.[50] However, carrying out the latter reaction in methanol or further irradiation of the *ortho* adduct gives the product **38** of a novel rearrangement.



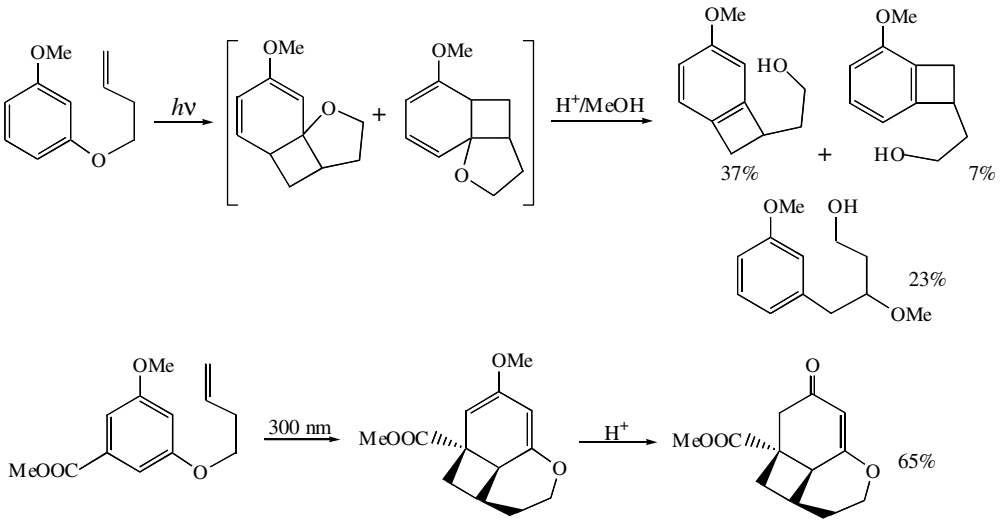


FIGURE 41.8 Intramolecular photocycloaddition of 4-phenoxybut-1-enes under acid conditions.

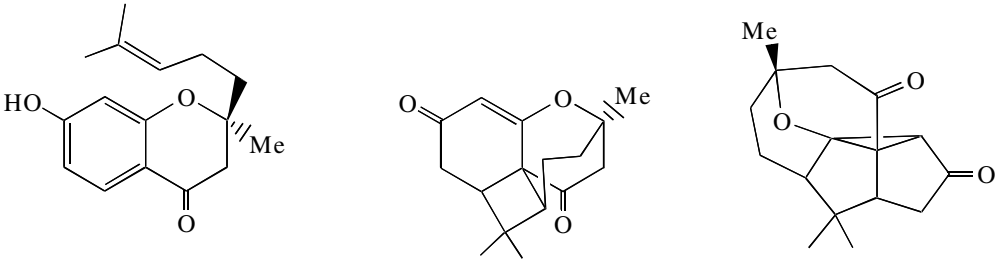

36 **37** **38**

Numerous examples have been reported in the literature of the intermolecular *ortho*-photocycloadditions of ethenes to the benzene ring. Some of these arise by direct or sensitized excitation of a ground-state complex or by way of an exciplex, while others may be assumed to result simply from addition of the S_0 ethene to the S_1 arene.[35] However, a common feature for systems for which the *ortho* adduct is the major product is that an electron donor–acceptor relationship exists between the addends. Depending on the substituents, these bicyclo-octa-2,4-dienes may be thermally stable or, as in intramolecular systems, undergo ring opening to the cyclooctatriene isomer followed by photochemical electrocyclization. In other cases, where the ethene has dienophilic activity, 2:1 adducts are formed. Most of the studies of intermolecular *ortho*-photocycloaddition were reported over 10 years ago,[35] but more recently this process under acid conditions, with 6-chloro-1,3-dimethyluracil and benzene and its simple derivatives, has attracted attention.[51–55] These *ortho* adducts ring open to the cyclooctatriene, which then undergo various photorearrangements. The primary process is illustrated in Figure 41.9 for the addition to mesitylene.[55]

The intra- and intermolecular photoadditions of acetylenes to the benzene ring are solely *ortho* processes, regardless of the electron donor–acceptor relationships of the addends; thus, unfortunately, these systems do not provide an access to semibullvalenes. The bicyclo[4.2.0]octa-2,4,7-trienes formed commonly ring open to the stable cyclo-octatetraenes.[35] These *ortho*-photocycloadditions are generally characterized by low quantum efficiencies (~0.03), and in some cases evidence has been reported that indicates that the reaction may proceed from the photoexcited acetylene. Examples of these processes are given in Figure 41.10.

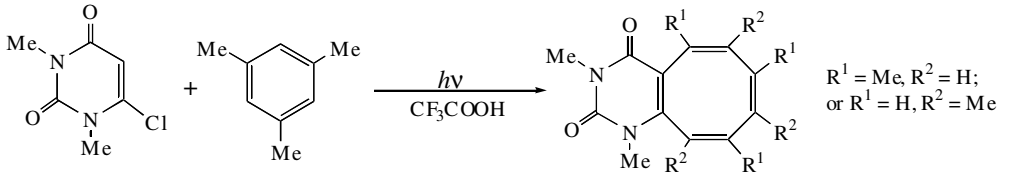

FIGURE 41.9 Photocycloaddition of 6-chloro-1,3-dimethyluracil to mesitylene.

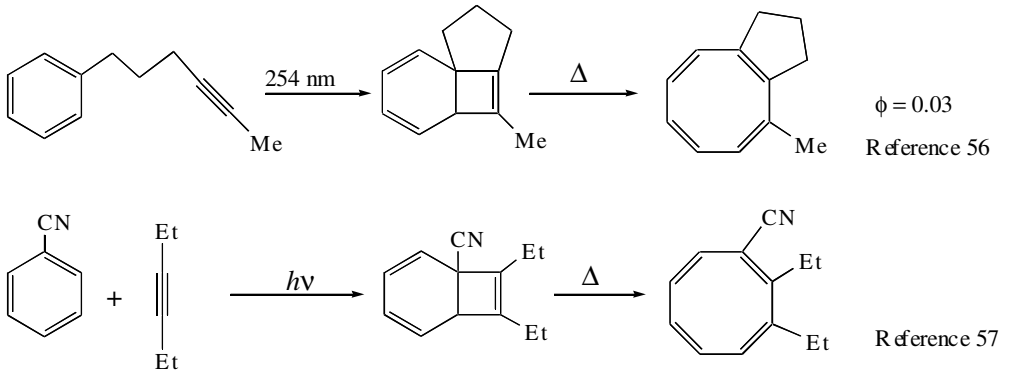

FIGURE 41.10 Intra-and inter-molecular photocycloaddition of acetylenes to the benzene ring.

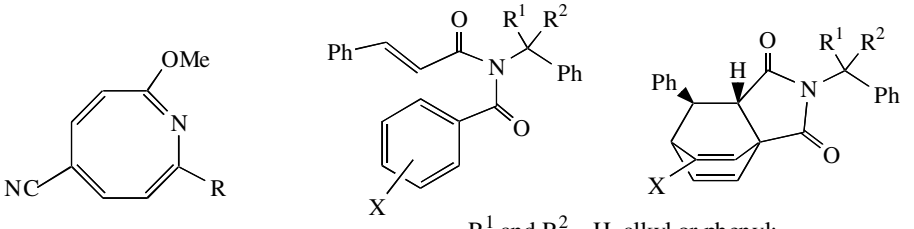
The cyano group of benzonitrile or acrylonitrile behaves in a similar manner to acetylenes in its addition to benzenes. The addition is particularly favored for benzenes, which are 1,4-substituted with an electron donor and an electron acceptor group. The adducts undergo ring opening and provide a convenient one-step route to azocines **39**.[58]



39 R = Ph or -CH=CH_2 **40** **41**

para-Photocycloaddition to the benzene ring is a rare event and is generally a minor process except for 1,2-dienes;[59] however, *N*-benzoyl-*N*-benzylcinnamides **40** and related compounds undergo benzil-sensitized intramolecular cycloaddition in benzene solution to give the bicyclo[2.2.2]octadienes **41**.[60]

Photo-Fries Reaction and Related Processes

Miguel Angel Miranda

Francisco Galindo
Universidad Jaume I de Castellon

42.1 Definition of the Reaction

The photo-Fries rearrangement, analogous to the classical Lewis acid-catalyzed Fries counterpart, was first reported by Anderson and Reese in 1960.[1] The prototype for this reaction is the photochemical transformation of phenyl acetate (**1**) into *o*- and *p*-hydroxyacetophenone (**2** and **3**) (Scheme 1). Since the initial discovery, a number of variations have been devised, and the process has been extended to systems (**4**) such as aryl carbonates, carbamates, sulfonates, and sulfamates, as well as anilides, sulfonanilides, and sulfenanilides. Analogous 1,3-migrations in the corresponding enol derivatives (**7**) have been observed (Scheme 2). In this context, it should be mentioned that the so-called *photo-Claisen rearrangement* is closely related to the photo-Fries rearrangement; it is experienced by aryl ethers (instead of aryl esters) and follows an analogous mechanism.[2] Much of the work on the photo-Fries rearrangement was done during the first decade after the discovery of the reaction and is summarized in several reviews.[3–6] In this chapter, we limit ourselves to the most recent achievements on the rearrangement of aryl esters, paying special attention to the key mechanistic aspects and the most relevant synthetic applications.

42.2 Mechanism

Many reports have appeared during the last few years in connection with the mechanism of the photo-Fries reaction. These contributions have confirmed that the photo-Fries rearrangement is a singlet reaction that occurs through homolytic cleavage of the carbonyl-oxygen single bond to give a caged radical pair. In-cage recombination affords the acyl migration products, while hydrogen abstraction by the aryloxy radical leads to the transformation to phenols, which are the most common byproducts. This is summarized below for phenyl acetate (**1**) (Scheme 3); however, some recent studies point to the fact that in certain esters the rearranged products could arise from upper triplet states.[7] The most convincing arguments in support of this rationalization include: (1) detection of the phenoxyl radical by optical spectroscopy[8] and by spontaneous Raman spectroscopy[9] in the photolysis of phenyl acetate; (2) spin trapping of acetyl or benzoyl radicals in the photolysis of phenyl acetate or phenyl benzoate, respectively, using 2-methyl-2-nitrosopropane;[10] (3) measurement of magnetic isotope effects and external magnetic

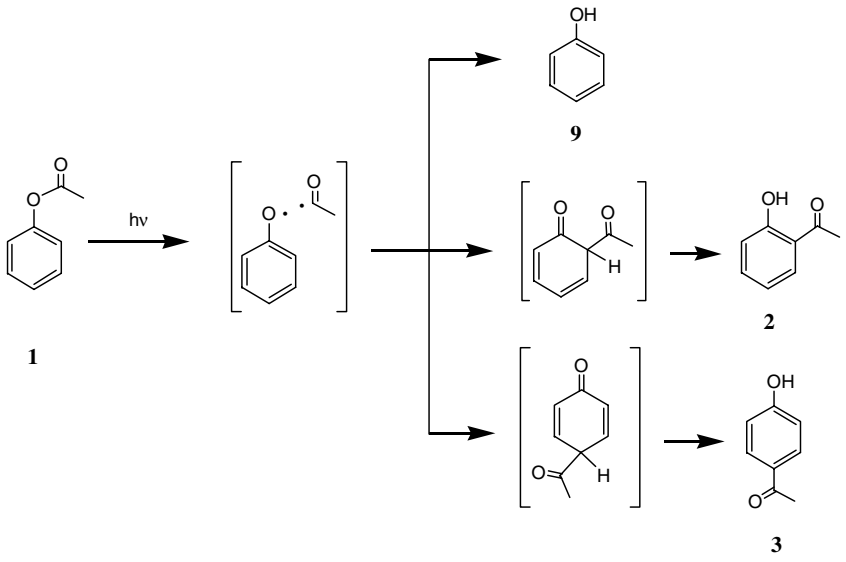
field effects upon the photo-Fries rearrangement of 1-naphthyl acetate and its ^{13}C-carbonyl-labeled analog;[11] (4) measurement of kinetic isotope effects (^{18}O at the phenolic oxygen, ^{14}C at the α-carbon, and ^{14}C at the *ortho*-carbon), as well as magnetic isotope effects (^{13}C at the α-carbon) in the photo-Fries rearrangement of *p*-methoxyphenyl acetate;[12] (5) photolysis of the intermediate *ortho*-cyclohexadienone to yield a ketene as photoproduct by means of the two-laser/two-color technique;[13] (6) formation of identical coupling products by independent generation of the same radicals participating in the intramolecular rearrangement from different sources (intermolecular version of the photo-Fries rearrangement);[14] and (7) calculations made using molecular orbital theory, which point to CO breaking from a dissociative $\pi\sigma^*$ state.[15]



SCHEME 3

42.3 Synthetic Applications

Exploitation of the photo-Fries rearrangement as a general synthetic method depends on the degree of variability in the phenolic and the acyl substructures, as well as the possibility of controlling the outcome of the process through manipulation of the experimental conditions. These aspects have been extensively investigated during recent years.

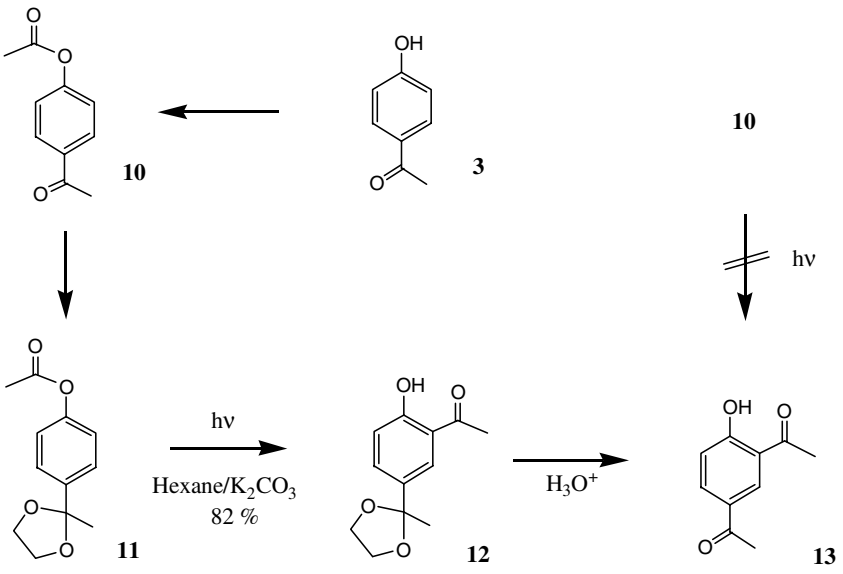
Variations in the Phenolic Moiety

Soon after its discovery, the photo-Fries reaction was applied to esters of a wide variety of phenols;[3,4] however, the presence of certain electron-withdrawing substituents (for instance acyl groups) in the phenolic ring was found to inhibit the rearrangement, due to the electrophilic nature of such substituents. The fact that the photochemical version of the rearrangement proceeds in neutral media and at room temperature has allowed the polyacylation of phenols, using enol acetates or cyclic acetals as carbonyl blocking groups.[16–19] This is shown below for the conversion of *p*-hydroxyacetophenone (**3**) into the hydroxydiketone (**13**) (Scheme 4).

In addition to the esters of simple phenols, the condensed polynuclear analogs are also prone to undergo the photo-Fries rearrangement. In this context, the studies on naphthyl esters[20–22] can be cited among the most significant work. Likewise, this photoreaction has been employed for the oxygen-to-carbon migration in condensed heterocyclic compounds. Some examples are the ring acylations achieved by photolysis of the acyloxy derivatives of coumarins,[23] benzopyrans,[24] indoles,[25] and dihydrobenzofurans.[26] Thus, the absolute configuration of rutaretin methyl ether (**20**) has been established by transformation into a derivative, whose independent synthesis was achieved from *S*-marmesin, through a sequence that involves photo-Fries rearrangement of the diacetate **14** (Scheme 5).[26] Analogous synthesis of natural products using the photo-Fries reaction as a key step can be found in the recent literature.[27]

Variations in the Acyl Moiety

When the acyl group carries a second functionality (double or triple bond, hydroxyl group, carbonyl group, etc.), interaction of the latter with the *ortho*-hydroxy group, subsequent to the rearrangement step, may be a general principle for the construction of heterocyclic ring systems. This has been applied



SCHEME 4

to the synthesis of furanones,[28,29] chromones,[30–32] chromenes,[33–35] flavones,[36–38] aurones, xanthones,[39–42] thioxanthones,[43] or acridones.[44]

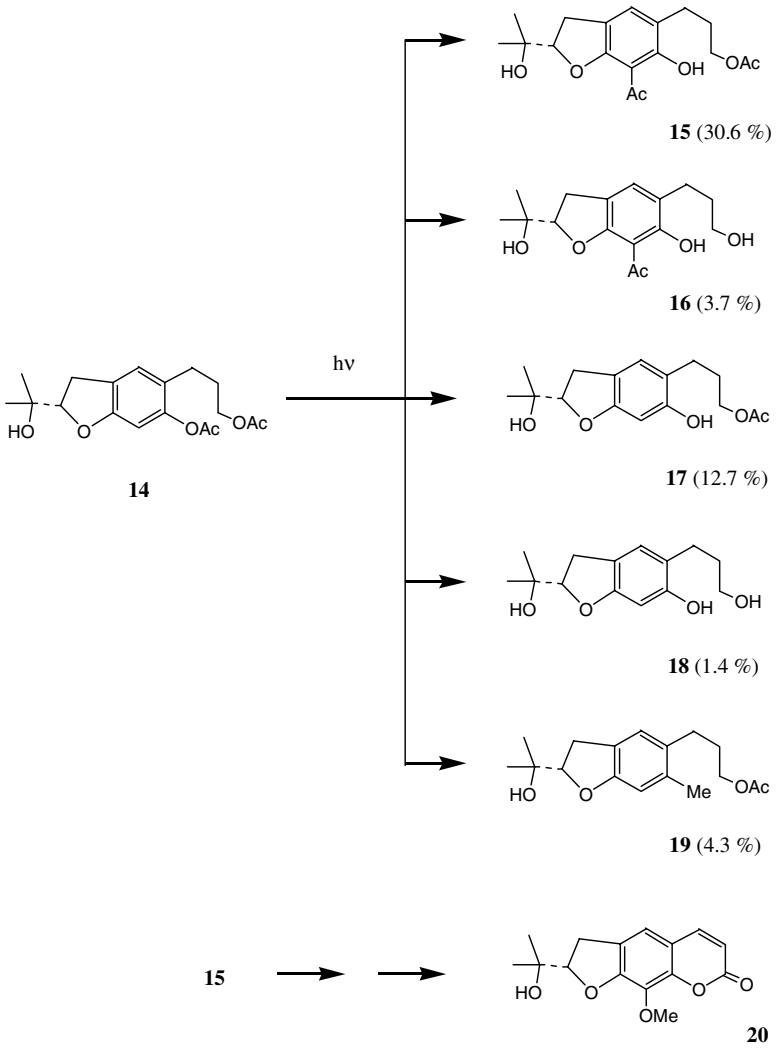
For instance, photolysis of aryl esters of phenylpropiolic acid (**21**) gives rise to *o*-hydroxyaryl phenylethynyl ketones (**22**). The latter compounds can undergo cyclization in two different ways, depending upon the reaction conditions: When potassium carbonate in acetone is used, flavones (**23**) are formed by a 6-endo-dig process;[45] by contrast, the use of sodium ethoxide in ethanol favors the 5-exo-dig process,[45] to give aurones (**24**) as the major products (Scheme 6).[38] The side-chain functionality can be masked, as in the case of the protected ketoesters (**25**), whose irradiation and subsequent deprotection provide an alternative entry to the flavone system (Scheme 6).[37]

In another application, the total synthesis of bikaverin (**29**) has been achieved using the photo-Fries rearrangement of the protected everninic acid ester (**27**) as a key step for the construction of the benzo[*b*]xanthene skeleton (Scheme 7).[40]

Use of Heterogeneous Media

In view of its paradigmatic nature as a process involving in-cage recombinations vs. diffusion of organic radical pairs, the photo-Fries rearrangement has been chosen as a model reaction to study the influence of heterogeneous media as modifiers of reactivity and selectivity. In an early study, the photo-Fries rearrangement of aryl esters was attempted on the surface of silica gel.[46] Subsequently, cyclodextrins have been employed to carry out the photo-Fries rearrangement of aryl esters in a restricted environment.[47–51] The initial observations[47,48] appeared to indicate cyclodextrin-enhanced *para*-selectivity; however, more recent studies[49–51] report an increase in the *ortho*-product attributable to cyclodextrin complexation. Photo-Fries rearrangements of naphthyl[52] and sulfonate[53] esters have also been studied in the presence of cyclodextrins. Other modifications involve the use of starch, amylose, sodium dodecylsulfate,[54,55] potassium carbonate,[18,56] nafion membranes,[57,58] alkyl alkanoates, or acrylic polymers[59] to create a heterogeneous irradiation system. Recently, the photo-Fries rearrangement has been used to study the morphology of the reaction sites in stretched and unstretched polyethylene films[60] as well as in poly(vinyl acetate).[61]

More conventional liquid–liquid biphasic conditions have been also conveniently employed to increase the efficiency of the photo-Fries reaction. For instance, *p*-methoxyphenyl esters of α,β-unsaturated carboxylic acids (**30**) undergo photochemical rearrangement, followed by basic cyclization to give



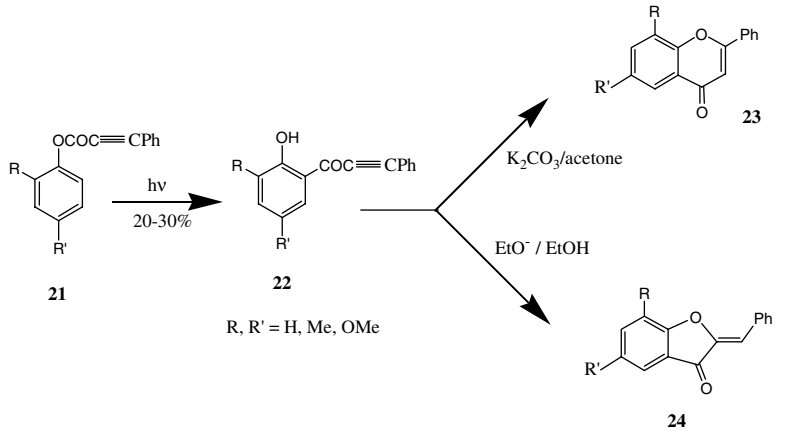
SCHEME 5

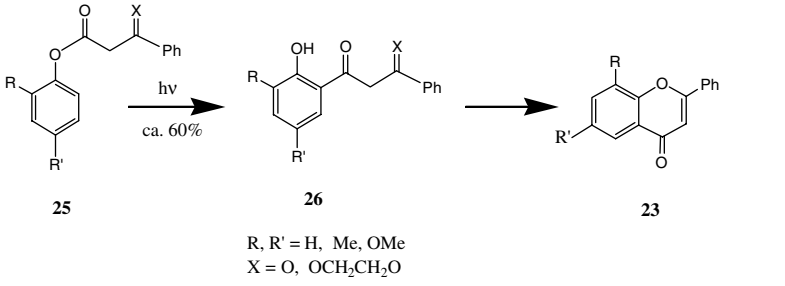
4-chromanones (**32**) with moderate overall yields. Using a two-phase system, benzene/aqueous sodium hydroxide, chromanones are obtained directly in nearly quantitative yields. Subsequent reduction/dehydration affords *2H*-chromenes (**33**), interesting because of their antijuvenile hormone activity (Scheme 8).

Inorganic mesoporous materials such as zeolites have also served as hosts for aromatic esters whose irradiation leads to changes in the selectivity of the photoproducts (*ortho* preference) in comparison with the rearrangement in homogeneous media.,[62,63] Finally, the photochemical Fries rearrangement of naphthyl acetate has shown the occurrence of solvent-solute clustering in supercritical carbon dioxide.[64]

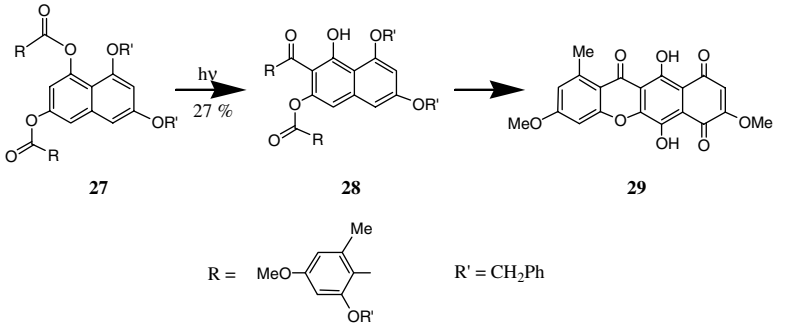
42.4 Industrial Applicability

Much attention has been paid to the photo-Fries rearrangement of aromatic polyesters due to the remarkable photostabilization produced by the resulting polymer-bound *o*-hydroxycarbonyl chromophores. This property has been attributed to the high extinction coefficient of the photo-Fries products (internal filter) and to their ability to dissipate the absorbed energy by non-photochemical pathways,

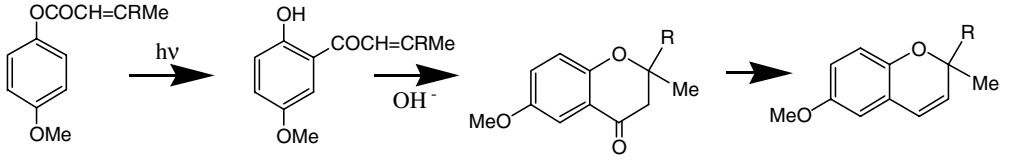




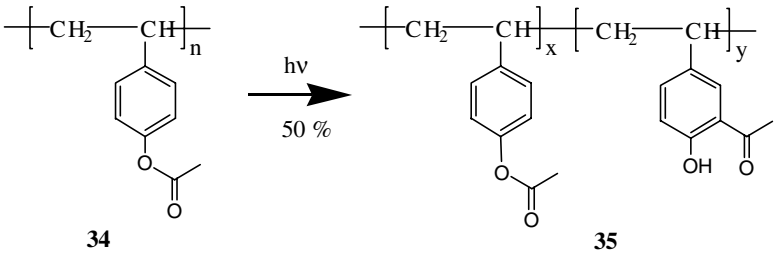
SCHEME 6



SCHEME 7



SCHEME 8



34 **35**

SCHEME 9

such as excited-state proton transfer.[65,66] Polycarbonates,[67–70] poly(arylcinnamates),[68,71,72] polyurethanes,[73–75] fluorene-based polyesters,[76] or 1- and 2-naphthyl methacrylate copolymers[77,78] are among the polymeric materials capable of undergoing this type of photochemical transformation. In some cases, a wavelength-dependent photochemistry of the polymer has been observed,[67,71,72] due to competition between the photo-Fries reaction and other photoprocesses (crosslinking, oxidation, etc.)

Another field of application is the design of polymeric imaging systems.[79] The lithographic potential of a photochemical reaction is based on the possibility of dissolving selectively either the exposed or the unexposed areas of a polymer film. Because all the photo-Fries products are phenols, the irradiated polyester should be easily dissolved in aqueous base, while the unchanged starting material should remain undissolved. The key photochemical step of this sequence is shown above for the conversion of poly(*p*-acetoxystyrene) (**34**) into (**35**) (Scheme 9).[80]

Photochemistry of Aryl Diazonium Salts, Triazoles and Tetrazoles

James Grimshaw
Queen's University of Belfast

43.1 Introduction

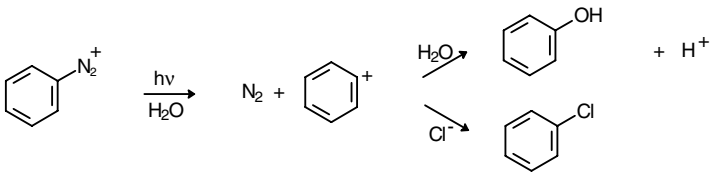
An observation from 1887 noted that solid benzenediazonium nitrate turns rose-red on exposure to sunlight.[1] This sensitivity to light of diazonium salts was exploited in the textile industry as early as 1890 when a process for printing on silk or cotton was devised involving the photo-decomposition, under stencils, of an applied diazonium salt followed by coupling of the residual material with a phenol.[2] Photodecomposition of diazonium salts with loss of nitrogen, followed by coupling of the residual salt with a phenol, forms the basis of the diazo-copying process, which at one time was used extensively for copying large engineering drawings. Some photolithographic processes also utilize the properties of diazonium salts. The research supporting these technical applications led to investigations into the stability to light of aromatic heterocycles having two adjacent nitrogen atoms.[3] From 1959 on, photochemical reactions, which involve the evolution of nitrogen from triazoles, tetrazoles, and related systems began to be examined in detail.

43.2 Arenediazonium Salts

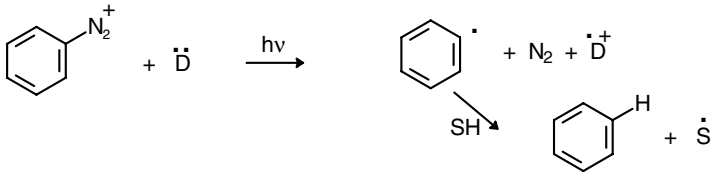
In aqueous solution, diazonium salts show absorption maxima in the ultraviolet (UV) region; benzenediazonium ion has λ_{max} 261 nm (log ε 4.3) and 300 nm (log ε 3.17).[4] Both absorption bands are shifted toward the visible by electron-donating substituents; 4-dimethylaminobenzenediazonium has λ_{max} 382 nm (log ε 4.6).[5] Photolysis in aqueous solution leads to phenol as the main product, according to Scheme 1. Some replacement of the diazonium group by an atom of chlorine or bromine is also found in solutions containing chloride or bromide ions.[6]

Quantum yields for the photochemical decomposition of aryldiazonium salts in aqueous solution are less than unity. A value of 0.34 has been recorded for decomposition of 4-phenylaminobenzenediazonium

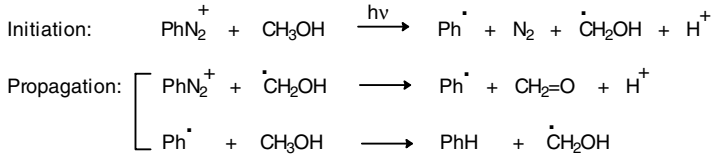
0-8493-1348-1/04/$0.00+$1.50



SCHEME 1



SCHEME 2



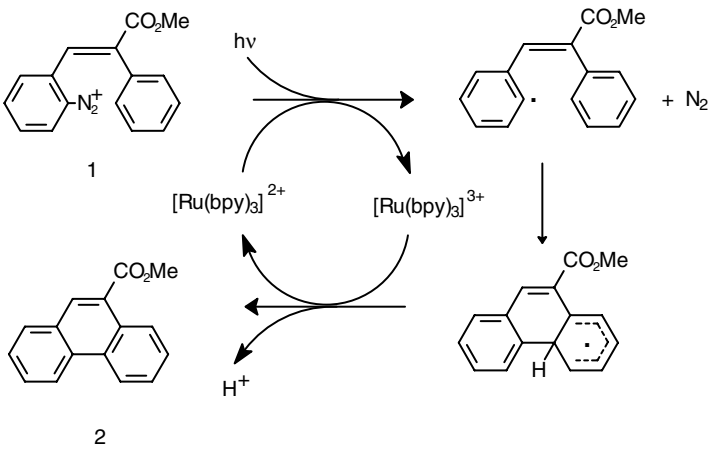
SCHEME 3

on irradiation at 380 nm.[7] Quantum yields of 0.57[8] and 0.97[9] have been noted for the decomposition of 4-dimethylaminobenzenediazonium ions.

The thermal decomposition of aryldiazonium salts also gives phenols, and in a few cases the photochemical processes offer superior yields.[10] Preparation and photodecomposition of diazonium salts in 50% fluoroboric acid has proved useful for the replacement by fluorine in cases where the diazonium salt is exceptionally stable and the usual Schiemann reaction gives poor yields.[11] However the practical problems of avoiding overheating and the eventual screening of light by the reaction product limit the usefulness of these photochemical processes.

The photolysis of benzenediazonium salts in the presence of an electron donor (D) leads to photoelectron transfer according to Scheme 2, followed by carbon–nitrogen bond cleavage to give a phenyl radical. The radical abstracts a hydrogen atom from the solvent (S–H), resulting in overall replacement of the diazonium group by hydrogen. Solvents such as methanol or isopropanol can function as the electron donor but with varying efficiency, depending in the acceptor ability of the diazonium salt.[12] Thus, diazonium salts derived from aminodiphenylamines are decomposed in ethanol to form products derived from the phenyl cation, and photoelectron transfer is not involved.[13] Benzenediazonium salts with less strongly electron-donating substituents (4-methyl or 4-methoxy) afford a mixture of products upon irradiation in methanol because both reaction Schemes 1 and 2 operate. Benzenediazonium salts with electron-withdrawing substituents (4-nitro or 4-chloro) give products only by replacement of the diazonium group by hydrogen.

Quantum yields for the photoelectron transfer process in methanol are generally greater than unity, because the solvent radical takes part in a chain reaction (Scheme 3), the efficiency of which depends on the concentration of the diazonium salt and on the substitution pattern.[14] Quantum yields for decomposition are around 80 for 4-nitrobenzenediazonium (10^{-2} *M*), 5 for 4-chlorobenzenediazonium (10^{-2} *M*), and about 2 for 4-methylbenzenediazonium (5×10^{-3} *M*). Added 2-methyl-2-nitrosopropane acts as a scavenger for phenyl radicals and, under these conditions, the quantum yield for diazonium salt



SCHEME 4

decomposition falls. At the same time, the yield of cation-derived product increases at the expense of radical derived materials. This behavior is probably general but few examples seem to have been recorded.

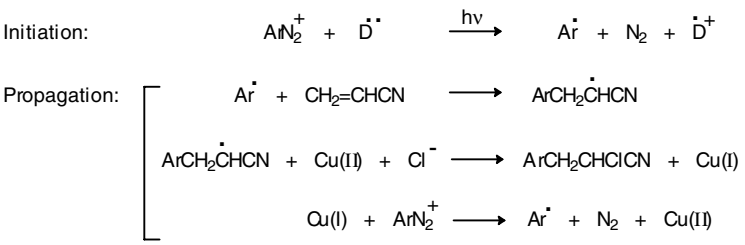
Both the arene cation and the arene radical can be detected using ESR spectroscopy after irradiation of diazonium salts in a glassy matrix at 77 K. The ground state of the phenyl cation bearing an electron donating *para*-substituent is a $(\pi)^5(sp_2)^1$ triplet, and this is easily distinguished from the phenyl radical that may also be formed.[15,16] Phenyl cations in the singlet ground state cannot, of course, be detected by ESR spectroscopy. Irradiation of 4-dimethylaminobenzenediazonium salts at 77 K gives rise to the two reactive intermediates. Warming to 120 K results in gradual decay of the triplet, leaving the radical relatively unaffected. Correlation between the UV and ESR signals allows the absorption at λ_{max} 455 nm to be assigned to the triplet aryl cation.[17]

Other solvents, which lead exclusively to radical derived products from the photolysis of diazonium salts, include formic acid and dimethylformamide. Anions can also act as donors in the photochemical electron transfer process; here, the efficiency increases with decreasing electrochemical oxidation potential of the anion. Tetraphenylboron ion is a good electron donor, while fluoroborate is a poor donor.[18]

Diazonium salts are excellent quenchers of aromatic hydrocarbon triplet states by an electron transfer process. The anthracene radical cation can be detected by UV monitoring as one reaction product after laser flash generation of anthracene triplet in the presence of a diazonium salt.[19] In more concentrated solutions and in the situation where the diazonium and the hydrocarbon are solubilized in aqueous sodium dodecylsulfate micelles, electron transfer occurs from the singlet excited state.[20] A related reaction is electron transfer between the ion pair involving benzenediazonium cation and anthracenesulfonate anion in chloroform, which results in decomposition of the diazonium salt.[21] CIDNP effects during the irradiation of ^{15}N- and ^{13}C-labeled diazonium salts, sensitized by perylene or rubrene, have demonstrated both electron back-transfer within the reaction cage and also escape of both nitrogen and phenyl radicals from the cage.[22,23]

Benzenediazonium salts quench the luminescence of $[Ru(bpy)_3]^{2+}$ by an electron transfer step. The reaction is stoichiometric with no significant back electron transfer from the aryl radical to the resulting Ru(III) complex; however, Ru(III) complexes can be reduced electrochemically to Ru(II). Thus, irradiation of the diazonium salt and $[Ru(bpy)_3]^{2+}$ in the cathode chamber of an electrochemical cell becomes a catalytic process for conversion of the benzenediazonium salt to a phenyl radical.[24]

The photochemical reaction between the diazonium salt **1** and $[Ru(bpy)_3]^{2+}$ produces good yields of the Pschorr-type product **2**, and the process is catalytic; here, the reaction first gives a phenyl radical. This intermediate cyclizes, and then back electron transfer from the cyclized radical to Ru(III) regenerates the catalyst complex (Scheme 4).[25] In contrast, direct photocyclization of **1** in acetonitrile gives poor yields of the phenanthrene. The intermediate in this process now becomes the phenyl cation, and the

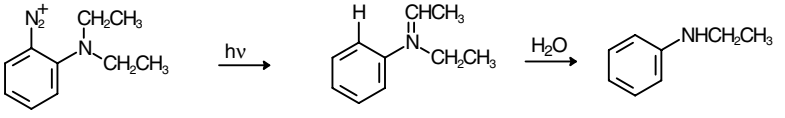


SCHEME 5

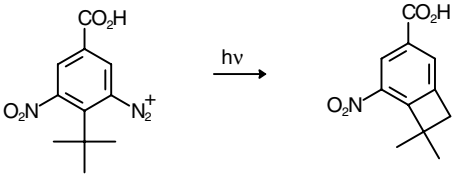
principal side product results from reaction of the cation with acetonitrile solvent. Attempts to achieve photocatalysis of five-membered ring cyclizations to form fluorenone, fluorene, and dibenzofuran products result in poor yields due to the unfavorable geometry for the radical cyclization step.[26]

The Meerwein reaction between phenyl radicals, thermally generated from arenediazonium salts, and alkenes in the presence of copper(I) ions can also be initiated photochemically. Irradiation of the diazonium salt in the presence of copper(II) ions leads to photoelectron transfer and the generation of phenyl radicals. Addition of the radical to an alkene bond becomes a chain reaction mediated by copper ions according to Scheme 5. Quantum yields for the evolution of nitrogen are in the region of 700.[27]

Photodecomposition of some *ortho*-substituted aryldiazonium ions leads to unusual reaction products due to hydrogen atom transfer between the *ortho*-substituent and the radical center derived by loss of nitrogen from the diazonium ion. Thus, 2-diethylaminobenzenediazonium salts yield *N*-ethylaniline via the intermediate **3**. Deuterium is not incorporated into the benzene ring from either D_2O or CD_3OD.[28] Decomposition of the diazonium salt **4** leads to a benzocyclobutene as the principal product. The influence of the nitro substituent is important, because the un-nitrated diazonium salt is decomposed to give a phenol in the normal manner.[29]



3



4

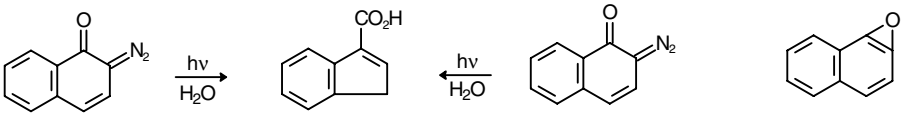
Diazonium salts, relatively stable to heat, have been used as photoinitiators in polymerization processes. Both phenyl cations and radicals generated during the illumination stage will initiate polymerization of vinyl ethers and the crosslinking of low-molecular-weight polymers with reactive alkene substituents.[30]

43.3 1,2-Arenediazo-Oxides

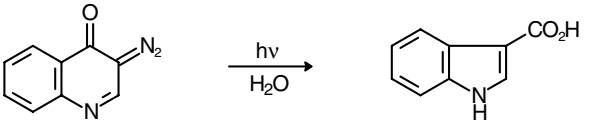
The 2-hydroxybenzenediazonium ion is in acid-base equilibrium ($pK_a = 1.14$)[31] with 2-diazocyclohexa-3,5-dien-1-one **5** (the diazo-oxide form). Diazo-oxides show absorption maxima at longer wavelengths than the corresponding diazonium salt form. Thus, 1-diazo-2-oxo-1,2-dihydrobenzene has λ_{max} 395 nm

(log ε 7.0) in water, while in 50% sulfuric acid, where the predominant species is the diazonium ion, λ_{max} 353 nm (log ε 6.3) is found. Photolysis in 50% sulfuric acid leads mainly to products derived from the corresponding phenyl cation analogous to Scheme 1.[32] In nonpolar solvents and in the gas phase, compound **5** is in equilibrium with the 1,2,3-oxadiazole form, and in these solvents the intensity of the UV-absorption band at 395 nm is greatly diminished. The diazo-oxide form predominates in polar solvents.[33] X-ray investigation of 1-oxo-2-diazo-1,2 dihydronaphthalene shows this to be in the diazo-oxide form in the crystalline state.[34] Irradiation of either the diazo-oxide **5** or the oxadiazole form leads to loss of nitrogen and the reaction steps discussed below.

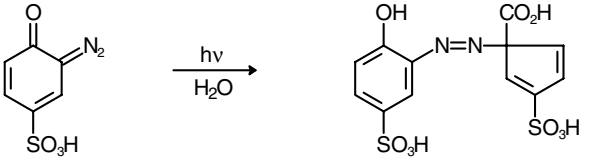
Photolysis of a diazo-oxide is the critical step in the diazo-copying process so that many of these reactions have been studied in detail. Between 1944 and 1958, Süs demonstrated that many 1,2-diazo-oxides are photolysed, with loss of nitrogen and rearrangement to a cyclopentadienecarboxylic acid. Examples include diazo-oxides from benzene **5**, naphthalene **6** (a and b) and further condensed aromatic hydrocarbons,[35–38] pyridine, quinoline **8**, benzotriazole and benzimidazole derivatives.[36,39] Süs ascribed structures to the products in which the alkene bond was not conjugated to the carboxyl group. Modern work with benzene and naphthalene derivatives indicates that the products have the conjugated enecarboxylic acid form. The conversions proceed with high quantum yield for the naphthalene diazo-oxides where $\Phi = 0.72$.[40] In an acidic pH range, some diazonium salts can couple rapidly with the corresponding cyclopentadienecarboxylic acid, leading to products such as **9**.



6a 6b 7

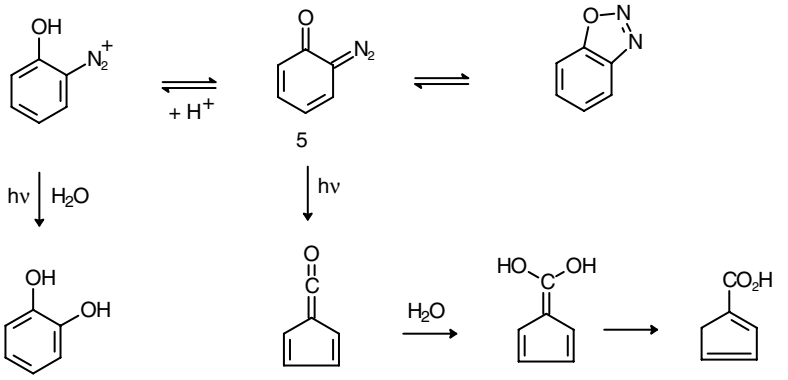


8

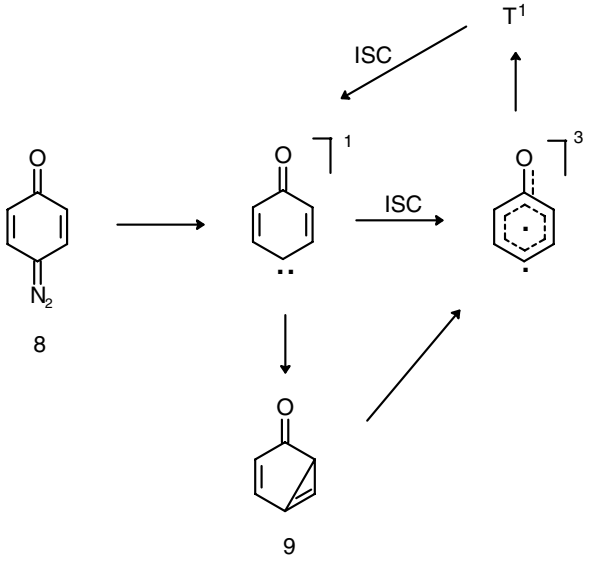


9

Fast-reaction techniques, employing laser flash excitation followed by UV monitoring of the reaction, show that photolysis of diazo-oxides derived from benzene[41] and naphthalene[42] follows the course illustrated in Scheme 6 for the benzene series. In aqueous solution, only the ketene and the ketene hydrate are observed as short-lived intermediates.[43] Rates of the intermediate reactions have been followed over a large pH range and show the expected profiles due to acid-base catalysis. Photolysis within a film of Novolak-resin shows evidence for the short-lived carbene intermediate, and it has been proposed that this species is stabilized as the oxirene form.[44] However, photolysis of the ^{13}C-labeled naphthalene derivatives cannot involve an oxirene intermediate **7** as no scrambling of the ^{13}C label is observed in the products.[45]



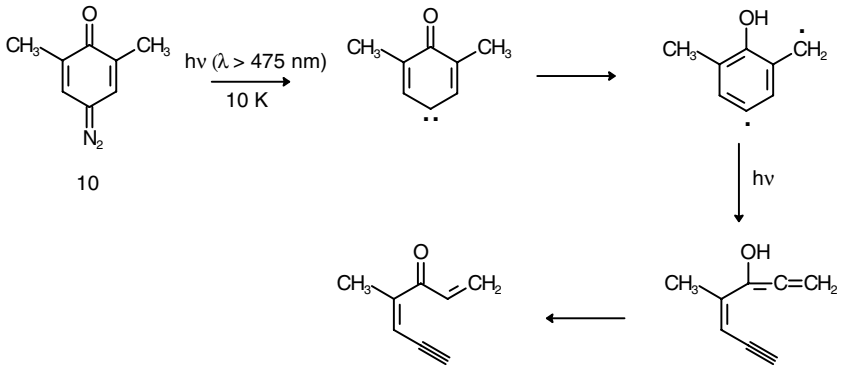
SCHEME 6



SCHEME 7

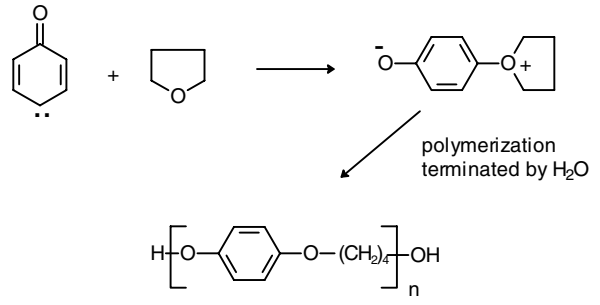
43.4 1,4-Aryldiazo-Oxides

The 4-hydroxybenzenediazonium ion is a strong acid that exists in polar and nonpolar solvents as the conjugate base form, 4-diazocyclohexa-2,5-dienone (the 1,4-diazo-oxide) with λ_{max} 342 nm (log ε 4.47) and 448 nm (log ε 1.80).[46] The 1,4-naphthalenediazo-oxides are also well known. Spectroscopic data indicate considerable interaction between the carbonyl and diazo functions in these molecules.[47] Irradiation of 1,4-diazo-oxides follows the course indicated in Scheme 7 for 1,4-benzenediazo-oxide **8**. Loss of nitrogen affords a singlet carbene, which is transformed by ISC into the more stable triplet form. These triplet carbenes have been characterized by spectroscopy in an argon matrix[48] and show an infrared (IR) carbonyl stretching frequency in the range 1550 to 1518 cm^{-1}, indicating considerable delocalization of one electron into the carbonyl function. The triplet has an adsorption maximum in the UV close to that of the parent diazo-oxide. Further irradiation to the T^1 state is followed by ISC and collapse to the short-lived singlet state. The singlet converts either to the triplet or to the bicyclohexadienone **9**. Thus, a photostationary state is established between the triplet and **9**. Isomer **9** can be isolated in an argon matrix



10

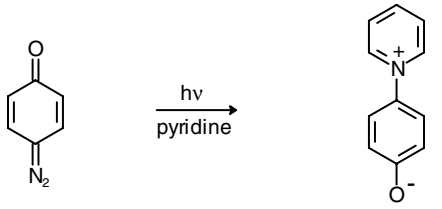
SCHEME 8



SCHEME 9

and on warming collapses to the triplet carbene.[48,49] Exceptions to this scheme are found with diazo-oxides having a methyl group adjacent to the carbonyl function. Within an argon matrix, the triplet carbene from **10** reacts by hydrogen atom transfer and collapse of the resulting biradical to an open chain structure (Scheme 8).[50]

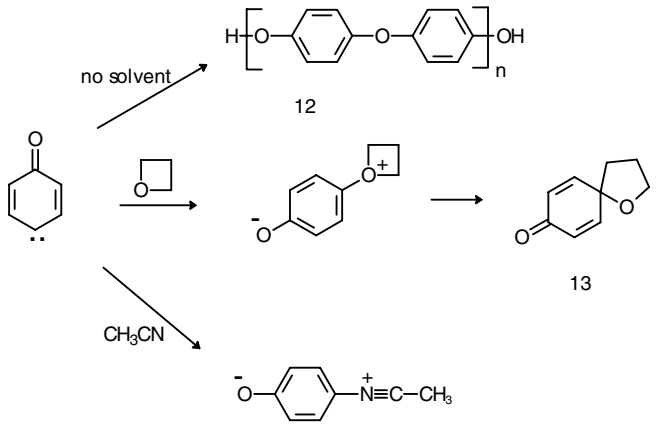
Preparative scale photochemical reactions of 1,4-diazo-oxides yield products expected from an electrophilic carbene intermediate. The singlet carbene is stabilized in polar solvents.[51] It reacts with primary alcohols as an electrophile, giving the corresponding hydroquinone mono-ether.[52] With isopropanol, and probably other secondary alcohols, hydrogen atom abstraction occurs, giving the phenoxyl radical.[53]



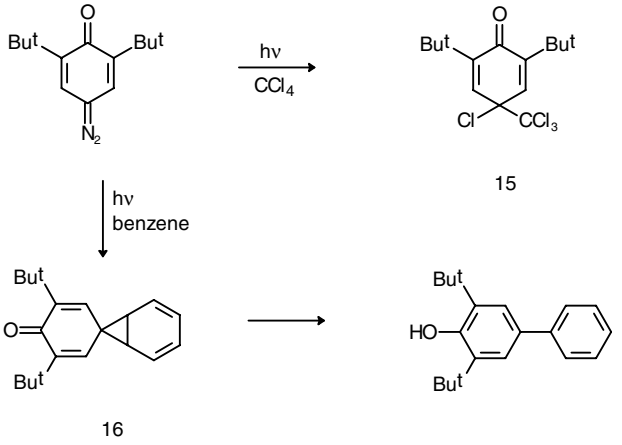
11

The electrophilic behavior of these carbene intermediates is also shown by their reactions with pyridine and with cyclic ethers as electron donors. Pyridine forms betaines of the type **11**, which are strongly colored.[54] In 1956, Süs noted the formation of strongly colored photoproducts with pyridine but assumed these to be C-substituted rather than *N*-substituted pyridines. Reaction with tetrahydrofuran produces a 1:1 copolymer, which probably arises by the mechanism shown in Scheme 9.[55] The photopolymerization

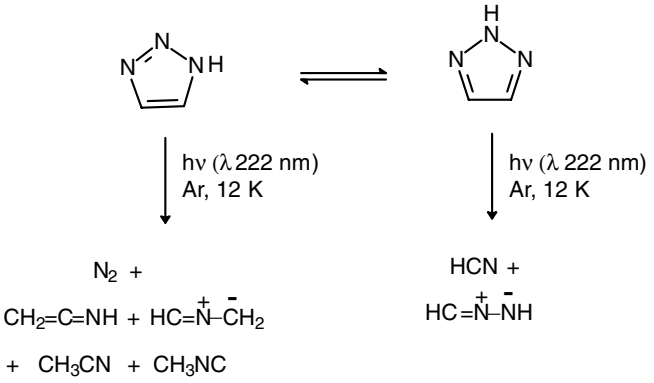
of solid 1,4-benzenediazo-oxide, which yields the polyether **12**, probably also proceeds in a similar manner. Reaction with oxetane is terminated by a Stevens rearrangement of the intermediate ylide to the spiro-compound **13**.[56] Reaction with acetonitrile also forms an ylide **14**.



The atom abstracting behavior of the carbene center is shown by reaction with carbon tetrachloride to form the cyclohexadienone **15**.[57] Reactions in alkane solvents also lead to hydrogen atom abstraction, and this step is intermediate in the cross polymerization of piperylene oligomers by irradiation in the presence of 1,4-benzenediazo-oxide.[58]



Photodecomposition of 1,4-benzenediazo-oxides in benzene or toluene leads to diphenyl derivatives. Reaction with benzene and with perdeuteriobenzene has been shown to proceed via a tricyclic intermediate **16**.[59] Preparative scale reaction between benzene-1,4-diazo-oxide and toluene led to the isolation of only two products, 4-hydroxy-2′-methyl- and 4-hydroxy-4′-methyl-biphenyl. Presumably the presence of a third isomer was not recognized at the time.



SCHEME 10

43.5 The Diazo Process

Photochemical decomposition of diazonium salts is the key step in a reprographic process once much used with large-scale engineering drawings. Both the Xerox reprographic systems and computer drawing programs have rendered the diazo process much less important than it formally was. Photoresist lacquers used in the manufacture of printed circuit boards employ variations of the diazo process. The earliest process, developed in 1890, used primuline as the source of the diazonium salt.[2] Cloth or paper was coated with primuline and then diazotized *in situ*. Exposure to light through a stencil left a positive image in the undecomposed diazonium compound. This image was developed in an alkaline phenol solution.

Kalle A-G of Wiesbaden developed the first commercially successful process.[60] It is often referred to as the Kögel process (from the author's name attached to the U.S. patent).[61] The Kögel process uses paper coated with both a diazo-oxide and a phenolic component, and the coating is made faintly acidic to slow down coupling of the two components while increasing the shelf life of the material. After exposure to a strong light, a positive image forms by decomposition of the diazo component, and development is achieved by exposing the paper to ammonia vapor when the remaining diazo component couples with the phenol. The usual diazo-oxide employed is a 2-diazo-1-oxo-1,2-dihydronaphthalene bearing a sulfonic acid substituent. Various phenols have been used to give images of different colors. This process has the great advantage that it requires no aqueous solutions; the final prints are dry and are immediately usable.

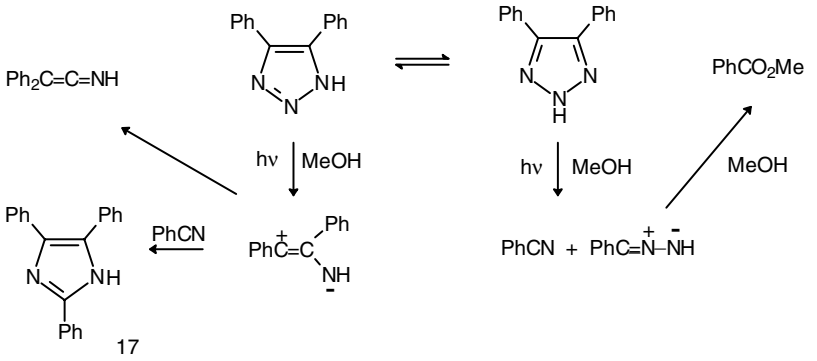
The Chemische Fabrick L. van der Grinten, of Venlo devised an alternative system,[62] known as a one-component system, that uses paper coated with a stabilized diazonium salt, but no phenol. Coupling is achieved after exposure by developing the paper in an alkaline solution of a phenol. The original diazonium salt used was 4-diethylaminobenzenediazonium associated with a complex anion. Choice of the phenolic component allowed modification of the color of the final image.

43.6 1,2,3-Triazoles

1,2,3-Triazoles with no substituent on nitrogen exist in a rapid tautomeric equilibrium between the *1H* and *2H* forms (Scheme 10). An independent photolysis pathway exists for each tautomer. For the parent

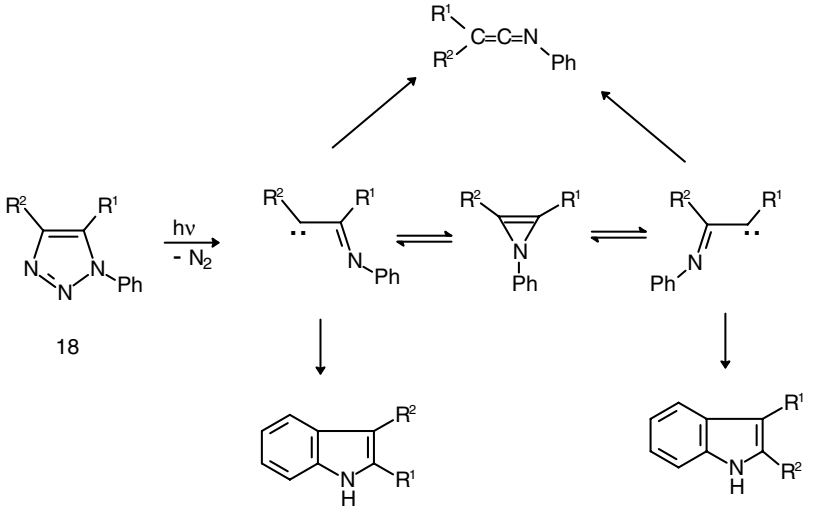
triazole molecule, the first formed intermediates have been characterized at 12 K in an argon matrix. The *1H* isomer loses nitrogen to leave a C_2H_3N residue as several interconverting isomers. The *2H* tautomer loses hydrogen cyanide to leave a 1,3-dipolar residue.[63]

Preparative-scale photolysis of 4- and 5-phenyltriazoles affords products derived from related reactive intermediates.[64] The recombination of intermediates to form unexpected products such as the imidazole 17 is illustrated by the irradiation of 4,5-diphenyl-1,2,3-triazole.

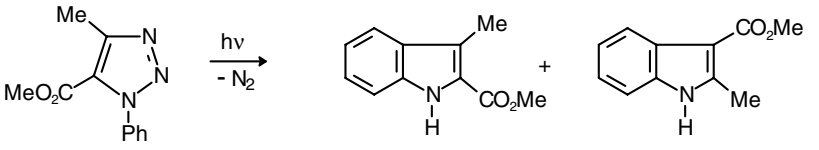


17

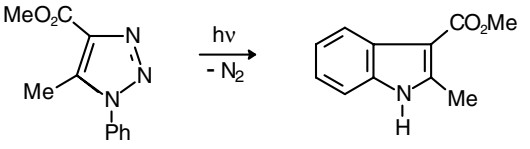
1-Phenyl-1,2,3-triazoles **18** do not show this tautomeric equilibrium, and photolysis leads only to the loss of nitrogen. The residual biradical is usually represented as a carbene. It is in equilibrium with an aziridine form, and the reverse equilibrium leads to a mixture of two isomeric carbenes. Two competing reactions then lead to the stable products. First, Wolff rearrangement of the carbene yields a ketene imide. Second, cyclization of the carbene center onto the phenyl group leads to an indole. Two isomeric indoles may be isolated because of rearrangement of the carbene via the aziridine.[65] Ring opening of the aziridine reactive intermediate favors formation of a carbene with an electron-withdrawing group on the carbene carbon center; thus, whereas photolysis of **19** gives two indoles via this carbene rearrangement, reaction of **20** leads to only one indole product. Photolysis of 1,5-diphenyl-1,2,3-triazole gives both 2- and 3-phenylindoles due to interconversion of the carbene intermediates via an aziridine.[66]



18



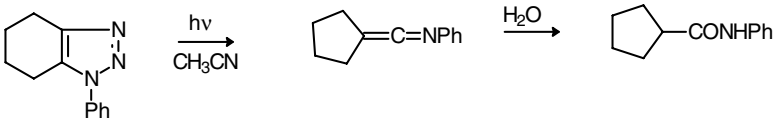
19



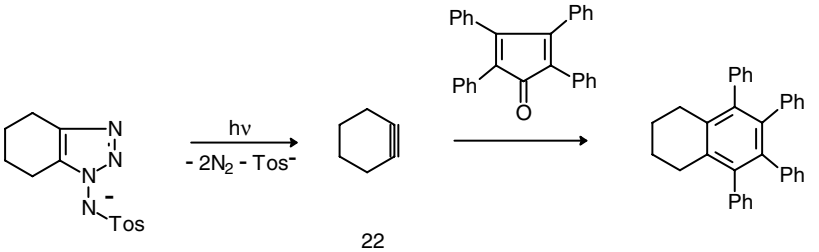
20

The relative rates of Wolff rearrangement and cyclization to the indole depend on the substituent pattern. Fast rearrangement of hydrogen and trimethylsilyl groups in position 5 of the triazole ring is observed so that no indole product can be detected in these reactions. With a phenyl substituent in position 5, both the Wolff rearrangement and cyclization to the indole are observed.[66,67] Photolysis of **21** gives products mainly via the Wolff rearrangement.[68]

Photolysis of 1-tosylamino-1,2,3-triazole anions leads to loss of two molecules of nitrogen and the generation of an alkyne. Strained cycloalkynes, for example **22**, have been generated in this way and trapped as Diels–Alder type adducts.[69]



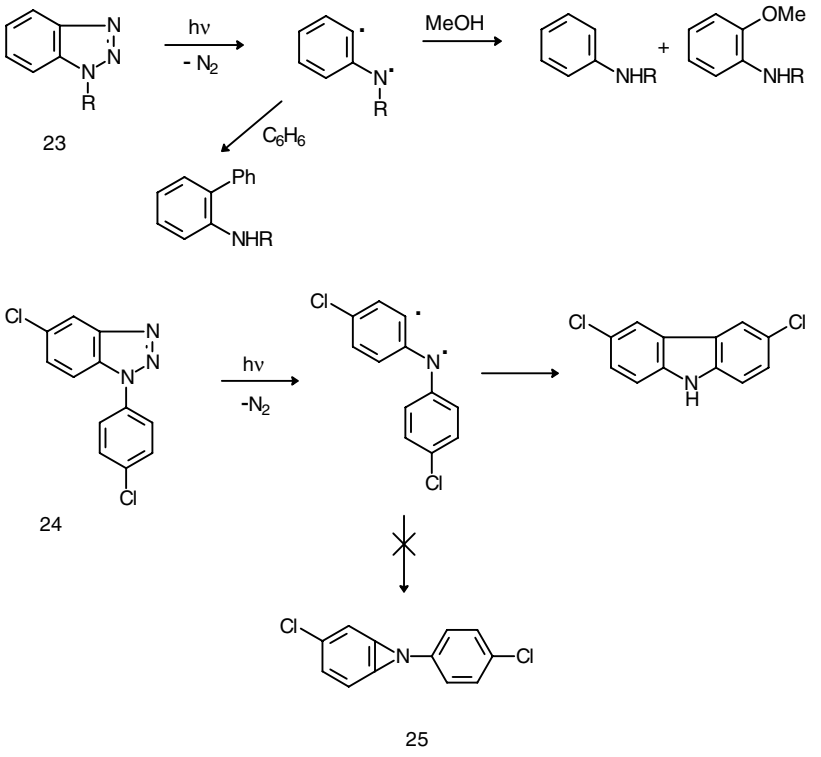
21



22

43.7 Benzotriazoles

Photolysis of benzotriazoles 23 leads to loss of nitrogen and generation of a 1,3-biradical intermediate. When R = H or alkyl, the intermediate attacks a solvent molecule as shown.[70,71] Photolysis of 1-phenylbenzotriazoles at room temperature takes a different course. An intramolecular radical insertion step leads to a carbazole in good yields.[67,71] Reaction of the dichloro compound **24** gives only one dichlorocarbazole, indicating that the intermediate biradical does not undergo rapid ring closure to give **25** followed by three-membered ring opening. The ESR spectrum of the biradical from 1-phenylbenzotriazole at 77 K is consistent with a triplet ground state, which converts to the singlet and then rapidly cyclizes to carbazole.[72]

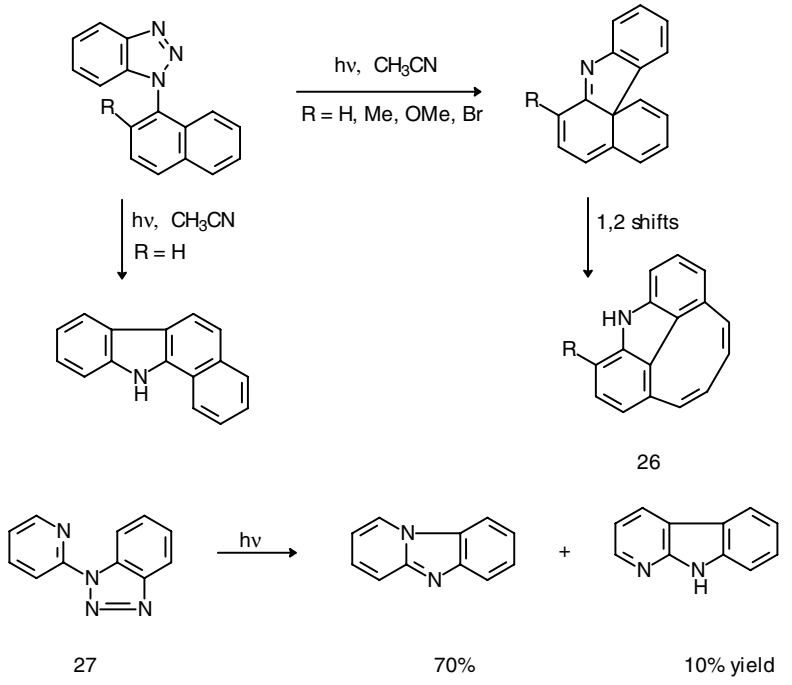


23

24

25

The intermediates from *N*-(1-naphthyl)benzotriazoles cyclize on both the 2- and 8[a]-positions of the naphthalene ring. Where a substituent is already located on the 2-position of the naphthalene ring, this second reaction becomes predominant. Subsequent dark reactions lead to the eight-membered ring carbazole derivative **26**.[73] Cyclization of the biradical intermediate from the benzotriazole **27** occurs principally on the pyridine nitrogen atom.[74]



26

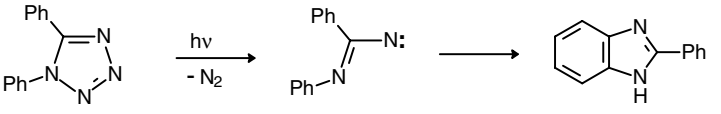
27

70%

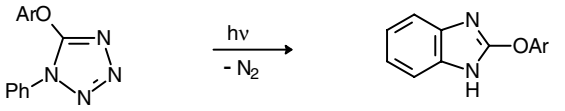
10% yield

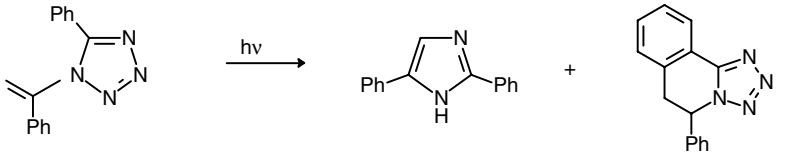
43.8 Tetrazoles

1,5-Disubstituted tetrazoles lose nitrogen on photolysis to generate a biradical intermediate, usually formulated as the nitrene (for example, **28**). Benzimidazoles are formed from 1-phenyltetrazoles by cyclization of the intermediate onto the *N*-phenyl ring.[75,76] Where an *N*-vinyl group is present, cyclization occurs on the vinyl group to form an imidazole. Photoreaction of **29** shows a competition between expulsion of a molecule of nitrogen and electrocyclization to **30**, which generates a new six-membered ring.[77]



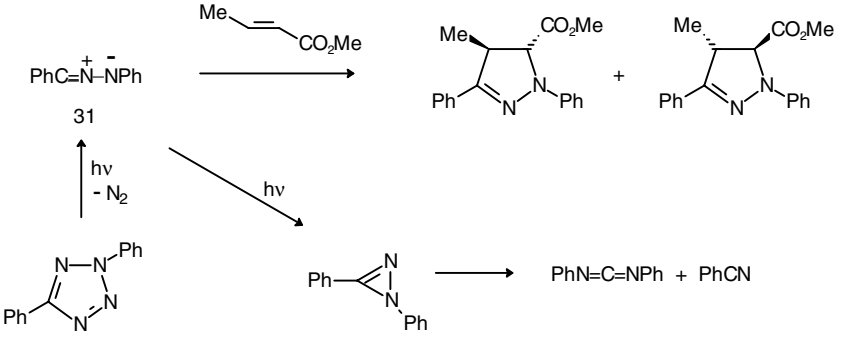
28

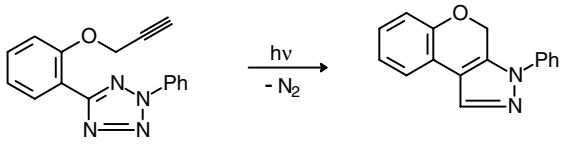




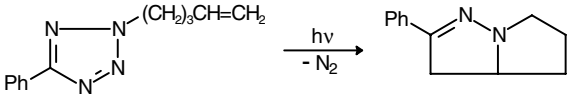
29 30

3,5-Disubstituted tetrazoles are photolysed to nitrilimines with loss of nitrogen. Nitrilimines are short lived at room temperature and can be trapped by 1,3-dipolar addition to an alkene or alkyne.[78] 1,3-Diphenylnitrilimine **31** has been characterized by matrix isolation at 10 K.[79] Prolonged irradiation of the nitrilimine under these conditions leads to conversion to diphenylcarbodiimide and benzonitrile. Intramolecular addition of nitrilimines to an alkene bond in **32** or the alkyne bond in **33** has been used to generate five- and six-membered rings.[80,81]





32



33

Tetrazolo[1,5-*b*]pyridazines **34** also lose nitrogen on photolysis. In these cases, the intermediate biradical rearranges to a diazonitrile. This molecule also loses nitrogen on exposure to light to leave a carbene from which the final stable products are generated. Electrocyclization of the diazonitrile is a competing reaction leading to a 3-*H*-pyrazole **35**:[82]

Photochemical Reactivity of Azides

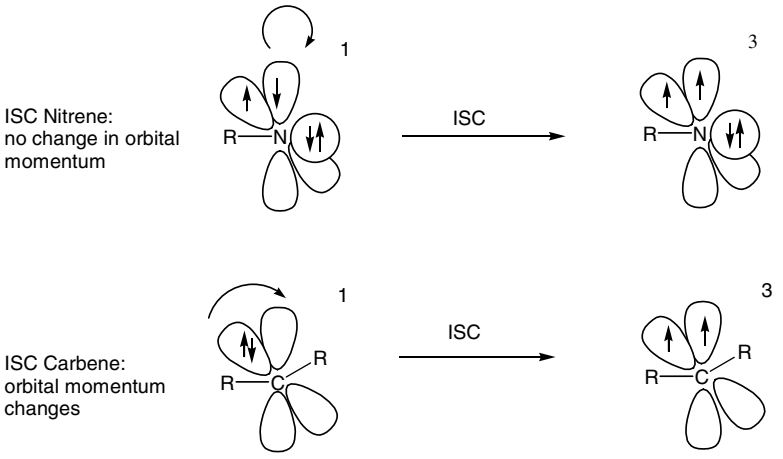
Götz Bucher
Ruhr-Universität Bochum

44.1 Introduction

Photolysis of organic azides leads almost exclusively to the extrusion of molecular nitrogen. The resulting nitrenes, a class of organic 1,1-biradicals, may react from two different spin states (singlet or triplet) and show a very complex chemistry. Nitrenes are the crucial intermediates in azide photochemistry. This chapter provides a survey about the current state of knowledge on nitrene reactivity, focusing on recent results, particularly on the chemistry of singlet aryl nitrenes. For additional information, the reader may consult the corresponding chapter from the first edition of this handbook[1] or one or more of the older reviews and monographs on nitrene chemistry.[2–16]

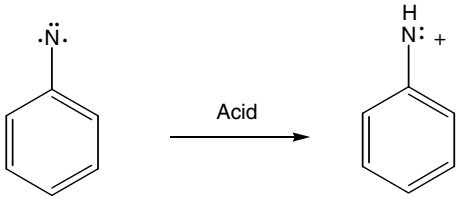
Direct photolysis of an organic azide will initially yield a singlet nitrene, which in most cases will be an excited state of a ground-state triplet species. In the important case of aryl nitrenes, the singlet nitrene is an open-shell species bearing two unpaired electrons with antiparallel spins in two singly occupied *p*-orbitals. Both the R–N binding electrons and the lone pair on the nitrene nitrogen atom reside in sp hybrid orbitals. Due to this particular electronic configuration of singlet nitrenes, spin reversal to the ground triplet state is not accompanied by a change in orbital momentum as in carbene chemistry. Hence, intersystem crossing (ISC) to the triplet ground state is not aided by spin-orbit coupling, and intermolecular and in particular intramolecular reactions of the singlet nitrene may therefore compete with the relatively inefficient ISC. Efficient formation of ground-state triplet nitrenes may be achieved by conducting the photoreaction at low temperature, as ISC (low Arrhenius pre-exponential factor, no barrier) then becomes more favorable than competing intramolecular reactions (high A-factor, barrier). Alternatively, triplet nitrenes may be formed by sensitized photolysis of azides or by photolysis of azides in the presence of heavy-atom-containing addends such as ethyl iodide.[17]

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1

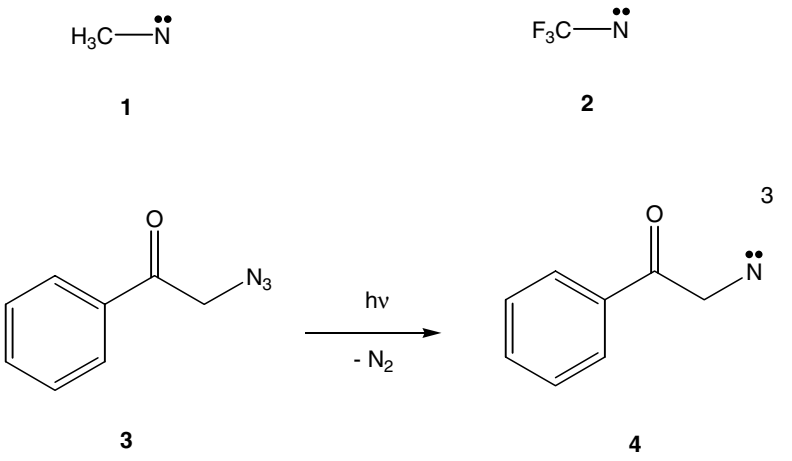
Photolysis of aryl azides in acidic media represents a special case. At low pH, singlet aryl nitrenes may be N-protonated, rapidly yielding singlet nitrenium ions. These ionic reactive intermediates undergo reactions different from those of singlet nitrenes.



SCHEME 2

44.2 Alkyl Azides

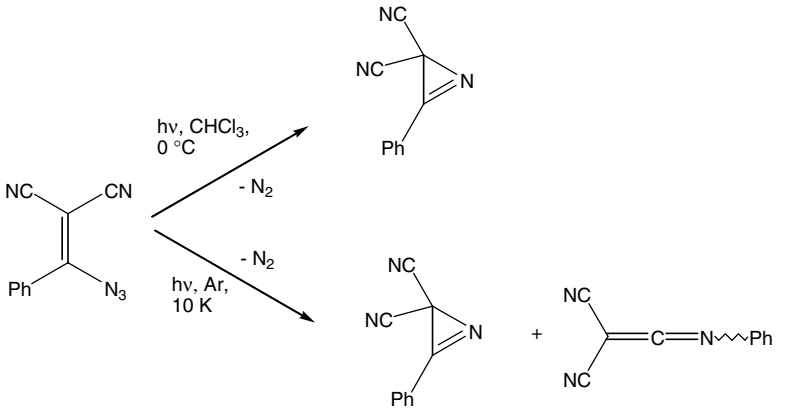
Photolysis of alkyl azides leads to the formation of singlet alkyl nitrenes. According to high-level *ab initio* calculations, singlet methyl nitrene **1** is a minimum on the CH_3N hypersurface, but the barrier for a 1,2-hydrogen shift yielding formimine is very small.[18] Overall, 1,2-migration of adjacent groups is the major reaction pathway for singlet alkyl nitrenes, and the ground-state triplet species are hardly formed at all, even at low temperature. Due to the stability of the carbon-fluorine bond, trifluormethylnitrene **2** represents a remarkable exception to this rule.[19] Triplet alkyl nitrenes may be obtained by inter- or intramolecular sensitization of alkyl azide photolysis. An example for the latter methodology was presented in the photolysis of α-azidoacetophenone **3**.[20] Excitation of **3** leads to the ketone triplet excited state, which can either undergo Norrish type I cleavage, leading to the benzoyl radical, or transfer its excitation energy to the azido functionality with formation of the triplet nitrene **4**. According to product studies, decay of triplet nitrene **4** mainly takes place by hydrogen abstraction and other free-radical reaction pathways.



SCHEME 3

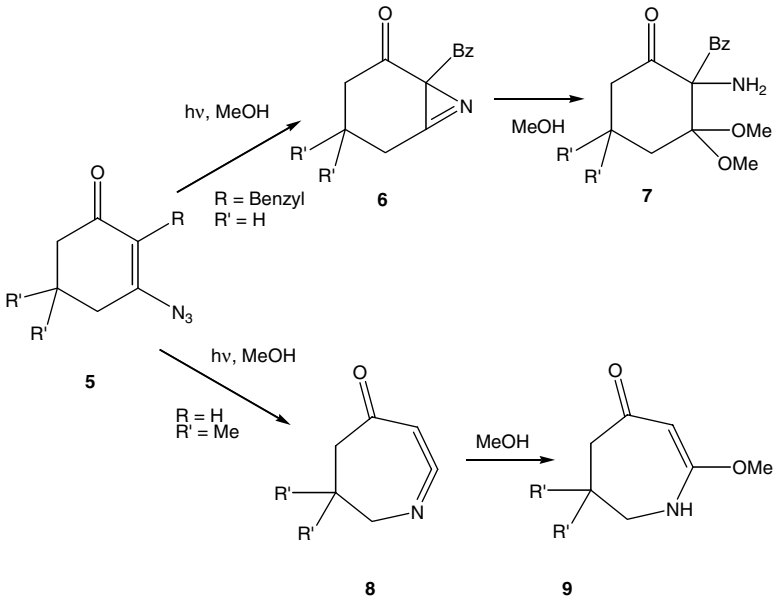
44.3 Vinyl Azides

Photolysis of vinyl azides leads to highly reactive singlet vinyl nitrenes, which can either undergo intramolecular cycloaddition to azirines[21–23] or rearrange to ketenimines by a 1,2-shift of the geminal substituent. A recent example of a system showing both reactions is α-azido-β,β-dicyanostyrene. Photolysis of this vinyl azide under conditions of matrix isolation spectroscopy yielded a mixture of an azirine and a ketenimine. Irradiation in chloroform at 0°C, on the other hand, gave exclusively the azirine.[24]



SCHEME 4

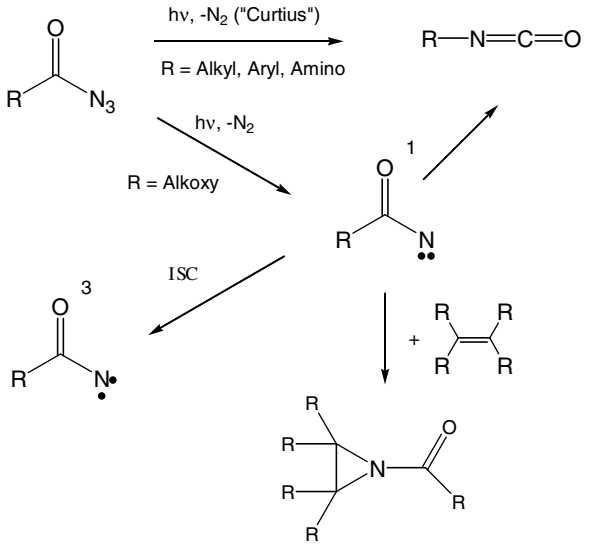
Anti-Bredt azirines may be formed upon photolysis of cycloalkenyl azides. In most cases, these strained species will be highly unstable, and evidence for their formation can only be obtained indirectly by product analysis. Photolysis of 3-azido-2-benzyl-2-cyclohexen-1-one **5** in methanolic solution gave a 50% yield of ketal **7**.[25] The formation of **7** can be rationalized in terms of twofold nucleophilic attack of methanol at C6 of azirine **6**. Omitting the benzyl substituent results in the formation of tetrahydroazepinone **9**, which is likely formed by reaction of cyclic ketenimine **8** with methanol.[26]



SCHEME 5

44.4 Acyl Azides

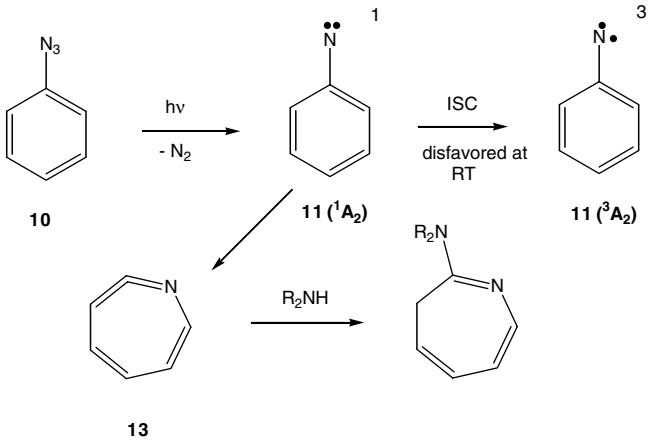
Excitation of acyl azides may lead to loss of nitrogen concomitant with rearrangement to an isocyanate. This reaction is called the *Curtius rearrangement* and is frequently observed upon photolysis of acyl azides R-CO-N_3 (R being carbon centered).[27] Singlet nitrenes may be formed in competition with the Curtius rearrangement. The efficiency of the Curtius rearrangement depends strongly on the type of substitution at the carbonyl carbon. Photolysis of amides of azidoformic acid (R = dialkylamino) yields aminoisocyanates efficiently, even under conditions of matrix isolation spectroscopy.[28] Esters of azidoformic acid (R = alkoxy), on the other hand, give singlet acyl nitrenes upon photolysis. The fate of these highly reactive species depends on the experimental conditions. Reactions include ISC to the ground-state triplet[29,30] acyl nitrenes, which further decay by hydrogen abstraction or dimerization to azodicarboxylates. Singlet acyl nitrenes may also undergo stereospecific addition to C=C bonds to yield aziridines,[31] add to aromatic C=C bonds,[32] undergo a 1,3-dipolar cycloaddition to carbon–nitrogen triple bonds in nitriles,[32] or insert into C–H bonds.[33,32] More recent examples of acylnitrene chemistry include addition to fullerene C_{60}[34] or to carbon nanotubes.[35]



SCHEME 6

44.5 Aryl Azides in Nonacidic Media: The Chemistry of Singlet Aryl Nitrenes

The photolysis of aryl azides primarily leads to the formation of singlet aryl nitrenes, which have an open-shell $\sigma^1\pi^1$ electronic configuration. As described in the introduction to this chapter, this leads to a drastically reduced rate of intersystem crossing due to the lack of spin-orbit coupling. At ambient temperature, singlet aryl nitrenes, therefore, do not predominantly relax to the ground-state triplet nitrenes. Instead, they undergo an intramolecular rearrangement to strained didehydroazepines, which can be trapped by primary[36,37] or secondary amines[38–42] or by intramolecular hydrogen transfer from a hydroxy group.[43]

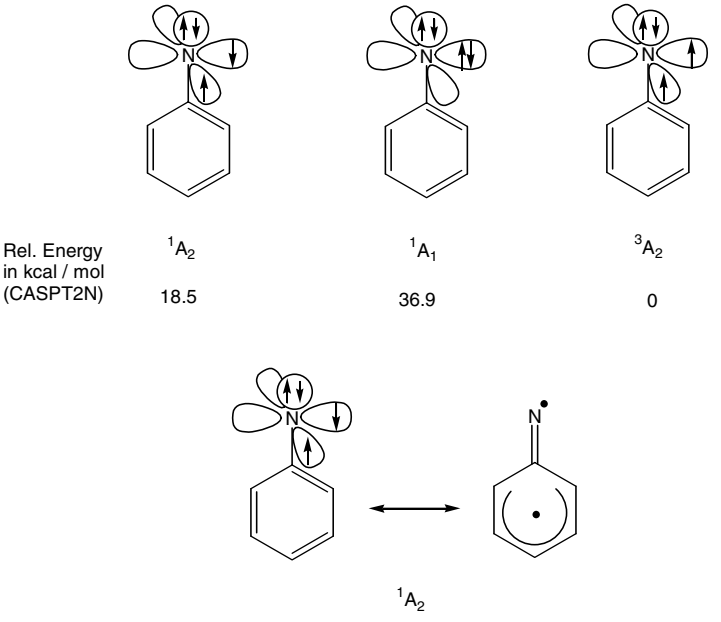


SCHEME 7

The development of highly correlated methods of *ab initio* theory has provided us with insight into the properties of singlet aryl nitrenes. Time-resolved laser flash photolysis (LFP) with picosecond time-

resolution has made it possible to observe singlet aryl nitrenes directly. Matrix isolation spectroscopy has revealed a wealth of spectroscopic data on triplet aryl nitrenes and didehydroazepines. In combination, these methods have given us a detailed and consistent description of the properties of aryl nitrenes, which will be the subject of the following section.

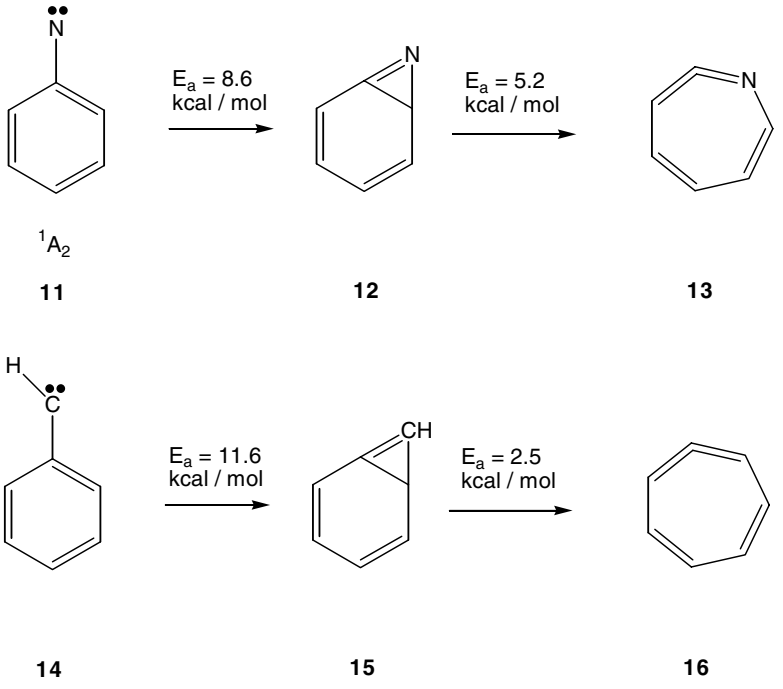
Phenylnitrene **10** can assume different electronic configurations. Of particular relevance are the $^3A_2$ (triplet ground state), $^1A_2$ (open-shell $\sigma^1\pi^1$), and $^1A_1$ (closed-shell σ^2) configurations. The experimentally determined energy gap between the $^3A_2$ ground state and the first singlet excited state is 18.33 ± 0.69 kcal/mol.[44,45] This value is reproduced well by calculations at the CASPT2N/6–311G(2-*d*,*p*) level of theory (ΔE [$^1A_2 - {}^3A_2$] = 18.5 kcal/mol),[46] which also confirm the $^1A_2$-open-shell $\sigma^1\pi^1$ character of the first singlet excited state of phenylnitrene.[47–50] The second singlet excited state bears the $^1A_1$ closed-shell σ^2 character and is calculated to be higher in energy by 18.4 kcal/mol than the $^1A_2$ state. The open-shell $^1A_2$ state can be described as an iminyl-cyclohexadienyl-type diradical, whereas the closed-shell $^1A_1$ state can be compared with a typical singlet carbene.



SCHEME 8

Open-shell singlet diradicals such as the $^1A_2$ state of phenylnitrene should show a reactivity differing significantly from the reactivity of typical electrophilic closed-shell intermediates such as singlet phenyl carbene. All intermolecular reactions requiring the presence of empty or doubly occupied *p*-orbitals, such as addition to a C=C double bond or insertion into an O–H bond can be expected to be retarded, while intramolecular reactions, which can be described as formal intramolecular free-radical recombination, should be fast. High level *ab initio* calculations confirm this expectation. Ring-expansion of singlet ($^1A_2$) phenylnitrene **11** to didehydroazepine **13** proceeds via the bicyclic azirine **12** as intermediate. The barrier for formation of azirine **12** is calculated (CASPT2N/6–31G*//CASSCF(8,8)/6–31G*) to be 8.6 kcal/mol.[46] Azirine **12**, which is predicted to be higher in energy than singlet nitrene **11** by 1.6 kcal/mol, then rearranges to didehydroazepine **13** over a barrier of 5.2 kcal/mol. According to the CASPT2N calculations, the reaction **11** → **13** is exothermic by 1.3 kcal/mol, and formation of azirine **12** is calculated to be the rate-determining step of the reaction.[46] On the same level of theory, the transition state connecting singlet phenyl carbene **14** with bicyclic cyclopropene **15** is calculated to be higher in energy than **14** by 11.6 kcal/mol, while the barrier for ring-opening of **15** to cycloheptatetraene **16** is predicted to be very low (2.5 kcal/mol.).[46] These findings convincingly rationalize the experimental observations:[16]

- *Singlet phenylnitrene:* Low barrier for rearrangement in combination with a low ISC rate constant leads to almost exclusive rearrangement to didehydroazepine **13**. In some cases, this rearrangement can be reversible.
- *Singlet phenylcarbene:* High barrier for rearrangement in combination with high ISC rate constant leads to exclusive ISC to the ground-state triplet carbene, if the singlet carbene is not trapped by the solvent, the diazo precursor, or added quenchers.



(CASPT2N/6-31G*//CASSCF(8,8)/6-31G*)

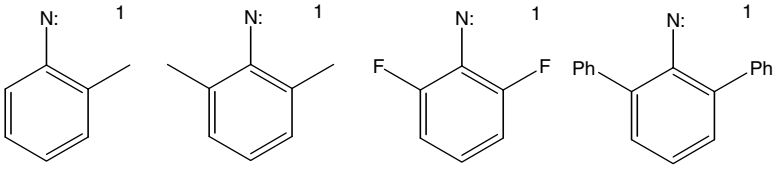
SCHEME 9

Picosecond time-resolved laser flash photolysis (ps-LFP) has made it possible to observe singlet phenylnitrene **11** directly and to measure the rate constants for ring expansion to didehydroazepine **13** and for ISC.[51–54] In *n*-pentane solution at 233 K, singlet phenylnitrene **11** has a sharp absorption band at λ_{max} = 350 nm in addition to a very weak band at λ_{max} = 540 nm.[51] Its lifetime at ambient temperature is of the order of ~1 ns, and it decays mainly by rearrangement to didehydroazepine **13.** The rate constant for ISC to triplet phenylnitrene was determined as $k_{ISC} = 3.2 \pm 0.3 \times 10^6\ s^{-1}$, and the activation parameters for rearrangement were found to be E_a = 5.6 ± 0.3 kcal/mol with log (A/s^{-1}) = 13.1 ± 0.3.[51] Triplet phenylnitrene had been characterized earlier by matrix isolation spectroscopy.[55] Irradiation of phenyl azide, matrix-isolated in nitrogen or argon at 12 K, at λ = 334 nm yielded a mixture of mostly triplet nitrene **11** ($^3A_2$) and some didehydroazepine **13**. Visible (λ = 485 nm) irradiation of this mixture resulted in the depletion of the bands due to triplet nitrene **11** and in a growth of the bands assigned to didehydroazepine **13.** Irradiation with λ = 334 nm again shifted the photostationary equilibrium toward nitrene **11.** Due to the relatively low ISC rate constant of singlet phenylnitrene **11** ($^1A_2$), triplet phenylnitrene is not accessible by photolysis of phenyl azide **10** at ambient temperature. It can be obtained by photolysis of carbamates derived from 9-fluorenone oxime, albeit in low yield.[56] In solution, it decays mainly by dimerization, yielding azobenzene, and by hydrogen abstraction.[56]

Replacing one or more of the hydrogen atoms in singlet phenylnitrene **11** with other substituents may drastically alter its reactivity. The following types of substituent effects are encountered:

1. Substituents effects can be related to steric interaction, if the substituents are placed *ortho* to the nitrene center.
2. Significant changes in the reactivity of nitrenes may also occur if the azides are substituted with strong π-donors or π- or σ-acceptors (such as the dimethylamino or nitro substituents, fluorine atoms).
3. Substitution of the aromatic ring with heavy-atom substituents will increase k_{ISC} by enhanced spin-orbit coupling and, therefore, result in a higher yield of triplet nitrenes.
4. Replacing the benzene nucleus of the azide by a larger aromatic system may change nitrene reactivity.
5. The presence of reactive substituents (acyl, nitro, OH, NH_2, certain alkyl groups) *ortho* to the nitrene center may lead to alternative reaction channels.

The presence of substituents *ortho* to the nitrene center has a significant impact on the kinetics of the nitrene → didehydroazepine rearrangement. If only one substituent is present in the 2-position, the nitrene generally attacks the C=C bond pointing away from the substituent.[39] According to high-level *ab initio* calculations (CASPT2N/6–31G*),[57] the barrier for cyclization of singlet 2-methylphenylnitrene **17** away from the methyl group is lower by 2.0 kcal/mol than the barrier for cyclization toward the methyl group. A significant stabilization of the singlet nitrene is achieved only if both *ortho* positions are substituted. Thus, singlet 2-methylphenylnitrene **17** does not live longer than parent singlet phenylnitrene **11** (τ ~ 1 ns in *n*-pentane at 298 K), while singlet 2,6-dimethylphenylnitrene **18** has a lifetime τ = 15 ± 3 ns (*n*-hexane, 298 K).[58] Similar effects are found for *ortho*-chlorine and *ortho*-fluorine substitution.[57,59] 2,6-Fluorine disubstitution leads to a significant rise of the singlet nitrene lifetime. Singlet 2,6-difluorophenylnitrene **19** has a lifetime τ = 240 ± 20 ns in *n*-hexane (298 K), with an experimental barrier E_a = 7.3 ± 0.7 kcal/mol. (log [A/s^{-1}] = 11.5 ± 0.5).[59] A dramatic increase in singlet nitrene lifetime was also reported for *ortho*-phenyl-substituted systems such as singlet 2,6-diphenylphenylnitrene **20**.[60]

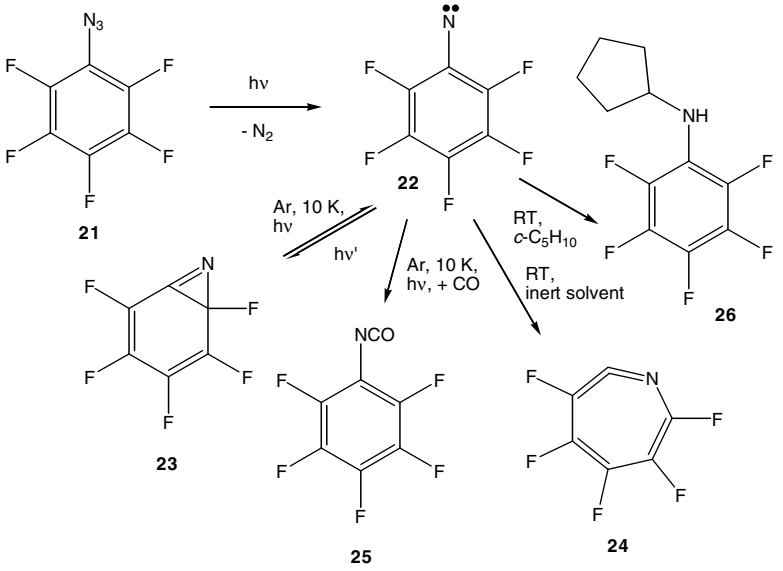


17 **18** **19** **20**

SCHEME 10

Fluorine substitution affects nitrene reactivity not only by sterically shielding the *ortho* carbon atoms but also by increasing the electron-deficient character of the nitrene center. This is particularly obvious from the unusually high reactivity of fluorinated derivatives of singlet phenylnitrene in intermolecular reactions. Matrix-isolated pentafluorophenylnitrene **22** was found not to undergo the ring expansion reaction to the pentafluorodidehydroazepine **24**.[61] Instead, photochemical reaction with carbon monoxide yielding pentafluorophenyl isocyanate **25** was observed.[61] Later, the same nitrene **22** (and 2,6-difluorophenylnitrene **19**) was found to isomerize to the corresponding bridged azirines (**23** in the case of nitrene **22**) upon irradiation in argon matrix.[62] Photolysis of azide **21** in alkane solvents at ambient temperature leads to almost exclusive formation of N–H insertion products such as the *N*-cyclopentylpentafluoroaniline **26**, which is formed upon photolysis of **21** in cyclopentane.[63] Singlet pentafluorophenylnitrene **22** reacts with some Lewis bases, such as pyridine or THF, to give ylides.[17] At ambient temperature, the perfluorodidehydroazepine **24** is also formed and can be trapped.[17,64] The high reactivity of singlet nitrene **22** in intermolecular reactions is also evident from the fact that it is able to add to the

C=C bonds of benzene.[17] Absolute rate constants for the reactions of singlet **22** were determined by LFP.[59,64] In methylene chloride, the ISC rate constant was determined as $k_{ISC} = (1.05 \pm 0.05) \times 10^7$ s^{-1}. The activation parameters for ring-expansion to perfluorodidehydroazepine **24** were determined as E_a = (8.8 ± 0.4) kcal/mol. with log (A/s^{-1}) = 13.8 ± 0.3.[64] The reaction with pyridine is rapid and proceeds via a barrier of only 1.6 ± 0.6 kcal/mol.



SCHEME 11

Other highly fluorinated derivatives of phenyl azide were investigated as well. Photolysis of perfluoro-4-azidobiphenyl **29** in CH_2Cl_2 at 294 K yielded the corresponding singlet nitrene **30**, which was found to have a relatively long lifetime τ = 254 ± 5 ns. The barrier for ring expansion (E_a = [9.4 + 0.4] kcal/mol) was found to be even higher than in singlet perfluorophenylnitrene **22**.[64] Photolysis of a series of 4-azido-2,3,5,6-tetrafluoro-benzamides (such as **31**) in the presence of pyridine led to pyridine ylides **33**. The growth kinetics of **33** could be resolved by LFP, which allowed for a determination of the rate constants of the reactions of nitrene **32** with further quenchers. Singlet nitrene **32** reacts with dimethylsulfide with a rate constant close to the diffusion-controlled limit ($k_q = 1.27 \times 10^9$ M^{-1} s^{-1}), while reactions with tetramethylethylene ($k_q = 1.62 \times 10^8$ M^{-1} s^{-1}) or diethylamine ($k_q = 2.51 \times 10^8$ M^{-1} s^{-1}) are slightly slower.[65]

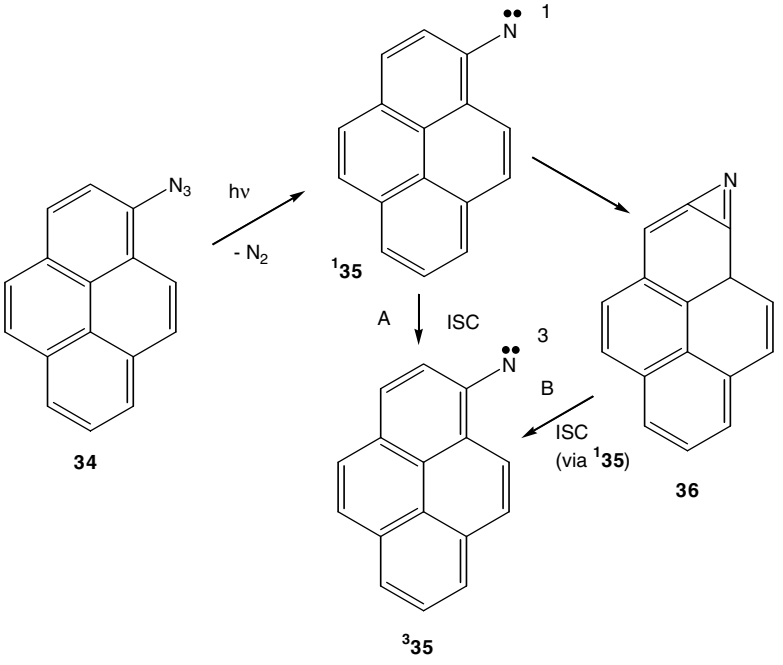
The effect of substituents placed *para* to the nitrene center was investigated in a series of matrix isolation, laser flash photolysis, and product studies. Table 44.1 lists a number of rate constants (k_{ISC} for intersystem crossing to the triplet ground-state and k_R for rearrangement to the didehydroazepine). For comparison, the kinetic parameters of several other singlet aryl nitrenes are also given.

If one compares the data for singlet aryl nitrenes substituted at the 4-position, where steric effects are not likely to play an important role, it becomes evident that only strong π-electron donor substituents such as the methoxy and in particular the dimethylamino groups have a significant effect on intramolecular singlet nitrene reactivity. They influence nitrene reactivity via an enormous increase in the intersystem crossing rate constant k_{ISC}. It is noted that, up to now, this effect is not understood.[66] The increase in k_{ISC} is rationalized more easily in the case of heavy-atom-substituted singlet aryl nitrenes, where the effect can be explained in terms of spin-orbit coupling. The increase in k_{ISC} in the series singlet 4-fluoro-, 4-chloro-, 4-bromo-, and 4-iodo-phenylnitrene[66] can be correlated with the known atomic spin-orbit coupling constants for fluorine (269 cm^{-1}), chlorine (587 cm^{-1}), bromine (2460 cm^{-1}), and iodine (5069 cm^{-1}).[69] More important than the spin-orbit coupling constant of the halogen atom, however, seems to be the distance between the halogen atoms and the nitrene center, as k_{ISC} is huge in the case of singlet 2,4,6-tribromophenylnitrene,[53] where the N–Br distance is much shorter than the N–X distance in the 4-substituted derivatives. Electron-acceptor substituents in the *para* position, on the other hand, do not appear to influence intramolecular singlet nitrene reactivity to a large extent. LFP experiments performed on cyano-substituted derivatives of phenyl azide revealed only subtle effects.[67] A nitro group situated in the *para* position, on the other hand, has been reported to lead to a significant increase in intermolecular singlet nitrene reactivity.[70] Singlet 4-nitrophenylnitrene has eluded direct detection so

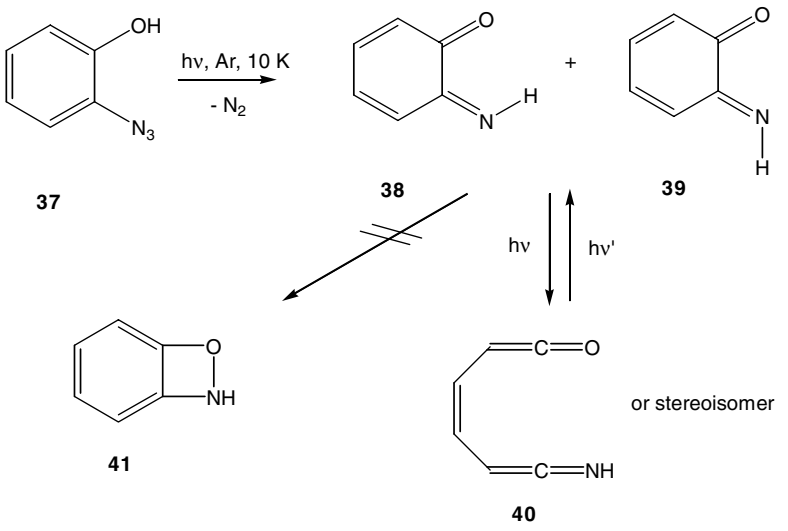
far,[66] whereas triplet 4-nitrophenylnitrene could be detected by ns-LFP[70] as well as by low-temperature spectroscopy.[71]

The photochemistry of aryl azides incorporating larger aromatic systems has received only limited attention so far. Studies include an early LFP study on 1-azidopyrene **34**.[72] This azide was reported to yield singlet 1-pyrenylnitrene ^{1}**35** (τ = 22 ns in benzene at ambient temperature; pathway A in Scheme 13), which in turn underwent exclusive ISC to triplet 1-pyrenylnitrene ^{3}**35**. In a later study, the short-lived transient was reassigned to azirine **36** (pathway B in Scheme 13).[73] Photolysis of 1-naphthyl azide at 196 K in the presence of diethylamine yielded naphthalene-1,2-diamines, which could only be attributed to a quenching of similar bicyclic azirines.[74,73] This was later confirmed by time-resolved infrared spectroscopy.[42] It is evident from these results, that ring-expansion to didehydroazepines is disfavored for larger aromatic systems. The reaction, however, has been observed upon photolysis of 1- or 2-azidonaphthalene in nitrogen or argon matrices at 12 K.[75]



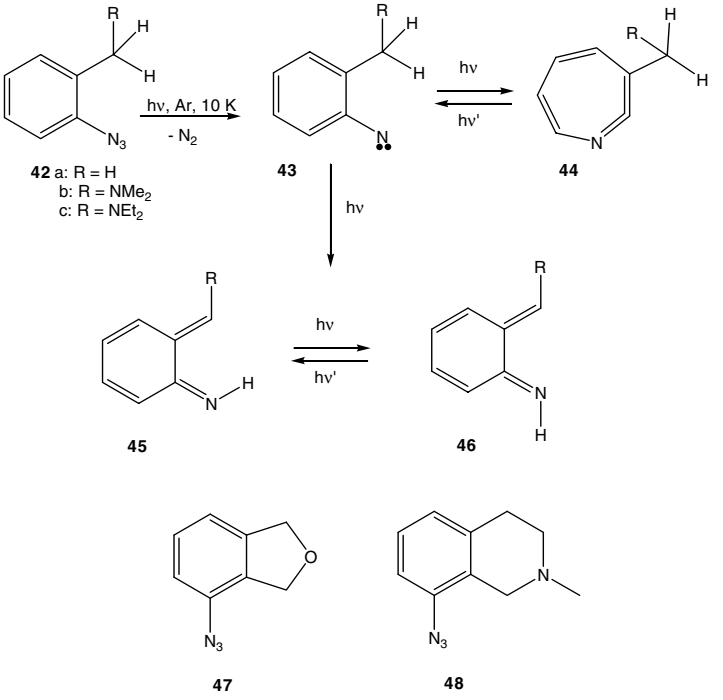
SCHEME 13

If a nitrene bears a substituent in the *ortho* position, a chemical reaction between the nitrene center and this substituent can ensue. A variety of different substituents have been found to undergo reactions with a neighboring nitrene center. Among them are alkyl or aryl groups as well as hydroxy or amino functionalities, acyl or nitro substituents, and nitrogen heterocycles. Hydroxy- or amino-groups are among the simplest substituents to undergo reactions with an *ortho*-nitrene. Broadband photolysis ($\lambda >$ 370 nm) of 2-hydroxy-phenyl azide **37**, matrix-isolated in argon at 10 K, yielded a mixture of the stereoisomeric quinone imines **38** and **39** and one stereoisomer of cumulene **40**.[76] The quinone imines **38/39** and the cumulene **40** could be interconverted photochemically. Neither benzoxazetine **41** nor 2-hydroxy-phenylnitrene itself was observed. Similarly, photolysis of matrix-isolated (Ar, 10 K) 2-aminoazidobenzene gave a mixture of three stereoisomeric quinonediimines. In this case, no cumulenic product was formed as in the photochemistry of **37.** This was explained by unfavorable thermodynamics of the ring-opening reaction.[76]



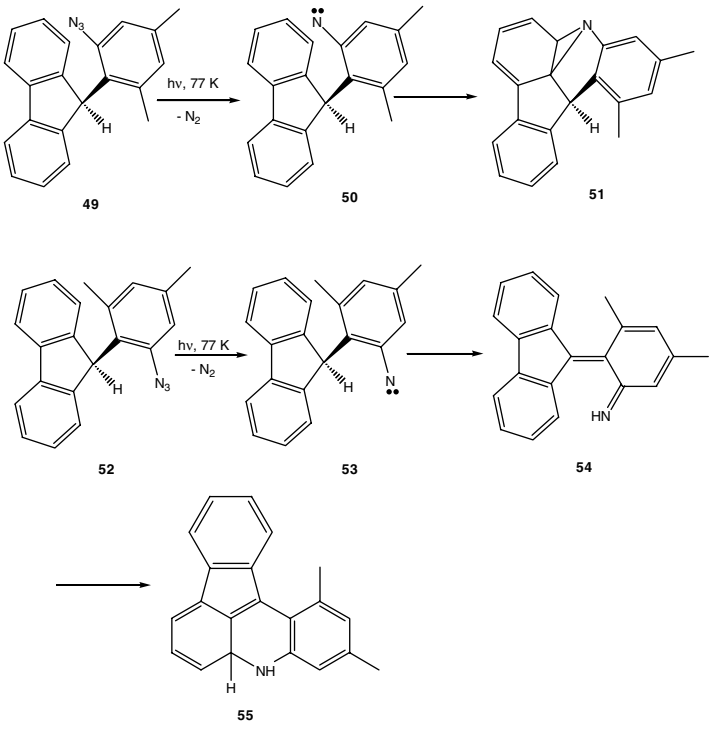
SCHEME 14

A methyl group in the *ortho*-position, while less reactive than a hydroxy or amino functionality, may still react with the adjacent nitrene center. In the parent system *o*-tolylnitrene **43a** (R = H), the photochemical 1,4-hydrogen shift yielding two stereoisomers **45a** and **46a** (R = H) of *o*-iminoquinone methide has been reported to be very inefficient.[77] The reaction gets more favorable if the benzylic hydrogen atoms are activated by electron-donor substituents or by aryl groups. Dialkylamino substituents (R = NR_2) are particularly effective in this respect, but methoxy groups and even halogen atoms still activate the reaction.[78] Benzylic dialkylamino substitution such as in **42c** (R = NEt_2) allows for the monophotonic generation of iminoquinone methides **45c**/**46c** (R = NEt_2) at ambient temperature and their characterization by ns-LFP.[79] The reaction requires a certain amount of flexibility in the side chain. Thus, photolysis of matrix-isolated azidophthalan **47** does not yield an iminoquinone methide, while the reaction is successful for azidotetrahydroisoquinoline **48**.[78] These observations correlate well with the barriers calculated for the 1,4-hydrogen shift.[78] According to the calculations (B3LYP/6–31G(d)), the 1,4-hydrogen shift from the singlet nitrene has a barrier of $\Delta H^{\#}$ = 20.3 kcal/mol for *o*-tolylnitrene **43a** (R = H), which is lowered to $\Delta H^{\#}$ = 9.3 kcal/mol by a dimethylamino group as in **43b** (R = NMe_2). In the case of azide **48**, however, the calculated barrier for 1,4-hydrogen shift is Ea = 20.7 kcal/mol, and for phthalan **47** E_a = 32.2 kcal/mol. Thus, the formation of iminoquinone methides is likely to be a photochemical reaction that occurs either from the vibrationally hot first singlet excited state of the nitrene or from a higher nitrene excited state. The reactive derivatives **42b** (R = NMe_2) and **42c** (R = NEt_2) may represent exceptions to this rule.



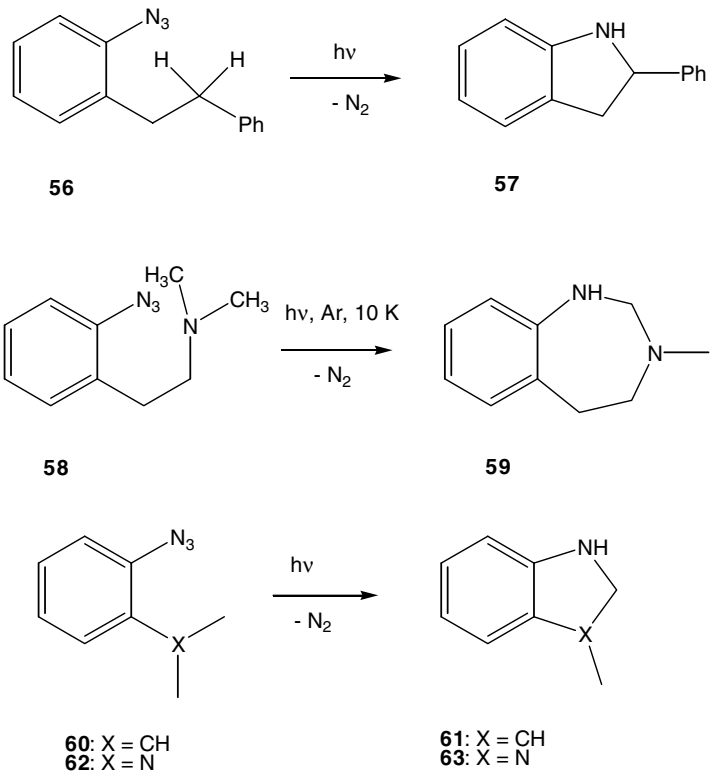
SCHEME 15

Aryl substituents also activate benzylic C–H bonds adjacent to a nitrene center. An interesting study on this topic has dealt with the atropoisomeric 3,5-dimethyl-2-(9-fluorenyl)phenylazides **49** and **52**.[80] The low-temperature photochemistry (77 K) of these rotameric azides proved to be fundamentally different: Photolysis of **49** resulted in the formation of nitrene **50** in addition to azanorcaradiene **51**, while photolysis of **52** gave nitrene **53** in addition to iminoquinone methide **54**. This subsequently underwent intramolecular cycloaddition to yield dihydroindenocridine **55.** Laser flash photolysis showed that the formation of iminoquinone methide **54** from azide **52** occurred in less than 10 ns. Deuteration of the 9-position of the fluorene chromophore resulted in a significantly diminished yield of **55**. LFP of the rotameric azide **49** yielded the rate constant for the formation of azanorcaradiene **51** which was determined as $k = 7.1 \times 10^5\ s^{-1}$.[80]



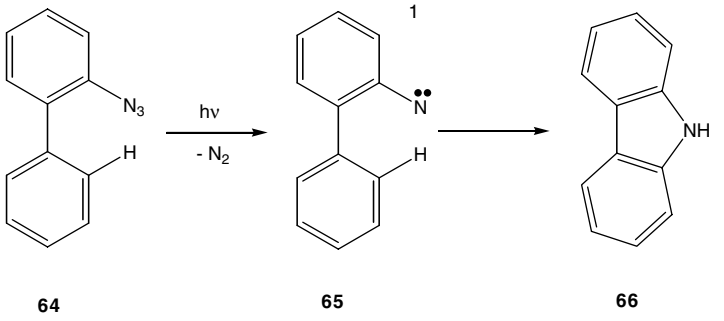
SCHEME 16

Intramolecular hydrogen abstraction from methylene or methyl groups further away from the aromatic nucleus has been reported for 2-(ω-phenylethyl)phenyl azide **56**, which upon photolysis (Ar, 12 K) yields 2-phenylindoline **57** in addition to a didehydroazepine.[81] Similarly, photolysis of 2-(ω-dimethylaminoethyl)phenyl azide **58** (Ar, 10 K) yields the seven-membered ring **59** via the triplet nitrene.[78] The efficiency of intramolecular nitrene hydrogen abstraction reactions strongly depends on both the C–H bond energies and a favorable spatial arrangement of the nitrene center and the reacting C–H bond. If a C–H bond is forced into the vicinity of a nitrene, such as in 2-isopropylphenylazide **60** or 2-dimethylaminophenylazide **62**, efficient H-transfer can occur, even if the reacting C–H bond is not activated. Thus, 2-isopropylphenyl azide **60** has been reported to yield 2-methylindoline **61** under conditions of matrix isolation (photolysis, stepwise reaction via the triplet nitrene)[78] and in solution (thermolysis),[82] while photolysis of matrix-isolated 2-dimethylaminophenyl azide **62** yields 1-methyl-benzimidazoline **63** without evidence of a detectable intermediate.[83]



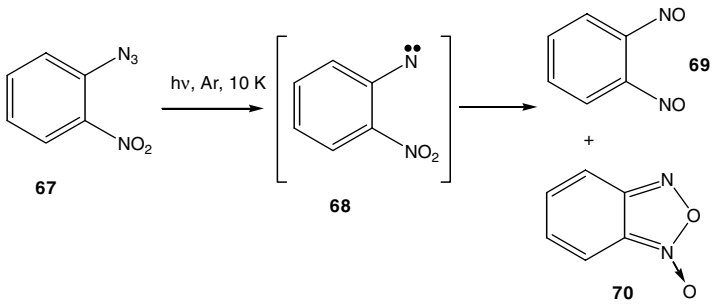
SCHEME 17

The photolysis of 2-azidobiphenyl **64** or similar aryl nitrene precursors yields carbazole **66** by insertion of the singlet nitrene **65** into the *ortho* C–H bond of the neighboring benzene ring.[84] This efficient reaction may be extended to the synthesis of other heterocycles.[85,86]



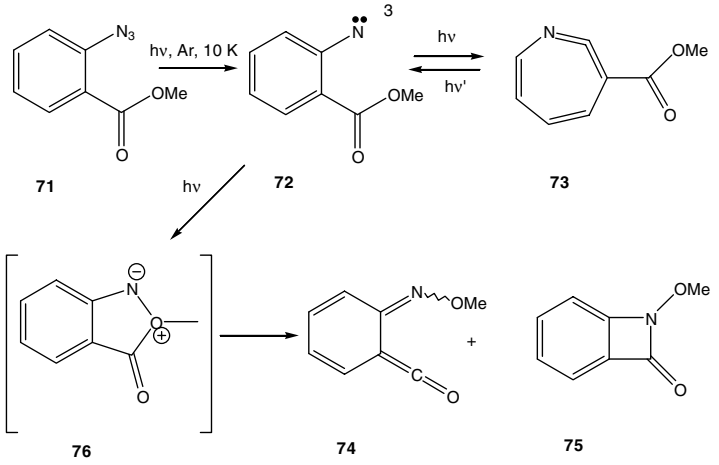
SCHEME 18

Photolysis ($\lambda > 350$ nm) of 2-nitrophenylazide **67,** matrix-isolated in Ar at 10 K, has been reported to lead directly to a mixture of *ortho*-dinitrosobenzene **69** and benzofuroxan **70**.[87] 2-Nitrophenylnitrene **68** was not detected.



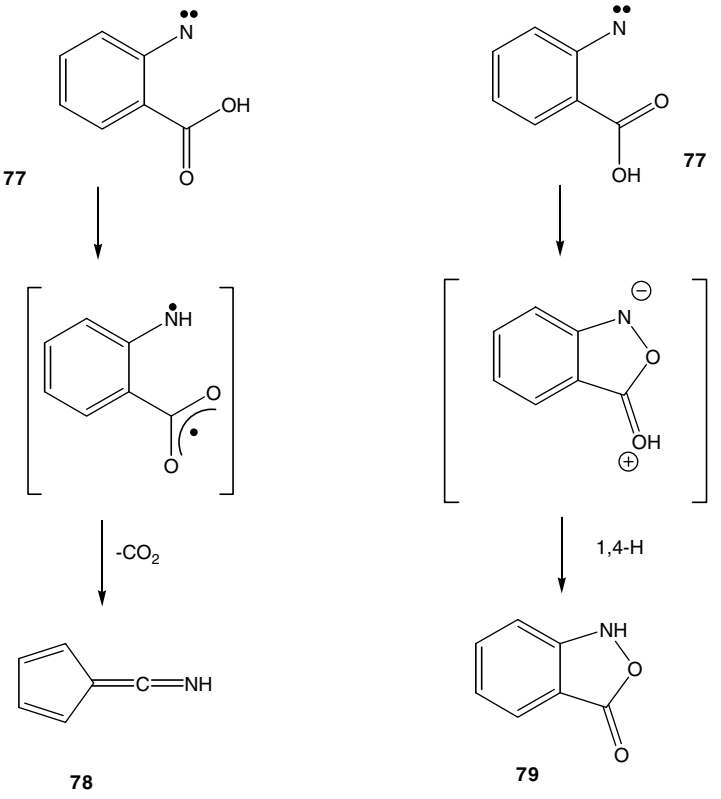
SCHEME 19

Oxygen transfer from an *ortho* substituent to a nitrene was also observed in the photolysis of 2-methoxycarbonylphenylazide **71**.[88] In this system, both the nitrene **72** and the didehydroazepine **73** could be observed. Besides these products of standard azide photochemistry, two stereoisomers of the oximinoketene **74** and the *N*-methoxy-azetidinone **75** were detected. The oxygen transfer can be rationalized to occur via an oxonium ylide **76**, which subsequently ring-opens to ketene **74** that is in photostationary equilibrium with azetidinone **75**.



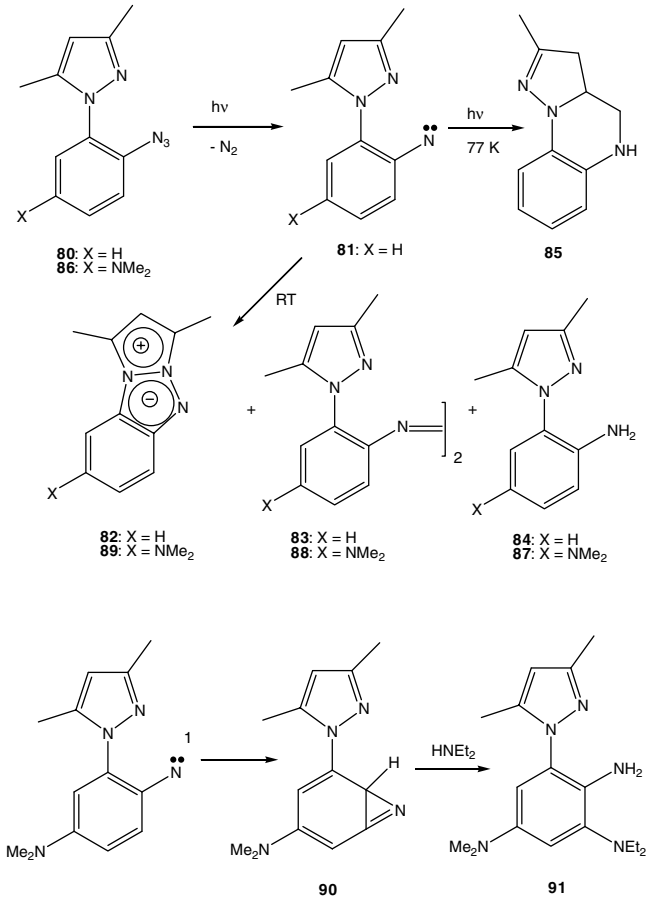
SCHEME 20

Photolysis of matrix-isolated 2-azidobenzoic acid was found to yield mainly ketenimine **78** and benzisoxazolone **79** in addition to some didehydroazepine.[89,90] Depending on the orientation of the carboxy group, the reactions of nitrene **77** split into two channels: Formation of a carbonyl ylide followed by a 1,4-hydrogen shift yields **79**, while H-transfer from the carboxy group to the nitrene center followed by decarboxylation and ring-contraction of the resulting diradical results in the formation of ketenimine **78**.



SCHEME 21

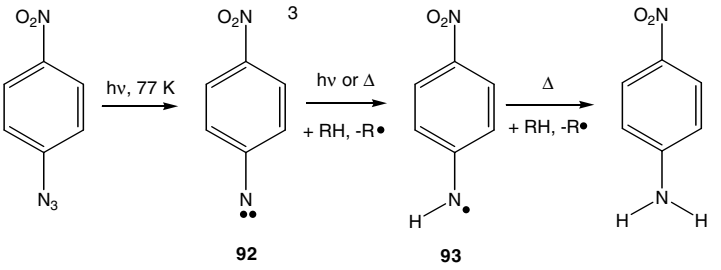
The photochemistry of aryl azides substituted with an *ortho*-dimethylpyrazolyl substituent was investigated both by product analysis and by low-temperature spectroscopy.[91–93] Photolysis of azide **80** in ethanol at 295 K led to the formation of the stable heteropentalene **82**, azo compound **83**, and aniline derivative **84**. Addition of diethylamine resulted in trapping of a didehydroazepine, which thus has to be in thermal equilibrium with singlet carbene ^{1}**81**. Low-temperature photolysis (90 K, glassy ethanol) of **80**, on the other hand, resulted in the formation of triplet nitrene ^{3}**81**, which mostly dimerized to the azo dimer **83** upon thawing of the matrix. If ^{3}**81** was subjected to long-wavelength irradiation, high yields of the dihydroquinoxaline **85** were formed by hydrogen abstraction of the pyrazole methyl group followed by radical recombination. Introduction of an additional dimethylamino substituent *para* to the nitrene completely changed the photochemistry of the pyrazolyl-substituted nitrene.[93] Irradiation of azide **86** (ethanol, 295 K) yielded reaction products typical of a triplet nitrene, such as the aniline **87** or azo compound **88**, and no heteropentalene **89**. In the presence of diethylamine as external quencher, no azepine derivative was isolated. Instead, the triaminophenylpyrazole **91** was formed. The formation of **91** can be rationalized only by trapping of an intermediary bicyclic azirine **90** by diethylamine (see bottom part of Scheme 22). A nitro group *para* to the nitrene center was also found to supress didehydroazepine formation, while slightly increasing nitrene reactivity in intermolecular reactions.[94]



SCHEME 22

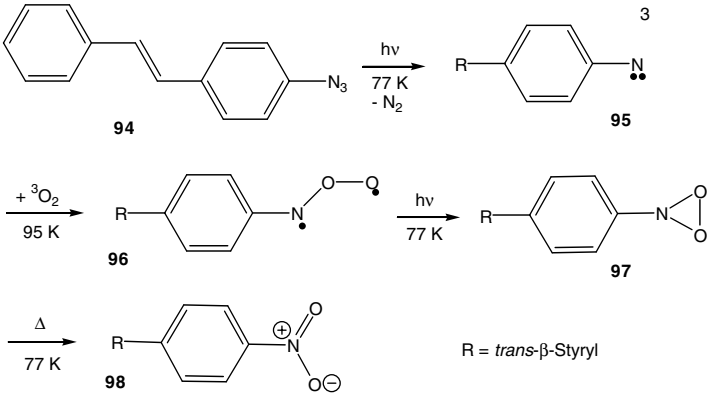
44.6 Reactions Typical of Triplet Aryl Nitrenes

Triplet nitrenes generally undergo reactions typical of free radicals or triplet carbenes, such as hydrogen (or heteroatom-) abstraction or dimerization.[56] Dimerization leads to azo dyes and is most frequently observed if an aryl azide is photolyzed at liquid nitrogen temperature and if the glassy matrix is then thawed. Hydrogen abstraction from the solvent is another reaction typical of triplet nitrenes. Both triplet pentafluorophenyl nitrene ^{3}**22** and triplet perfluoro-2-naphthyl nitrene are able to abstract a hydrogen atom from *n*-hexane or *n*-heptane, if the frozen solvent is thawed.[95] For triplet 4-nitrophenylnitrene **92** and triplet 4-nitreno-4′-nitro-*trans*-stilbene, the formation of the corresponding aniline derivatives was shown to occur in a two-step process via an aminyl radical, such as **93**.[71,96]



SCHEME 23

Triplet aryl nitrenes can in principle react with triplet oxygen. The reaction proceeds via nitroso *O*-oxides, which then isomerize to nitro compounds, possibly via azadioxiranes. Experimental evidence for this reaction sequence was obtained with a series of *para*-substituted derivatives of phenyl azide.[97] Thus, photolysis of azide **94**, matrix-isolated at 77 K in glassy MTHF saturated with oxygen, yielded triplet nitrene **95**. Warming the glassy matrix to 95 K led to oxidation of triplet nitrene **95** to nitroso *O*-oxide **96**. Irradiation of nitroso *O*-oxide **96** with high-intensity light then resulted in formation of intermediate **97** which decayed thermally at 77 K ($t_{1/2} \sim 4$ minutes) to yield nitro compound **98**.



SCHEME 24

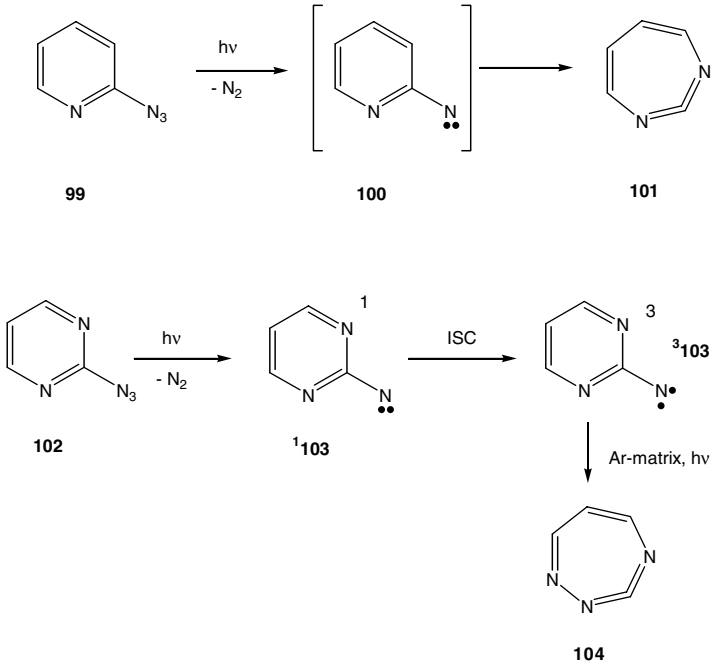
Triplet nitrene oxidation appears to work best if it is performed by thawing an organic glass (77 K) containing both the triplet nitrene and triplet oxygen. At ambient temperature, triplet nitrene formation is inefficient for most nitrenes. At temperatures of matrix isolation (10 K), triplet nitrenes are formed efficiently. Under these conditions, however, the reaction with oxygen is obviously hindered by a barrier. To the best of the author's knowledge it has never been observed in a noble gas matrix.

44.7 Heteroaryl Azides

Heteroaromatic azides often show photochemistry that is very similar to the photochemistry of simple homoaromatic azides. Ring expansion to cyclic ketenimines is observed, if the photolysis is performed at ambient temperature, and triplet nitrenes are formed upon low-temperature irradiation. If a nitrogen atom is placed adjacent to the nitrene center, such as in 2-pyridylnitrene **100**, addition generally takes place away from the nitrogen atom. In the case of the photolysis (or pyrolysis) of the 2-azidopyridine **99**, the reaction leads to the cyclic carbodiimide **101**.[98–100] A complication arises from the fact that derivatives of 2-azidopyridine and related heterocycles frequently undergo a thermal isomerization to tetrazolopyridines, which also undergo photochemical dediazotation, albeit with a low quantum yield.[98,99]

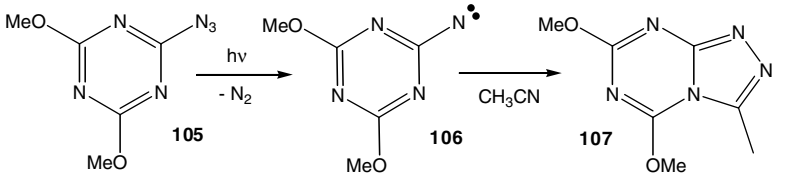
As with simple aryl nitrenes, *ortho* halogen-substitution (such as in tetrafluoro-4-pyridylnitrene) suppresses the ring-expansion chemistry.[101]

Ring-expansion is also disfavored if both *ortho* positions are occupied by nitrogen atoms, such as in 2-pyrimidyl nitrene. Laser flash photolysis of 2-azidopyrimidine **102** (CH_2Cl_2, 295 K) allowed for the detection of singlet 2-pyrimidinylnitrene ^{1}**103**, which decayed exclusively by intersystem crossing ($\tau = 13$ ns, $k_{ISC} = (8 \pm 2) \times 10^7\ s^{-1}$) to the triplet nitrene ^{3}**103**.[102] The cyclic carbodiimide **104** was only obtained upon extended irradiation of matrix-isolated (Ar, 14 K) triplet nitrene ^{3}**103**.[102]



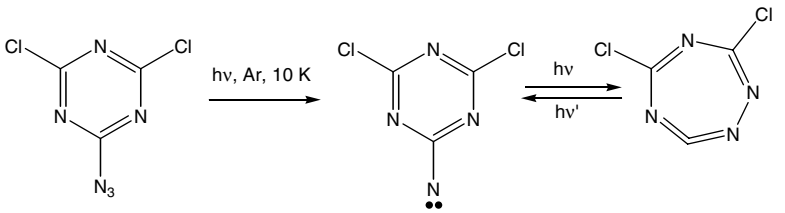
SCHEME 25

In the series of azido-1,3,5-triazines, a similar trend was observed. Photolysis of azidotriazines such as **105** yielded only typical nitrene-derived products, whereas products indicative of dehydrotetrazepine formation were not observed.[103–106] In acetonitrile solution, an interesting cycloaddition of the nitrene **106** to the solvent was observed that led to pyrazolotriazine **107**, which subsequently rearranged further.[107]



SCHEME 26

The photochemistry of azidotriazines depends on substitution. Photolysis of 2-azido-4,6-dichloro-1,3,5-triazine **108**, matrix-isolated in Ar at 10 K, led to formation of both triplet nitrene **109** and didehydrotetrazepine **110**, which could be interconverted photochemically. Extended photolysis, however, resulted in the formation of an unidentified ring-opened product.[108] Laser flash photolysis experiments indicate that both **109** and **110** are formed at ambient temperature.[109]

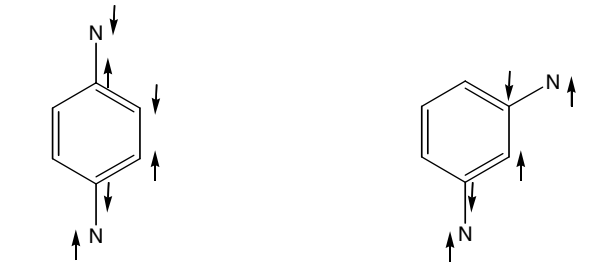


108 **109** **110**

SCHEME 27

44.8 High-Spin Nitrenes

Photolysis of azides that contain more than one azido functionality will in most cases lead to di- or oligonitrenes. These reactive species are formed by stepwise dediazotation reactions. They have recently attracted considerable attention due to the potential use of high-spin intermediates as "organic magnets". Just as in polycarbene chemistry,[110] *para*-phenylene linkage of two nitrene centers generally leads to singlet diradicals,[111,112] while a *meta*-phenylene linkage results in quintet dinitrenes. The different ground-state spin multiplicities can be explained in terms of spin polarization. For simple diradicals, this is demonstrated in the following scheme.

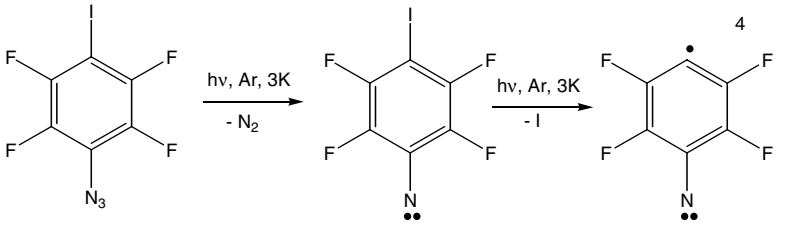


para-Phenylene-bridged:
Low-Spin

meta-Phenylene-bridged:
High-Spin

SCHEME 28

If three nitrene moieties are placed in the 1,3,5-position in an aromatic system, the resulting trisnitrene should have a septet ground state as was indeed observed in several cases.[101] Spin polarization predicts a quartet ground state for the phenylnitrene-4-yl radical. This was confirmed for 2,3,5,6-tetrafluorophenylnitrene-4-yl **113**, which could be prepared by stepwise photodediazotation and photodeiodination of matrix-isolated 4-iodo-2,3,5,6-tetrafluorophenyl azide **111**.[113]

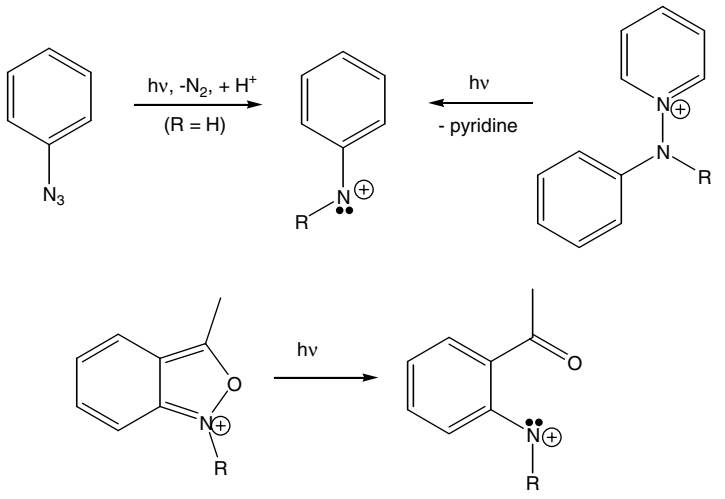


111 **112** **113**

SCHEME 29

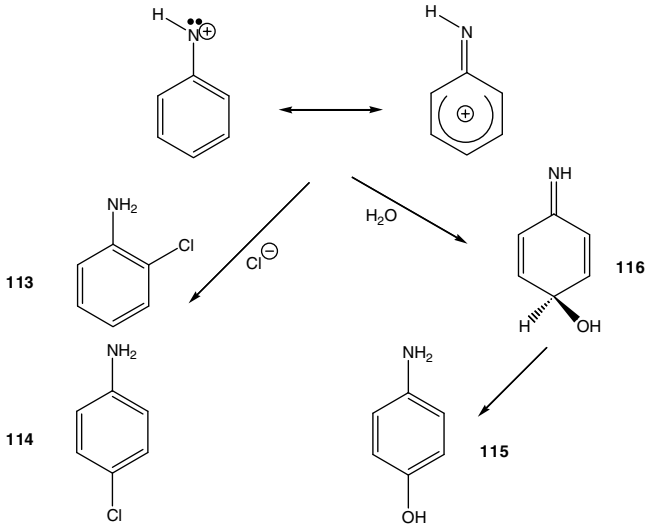
44.9 Aryl Azides in Acidic Media: Photogeneration of Nitrenium Ions

Photolysis of aryl azides in acidic media leads to rapid protonation of the initially formed singlet nitrenes with formation of singlet nitrenium ions. Nitrenium ions are nitrogen-centered diradicals that are formally isoelectronic with carbenes. They have been in the focus of research for their role as "ultimate carcinogen" in the metabolism of certain aromatic amines.[114–117] Nitrenium ions can also be made by photolysis of 2,2-benzisoxazolium (anthranilium) salts[118–124] or by irradiation of *N*-aminopyridinium salts.[122,123,125]



SCHEME 30

The parent nitrenium ion, NH_2^+, was shown both experimentally[126] and by *ab initio* calculations[127,128] to have a triplet ground state. In aryl nitrenium ions, on the other hand, this ordering of states is reversed, and the ground state is a singlet, as was shown in a number of theoretical studies.[129–133] In the phenylnitrenium ion, the singlet state is strongly favored over the triplet state because the benzene ring can act more efficiently as a π-donor if it interacts with an empty nitrogen p-orbital (singlet state) rather than with a half-filled nitrogen p-orbital (as in the triplet state).[132] Due to the very electron-deficient nature of the nitrenium N-atom, this delocalization of positive charge is very important. In fact, the singlet phenylnitrenium ion can be described as an imino-functionalized cyclohexadienyl cation. If the aryl substituent is functionalized with strong π-acceptor substituents (e.g., nitro or a ring nitrogen atom), the nitrenium ion may also have a triplet ground state.[121,134]

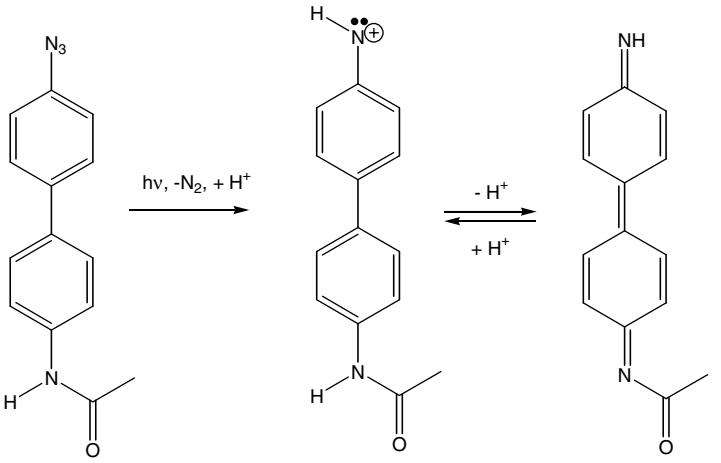


SCHEME 31

The products isolated upon photolysis of phenyl azide **10** in acidic medium agree with this description. At low pH (aq. HCl), *o*- and *p*-chloroaniline **113** and **114** and 4-aminophenol **115** were among the main products.[135] All of these products can be rationalized in terms of cyclohexadienyl-cation-type reactivity of the phenylnitrenium ion. Aminophenol **115** is formed via the iminocyclohexadienol **116**, which was observed by time-resolved spectroscopy.[135]

If aryl azides are irradiated in acidic medium in the presence of arenes, derivatives of diphenylamine are formed.[119] For the diphenylnitrenium ion, σ-complexes with benzene have been detected by laser flash photolysis.[136] In reactions with alkenes, nitrenium ions react more rapidly with electron-deficient olefins. Rate constants for the reaction of diphenylnitrenium with electron-rich olefins such as cyclohexanone trimethylsilyl enol ether are of the order of 1.9×10^9 M^{-1} s^{-1}.[123] In the reaction of 2-fluorenylnitrenium with 2′-deoxyguanosine, reaction at C8 of the guanine base takes place.[137]

Photolysis of azides in acidic media can only yield monosubstituted nitrenium ions. In most cases, the protonation of singlet nitrenes is a highly efficient reaction. Thus, the rate of protonation of singlet 2,4,6-tribromophenylnitrene by perchloric acid in aqueous acetonitrile has been determined as $k_{H+} = (3.5 + 0.1) \times 10^9$ M^{-1} s^{-1}, which is close to the diffusion-controlled limit.[53] In the case of the 4-biphenylyl- and 2-fluorenylnitrenium ions, nitrene protonation in CH_3CN/H_2O also occurred on the picosecond time scale.[135,138] Some nitrenium ions may undergo follow-up deprotonation reactions. The nitrenium ion **117**, which is derived from the strong carcinogen *N*-acetylbenzidine, exists at physiological pHs as a mixture of the reactive **117** and the long-lived conjugate *bis*-imine base **118**.[139]



SCHEME 32

Recent advances in time-resolved vibrational spectroscopy (time-resolved infrared [TR-IR] and time-resolved resonance raman spectroscopy) have provided further evidence for the description of aryl nitrenium ions as imino-cyclohexadienyl cations. The C–N stretching frequency in singlet diphenylnitrenium ion (generated by LFP of a *N*-diphenylaminopyridinium salt in acetonitrile) was measured by time-resolved infrared spectroscopy to be $\tilde{\nu}$ = 1392 cm^{-1}, which is significantly higher than the $\tilde{\nu}$ = 1320 cm^{-1} of diphenylamine.[122] In the UV/Vis, the diphenylnitrenium ion shows a λ_{max} = 425 and 660 nm, with a lifetime τ = 1.5 μs.[125]

Similar conclusions were reached for *N*-aryl-*N*-methylnitrenium ions, which were characterized by TR-IR spectroscopy[140] as well as for the 2-fluorenylnitrenium ion and the 4-biphenylylnitrenium ion, which were generated by photolysis of the corresponding azides in water/acetonitrile mixtures and characterized by time-resolved resonance raman spectroscopy.[141,142] Overall, nitrenium ion chemistry constitutes a very active field of research, and further exciting discoveries can be anticipated.

Oxidation of Aromatics

Angelo Albini
University of Pavia

Maurizio Fagnoni
University of Pavia

45.1 Introduction

The stability of aromatic compounds limits the application of thermal oxidation methods, which generally require rather drastic conditions; therefore, the mild conditions of photosensitized reactions are particularly appealing for oxidizing these compounds. Depending on structure and conditions, the photoinduced oxidation of aromatic derivatives may takes place via each one of the three main mechanisms of photosensitizations which, as detailed elsewhere, differ in the reagent interacting with the sensitizer in the primary step, as indicated below.

In type I oxygenation, the *substrate* is activated by energy transfer or, more frequently, by hydrogen abstraction. The radical formed in this fashion is trapped by oxygen, and the reaction continues through a radical chain mechanism:[1,2]

$$\text{Sens}^* + \text{Ar–X–H} \rightarrow \text{SensH}^{\bullet} + \text{Ar–X}^{\bullet} \tag{45.1}$$

$$\text{Ar–X}^{\bullet} + \text{O}_2 \rightarrow \text{Ar–X–O}_2^{\bullet} \rightarrow \text{Products} \tag{45.2}$$

In type II oxygenation, *oxygen* is sensitized by electron transfer and the chemical reaction involves singlet oxygen.[2–5]

$$\text{Sens}^* + \text{O}_2 \rightarrow \text{Sens} + {}^1\text{O}_2 \tag{45.3}$$

$${}^1\text{O}_2 + \text{Ar–H} \rightarrow \text{Products} \tag{45.4}$$

In a third mechanism, sometimes referred to as type III photooxidation, the sensitizer interacts with the *substrate* via electron transfer generating the radical cation. In some cases, the radical anion of the sensitizer is oxidized back by oxygen, generating the *superoxide* anion, and the bonding step involves the radical cation and either the superoxide anion or, as is probably more often the case, molecular oxygen:[6,7]

$$\text{Sens}^* + \text{Ar–H} \rightarrow \text{Sens}^{-\bullet} + \text{Ar–H}^{+\bullet} \tag{45.5}$$

$$\text{Sens}^{-\bullet} + \text{O}_2 \rightarrow \text{Sens} + \text{O}_2^{-\bullet} \tag{45.6}$$

$$\text{Ar–H}^{+\bullet} + \text{O}_2^{-\bullet} \text{ or } \text{O}_2 \rightarrow \text{Products} \tag{45.7}$$

Variations of the last process are reactions in which oxygen traps an exciplex with some degree of charge transfer (and, by extension, a biradical or zwitterionic intermediate of some cycloaddition reaction), or the aromatic is in some way activated by complexation (e.g., on a solid surface). Charge-transfer complexes between an aromatic molecule and molecular oxygen also play a role.

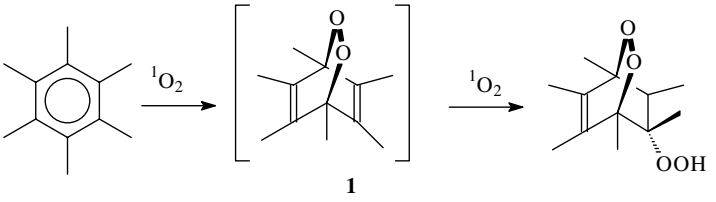
In the following discussion, the reactions are presented according to the substrate undergoing the reaction, an aromatic hydrocarbon, an electron-donating substituted aromatic, a vinylarene, and an aromatic reacting at the side chain ring, and within each class according to the mechanism involved.

45.2 Oxidation of the Ring in Aromatic Hydrocarbons

Singlet Oxygen Reactions

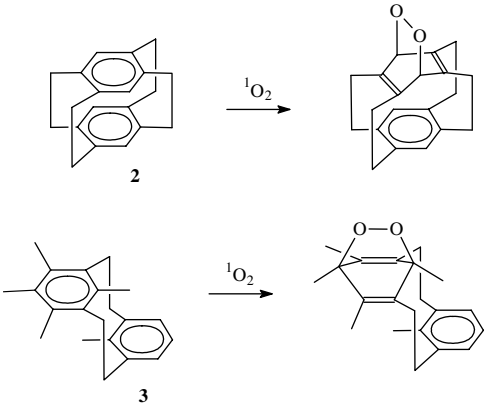
The most important oxidations directly affecting the aromatic ring involve singlet oxygen. As detailed elsewhere in this book, this is a strong dienophile, the reactions of which are facilitated by the small dimensions and minimal steric hindrance. Therefore, $[\pi^4 + \pi^2]$-cycloaddition is expected to occur, with the limitation imposed by the aromaticity loss implied in the process. In fact, singlet oxygen addition takes place with a preparatively useful quantum yield with polynuclear aromatics (*viz.* the same substrates that undergo electrophilic addition in competition with substitution), whereas with simple benzene or naphthalene derivatives the process is slow or insignificant. The rate of reaction increases with the addition of further condensed rings (1,4-dimethylnaphthalene, 1.2×10^4; anthracene, 1.5×10^5; naphthacene, 1.2×10^7; pentacene, 4.2×10^9 mol^{-1} s^{-1} in benzene at 25°C), and both the rate and the regiochemistry of attack are rationalized by the Frontier Molecular Orbital approach.[8–11]

In the benzene series, a strong electron-donating substituent is required for the reaction with singlet oxygen (see next section). Within hydrocarbons, the reaction is significant only when polysubstitution induces some deviation from planarity and thus a loss of aromaticity. Thus, both penta- and hexamethylbenzene undergo $[\pi^4+\pi^2]$-cycloaddition; the first formed *endo*-peroxide (**1**; see Eq. (45.8)) is not isolated and adds a second molecule of singlet oxygen through an ene reaction:[12]



1 (45.8)

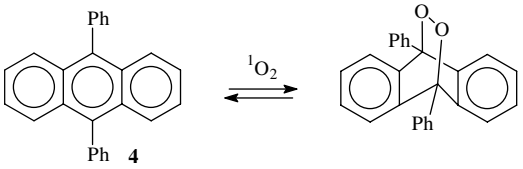
Endo-peroxides are isolated from the oxidation of cyclophanes such as compounds **2** and **3** (see E. (45.9)).[13,14] Oxygen addition to the central ring has been suggested to occur also with a benzo[3,4]cyclobuta[1,2-*b*]biphenylene; the final products result from the oxidative cleavage of that ring:[15]



2 **3** (45.9)

1-Methylnaphthalene (but not the 2-substituted isomer) as well as all dimethyl- and polyalkylnaphthalenes undergo dye-sensitized oxidation to give endoperoxides. With asymmetric substrates, the preferred attack is at the more substituted ring or where there is an α substituent; a second (ene) addition follows also with these substrates when possible.[16–19] In a series of chiral 1-(1-naphthyl) alcohols, the corresponding endoperoxides are formed in high yields and with remarkable (8:2 to 9:1) diastereoselectivity. This has been rationalized in terms of steric and electronic control and extends to other 1-(1-X-ethyl) derivatives — for example, with X = Cl, Br, or $SiMe_3$ but not with X = OAc or $OSiMe_3$, nor to 1-*t*-butylnaphthalene. The selectivity is reversed when a methyl group is present in position 2 on the ring.[20–22]

Phenanthrene is not highly reactive with singlet oxygen, and the 1,4-dimethyl derivative adds across the substituted positions.[4] On the other hand, anthracene and most of its derivatives react readily and give the 9,10-endoperoxides (see, for example, **4**):[10,23]



(45.10)

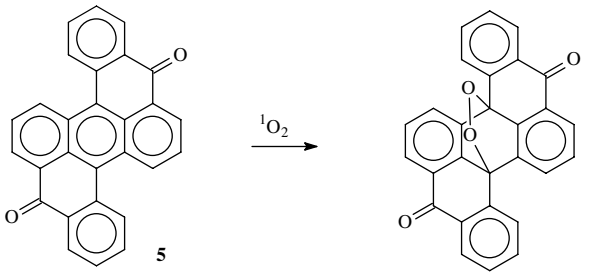
The photoreaction in the presence of oxygen has been long known, although initially it was confused with the likewise easy photodimerization of this compound[24] and only later has been recognized as a self-sensitized process involving singlet oxygen.[25] The ability of anthracene and other polycyclic aromatics to sensitize oxygen has been well documented and may involve both the singlet and triplet state.[26–30] When both the S_1–T_1 and the T_1–S_0 energy gaps are larger than the energy of the $^1\Delta_g$ state of oxygen (22.4 kcal mol^{-1}), two spin-allowed energy transfer steps occur and the limiting quantum yield of sensitization is 2:

$$Ar\text{–}H^{1*} + O_2 \rightarrow Ar\text{–}H^{3*} + {}^1O_2 \tag{45.11}$$

$$Ar\text{–}H^{3*} + O_2 \rightarrow Ar\text{–}H + {}^1O_2 \tag{45.12}$$

Again, the introduction of substituents affects the regiochemistry. Thus, substantial amounts of the 1,4-endoperoxide are formed along with the 9,10-isomer in the case of 1,4-dimethylanthracene,[31,32] and only the former regioisomer is obtained when electron-donating substituents such as alkoxy or dimethylamino are present at positions 1,[33,34] although the reaction remains at the *meso* position with electron-withdrawing substituents, as is the case with heterocoerdianthrones (see below)[35] or with substituents at position 2.[36] Naphthacene and pentacene and some of its derivatives, such as the extensively investigated rubrenes, are likewise oxidized through a self-sensitized process.[37–42] The 11-ring-containing diphenanthro[5,4,3-*abcd*-5′,4′,3′-*jklm*]perylene appears to give the endoperoxide across the central benzene ring, and this reverts back at room temperature.[43] By the use of confocal microscopy it has been possible to detect the formation of an endoperoxide (and then of a *bis*-endoperoxide through a second addition) on a single molecule of the 8-ring-containing terrylene in a *p*-terphenyl host crystal.[44]

Endoperoxides revert thermally to the aromatic molecule and singlet oxygen. This topic has been extensively investigated, and a variety of singlet oxygen sources active at various temperatures has been made available by means of suitable structural variations.[45] Although the topic is not strictly pertinent to this chapter, one should at least mention the water-soluble naphthalene endoperoxides that have been developed for generating singlet oxygen at the physiological temperature.[46–48] The retrocycloaddition also occurs photochemically through a process that at least in some cases has been demonstrated to be adiabatic.[49,50] The oxidation of heterocoerdianthrone (**5**; Eq. (45.13)) is reversible, and the system can be used as a reversible actinometer with oxygen addition in the visible and reversion in the UV range:[51]

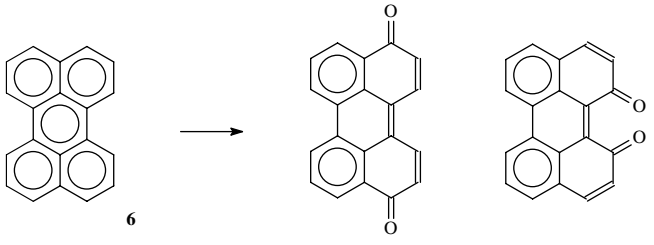


(45.13)

One of the approaches for the degradation of polycyclic aromatic hydrocarbons (PAHs) as pollutants is irradiation of the substrate absorbed onto a solid material, and here singlet oxygen seems to have an important role, besides other mechanisms that will be discussed further in this chapter. In the case of anthracene on a dry surface of silica or alumina, irradiation gives the dimer and the endoperoxide and further products arising from the latter compound;[52] likewise, acenaphthylene gives the dimers along with acenapthenedione and other products suggested to result from the addition of $^1O_2$.[53]

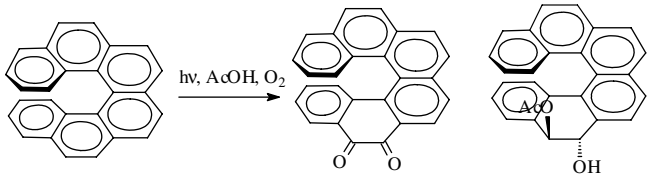
Non-Singlet Oxygen Reactions

Interest is increasing in the oxidation of aromatics through non-singlet oxygen mechanisms. The efficiency of the electron transfer mechanism (type III, above) by using a sensitizer such as 9,10-dicyanoanthracene is generally low due to the scarce reactivity of the aromatic radical cation in comparison to back electron transfer. The use of co-sensitizers such as biphenyl and terphenyls enhances the probability of the reaction and allows the oxidation of biphenyls to benzoic acids, of naphthalene to phthalic anhydride, and of phenanthrene to the same anhydride and biphenyldicarboxylic acid.[54] The same results can be obtained by adding magnesium perchlorate (omission of the salt causes the photohydrolysis of the sensitizer to anthraquinone).[55,56] With the same sensitizer, the oxidation of naphthalene gives different products when using different non-nucleophilic salts.[57] When the trityl cation (which does not form superoxide in the second step of the mechanism) is used as the sensitizer, only anthracene is oxidized to anthraquinone.[58] Perylene (**6**; Eq. (45.14)) is oxidized to two regioisomeric quinones in the presence of (hetero)aromatics containing water-soluble polymers, probably again through an electron transfer mechanism:[59]



(45.14)

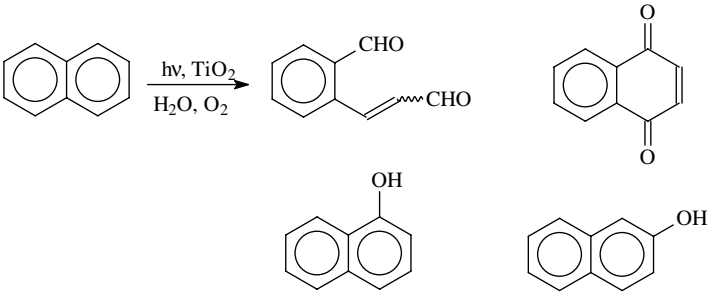
In the absence of added sensitizers, charge-transfer complexes between the aromatic substrate and molecular oxygen, which are revealed by a modification in the UV spectrum,[60,61] may react. A well-documented case is that of hexahelicene, which reacts under acidic conditions because protonation of the superoxide anion avoids reversion to the starting substrate; in acetic acid, a vicinal *trans*-acetoxy alcohol is formed:[62]



(45.15)

Irradiation of naphthalene in water leads to 2-formylcinnamaldehyde, 2-carboxycinnamaldehyde, and 7-hydroxy-1,4-naphthoquinone, possibly via initial photoionization and production of hydroxyl radicals[63] (with anthracene, a complex mixture is obtained).[64]

Photocatalysis by semiconductor powders, most usually titanium dioxide, has been applied to the oxidation of several aromatics.[65,66] In many such photocatalytic reactions, the key intermediates are hydroxyl radicals formed by oxidation of water. With rather good donors such as aromatic compounds, hole transfer on the excited semiconductor surface is a viable alternative; in this case, the reaction of the radical cation of the substrate or further intermediates arising from it with oxygen or superoxide anion may have a role. Photocatalyzed oxidation of naphthalene yields 2-formylcinnamaldehyde and 1,4-naphthoquinone as the primary products (Eq. (45.16)), similarly to what occurs upon direct irradiation of naphthalene in water:[67]

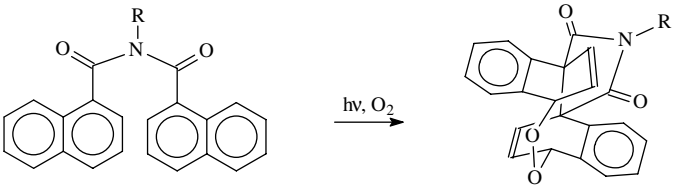


(minor products) (45.16)

Apart from the mechanistic interest, photocatalysis is a promising method for the removal of aromatics from polluted water.

Oxidation processes not involving molecular oxygen have been characterized. Some examples involve oxygen-activated species, besides the superoxide anion mentioned above. Thus, ring hydroxylation occurs by reaction with photogenerated atomic ^3P oxygen in the gas phase,[68] as well as in solution by addition of hydroxyl radicals formed by hydrogen peroxide fragmentation[69] or of hydroperoxyl radicals.[70] Alternatively, excited states of some compounds function as oxygen donors or fragment-producing atomic oxygen or hydroxyl radicals. This applies to excited heterocyclic *N*-oxides, to aromatic sulfoxides,[71,72] and, at least with electron-rich substrates such as methoxynaphthalenes, to nitroaromatics.[73]

Yet another mechanism for oxidation is trapping by oxygen of some intermediate formed in a photochemical reaction of an aromatic. Fitting examples seem to be the formation of cyclopentadienecarboxyaldehyde upon direct irradiation of an oxygen-equilibrated solution of benzene in water, presumably via oxidation of the product of photorearrangement, benzvalene,[74,75] and the formation of epidioxides upon irradiation of naphthylcarboxylimides (**7**; Eq. (45.17)), reasonably via oxygen addition to an intermediate biradical that would otherwise give the [4+4]-intramolecular cycloadduct:[76]

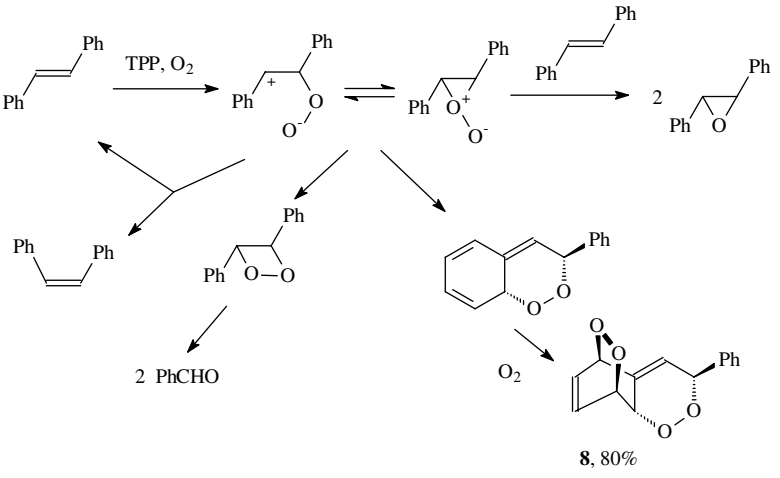


7

besides 2+2 and 4+2 dimers (45.17)

45.3 Oxidation of Vinylarenes

The oxidation of aryl-conjugated olefins occurs smoothly under various conditions and is of both mechanistic and preparative interest. The reaction may be limited to the olefin moiety or involve the aromatic ring. This depends on the structure but primarily on conditions; accordingly, in this section, singlet oxygen and electron transfer photooxygenations are discussed separately. Dye-sensitized singlet oxygen addition occurs easily and often involves the ring. In a typical case, β,β-dimethylstyrene mainly gives di-endoperoxides resulting from [4+2]-cycloaddition to form a dihydrobenzo-1,2-dioxin that rapidly adds a second molecule of singlet oxygen across the cyclohexadiene moiety, with minor amounts of benzaldehyde from the cleavage of the dioxetane and of the hydroperoxide resulting from the ene reaction.[77,78] In contrast, intra-zeolite-sensitized photooxygenation gives the hydroperoxide as by far the main product, whether this is due to an effect of the zeolite on the stability of the initial zwitterionic intermediates or to a conformation of the styrene in the cavity ill-suited to [4+2]-cycloaddition.[79] Likewise, the main product is the di-endoperoxide **8** with *trans*-stilbene (80%; see Eq. (45.18))[80] as well as with vinylnaphthalenes:[81]

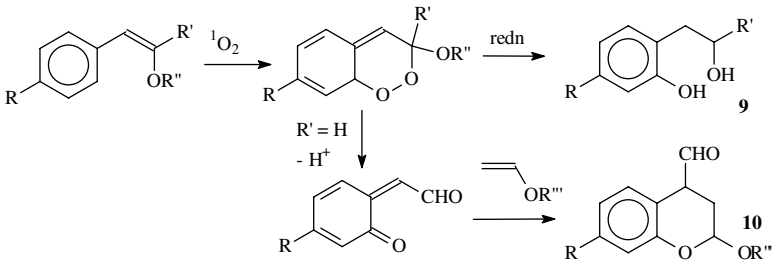


(45.18)

With 1,2-dihydronaphthalenes, competition between the ene reaction giving the 4-hydroperoxide and cycloaddition depends on the substituent;[82] with a chiral 1-phenyl-1,2-dihydronaphthalene-2-carboxylic acid and some related compounds, the *bis*-endoperoxide is the main product and is formed with high diastereoselectivity.[83] With (alkyl)indenes, the result is strongly dependent on conditions. At –78°C, the [4+2]-addition predominates (in this case, leading to rearranged di-epoxyperoxides), while in acetonitrile or methanol the [2+2]-mode predominates and cleaved dicarbonyls are obtained; the ene reaction is one of the processes occurring at room temperature.[84–86]

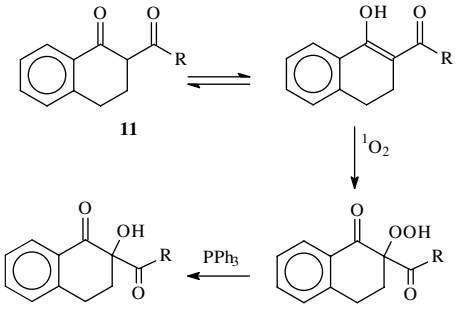
Alkyl substitution or incorporation of the vinyl moiety into a ring has various effects. The ene reaction is the exclusive process with α,α′-dimethylstilbene[87] and with 1-phenylcyclopentene,[88] while it competes with the [4+2]-cycloaddition in the case of 1-phenylcyclohexene.[88] In the case of 2-phenylnorbornene in methanol, both a methoxyhydroperoxide arising from attack to the double bond and two di-epoxy-endoperoxides arising from initial [4+2]-addition are observed.[89] A [2+2]-addition process, accompanied by formation of 1-(2-hydroxyphenyl)cyclopropancarboxyaldehyde, seemingly via a non-singlet oxygen path, takes place with 1-phenylcyclobutene.[90,91] An electron-donating substituent favors the [4+2]-cycloaddition, which occurs with β-methoxystyrenes and β-methoxyvinylnaphthalenes,[92–95] but 1,2-dioxetanes are formed from 1-silyloxyindenes.[96]

Di-endoperoxides are also formed from the enol ethers and silyl enol ethers of phenylpyruvic acid, phenylacetone, and phenylacetaldehyde; however, carefully controlled photooxygenation gives the mono-endoperoxides, which can be reduced to the *o*-hydroxyphenyl derivatives **9**[97,98] or used as the equivalent of *o*-quinone methides, as in the formation of compounds **10**:[94]



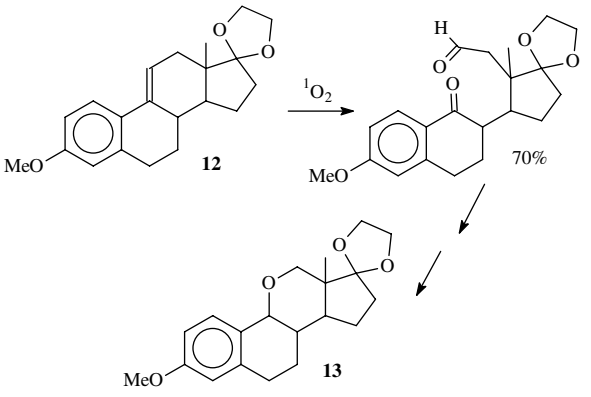
(45.19)

Tautomeric benzoylacetones (**11**) undergo an ene reaction with singlet oxygen via the enolic form, followed by rearrangement and elimination reactions from the initially formed hydroperoxide, which has been characterized at low temperature:[99,100]



(45.20)

Among derivatives with an electron-donating substituent on the aromatic ring, one should mention the reaction of some estrogens with vinylanisole structure, such as **12**, where the vinyl moiety is oxidatively cleaved:



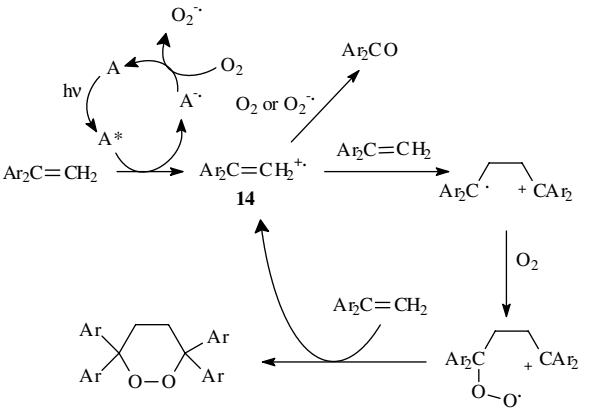
(45.21)

This reaction has been exploited for the synthesis of 11-oxaestrogens (**13**).[101–103]

None of the above singlet oxygen cycloaddition reactions nor, obviously, the ene reaction takes place with 1,1-diphenylethylenes (see below for reactions with allenes), and strongly donating groups may in this case change the course of the reaction with singlet oxygen to electron transfer, as observed with 1,1-*bis*(*p*-dimethylaminophenyl)ethylene (see below).

Conjugated arylbutadienes form the endoperoxides across the diene moiety, just as in the non-arylated derivatives; in particular, both (*E,E*)- and (*Z,Z*)-1-aryl-1,3-pentadienes give the *cis*-endoperoxide.[104] Phenyl- and 1,1-diphenylallenes, on the other hand, undergo both [2+2]-addition, leading to aryl ketones and diketones and [4+2]-addition, leading to arylation or epoxidation of the aromatic ring.[105]

A different mechanism operates upon electron-transfer-sensitized photooxygenation, generally carried out by using electron-accepting sensitizers such as 9,10-dicyanoanthracene, triphenylpyrylium salts, and others.[106–112] The arylalkene radical cation **14** is formed and then reacts either with the superoxide anion or, more likely, with oxygen. Kinetic factors are also important:[113]



(45.22)

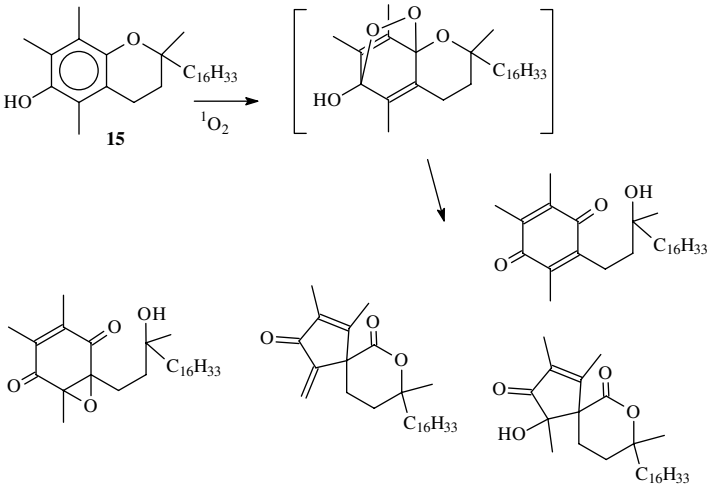
This path is important for good donors, such as polyphenylethylenes, that are cleaved to the corresponding ketones or aldehydes with minor amounts of epoxides (which may in turn be further oxidized to the cleaved carbonyls), reasonably via 1,2-dioxetanes. β-Methoxystyrenes[114] and 2,3-diphenyl-1,4-dioxene as well as 2,3,4,5-tetraphenyl-1,4-dioxin, are similarly oxidized.[115,116] α-Acetoxystyrenes give β-acetoxypropiophenones upon sensitized oxygenation by pyrylium salts.[117] In the case of alkoxyarylmethyleneadamantanes, a stable dioxetane is obtained via a charge-transfer mechanism.[118] Oxidative cleavage of stilbenes is much more efficient when the substrate is included with the (cationic) dye in zeolites.[119] Furthermore, it also occurs upon specific irradiation of the charge-transfer complex that stilbenes form with oxygen in zeolite NaY.[120,121]

An alternative entry to this chemistry is the use of a good electron donor as an indirect sensitizer. Thus, irradiation of α-methylstyrene in the presence of various alkylated 1,4-dimethoxybenzenes gives acetophenone and 1,1-phenylmethyloxirane as the main products, apparently via quenching of the singlet-excited dimethoxybenzenes by oxygen with formation of the superoxide anion and the radical cation of the donor, which then indirectly generates the radical cation of the olefin.[122,123] Another method is titanium dioxide photocatalysis.[124,125] The chemistry of the radical cation can take different paths in the presence of nucleophiles; the photooxidation of 3,3-dimethylindene in methanol gives methoxyhydroperoxides with the opposite regiochemistry depending on whether an electron transfer sensitizer or a singlet oxygen forming dye is used, because activated oxygen and the alcohol react in the opposite order in the two cases.[126]

With sensitizers such as dicyanoanthracene or 10-methylacridinium salts, electron-donating substituted 1,1-diarylethylenes undergo an electron-transfer-initiated chain reaction leading to 1,2-dioxanes via addition of the radical cation to neutral alkene, trapping of the resulting 1,4-distonic radical cation by oxygen, reduction of the 1,6-radical cation, and cyclization (a side path is cleavage to carbonyls as above).[127–131] The reaction has been extended to the intramolecular case with related 1,ω-*bis*(diarylethenyl)alkanes.[132] Noteworthy, 1,2-dioxanes are also formed in the absence of the sensitizer by selective irradiation of the contact charge-transfer band between electron-rich 1,1-diarylethylenes and oxygen.[133] Furthermore, with strongly donating substituents such as the dimethylamino group, the 1,2-dioxane is also formed under singlet oxygen conditions, apparently because electron transfer to singlet oxygen again gives the radical ion pair.[134] On the other hand, 1,2-diphenyl-1,2-diamines, aminoalcohols, and aminoketones undergo electron transfer with singlet oxygen and cleave via the radical cation.[135] Yet, a different oxidative process has been found in the photoreaction of triarylstibines with styrenes, which yields 2-aryl-1-phenylethanols, presumably via attack by styrene on the stibine-oxygen complex and Sb-assisted CC and C–O bond formation.[136]

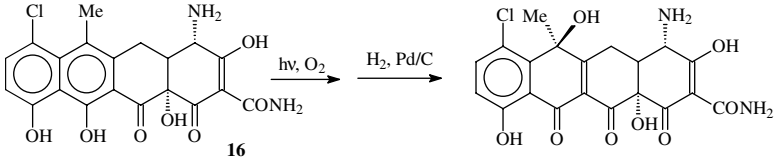
45.4 Oxidation of Phenols, Aryl Ethers, and Aromatic Amines

A variety of photooxidation paths are available to phenols. These substrates are both good hydrogen donors and good electron donors. Thus, hydrogen abstraction from the OH group or electron transfer followed by deprotonation from the radical cation are possible mechanisms (type I and type III) and both yield phenoxyl radicals, which then add to ground-state oxygen. On the other hand, under dye-sensitized conditions, the reaction follows a type II mechanism via singlet oxygen, but, here again, the interaction with phenol may lead to different paths — concerted addition, ene-type reaction or [4+2]-cycloaddition, or hydrogen abstraction, again giving the phenoxyl radical,[137] in addition to simple physical quenching that yields back the ground state. The conditions leading to the prevalence of the various mechanisms have been discussed in detail.[10] As for the products formed, the main process yielding 4-hydroperoxycyclohexadienones, which may result form whatever of the above paths is operative and indeed are also the products arising from the thermal radical oxidation of the same substrates. The hydroperoxides can be isolated from 4-substituted phenols or are otherwise directly converted to the quinones.[138–142] The sensitized photooxygenation has been considered as a model for enzymatic oxidation.[143] This has been applied to the degradation of biologically important phenols, such as *p*-hydroxyphenylacetic acid,[144] pyruvic acid, and α-tocopherol (**15**):[145,146]



(45.23)

2,5-Dihydroxybenzoic acid is formed from salicylic acid by reaction with singlet oxygen,[147] but the same product is formed also by ZnO photocatalysis, apparently via hole transfer.[148] In several cases, the reaction with singlet oxygen has been used as a mild method of functionalization for synthetic purposes. An example is the hydroperoxidation in 10 of estrone and estradiol as a key step for the conversion into the corresponding 19-norsteroids.[149] Another example is the hydroperoxidation in 6 of anhydrotetracycline (**16**; Eq. (45.24)) for the conversion into tetracycline[150] and the conversion of *N*-(ethoxycarbonyl)norcodeinone dienol acetate to the corresponding 14-hydroxynorcodeinone as the key step for the synthesis of 14-hydroxymorphinans from codeine:[151]



(45.24)

Another important method of oxidation is titanium dioxide photocatalysis, which again involves different reaction paths. These appear to be initiated by hydroxyl radical attack and finally lead to

mineralization of the organic substrate;[152] in this case, the main application is for the purification of polluted water, where phenols and in particular chlorophenols are often present as pollutants. The oxidation can also be carried out with some soluble inorganic complexes.[153]

Naphthols give naphthoquinones or other oxidized products through similar mechanisms.[154–156] Alkoxyphenols, polymethoxylated benzenes,[157–159] and naphthyl ethers[160,161] generally give di-epoxides, epoxyenones, or quinones as well as ring cleavage products that can be rationalized as arising from the rearrangement of the initially formed 1,4-endoperoxides. The electron transfer photosensitized oxidation of 1,2-dimethoxybenzene results in ring cleavage via a dioxetane,[162] and an analogous intermediate is probably involved in the photooxidation of 9,10-dimethoxyphenanthrene.[163]

Tertiary amines are essentially physical quenchers of singlet oxygen; however, chemical reaction, both type I and type II, may have a role and have in fact being observed with some electron-donating substituted dimethylanilines.[164] 2-Naphthylamine undergoes oxidative ring cleavage.[165]

45.5 Side-Chain Oxidation

Side-chain photooxidation occurs under various conditions. A typical mechanism is photosensitized electron transfer with sensitizers such as cyanonaphthalenes, cyanoanthracenes, or pyrylium salts, followed by deprotonation at the benzylic position, in view of the remarkable thermodynamic acidity of alkylbenzenes. The benzyl radicals formed react with molecular oxygen or superoxide anion to yield hydroperoxides that can decompose to aldehydes or ketones. Furthermore, the proton is not the only electrofugal group, and different cations may be cleaved from the benzylic position in the radical cation, such as a stabilized carbocation or a silyl cation (this topic is discussed more extensively elsewhere in this book). Typical examples are the formation of aryl aldehydes or ketones from alkylated benzenes[166–169] and naphthalenes as well as from fluorene and derivatives.[170–172] Similar reactions have been observed with benzyl alcohols and ethers,[173,174] as well as with bibenzyls, arylpinacols, and benzylsilanes.[175–178] As mentioned above, aromatic sensitizers can also activate oxygen and, with good singlet oxygen acceptors such as 1,4-dimethylnaphthalene, both paths — formation of the endoperoxide via [4+2]-cycloaddition and oxidation via benzyl radicals — compete to an extent that depends on the solvent polarity. Benzylic oxidation also takes place under different conditions and with various mechanisms, such as sensitization by quinones[179] or by protonated pteridine or flavin analogs,[180] photocatalysis by semiconductors,[181–183] irradiation in the presence of some inorganic compounds,[184] or simply by irradiation of oxygenated solutions, in this case possibly via an electron transfer complex with oxygen.[185–187] The charge-transfer band has been characterized for the toluene–oxygen complex in barium- and calcium-exchanged zeolite Y, where benzaldehyde is selectively obtained by irradiation in the visible region.[188]

A particular case of the benzyl radical cation fragmentation path with oxygen addition to the benzylic position is the electron-transfer-induced oxygenation of arylated cyclopropanes and three-membered heterocycles. In this case, a carbon–carbon bond is broken in the strained ring; oxygen is added to the distonic radical cation and gives five-membered heterocycles. Thus, cyclopropanes (**17**, Eq. (45.25)) are converted to dioxolanes,[189–191] oxiranes to ozonides,[189,192,193] and aziridines to 1,2,4-dioxazolidines;[189] the oxygenation may occur through a radical chain mechanism:

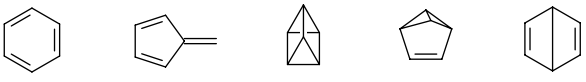
The Photochemistry of Substituted Benzenes: Phototranspositions and the Photoadditions of Alcohols

James A. Pincock
Dalhousie University

46.1 Introduction

"The aromatic nucleus, known for its rigidity in the ground state, becomes an extremely flexible and extrovert acrobat when being doped with a light quantum."[1]

Before 1956, benzene **1** and other substituted aromatics were considered to be photochemically unreactive. The historically important discovery in that year of the photoisomerization of benzene to fulvene **2**[2] changed this perception. Soon reports appeared on the photochemical preparation and characterization of other C_6H_6 isomers, *t*-butyl derivatives of prismane **3** (1965),[3,4] benzvalene **4** (1967),[5] and Dewar benzene **5** (1968).[6] Many examples of substituted cases are now also known.

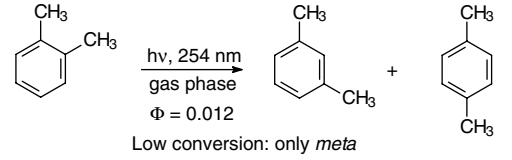


1 **2** **3** **4** **5**

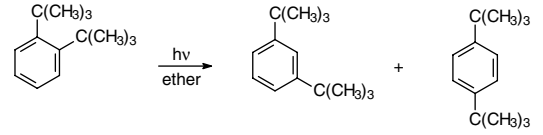
0-8493-1348-1/04/$0.00+$1.50

In an attempt to trap fulvene **2** by the Diels–Alder reaction with maleic anhydride, another new photoreaction was discovered.[7] A cycloadduct was obtained which was suggested to be formed by direct addition to the excited state of benzene. Since then, photoadditions of alkenes to benzene and substituted benzenes have been studied extensively and become a powerful tool for synthetic approaches to complex polycyclic compounds.[8,9]

The photochemical transposition reactions of substituted benzenes were first reported in 1964 by Wilzbach and Kaplan[10] for the xylenes (Eq. (46.1)) and Burgstahler et al.[11] for the di-*t*-butyl benzenes (Eq. (46.2)).

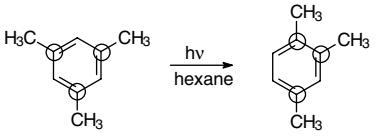


(46.1)



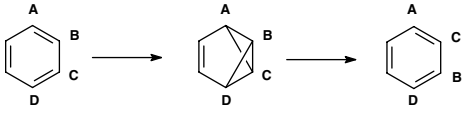
(46.2)

In the latter example, a steady-state composition of 0% *ortho*, 20% *meta*, and 80% *para* was reached starting with each of the three isomers. That these rearrangements proceeded by transposition of the ring carbons and not by alkyl group detachments was demonstrated by photolysis of [1,3,5-$^{14}C_3$]mesitylene (Eq. (46.3); the circles represent the labeled carbons).[12]



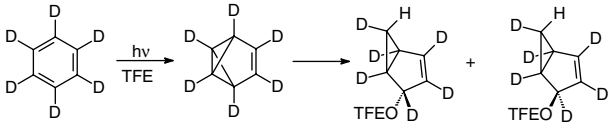
(46.3)

Substituted benzvalenes provide a reasonable intermediate for these transposition reactions, as their photochemical formation (make bonds AC and BD) followed by thermal or secondary photochemical reversal (break bonds AB and CD) leads to the transposition of atoms B and C (Eq. (46.4)).



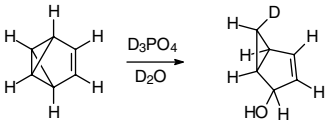
(46.4)

The photochemical preparation of benzvalene[5] was prompted by this proposal. Further strong support for benzvalenes as intermediates in the photochemistry of benzene and substituted benzenes also came from experiments in alcohol solvents under mild acidic conditions.[13,14] The primary products are bicyclo[3.1.0]hexene derivatives resulting from alcohol addition. Moreover, on photolysis of benzene-1,3,5-d_3 and benzene-d_6 in 2,2,2-trifluoroethanol (TFE), the products formed resulted from selective protonation at C_6 with endo stereochemistry (Eq. (46.5)).[15]



(46.5)

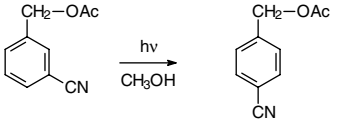
This observation is in agreement with results observed for protonation reactions in the ground state of the highly strained sigma bonds in benzvalene (Eq. (46.6)).[16]



(46.6)

This early work has been reviewed a number of times, including in the previous edition of this Handbook.[17–21]

Our interest in these phototransposition reactions began while studying the photochemistry in methanol of the *meta* isomer, 3-cyanobenzyl acetate (Eq. (46.7)).[22]



(46.7)

Because the normal carbon–oxygen bond cleavage observed for benzyl esters was very inefficient, another process was detected — namely, the formation of the *para* isomer, 4-cyanobenzyl acetate. A review of the literature revealed that, although phototranspositions had been studied in some detail in the past, virtually nothing was known about the effect that substitutents on the aromatic ring have in determining either the efficiency of conversion or the products formed. We, therefore, began by studying the phototransposition of 4-, 3-, and 2-methylbenzonitrile in acetonitrile to avoid the complication of competing ester photochemistry of Eq. 46.7.[22]

This review focuses on the four papers[23–26] examining phototransposition reactions of substituted benzenes and the photoaddition of 2,2,2-trifluoroethanol to the same compounds published recently from our own research. This parochial approach is a consequence of the fact that, to our knowledge, no other significant results on phototranspositions have been reported since the review in the previous volume of this Handbook.[21]

46.2 Photochemistry of 4-, 3-, and 2-Methylbenzonitrile (6, 7, and 8) in Acetonitrile[23]

Plots for the phototransposition reactions of the methylbenzonitriles **6** (*para*), **7** (*meta*), and **8** (*ortho)* are shown in Figures 46.1, 46.2, and 46.3, respectively. Irradiations were carried out with a Vycor-filtered, 450-W, medium-pressure Hanovia lamp using 200 mg of substrate in 280 mL of acetonitrile at 25°C. The plots are presented with values normalized to 100% for the three isomers but, in fact, the mass balance is very good: above 90% at 50% conversion for both **6** and **7**. Several points can be made about these reactions.

First, the isomers react with very different efficiencies with an order of reactivity of **6** (*para*) > **7** (*meta*) > **8** (*ortho*). Estimates of the relative reactivity of the isomers from low conversion data are **6**:**7**:**8** = 32:4:1; moreover, the reactions do not occur with high efficiency. Quantum yields of disappearance for **6** and **7** were only 0.025 and 0.003, respectively. Second, a photostationary state can be reached starting with either **6** (*para*) or **7** (*meta*) which is the same for both: 7% *para*, 26% *meta*, and 67% *ortho*. The *ortho* isomer reacts too slowly to reach this photostationary state, and the mass balance slowly drops. Third, low conversion data indicate that both 1,2- and 1,3-phototranspositions are occurring in the primary photochemical event. Thus, from Figure 46.1, in the photolysis of **6** (*para*) both the **7** (*meta*) and the **8** (*ortho*) isomers are being formed simultaneously in a ratio of 4.2:1. No delay in the formation of the

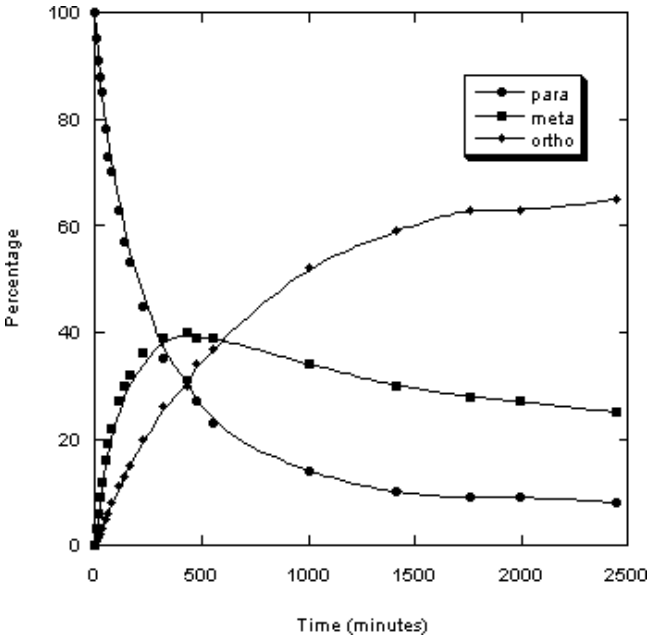


FIGURE 46.1

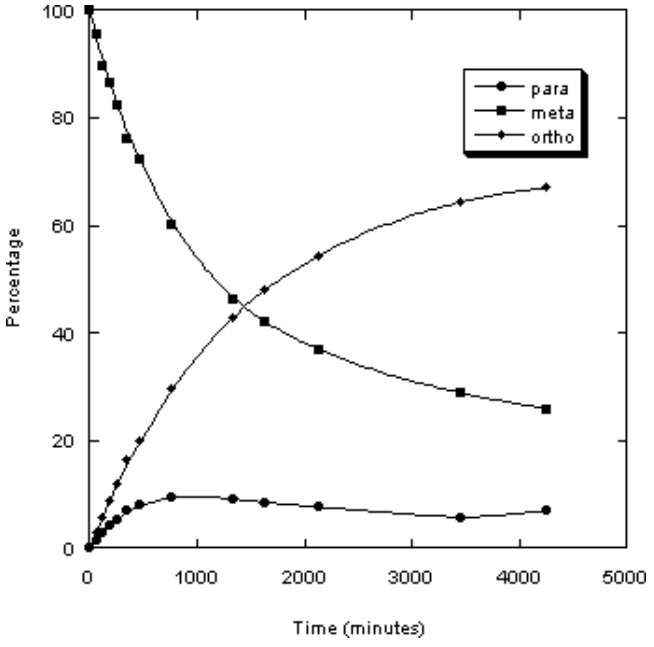

FIGURE 46.2

ortho isomer is observed as would be required if it were formed by secondary photochemistry of the *meta* isomer. Fourth, combining the efficiency data and the initial product ratios with molar absorptivity values for each isomer allows an estimate of the relative efficiencies for all six conversions in the photoequilibration process. These are shown in Scheme 1, scaled to a value of 1 for the least efficient process,

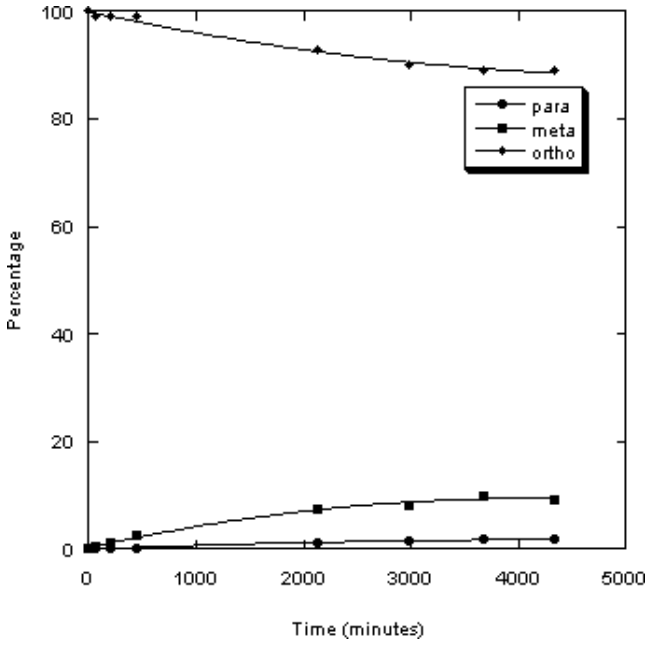

FIGURE 46.3

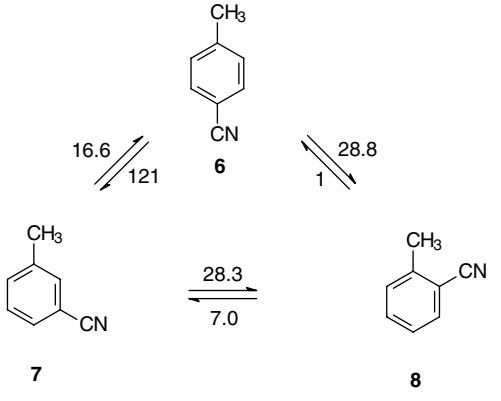
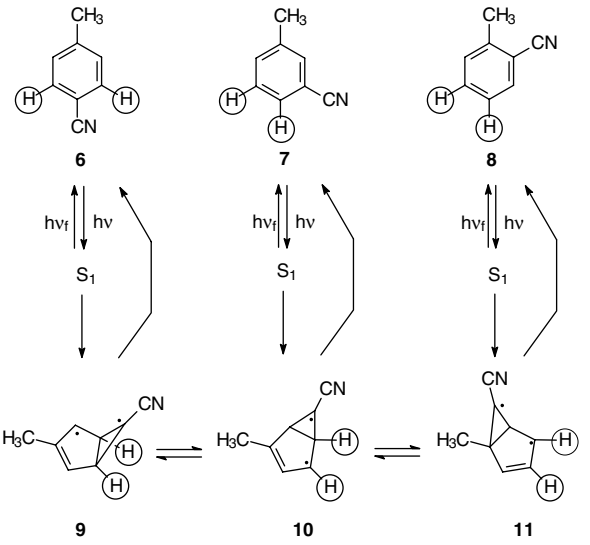


SCHEME 1

conversion of the **8** (*ortho*) to **6** (*para*). By contrast, the most efficient process, conversion of the **6** (*para*) to **7** (*meta*), has a relative efficiency of 121. As expected for a photoequilibration, the most reactive isomer (*para*) reaches the lowest yield (7%) at equilibration. Finally, diene quenching studies indicated that the phototranspositions occur from the excited singlet state, not the triplet state.

In order to determine if a specific carbon was the critical one in the phototransposition reactions of these aromatic nitriles, 2,6-dideutero-4-methylbenzonitrile **6**-d_2 was examined. This substrate has all of the chemically distinct carbons labeled with a substituent so that their positions in the phototransposition can be monitored. As shown in Eq. (46.8), only the cyano-substituted carbon undergoes phototransposition, giving the specifically labeled products **7**-d_2 and **8**-d_2 (as determined by ^{13}C nuclear magnetic resonance [NMR] spectra of reaction mixtures).



SCHEME 2

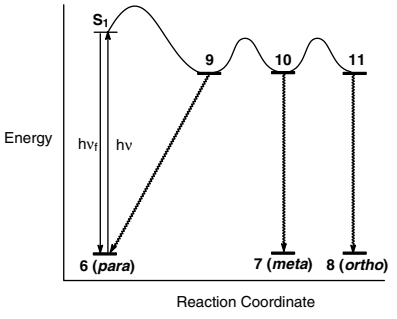


FIGURE 46.4

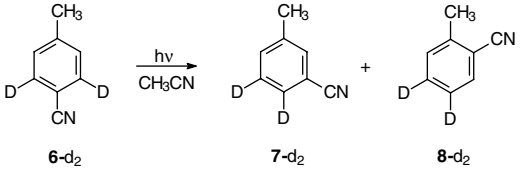
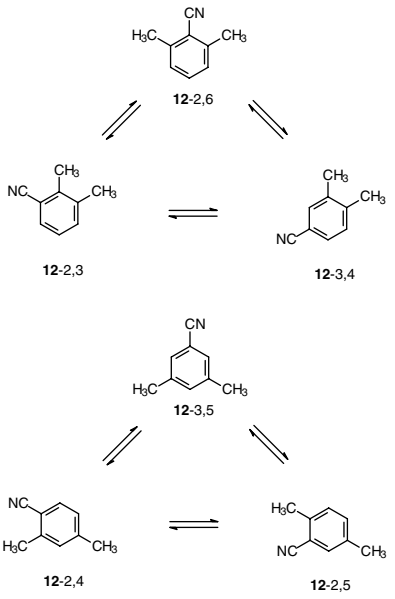


(46.8)

On the basis of these results, we proposed the mechanism outlined in Scheme 2 and the potential energy surface (Figure 46.4). Excitation of the **6** (*para*) isomer, for example, gives S_1, which is a spectroscopic minimum as determined by fluorescence measurements ($\Phi_f = 0.16$, $\tau_s = 9.1$ ns, $E_{0,0} = 101$ kcal/mol). The S_1 state either decays to S_0 or undergoes *meta* bonding to give the biradical **9** (analogous to the "pre-fulvene biradical" proposed for benzene photochemistry). The cyano-substituted carbon then migrates around the periphery of the other five carbons, allowing for the equilibration of the biradicals **9**, **10**, and **11**. By breaking the bridgehead sigma bond, each of these biradicals (presumably ground-state singlets) can return to its corresponding aromatic isomer.



SCHEME 3

Excitation of either of the other isomers puts it on the same surface that equilibrates **9**, **10**, and **11**, although the barrier and thus the efficiency for getting to this surface may be very dependent on the starting isomer. We are in the process of studying the effect of temperature on these phototransposition reactions to see if we can obtain a better understanding of both the barriers on the surface that connects S_1 of each of the isomers to the biradicals and, as well, the surface connecting **9**, **10**, and **11**. We are also attempting high-level MO calculations to see if they would be helpful in understanding these surfaces.

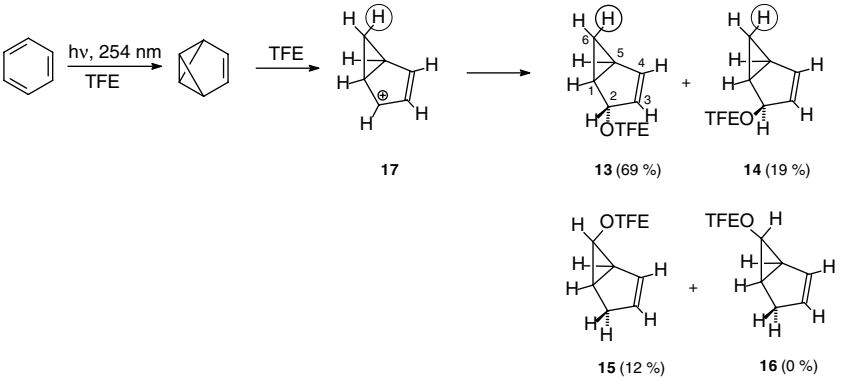
In contrast to the excited-state behavior of benzene- and alkyl-substituted benzenes, where benzvalenes are proposed as the critical intermediates, we have not included them in the mechanism. The observation of both 1,2- and 1,3-phototranspositions in the primary photochemical event requires intermediates like the biradicals proposed.

This proposal is also supported by the photochemistry of the six dimethylbenzonitriles, **12**.[26] These six isomers also photoequilibrate in acetonitrile but in two independent triads. The first triad is comprised of **12**–2,6, **12**–2,3, and **12**–3,4; the second triad is **12**–3,5, **12**–2,5, and **12**–2,4 (Scheme 3). Phototransposition converts the members of one triad to other members of the same triad, although only **12**–3,4 was reactive enough to approach a steady-state ratio. This observation again can be explained if only the cyano-substituted carbon is involved in a transposition reaction with the other five carbons of the ring.

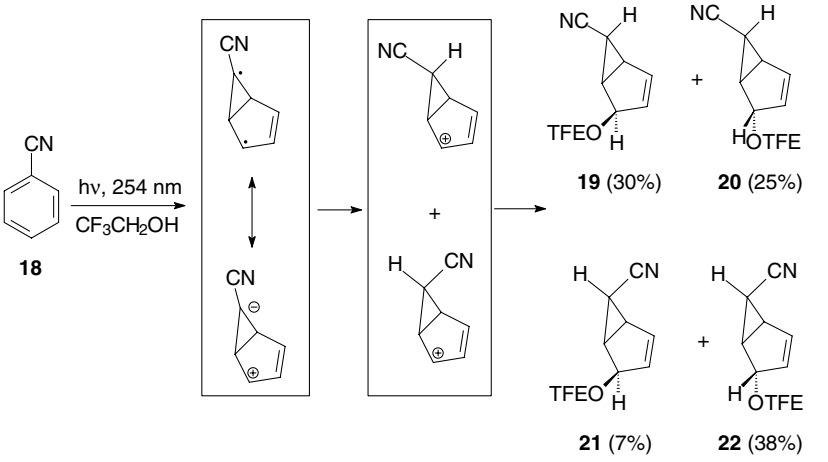
A similar observation has been made for the photochemical transposition reactions in the gas phase of the six isomers of dimethylpyridine.[27] For these compounds, the mechanistic proposal is that the nitrogen atom is the unique one that forms the one-atom bridge in the 6-aza-bicylo[2.1.0]hexenyl biradical and that it migrates around the periphery of the five carbon atoms.

46.3 Photochemistry of Benzonitrile 18 in 2,2,2-Trifluoroethanol[24]

A better understanding of the structure and reactivity of the bicyclic diradical intermediates, **9**, **10**, and **11** proposed in the previous section in Scheme 2 is available from trapping results with TFE, chosen on the basis of literature precedent.[13] We began by repeating and confirming the previous reports, (see Eq. (46.5)[15] on the photochemistry of benzene in TFE (Scheme 4). At low conversion, the major products are **13** and **14**. In agreement with the previous report, by monitoring at low conversions, product **15** was



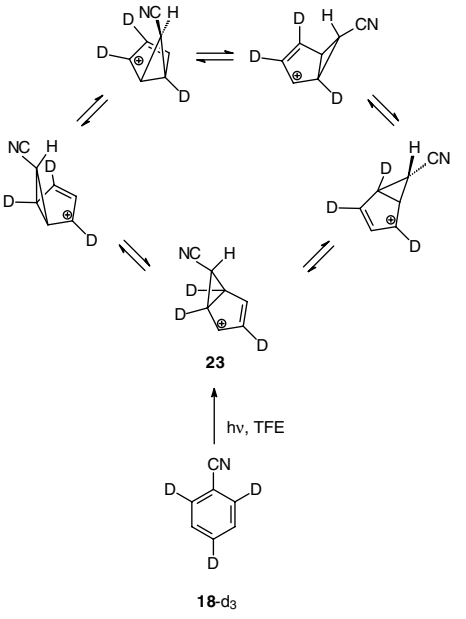
SCHEME 4



SCHEME 5

found to be a secondary product derived from the photochemistry of **13** and/or **14**. We saw no evidence for formation of the fourth possible isomer **16**. Photolysis of benzene-d_6 in TFE gave the same three products but they now contained only the one proton derived from the solvent. By ^{1}H NMR coupling constants in the cylopropyl ring (~7 Hz when the hydrogen at C6 is *exo* and ~3 Hz when it is *endo*), that proton was clearly at C6 and *endo* in both **13** and **14** (circled in Scheme 4). This result is in agreement with the previously proposed (see Eq. (46.5)) and accepted mechanism, that formation of the alcohol addition products in benzene photochemistry results from *endo* protonation of benzvalene followed by *exo* (major) and *endo* (minor) trapping of the bicyclic allylic cation **17** by TFE.

Photolysis of benzonitrile **18** in TFE gave the four primary photoproducts **19** to **22** as shown in Scheme 5. Because the proton at C6 is solvent derived, the fact that it is observed to be both *endo* (**19** and **20**) and *exo* (**21** and **22**) suggests that a substituted benzvalene is not the critical intermediate. In fact, this observation is in agreement with our mechanistic proposal in Scheme 2, that the important intermediate is analogous to the open singlet "biradicals" **9**, **10**, and **11**. These singlet "biradicals" are expected to have considerable ionic character with negative charge at the cyano-substituted carbon (Scheme 5). Trapping of this zwitterion by TFE protonation at C6, followed by reaction with the nucleophile, gives the observed products.



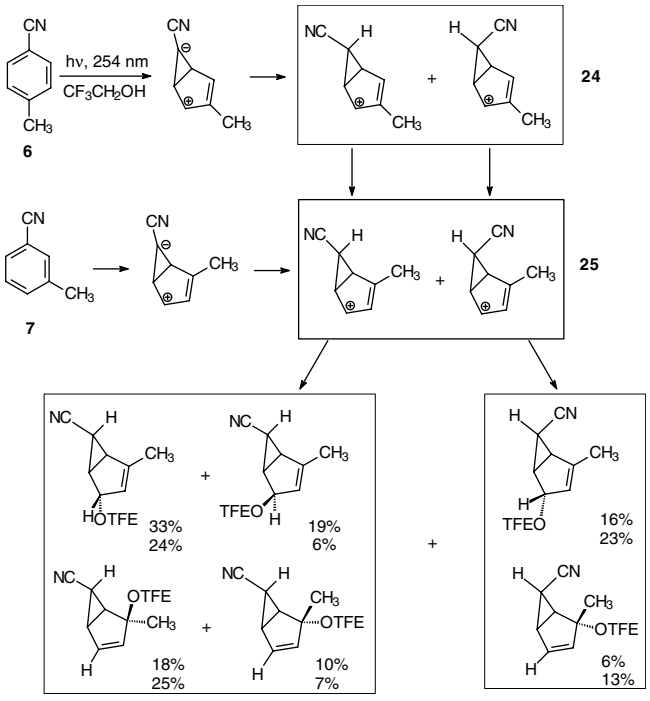
SCHEME 6

Because deuterium substitution had proven to be a useful mechanistic probe for understanding the phototransposition reactions of the methylbenzonitriles, we also examined the deuterated isomer, 2,4,6-trideuteriobenzonitrile, **18**-d_3. Our expectation was that the products would be as in Scheme 5, except specifically deuterated at C1, C3, and C5, if formed from the intermediate **23** (Scheme 6). Indeed, the products had the expected structures, but the deuterium atoms were equally distributed among all five of the carbons C1 to C5 in each of isomeric products **19** to **22** (Scheme 5). This observation can be explained by rapid equilibration of the bicyclo[3.1.0]hexenyl cations by an allowed thermal 1,4-sigmatropic shift. This pathway requires inversion of configuration of the migrating carbon, C6, which keeps the H *endo* (as shown in Scheme 6) leading to **19** and **20** or *exo* leading to **21** and **22**. Therefore, the stereochemistry of the original protonation of the zwitterion determines the stereochemistry of **23** and the final products but not the deuterium distribution. This rearrangement must be very fast to compete with trapping of the cation by TFE. Rapid equilibration of similar cations has been observed previously by NMR. For instance, the heptamethyl derivative has a free energy of activation for rearrangement of only 9 kcal/mol at –89°C.[28]

46.4 Photochemistry of 4-, 3-, and 2-Methylbenzonitrile (6, 7, and 8) in TFE[24]

With an understanding of the photochemistry of benzonitrile in TFE, we next proceeded to the three methyl substituted isomers. The results are shown in Scheme 7. The first point of interest is that no phototranspositions were observed. Instead, reaction with TFE occurred to give a mixture of six addition products that were characterized by ^{1}H and ^{13}C NMR. Second, the same products were obtained from both **6** (*para*) and **7** (*meta*), although in somewhat different ratios. The yields are shown as normalized percentages in Scheme 7, the first number from **6** as substrate and the second from **7**. Again, **8** (*ortho*) was essentially photochemically inert.

These observations are consistent with the previously proposed mechanism for benzonitrile (Schemes 5 and 6). Trapping of the biradical/zwitterion by protonation must be faster than rearrangement because phototranspositions are not observed. The two zwitterions formed, one from 3-methyl and one from



SCHEME 7

4-methylbenzonitrile, will be different but both are protonated either *exo* or *endo* at C6 (Scheme 7). Once formed, the cations will undergo the 1,4-sigmatropic equilibration, but now the five possible cations are not degenerate because of the methyl substitution. The stable ones will have the methyl group at the terminal end of the allylic cation, **25** *exo* and *endo*, rather than **24** *exo* and *endo*. Trapping of **25** by TFE gives the six stereoisomers. The missing isomers are those with both the cyano and TFE groups *endo*.

Photochemical *meta* cycloaddition reactions of benzonitrile and the methylbenzonitriles with alkenes and dienes have been reported previously, and the results are summarized in a recent review.[9] Examples include benzonitrile itself with seven alkenes and dienes (Table 2 in Reference 9) and each of the three isomeric methylbenzonitriles with *E*-1,2-dichloroethene, furan, and cyclopentene (Table 3 in Reference 9). In all cases, cycloadditions were observed to give, along with other products, the dihydrosemibullvalenes expected from the trapping of a bicyclic intermediate analogous to that proposed for the phototranspositions and photoadditions to TFE. However, none of these products resulted from an intermediate that had the cyano group at C6.

This observation indicates that the two reactions are quite different mechanistically. The orientation in cycloadditions of alkenes and dienes apparently proceeds by a polarization of S_1 of the arene by the approach of the alkene or diene. This polarization is determined by substituent stabilization of developing charges. For the phototranspositions and photoadditions of TFE reported here, S_1 of the arene is assumed to undergo a unimolecular deformation to a reactive intermediate before rearrangement or trapping.

46.5 The Phototranspositions in Acetonitrile and the Photoaddition of TFE to Substituted Benzenes: A Survey[25]

Because the reactions described previously are providing fundamental information about how substitutents affect the geometry and reactivity of substituted aromatics, a survey of substituents was undertaken. The results are summarized in Table 46.1 and Figure 46.5.

TABLE 46.1 Summary of Phototranspositions (PTs) in Acetonitrile and Photoadditions (PAs) of TFE of Substituted Benzenes, C_6H_4XY

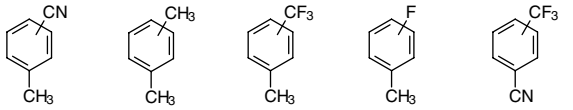
Compound	X	Y	Isomer	Phototranspositions	Photoadditions
Benzene	H	H	—	Yes, with 1,3,5-d_3[a]	Yes, *endo*[b]
Toluene	CH_3	H	—	—	Yes, *endo*[b]
Anisole	CH_3O	H	—	—	No
Fluorobenzene	F	H	—	—	No
Benzonitrile (**18**)	CN	H	—	—	Yes, *endo* + *exo*[b]
Trifluoromethylbenzene	CF_3	H	—	—	Yes, GC/MS only
Methyl benzoate	CO_2CH_3	H	—	—	No
Xylene	CH_3	CH_3	*ortho*	*meta:para* = 11:1[c]	Yes, *endo*[b]
			meta	*ortho:para* = 6.0:1[c]	No stable products[d]
			para	*meta:ortho* > 25:1[c]	No stable products[d]
				ortho:meta:para = 1:1.4:0.3[d]	
Methylbenzonitrile (**6**, **7**, **8**)	CH_3	CN	*ortho*	*meta:para* = 7.1:1[c]	No[e]
			meta	*ortho:para* = 1.7:1[c]	Yes
			para	*meta:ortho* = 4.2 :1[c]	Yes
				ortho:meta:para = 1:4:32[d]	
Methylanisole	CH_3	OCH_3	*ortho, meta, para*	No	No
Methoxybenzonitrile	OCH_3	CN	*ortho, meta, para*	No	No
Dicyanobenzene	CN	CN	*ortho, meta, para*	No	No
Methyl 4-toluylsulfone	CH_3	SO_2CH_3	*para*	No	No
Trifluoromethyltoluene	CH_3	CF_3	*ortho*	*meta:para* > 10:1[c]	Yes, GC/MS only
			meta	*ortho:para* = 0.25[c]	Yes, GC/MS only
			para	*meta:ortho* > 20:1[c]	No
				ortho:meta:para = 1:0.67: 0.16[d]	
Trifluoromethylbenzonitrile	CF_3	CN	*ortho*	*meta:para* = 1.7:1[c]	No
			meta	*ortho:para* = 0.81:1[c]	No
			para	*meta:ortho* = 7.2:1[c]	No
				ortho:meta:para = 1:2.7:3.1[d]	
				In both acetonitrile and TFE	
Fluorotoluene	CH_3	F	*ortho*	Very slow	No
			meta	*ortho:para* = 5.0:1[c]	No
			para	Very slow	No

[a] Reference 15.
[b] Stereochemisty of the proton at C6 of the bicylo[3.1.0]hexene products; *endo* only implies a benzvalene intermediate.
[c] Product ratio at very low conversion; high values from the *ortho* or *para* starting material suggest that 1,2-transpositions dominate.
[d] Relative reactivity.
[e] Reference 25.

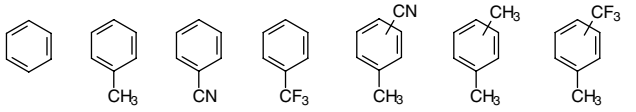
For benzene and monosubtituted benzenes, in the absence of deuterium substitution, only TFE additions can be observed. These additions occur for benzene and alkylbenzenes as well as those that are substituted with electron-withdrawing groups (CN, CF_3) but not electron-donating groups (CH_3O). Unfortunately, the addition products to trifluoromethylbenzene were not characterized because even evaporation of the solvent resulted in non-analyzable (^{1}H NMR) decomposition products (oligomers?). For the disubstituted arenes, electron-withdrawing groups again seemed to favor both phototranspositions and photoadditions of TFE. The trifluoromethyltoluenes **26** (*para*), **27** (*meta*), and **28** (*ortho*) are perhaps the most interesting.

Plots for the phototransposition of these three compounds in acetonitrile are shown in Figures 46.6, 46.7, and 46.8, respectively. In comparison with the three methylbenzonitriles in Figures 46.1 to 46.3, several points are noteworthy. First, the reactions of the trifluoromethyl arenes are faster, with photostationary states being reached in about a tenth of the time. Second, the photostationary state reached is comprised of 9% *para*, 37% *meta*, and 55% *ortho* (i.e., *ortho* is the dominant isomer). The reverse was observed for the methylbenzonitriles (i.e., *para* was the dominant isomer). Finally, examination of product

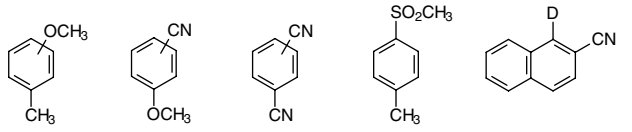
1. Substrates that isomerize in acetonitrile.



2. Substrates that form addition products with TFE.



3. Substrates that do not isomerize in acetonitrile



4. Substrates that do not form addition products with TFE.

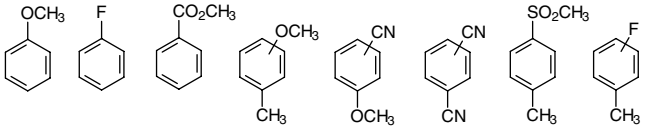


FIGURE 46.5

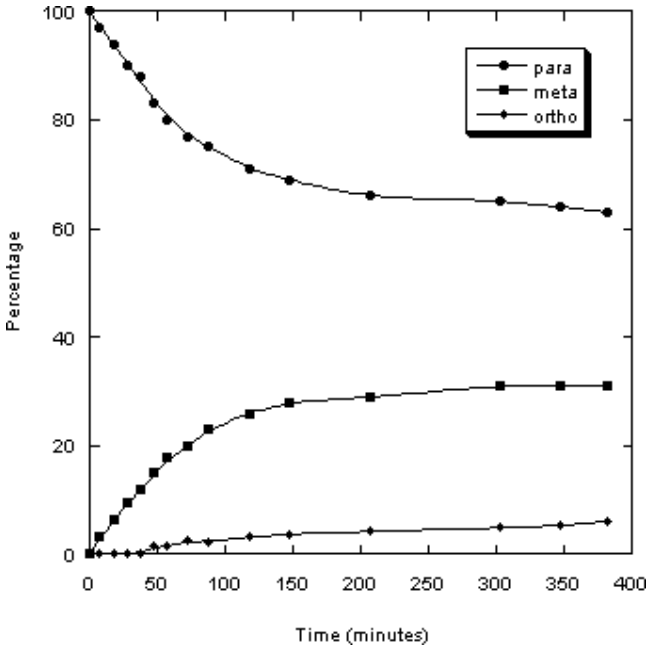

FIGURE 46.6

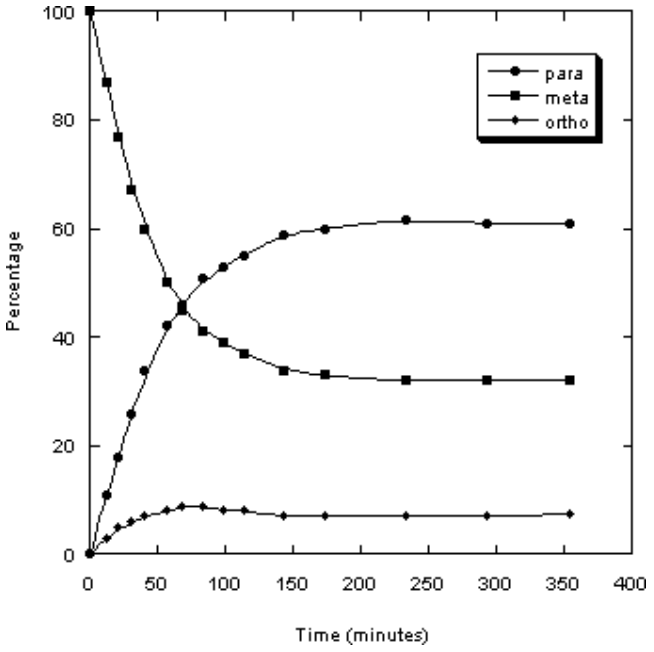

FIGURE 46.7

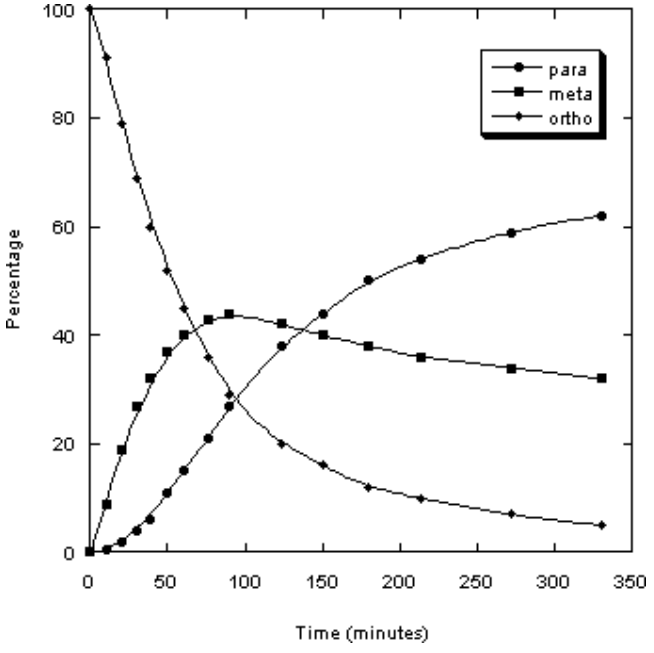

FIGURE 46.8

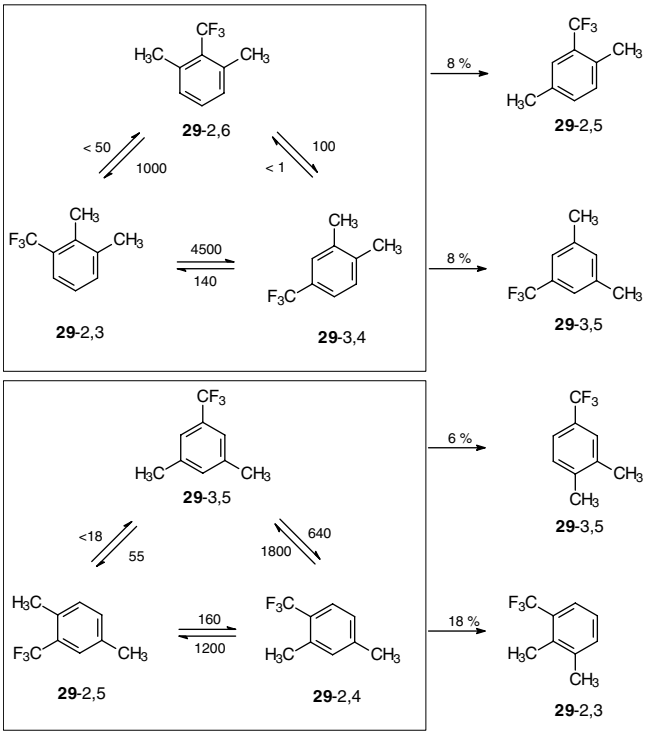
ratios at very low conversions indicated that 1,2-phototranspositions were much favored over 1,3-. The ratio of *meta*:*para* from *ortho* was greater than 10:1, and the *meta*:*ortho* ratio from *para* was greater than 20:1. These observations suggest that benzvalene intermediates, which allow only 1,2-transpositions, may be more important than for the benzonitriles. The fact that the stable hexa(trifluoromethyl)benzvalene can be



SCHEME 8

isolated from the photochemistry of hexa(trifluoromethyl)benzene indicates that trifluoromethyl groups clearly stabilize these strained σ-bonds.[29] The best probe for benzvalene intermediates would be the stereochemistry (*endo* vs. *exo*) of the protonation in the TFE. Unfortunately, these photoadducts could be observed (by gas chromatography/mass spectrometry [GC/MS]) but not characterized. Another interesting observation in Table 46.1 for the three trifluoromethybenzonitriles is that they undergo phototransposition reactions in both acetonitrile and TFE.

46.6 Photochemistry of the Six Isomers of Dimethylbenzotrifluoride 29 in Acetonitrile[30]

In order to probe which of the substituents was responsible for the phototransposition reactions of trifluoromethyl substituted benzenes, the six isomers of dimethylbenzotrifluoride **29** were synthesized and their photochemistry in acetonitrile examined (Scheme 8). This scheme is analogous to that for the dimethylbenzonitriles in Scheme 3 with the advantage that the reactions are more efficient and go to equilibrium for most substrates. An example is shown in Figure 46.9 for 2,4-dimethylbenzonitrile. These results are summarized in Table 46.2, where the time required for 10% conversion of the substrate is given along with the ratio of the major products from each. The major photochemical process (Figure 46.9, upper three traces) again divides the isomers into the two triads of Scheme 8, demonstrating that the trifluormethyl-substituted carbon is the principle one responsible for phototransposition. Using the relative efficiencies and the product ratio for each isomer allows a relative scale of reactivities for each of the 12 possible conversions to be evaluated (shown with each arrow in Scheme 8), arbitrarily scaled to a value of 4500, the most efficient process, for conversion of **29**–2,3 to **29**–3,4. The values range from <1 to 4500. This large range means that the substrates with the lower reactivity would appear to be photostable unless one was specifically looking for phototranspositions.

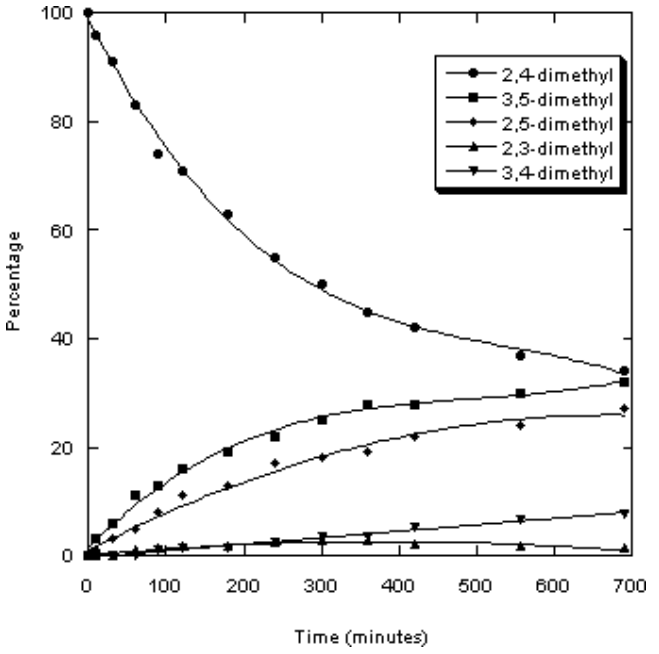


FIGURE 46.9

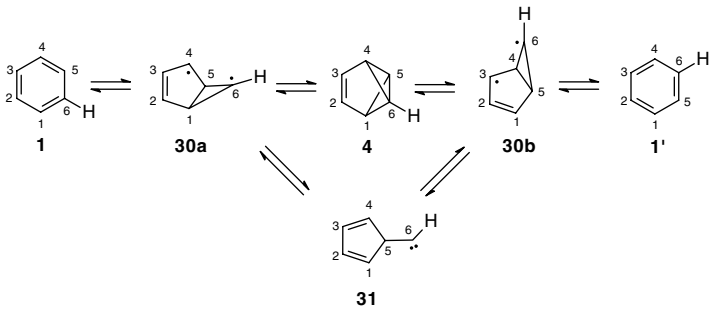
TABLE 46.2 Photolysis of Dimethylbenzotrifluorides 29 in Acetonitrile

Isomer	Time for 10% Conversion (minutes)	Major Products and Their Ratio at Low Conversion	Leakage
29–2,6	80	**29**–2,3 : **29**–3,4 = 10	**29**–2,5 = 8%
29–2,3	20	**29**–3,4 : **29**–2,6 > 100	—
29–3,4	665	**29**–2,3 : **29**–2,6 > 100	**29**–3,5 = 8%
29–3,5	130	**29**–2,4 : **29**–2,5 = 12	**29**–3,4 = 6%
29–2,4	30	**29**–3,5 : **29**–2,5 = 1.6	**29**–2,4 = 18%
29–2,5	500	**29**–2,4 : **29**–3.5 > 50	—

An important point to make is that some potentially efficient processes will be invisible. For instance, the two least reactive compounds, **29**–3,4 and **29**–2,5, could be interchanging the CF_3-substituted carbon with the neighboring H-substituted carbon with no net structural change. The two steps that may be the most important ones in controlling these reactivities are (1) formation of the bicyclic biradical with the CF_3 group at C6, and (2) migration of that carbon. Overall, the fastest process of the 12 possible ones is that which converts, in a 1,2-transposition step, the sterically crowded **29**–2,3 to **29**–3,4. Conversion of the other sterically congested isomer **29**–2,6 to **29**–2,3 is somewhat slower (1:4), perhaps because the cyclopropyl ring of the intermediate bicyclic biradical will be trisubstituted, as opposed to disubstituted from **29**–2,3; therefore, its efficiency of formation is slower. The slowest process, conversion of **29**–3,4 to **29**–2,6, is the one that makes this most congested isomer. The most reactive compound in the lower triad of Scheme 8 is **29**–2,4, which again will generate a cyclopropyl intermediate that is disubstituted. We conclude that the CF_3 group is necessary to form the reactive biradicals because of the requirement for an electron withdrawing group at C6 and that methyl substitution on the cyclopropyl ring also helps. Relief of steric congestion is also an important factor.

In parallel with the major photochemical events, some of the substrates show leakage from one triad to the other. This is shown in Figure 46.9 (lower two traces), where leakage gives **29**–2,3 which then



SCHEME 9

undergoes its own phototransposition, mainly to **29**–3,4. These leakage processes, along with the percentage of this pathway, are given in Table 46.2 and shown on the right-hand side of Scheme 8. These processes represent transposition of the methyl-substituted carbons, an example of the first phototransposition ever reported,[10] the isomerization of the xylenes. They provide a minor but significant perturbation in the triads. The relative reactivity of the xylenes in acetonitrile are 1:1.4:0.3 for *ortho*, *meta*, and *para*, respectively.[25] In fact, all of the leakage processes are from the more reactive isomers, three from *meta* dimethyl substrates (**29**–2,5, **29**–3,5 and **29**–2,4) and the fourth from an *ortho* isomer (**29**–3,4).

46.7 Molecular Orbital Calculations

Clearly, computational results could be helpful in understanding the effect that these substituents have on the processes that begin with excitation from S_0 to S_1 followed by conversion of S_1 along the potential energy surface that leads to biradicals, benzvalenes, and other intermediates. Recent high-level calculations for these pathways have been reported for benzene itself and serve as a useful starting point.

Bernardi et al.[31] have reported an MC-SCF study of the S_1 and S_2 surface for benzene. The interest in the S_2 surface is a consequence of the fact that this state leads to Dewar benzene **5**, along with benzvalene **4**. In contrast, S_1 is converted only to benzvalene, which is more relevant to our experimental observations in solution. On the S_1 surface, using a 4–31G basis set, the only minimum found was the initially formed excited state, 110.9 kcal/mol above the ground state, still of D_{6h} symmetry but with slightly longer bond lengths, 1.43 Å vs. 1.39 Å and a C1 to C5 distance of 2.48 Å. A transition state, with a shorter C1 to C5 distance of 2.06 Å leading toward the bicyclic biradical, was found at 133.9 kcal/mol (23.0 kcal/mol above S_1) which proceeds through a conical intersection to the ground state of the biradical where the surface is very flat and has several minima and transition states separated by only a few kcal/mol. The minimum on this flat region, a prebenzvalene diradical **30a** (C1 to C5 distance of 1.60 Å) (Scheme 9), at 125.0 kcal/mol does not have C_s symmetry but is slightly distorted towards benzvalene. The barrier (only 0.12 kcal/mol higher than this minimum) to benzvalene (104.2 kcal/mol) is very small; the barrier to benzene **1**, also small, is only 1.4 kcal/mol. In a second publication from the same groups,[32] dynamics calculations and semiclassical surface-hopping trajectories were used. These methods showed that only a small fraction of the trajectories proceed along the reaction path from S_1 through the conical intersection to the prefulvene biradical. Most trajectories result in return to S_0 of benzene.

Although phototransposition reactions were not discussed in these papers, these computational results suggest a reasonable pathway from S_1 to **30a** over a small barrier (0.12 kcal/mol) to benzvalene **4** and then over a 20.9 kcal/mol barrier to **30b** (Scheme 9). If **30a** returns to benzene, no transposition will occur, but if **30b** does then C5 and C6 are interchanged, leading to transposition if suitable labels are attached to the carbons. In fact, conversion of **4** to **30b** may not be necessary as there is experimental[33] and computational evidence[34] that this conversion of **4** to benzene occurs by concerted pathway of lower energy that does not involve biradicals. For some substituents, conversion of **30a** to **30b** may occur

without the intervention of a benzvalene. Finally, photolysis in TFE would result in rapid trapping of **30a** to give the photoaddition products, thus preventing phototransposition.

In a more recent publication, von R. Schleyer[34] and co-workers examined the ground-state surface for benzene pyrolysis using CCSD calculations to obtain energies. The transition state (100.9 kcal/mol above benzene) for the concerted conversion of benzvalene to benzene is quite asymmetric, the two breaking bonds differing in length by 0.6 Å (2.32 and 1.70 Å), and an E_a of 29.3 kcal/mol was calculated. They also point out that biradical structures such as **30** in Scheme 9 have several possible geometries, **30**-*exo* and **30**-*endo* for the hydrogen at C6, with and without C_s symmetry, all being very close in energy to the transition state. The relative energy of these structures and whether they are minima or not is dependent on the method of calculation.

Another intermediate that has been found on this surface is 2,4-cyclopentadienylcarbene **31**, identified as a key intermediate in the photochemical conversion of benzene **1** to fulvene **2**.[34] Again, several geometries are possible for **31** with the hydrogen at C6 *exo* and *endo*. The *endo* form (107.1 kcal/mol above benzene) is more stable, but a stable form of the *exo* species could not be located as it always collapsed to benzvalene. The structure of the *endo* form is also asymmetric, indicating a hyperconjugative interaction between the carbene center and one of the sigma bonds of the cyclopentadiene ring. This carbene exists in a shallow minimum with low energy barriers to benzene **1** (7.6 kcal/mol), benzvalene **4**, (2.6 kcal/mol), and fulvene **2** (4.6 kcal/mol). In agreement with experiment,[36] collapse to benzvalene is the lowest energy pathway. For the phototransposition reaction, the carbene could also be an intermediate/transition state that connects the two biradical structures (Scheme 9).

For the photoadditions of TFE to benzene and substituted benzenes, cyclopentadienyl carbenes are also possible as intermediates. Protonation will result in the formation of cyclopentadienylmethyl cations. These primary cations would be expected to collapse to the more stable allylic ones (i.e., **17** in Scheme 4), which will be relatively long lived, as the thermal opening to the benzenium ion, although exothermic, is thermally forbidden. In fact, the activation energy for this process has been estimated at 19 kcal/mol at –20°C.[37]

These calculations demonstrate that the potential energy surfaces connecting these intermediates are difficult to evaluate because of the very small energy differences between the various possibilities. Substituents will likely have a significant perturbing effect on their relative stabilities. We are in the process of doing such calculations on substituted (CN, F, OH) cases.

46.8 Summary

The reactions described are clearly giving fundamental information about changes in electron distribution and geometry that occur on excitation of substituted benzenes to S_1. Because electron-withdrawing groups seem to be the most effective at inducing these reactions, we plan to examine other examples. As well, traps other than TFE are being examined with the idea that the addition products might be more easily characterized. Intramolecular traps are also of interest. As the opening sentence of this review states, excited states of aromatics are indeed "extremely flexible and extrovert acrobatics."

The Photostimulated $S_{RN}1$ Process: Reaction of Haloarenes with Carbanions

Roberto A. Rossi
Universidad Nacional de Córdoba

Alicia B. Peñéñory
Universidad Nacional de Córdoba

47.1 Introduction

For unactivated aromatic and heteroaromatic substrates, where a polar substitution is not favorable, nucleophilic substitution is feasible through processes that involve electron transfer (ET) steps. In these reactions, an aromatic compound bearing an adequate leaving group is substituted at the *ipso* position by a nucleophile in a unimolecular radical nucleophilic substitution mechanism (or $S_{RN}1$), which is a chain process that involves radicals and radical anions as intermediates.

The process has a considerably wide scope in relation to substrates, nucleophiles, and synthetic possibilities. In addition to halides, other leaving groups are known, such us $(EtO)_2P(O)O$, RS (R = Ar, alkyl), $ArSO_2$, PhSe, RSN_2 (R = *t*-Bu, Ph), N_2BF_4, R_3N^+). For substrates having two leaving groups, disubstitution by the same nucleophiles can be obtained.

Many substituents are compatible with the reaction, such as alkyl groups, OR, OAr, SAr, CF_3, CO_2R, NH_2, NHCOR, NHBoc, SO_2R, CN, COAr, NR_2, F, among others. Even though the reaction is not inhibited by the presence of negatively charged substituents such as carboxylate ions, other charged groups such

as oxyanions hinder the process. In general, substituents such as NO_2 groups are not suitable for $S_{RN}1$ substitution on aromatic substrates.

Some of the most common nucleophiles through which a new CC bond can be formed are carbanions from hydrocarbons, nitriles, ketones, esters, *N*,*N*-dialkyl acetamides and thioamides, and mono- and dianions from β-dicarbonyl compounds. The synthesis of indoles, isocarbostyrils, isoquinolines, benzazepines, binaphthyls, etc. and an important number of natural products has been achieved by ring closure reactions of carbanions with suitable substrates through the $S_{RN}1$ mechanism. Several reviews have been published in relation to aromatic $S_{RN}1$ reactions[1–4] and to the synthetic applications of the process.[5,6]

47.2 Mechanism

The $S_{RN}1$ mechanism is a chain process, for which the main steps are presented in Scheme 1. Overall, Eqs. (47.1) to (47.3) depict a nucleophilic substitution in which radicals and radical anions are intermediates.

This chain process requires an initiation step. Among the methods used for initiation we find the formation of the radical anion of the substrate by the reaction with alkali metals in liquid ammonia or electrochemical initiation at a cathode; however, the most extensively used method is photoinitiation. Other approaches include the use of Fe^{+2}, SmI_2, or Na(Hg). In a few systems, a thermal (spontaneous) initiation is observed.

Once the radical anion of the substrate is formed, it fragments into a radical and the anion of the leaving group (Eq. (47.1)). The aryl radical can react with the nucleophiles to furnish a radical anion (Eq. (47.2)) that, by ET to the substrate, forms the intermediates required to continue the propagation cycle (Eq. (47.3)). The mechanism has termination steps that depend on the substrate, the nucleophile, and experimental conditions. Not many initiation events are needed, but in this case the propagation cycle must be fast and efficient to allow for long chains to build up.

The most common mechanistic evidence used is inhibition by radical traps such as di-*t*-butylnitroxide (DTBN), 2,2,6,6-tetramethyl-1-piperidinyloxy (TEMPO), galvinoxyl, oxygen, etc., as well as by good electron acceptors such as *p*-dinitrobenzene (*p*-DNB). To assess the formation of radicals along the propagation cycle, radical probes have also been used which afford products derived from ring closure, ring opening, and rearrangement of the radicals.

A reaction between a nucleophile and an aryl halide may be rather unreactive at initiation but quite reactive at propagation. The addition of tiny amounts of another nucleophile that is more reactive in the photoinitiated step increases the generation of the reactive intermediates and allows the less reactive nucleophile to start its own propagation.

47.3 Photochemical Initiation

Photoinitiation is one of the most widely used methods and has proven extremely suitable for synthetic purposes. Spontaneous or thermal ET is a possible initiation whenever the substrate is a very good electron acceptor and the nucleophile a very good electron donor.

The enolate ions of aliphatic ketones can react in the dark with iodobenzene and its derivatives in DMSO.[7,8] The occurrence of these spontaneous initiations is facilitated by the electron affinity of the substrates and the ~55°C increment in temperature with respect to liquid ammonia in which no dark reaction takes place. Other substrates that can react in the dark with enolate ions of ketones are halo-substituted pyrimidines,[9,10] pyrazines,[10] pyridazines,[10] and quinoxalines.[11] Although some reactions occur in the dark, photostimulation is recommended to achieve higher yields of substitution in shorter reaction times.

Even though photoinduction is the most commonly used initiation method, not many studies on the mechanism involved have been reported. This step can involve ET within an excited charge-transfer complex (CTC) formed between the nucleophile and the substrate. This type of initiation has been proposed for the reaction of $^{-}CH_2COMe$ ions with iodobenzene and bromobenzene in DMSO,[12] for nitrile carbanions with haloarenes such as 2-bromonaphthalene or *p*-bromobiphenyl in liquid ammonia,[13] and in the reaction of iodobenzene[14] and PhSEt[15] with $(EtO)_2PO^-$ ions in DMSO and DMF, respectively. Acceleration by KI in the substitution of haloarenes with $(EtO)_2PO^-$ ions or with 2-naphthoxide ions has been explained on the same basis.[16,17] Initiation by a CTC has also been suggested for the photoinduced reaction of neophyl iodide with carbanions in DMSO.[18]

Electron transfer from excited nucleophiles is another possibility for initiation, as most of them show absorption at the wavelengths commonly used ($\lambda > 350$ nm). An example of this is the reaction of organic sulfides under laboratory light with Ph_2P^- ions that absorb strongly in the visible region ($\lambda = 475$ nm).[15] Further evidence for this type of initiation is the fluorescence quenching of the diphenylindenyl anion by bromobenzene.[19]

Initiation of the reaction of 1-chloro-2-naphthoxide anion with Na_2SO_3 has been proposed to occur by ET between the excited triplet state of the substrate and its ground state.[20] This reaction can be dye-photoinitiated[21] or initiated by visible light with a Ru complex as sensitizer and a Co complex as the intermediate electron carrier.[22] For the 1-bromo derivative, photohomolytic CBr bond dissociation is proposed.[23]

For a given aryl moiety, a rough correlation exists between the reduction potential and its reactivity in ET reactions.[24–27] The order of reduction potential in liquid ammonia, PhI > PhBr > $PhNMe_3I$ > PhSPh > PhCl > PhF > PhOPh, coincides with the reactivity order determined under photoinitiation. By using competition experiments of pairs of halobenzenes toward $^{-}CH_2COBu$-*t* ions under photoinitiation, the span in reactivity from fluorobenzene to iodobenzene was found to be about 100,000.[28]

Quantum yields of photoinitiated reactions have been used as a qualitative measure of the chain length. The quantum yields for substitution of haloarenes with nitrile-stabilized carbanions range from 7 to 31 in liquid ammonia.[13] Quantum yields from 50 to 20 have been determined for the substitution of halonaphthoxides and iodobenzene by $(EtO)_2PO^-$ ions.[14]

Nevertheless, the photoinduced initiation reaction may have a low quantum yield due to a fast backward ET that annihilates the ion pair before cage separation occurs. This will result in a poorly efficient source of radicals. In the case of nucleophiles reactive at the initiation and propagation pathways, the quantum yields for substitution (Φ_{global}) depend both on the efficiency of initiation and on the turnover in the propagation steps. Thus, the magnitude of the chain length of any $S_{RN}1$ reaction can easily be derived from the overall quantum yield by knowing the quantum yield of initiation. The latter could be obtained provided that the propagation cycle is eliminated or reduced significantly in comparison with the initiation step. The chain length can then be obtained from Eq. (47.4).

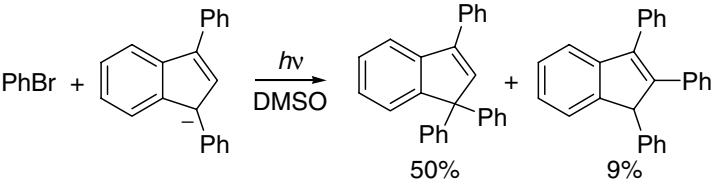
$$\text{Chain Length} = \Phi_{propagation} = \Phi_{global} / \Phi_{initiation} \tag{47.4}$$

The quantum yield for substitution of neophyl iodide by $^{-}CH_2COPh$ ion was determined to be 0.127.[18] The quantum yield of initiation, evaluated by suppressing the propagation steps with the presence of DTBN as radical trap, has a value of 10^{-3}. Based on both quantum yields, the chain length or $\Phi_{propagation}$ obtained for the reaction is approximately 127. This is the first report of $\Phi_{propagation}$, which is a direct

measure of the chain length for a $S_{RN}1$ process, demonstrating that overall quantum yields lower than unity cannot be taken as criteria for the absence of a chain reaction.

47.4 Carbanions Derived from Hydrocarbons

A relatively limited set of carbanions derived from hydrocarbons has been used as nucleophiles in $S_{RN}1$ reactions. In the photoinitiated reactions of indenyl, 1- and 2-phenyl-, 2,3- and 1,3-diphenylindenyl anions, products of mono-, di-, and triphenylation are formed. A higher yield of substitution is obtained with the 1,3-diphenylindenyl anion, which affords 1,1,3-triphenylindene as well as 1,2,3-triphenylindene:[19,29]



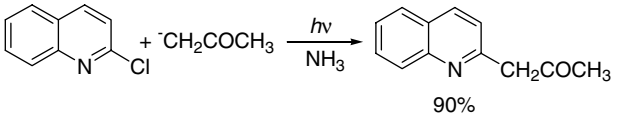
(47.5)

The products from the reaction of Ph_3C^- ion[30] with bromobenzene, iodobenzene, or diphenylsulfoxide and from cyclooctadienyl anion[31] with chlorobenzene, bromobenzene, 9-bromoanthracene, and 1-bromonaphthalene are explained on the basis of a $S_{RN}1$ type of mechanism.

47.5 Enolate Ions from Ketones

The enolate ions of acyclic and cyclic aliphatic ketones are among the most studied carbanions in photostimulated $S_{RN}1$ reactions. Absolute values of rate constants for the reactions of aryl radicals with nucleophiles have been determined electrochemically for a large number of cases. Most of the values are close to the diffusion limit. For instance, the range of rate constants for the coupling of 2-, 3-, and 4-cyanophenyl; 1-naphthyl; 3-pyridyl; and 3- and 4-quinolyl radicals with $^-CH_2COMe$ ions is on the order of 10^9 to 10^{10} M^{-1} s^{-1} in liquid ammonia.[26,32,33]

The solvents and the reaction conditions of choice are usually liquid ammonia or DMSO and irradiation. The enolate ions of acyclic aliphatic ketones such as acetone,[34–37] pinacolone,[37–40] 2-butanone,[41] 3-methyl-2-butanone,[41,42] 3-pentanone,[42,43] 4-heptanone,[43] and 2,4-dimethyl-3-pentanone[10,37,42,43] react through the $S_{RN}1$ mechanism with aryl and heteroaryl halides to afford the α-arylation products under photoinitiation. An example is shown in Eq. (47.6):



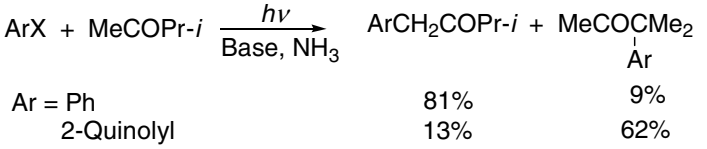
(47.6)

In some cases, α,α-diarylation can also occur but generally in low yields (< 15%).

The yield of substitution is highly dependent on the solvent. For instance, in the reaction of the enolate ion of acetone with 2-chloroquinoline (Eq. (47.6)) with the same reaction time, lower yields are obtained by changing the solvent from liquid ammonia (90%) to THF (82%), DMF (74%), dimethoxyethane (28%), diethyl ether (9%), or benzene (4%).[44] For this reason, the reactions are usually performed in liquid ammonia or DMSO under irradiation.

With unsymmetric dialkyl ketones isomeric enolate ions can be formed. The equilibrium concentration of the two possible enolates and the selectivity of the attacking radical mainly determine the distribution of the two possible arylated products.

For example, phenylation occurred preferentially at the more substituted α-carbon with the anion of 2-butanone (41 to 61%),[7,41] while, with the anion from *i*-propylmethylketone, the 1-phenyl derivative predominates.[41,45] However, the tertiary to primary substitution ratio obtained in the reaction of the same anion with 2-chloroquinoline is approximately 4.8 (Eq. (47.7)).[42] Substituents being located *ortho* to the leaving group of the substrate usually favors the attack at the primary α-carbon of the anion.[46,47]

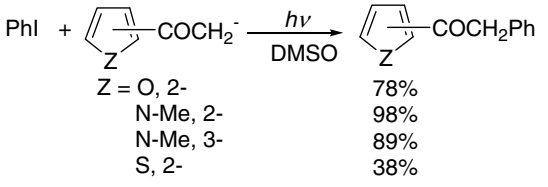


(47.7)

Anions of cyclic ketones can be α-phenylated.[37,43,48] No substitution product is formed with the enolate ion of cyclohex-2-en-1-one.[43]

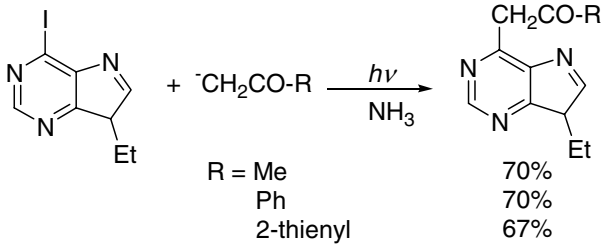
The $^{-}CH_2COPh$ ion reacts with haloheteroarenes in liquid ammonia under irradiation[9,48] and even in the dark.[10] Low yields are obtained in the reaction of substituted iodoarenes with the anion of 2,4-dimethyl-6-methoxyacetophenone either in DMSO or liquid ammonia.[49] However, besides heteroarylation, phenylation by halobenzenes of $^{-}CH_2COPh$ ion is feasible under photostimulated conditions in DMSO.[50]

The anions of other aromatic ketones such as methyl 2-naphthylketone,[51] 2-acetylfuran,[48,52–54] 2-acetylthiophene,[52,55] 3-acetylthiophene,[55] 2- and 3-acetyl-*N*-methylpyrrole,[56] anthrone,[50] and tetralone[48,54,57] can also be arylated.



(47.8)

7-Ethyl-4-iodo-7*H*-pyrrolo[3,2-*d*]pyrimidine (6-iodo-9-ethylpurine) reacts under irradiation with the anions of several cyclic and alicyclic ketones to afford substitution products in good yields:[48,53]

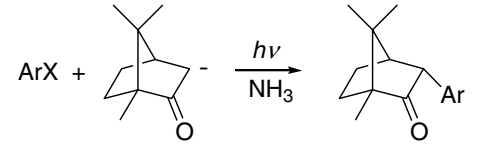


(47.9)

However, 2-iodopurine reacts through an ionic process.[58] 3-Halo (X = Cl, Br, I) 2-aminobenzo[*b*]-thiophene,[59] 3-iodobenzo[*b*]thiophene,[60] and 2-chloro- or 2-bromothiophene are poorly reactive.[61] A slightly higher reactivity is observed with 3-bromothiophene.[61]

β-Hydrogen abstraction is an important side-reaction when the enolate of di-*i*-propyl ketone is allowed to react with halobenzenes.[43] This reaction does not prevent high yields of substitution obtained with this anion upon reacting with heteroaryl halides such as 2-bromopyridine,[37] 2-chloroquinoline,[42] and 2-chloro- and 4-chloropyrimidines[10] under irradiation.

An interesting reaction is the arylation of the enolate ion of (+)-camphor.[62] The excellent yield obtained for the almost exclusive *endo*-arylation at C3 opens up a new stereospecific C3-arylation route of (+)-camphor by this mechanism (Eq. (47.10)).[62]

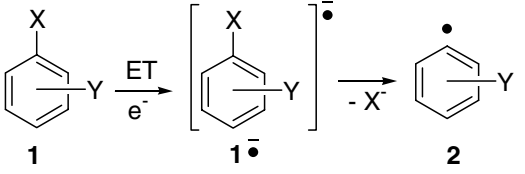


ArX = PhX, Cl, Br	92%, 95%
p-$MeOC_6H_4Cl$	71%
p-PhC_6H_4Br	76%
1-chloronaphthalene	100%

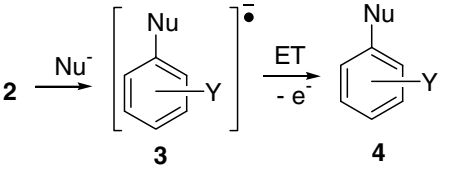
(47.10)

Substrates with Two Leaving Groups

One of the main goals of the $S_{RN}1$ mechanism is the possibility of obtaining disubstituted compounds when the reaction is performed with substrates bearing two leaving groups. These types of compound may react to form monosubstitution and/or disubstitution products depending on the leaving groups, their relative positions in the molecule, and on the nucleophile. In the case of dihalobenzenes, for example, the occurrence of mono- and/or disubstitution is interpreted based on the following mechanistic proposal. The radical anion $\mathbf{1}^{-\bullet}$ of dihalobenzene **1** fragments at the more labile C-halogen bond to furnish a haloaryl radical **2** (Eq. (47.11)), which in turn forms the radical anion of the monosubstituted compound **3** by reaction with the nucleophile. Radical anion **3** can transfer its extra electron to the substrate, and in this case the monosubstitution product **4** with retention of halogen is formed (Eq. (47.12)).

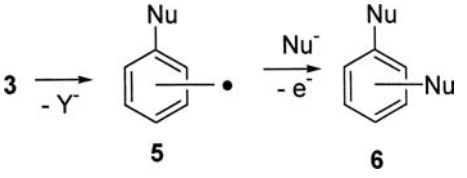


(47.11)



(47.12)

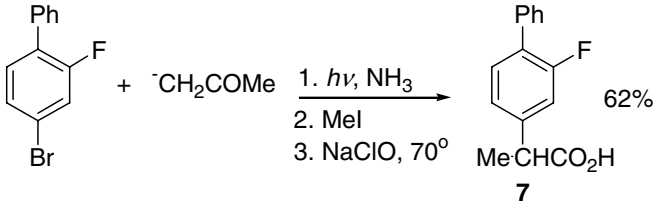
Alternatively, the intramolecular electron transfer to the second CY bond results in fragmentation to form a radical **5**, which by coupling with a second molecule of the nucleophile affords the disubstitution compound **6**:



(47.13)

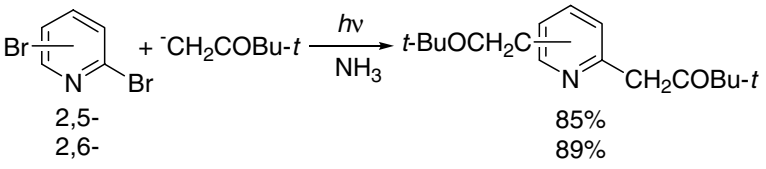
In this case, the monosubstitution product **4** is not an intermediate in the formation of compound **6**. Although the rate of formation of product **4** is bimolecular, depending on the concentration of **1**, and the rate of fragmentation to form radical **5** (that ultimately gives product **6**) is unimolecular, the competition of the two processes is almost independent on the concentration of **1**. The ratio of products **4** to **6** depends on the halogen, its electron affinity in relation to the substrate that acts as another acceptor, and its position on the aromatic ring, as well as on the nature of the nucleophile.

m-Fluoroiodobenzene[35] and 2-fluoro-3-iodopyridine[39] react with retention of fluorine. Synthesis of antiinflammatory drugs, such as fluorobiprophen **7**, can be achieved by reaction of 4-bromo-2-fluorobiphenyl with $^{-}CH_2COMe$ ion followed by methylation and oxidative demethylation:[63]



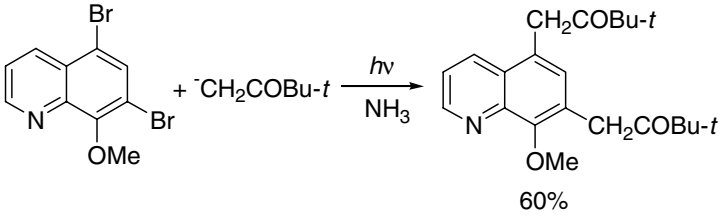
(47.14)

Disubstitution is possible for *p*-dichloro, *p*-dibromo, and *p*-bromoiodo benzenes under irradiation.[64] Disubstitution also occurs by reaction of 2,5- and 2,6-dibromopyridines and 2,3-, 2,6-, and 3,5-dichloropyridines with $^{-}CH_2COBu$-*t* ion:[37,65]



(47.15)

Monosubstitution, resulting from the selective displacement of chlorine from C4, is obtained in the reaction of $^{-}CH_2COBu$-*t* ion with 4,7-dichloroquinoline,[65] and disubstitution is achieved by its reaction with 5,7-dibromo-8-methoxyquinoline:[54]



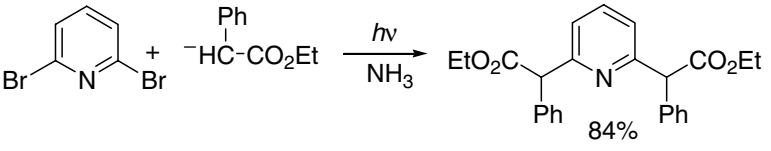
(47.16)

On the other hand, monosubstitution at C7 is the only route to products obtained in good yields in the reactions of 5-chloro-7-iodo or 5,7-dichloro-8-*i*-propoxyquinoline with the anions derived from CH_3COR (R = Me, Et, *t*-Bu, 2-furanyl) (70 to 80% yields).[54] Cyclization of these substituted compounds is possible to obtain furan derivatives (see Section 47.9).

47.6 Carbanions Derived from Esters, Carboxylate Salts, *N,N*-Disubstituted Amides, Thioamides, Imides, and β-Dicarboxylic Compounds

Carbanions Derived from Esters and Carboxylate Salts

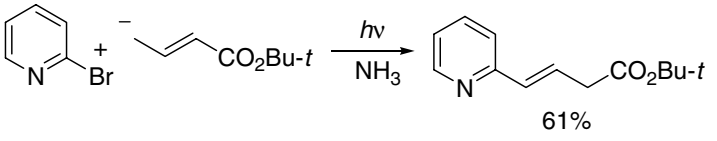
α-Arylacetic esters can be obtained through the reaction of haloarenes with $-CH_2CO_2Bu$-*t* ion under light stimulation. For instance, the photostimulated reaction of 2,6-dibromopyridine with the anion derived from phenylacetic acid ethyl ester afforded the disubstitution product in high yields:[65]



(47.17)

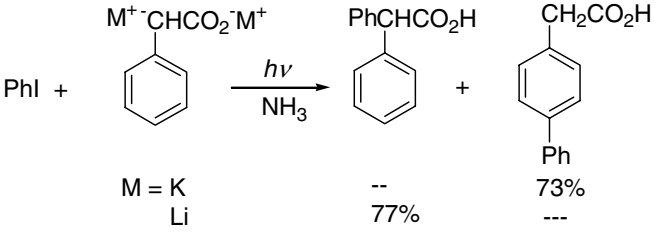
Lower yields of substitution are usually achieved with the anions of tertiary esters bearing β hydrogens.[45,66] A low percentage of substitution is also obtained in the reaction of the secondary anion of *t*-butylpropionate with 2-bromonaphthalene and *p*-bromobiphenyle.[13]

Other carbanions that can be arylated under photoinitiation are the anions of ethyl phenyl acetate,[65,67] methyl diphenyl acetate,[65] and *t*-butyl-3-butenate.[67] Phenylation and heteroarylation of the latter carbanion occur at the terminal site of the π system:[67]



(47.18)

The dianion of phenylacetic acid, when irradiated in the presence of haloarenes, can be arylated at the *p*- or α-carbon depending on the counter ion used:[68]



(47.19)

Carbanions Derived from *N,N*-Disubstituted Amide, Thioamide, and Imides Ions

The synthesis of *N,N*-disubstituted-α-arylacetamides can be achieved by reaction of haloarenes with carbanions from *N,N*-disubstituted amides in liquid ammonia under light initiation.[69] The potassium salt of *N*-acetylpiperidine does not react, probably due to its low solubility in liquid ammonia. The anions derived from acetamide and *N*-methyl acetamide are also unreactive.[69]

In the reaction of $^{-}CH_2CONMe_2$ ion with different haloarenes, monoarylation is the main reaction when the nucleophile:substrate ratio is 10 to 15.[63,70] Diarylation becomes more important when the ratio is equal to 2.[70] Yields of about 50% of monosubstitution and 20% of disubstitution are obtained from most substrates when the ratio is equal to 5:[63,70]

$$ArX + {}^{-}CH_2CONMe_2 \xrightarrow[NH_3]{h\nu} ArCH_2CONMe_2 + Ar_2CHCONMe_2 \qquad (47.20)$$

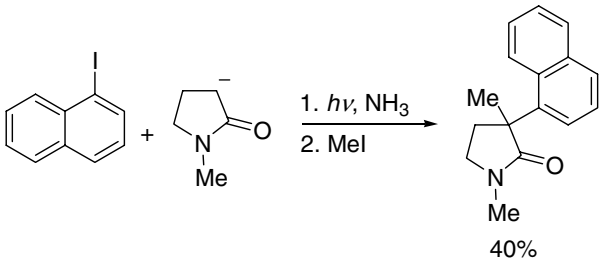
The photoinitiated reaction of haloarenes with the anion $^{-}CH_2CONMe_2$ followed by addition of methyl iodide is an approach to the synthesis of aryl propionic acids. The acids are obtained by hydrolysis.[63] Competition with the benzyne mechanism (i.e., the reaction of the former anion with 4-bromo-2-fluorobiphenyl) and addition to the carbonyl group (when the same anion reacts with *m*-chlorobenzophenone) are responsible for the low yields of substitution from the amide derivatives of fluorobiprophen and ketoprophen, respectively.[63]

Unsymmetrical α,α-diarylated amides can be prepared by reaction of the anions derived from monoarylated products ($Ar^1CH_2CONMe_2$) with haloarenes (Ar = 1-naphthyl, 9-phenanthryl, 9-anthracenyl and Ar^1 = Ph; Ar = Ph and Ar^1 = 9-phenanthryl, 9-anthracenyl):[70]

$$ArX + {}^{-}CHAr^1CONMe_2 \xrightarrow[NH_3]{h\nu} ArAr^1CHCONMe_2 \qquad (47.21)$$

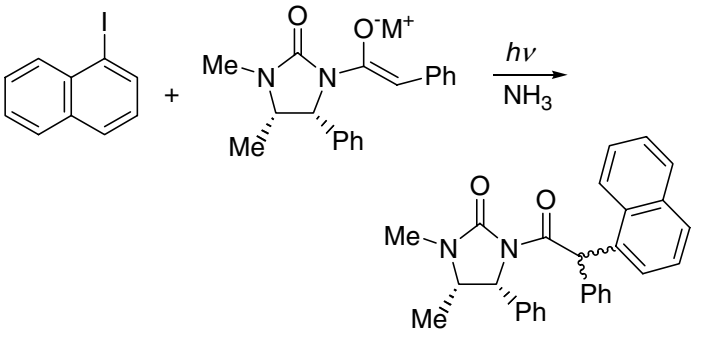
The yields of these unsymmetrical diarylamides depend on the substrate–nucleophile pair used. For the same product and thus for the same radical anion (Ar = Ph and Ar^1 = 9-phenanthryl, or vice versa), the best yield is obtained with the least stabilized anion, where a less significant loss in π energy occurs.[50]

Lactam nucleophiles, such as the anion of 1-methyl-2-pyrrolidinone, react with aryl halides under irradiation.[69] When the reaction of 1-iodonaphthalene with the aforementioned anion is quenched with methyl iodide, the 3-(1-naphthyl)-3-methyl- substituted compound is obtained:[71]



(47.22)

An interesting example of stereoselective coupling of an aromatic radical with a nucleophile is found in the reaction of 1-iodonaphthalene with an imide ion containing a chiral auxiliary. In this reaction, the diastereomeric isomers of the substitution compound are formed:[72]

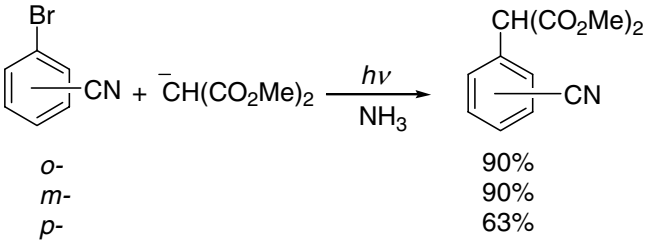


(47.23)

This reaction is highly dependent on the metal counter ion used. All the ions studied — Li, Na, K, Cs, Ti(IV) — are selective, but the highest stereoselectivity is achieved with Li at low temperature (–78°C) and with Ti(IV) (*ca.* 99%).[72] It has recently been reported that the anion derived from *N*-acetylthiomorpholine reacts with aryl iodides in DMSO under irradiation to afford good yields of substitution (60 to 70%).[73]

β-Dicarbonyl and Related Carbanions

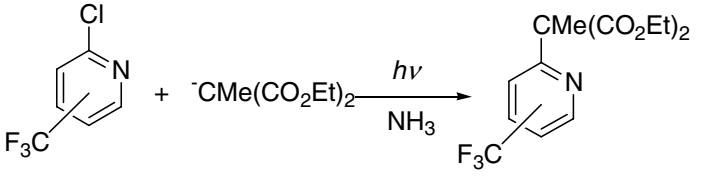
1,3-Dianions from β dicarbonyl compounds react quite well at the terminal carbon site, under irradiation.[43,74] Monoanions do not react with 2-bromopyridine,[37] 2-chloroquinoline,[42] or *o*-bromobenzamide but do react with more electrophilic substrates, such as bromobenzonitriles:[75]



(47.24)

Monosubstitution is achieved in the photoinitiated reaction of different carbanions, such as $^{-}CH(CO_2Et)_2$, $^{-}CH(COMe)_2$, and $^{-}CH(COMe)CO_2Me$ (60 to 83%) with 5-chloro-7-iodo-8-methoxide-quinoline or the 8- *i*-propoxide quinoline.[76]

The reactivity of 2-chloro- trifluoromethyl pyridines depends on the position of the CF_3 substituent. For example, the reaction with $^{-}CH(CO_2Et)_2$ ions fails with the C3- and C4-substituted derivative, while substitution is obtained with the CF_3 group at C5 or C6 with -$CMe(CO_2Et)_2$ ions (100 and 44% yields, respectively):[77]

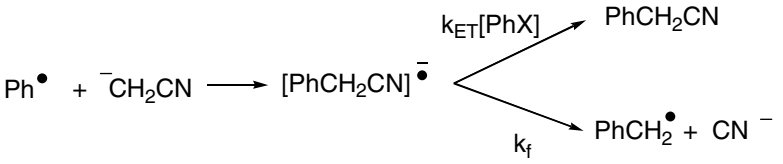


(47.25)

The photoinitiated reactions of 2-bromobenzonitrile and 2-bromo-3-cyano-pyridine with the carbanion of ethyl cyanoacetate afford the substitution product in good yields (90 and 80%, respectively) by an $S_{RN}1$ process.[75] On the other hand, a non-chain radical nucleophilic mechanism is proposed to occur in the almost quantitative substitution of *o*-Cl, *o*-Br, and *p*-$O_2NC_6H_4X$ (F, Cl, Br, I) with this anion in DMSO.[78–80]

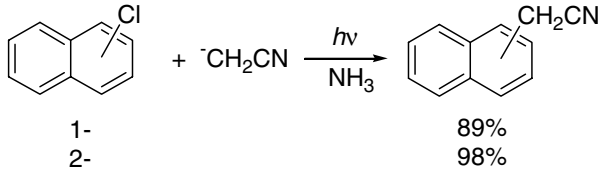
47.7 Carbanions Derived from Nitriles

In the coupling reaction of a phenyl radical with carbanions derived from nitriles, the radical anions formed bearing the extra electrons are mainly localized on the CN moiety or at the CCN bond favoring the fragmentation into stabilized benzyl-type radicals. (Scheme 2). For example, in the reaction of $^{-}CH_2CN$ ion with halobenzenes, toluene is the main product observed.[81,82] On the other hand, with 1-chloronaphthalene,[34,83] polycyclic aromatic halides,[83] or substituted haloarenes with a COPh group[83] or halopyridines,[84] the straightforward substitution products $ArCH_2CN$ are formed. With these substrates, the aryl group accommodates the extra electron of the radical anion avoiding fragmentation. For instance, α-arylated nitriles are almost exclusively formed by reaction of $^{-}CHRCN$ ions (R = H, Me, Ph) with



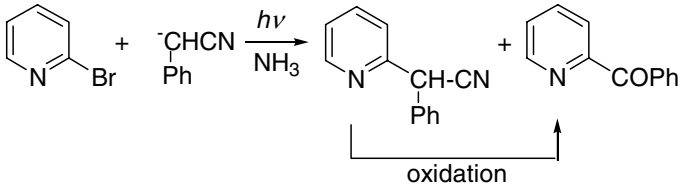
SCHEME 2

stabilized π aromatic compounds, such as naphthyl (Eq. (47.26))[34,83,85] and quinolyl moieties,[86] among others.



(47.26)

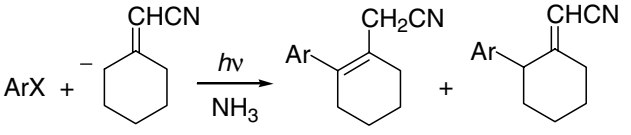
The nitriles obtained by reaction of ⁻CHPhCN ion with heteroaryl halides can lead to the corresponding ketones in excellent yields (77%) by oxidative decyanation under phase-transfer conditions (PTCs):[86]



(47.27)

Exclusive substitution at C2 occurs under photostimulation, by reaction of ⁻CHPhCN ion with 2,4-dichloropyrimidine (58% yield).[65] On the other hand, a mixture of monosubstitution, disubstitution, and monosubstitution with reductive dehalogenation occurs in the reaction of this anion and the anion derived from 2-phenyl butyronitrile with 2,6-dibromopyridine.[65] Both anions react with 3-bromoquinoline-1-oxide to afford the corresponding 3-substituted quinoline-1-oxides (82 to 91%) by a thermal-initiated $S_{RN}1$ mechanism.[87]

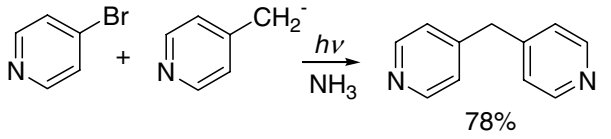
The carbanion of cyclohexylideneacetonitrile reacts with *p*-bromo and *p*-iodo-anisoles and 1-iodonaphthalene to afford good yields of the isomeric substitution products (60 to 69%) at Cγ together with traces of 2,2-(diaryl)cyclohexylidene acetonitrile:[88]



(47.28)

47.8 Other Carbanions

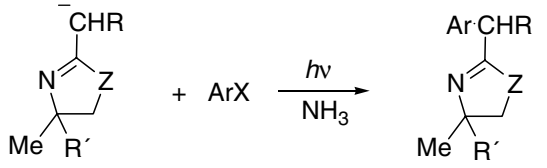
Picolyl anions can be used as nucleophiles in $S_{RN}1$ reactions:[89,90]



(47.29)

On reaction with bromobenzene and iodobenzene, these ions afford products derived from competition of the benzyne and $S_{RN}1$ mechanisms.[90]

Other carbanions proposed to react by the $S_{RN}1$ process are the anions from 2,4,4-trimethyl-2-oxazoline, 2-benzyl-4,4-dimethyl-2-oxazoline, 2,4-dimethylthiazole, 2-benzyl-4,4-dimethylthiazole, and dimethyl methylphosphonate.[67] Competition with a benzyne process has been determined in some of these reactions. Some examples are illustrated in Eq. (47.30).

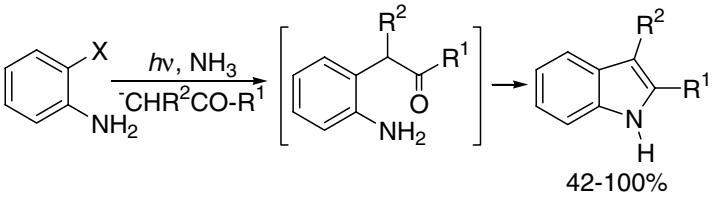


Z = O, R´= Me, R = H, Ph
Z = S, R´= H, R = H; R´= Me, R = Ph

(47.30)

47.9 $S_{RN}1$ and Ring Closure Reactions of Aryl Halides Bearing an *ortho* Substituent

The most studied approaches to ring closure reactions is the $S_{RN}1$ substitution of aromatic substrates that have an appropriate substituent in a position *ortho* to the leaving group. An important example of this approach is the synthesis of substituted indoles by the photoinduced substitution reaction of *o*-haloanilines (bromo, iodo) with carbanions from ketones, followed by spontaneous ring closure in the reaction media:[91–93]

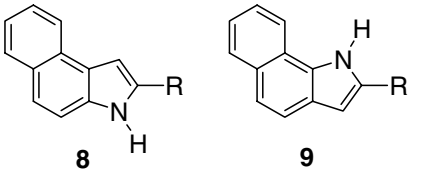


(47.31)

When the reaction is performed with the enolate ion of an aldehyde, 3-substituted indoles are obtained (26 to 49% yield).[91]

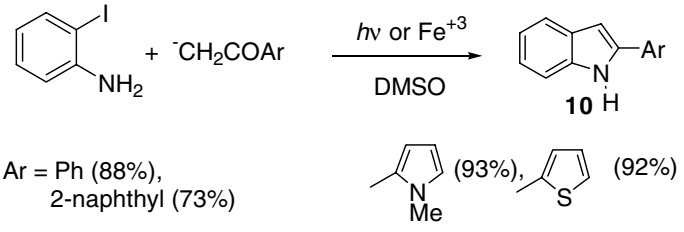
Indoles bearing a –CHO or –COMe functionality at the 2-position are synthesized after hydrolysis of the corresponding dimethylacetals obtained from the reaction of *o*-iodoaniline with $^{-}CH_2COCH(OMe)_2$ or $^{-}CH_2COC(OMe)_2Me$ ions in 45 and 55%, respectively.[91]

The synthesis of benzo[*e*] and benzo[*g*]indoles (**8** and **9**) can be performed by reaction of 2-amino-1-bromo or 1-amino-2-bromo-naphthalene with the carbanions $^{-}CH_2COBu$-*t* and $-CH_2COCH(OMe)_2$.[94]



R	**8**	**9**
t-Bu	67%	82%
$CH(OMe)_2$	52%	65%

The enolate anions of aromatic ketones do not react in liquid ammonia with *o*-iodoaniline, but they cyclize to indoles **10** in DMSO under light (acetophenone, 2-naphthyl-methyl ketone) or Fe^{+2} (acetophenone, 2-acetyl-1-methyl-pyrrole and 2-acetylthiophene) initiation:[95]



(47.32)

2-*t*-Butylindoles bearing substituents in the phenyl ring (**11**) and tricyclic indoles (**12**) can be synthesized by a combination of S_NAr, reduction of the nitro group and photoinduced $S_{RN}1$ reactions with the pinacolone anion.[96]

R^1 = Me, R^2 = $HO(CH_2)_2S$-, (75%)

R^1 = $HO(CH_2)_2S$-, R^2 = Me, (60%)

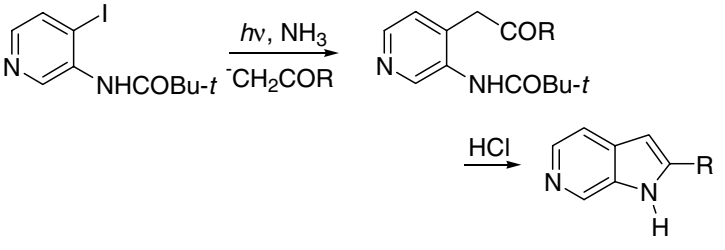
R^1= Me·N⟨⟩N–, R^2 = H, (85%)

Y = S (52%)

Y = NH (43%)

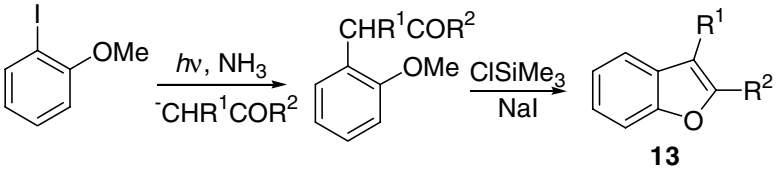
Y = NMe (46%)

The photostimulated reaction of *vic* aminohalo pyridines with the anion of $^-CH_2COBu$-*t* or $^-CH_2COMe$ ions leads to azaindoles in high yields (75 to 95%).[39] When the amino group is protected as a pivaloylamino derivative, the substitution compounds obtained by the photoinduced reaction of 2-amino-3-iodo-, 3-amino-4-iodo-, and 4-amino-3-iodopyridines with $^-CH_2COMe$ or $^-CH_2COBu$-*t* ions afford 5-, 6- and 7-azaindoles in almost quantitative yields by cyclization upon deprotection of the amino group and dehydration under acidic conditions:[39]



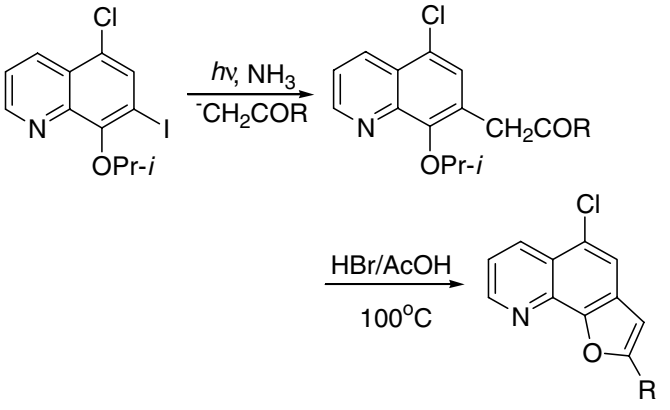
(47.33)

The compounds formed in the $S_{RN}1$ reaction of the enolate of a ketone or aldehyde (MeCOR, R = H, Me, *i*-Pr, *t*-Bu) with *o*-alkoxyhalobenzenes undergo spontaneous cyclodehydration after deblocking of the alkoxy function to afford benzo[*b*]furan **13** derivates quantitatively, as in the reaction with *o*-iodoanisole (Scheme 3).[46] This approach is also used in the synthesis of furo[3,2-*h*]quinolines and furo[3,2-*b*]pyridines, which are quantitatively formed by acidic treatment of the products obtained in the $S_{RN}1$ reaction of 5-chloro-7-iodo-8-*i*-propoxyquinoline and 2-bromo-3-*i*-propoxypyridine, respectively, with the enolate ions of ketones ($^-CH_2COR$, R = Me, Et, *t*-Bu, 2-furanyl, *p*-anisyl):



13

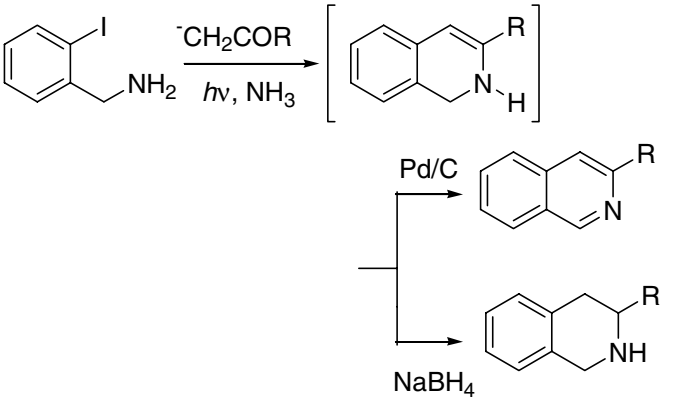
SCHEME 3



(47.34)

Cyclization at the product is also possible by reaction of 2-methoxide-3-iodopyridine with $^{-}CH_2COBu$-*t* ion.[54]

The $S_{RN}1$ mechanism can be an excellent route to isoquinolines rings and derivatives by reaction of *o*-iodobenzylamines with ketone enolate ions under irradiation.The substitution products formed in their irradiated reactions spontaneously cyclize to give a non-isolable intermediate which affords isoquinolines by Pd/C dehydrogenation (Eq. (47.35a)) or tetrahydroisoquinolines by reduction with $NaBH_4$ in approximately 100% yields (Eq. (47.35b)):[97,98]

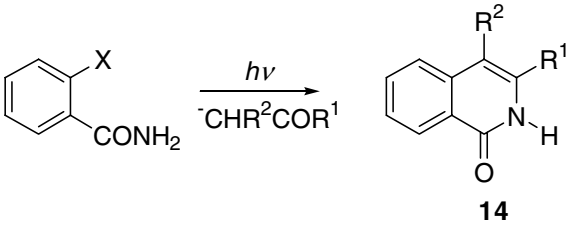


(47.35a)

(47.35b)

11,12-dihydrobenzo[*c*]phenanthridines and phenanthridones are obtained by reaction of tetralone enolate ion with *o*-iodobenzylamines or *o*-iodobenzoic acids, respectively, in moderate to good yields.[57]

Isoquinolones (or isocarbostyrils **14**) are accessible by the reaction of *o*-bromo or *o*-iodobenzamides with carbanions in acceptable yields (60 to 90%):



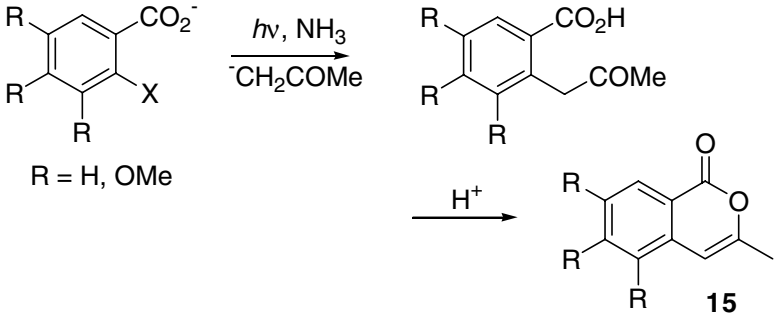
14

R^1 = Me, *i*-Pr, *t*-Bu, CH_2OMe, Et, $(CH_2)_2C_6H_5$, *p*-$MeOC_6H_4$
R^2 = H, $CH_2C_6H_5$, Me

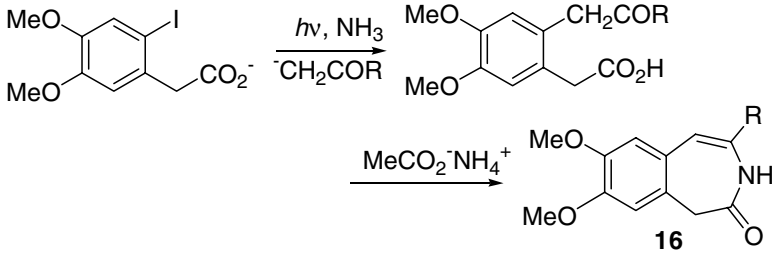
(47.36)

With *N*-methylbenzamides, the yields of substitution products are lower.[99,100] The $S_{RN}1$ reaction between substituted *o*-iodobenzamides and the enolate anion of 2-acetylhomoveratic acid can be used for the synthesis of derivatives of the benzo(*c*)-phenanthridone and berberine alkaloids.[101]

The $S_{RN}1$ reaction of *o*-iodo and *o*-bromo-benzoate salts with $^-CH_2COMe$ ion affords the substitution product (*ca.* 78% yield), which upon acid treatment with toluene *p*-sulphonic acid gives the corresponding isocoumarin **15** (90%) (Scheme 4).[99] Benzazepines **16** can be produced upon ammonium acetate treatment of the substitution compound obtained in the reaction of (*o*-iodophenyl) acetic acid derivatives with enolate ions from ketones ($^-CH_2COR$, R = Me, *i*-Pr, *t*-Bu; 50, 60, and 56%, respectively) (Scheme 5).[47]

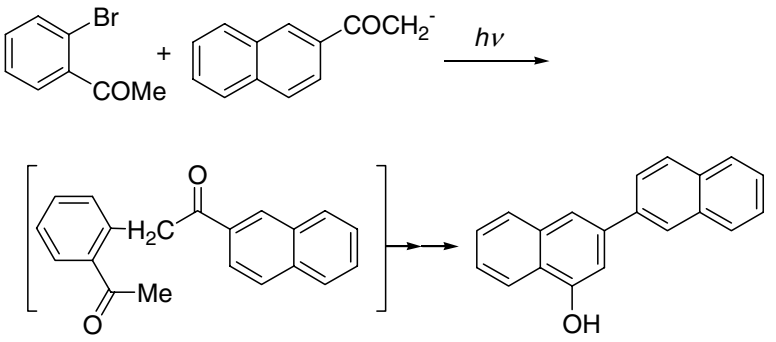


SCHEME 4



SCHEME 5

The reaction of the enolate ion of methyl 2-naphthylketone with *o*-bromoacetophenone affords 2,2′-binaphthyl under irradiation in liquid ammonia (72%) or in DMSO (82%) Eq. (47.37).[51]

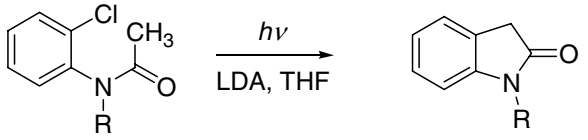


(47.37)

Unsymmetrically substituted binaphthyls (25 to 80%) can also be synthesized by this procedure.[49,51] Naphthylquinolines and naphthylisoquinolines can be formed by reaction of 3-acetyl-2-chloro- and 4-acetyl-3-chloropyridines with the anions from methyl 1- or 2-naphthylketone.[102] Another approach involves reaction of *o*-bromobenzamide with the same nucleophiles.[102]

47.10 Intramolecular $S_{RN}1$ Reactions

The intramolecular $S_{RN}1$ reactions of substrates that have both a nucleophilic center and a leaving group give an interesting example of a ring closure reaction. An example of this is the synthesis of oxindoles by the intramolecular cyclization of *N*-alkyl-*N*-acyl-*o*-haloanilines in the presence of LDA in THF or KNH_2 in liquid ammonia:[103–105]

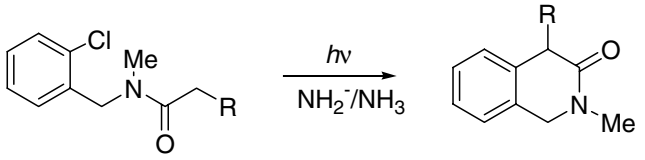


R = Me (81%)
R = $CH_2C_6H_5$ (32%)

(47.38)

N-Methyl-α,β-unsaturated anilides undergo intramolecular arylation exclusively at the α-position to afford 3-alkylideneoxindoles. The best yields of substitution (63 to 90%) are obtained with KNH_2 in liquid ammonia under photoinitiation.[105]

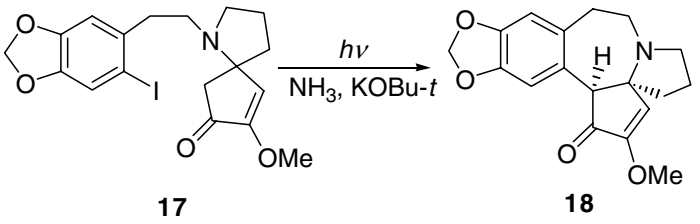
1,4-Dihydro-2*H*-isoquinolin-3-ones can be achieved in fair to good yields by the cyclization of the carbanions from *N*-acyl-*N*-methyl-*o*-chlorobenzylamines under photostimulation:[105]



R = H 62%
R = Me 60%
R = Et 54%

(47.39)

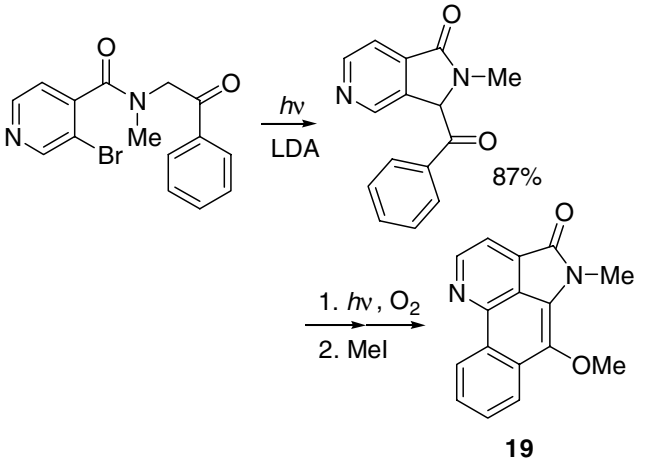
The iodoketone **17** cyclizes to the cephalotaxinone (**18**) under metal or light stimulation (45 and 94% yields, respectively):[106–108]



(47.40)

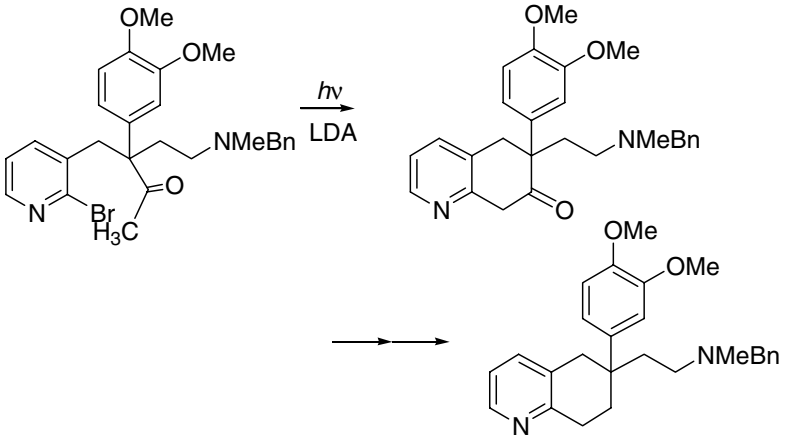
The studies of this system were extended to other analogs in order to determine the ring-size preferences in the cyclizations, the effects of hydrogens β to the carbonyl group, and the regioselectivity with ketones that can give two enolate ions.[45,66,107,108]

The key step in the synthesis of the azaphenanthrene alkaloid eupoulauramine **19** (56% yield) is an intramolecular $S_{RN}1$ reaction, followed by *in situ* stilbene photocyclization and further methylation Eq. (47.41).[109]



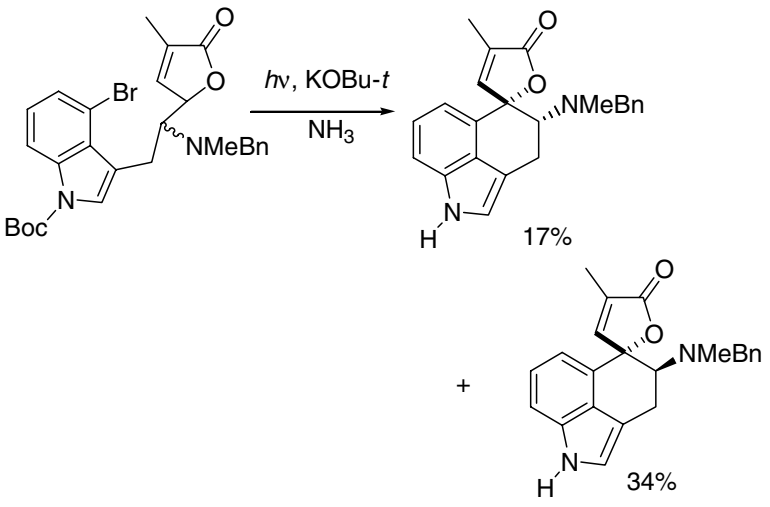
(47.41)

A similar strategy is followed in the synthesis of (±)tortuosamine (54%):[110]



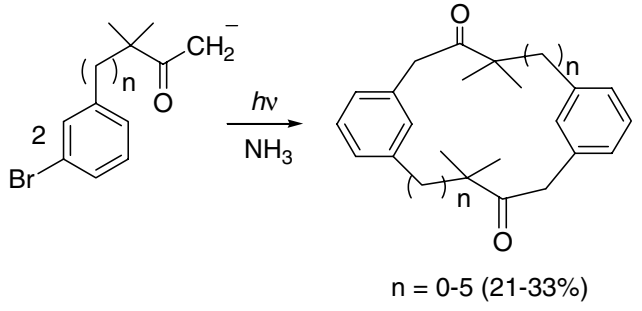
(47.42)

The $S_{RN}1$ mechanism is an excellent alternative to accomplish the following intramolecular cyclization reaction, which constitutes one of the steps in the synthesis of rugulovasine, novel structures within the family of ergot alkaloids:[111,112]



(47.43)

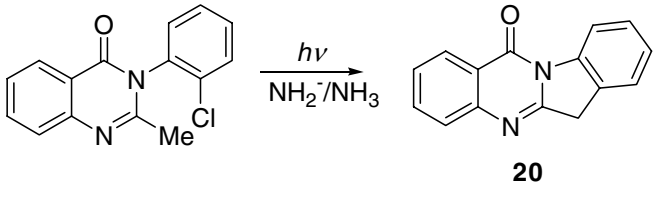
The preparation of *m*-cyclophanes is possible through a combination of inter- and intramolecular $S_{RN}1$ substitutions with substrates bearing the leaving group and nucleophilic center in the same molecule Eq. (47.44).[113,114]



(47.44)

Another approach to the synthesis of *m*- and *p*-cyclophanes is the reaction of *m*- and *p*-dibromobenzene with appropriate dianions, although in low yields.[115,116]

The carbanion derived from 3-(*o*-chlorophenyl)-2-methyl-3*H*-quinazolin-4-one cyclizes in liquid ammonia under irradiation to yield 6*H*-indolo[2,1-*b*]quinazolin-12-one **20** (60%):[117]



(47.45)

Photochemical Decarbonylation of Ketones: Recent Advances and Reactions in Crystalline Solids

Miguel A. Garcia-Garibay

Luis M. Campos
University of California

48.1 Introduction

The photochemical decarbonylation of ketones can be traced back to 1910 when acetone was photolysed in the gas phase to yield ethane and carbon monoxide.[1] A radical process involving α-cleavage (Norrish type I reaction)[2,3] and decarbonylation[4] as two separate steps was proposed a few years later by Norrish and Appleyard (Scheme 1). Each of the two cleavage reactions has been the subject of numerous theoretical and mechanistic studies that have been covered in several reviews.[5–7]

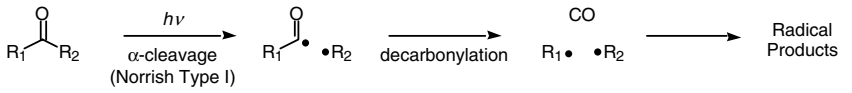

SCHEME 1

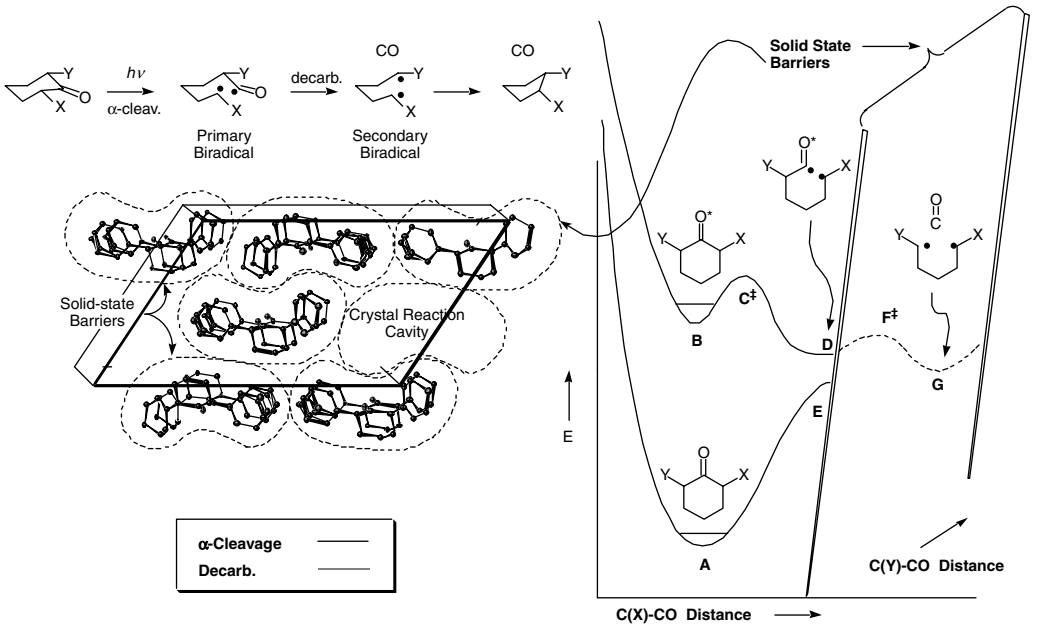

FIGURE 48.1 Hypothetical energy surface for α-cleavage and decarbonylation reactions illustrating the confining effect of a crystalline lattice. Reactions in crystals require low activation energies at points C‡ and F‡ and sufficiently long lifetimes at points B and D in order to increase the probability of efficient decarbonylation.

Current interest in the photodecarbonylation process is primarily maintained by applications that require a simple and reliable method for the preparation of biradicals, radical pairs, and free radicals. At the same time, the relatively well-documented kinetics of the two elementary cleavage reactions and the dynamics of the radical intermediates constitute ideal chemical probes to investigate the structure and dynamics of several micro-heterogeneous media and supramolecular environments. Recent applications range from studies addressing fundamental aspects of chemical dynamics, spin–spin interactions,[8] and computational chemistry[21] to studies addressing self-diffusion in zeolite networks,[9] the dynamics of radicals in polymers,[10] generation of chelotropic NO traps,[11] and long-range electron transfer in DNA,[12] among others. Furthermore, while reactions of radical pairs and biradicals in the gas phase and in solution can be relatively complex, strategies have been developed to control their chemical behavior so that they can be preparatively useful.

Great interest in the decarbonylation process over the last few years has resulted from studies at the two extremes of the kinetic spectrum. On the one end, femtosecond studies in the gas phase have addressed the dynamics of the reaction within time scales that are barely enough for a few molecular vibrations and modest radical–radical separation but not enough for large-amplitude molecular motions. At the other end, studies in crystalline solids focus on reactions where excited molecules and reactive intermediates can only explore a very small fraction of the gas phase energy surface (Figure 48.1; the details of the photochemistry/photophysics are discussed in Section 48.3). When radical pairs and biradicals

are formed in crystals, they are generated under conditions where the two radical centers are forced to coexist within their van der Waals distance for a relatively long period of time (points D and G in Figure 48.1). In Figure 48.1, we represent a hypothetical energy surface determined by the α-cleavage and decarbonylation coordinates. The steric barriers imposed by close neighbors in the crystal lattice or reaction cavity are represented by the dashed-line boundaries. These barriers restrain the separation of the two radical centers and inhibit large atomic displacements in solid-to-solid reactions.

Decarbonylation reactions in crystals must occur by a series of events leading from point A to point G, but many diversions exist along the way. In summary, the reaction begins by electronic excitation from the ground state ketone A to the nπ* excited state surface at point B. While both singlet and triplet surfaces can be dissociative, biradicals initially formed in crystals in the singlet state are likely to be unproductive due to rapid return to the ground state. α-Cleavage is accomplished by passage through transition state $C^{\ddagger}$ when the distance of the C(X)–CO sigma bond is increased to form a constrained acyl–alkyl biradical, D. Whenever the energy of transition state $C^{\ddagger}$ is very high, the α-cleavage reaction is slow and the excited state returns to the ground state (A) by emission of a photon, either fluorescence or phosphorescence, and by thermal deactivation (internal conversion). Once formed, primary acyl–alkyl biradicals (D) may reach the singlet, hot, ground-state surface at E and go back to starting point A in an unproductive cycle of A ⇒ B ⇒ $C^{\ddagger}$ ⇒ D ⇒ E ⇒A. In order to reach target dialkyl biradical G, acyl–alkyl biradical D must lose CO by passing through transition state $F^{\ddagger}$, following the path A ⇒ B ⇒ $C^{\ddagger}$ ⇒ D ⇒ $F^{\ddagger}$ ⇒ G.

Singlet-state nπ* reactions that occur in the gas phase and in solution may not be observed in crystals because the acyl–alkyl radical pair (E) is subject to the perfect "cage effect".[13] Radical–radical recombination in the singlet-state acyl–alkyl biradical (from E ⇒A) may occur within the time scale of a single bond vibration. However, because many decarbonylation reactions have been documented in crystals, conditions may be satisfied for α-cleavage to compete with excited-state decay and for decarbonylation to compete with recombination of the acyl–alkyl radical pair. In this chapter, we review various aspects of the α-cleavage and decarbonylation steps in the reaction, describe recent theoretical advances, and conclude with examples that reflect our current understanding of the reaction in the solid state.[14]

48.2 General Considerations

While α-cleavage and decarbonylation are observed with many simple ketones, the two sequential reactions are only one of many possible outcomes after excitation of the reactive nπ* excited state. Before we analyze several aspects of the two elementary reactions in detail, it may be useful to cover a few general guidelines that help us evaluate the feasibility of the decarbonylation process. In general terms, the efficiency of decarbonylation is directly related to the stability of radical intermediates generated at each of the two steps of the overall reaction. A good correlation between the bond dissociation energies (ΔH^0) and the rates of α-cleavage and decarbonylation indicate a Hammet-type relation between the two reaction free energies and their respective activation barriers.[15] Because reactions occur specifically from nπ* excited states, they are most commonly observed with nonconjugated ketones that have high-energy ππ* excited states. The kinetic requirements for the α-cleavage reaction are relatively straightforward. α-Cleavage in the singlet nπ* state is relatively inefficient as compared with intersystem crossing; however, singlet reactions may be observed in solution with compounds that have very large reaction rate constants (i.e., $k_{\alpha(S)} > 10^8$–10^9 s^{-1}). In contrast, triplet-state reactions are significantly more efficient due to the longer triplet lifetimes (up to 10^{-3} s) and the larger rate constants for the triplet triplet-state α-cleavage. In addition, the longer lifetimes of the primary triplet radical pairs allow them to escape solvent cages, when reactions are carried out in liquid media.[3] Naturally, a successful α-cleavage does not guarantee formation of the second biradical or radical pair. For instance, aryl-alkyl ketones with a low-lying nπ* state may undergo efficient α-cleavage, but formation of a phenyl radical by decarbonylation of benzoyl [Ph-C•(O)] is not observed ($k_{-CO} = 1.5 \times 10^{-7}$).[16] In analogy with α-cleavage, decarbonylation is faster when the bond dissociation energy of the R-CO• bond is lower so that stable alkyl radicals R• are formed.

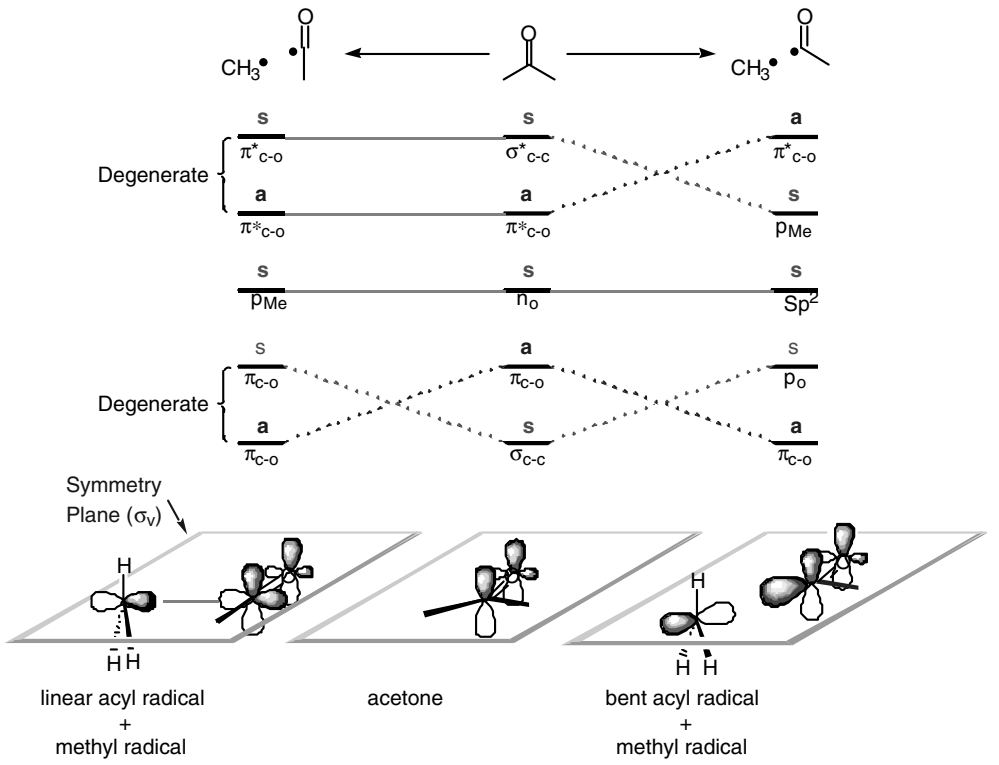

FIGURE 48.2 Orbital correlation diagram illustrating the α-cleavage of acetone. A linear acyl radical (left) is predicted to be photochemically generated from the nπ* excited state of acetone. The orbital symmetry is represented by the letters **a** (asymmetric) and **s** (symmetric), with respect to the σ_v mirror plane.

48.3. Theoretical Aspects

Excited states and radical intermediates generated in gases and in liquids may explore a wide range of molecular structures and reaction paths by taking advantage of molecular translation, rotation, and internal (conformational) motions. In contrast, most molecular degrees of freedom that are present in the gas phase and in solution are transformed into collective lattice vibrations or phonons, when molecules are "trapped" in crystals. Unable to find reaction partners or to explore a variety of nuclear configurations, reactants in solids are restricted to least-motion-reaction pathways along trajectories that are allowed by orbital-symmetry and occur with minimum atomic and molecular motion.[17] Consequently, reaction trajectories in crystals must be very short and have no significant electronic barriers.

The Norrish type I and decarbonylation reactions satisfy these requirements. The orbital symmetry for α-cleavage along the nπ* surface has been studied by several authors.[18] As illustrated in Figure 48.2, the stretching of a C_α-CO bond for the generation of linear (left) or bent acyl (right) and planar methyl radicals is analyzed in terms of a symmetry plane that is conserved along the reaction coordinate. At a first approximation, the path toward the bent acyl radical from the nπ* excited state should be *forbidden*, while the path toward the linear radical should be *allowed*. While symmetry considerations alone suggest that linear acyl radicals should be formed, it has been suggested that they are approximately 26 kcal/mol higher in energy than the bent form.[19] In reality, symmetry constraints are relieved by excited state pyramidalization and partial linearization along the reaction coordinate so that a ground-state, bent, acyl radical is formed with a relatively small energetic cost in the form of a small energy barrier.[20] Experimentally determined energy barriers for α-cleavage in aliphatic nπ* ketones in solution range from close

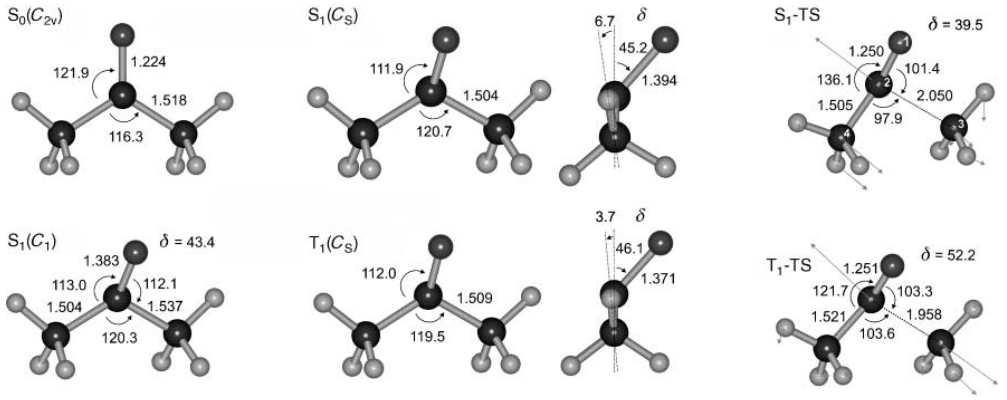

FIGURE 48.3 Optimized structures at the CAS-SCF(10,8)/6–31G* level of theory of acetone in the ground state and S_1 and T_1 excited states (distances in Å and angles in degrees). (Adapted from Reference 21a.)

to 0 to as much as 15 kcal/mol, depending on bond dissociation energies and the spin multiplicity of the excited state.[5a]

Small energy barriers for the dissociation of $n\pi^*$ ketones guarantee reaction rates that are large enough to compete with other decay pathways; however, small barriers alone may not be sufficient to warrant bond dissociation within the confining volume of a crystalline solid. Thus, one should address the following question: Are the inter-radical separation and relative orientation required to form low-energy, ground-state biradicals or radical pairs possible within a crystal? A detailed UB3LYP/6–31G(d) and complete active space/self-consistent field (CAS-SCF) analysis of the ground-state, singlet, and triplet energy surfaces of acetone recently reported by Zewail et al.[21] provides some answers to this question. The optimized structures of stationary points and transition states for the type I cleavage along the S_1 and T_1 surfaces, shown in Figure 48.3, confirm that the ideal plane of symmetry used in Figure 48.2 is not conserved. Prominent structural features of the minimum energy structures of the excited states (S_1 and T_1) include the pyramidalization of the carbonyl group and elongation of the CO bond. The distances of the breaking bond in the transition states along the singlet and triplet surfaces are relatively short (2.050 and 1.958 Å, respectively), and the nuclear displacement vectors in the transition-state imaginary modes describe the separation of the two radical fragments along the axis of the breaking C_α-CO bond.

Calculations suggest that molecular structural changes along the S_1 and T_1 surfaces are relatively small and provide clues for the smaller efficiency of the singlet state α-cleavage reaction. Although both surfaces have nearly the same structure at the transition state (Figure 48.3), generation of the primary radical pair from the S_1 surface involves relaxation via a conical intersection, also allowing for ultra-fast radiationless decay.[22] A three-dimensional surface and a contour plot show a nearly flat region along the minimum energy pathway in the S_1 surface of acetone (Figure 48.4). Additionally, the surfaces reveal a transition state S_1–TS that is 18 kcal/mol above the S_1 minimum (S_1-minimum, located 110 kcal/mol above the S_0 minimum) and a conical intersection (S_0/S_1–CI) after the S_1 transition state. The theoretical structure of acetone at the CI is that of an almost linear acyl radical (CCO angle = 169.7°) and a methyl radical that is 2.874 Å from the acyl radical center. The degeneracy at the conical intersection is removed by nuclear displacements along the direction where a radical pair or a hot acetone molecule is generated. A pathway to return back to the ground state is probably responsible for the relatively low pre-exponential factors ($A = 10^8\ s^{-1}$) observed for the singlet state α-cleavage of simple aliphatic ketones.

Not shown in Figure 48.4, but illustrated in the reaction coordinate in Figure 48.5, intersystem crossing (ISC) leads to the T_1 minimum in the $n\pi^*$ surface which, in the case of acetone, is approximately 80 kcal/mol above the S_0 minimum (Figure 48.5).[23,24] The quantum yield for ISC in solution is 0.90,[25] and it depends on excitation energy when irradiation is carried out in the gas phase. α-Cleavage from the S_1 surface may be efficient when the proper amount of excitation energy is provided in the gas phase. Upon excitation with light greater in energy than the transition state of the S_1 surface [$h\nu \geq E(S_1\text{–TS})$, or ~110

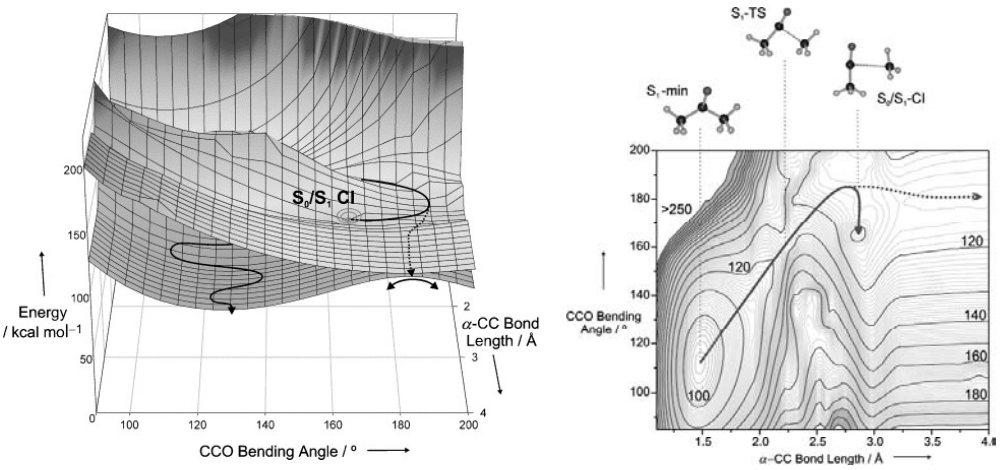

FIGURE 48.4 The three-dimensional graph of the S_1 and S_0 surfaces reveals a conical intersection (CI) where the S_1 relaxes to the S_0 surface. The contour plot shows the minimum energy path in the S_1 surface connecting the S_1-min to the S_0/S_1–CI via the transition state S_1–TS. The dashed arrow in both plots shows a disfavored path for α-cleavage for which another barrier must be surpassed in order to generate the free primary radical pair along the S_1 surface. The calculation was performed at the TD-UB3LYP/6–31G(d)//CASSCF(10,8)/6–31G(d) level of theory. (Adapted from Reference 21a.)

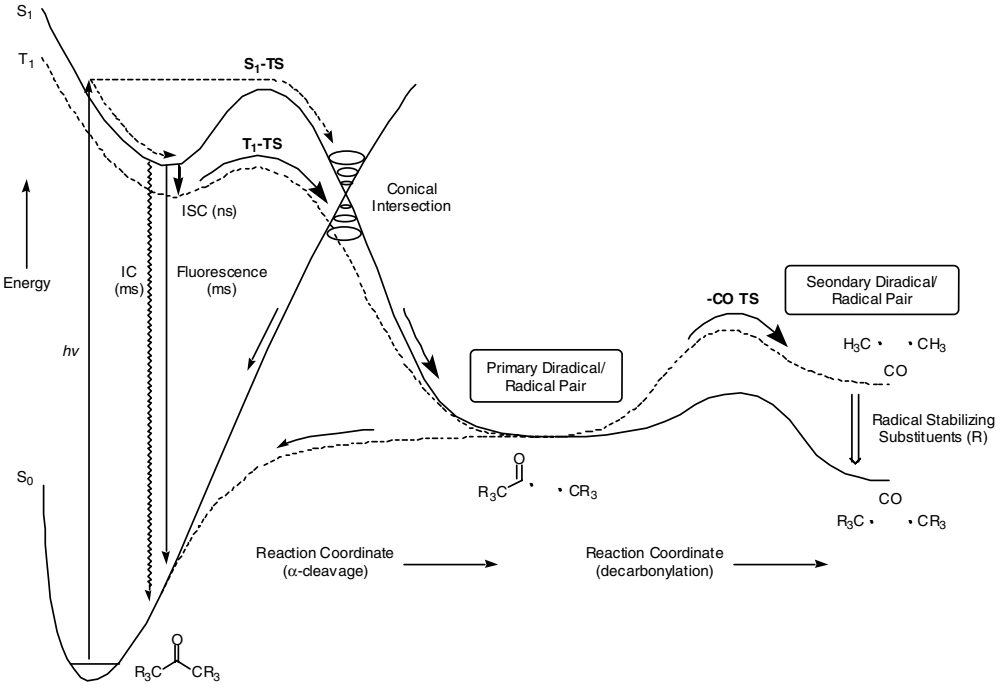

FIGURE 48.5 Reaction coordinate (RC) derived from computational studies of the Norrish type I reaction.[21] The RC shows α-cleavage from both S_1 and T_1 surfaces to yield the acyl–alkyl biradical/radical pair. Subsequent decarbonylation of the acyl radical generates the alkyl–alkyl biradical/radical pair.

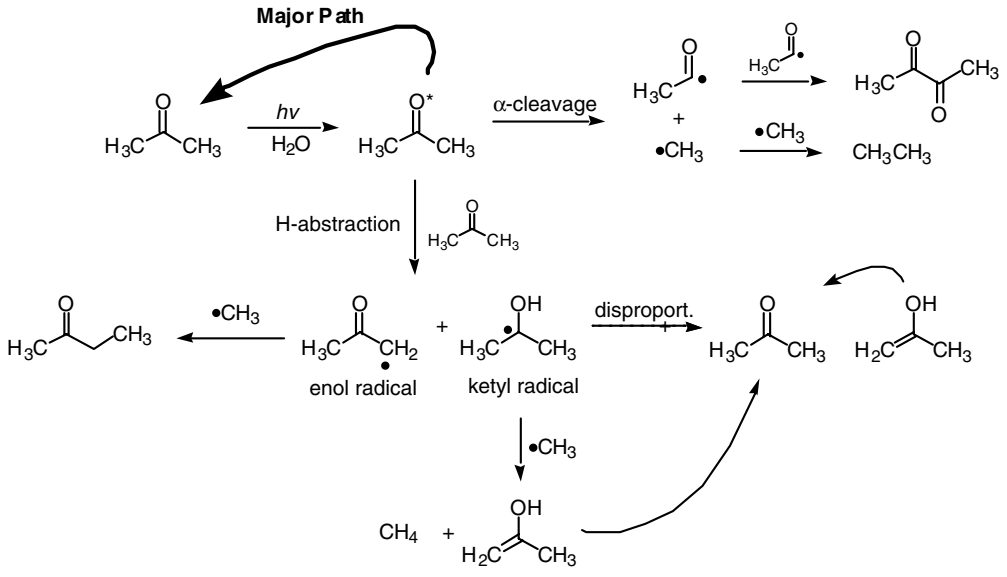

SCHEME 2

kcal/mol in the case of acetone], it may be possible to overcome the S_1 barrier to cleave via the conical intersection or decay to the ground state. However, gas-phase excitation with $h\nu < E(S_1\text{–TS})$ results primarily in intersystem crossing to the T_1 surface.[26] The transition state along the triplet surface (T_1–TS) lies about 13 to 15 kcal/mol above the T_1 minimum, so that α-cleavage along the vibrationally excited T_1 surface is more likely to occur in the gas phase.[27–29]

Finally, decarbonylation of the acetyl radical occurs after overcoming a 17-kcal/mol barrier in an overall endothermic fragmentation in the gas phase. As for α-cleavage, the height of the barrier should decrease significantly by substituting the methyl hydrogens with radical stabilizing substituents that may facilitate decarbonylation reactions in the liquid and solid states.

48.4 α-Cleavage Reactions in the Liquid Phase

While reactions in the gas phase may occur along electronically and vibrationally excited surfaces if high-energy photons are used, reactions in liquids and in solids tend to proceed along the lowest vibrational states as excess excitation energy can be dissipated very rapidly. With a triplet-state barrier of 13 kcal/mol, the rate constant of α-cleavage for acetone in solution is too small to compete with other decay pathways.[30] The lifetime of triplet acetone in inert solvents (e.g., H_2O) is limited by radiationless decay and quenching by adventitious impurities.[31] However, excitation of acetone gives trace amounts of products arising from a bimolecular reaction where the excited carbonyl of one molecule abstracts a hydrogen atom from the methyl group of another molecule in the ground state to form enol- and ketyl-free radicals (Scheme 2). Small yields of α-cleavage reaction also occur in solution and may be observed under some experimental conditions. For example, chemically induced dynamic nuclear polarization (CIDNP) experiments with laser excitation in H_2O reveal polarized signals for ethane and biacetyl along with other minor products (Scheme 2).[32]

The excited state kinetics of simple acetone derivatives in solution are similar. As expected for a weak $n\pi^*$ transition, the rates of fluorescence emission are low and the fluorescence quantum yields small ($\Phi_{Fluor} \leq 0.002$). Singlet lifetimes of a few nanoseconds are primarily limited by intersystem crossing to the triplet state with rate constants of $\sim 10^8\ s^{-1}$ (Table 48.1).[33]

TABLE 48.1 Singlet Excited State Lifetimes, Quantum Yields of ISC and ISC Rate Constants for Several Non-Conjugated Ketones

Ketone	τ_s (ns)	Φ_{ISC}	κ_{ISC} ($\times 10^8$ s^{-1})
Acetone	2.0	0.90	4.5–5.0
2-Pentanone	1.8	0.64	3.1
2-Hexanone	—	0.27	3.7

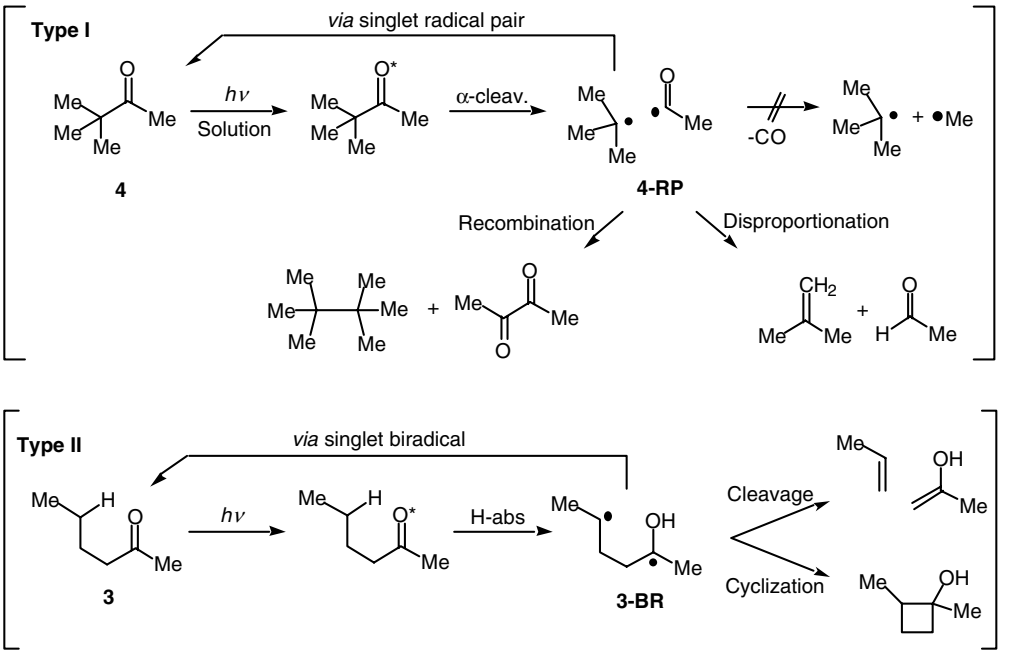
As illustrated in Table 48.2, α-cleavage in solution becomes important for ketones with radical-stabilizing groups in the α-position and, in favorable cases, the solution-phase reaction may proceed from both singlet and triplet states. However, ketones with flexible chains that have γ-hydrogens can also undergo the Norrish type II hydrogen abstraction process[34] in competition with the α-cleavage reaction (Scheme 3).[35]

Shown in Table 48.2 are the quantum yields for the disappearance of several aliphatic ketones (Φ^0) and the quantum yield of products from the Norrish type I and type II reactions in the singlet (Φ_I^S, Φ_{II}^S) and triplet (Φ_I^T, Φ_{II}^T) excited states. As these examples illustrate, saturated ketones with γ-hydrogens (e.g., **2** and **3**) do not undergo α-cleavage reactions in significant yields but undergo type II γ-hydrogen transfer from both singlet and triplet states. Type II reactions give 1,4-ketyl-alkyl biradicals (**3-BR**) that react from the singlet state by cleavage of the C_2-C_3 bond to give an alkene and an enol — which can subsequently tautomerise to the ketone — or by cyclization to form *cis*- and *trans*-cyclobutanol (Scheme 3). Singlet 1,4-biradicals can also revert to the ground-state ketone by a reverse hydrogen transfer. Type I reactions are observed from compounds giving rise to more stable secondary and tertiary radicals. *t*-Butyl-alkyl ketones **4–6** (Table 48.2) undergo efficient α-cleavage from both singlet and triplet states to form free radicals that react by random encounters. Although free acyl radicals from *t*-butylketones **4** to **6** have millisecond lifetimes under typical experimental conditions, no decarbonylation reactions are observed.

48.5 Decarbonylation of Acyl Radicals.

Similar to the rates of α-cleavage reactions, the rates of acyl radical decarbonylation depend very strongly on the stability of the alkyl radicals formed. It was first suggested by Fischer and Paul[15] that the rate



SCHEME 3

constants of decarbonylation (k_{-CO}) are a linear function of the R–CO bond dissociation energy, $DH_{(R–CO)}$. With a compilation of literature values available in 1987, it was shown that the corresponding $DH_{(R–CO)}$ values vary by ~30 kcal/mol and the corresponding rate constants by an astounding 15 orders of magnitude! One of the strongest bonds is that of benzoyl (Ph–CO), which has an estimated value of $DH_{(R–CO)}$ = 26 kcal/mol. On the other hand, α,α-dimethyl-α-phenylacetyl ($PhC(Me)_2$–CO) is less stable than the separated dimethylbenzyl radical and the CO molecule and has an approximate value of $DH_{(R–CO)}$ = –5 kcal/mol. The decarbonylation rate constants at ambient temperature for these two radicals change from an exceedingly slow k_{-CO} Å 10^{-7} s^{-1} for Ph–CO (a lifetime of over 100 days!)[16] to a remarkably fast k_{-CO} Å 10^{8} s^{-1} for $PhC(Me)_2$–CO (a lifetime of 10 ns).[36] These differences are expected if one considers the formation of a highly unstable σ-localized phenyl radical, with formation of a secondary, resonance delocalized, dimethylbenzyl radical.

Table 48.3 provides the activation parameters and ambient temperature rate constants for reactions involving the formation of methyl-, primary-, secondary-, tertiary-, benzylic-, secondary benzylic-, and tertiary benzylic radicals.[4a] As shown in the table, pre-exponential factors are near 10^{13} s^{-1} for alkyl substituents and slightly lower (10^{11}–10^{12} s^{-1}) when the entropically more demanding benzylic radicals are formed. The activation energies in the same set of compounds vary from 17.2 to 4.1 kcal/mol.

It has been suggested that the decarbonylation of acyl radicals may be used as a radical clock to gain information on the rate constants of competing reactions.[39] In the case of ketone photochemistry, the yields of decarbonylation products may be compared with the yields of CO-containing products to obtain information on the rate constants of diffusion, conformational motions, and intersystem crossing, which may determine the rate of reaction of the acyl radical. The rate constant of an ideal radical clock should be independent of polarity, viscosity, and spin multiplicity. Some of these effects have been analyzed in the case of two acyl radicals. Studies with $PhCH_2CO$ and *t*-BuCO suggest that changes in solvent polarity and viscosity result in rate constant changes no greater than a factor of 2 to 3 (Table 48.4).[40] It has also been suggested that rate constants of acyl decarbonylation in radical pairs and biradicals should be independent of their spin multiplicity and similar to those of analogous free radicals.

TABLE 48.3 Thermal Activation Parameters and 296 K Rate Constants for Decarbonylation of Several Acyl Radicals[a]

Acyl Radical	Solvent/Phase	log(A) (s^{-1})	Ea_{RCO} (kcal/mol)	k_{-CO} at 296 (s^{-1})

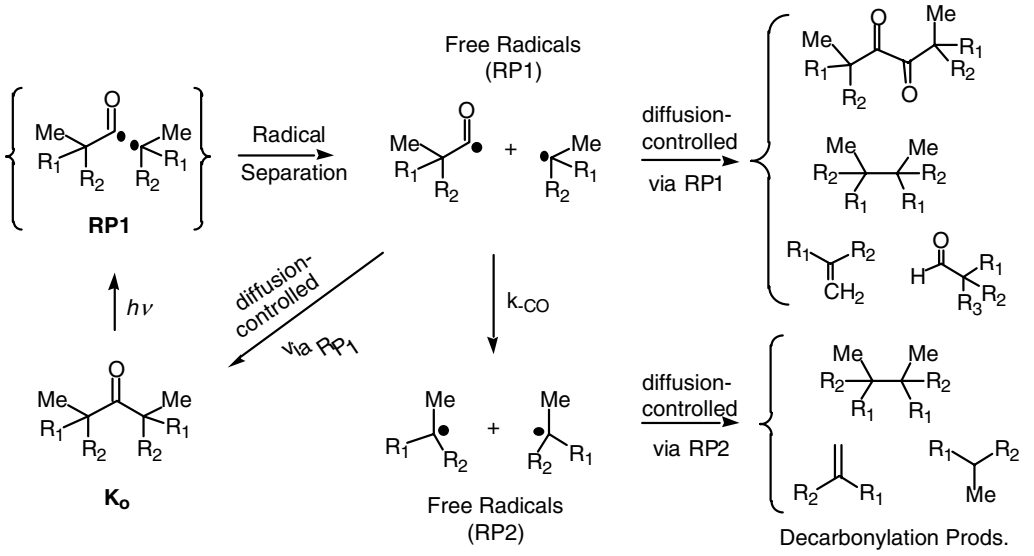
48.6 Solution Photodecarbonylation of Alkyl-Substituted Ketones

The expected correlation between photodecarbonylation efficiencies and the stability of the radicals formed can be illustrated with symmetric ketones giving rise to primary, secondary, and tertiary radicals in solution (Scheme 4). Results from irradiation of diethylketone (3-pentanone) in the gas and in solution are similar to those obtained with acetone.[30,41] In contrast, with two methyl groups on each α-carbon, the excited state of di-*iso*-propylketone **7** α-cleaves and loses CO to give decarbonylated products in ~51% chemical yield. Finally, as expected from the presence of three radical-stabilizing methyl groups on each α-carbon, di-*t*-butylketone **8** was reported to decarbonylate with a quantum yield of $\Phi = 0.7$ from both singlet ($\Phi 1 = 0.3$) and triplet ($\Phi 3 = 0.4$) states and a yield of CO formation of 90%.[33]



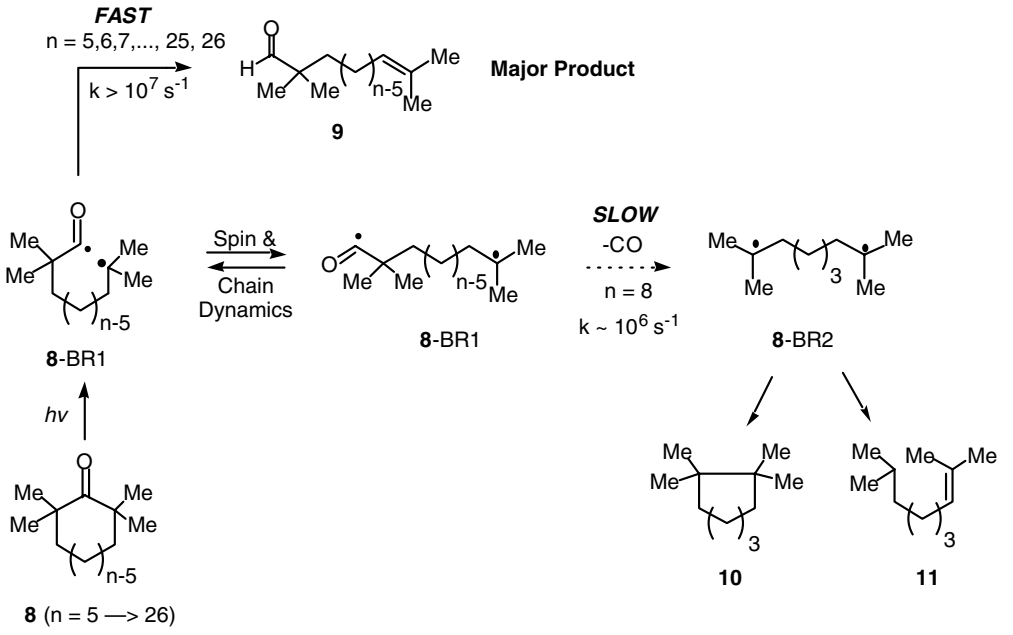
Ketone	R_1 R_2	k_{-CO} (s-1)	% Decarb. Prods. (298 K)
Diethylketone (**2**)	H H	2.1×10^2	< 2%
Di-*i*-propylketone (**7**)	Me H	1.4×10^4	51
Di-*t*-butylketone (**8**)	Me Me	8.3×10^5	>90

SCHEME 4

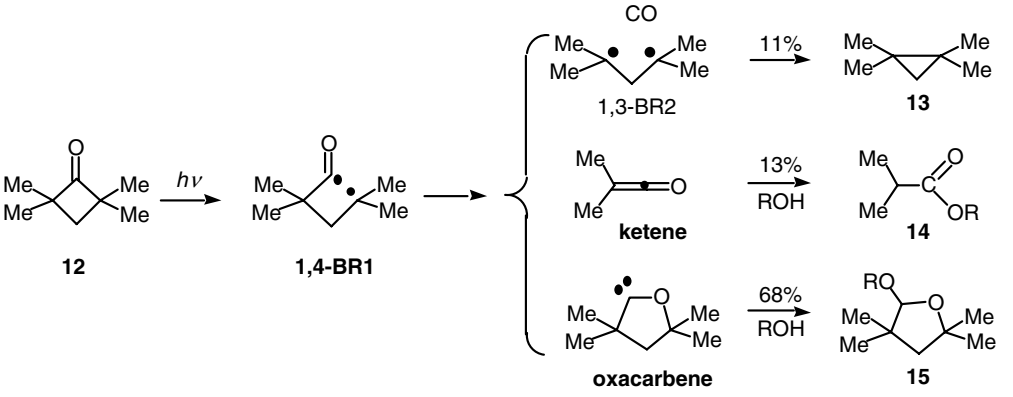
The high decarbonylation efficiency of di-*t*-butyl ketone **8** implies that the acyl and alkyl fragments of the primary pair can separate and remain separated as free radicals long enough for the pivaloyl radical to lose CO with a time constant of ~1.2 to 1.5 μs.[42,43] In contrast, the decarbonylation efficiency of the cyclic ketone analogs in Scheme 5 is remarkably reduced by the average proximity of the two radical termini, which facilitates faster radical–radical reactions.

It has been shown that triplet biradicals **8**-BR1 (Scheme 5) generated from tetra-alkyl ketones at ambient temperature in nonviscous liquids experience very fast conformational equilibration so that the rate-limiting step for product formation is intersystem crossing to the singlet state **8**-BR1. Studies have shown that rate constants for intersystem crossing for acyl–alkyl biradicals are primarily determined by spin-orbit coupling, which depends on the average distance between the two radical termini. With rates of intersystem crossing for a large range of acyl–alkyl biradicals falling within a range of 10 to 100 ns, the decarbonylation of dimethyl-substituted acyl radicals (expected to have a rate constant similar to that for a free pivaloyl radical in solution, or 1.2–1.5 μs) is very unfavorable.[42,44–46] Solution studies by several authors with α,α,ω,ω-tetramethyl-cycloalkanones with ring sizes between 5 and 26 ($\mathbf{8}_5$ - $\mathbf{8}_{26}$) have shown that intersystem crossing and radical–radical reactions in the tetramethyl acyl–alkyl biradicals **8**-BR1 are indeed faster than decarbonylation (Scheme 5).[42,46] A notable exception is tetramethylcyclooctanone $\mathbf{8}_8$, for which decarbonylation was detected, presumably reflecting the thermodynamically unfavorable end-to-end cyclization of the medium size ring.[42]

The photochemistry of tetramethyl-cycloalkanones with three- and four-membered rings differs substantially from those of the higher analogs (Schemes 6 and 7). The release of ring strain upon α-cleavage in tetramethylcyclobutanone accelerates the reaction to the extent that it occurs faster than intersystem crossing in the singlet-excited state. As illustrated in Scheme 6, irradiation of tetramethylcyclobutanone **12** in methanol solution generates a 1,4-acyl–alkyl biradical **1,4**-BR1.[47] Acyl–alkyl biradicals can decarbonylate to give a 1,3-biradical **1,3**-BR2, which goes on to give cyclopropanone, they can cleave along



SCHEME 5



SCHEME 6

the 2,3-bond to generate isobutylene and dimethyl ketene, or they may ring-expand to give an oxacarbene intermediate. Reactions carried out in alcohol result in formation of cyclopropane **13** in 11% yield, isobutyric ester **14** in 13% yield, and cyclic ketal **15** in 68% yield. Compounds **14** and **15** form by reaction of the intermediate dimethylketene and oxacarbene, respectively, with the alcohol solvent.

Studies on the photochemistry of tetramethylcyclopropanone **17** have revealed efficient α-cleavage and decarbonylation reactions to give 2,3-dimethyl-2-butene **19** as the only product (Scheme 7). Interestingly, cyclopropanone **17** is prepared by an efficient decarbonylation of 2,2,4,4-tetramethylcyclobutanedione **16**.[48] Cyclopropanones, in general, are highly reactive compounds that can thermally equilibrate with oxyallyl, the open-shell 1,3-diyl **18**. While cyclopropanones are highly susceptible to nucleophilic attack to form hydrates and hemiketals, oxyallyl was shown to react rapidly with oxygen and furan.

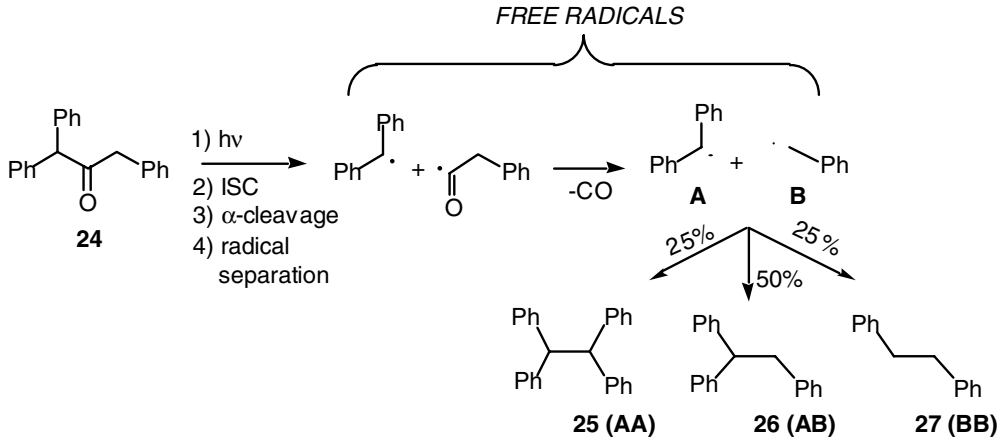
48.7 Solution Photodecarbonylation of Diaryl-Substituted Ketones

The presence of α- and α′-phenyl groups in 1,3-diphenylpropanones (dibenzyl ketones) results in one of the most efficient and general substrates for photodecarbonylation reactions.[49,50] As a representative set, compounds **20** to **23** (Scheme 8 and Table 48.5) give rise to diphenylethanes as the only observable products in high chemical yield. The reaction is facilitated by high triplet yields, efficient α-cleavage, rapid separation of benzyl and 2-phenylacetyl radicals in solution, and the loss of CO from the phenyl–acetyl fragment with a time constant of ~120 ns (Scheme 8).[36] Combination of the two benzyl radicals gives rise to diphenylethanes with quantum yields higher than 0.65 and chemical yields approaching 100%. An exceptional stability was observed for the 4-cyanophenyl derivative **23**, which was proposed to undergo an intramolecular quenching process.[50]



SCHEME 9

As expected from random free-radical recombination, three products are formed in statistical yields when the two benzyl radicals are different (Scheme 9).

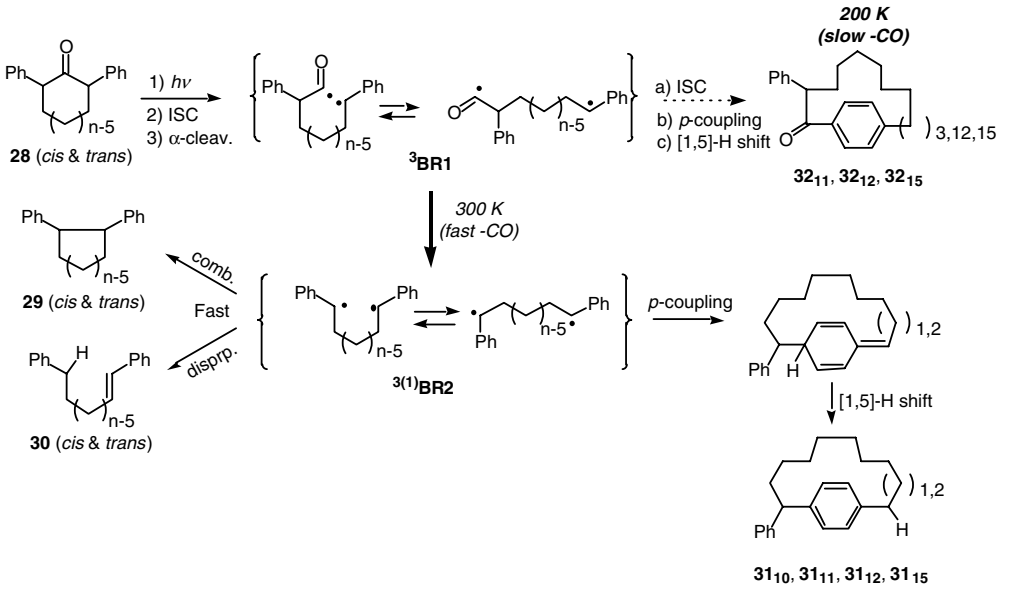
As a typical example, excitation of 1,1,3-triphenyl-2-propanone **24** leads to formation of diphenylmethyl (A) and benzyl (B) radicals which re-encounter to yield tetraphenylethane **25** (AA), triphenylethane **26** (AB), and diphenylethane **27** (BB) in statistical 1:2:1 ratios and with a high chemical yield.[51]

With decarbonylation reactions that occur with a time constant of ~25 ns (see Table 48.3), the formation of α-alkyl-benzyl radicals increases the efficiency of the reaction in α,α′-diphenylcycloalkanones, even when the radical centers in the acyl–alkyl biradicals are held relatively close to each other. Thus, unlike the tetramethyl cycloalkanones in Scheme 5, which fail to decarbonylate before intersystem crossing to the singlet state, α,α′-diphenylcycloalkanones **28** undergo a very fast efficient photodecarbonylation reaction in solution. Several studies have been carried out with α,α′-diphenylcycloalkanones **28** with ring sizes that range from 6 (**28**$_6$)[52,53] to 15 (**28**$_{15}$)[54] (Scheme 10). As indicated in Scheme 10, decarbonylation of the triplet acyl–alkyl biradicals (^{3}BR1) at ambient temperature is generally faster than intersystem crossing to the singlet state. While the time constant for intersystem crossing and reaction for dibenzyl biradicals formed is on the order of 200 ns,[55] decarbonylation is expected to occur with a time constant of ~25 ns, assuming a similar value as the PhCH(Me)CO free radical in Table 48.3.

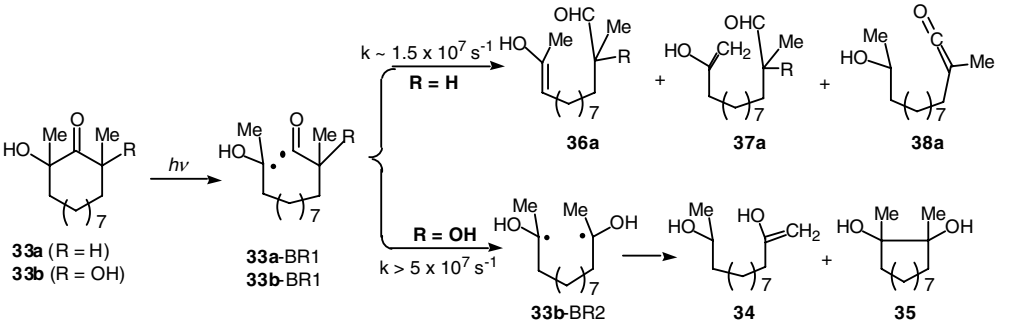
Once formed, the triplet dibenzyl biradicals (^{3}BR2) explore their conformations and intersystem cross to give closed-shell products **29**, **30**, and **31** with rate constants and reaction yields that depend on the length of the alkyl chain. Compounds with small ring sizes (**28**$_6$ to **28**$_8$) react primarily by combination (**29**$_6$ to **29**$_8$) and/or disproportionation (**30**$_6$ to **30**$_8$), and compounds with large ring size react also by attack of one benzyl radical to the *para*-position of the benzyl radical at the other end of the chain. Cyclophanes **31**$_{10}$, **31**$_{11}$, **31**$_{12}$, and **31**$_{15}$ are formed in that manner after a [1,5]-hydrogen shift from the original methylene–cyclohexadiene structure. When reactions are carried out at low temperatures, the rate of decarbonylation of the acyl radical is decreased as compared to the rate of intersystem crossing so that products can form in the singlet acyl–alkyl biradical, including product from attack to the *para*-position of the benzyl radical to form the cyclophane ketones **32**$_{11}$, **32**$_{12}$, and **32**$_{15}$.

48.8 Solution Photodecarbonylation of Ketones with Other α-Substituents

Other radical stabilizing substituents may also facilitate the photodecarbonylation reaction in solution, but very few have been systematically studied. Recent studies with the dodecanones **33a**[56] and **33b**[57] illustrate the enabling effect of α-hydroxyl groups on the decarbonylation reaction (Scheme 11). Although



SCHEME 10

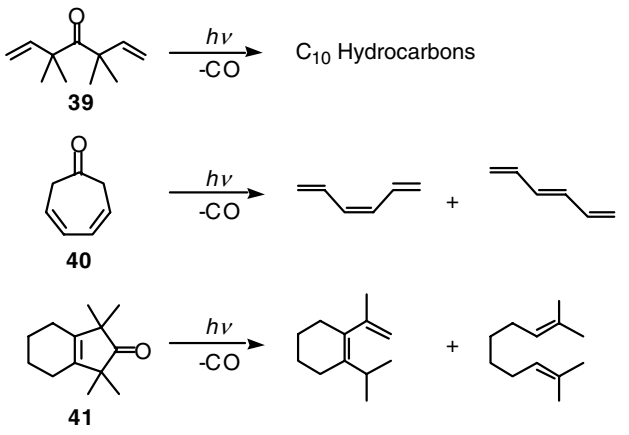


SCHEME 11

efficient α-cleavage from the triplet state of the two ketones generates the primary acyl–ketyl biradicals **33a**-BR1 and **33b**-BR1, only the latter decarbonylates fast enough to generate the secondary diketyl biradical **33b**-BR2 in significant yields. Analysis of time-resolved CIDNP data from **33a** showed that **33a**-BR1 intersystem crosses to the singlet state and reacts by disproportionation to give to **36a–38a** with a rate constant that is ~35 times faster than the rate constant for decarbonylation ($k_{rxn} = 1.5 \times 10^7\ s^{-1}$ and $k_{-CO} = 4.2 \times 10^5\ s^{-1}$). In contrast, with methyl and hydroxy groups in the two α-positions, the rate of decarbonylation of the acyl–ketyl biradical **33b**-BR1 was estimated to be $k_{-co} > 5 \times 10^7\ s^{-1}$, which is 111-fold faster than that of **33a**-BR1. Therefore, in the case of ketone **33b**, products **34** and **35** from biradical **33b**-BR2 are highly favored over products from the short-lived acyl–ketyl biradical **33b**-BR1.

A wide range of radical-stabilizing substituents in the α- and α′-positions may facilitate the photodecarbonylation of ketones in solution and a few examples in Scheme 12 illustrate the enabling effect of vinyl substituents in both cyclic[58] and acyclic compounds.[59]

Remarkably, the photodecarbonylation of ketones **39**, **40**, and **41** proceeds in >90% chemical yield whether occurring via free radical for **39** or biradical intermediates for **40** and **41**. Tetramethyldivinyl



SCHEME 12

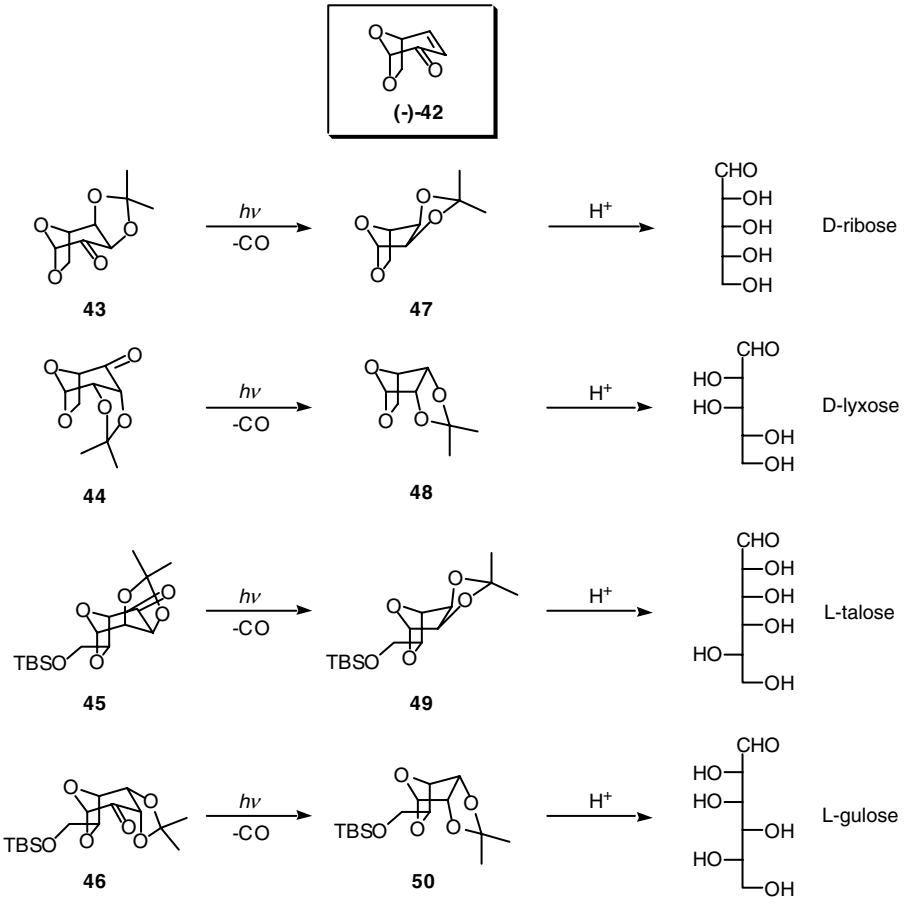
acetone **39** was reported to give CO along with a product mixture characterized as C_{10} hydrocarbons, presumably formed by combination of two dimethylvinyl free radicals. Similarly, the efficient formation of decarbonylation products from cyclic ketones **40** and **41** indicates that the loss of CO must occur faster than intersystem crossing and reaction of acyl–alkyl biradical intermediates. The formation of *cis*- and *trans*-hexatrienes from **40** and the formation of a disproportionation product from **41** may be taken as indications of a stepwise radical process rather than concerted elimination of CO by chelotropic reaction.

In another interesting set of examples, the photochemistry of ketones **43** to **46** illustrates the effect of α-hydroxy and α′-ketal groups on the decarbonylation reaction in solution.[60] Compounds **43** to **46** were recently prepared from the optically active α,β-unsaturated compound (–)-**42** and were shown to photodecarbonylate to give products **47** to **50** by enantiospecific radical–radical combination reactions in relatively good chemical yields. The utility of this reaction for a novel strategy for carbohydrate synthesis was nicely demonstrated. The examples in Scheme 13 illustrate reactions leading to the synthesis of D-ribose and D-lyxose, as well as the hexoses, L-talose and L-gulose.

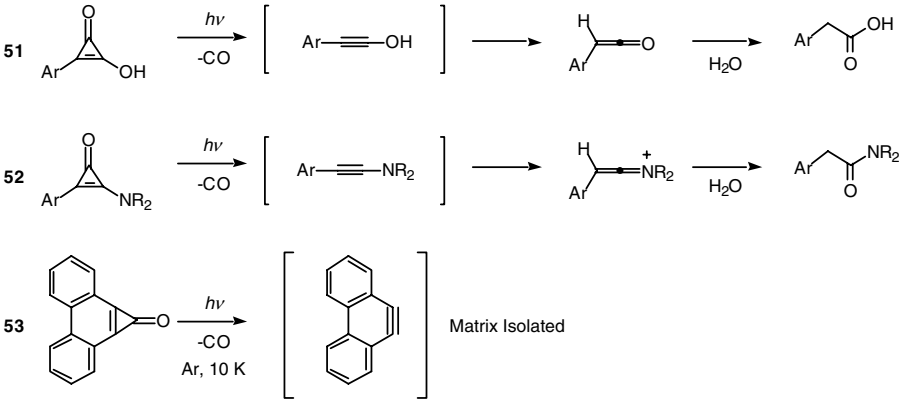
Ketone decarbonylation reactions have been useful for the preparation of highly reactive molecules. A few examples include the preparation of ynols,[61] yneamines,[62] and strained alkynes[63] by *in situ* photolysis of cyclopropenones **51** to **53** (Scheme 14). These high-energy compounds are short-lived transients that must be either detected by fast kinetic methods or kinetically stabilized in cryogenic matrices to facilitate their detection. Phenanthrocyclopropenone **53** was generated *in situ* by photolysis of a *bis*(diazo)ketone or by photodecarboxylation of dicarboxyphenathrene anhydride.[63]

48.9 Photodecarbonylation Reactions in Crystals

The first few examples illustrating the photochemical decarbonylation of pure crystalline ketones were reported by Quinkert and co-workers in 1971 (Scheme 15).[64] It was shown that irradiation of α,α′-diphenyl-indanones **54** to **57** in solution and in crystals proceeded to give decarbonylation products in very high chemical yields, but with remarkably medium-dependent chemo- and stereo-selectivities.[65] Photochemical reactions in crystalline solids were substantially more chemoselective and stereospecific than those carried out in solution. Crystals of *cis*- and *trans*-diphenyl indanones **54** and **55** yielded the corresponding *cis*- and *trans*-diphenylbenzocyclobutanes **58** and **59** in 95% yield, respectively, while crystals of *cis*- and *trans*-α,α′-dimethyl-α,α′-diphenyl-indanones **56** and **57** yielded benzocyclobutanes **60** and **61** as the main products in 90 and 86% yields, respectively. When reactions were carried out in dilute solution, significantly lower selectivities and specificities were observed. Compounds **54** and **55** yielded benzocyclobutanes **58** and **59** in a very similar ratio, suggesting an equilibration process involving

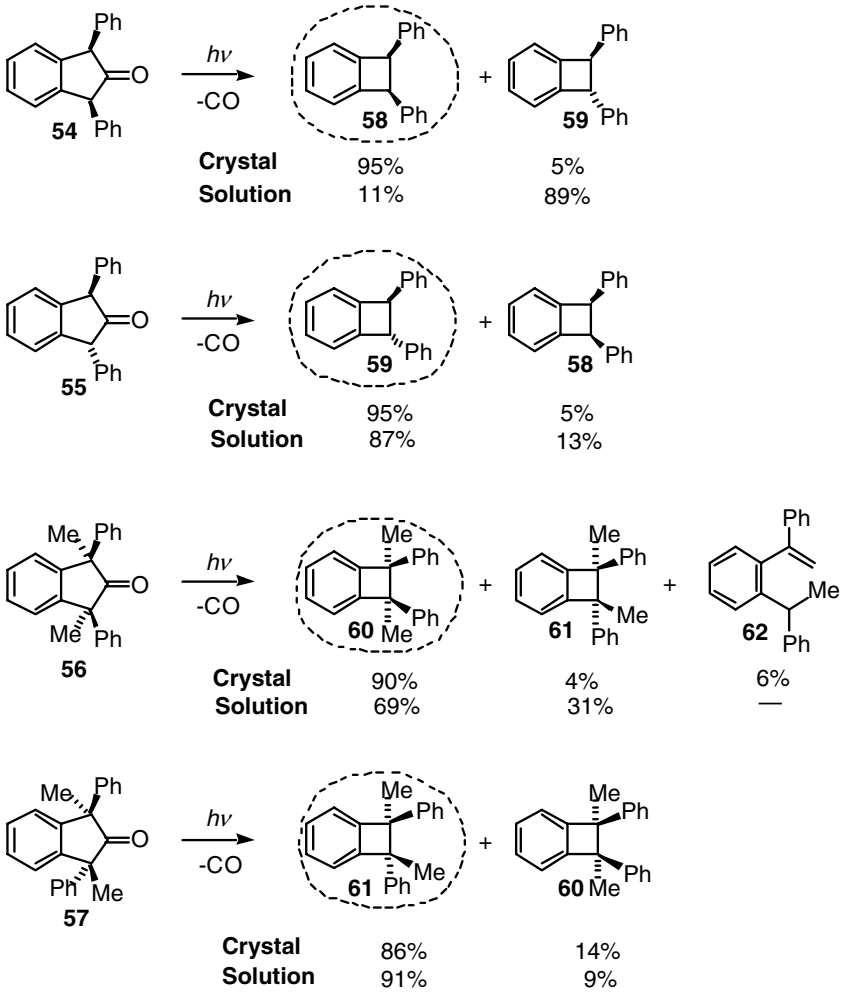


SCHEME 13



SCHEME 14

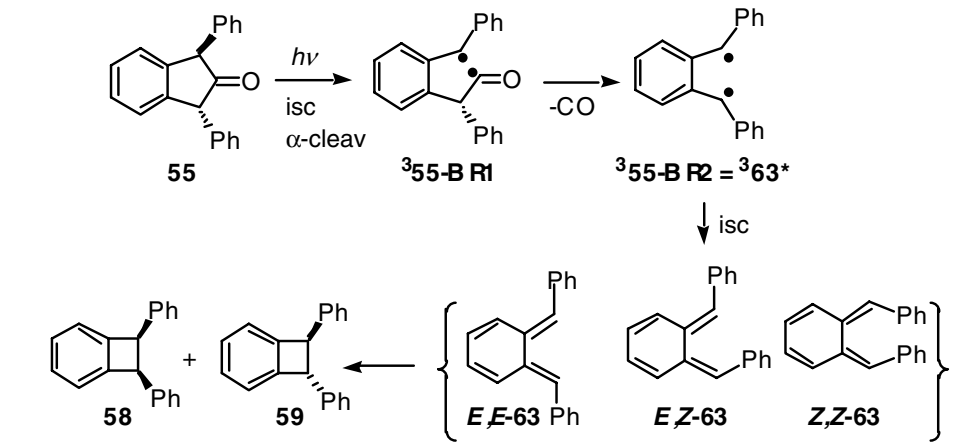
common intermediates. In contrast, different product mixtures from the sterically more encumbered **56** and **57** suggested that full equilibration may not take place for the corresponding intermediates. Product mixtures from these ketones included substantial amounts of the vinyl benzene derivative **62** in addition to benzocyclobutanes **60** and **61**.



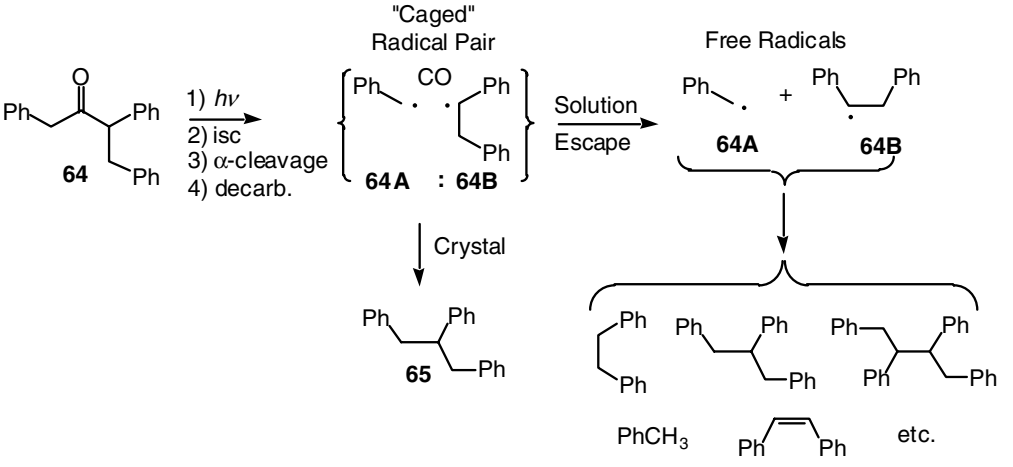
SCHEME 15

The reaction mechanism for the photolysis of 3-indanones in solution has been investigated in some detail. As illustrated in Scheme 16 with 3-indanone **55**, the reaction occurs efficiently in the triplet excited state by stepwise α-cleavage and decarbonylation reactions to give the triplet 1,4-biradical ^{3}**55**-BR2 which corresponds to the triplet excited state (^{3}**63***) of *ortho*-quinodimethanes **63**. Although products (*E,Z*)-**63**, (*E,E*)-**63** and (*Z,Z*)-**63** can be detected by spectroscopic methods, they give rise to benzocyclobutanes **58** and **59** by 8π-electron electrocyclic ring closure.[64] It has been suggested that the vinyl-benzene derivative **62** is formed by [1,5]-hydrogen shift from the analogous *ortho*-quinodimethane from the methyl-substituted 3-indanone **56**. Although it has not been investigated whether an *ortho*-quinodimethane intermediate is also formed in crystals of indanones **54** to **57**, the relative large changes in shape and volume suggest that a 1,4-biradical may close directly to the benzocyclobutane by a least motion pathway.

Twelve years after the pioneering work of Quinkert et al., while the "cage effect" of several diphenyl propanones in several reaction media were being studied,[66] the photodecarbonylation of crystalline 1,3,4-triphenyl-2-pentanone **64** was reported by Turro and co-workers (Scheme 17).[67] It was shown that irradiation of **64** in solution gave a complex mixture of products arising from random free-radical–radical reactions of **64A** and **64B**. In contrast, reactions carried out in crystals to very low conversion values gave



SCHEME 16

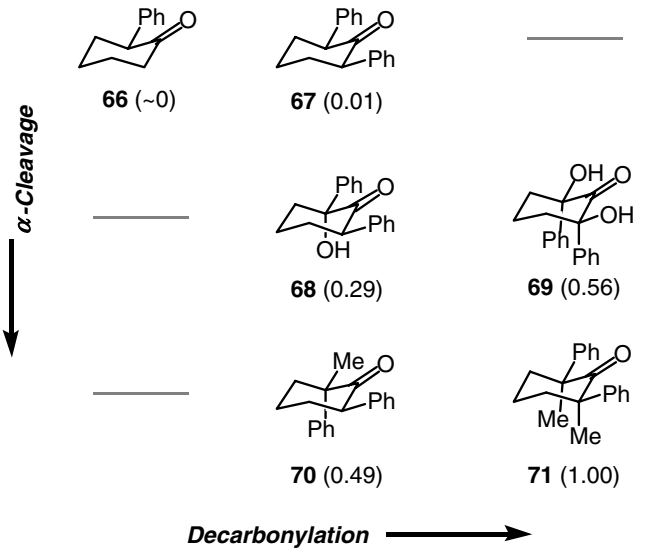


SCHEME 17

1,2,3-triphenylpropane **65** with a remarkable 98% selectivity by radical–radical combination of the caged radical pair {**64A**:**64B**}.

48.10 Photochemical Efficiencies in Crystals of α-Phenyl-Substituted Cyclohexanones

Although the reports by Quinkert and Turro suggested the feasibility of the decarbonylation reaction in crystals and demonstrated a very high chemo- and stereoselectivity, the factors that may facilitate or impede solid-state reactivity remained unexplained. Recognizing that the efficient α-cleavage and rapid acyl-radical decarbonylation of ketones with radical stabilizing α- and α′-phenyl substituents may determine the reactivity of ketones **54** to **57** and **64** (Schemes 15 and 17), Choi et al.[68] carried out the first systematic search for a correlation between the reactivity of solids and the stability of the radicals involved in the reaction (Scheme 18).



SCHEME 18

The crystalline cyclohexanones **66** to **71**, with various α-substituents, were selected for their study. The *cis*-/*trans*- configurations and axial–equatorial conformations of the substituents shown in Scheme 18 were established by x-ray diffraction. It was also shown that the phenyl groups are oriented in such a way that benzylic delocalization of the putative radical species may occur. Knowing that compounds **66** to **71** react in solution by α-cleavage with similar quantum yields of ketone disappearance (Φ_{-CO} > 0.6),[52,53,59] it was suggested that reactivity differences in the solid state could be assigned both to the ease of α-cleavage from the triplet excited state and the ease of decarbonylation of the acyl–alkyl biradical. To determine this, relative quantum efficiencies were determined in side-by-side irradiations with microcrystalline samples dispersed in KBr matrices using monochromatic ultraviolet light. The extent of reaction was determined by measuring changes in absorbance of the CO band as a function of irradiation time to obtain initial reaction velocities proportional to the intensity of the irradiating light (which was kept constant) and to the quantum yield of reaction.

The results in Figure 48.6 and the relative quantum yields in parentheses in Scheme 18 show a strong correlation between the radical-stabilizing effects of the α-substituents in **66** to **71** and their solid-state reaction efficiencies. A reaction mechanism involving a triplet-state reaction was suggested to explain the photostability of **66** and the 100-fold reactivity difference observed. It was suggested that the rates and efficiencies of triplet-state α-cleavage should be similar for the pair of ketones in each row of Scheme 18. Similar benzyl–acyl biradicals are formed from **66** and **67**, hydroxybenzyl–acyl biradicals from **68** and **69**, and methylbenzyl–acyl biradicals from **70** and **71**. It was also suggested that an increase in relative quantum yields in going from left to right can be correlated with an increase in the yield of decarbonylation.

The lack of reactivity from 2-phenylcylcohexanone **66** may be understood in terms of a cycle given by steps 1, 2, and 3 in Scheme 19. The reaction starts in the triplet excited state with an α-cleavage reaction to give a 1,6-biradical where the acyl and benzyl radical termini are held very closely but are unable to give closed-shell products (step 1).[70] Because decarbonylation of the benzyl–acyl biradical derived from **66** would yield a very unstable primary radical center, it is reasonable to suggest that the reaction is too slow to compete with intersystem crossing to the singlet state (step 2). While the singlet biradical ^{1}BR1 from **66** reacts in solution by disproportionation with a quantum yield for ketone disappearance of 0.6, formation of ^{1}BR-1 in crystals should be ideally set to return the starting material (step 3), thus accounting for lack of product formation in the solid state. In contrast, with phenyl groups at the two α-carbons,

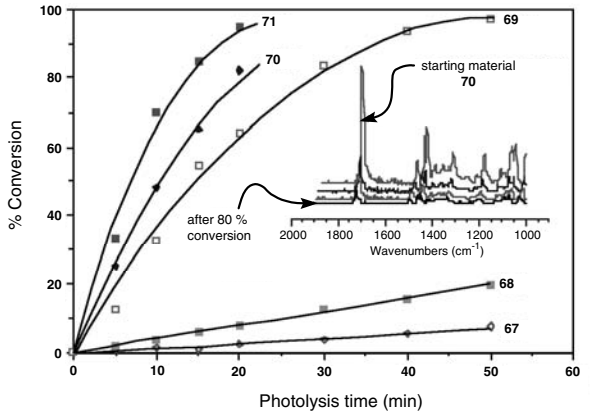


FIGURE 48.6 Normalized conversion vs. irradiation time of microcrystals of cyclohexanones **66** to **71** dispersed in KBr matrices. Inset: Representative FT-IR data from compound **70**.

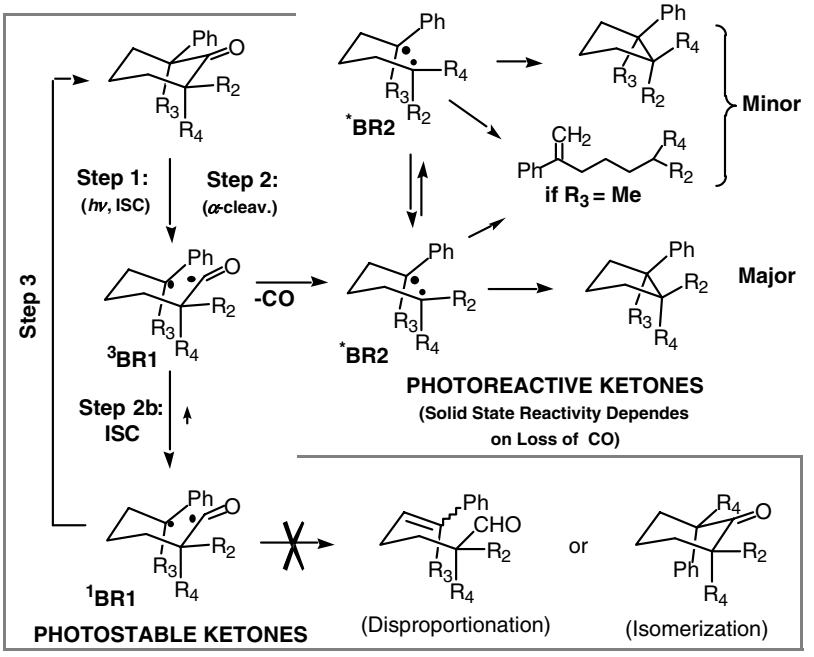


SCHEME 19

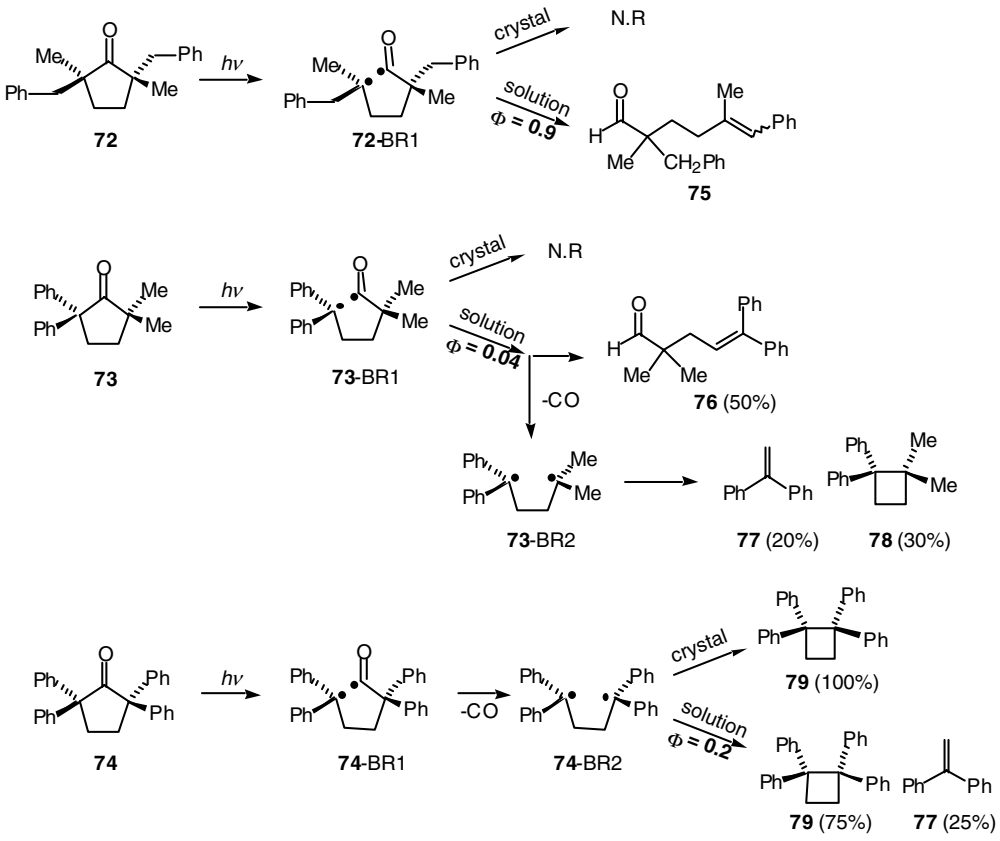
decarbonylation of the benzyl–acyl biradicals from *cis*-2,6-diphenylcyclohexanone **67** can give a 1,5-*bis*(benzylic) biradical in competition with steps 2 and 3. While irradiation of **67** in solution yields a conformationally extended biradical that gives mixture of *cis*- and *trans*-diphenylcyclopentane and *cis*- and *trans*-1,5-diphenyl-1-pentene with a high quantum yield ($\Phi \geq 0.6$), irradiations in the solid state give *cis*-diphenylcyclopentane with high selectivity but with a significantly lower efficiency. One may conclude qualitatively that the rate constant for intersystem crossing to the acyl–benzyl biradical **67**-^{1}BR1 is still much greater than the rate of decarbonylation to the *bis*(benzyl) radical pair **67**-^{3}BR2.

The 29- and 49-fold increase in reaction efficiency in going from **67** to **68** and **69** can be assigned to an increase in the efficiency of the α-cleavage reaction. The α-hydroxy and α-methyl substituents in the

latter compounds should lower the bond dissociation energy of the α-bond and reduce the activation energy of the α-cleavage reactions. While reactions of **68** and **69** in solution are less selective than reactions in crystals, both compounds gave mixtures of combination and disproportionation products in the two reaction media. Finally, one may speculate that the rates of α-cleavage of **68** and **70** or **69** and **71** should be very similar to each other and assign the twofold increase in reaction efficiencies observed in going from **68** to **70** and from **69** to **71** to the effects of substituents on the decarbonylation reaction. Ambient temperature rate constants for decarbonylation of analogous free acyl radicals in solution are ~10^8 s^{-1} (Table 48.3), suggesting the approximate order of magnitude for the rate of intersystem crossing in the solid state. It is well known that short biradicals tend to have very short lifetimes due to their fast intersystem crossing rates. The intersystem-crossing limited lifetimes of acyl–alkyl biradicals from the Norrish type I reaction of cyclopentanones are only 10 to 15 ns. Although closer inter-radical distances are expected to result in shorter lifetimes, to our knowledge no data exist for acyl–alkyl biradicals derived from cyclobutanones or cyclopropanones. The distance dependence of biradical lifetimes has also been documented with the triplet α,ω-1,n-diyls[71] where the lifetimes decrease from ~900 ns for 1,5-biradicals and 200 ns for 1,4-biradicals down to 15 to 20 ns for 1,3-biradicals.[69b,72] A dramatic increase in the rate of intersystem crossing as the distance between the two radicals decreases is assigned to an increase in spin-orbit coupling, which mediates the transition between triplet and singlet states. While it is likely that triplet lifetimes in crystals may be short and may lead to acyl–alkyl radical recombination back to the ground state, it is also known that biradical lifetimes tend to increase in highly viscous media when chain dynamics becomes the rate-limiting step.[73] However, given that chain extension (or radical separation) in crystals is not possible, slow radical–radical reactions and singlet–triplet equilibration are unlikely.

48.11 Photodecarbonylation of Crystalline Cyclopentanones

The mechanistic conclusion regarding the effects of substituents drawn from the study of the cyclohexanones in Scheme 18 were supported by analysis of several tetrasubstituted cyclopentanones (**72** to **74**) with α-alkyl and α-phenyl substituents (Scheme 20).[74] It was established that compounds **72** to **74** react cleanly in solution to give the products shown in Scheme 20. Quantum yields of ketone disappearance ranged from $\Phi_{-K} = 0.04$ for **73** to $\Phi_{-K} = 0.9$ for **72**. *trans*-2,5-Dimethyl-2,5-dibenzylcyclopentanone **72** reacted in solution by α-cleavage and disproportionation of the acyl–alkyl biradical **72**-BR1, with no traces of decarbonylation products. A mixture of *cis*- and *trans*-aldehydes **75** was formed in solution by a very efficient α-cleavage reaction followed by a highly favorable disproportionation of singlet **72**-BR1. Given the high photoreactivity of **72**, the results with 2,2-diphenyl-5,5-dimethyl-cyclopentanone **73** are initially surprising. Assuming that excited state α-cleavage of **73** is as efficient as that of **72**, its low photoreactivity ($\Phi_{-K} = 0.04$) is an indication that the acyl–alkyl biradical **73**-BR1 returns to the starting material faster than any competing reaction. The formation of 1,1-diphenylethane **77** and cyclobutane **78** from a 1,1-dipheny-4,4-dimethy-1,4-biradical in a combined 50% yield and a quantum yield of ketone disappearance of 0.04 indicate that decarbonylation occurs with a quantum yield of ~0.02. The high disproportionation efficiencies of **72**-BR1 may reflect the ease of a seven-membered transition state, transfer of a benzylic hydrogen and formation of a very stable double bond as the singlet state of **72** BR1 reacts to form aldehyde **76**. In contrast, the transfer of a secondary hydrogen in a relatively strained transition state appears to disfavor the disproportionation of **73**-BR1 as compared to regeneration of the starting ketone. Not surprisingly, while the solution photochemistry of **72** and **73** were very different, the two ketones failed to react in the solid state. On the contrary, the solution and solid-state reactivity of tetraphenylcyclobutanone **74** was remarkably efficient.[75] While the two phenyl groups on each α-position facilitate the sequential α-cleavage and decarbonylation reactions in the two media, the resulting 1,4-biradical reacted differently in the two reaction media. While reactions in solution yielded cyclobutanone **79** and 1,1-diphenylethane **77** by cyclization and cleavage, reactions in crystals lead exclusively to cyclobutanone **79** in nearly quantitative chemical yields in a very clean solid-to-solid reaction. From a mechanistic standpoint, results in crystals are consistent with the mechanism in Scheme 19. Reactions begin

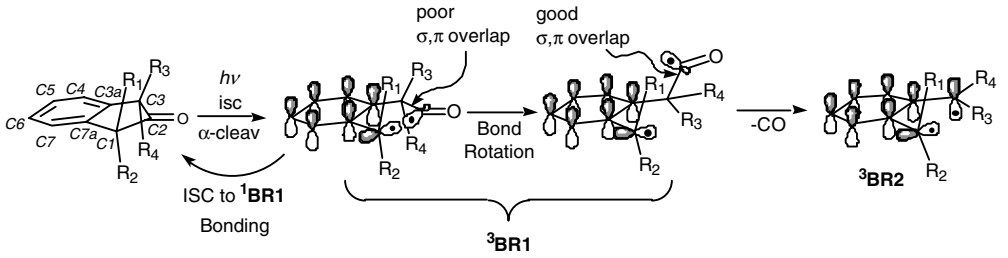


SCHEME 20

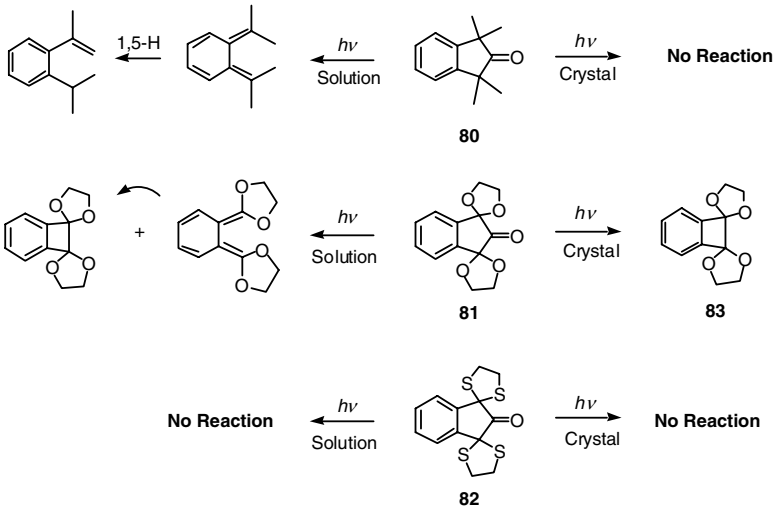
by triplet state α-cleavage to generate the acyl–alkyl biradicals ^{3}BR1. Because formation of tertiary alkyl radicals by decarbonylation of ^{3}**72**-BR1 and ^{3}**73**-BR1 is not fast enough to compete with intersystem crossing, the corresponding singlet biradicals return to ground state by reforming the σ-bond that was broken in the initial α-cleavage step. In contrast, decarbonylation of ^{3}**74**-BR1 proceeds very rapidly by formation of CO and a relatively stable diphenylmethyl radical center. The exclusive formation of tetraphenylcyclobutane **79** may reflect the close proximity of the two radical centers or a preference associated with the reaction pathway that requires the smallest change in volume within the close-packed environment of the crystal.

48.12 Conformationally Restricted Benzylic Stabilization in Crystalline 2-Indanones

Although the solid-state reactivity of several 2-indanones was demonstrated by Quinkert et al.[64,65] in the 1970s, one might ask whether intermediate radicals are able to experience benzylic stabilization by conjugation with the central phenyl group. While irradiation of 2-indanones in solution may lead to triplet acyl–alkyl biradicals (^{3}BR1) where bond rotation allows for conjugation of the emerging benzylic radicals with the central double bond, we may not be able to use reactions in crystals to explore such stabilizing interactions if fast rotation within the solid is hindered. This is illustrated in Scheme 21 by initial cleavage of the C1C2 σ-bond to give a C1-alkyl–C2-acyl biradical labeled ^{3}BR1. It may be expected that fast decarbonylation of ^{3}BR1 may require alignment of the breaking C2C3 bond with the π-orbital of the central phenyl ring to form a stable benzylic radical and a molecule of CO. If rotation about the



SCHEME 21

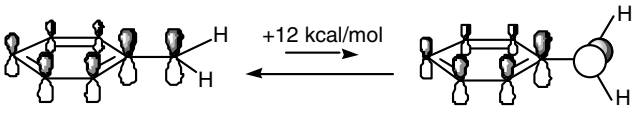


SCHEME 22

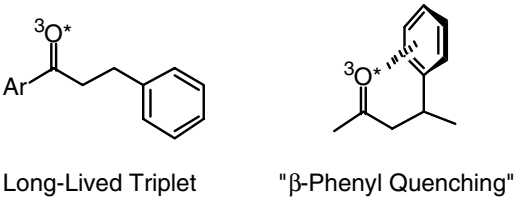
C3C3a bond is not possible in crystals, decarbonylation of ^{3}BR1 may be slower than intersystem crossing to ^{1}BR1 which can go back to the starting ketone (Scheme 21).

Because the compounds studied by Quinkert, including 2-indanones **54** and **55**, have α-phenyl-substituents at C1 and C3, one cannot conclude whether the benzocyclopentanone π-system may contribute to the stability of the intermediate biradicals and facilitate the solid-state reaction. In order to answer this question and to test the effect of methyl, oxygen, and sulfur as α-substituents, the solid reactivities of 2-indanone derivatives **80**, **81**, and **82** (Scheme 22) were recently investigated and compared to those of **54** and **55** (Scheme 15); a reasonable answer was rapidly found.[76]

A comparison of the solid-state results obtained with tetramethyl-2-indanone **80** with the 1,3-diphenyl-2-indanones **54** and **55** suggests the 2-indanone chromophore on its own does not facilitate the solid-state reaction. The lack of solid state reactivity of **80** indicates that return of the acyl–alkyl biradical to the ground state is significantly more efficient than decarbonylation. Experiments and calculations[78] indicate that the difference in energy between benzyl radical conformations with parallel and orthogonal p-π-orbital alignment is ~12.5 kcal/mol, with the orthogonal alignment being disfavored (Scheme 23). Assuming the relation between R–CO bond dissociation energies DH_{R-CO} and decarbonylation rate constants (k_{-CO}) proposed by Fisher and Paul,[15] one may expect that different alignments caused by rotation of the Ph–CH_2CO will lead to differences in DH_{R-CO} of ~12 kcal/mol and differences in k_{-CO} of about three orders of magnitude.



SCHEME 23



SCHEME 24

Knowing that simple alkyl substituents in **80** are unable to facilitate the solid-state reactivity of 2-indanones, the solid-state reactivity of 1,3-*bis*(ethylenedioxy)-2-indanone **81** can be assigned to the effect of the alkoxy-substituents. The lack of reactivity of the *bis*(thioacetal) **82** is consistent with the well-known intramolecular quenching of excited carbonyls by sulfur.

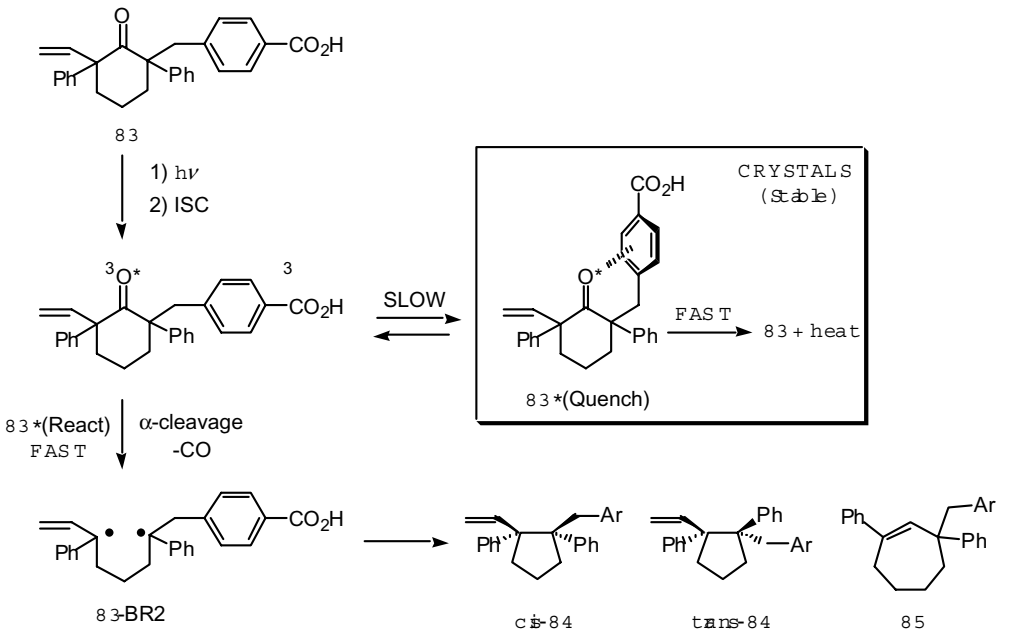
48.13 Suppression of α-Cleavage by β-Phenyl Quenching in Crystalline Ketones

Although several α,α′-diphenyl-substituted ketones can react cleanly and smoothly in the solid state, it may be expected that additional substituents and structural factors will have a strong effect on the efficiency of the reaction. It is known that ketones with β-phenyl groups are susceptible to conformation-dependent quenching by charge-transfer interactions between the carbonyl $n\pi^*$ excited state and the β-phenyl substituent (Scheme 24).[79–81] Scaiano et al.[82] have shown that β-phenyl quenching can reduce the triplet lifetime of crystalline propiophenones by a factor of 10 to 20 from 8 μs down to 0.7 and 0.4 μs, depending on the proximity of the β-phenyl to the carbonyl and on packing differences between racemic and chiral crystals.

With hopes that mechanistic knowledge gathered from excited state processes in solution and in the solid state may be transfesrable from one crystalline structure to another, the photochemistry of the β-phenyl substituted isomers *cis*-**83** and *trans*-**83** was investigated in solution and in crystals (Scheme 25). With 2-phenyl-2-vinyl and 6-phenyl-6-benzyl substituents, cyclohexanones *cis*-**83** and *trans*-**83** are expected to have very efficient α-cleavage and decarbonylation reactions, unless the β-phenyl group is positioned for intramolecular charge-transfer quenching. In fact, molecular structures obtained by single-crystal x-ray analysis revealed solid-state conformations expected to undergo a very efficient intramolecular quenching (Figure 48.7).

Photochemical experiments carried out in solution led to the efficient formation of *cis*- and *trans*-diphenyl cyclopentanes **84** and cycloheptene **85** in a 10:5:1 ratio after >95% conversion. In contrast, photolysis of *cis*-**83** and *trans*-**83** in the crystalline solid state gave only traces of cyclopentanes *cis*-**84** and *trans*-**84**, respectively, even after 12-hr irradiation.[83] The differences between solution and solid-state photochemical reactivity in the cases of *cis*- and *trans*-**83** were explained by considering the conformations present in the two crystals and the conformational dynamics of the two molecules in solution.

As illustrated in Figure 48.7, compounds *cis*- and *trans*-**83** adopt twist-boat conformations with the benzyl groups in pseudoequatorial positions. An efficient β-phenyl quenching interaction in both crystals is facilitated by the close proximity of the carbonyl oxygen and the edge of the aromatic ring. It was suggested that solution results reflect the presence of reactive (***83** React) and nonreactive conformers (***83** Quench), which are unable to equilibrate within their very short lifetimes (Scheme 25).



SCHEME 25

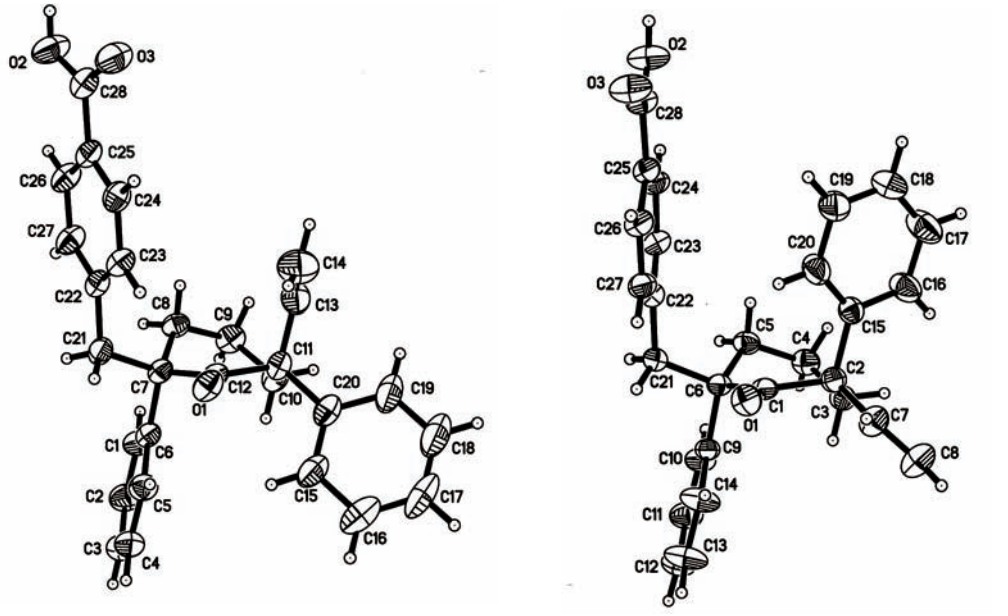


FIGURE 48.7 ORTEP views of compounds *cis*-**83** (left) and *trans*-**83** (right) showing their twist-boat conformations and the disposition of the benzyl group with respect to the ketone carbonyl leading to a very efficient β-phenyl quenching.

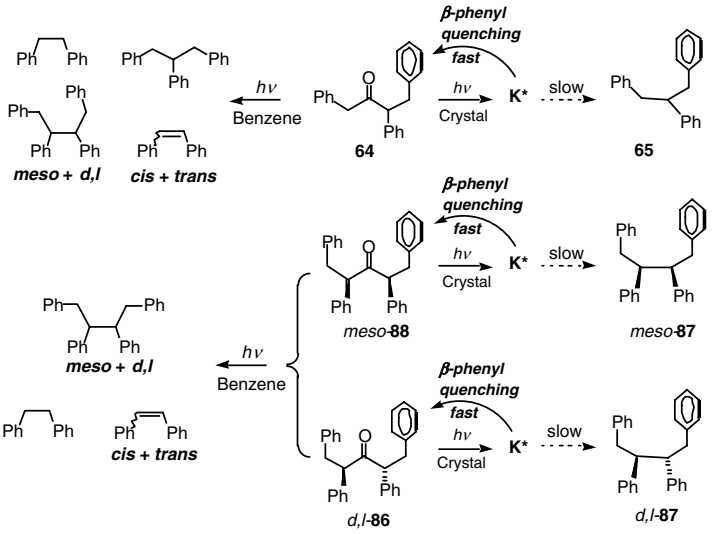
Both β-phenyl quenching and α-cleavage for the α,α′-diaryl ketones in solution are known to occur within sub-nanosecond time scales. The results with crystals of *cis*- and *trans*-**83** are consistent with their molecular structures and add confidence to the use of structure–reactivity correlations known from solution to reactions occurring in crystalline solids.



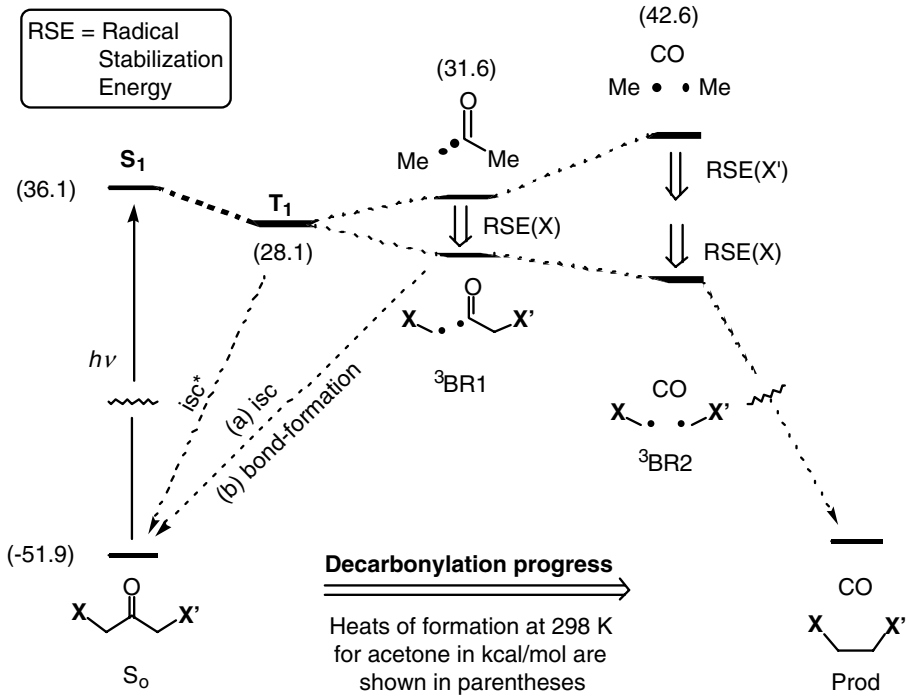
SCHEME 26

Additional examples of β-phenyl quenching in crystals have been recently documented by comparing the relative solid state efficiency of β-phenyl-containing compounds with analogous structures lacking the quenching motif (Scheme 26). Among these is the α-benzyl-1,3-diphenyl acetone **64**, which was reported by Baretz and Turro to react inefficiently. Although photochemical reactions in crystals of triphenylbutanone **64** and *meso*- and *d*,*l*-**86** proceeded in very low yields after long irradiation periods (e.g., less than 5% conversion in 12 hr), reactions in crystals were highly chemoselective and stereospecific. As indicated in Scheme 26, the only products detected in crystals were those formed by decarbonylation and stereospecific radical–radical combination. The *meso*- and *d*,*l*-diastereomers of ketone **86** reacted to give diphenylethanes *meso*-**87** and *d*,*l*-**87**, respectively, as the only solid state products.[84]

48.14 Engineering Reactions in Crystals: Energetic Considerations

The reliable design of reactions in crystalline solids may bring the development of synthetic and materials applications. Our intuition of reactions in crystals is slowly changing as more is known about their possibilities and limitations. As improbable as it may seem, the sequential cleavage of two σ-bonds may become one of the most reliable reactions in the solid state. Although the homolytic cleavage of σ-CC bonds from ground-state ketones would require thermal energies incompatible with the integrity of their low melting solids, the absorption of a UV photons provides a reacting ketone with ~70 to 80 kcal/mol of excitation energy that may be channeled into the two sequential bond-breaking processes required to form two alkyl radicals and a molecule of CO (Scheme 27). However, it may be stressed that the key to reactions in crystals is to have the triplet-state α-cleavage reaction ($T_1 \rightarrow {}^3BR1$) faster than intersystem crossing to the ground state ($T_1 \rightarrow S_0$) and decarbonylation reactions (${}^3BR1 \rightarrow {}^3BR2$) that are faster than acyl–alkyl recombination back to the starting ketone (${}^3BR1 \rightarrow S_0$). Given that a strong correlation exists between the heat of bond-cleavage reactions and their activation energies, it has been suggested that sufficiently fast α-cleavage and decarbonylation should be more likely when they are exothermic.

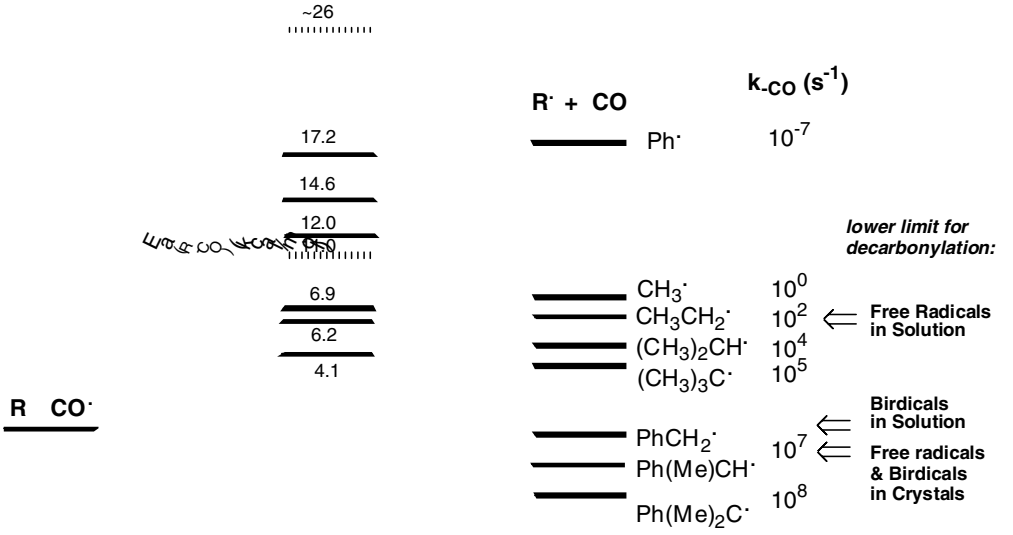
Taking acetone as a benchmark and knowing that bond dissociation energies are related to the radical stabilization energies of the α-substituents, one can estimate whether the extent of radical stabilization provided by substituents X and X′ is sufficient to make each cleavage step thermochemically favorable (Scheme 27, radical stabilization energies, RSE(X) and RSE(X′)). In the case of acetone, the triplet state



SCHEME 27

has an excitation energy of ~79 kcal/mol.[85] In agreement with the low reaction yields in solution and the energy-dependent results observed in the gas phase, α-cleavage and decarbonylation are endothermic by 3.5 and 11 kcal/mol, respectively.[86] One may predict more efficiently α-cleavage for acetone derivatives with α-bonds that are weaker than 79 kcal/mol and more efficient decarbonylation for acyl radicals with R–CO bonds that are weaker than 11 kcal/mol. However, because the initial α-cleavage occurs at the weakest bond, one may expect that substituents that lower the bond dissociation energy (BDE) of the two α-bonds by >11 kcal/mol are required.

Support for a thermochemical prediction of solid-state reactivity according to the model in Scheme 27 was based on observations with the effects of alkyl and benzyl substituents discussed above along with thermochemical and kinetic data available in the literature. A summary of activation energies, reaction enthalpies, and approximate reaction rate constants for decarbonylation of acyl radicals at ambient temperature is illustrated in Scheme 28. The formation of phenyl, methyl, ethyl, *iso*-propyl, and *t*-butyl radicals from their acyl radical precursors is endothermic. Not surprisingly, the formation of carbonyl compounds by reaction of these radicals with CO gas at medium or high pressures has been used in several synthetic applications. However, with ~12 kcal/mol of resonance stabilization, the formation of benzyl radicals from 2-phenylacetyl is almost thermoneutral, has an activation barrier of only 7 kcal/mol, and occurs in solution with a rate constant of 10^7 s^{-1}. Examples of crystalline ketones giving rise to benzyl radicals have been documented, although their reactions are very inefficient. It may be estimated also from literature values that formation of α-methylbenzyl and α,α-dimethylbenzyl from their acyl radical precursors should be exothermic by ~4 and 8 kcal/mol, respectively. Activation energies and rate constants are 6.2 kcal/mol and 4×10^7 s^{-1}, respectively, for α-methylbenzyl and 4.1 kcal/mol and 1.5×10^8 s^{-1} for α,α-dimethylbenzyl (Scheme 28). Also shown in Scheme 28 is an approximate lower limit for the rate of decarbonylation to compete with radical–radical reactions, estimated from experimental observations in inert media and at ambient temperature.



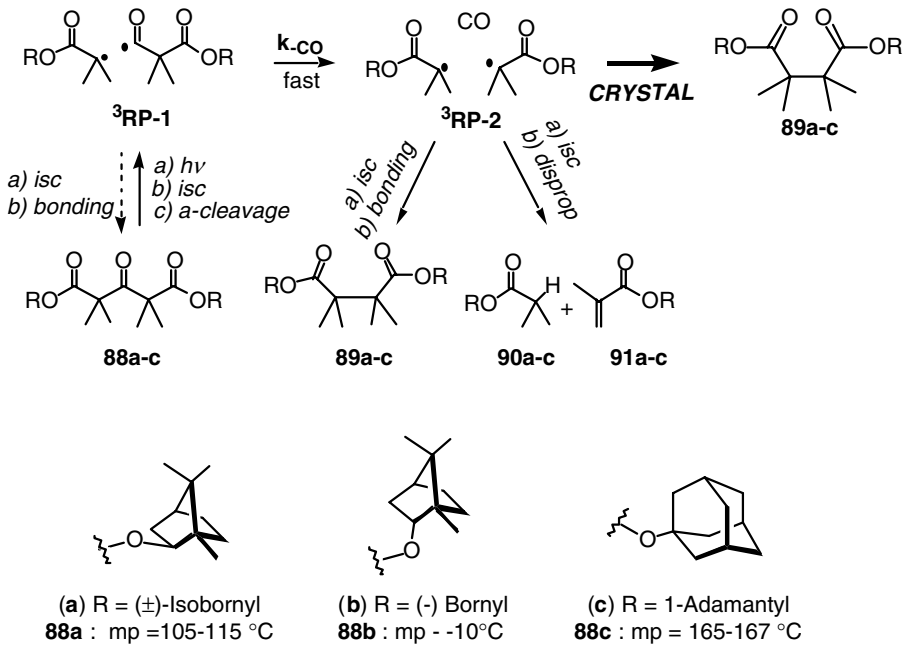
SCHEME 28

A simple test of the thermochemical postulate in Schemes 27 and 28 was recently reported in the literature.[87] From a wide range of potential α-substituents with radical stabilization energies above 11 kcal/mol, ester groups were selected. Based on literature reports,[88] it was expected that an ester carbonyl and two methyl groups would stabilize a carbon radical by >12.3 kcal/mol with respect to the unsubstituted methyl radical. The resulting radical would be stabilized by keto–enol delocalization and by the effect of the methyl substituents. Given that photochemical decarbonylation of ketodiesters had not been previously documented, it was of interest to test if their photochemistry would conform to the prediction. Three crystalline 1,3-acetonedicarboxylates, **88a** to **88c**, were investigated and all three reacted cleanly and smoothly in the solid state (Scheme 29).

As predicted, only decarbonylation products were observed in solution and in crystals. However, while free radicals in solution reacted by combination to give succinates **89a–c** and by disproportionation to give isopropionates **90a–c** and acrylates **91a–c**, reactions in crystals gave rise to the exclusive formation of radical–radical combination products **89a–c** when carried out to low conversion values. Although lower selectivities were observed in reactions carried out to high conversion for low melting crystals of **88b**, irradiation of higher melting ketones **88a** and **88c** proceeded from solid to solid to give the combination product in high chemical yields.

The thermochemical model predicts that reaction efficiencies in crystals will depend on the stability of the radicals formed. To further test this model, a series of highly crystalline adamantyl 1,3-ketodiesters with various methyl substituents were analyzed to compare their reaction efficiencies under conditions that involve the formation primary, secondary, and tertiary enol radicals.[89] After showing that ketodiesters with α-hydrogens crystallize in the keto form, compounds **92a** to **92f** were photolysed in dilute benzene solutions and in crystals (Scheme 30). The results obtained provided a strong support for the thermochemical model. α-Cleavage and decarbonylation reactions involving the formation of primary enol radicals were extremely inefficient in solution and no products were observed in the solid under conditions where melting was rigorously prevented.

Only crystals of **92d**, **92e**, and **92f**, which react through secondary (**R2b**) and tertiary (**R2c**) enol radicals, reacted in the solid state (Scheme 30). Although the relative efficiencies of these compounds were very similar in solution, a plot of conversion vs. irradiation times for reactions in crystals (Figure 48.8) illustrates reaction efficiencies with a ranking **92f** > **92e** > **92d**. Compounds **92a** and **92b** reacted only after some melting had occurred. Compound **92c** was not studied experimentally but was



SCHEME 29

92f	Me	Me	Me	Me

SCHEME 30

included in calculations described below. The observed reactivity order reflects the formation of two tertiary enol radicals from **92f**, tertiary and secondary enol radicals from **92e**, and two secondary enol radicals from **92d**. Crystals of **92d** were analyzed as a mixture of *meso*- and *d,l*-isomers and melted after ~10% conversion.

A computational study to confirm the validity of the thermochemical model and to gain more insight into the effect of ester substituents was subsequently published.[90] The heats of formation of acetone and the methyl ester analogs of ketodiesters **92a** to **92f** and their intermediate radicals were calculated at 298 K with the B3LYP/6–31G* density functional method. The heats of formation obtained were used to

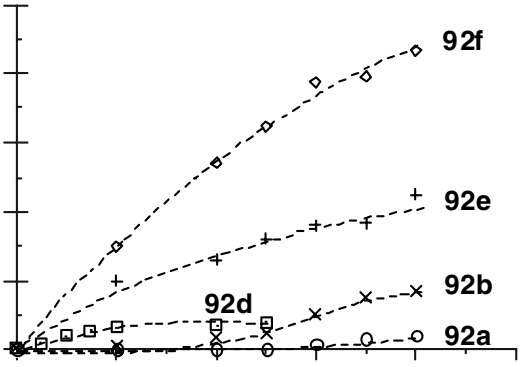

FIGURE 48.8 Yields of decarbonylation of ketones **92a** to **92f** in the solid state as a function of irradiation time. Ketones **92a** and **92b** reacted only after melting with ~2 hr of irradiation. Mixtures of *meso*- and *d,l*-**92d** melted at ambient temperature after reaching about 10% conversion.

TABLE 48.6 Calculated Bond Dissociation Energies (BDE in kcal/mol) for the First and Second Homolytic Dissociations in the Decarbonylation of Acetone and Ketodiesters 92a–f

Reactant	BDE-1	Radicals (BDE-1)	BDE-2	Radicals + CO (BDE-2)
CH_3COCH_3	81.14	CH_3, CH_3CO	9.58	2 CH_3
92a	72.38	R1a, R2a	–1.02	2 **R2a**
92b	67.10	**R1a, R2b**	–1.02	**R2a, R2b**
92c	62.08	**R1a, R2c**	–1.02	**R2a, R2c**
92d	65.90	**R1b, R2b**	–6.49	2 **R2b**
92e	61.64	**R1b, R2c**	–6.49	**R2b, R2c**
92f	55.48	**R1c, R2c**	–9.48	2 **R2c**

determine the BDEs and radical stabilization energies (RSEs) as a function of methyl and ester substituents. The results from those calculations are summarized in Table 48.6 and Figure 48.9. The spectroscopically determined triplet energies of ketodiesters **92a** to **92f** (~82 kcal/mol) were very similar to those of acetone (~79 kcal/mol) and suggest a common starting point to compare the enthalpy changes upon α-cleavage and decarbonylation reactions.[91] The BDE values calculated for α-cleavage and decarbonylation of acetone with the B3LYP/6–31G* method (81.14 and 9.58 kcal/mol, respectively) were in very good agreement with those obtained with higher levels of theory and experimentally (83.5 and 11 kcal/mol, respectively). The formation of a primary enol and an acyl radical from ^{3}**92a** was calculated to be exothermic by ~10 kcal/mol. This reaction is very inefficient in solution and is not observed at all in the solid state. Calculations show that formation of secondary enol and acyl radicals from **92b** and **92d** is exothermic by 15 to 16 kcal/mol. Both compounds react by α-cleavage in solution and in crystals, but only **92d** decarbonylates efficiently. In fact, decarbonylation of acyl radicals from **92a**, **92b**, and **92c** gives primary enol radicals in reactions that are calculated to be exothermic by only 1.02 kcal/mol, and none of these ketones decarbonylates in the solid state. In agreement with the experimental observations, the formation of secondary enol radicals by decarbonylation of acyl radicals from **92d** and **92e** was calculated to be exothermic by 6.5 kcal/mol, and formation of tertiary enol radical from **92f** was calculated to be exothermic by 9.5 kcal/mol.

The need for exothermic α-cleavage and decarbonylation is strongly supported by the results in Figure 48.9, where changes in enthalpy for ketones that react in the solid state are shown with heavy arrows. A comparison of the results from **92b** and **92c** with those obtained from **92d** and **92e** stresses

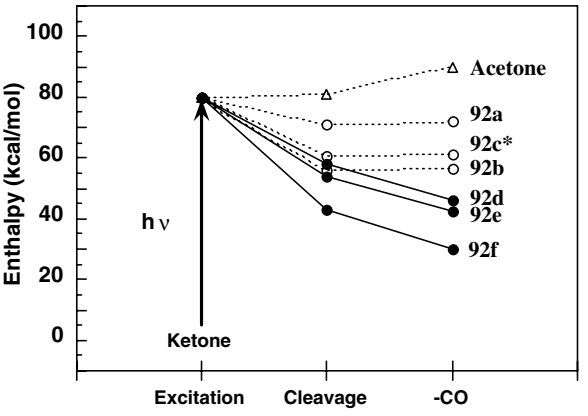

FIGURE 48.9 Calculated heats of reaction (B3LYP/6–31G*) correlating the experimental results of the photochemical decarbonylation of acetone and acetone dicarboxylates **92a** to **92f**. *Compound **92c** has not been studied experimentally.

the notion that efficient α-cleavage in the solid state is not enough for product formation, unless it is followed by a second, irreversible radical–radical reaction.

48.15 Solid-to-Solid Photochemical Reactions

An ideal solid-state photochemical reaction would offer high selectivity and specificity with good quantum and chemical yields; however, while high selectivity and specificity are frequently achieved, there may be limitations on the chemical yields that may be obtained for reactions in crystals. High reaction selectivities in crystals can be generally understood in terms of conformational bias and least-motion pathways for unimolecular reactions and, in terms of the distances and orientation between prospective reactants, in bimolecular reactions. In the case of decarbonylation reactions, several examples of solid-to-solid reactions have been documented in great detail. For instance, photolysis of ketone **70** in solution resulted in a 50:50 mixture of products *cis*-**94** and *trans*-**94**, respectively, in modest chemical yields, while reactions in crystals yielded a *cis*-**94**:*trans*-**94** ratio of 19:1 in nearly quantitative yield.[93] It was shown that reaction selectivity does not change as a function of total conversion when reactions were carried out under optimized conditions (see below). The preferential formation of *cis*-**94** can be readily understood when the structures of the reactant and the two possible products are compared. X-ray structures of ketone **70** and its solid-state photoproduct *cis*-**94** revealed a high degree of structural similarity (Figure 48.10). While formation of *cis*-**94** requires loss of CO and bonding between the two benzylic radicals by a least motion pathway, formation of *trans*-**94** requires bond rotation to form the *trans*-diol in a process that involves a large change in shape and volume.

Although the rigidity of crystalline solids facilitates some reactions while preventing others, rigidity alone is not enough to warrant the high selectivity observed in a structurally homogeneous solid. Experiments carried out with ketone **70** in hydroxylic media spanning more than eight orders of magnitude in viscosity, from methanol to sucrose glasses (caramel), had a modest effect on the selectivity of the reaction which remained close to 1:1 (Figure 48.11). The high selectivity observed in crystals is probably a manifestation of the nearly ideal conformational and environmental homogeneity offered by a crystalline solid.

Experimental factors affecting and controlling the outcome of photochemical reactions in crystals have been recently reviewed.[92] Among them, crystal size, excitation wavelength, and reaction temperature are particularly important. Given that crystalline solids are very strongly absorbing media, irradiations carried out at the tail of the UV-Vis absorption spectrum must be used to facilitate penetration of light

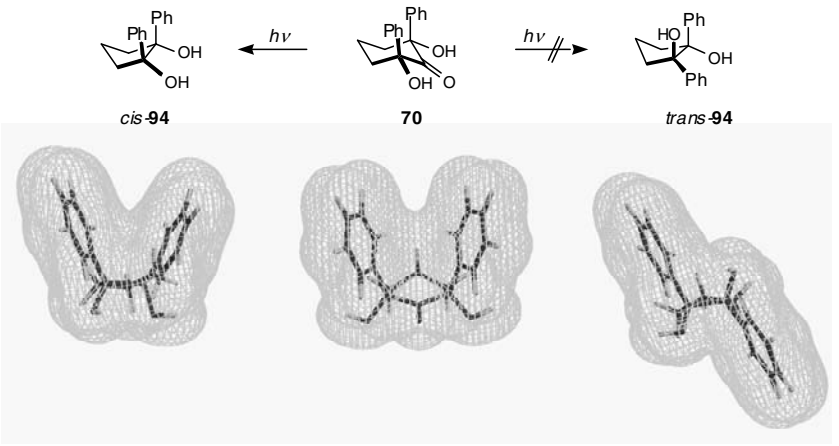

FIGURE 48.10 A comparison of the x-ray structure of ketone **70** with those of its two combination products (*cis*-**94** on the left and *trans*-**94** on the right) helps rationalize the high selectivity observed when reactions are carried out in crystals.

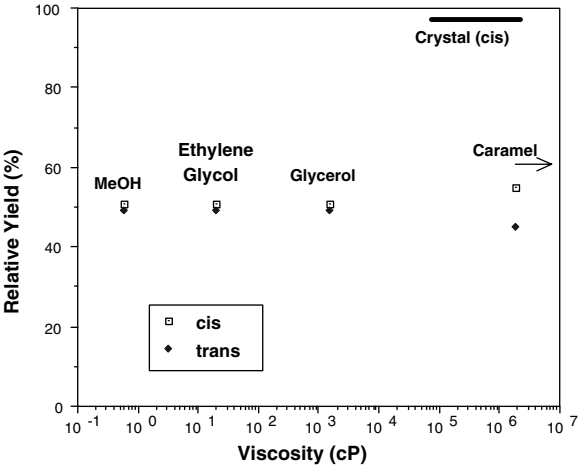

FIGURE 48.11 Effect of viscosity on the selectivity of product formation upon decarbonylation of *cis*-2,6-diphenyl-2,6-dihydroxycyclohexanone **70**. The viscosity of sucrose glasses (caramel) noted in the plot is the value reported value at 100°C.[94]

deep into the bulk of the solid. It is frequently observed that microcrystalline samples retain the selectivity observed in large single crystals while minimizing the problems associated with the limited penetration of light into the large single crystals. Excitation into the lowest energy levels of the excited state limits local heating from internal conversion and helps prevent local melting. Furthermore, light absorption by the photoproduct should be completely avoided. In the case of ketone **70**, irradiation was carried out with monochromatic light at $\lambda = 350$ nm or with a $\lambda > 350$-nm cutoff filter (Figure 48.12).

Decarbonylation reactions such as that of ketone **70** can be easily carried out in a multigram scale with microcrystalline samples and it may be possible to scale up the reaction further. Several decarbonylation reactions have been documented to trap CO gas within the crystal lattice and to proceed by phase-transition mechanisms. It has been suggested that reactions in solids occur heterogeneously with a reaction front determined by exposure to light. When product molecules begin to form, they go into a

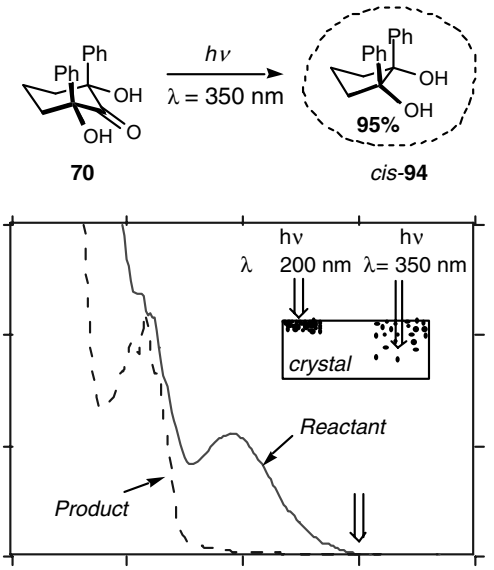

FIGURE 48.12 Ultraviolet absorption spectra of ketone **70** and its solid-state photoproduct **94** illustrating the wavelength selected for excitation in the solid state ($\lambda \geq 350$ nm). Irradiation at this wavelength allows for deeper penetration in the crystal and reduces local heating from excess photon energy.

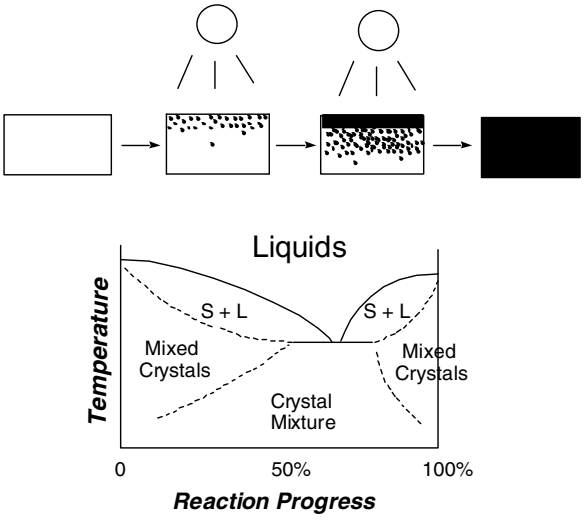

FIGURE 48.13 Schematic representation of the phase diagram for a solid-state reaction that occurs by formation of a solid solution with separation of the product phase. Reactions in crystals must be carried out at temperatures below the eutectic of the two-component phase diagram to ensure that reaction occurs in the solid phase.

solid solution in the crystal lattice of the reactant until the solubility limit is attained (mixed crystals; see Figure 48.13). As the mole fraction of product molecules continues to increase, a new crystal phase may begin to nucleate with a composition that may include both the product and the reactant. The coexistence of two solid phases and two components causes the formation of a eutectic point, which determines the lowest temperature where liquid phases may exist. Several examples of eutectic transitions in reacting crystal have been documented in the literature by differential scanning calorimetry (DSC). It has been

suggested that reactions in crystals will proceed with good environmental control only when they are carried out at temperatures that are below the eutectic transition.

48.16 Conclusions

The photochemically induced Norrish type I cleavage and acyl radical decarbonylation reactions of ketones promise to become a reliable method for the generation of biradicals and radical pairs in crystalline solids. Progress to date has been based on a few simple assumptions, which include the use of mechanistic knowledge from gas phase and solution to formulate the mechanisms and energetics of reactions in crystals. It has been assumed that spin–spin interactions and conformational restrictions in the solid state do not alter the energetics of reactions in crystals by a large measure, so that excitation energies and radical stabilization energies can be used to make predictions regarding the feasibility of α-cleavage and decarbonylation processes. The importance of subtle but predictable effects on the solid-state reactions have begun to emerge, and it is expected that more examples will expose interesting effects unique to reactions in crystals. The successful generation of radical pairs in crystalline ketones gives a promising forecast that should open the doors for many systematic, mechanistic, and synthetic studies, as well as many potential applications in material science.

Carbene Formation in the Photochemistry of Cyclic Ketones

S. M. Roberts
University of Liverpool

49.1 Introduction

It is now well established, based largely on early studies by Yates and Turro, that irradiation of cyclobutanones leads to the formation of an oxacarbene as one of the preferred reaction pathways (Scheme 1).[1] The highly reactive oxacarbene can be intercepted by trapping with water or an alcohol to give a lactol or an acetal, respectively (Scheme 1). The same reaction manifold is followed by some cyclopentanones, especially when the five-membered ring is part of a strained structure (Scheme 2).[2] The trapping reagent can be delivered in an intermolecular fashion or intramolecularly; in the latter case, complex polycyclic molecules can be constructed in good yields in a simple way (Scheme 3).[3,4] More rarely the oxacarbene has been trapped by an alkene.[5]

The ring expansion reaction has been used in multistep organic syntheses of natural products and analogs, most notably in the preparation of prostaglandins and prostanoids,[6] thromboxane mimetics,[7] and muscarine[8] (Scheme 4).

49.2 Mechanistic Considerations

The mechanism involved in the conversion of a cyclic ketone into an oxacarbene has been hotly debated over the past 40 years. The involvement of a carbene is beyond question following detailed work by, for example, Sheridan et al.[9] involving low-temperature irradiation of the tricycloalkanone **1** and the tetramethylcyclobutanone **2** in tandem with infrared and ultraviolet spectroscopy. Intermediates derived from the benzobutanedione **3** included the oxacarbene, and these were examined through laser flash photolysis. The oxacarbene was trapped by the usual scavengers — for example, selected alcohols.[10]

49.3 Recent Synthetic Applications

The ring-expansion of cyclobutabenzofuranones has provided a route to benzodioxabicyclo[3.3.0]octanes incorporating a *bis*-furan unit, a structural feature within the molecular skeleton of the aflatoxin family of mycotoxins (Scheme 5).[11]

Lee-Ruff and co-workers[12] have continued their interest in the photochemistry of cyclobutanones. Specifically, they have profitably extended the chemistry of the oxacarbenes by trapping these intermediates with selected amines, to good effect. Thus, the Canadian team photolysed the ketones **4** and **5** in the presence of purines as well as water and alcohols to produce the corresponding nucleoside analogs, lactols, and acetals, respectively (Scheme 6 and Table 49.1).[13,14]

The method has been adapted to prepare 2′,3′-dideoxy-3′-C-hydroxymethyl nucleosides with significant biological activity. Specifically, nucleoside analog **6** was found to inhibit human immunodeficiency virus 1 (HIV-1) replication in acute infection. Complete suppression of the virus was observed at a dose of 100 μ*M*, a level that was shown to be nontoxic to uninfected cells.[15]

Photochemistry of Vicinal Polycarbonyl Compounds

Mordecai B. Rubin
Israel Institute of Technology

50.1 Introduction

Organic chemists have been concerned for over 100 years with the question of how many carbonyl groups may be juxtaposed and what will be the properties of the resulting vicinal polycarbonyl compounds. At the present time, the number of vicinal carbonyl groups has reached a maximum of five in compounds such as diphenyl pentaketone (1,5-diphenylpentanepentone, **1**); use of the term *vicinal oligocarbonyl compounds* might be more appropriate but is not accepted usage. Reviews on the chemistry of these compounds appeared in 1975[1] and 2000.[2] Syntheses are quite straightforward; a considerable number of compounds have been prepared and characterized. Their most characteristic chemical property is extremely facile addition of nucleophilic reagents to a central carbonyl group, as illustrated below, which relieves the maximum number of unfavorable dipolar interactions of vicinal carbonyl groups. The chemistry of these compounds has been referred to as the "chemistry of the highly activated carbonyl group." For example, active methylene compounds undergo uncatalyzed addition to the central carbonyl group of vic-triketones to yield the aldol products. Rapid hydration, simply upon exposure to air, is a common problem (Figure 50.1; see Section 50.9).

50.2 Spectra

Absorption

Longest wavelength absorption maxima (n,π^*) for ketones with one to five vicinal carbonyl groups are presented in Table 50.1. The maxima shift steadily to longer wavelengths with increasing numbers of

0-8493-1348-1/04/$0.00+$1.50

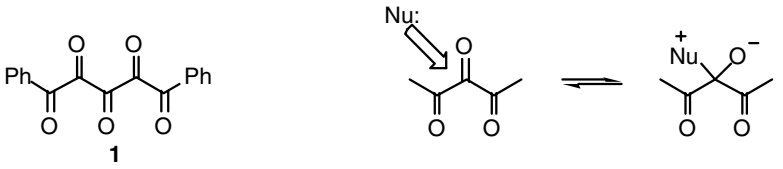

FIGURE 50.1

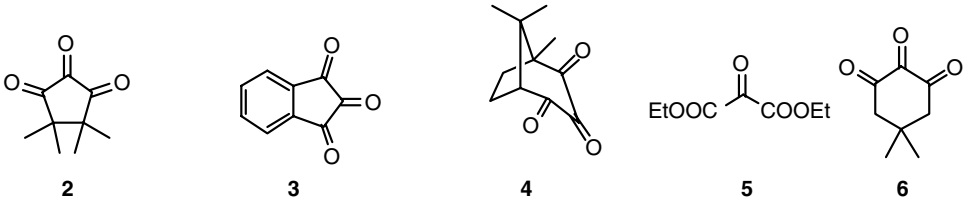

FIGURE 50.2

TABLE 50.1 Long Wavelength Absorption Maxima[a,b] of Ketones $R(CO)_nR$

Source: Adapted from Horner and Maurer.[32]

carbonyl groups; many compounds are highly colored. Cyclic compounds absorb at longer wavelengths, as illustrated by three typical examples: tetramethycyclopentane-1,2,3-trione (**2**) at 685 nm, indanetrione (**3**) at 606 nm, and bicyclo[3.2.1]octane-2,3,4-trione (**4**) at 538 nm. Additional n,π^* bands are observed at shorter wavelengths as well as π,π^* bands when aromatic end groups are present. The generalization that the position of the longest wavelength absorption band of α-diketones depends on the torsion angle between the carbonyl groups also seems to apply to polyketones, although systematic investigation has not been performed.

Except for diethyl mesoxalate (**5**, λ_{max} = 347 nm),[3] which behaves very much like a simple ketone (see below for photoreactions), the ultraviolet/visible light (UV-Vis) spectra of tricarbonyl compounds incorporating ketone and ester groups have not been measured. The abundant and synthetically useful α,β-diketoesters have been reported to be yellow substances, but no details are available (Figure 50.2).

Emission

The phosphorescence spectrum of **5**, measured in 1967,[3] exhibited maxima in 1,1-difluorotetrachloroethane at 530 and 537 nm, corresponding to triplet energies of about 54 kcal mol^{-1}. No attention has been paid to date to the photophysics (or photochemistry) of α,β-diketoesters. Emission from acyclic vic-tri- and tetraketones could not be detected with conventional equipment.[4] The phosphorescence maximum of 5,5-dimethylcyclohexane-1,2,3-trione (**6**) was suggested in 1971 to occur at about 615 nm ($\Phi_{phos} < 0.001$) on the basis of results obtained in a study of oxidation of the corresponding 1,3-diketone.[5]

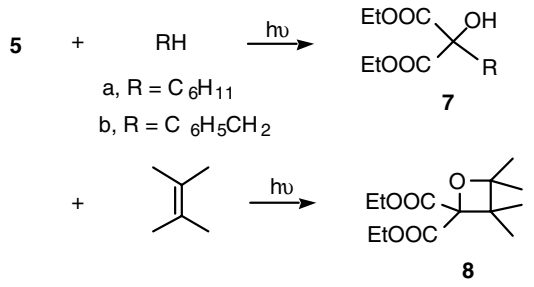

FIGURE 50.3

Indanetrione (**3**) provides an interesting contrast that may be related to the rigid, coplanar structure of this molecule. The first emission studies were reported in 1981.[6,7] Fluorescence was observed ($\Phi_{fl}(CH_2Cl_2)$ Å 650 nm) in a variety of solvents; the authors suggested a specific interaction between the central carbonyl group of **3** and solvents containing C=O or CN groups. The emission was assigned as fluorescence on the basis of the mirror image relationship between absorption and emission, solvent effects, the low value of the extinction coefficients of **3**, the short lifetime (~20 ns for a thin film), and CNDO-CI calculations. Recently, specific interactions between ethers (tetrahydrofuran and 2-methyltetrahydrofuran) and the excited states of **3**, benzo-**3**, and 5-methoxy-**3** have been studied experimentally and theoretically (AM1 calculations).[8]

Phosphorescence of **3** ($\lambda_{em}(CH_3CN)$ = 687 nm, $E_{T=}$ 42 kcal mol^{-1}, lifetime 6.5 μs) was observed using laser excitation.[9] The absorption spectrum of the triplet exhibited maxima at 360 and 570 nm. It was also shown that photoexcited **3** sensitized the formation of singlet oxygen with a quantum yield of 0.65. Rigid binding of indanetrione in a phthalic anhydride matrix was invoked to account for the observation of room-temperature phosphorescence (λ_{em} = 713 nm) in a phthalic anhydride matrix;[10] no other cases of such room-temperature behavior could be detected in matrices or in solution.

50.3 Diethyl Mesoxalate

Diethyl mesoxalate (**5**, λ_{max}(heptane) = 367 (24) and 372 (25)) is the only tricarbonyl compound containing ester group(s) whose photochemical behavior has been investigated. It exhibits normal ketone photochemistry. Photolyses in cyclohexane or toluene solutions at $\lambda > 320$ nm gave moderate yields of the addition products (**7**) expected from H-atom abstraction followed by radical coupling;[11] a number of additional products were not characterized.

Irradiations at 366 nm (unspecified solvent) in the presence of a twofold excess of the following olefins gave oxetanes **8** analogous to the classical Paterno–Buchi reaction of monoketones (Figure 50.3): 1,1-diphenyl ethylene (product yield 64%), α-methylstyrene (76%), norbornene (78% exo, 19% endo isomer), isoprene (90% of product from reaction at the more highly substituted double bond), and 2,3-dimethylbutadiene (42% plus polymer).[3]

50.4 Dialkyl Triketones

The unsymmetrical dialkyl triones **9a** and **9b** were irradiated in refluxing ether solution (~0.2 *M*) with a commercial sunlamp.[12] Photostationary states containing triketones with all permutations of akyl end groups (**9** and **10**) were reached in both cases, together with a yield of about 4% of CO and traces of biacetyl. In the case of **9b**, the photostationary state consisted of an equimolar mixture of all three products (**9b**, **10b**, **10c**); with **9a**, the ratio of **10a**:**9a**:**10b** was 3:1:1. The fact that the same transformations could be effected in the dark under conditions in which acyl free radicals can form (oxygen plus an aldehyde, di-*t*-butyl peroxide plus an aldehyde) prompted the suggestion of a free-radical chain reaction, although quantum yields were not determined. As illustrated below, the photochemical step was suggested to

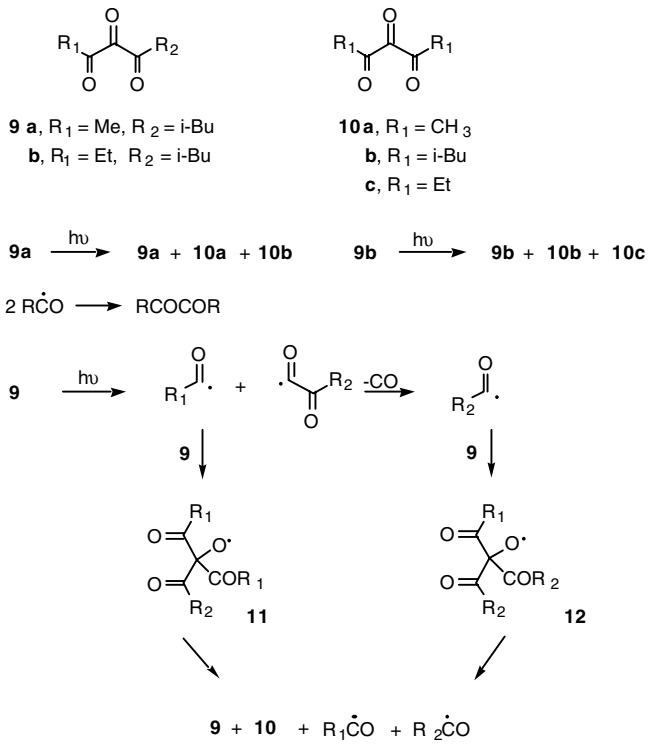

FIGURE 50.4

involve cleavage of an inter-carbonyl bond to give acyl and α-ketoacyl radicals. The small amount of CO observed was attributed to decarbonylation of these radicals. The major process was proposed to be the addition of acyl radicals to the carbon atom of the central carbonyl group of trione, resulting in formation of the oxyradicals **11** or **12**. Fragmentation of these can occur in three ways, leading either to regeneration of the original triketone or formation of a new one plus formation of an acyl radical that continues the chain. The resulting chain reaction finally leads to a photostationary state, the composition of which depends on the alkyl end groups involved, as noted above. Chain termination results in formation of biacetyl that was observed in trace yield. About 15% of a nonvolatile, uncharacterized residue was observed. Tetraketones, which could result from the addition of α-ketoacyl radicals to triones, were not reported (Figure 50.4).

The work described above appeared as a preliminary communication about 40 years ago. A full paper has never appeared nor, to our knowledge, has any subsequent work been performed with these or other dialkyl polyketones. Thus, a variety of interesting synthetic and mechanistic questions remain unanswered.

50.5 Diaryl Triketones

Diaryl triketones do not show the same reactivity as their dialkyl counterparts.[13] This is illustrated by the fact that 19-hr irradiation through Pyrex using the full spectrum of a 1000-W, high-pressure, mercury-vapor lamp was required for 90% disappearance of 250 mg of diphenyl triketone (**13**) in degassed *p*-xylene solution. The major products isolated were *p*,*p*′-dimethylbibenzyl, benzaldehyde, and *p*-methylbenzyl phenyl ketone; in addition, minor amounts of oxidation products such as *p*-methylbenzyl benzoate were identified, as well as traces of benzil. Quantum yields for the disappearance of **13** at 436 nm in degassed or air-saturated *p*-xylene solutions were about 3×10^{-4}; nearly identical values were obtained

in benzene solution, and somewhat higher values were obtained at 313 nm. Analogous chemistry was observed in the reactions of **13** in toluene (bibenzil, benzaldehyde, benzylphenyl ketone), cyclohexane (bicyclohexyl, cyclohexanol, benzaldehyde, phenylcyclohexyl ketone, cyclohexylbenzoate, and traces of benzil), and benzene (biphenyl, benzaldehyde, and phenylbenzoate). The biphenyl obtained from reaction in hexadeuterobenzene was pentadeuterobiphenyl ($C_{12}H_5D_{5)}$, suggesting addition of an intermediate phenyl radical to hexadeuteriobenzene followed by oxidation of the intermediate. *p,p′*-Disubstituted diaryl triketones showed similar behavior, and very sluggish reactivity was also observed with di-*t*-butyl triketone (**14**) in toluene; the products were bibenzyl, trimethylacetaldehyde, and benzyl-*t*-butyl ketone, plus an uncharacterized addition product. Bicyclic trione **4** also reacted very slowly.

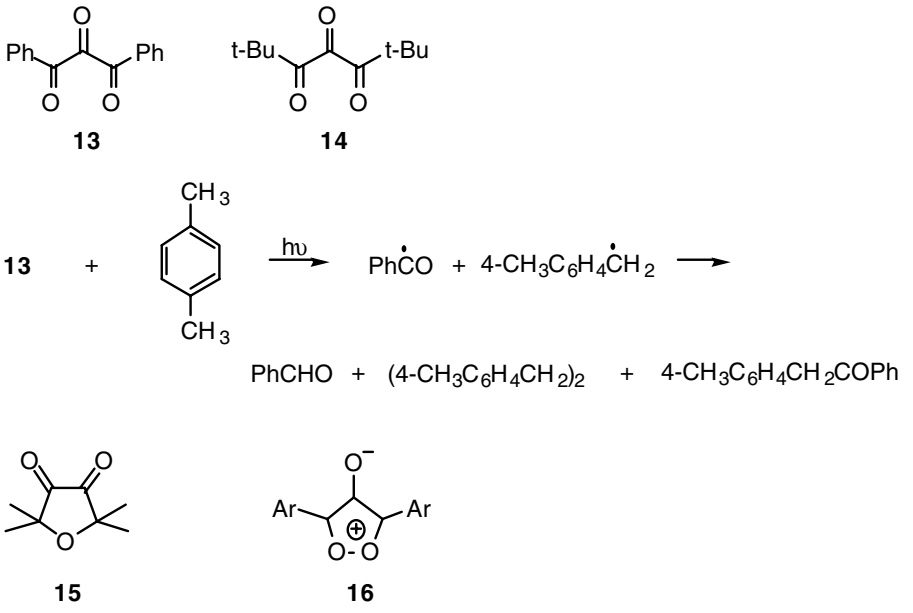

FIGURE 50.5

All the results are consistent with intermediate formation of aroyl or acyl and solvent-derived radicals, as illustrated below for the reaction with *p*-xylene. It was not possible to determine if these are formed via an initial H-atom abstraction by trione from solvent or via an α-cleavage of **13** followed by H-abstraction. The low quantum yields precluded a variety of experiments, such as, for example, examination of deuterium isotope effects on quantum yields. A report that **13** in benzene solution was converted to benzil in Cairo sunlight[14] could not be confirmed in Haifa sunlight.[15]

Irradiation of **13** in the presence of *p*-methoxybenzaldehyde did not afford any *p*-methoxyphenyl phenyl triketone. Similarly, heating a mixture of **13** and *p*-methoxybenzaldehyde in the presence of di-*t*-butyl peroxide had no effect, in contrast to the behavior observed with di-alkyl triones.

A satisfactory explanation for the lack of photochemical reactivity of diaryl triketones has not been forthcoming, but it is clear that radiationless deactivation is the (almost) exclusive process, as confirmed by laser-induced optoacoustic studies.[13] While this sluggishness might be attributed to the low singlet and triplet energies of such molecules, analogous tetraketones, which must have even lower excited state energies, show reasonable photochemical reactivity. Furthermore, α-diketones, such as 2,2,5,5-tetramethyl-tetrahydrofuran-3,4-dione (**15**, λ_{max} = 559 nm), that absorb at longer wavelengths than diphenyl triketone exhibited normal diketone photochemistry with respectable quantum yields.[16] Deactivation of excited diaryl triones could involve cleavage to a pair of radicals that recombine efficiently; we note that

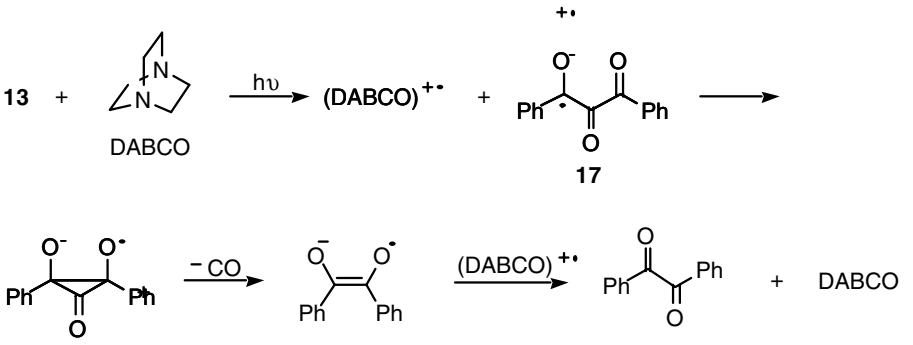

FIGURE 50.6

such radicals could also combine to give ketene **37** (see Section 50.7). An intriguing alternative suggestion that diphenyl triketone is converted by light to the mesoionic form **16**, which undergoes facile thermal reaction to regenerate **13**, could not be supported experimentally. No thermally reversible spectroscopic change was observed on irradiation of **13** in methylcyclohexane using the full spectrum of a mercury vapor lamp through Pyrex at a number of temperatures between +20 and –170°C. X-ray crystallographic evidence that **16** is not important in the electronic ground state of **1** has been provided by Cannon et al.[17]

Very different results were observed when **13** was irradiated in the presence of the electron donor DABCO. The reaction proceeded more efficiently and produced benzil as the only product. Single electron transfer (SET) from DABCO to the trione was assumed to be the reaction of the excited trione, which gives radical anion **17** as the initial photoproduct. Subsequent radical ion chemistry, as illustrated below, was suggested to account for the formation of benzil with regeneration of DABCO. Similarly, irradiation of bicyclic trione **4** in the presence of DABCO afforded the decarbonylation product camphorquinone. The same result could be obtained with **13**, albeit with lower efficiency, using *p,p′*-dimethoxybenzene instead of DABCO as the electron donor.

Irradiation of **13** in benzene solution containing 2,3-dimethyl-2-butene did not give products of olefin cycloaddition or of H-atom abstraction in contrast to the results described in the following section (Figures 50.5 and 50.6).

50.6 Cyclic Triketones

These compounds have been investigated by a number of workers, with particular attention paid to 1,2,3-triketoindane (**3**), the dehydration product of commercially available ninhydrin. Although quantum yields were not determined, the photochemical inertness of **3** in dry acetonitrile is clear from the fact that 250-hr irradiation of a degassed solution with a moderately powerful light source resulted in only 5% conversion![9] The products were the dimeric lactones, which have been shown to be products of the irradiation of benzocyclobutenedione (**21**) under similar conditions;[18] bisketene **20** was shown to be the precursor of these lactones. α-Cleavage of the triplet state of **3** to biradical **18** followed by decarbonylation to **19**, and intersystem crossing to **20** was suggested to occur with triketoindane. Recombination of the initially formed biradical **18** after intersystem crossing could provide a deactivation mechanism accounting for the low quantum yields. Irradiation in the presence of oxygen resulted in exclusive formation of phthalic anhydride, a result reminiscent of α-diketone photochemistry (Figure 50.7).

The results described above were confirmed in the first part of a paper that reported high-intensity ("laser-jet") irradiation of **3**, where about 10% of benzocyclobutenedione (**22**) was obtained.[19] It was suggested that the intermediate bisketene **20** has a very short lifetime and decays rapidly to carbene **21** so it was not possible for it to absorb light under normal irradiation intensities. However, some fraction of the ketene did absorb in the high-intensity experiments and cyclized to **22**, shown to be stable under the conditions of the experiment.

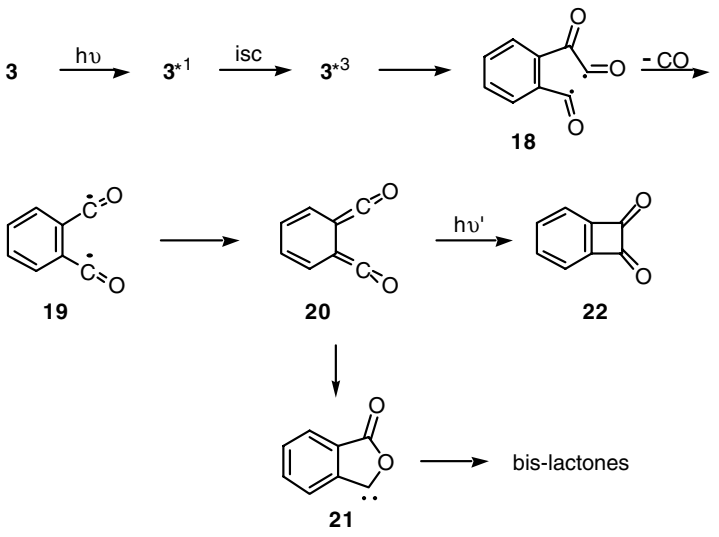

FIGURE 50.7

Very different results were obtained in extensive investigations of the reaction of deaerated solutions of **3** in the presence of olefins using a lamp with emissions centered at 300 nm (Rayonet RPR-3000; excitation to a higher singlet). Quantum yields of about unity were observed for a considerable number of olefins. The exceptions were olefins bearing electron-withdrawing groups, such as maleic anhydride and dimethyl fumarate, that were unreactive. Both hydrogen atom abstractions (path a) to afford allylic hydroxyketones (**23**, **24**) and/or cycloadditions of the Paterno–Buchi type (path b) to give oxetanes (**25**) and dioxenes (**26**) were observed. A general outline of the suggested mechanistic path for these reactions is shown in Figure 50.8. Initial excitation of **3** to a higher singlet state is followed by intersystem crossing to a triplet state of **3** which forms an exciplex with olefins (partial charge transfer), the orientation of which is governed by stereoelectronic factors. This exciplex, common to both types of reaction, then undergoes either (1) H-atom abstraction to ketyl radical **27** and allylic radical **28**, or (2) addition of olefin to **3**, giving the biradical **29**. Allylic radical **28** then couples with the ketyl radical **27** to form product; this may occur at the terminus of the allylic system, giving **23** or **24**. Similarly, two possibilities exist for the biradical **29**: cyclization to oxetane **25** or cyclization to dioxene **26**. The photochemistry is very similar to that observed in reactions of monoketones with olefins, except for the added possibility of dioxene formation; it should be noted that initial reaction occurs at the central carbonyl group of **3**, as expected. Intramolecular H-atom transfer in biradical **29** to give an allylic ether (**30**), a reaction sometimes observed with α-diketones, has not been detected. Formation of the pinacol **31** was observed in the reaction of **3** with cyclohexene. We note that electron transfer followed by proton transfer is equivalent to H-atom transfer.

The results of any particular case depended on the olefin used, with stereoelectronic effects in exciplex formation assumed to play a key role in determining the outcome of reaction. 2,3-Diphenyl-1,4-dioxene, having no allylic hydrogen atoms, gave oxetane exclusively, while 2-neopentylpropene gave exclusively the H-abstraction product (coupling at the primary rather than the neopentyl position was observed in this special case).[20] The reaction with 2,3-dimethyl-2-butene was studied in detail;[21] both radical coupling products were obtained (17.5% yield), but the major products were oxetane (29%) and dioxene (53%). In contrast, 2-methyl-2-butene afforded 82% of the two coupling products and 18% of oxetane.

A flash photolysis study of the quenching of indanetrione triplets by 22 olefins has been reported.[22] Pseudo-first order kinetics were observed for decay of the triplet of **3** at 570 nm, and the second-order rate constants (k_q) for triplet quenching by olefin were obtained; values of k_q ranged from 1.35×10^5 M^{-1}

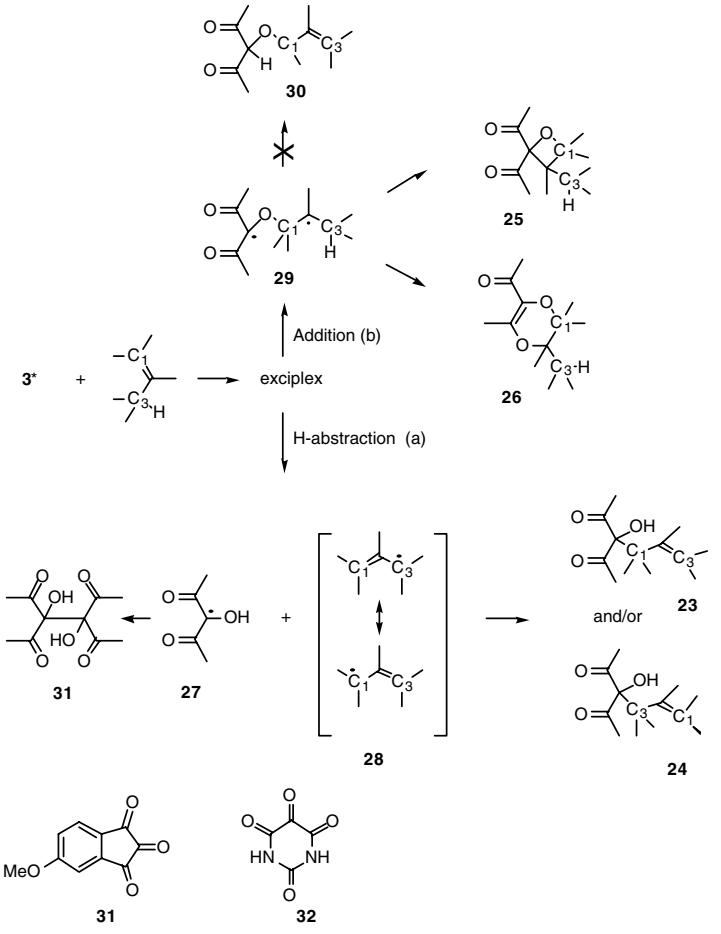

FIGURE 50.8

s^{-1} for 2-methyl-1-butene to 1.8×10^9 M^{-1} s^{-1} for 2.5-dimethyl-1.4-hexadiene. A plot of log k_q vs. ionization potential for seven olefins gave a straight line with a slope of –2.7/eV, supporting the suggestion that a complex with partial charge transfer is involved. The chemistry of these olefins ranged from exclusive H-atom abstraction to predominant cycloaddition, suggesting that the same initial interaction between excited indanetrione and olefin is responsible for all of the observed chemistry. Higher values for ionization potential were reflected in a higher degree of cycloaddition.

Reaction of **3** with *cis*- or *trans*-stilbene using a light source whose emission was centered at 350 nm resulted only in *cis* and *trans* isomerization to give identical mixtures from each pure isomer. Because the triplet energy of **3** is appreciably lower than that of either stilbene isomer, the isomerization cannot involve triplet energy transfer. It must proceed via a reversible interaction between trione and olefin, possibly via a biradical of type **29** in which the stereochemical integrity of the isomers is lost.

Investigation of the photochemical reactions of 5-methoxyindanetrione (**31**) gave results very similar to those obtained with the unsubstituted trione.[22] A plot of k_q values for **3** vs. the values for **31** gave a straight line with a slope close to unity. The authors concluded that the methoxy substituent did not change the reactive excited state of the trione.

The behavior of alloxan (**32**) with olefins in deaerated acetone solution with a light source having maximum emission at 300 nm was very similar to that of indanetrione.[23] Only H-abstraction products were observed with 2,4-hexadiene, 2-neopentylpropene, 2-methyl-2-butene, and 1-methyl-1-cyclopentene. Ethyl-1-propenyl ether yielded H-abstraction products (38%), oxetanes (6%), and dioxenes (56%). Stereoelectronic effects in formation and reaction of a common exciplex with charge transfer character were suggested to account for the results. As observed with **3**, both maleic anhydride and dimethyl fumarate gave no reaction with **31** while *cis*- and *trans*-stilbene were converted to the same mixture of *cis* and *trans* isomers (Figures 50.7 and 50.8).

50.7 Tetraketones

Photochemical reactions of the acyclic tetraketones diphenyl (**33a**), di-*p*-tolyl (**33b**), di-*p*-anisyl (**33c**), di-*p*-bromophenyl (**33d**), dimesityl- (**33e**), and di-*t*-butyltetraketones (**33f**), as well as the cyclophane tetraketone **34**, have been investigated.[24] They provide an interesting contrast to triketone photochemistry. Quantum yields for the disappearance of **33a** in degassed benzene solution at 546 nm were about 0.02; chemical yields of crystalline product(s) were high, approaching quantitative if careful precautions were taken to ensure dryness and absence of oxygen. The flexible acyclic compounds **33a–d** were converted into rigid, tricyclic diketo-orthoester-lactones, as illustrated below. The reaction involves two molecules of tetrone with the loss of one molecule of CO. The exclusive product with **33b–d** was the isomer **35**, which incorporated an α-diketo moiety and an aryl group, with about 10% of isomer **36** having two benzoyl groups in the case of diphenyl tetraketone (**33a**).

The reaction of **33a** was shown, by matrix isolation photolysis at 10 K and other methods, to involve acyloxyketene **37** as an intermediate. It was shown in separate experiments that **37**, synthesized by conventional treatment of the corresponding acid chloride, reacted with tetraketones to form the same adducts **35** and **36** in the same ratio as had been observed in the photochemical reaction of **33a**. The photolysis then involves conversion of excited tetraketone to **37** and CO followed by thermal reaction of **37** with tetraketone presumably via β-lactones. Limited evidence supports the singlet state as the reactive specie. If this is correct, a cyclic mechanism, as illustrated in Figure 50.9, could be involved; a triplet state reaction would require zwitterionic or biradical intermediates, as illustrated.

The exceptions to this behavior were dimesityl (**33e**) and di-*t*-butyl (**33f**) tetraketones and the cyclic tetraketone **34**, all of which have bulky groups flanking the tetraketone moiety and were photochemically inert. Steric effects might be responsible for inhibiting the formation of ketene in these cases; however, a competing photochemical reaction was shown to occur with **33e**. This involved abstraction of a hydrogen atom from an *ortho*-methyl group, a well-known reaction of *o*-methyl-substituted benzophenones and α-(*o*-tolyl)-α,β-diketones. Irradiation of **33e** in benzene solution containing *t*-butyl-OD (shown to react extremely slowly with the tetrone) resulted in significant deuterium incorporation into *o*-methyl groups. This was suggested, as shown in Figure 50.10, to involve initial formation of biradical **40**, which isomerizes to enol **41**, the latter then undergoing deuterium exchange and finally ketonization to the observed product. Similar processes might be involved with **33f**. Ring constraints prohibiting a cyclic mechanism could also apply to cyclophane **34**.

A similar mechanism to form ketenes from triketones without elimination of CO appears unlikely, as it involves a four-membered intermediate.

50.8 Pentaketones

A cyclic mechanism analogous to that suggested for tetraketones could occur with pentaketones. The same acyloxyketenes would form together with ethylenedione (C_2O_2) or 2CO, as illustrated in Figure 50.11. Addition of ketene to ground-state pentaketone could then afford tricyclic compounds such as **42** or **43**. Such experiments have given mixtures of products from which no identifiable pure substance could be isolated,[25] and further experimentation is required.

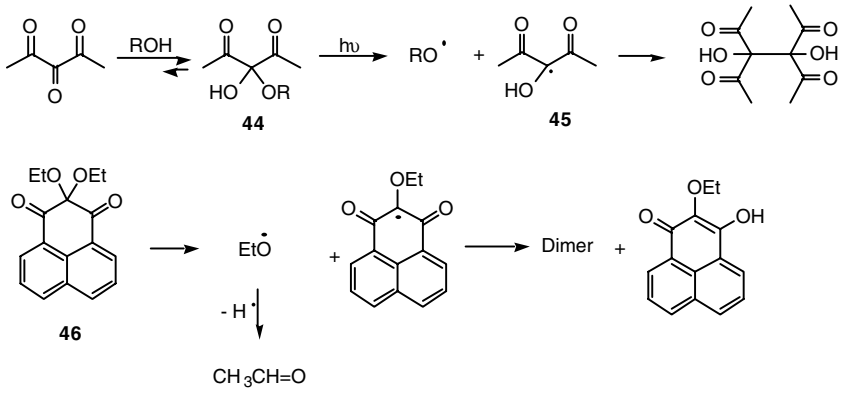

FIGURE 50.12

50.9 Hydrates and Hemiketals: A Trap for the Unwary

The facile reaction of vic-polycarbonyls at their central carbonyl group(s) was noted in the introduction. Normal synthetic procedures usually yield the hydrates **44** which must then be dehydrated to afford the desired polycarbonyl compounds; a variety of procedures are available for this purpose.[1,2] The equilibrium in such reactions is usually far to the right. Hemihydrates as well as di- and higher hydrates have also been observed. Rigorous exclusion of moisture in photochemical reactions is necessary if one wishes to observe the photochemistry of the free polycarbonyl compound. Similar reaction with alcohols (or other protic compounds) afford hemiketals. One ignores these possibilities at one's peril (Figure 50.12).

A number of reports of photopinacolization of tricarbonyls upon irradiation in hydroxylic solvents have appeared with incorrect mechanistic interpretations. The first of these was a 1903 report by Ciamician and Silber,[26] the fathers of organic photochemistry, who irradiated **32** in ethanol solution and obtained the corresponding pinacol, alloxantin. A similar report on the formation of alloxantin from irradiation of **32** hydrate in isopropyl alcohol appeared in 1950. It was assumed that initial H-atom abstraction by **32** results in formation of the ketyl radical which then dimerizes. This conclusion is not correct. These pinacols are, in fact, the products of β-cleavage of the hydrate (or hemiketal) leading to formation of ketyl radicals **45** plus hydroxy or alkoxy radicals; subsequent dimerization of the ketyl radicals affords the pinacol. Support for this point of view was provided by experiments in which

ninhydrin and **32** hydrate were irradiated in *t*-butyl alcohol, a notoriously poor H-atom donor.[27] Products were the pinacol and acetone, the decomposition product of *t*-butoxy radicals. Other workers showed that irradiation of ninhydrin or of **32** hydrate led to a coupled decomposition of water due to the intermediate formation of hydroxyl radicals; some α-cleavage was also observed.[28,29] Abstraction of the H-atom is indeed one of the reactions of excited polycarbonyls, but experiments in an aqueous or alcohol medium are not relevant.

Irradiation of the diethylketal (**46**) of phenalenetrione was shown by Stern–Volmer studies (cyclohexadiene quencher) to involve both singlet and triplet states.[30] Products were the diethyl ether of the corresponding pinacol and a derivative of the dihydrotrione, again a β-cleavage process, accounts nicely for the observed results.

More recently, photolysis of **3** was investigated in alcohol solution using the full spectrum of a mercury lamp.[31] Here, again, the results undoubtedly were due to photochemistry of the corresponding hemiketals.

It is possible to irradiate free polycarbonyls in the presence of hydrate or hemiketal by using light of sufficiently long wavelength so that the hydrate does not absorb, but avoidance of water or other protic solvents in the first place is to be preferred if at all possible.

50.10 Summary

The photochemistry of vic-polycarbonyl compounds can be regarded by optimists as exhibiting a rich range of reactivity or, alternatively, by pessimists as a hodge-podge of differing reactions that depend very much on the specific substances being investigated. For tricarbonyl compounds, we find normal ketone photochemistry with diethyl mesoxalate, α-cleavage and subsequent radical chain reactions with dialkyl triketones, a high degree of inertness with diaryl triketones, and classical carbonyl behavior (with adjustment for the presence of multiple carbonyl groups) for cyclic indanetrione and related compounds. Tetraketones show interesting, albeit photochemically not very efficient, chemistry to give novel structures that would not be predicted in advance. The last remaining type of compound, the acyclic pentaketones, have not yielded the secrets of their excited state reactions as yet. The conclusion that emerges clearly is that there is much room for additional work in this area.

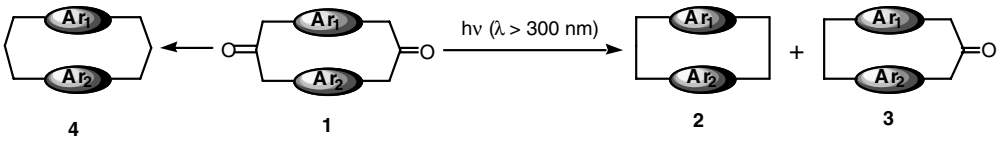
51.1 Photochemical Decarbonylation Reactions for the Synthesis of Cyclophanes

Electronically excited carbonyl compounds undergo various reactions, in which α-cleavage in solution constitutes an important synthetic method.[1] Quinkert et al.[2] first reported the light-induced decarbonylation of ketones in benzene in 1963. Engel[3] and Robbins and Eastman[4a] independently in 1970 found that the decarbonylation of dibenzyl ketone occurs very efficiently from an extremely short-lived quenchable triplet state with a quantum yield (Φ_{CO}) of 0.7 at 313 nm in benzene at 30°C. Robbins and Eastman also reported that the decarbonylation proceeds via a two-step mechanism involving the formation of the phenylacetyl radical.[4b]

[3.3]Cyclophanes ([3.3]CPs) undergo two types of photochemical reactions, irradiation of the $\pi\pi^*$ band of multibridged [3^n]CPs leads to the formation of polycyclic cage compounds via photocycloaddition of the facing benzene rings, followed by rearrangement of the carbocation species generated by protonation of a cyclobutane ring of the cycloadduct (as described in Chapter 23), while irradiation of the n,π^* band of [3.3]CP-2,11-diones **1**[5–7] undergoes decarbonylation to give [2.2]CPs **2** in high yields.[8]

In the course of our study on multilayered [3.3]metacyclophanes, we noticed that the n,π^* bands of the structural units, [3.3]metacyclophane-2,11-diones, appear in the 280- to 330-nm region. We found that photoexcitation of the n,π^* bands of [3.3]cyclophane-2,11-diones **1** in benzene extrudes CO smoothly to give [2.2]CPs **2** in high yields. This method also provides a general synthetic method for [3.2]CP-2-ones **3** by taking advantage of the fact that this reaction proceeds in a stepwise manner via [3.2]CP-2-ones **3**. Thus, this method provides an alternative synthetic route to [2.2]CPs and a simple

0-8493-1348-1/04/$0.00+$1.50



SCHEME 51.1 A new synthetic route to [2.2] and [3.2]cyclophanes **2** and **3** by photochemical decarbonylation of [3,3]cyclophane-2,11-diones **1**.

approach to the synthesis of [3.2]CPs, which are generally inaccessible in a direct manner, from the same starting material **1** for the synthesis of [3.3]CPs **4** (Scheme 1).

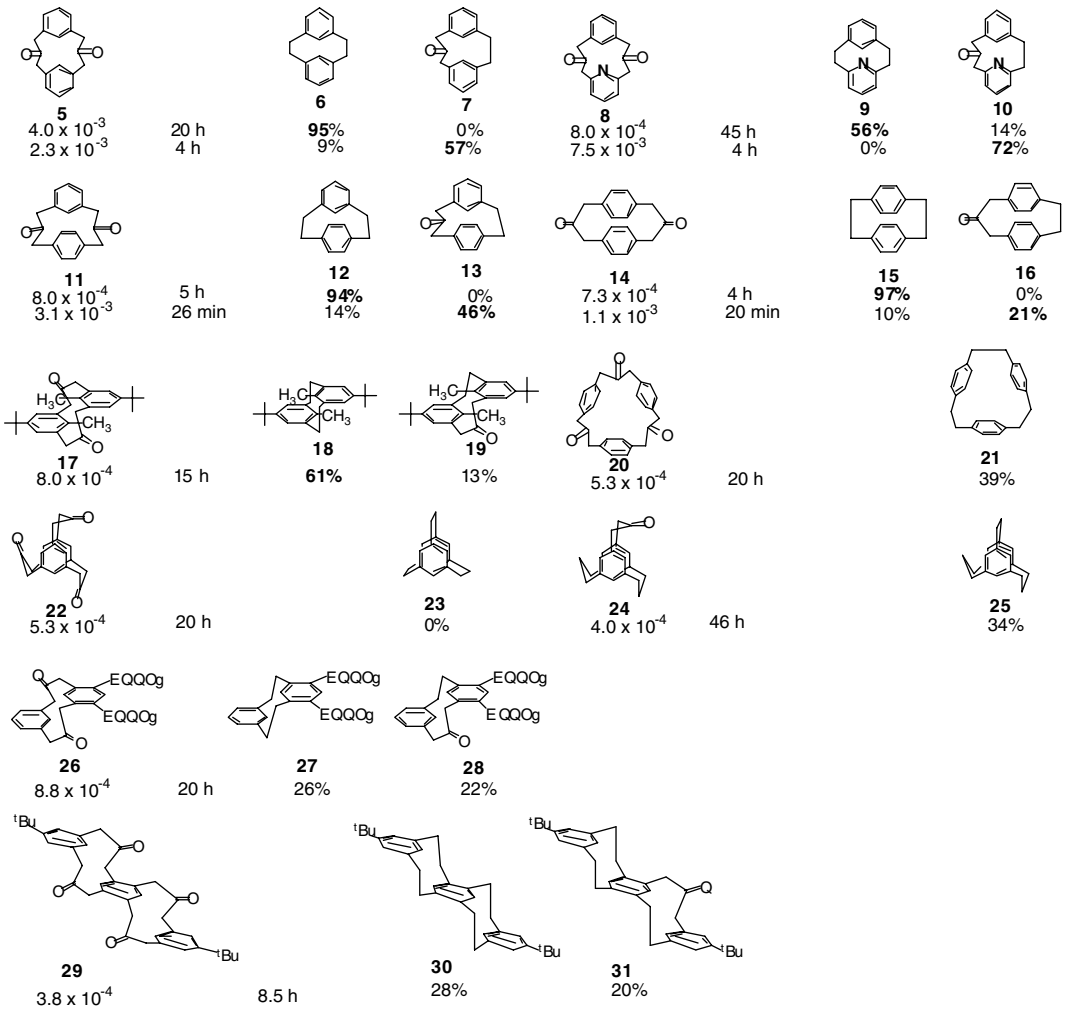
The general synthetic methods for [2.2]CPs have been already established.[9] Most of them employ the ring contraction reactions of the 2,11-diheteroatom-substituted [3.3]CPs. Photochemical elimination of sulfur or selenium atoms from [3.3]CP-2,11-disulfide or diselenide and flash vacuum pyrolysis of sulfur dioxide obtained by the oxidation of the corresponding sulfides are the most general methods. 2,11-Diaza[3.3]CPs are converted to the corresponding [2.2]CPs via their nitroso derivatives by reductive elimination of nitrogen.[10] Photoextrusion reactions of CO_2 from cyclic diesters can also be applied to the synthesis of [2.2]paracyclophanes (PCPs)[11,12] and [2.2]heterophanes, as described below.[13]

Recently, Vögtle et al.[14] reported the selective ketone pyrolysis as a new synthetic method for mono- and polycyclic hydrocarbons; that is, flash vacuum pyrolysis (10^{-5} Torr, 610 to 650°C) of [3.3]CP-2,11-diones **1** afforded [2.2]CPs **2** in moderate yields. This ketone pyrolysis is widely applicable to the synthesis of tribridged cyclophanes and of cyclophanes with a large cavity starting from $[3^n]$CP-(one)^n.[15]

Photochemical reaction of [3.3]CP-2,11-dione **1** in benzene gives the corresponding [2.2]CP **2** in satisfactory yield. The isolated yields of products and irradiation times are summarized in Table 51.1. A benzene solution (4.0 mmol/L) of [3.3]MCP-2,11-dione **5** was irradiated with a high-pressure mercury lamp (400-W) as the internal light source at ambient temperature while nitrogen was bubbled into the solution. The reaction was rather slow but [2.2]MCP **6** was obtained in 95% yield after 20-hr irradiation. When irradiation was discontinued after 4 hr, 9% of **6** and 57% of [3.2]MCP-2-one **7** were isolated. This indicated that the reaction proceeded in a stepwise manner. This method was also applicable to the synthesis of [2.2]pyridinophane **9** (56%), but longer irradiation time was required compared with the reaction of **5**. The reaction of [3.3]metaparacyclophane(MPCP)-2,11-dione **11** proceeded smoothly to give [2.2]MPCP **12** (94%). [3.3]PCP-2,11-dione **14** was the most reactive among the [3.3]CP-2,11-diones and afforded [2.2]PCP **15** (97%) after 30-min irradiation. The solvent benzene can be replaced with other solvents such as ethyl acetate. This reaction was successfully applied to the functionalized [2.2]CPs as exemplified by the synthesis of 7,15-di-*t*-butyl-4,12-dimethyl[2.2]MCP **18** and the synthesis of $[2^n]$CPs with large rings; [3.3.3]PCP-2,11,20-trione **20** gave [2.2.2]PCP **21** (39%) after 20-hr irradiation. [3.3.3](1,3,5)CP-2,11,20-trione **22** was inert to irradiation, and the formation of **23** was not observed; whereas, monoketone **24** provided [3.3.2](1,3,5)CP **25** (34%). This suggested the quenching of the photoexcited state of one carbonyl group by neighboring ground-state carbonyl groups in **22**.The reaction conditions can be adjusted to allow the preferential formation of [3.2]CP-2-one **3** from the time-controlled reaction of **1**. As described above, [3.2]MCP-2-one **7** was isolated in 57% after 4-hr irradiation along with [2.2]MCP 6 (9%). Similarly the [3.2]pyridinophane-2-one **10** was obtained in 72% yield after 4-hr irradiation with 16% recovery of **8**. Dione **11** yields [3.2]MPCP-2-one **13** (46%), and dione **14** gives [3.2]PCP-2-one **16** (21%); along with the corresponding [2.2]CPs after 40- and 20-min irradiations, respectively. Furthermore, this method is also applicable to the synthesis of $[2^n]$CPs as host molecules (**20** to **21**) and multilayered [2.2]MCPs (**29** to **30** and **31**).

The advantage of our photochemical method over Vögtle's[14,15] and other conventional methods[9] is the simple and easy experimental procedures, which do not require special apparatus; also, high yields of product are obtained. Thus, [3.3]CP-2,11-diones **1**, which are readily accessible by TosMIC (*p*-tolylsulfonylmethyl isocyanide)[16] coupling,[5–7] serve as common precursors to the synthesis of [3.3]CPs **4** as well as [2.2]- and [3.2]CPs **2** and **3**. The significance of the photodecarbonylation reaction resides in the fact that a series of [3.3]-, [3.2]-, and [2.2]CPs can be prepared from the same starting compound **1**. Therefore,

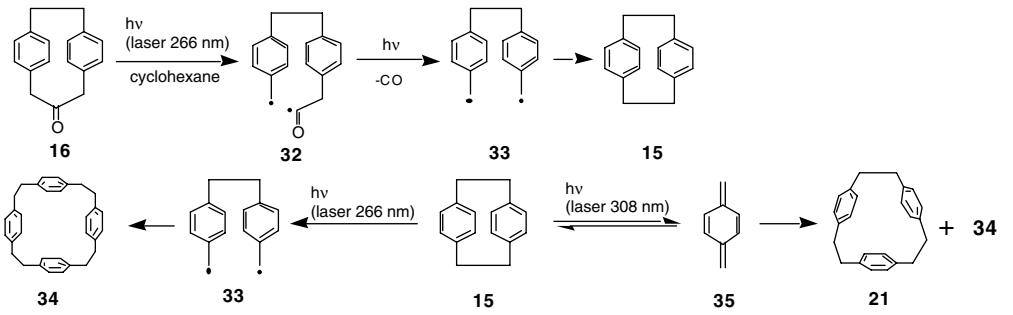
TABLE 51.1 Yields of [2.2]cyclophanes and [3.2]cyclophane-2-ones Prepared by Irradiation of Diones with a 400-W High-Pressure Hg Lamp



the method may be most conveniently used when a series of [3.3]-, [3.2]-, and [2.2]CPs is required (Scheme 2).

Miranda et al.[17] reported that irradiation (254-nm mercury lamp) of [3.2]PCP-2-one **16** in benzene led to [2.2]PCP **15** as the only product via acyl–alkyl biradical **32** and biradical **33**. A laser-flash photolysis study (266 nm) of **16** in cyclohexane indicated that biradical **33** is detectable at room temperature and does not cleave to *p*-xylylene **35** but cyclizes to [2.2]PCP **15** or dimerizes to [2^4]PCP **34**. Irradiation (laser, 308 nm) of a cyclohexane solution of **15** containing a triplet quencher (cyclooctadiene) showed two absorption maxima, which correspond to *p*-xylylene **35** and the biradical **33**. The cyclophanes [2^3]PCP **21** and [2^4]PCP **34** were formed by irradiation (laser, 248 or 266 nm) of cyclohexane solutions of [2.2]PCP **15**. While the formation of **34** agrees well with the intermediacy of **33**, the detection of [2^3]PCP **21** provided further evidence for the intermediacy of *p*-xylylene **35**, which can couple either its trimeric or tetrameric products.

The exclusive intramolecular coupling following decarbonylation reaction was supported by the exclusive formation of unsymmetrical [2.2] and [3.2]CPs from unsymmetrical starting ketones such as **8** and **11**. This reaction also proceeds in a stepwise manner. Experimental results show that the preferential



SCHEME 51.2 Photochemical reation of [3.2]paracyclophane-2-one.

formation of [3.2]CP-2-one **3** from the time-controlled reaction of **1** is effective when the reaction is slow, as is the case of the metacyclophane.

51.2 Photochemical Decarboxylation Reactions for the Synthesis of Cyclophanes

This synthetic route permits us to introduce strain by starting from an unstrained molecule that under appropriate conditions decomposes to form an intermediate that can then react by one main pathway. By taking advantage of the high yields and the simplicity of the photoextrusion of esters, Kaplan and Truesdale[11] reported the preparation of [2.2]PCP **15** (Scheme 3). When dilactone **41a**, which was prepared by the reaction of silver salt of 1,4-benzenedi-acetate **36** with 1,4-*bis*(bromomethyl)benzene **40a** in refluxing CH_3CN, was irradiated at room temperature in either MeOH or 1,2-dimethoxyethane, [2.2]PCP **15** was obtained.[11] The yield of **15** approached 70% when 1,2-dimethoxyethane was used as solvent but was somewhat lower in methanol. Hibert and Solladie reported that decarboxylation yields of the dilactones with substituents on the aromatic ring were strongly dependent on the nature of the substituent.[12] The methoxy group **41b** strongly enhanced the decarboxylation process as compared to the carbomethoxy group **41c**. Complete disappearance of the starting dilactone required 12 and 60 min for **41b** (R = OMe) and **41c** (R = CO_2Me), respectively (MeOH, 20°C). In addition, **41c** is first monodecarboxylated and the resultant monolactone is difficult to decarboxylate further. In this case, irradiation in quartz at a higher temperature (58°C) improved the yield of **41c** (85%). Thus, the experimental conditions must be modified depending on the substituent: irradiation through Pyrex at room temperature in the case of electron-donating substituents and through quartz at higher temperatures in the case of electron-withdrawing substituents (Scheme 4). This method could be applied successfully to the synthesis of the benzofused heterophane, *anti*-[2.2](2,6)benzothiazolophane **45**.[13] Irradiation (450-W, high-pressure mercury lamp) of dilactone **44** in MeOH for 6 hr gave the cyclophane **45** (57%). This type of decarboxylation reaction may be useful for the synthesis of a variety of heterophanes and benzenophanes comprised of rather unstable aromatic rings, as large numbers of synthetic methods for preparation of dilactone are available.

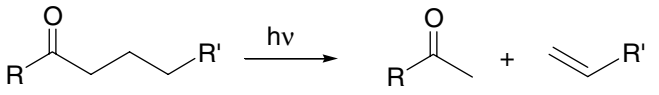
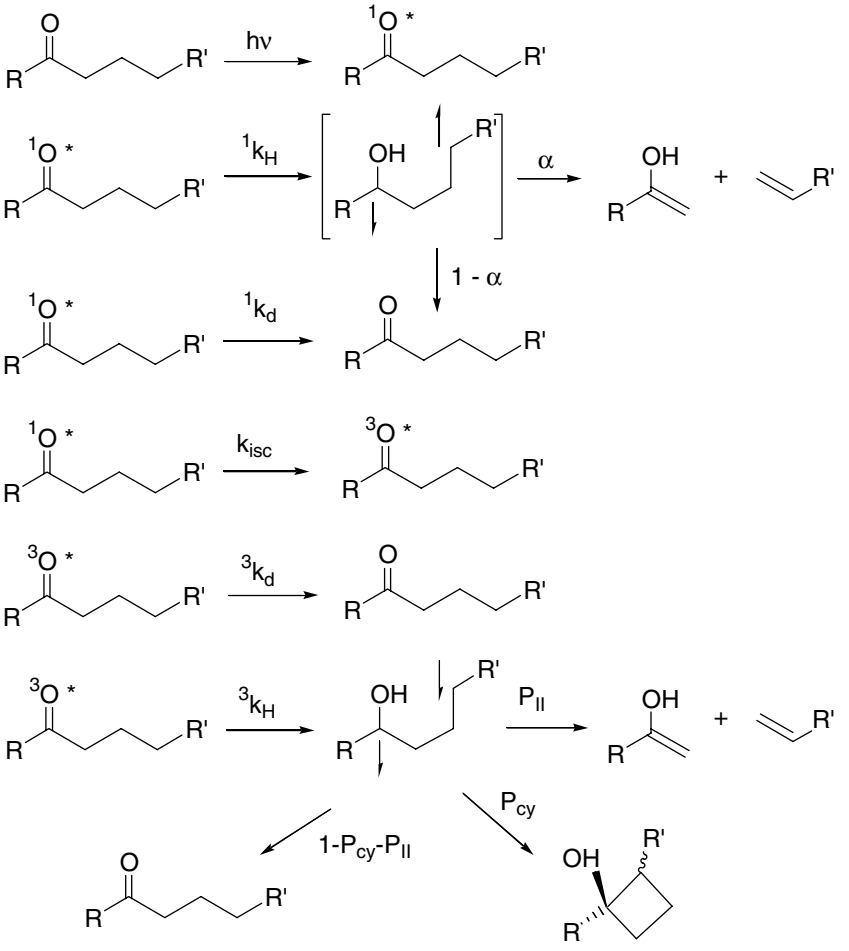
52.1 The Norrish Type II Photoelimination Reaction



52.2 Mechanism



52.3 Byproducts

cyclobutanols (usually)
cyclopentanols (rarely)
γ,δ-unsaturated ketones and cyclohexenones (γ-vinyl)
γ,δ-unsaturated ketones and cycloheptonones (γ-cyclopropyl)
γ,δ-unsaturated ketone (cleavage of δ-substituents)

52.4 History

A wide variety of carbonyl compounds undergo photoinduced intramolecular hydrogen atom abstraction to form biradicals that then undergo two common competing reactions: coupling to produce cyclic alcohols and disproportionation back to a ketone, to various enols, or to alcohols. The overall process closely parallels the well-known bimolecular photoreduction of ketones, the most common products of which are formed by radical coupling. These intramolecular hydrogen abstraction processes have been widely studied and several full reviews are available (including Chapter 58 of this book).[1–5]

The first and still best known example of such intramolecular hydrogen abstraction is the *type II* photoelimination discovered by Norrish,[6] who found that ketones with γ–CH bonds cleave to methyl ketones and alkenes rather than to acyl and alkyl radicals, the earlier discovered *type I* cleavage. Later workers found that both cleavage processes compete in certain ketones and that overall quantum yields are particularly low whenever the type II process occurs. For years, the type II reaction was considered to be concerted; a 1,5-hydrogen transfer together with CC bond cleavage in a six-atom cyclic transition state could lead to the alkene and the enol tautomer of the product ketone. Such a process would now be called a *retro-ene reaction*. In a key experiment, Calvert and Pitts[7] verified by IR that the enol is indeed formed first and then is rapidly converted to ketone. However, Yang and Yang[8] had already discovered competing cyclobutanol formation and suggested that cleavage and cyclization both arise from a common 1,4-biradical intermediate. As realization of this process grew, other workers investigated a large variety of ketones that form different kinds of biradicals and cyclic alcohols. However, the biradicals formed by hydrogen abstraction from positions other than the γ-carbon cannot cleave the way a 1,4-biradical does. Although cleavage and cyclization of 1,4-biradicals are linked mechanistically, the cleavage process is so easy to measure that Norrish type II elimination has been widely studied to gain basic mechanistic information about biradicals and about hydrogen abstraction reactions of excited ketones. This chapter is devoted primarily to this unique cleavage process discovered by and properly named for Norrish. Other sections of this handbook are devoted specifically to cyclic alcohol formation initiated by β-, δ-, and more remote intramolecular hydrogen abstraction, a general process now named after its actual discoverers, Yang and Yang.

Before the concerted vs. two-step question was further elucidated, another basic mechanistic puzzle was raised. One group found that type II cleavage of 2-pentanone was quenched by biacetyl, which was known to quench excited triplets rapidly.[9] Another group found that the reaction of 2-hexanone was not quenched under the same conditions.[10] The two groups obviously differed as to which excited state undergoes the reaction. The apparent conflict was neatly solved by the revelation that each of the two ketones reacts from both states, with 2-hexanone undergoing more unquenchable singlet reaction than 2-pentanone.[11,12]

Before the mid-1960s, most studies were performed on aliphatic ketones. Wan and Pitts then showed that phenyl alkyl ketones also undergo the reaction.[13] Wagner and Hammond[14] then showed that the type II reaction of phenyl ketones is completely triplet derived and suggested that their low quantum yields are caused by disproportionation of Yang's 1,4-biradical intermediate back to ketone. Wagner et al.[15,16] soon discovered that adding Lewis bases markedly increases the quantum yields of triplet type II reactions, often to 100%. This behavior was attributed to suppression of biradical reversion to ketone by hydrogen bonding of the biradical's hydroxy group to the Lewis base; the H-bond must be broken during disproportionation but not during cleavage or cyclization. In 1972, Wagner et al.[17,18] succeeded in trapping the biradicals with mercaptans; they found that the quantum yield for racemization of (+)-4-methyl-1-phenyl-1-hexanone, which could be caused only by disproportionation of the 1,4-biradical, equaled 1 minus the quantum yield for type II products. In so equating racemization at the γ-carbon with what has been called "radiationless decay", they proved what had been thought to be physical decay of the excited state instead was chemical reversion of a biradical intermediate to ketone.[18] At the same time Yang and Elliot[19] showed that the triplet, but not the singlet, component of the photoreactivity of 5-methyl-2-heptanone also produces extensive racemization at the γ-carbon. All of this work firmly established the 1,4-biradical as an intermediate in the triplet reaction but left open how much it is involved

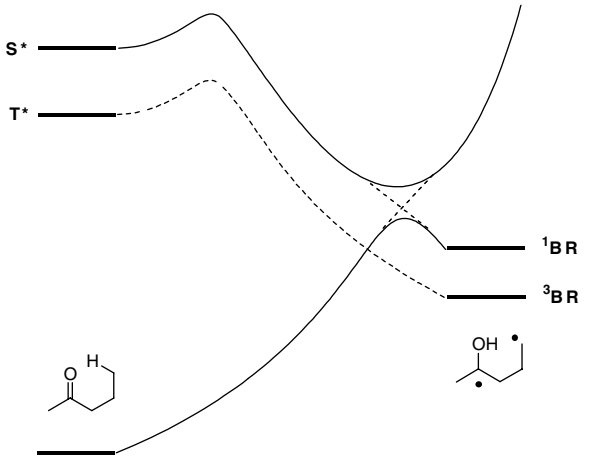


FIGURE 52.1 Potential energy diagram for excited-state hydrogen abstraction.

in the singlet reaction. Some unquenchable cyclization reactions indicated that singlet biradicals are indeed formed, even if they may not account for all the cleavage reaction.[20]

52.5 Quantum Efficiency

As the above description indicates, the Norrish type II reaction involves two consecutive intermediates: first an excited state (that can be singlet or triplet) and then a biradical. Consequently, it is necessary to understand how structure and environment affect the behavior of both species separately. The quantum efficiency for cleavage depends on how many competitive reactions *each* intermediate undergoes, as described by Eq. (52.1) (α is the percentage of singlet reaction that forms biradical; k_H is the rate constant for hydrogen abstraction; τ is the excited state lifetime, the reciprocal of the sum of the rates for all excited state decay processes; P_{II} is the percentage of triplet biradical that cleaves; and Φ_{ISC} is the percentage of excited singlet that crosses to triplet state).

$$\Phi_{II} = \alpha^1 k_H \tau_S + P_{II}\, \Phi_{ISC}{}^3 k_H \tau_T \qquad (52.1)$$

52.6 Excited State Reactivity

Nature of Excited State

Photoexcitation of carbonyls effectively breaks the double bond to form a 1,2-biradical, thus conferring on the more electronegative oxygen atom radical reactivity that closely parallels that of alkoxy radicals. Two multiplicities (singlet and triplet) and two electronic configurations (n,π^* and π,π^*) have been shown to display reactivity.

Singlet vs. Triplet

Aliphatic ketones have n,π^* lowest singlets that undergo intersystem crossing to their n,π^* lowest triplets with rates of $\sim 10^8$ s^{-1}, slow enough that some singlet reaction occurs. The reaction of a given ketone can be partitioned into its singlet or triplet components by the technique of differential quenching with conjugated dienes.[11] All triplet reactions can be quenched, and the singlet reaction is isolated by performing irradiations in dienes or substituted naphthalenes as solvent.[21] Figure 52.1 depicts the well known different potential energy surfaces followed by the two states.[3] The low quantum efficiency always observed for singlet reactions indicates that partial hydrogen abstraction promotes radiationless decay directly back to reactant at the point of a forbidden crossing or conical intersection between ground- and excited-state

TABLE 52.1 Excited-State Behavior of $CH_3COCH_2CH_2R$[1,24–26]

R	$\Phi^{S;II}$	Φ_{ISC}	$\Phi^{T;II}$	^1k_H (10^8 s^{-1})	^3k_H (10^8 s^{-1})
CH_3	0.025	0.81	>0.36	1.0	0.13

$(CH_3)_2CH$	0.07	0.18	0.17	20	3.8

surfaces.[22] The characteristic near-zero yields of cyclobutanol from the singlet state, even in alcohol solvents, suggest that some of the singlet reaction may actually occur in a concerted fashion, but triplet reaction occurs exclusively via biradicals that both cleave and cyclize.

The first real-time study of Norrish type II reaction dynamics was reported recently by Zewail and co-workers[23] for a series of methyl alkyl ketones. Their excited singlet states undergo intramolecular hydrogen transfer in 70 to 90 fs to form biradical intermediates with 400- to 700-fs lifetimes. It is interesting to compare this gas-phase study with the data listed in Table 52.1 for the solution photochemistry of simple alkanones; singlet state rate constants for hydrogen abstraction are around 10^9 s^{-1}, values that reflect the equilibrium conformational distribution of the ketones.[1,25]

The rapid (>10^{10} s^{-1}) intersystem crossing in most phenyl ketones usually produces exclusive triplet reactivity. A few intramolecular hydrogen abstraction reactions of aryl ketones have been shown to involve excited singlets at least partially.[27–29] This pattern occurs when the n,π^* singlet reaction is fast enough to compete with intersystem crossing; exclusive singlet reaction can occur if triplet reaction is so slow as to be totally suppressed by trace quenchers or by a rapid competing reaction.

The n,π^* triplet excitation energies of aliphatic ketones have not been measured exactly but generally are considered to be ~78 kcal mol^{-1}; their n,π^* singlet excitation energies are some 10 kcal higher. As Table 52.1 indicates, excited singlets of alkanones undergo hydrogen abstraction some ten times faster than do their lower energy triplet states. For both states, abstraction of even primary hydrogens is exothermic; the higher reactivity of n,π^* singlets relative to triplets most likely reflects greater reaction exothermicity. Even though the triplet excitation energy of phenyl alkyl ketones is only ~72 kcal mol^{-1}; both alkanone and phenyl ketone triplets display similar rate constants for attack on a given type of CH bond;[1,30] benzylic stabilization of the developing hydroxy radical site compensates for the lower energy of the phenyl ketone triplet. The activation energy for triplet state hydrogen abstraction from an unactivated methylene group is only ~3.5 kcal mol^{-1}.[31,32]

Substituent Effects, Conjugative: n,π^* Vs. π,π^*

Aryl ketones can have either n,π^* or π,π^* lowest triplets; the former are far more reactive than the latter. It has been known for some 40 years that *para* electron-donating substituents reduce the hydrogen abstraction reactivity of triplet phenyl ketones by inverting their triplet energy levels such that π,π^* are lowest.[33] Ketones with π,π^* lowest triplets do undergo hydrogen abstraction reactions but display two quite different forms of triplet reactivity. In systems with π,π^* triplets, only a few kcal mol^{-1} below their n,π^* triplets, most of the measured reactivity arises from low concentrations of the n,π^* triplet in thermal equilibrium with the lower π,π^* triplet.[32,34] Equation (52.2) describes observed rate constants for hydrogen abstraction, with the n,π^* state providing most or all of the reactivity when ΔE ($E_{n,\pi} - E_{\pi,\pi}$) < 5 kcal mol^{-1}.

$$k_H^{obs} = \chi_{n,\pi} k_H^{n,\pi} + \chi_{\pi,\pi} k_H^{\pi,\pi} \tag{52.2}$$

$$\chi_{n,\pi} = (1 - \chi_{\pi,\pi}) = e^{-\Delta E/RT}/[1 + e^{-\Delta E/RT}] \tag{52.3}$$

where χ is the percent population of one state.

Table 52.2 compares the effects of ring substituents on rate constants for triplet-state hydrogen abstraction by valerophenone, together with intrinsic $k_{n,\pi}$ values that reflect independently measured substituent effects on rate constants for bimolecular hydrogen abstraction ($\rho = 0.5$)[35] and derived values for the

percentage of n,π^* triplets in equilibrium with π,π^* triplets. The energy gaps between the two triplets are derived from the experimentally measured increases in activation energies for reaction produced by a substituent that causes the π,π^* triplet to be lowest, namely electron donors and conjugative electron-withdrawing groups.[32,36] Only very strong electron donors produce a large enough energy gap that reactivity becomes imperceptible.

The second type of π,π^* reactivity occurs in polynuclear aryl ketones with large $E_{n,\pi} - E_{\pi,\pi}$ values. It is often assumed incorrectly that π,π^* triplets are totally unreactive in hydrogen abstraction. This notion is contradicted by the observed triplet reactivity of some naphthyl ketones, which is only 0.01 to 0.001% that of an n,π^* triplet.[37,38] The original explanation for this large difference still seems reasonable; namely, the distinct spin localization in an n,π^* triplet as opposed to the delocalized spin in a π,π^* triplet.[37] This fact is usually depicted in terms of the n,π^* triplet resembling a 1,2-diradical[39] and thus manifesting the chemical reactivity of an alkoxy radical,[1,40] while the π,π^* triplets have little spin density on oxygen. Despite the intrinsic, if greatly diminished, reactivity of acylnaphthalene triplets, most reported type II cleavages of naphthyl ketones are very low quantum yield reactions from an unquenchable singlet.[27,28]

Substituent Effects: Inductive

As Table 52.2 shows, inductively electron-withdrawing ring substituents (F, CF_3, and N) enhance the reactivity of n,π^* triplets, magnifying the electron deficiency of the carbonyl oxygen. Cyano and carbonyl substituents *ortho* or *meta* have the same type of inductive effect as they are not conjugated to the benzoyl carbonyl in the triplet state. Substituents on the α-carbon of ketones influence excited-state reactivity, although no extensive study has been done. In particular, electron-withdrawing groups seem to increase reactivity. For example, α-fluorination markedly enhances n,π^* reactivity; however, it also promotes a π,π^* lowest triplet.[41] α-Ketohexanoic acid shows enhanced reactivity compared to 2-hexanone.[42] α-Alkoxy ketones also show unusually high reactivity,[43] although much of the increase is due to conformational and bond energy effects, as discussed below.

Solvent Effects

For ketones with n,π^* lowest triplets, there do not appear to be any significant solvent effects on k_H values. However, when the π,π^* triplet is of lower or comparable energy, polar solvents reduce overall reactivity by lowering the excitation energy of the π,π^* triplet and raising that of the n,π^* triplet, thus decreasing $\chi_{n,\pi}$ values.[34] In the case of *p*-methoxyphenyl ketones, quantum yields plummet in methanol.

Zepp and co-workers[44] investigated the photochemistry of valerophenone in aqueous solutions as a function of temperature, pH and wavelength. The results indicated that the rate constant for hydrogen abstraction is significantly lowered in aqueous media due to stabilization of the π,π^* excited state. The study also indicated constant high quantum yields for the photoreactions over the pH range of 9 to 2, but a significant decrease below pH = 2. This decrease was attributed to quenching of the triplet reactivity via protonation of the excited triplet state, behavior previously noted for other ketone reactions.

Nature of Hydrogen Atom

γ–CH Bond Energy Effects

Table 52.3 lists measured rate constants for triplet-state γ-hydrogen abstraction by γ-substituted butyrophenones.[5,45] The relative values should hold for any type of hydrogen abstraction by n,π^* triplets. The 1:30:200 primary/secondary/tertiary per-bond ratio is characteristic of electron-deficient species such as alkoxy radicals. γ-Substituents affect both the bond energies and the electron density of the CH bonds, each of which affects k_H values. The fourth column of Table 52.3 extracts a resonance factor by which conjugation of the γ-substituent with the developing γ-radical site enhances the rate constant. Thus, the positive conjugative effect of a cyano group counteracts its negative inductive effect. This factor was obtained by correcting the observed substituent effect on k_H for inductive deactivation, with a ρ_I value of –4.3 extrapolated from that for δ-substituents (see next section). These results are one example of how the type II reaction can be used to provide information about radical reactions. The table also includes the quantum yields for acetophenone formation, which will be discussed later, as they are determined mainly by biradical behavior and sometimes by excited state behavior. The important fact is that there is very little correlation between quantum efficiency and rate constants for γ-hydrogen abstraction.

Inductive Effects

Table 52.4 lists measured rate constants for triplet state γ-hydrogen abstraction by δ-substituted valerophenones.[5,45] Here, the substituents are not conjugated with the developing γ-radical site so their effects are entirely inductive. They indicate a ρ_I value of –1.85, which demonstrates the highly electron-deficient nature of the carbonyl n,π^* state. It should be noted that I, Br, and RSO substituents enhance reactivity by what has been suggested to be anchimeric assistance.[46]

Geometric Effects

For a bifunctional reaction to occur, two geometric factors must be optimized: the distance between the two reacting groups and their orientation with respect to each other. In the case of hydrogen abstraction,

the distance between the carbonyl and the CH group and the orientation of the C=O and CH bonds determine reactivity. Whereas in a bimolecular reaction the reactive functional groups of the two molecules are free to rotate into all possible relative orientations and diffuse to van der Waals contact distance, in an intramolecular reaction intervening bonds and structure limit the orientations and proximity available to two separate functional groups. The resulting conformational equilibria and kinetics affect rate constants for hydrogen abstraction and thus determine both rates and regioselectivity. Because these factors affect all intramolecular hydrogen abstractions, their general features are presented fully in Chapter 58, which covers all forms of intramolecular hydrogen abstraction by excited ketones. Only those features unique to or famously clarified by γ-hydrogen abstraction are presented here.

For some time there has been a simplistic belief that the hydrogen atom, being abstracted, should be restricted to lie along the long axis of the carbonyl *n*-orbital. This notion recognizes the directionality of *p* orbitals and the fact that n,π^* radical reactivity is centered on this particular *p* (or sp^2) orbital. However, many examples are known in which efficient hydrogen abstraction takes place, with the developing HO bond making a fairly large angle with respect to the nodal plane of the carbonyl π system.[47–50] It has been pointed out that such reactivity probably demonstrates a $\cos^2$ dependence on this angle,[3] that being the electron density function for a *p* orbital.

Scheffer[51,52] has studied a variety of ketones that undergo γ-hydrogen abstraction in their crystalline states. In analyzing their reactivity, he considered the *ground-state* parameters depicted in Scheme 1, where d is the distance between O and H; θ is the O–H–C angle; Δ is the C=O–H angle; and ω is the dihedral angle that the O–H vector makes with respect to the nodal plane of the carbonyl π system. Such a comparison of triplet reactivity with ground-state geometries is valid because n,π^* excitation is known to be so highly localized on the carbonyl group that geometric changes in the rest of the molecule are negligible, with only a slight lengthening of the carbonyl bonds:[53]

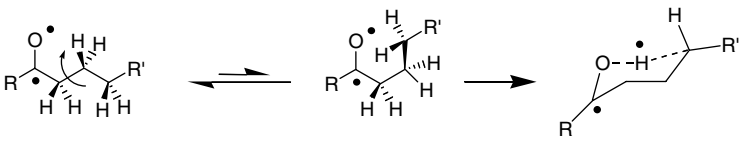
$$\Delta = 73–110^\circ,\ \theta = 85–120^\circ,\ \omega = 20–70^\circ,\ d < 3.1\ \text{Å}$$

Actually observed values for over two dozen examples in which x-ray crystal structures were obtained for reactive ketones are summarized in the scheme, together with the theoretically ideal values.[54,55] The



SCHEME 2

most important parameter appears to be d, because whenever two hydrogens at different distances <3.1 Å are available, the closer one is abstracted. Whenever a hydrogen is positioned this close to the carbonyl in the ground state, minimal molecular motion is required for reaction, and minimal motion is all that most crystal lattices allow. The value of θ obviously can vary greatly from the linear arrangement thought to be preferable. Likewise, the value of ω can depart significantly from the "ideal" 0°. Both of these deviations from ideality have long been known from the reactivity of many steroidal ketones.[3,41]

Several experimental observations have suggested zero reactivity when ω = 90°.[56–58] All of these involved rigid polycyclic ketones or crystalline media where the reactants are constrained to maintain their ground-state geometry. This lack of conformational mobility maximizes the possibility that a biradical formed by either α-cleavage or hydrogen abstraction might revert to starting ketone with 100% efficiency and thus present the false impression that hydrogen abstraction did not occur.

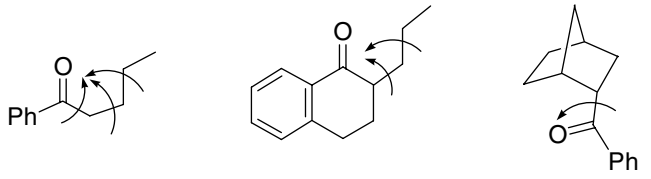
Conformational Effects

As discussed in Chapter 58, rate constants for intramolecular hydrogen abstraction reflect conformational effects.[3,59] We assume that interconversion among the various conformers of a given excited state competes with reaction and decay. One or more conformations may have geometries close to that required for reaction and are dubbed *favorable* or *reactive*. Also, *unreactive* geometries are usually observed in which the two functional groups are too far apart for reaction; these must be able to rotate into reactive conformations if they are to react rather than decay to ground state. Molecules that react as solids must have lowest energy conformations that are reactive. Most acyclic ketones exist preferentially in unreactive conformations, such that they may not react in the solid state. The lowest energy conformations of cyclic systems may have either reactive or unreactive geometries.

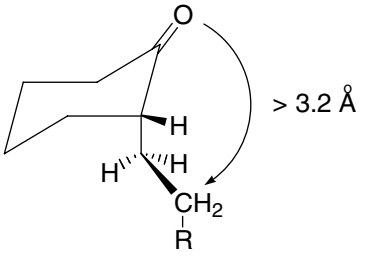
As Chapter 58 explains, excited states display three types of conformational dynamics. The Norrish type II reaction can be subject to any of these different dynamic boundary conditions.[59] The first dramatic example of ground-state control of triplet reactivity, in which conformational interconversion is slower than reaction of the initial excited-state conformation, was provided by Lewis' study of the Norrish type II reaction of benzoylcyclohexanes.[60] Photoenolization of *ortho*-alkyl ketones was the first reaction recognized to show rotational control of triplet reactivity[61] in which an irreversible bond rotation produces a reactive conformer of the excited state. Conformational equilibrium, in which bond rotations are faster than excited-state decay, is much more common; an early example is the type II reaction of benzoylcyclobutanes.[62]

Normally, the largest α-substituent eclipses the carbonyl group in ketones, with the lowest energy conformation being fully *anti* staggered and unreactive. The α,β–CC bond must become *gauche* for γ-hydrogen abstraction to occur. Extra β-substituents increase the fraction of reactive *gauche* conformers.[47] Because several *gauche* conformers are present, their combined population usually surpasses that of the *anti* conformer such that reaction is quite rapid (Scheme 2); moreover, the energy differences among the conformers are small enough that interconversion is rapid.

When the carbonyl and CH bond are part of a ring or substituents on a ring, the conformational limitations of the ring may either increase or decrease the population of favorable conformations. Lewis demonstrated how incorporation of rings between the carbonyl and the γ-carbon can increase rate constants for γ-hydrogen abstraction.[63] Scheme 3 shows some ketones in which the activation energy for abstraction of a secondary hydrogen remains the 3.5 kcal mol^{-1} that it is required for bimolecular reaction,[32,36] but the entropy of activation becomes less negative as rings freeze intervening CC bond rotations. Each such frozen rotation increases the rate constant by a factor of ~8, which corresponds to



SCHEME 3



SCHEME 4

4 eu. In all three cases, the major conformation is either a reactive one or of comparable energy, and the rings limit the number of unreactive conformers.

In general, however, *no constant factor exists by which rings change intramolecular reactivity.* They may decrease the population of a reactive conformation, as Alexander and Uliana showed for benzoylcyclobutane;[62] limit reaction to one site, as the selective δ-hydrogen abstractions in Paquette's synthesis of dodecahedrane exemplified;[64] or prevent population of a reactive conformer, as Turro and Weiss reported for cyclohexanones with axial α-alkyl groups (Scheme 4).[65]

Regioselectivity

Acyclic Systems

The predominance of γ-hydrogen abstraction by excited straight-chain ketones is so pronounced that for years it was thought that no ketone containing γ-hydrogens would react at any other position. A few notable exceptions were eventually found; δ-methoxyvalerophenone[66] and γ-benzoylbutyraldehyde[67] undergo both γ- and δ-hydrogen abstraction with comparable rate constants because both possess a highly reactive δ–CH bond and an inductively deactivated γ–CH bond. From these results, it was deduced that the intrinsic γ/δ selectivity in triplet ketones is 20:1.[47] No reaction occurs at any other position.

Houk has published several theoretical studies of intramolecular hydrogen transfer, including one that accurately reproduces the preference for 1,5- vs. 1,6-hydrogen transfers in triplet ketones.[55] Much of the preference is entropic, as expected, but little enthalpy difference exists between the two modes. A chair-like transition state was originally suggested for γ-hydrogen transfers.[47] The calculations predict a strong preference for a linear C–H–O arrangement (θ = 180°), which is more easily accommodated in a seven-atom transition state than in a six-atom one. Thus, relative enthalpies of activation reflect both ring size strain and orbital orientation in the transition state. It must be reiterated that actual ketones react even when θ approaches 90° in the ground state and may adopt a chair-like transition state.

In summary, ketones react preferentially with γ–CH bonds. Reducing their reactivity can allow more remote hydrogen abstractions to compete, but the only way to eliminate γ-hydrogen abstraction is to eliminate γ-hydrogens. This constraint does not apply to similar hydrogen abstraction reactions of thioketones and *N*-alkylimides.[5]

Cyclic Systems

The interposition of even one ring between the carbonyl and any γ–CH bonds imposes conformational restrictions that limit the molecular geometries possible. Consequently, regioselectivity becomes dominated by frozen rotations such that only certain CH bonds are close enough to the carbonyl to react. Such structures can enhance or suppress the reactivity of γ–CH bonds and also enhance the reactivity of more remote sites.

Charge Transfer Followed by Proton Transfer

Bimolecular photoreduction of ketones by good electron donors often proceeds by either electron transfer or charge transfer complexation followed by a proton transfer. Intramolecular hydrogen transfers do not seem to follow this pathway as often. There is good evidence from the behavior of aminoketones that tight overlap of the donor lone pair with the half-empty *n* orbital is necessary for triplet CT reaction. Rate constants for internal quenching in ω-dimethylaminoalkyl phenyl ketones are maximum for β- and γ-amino ketones, in which five- or six-atom rings can be formed by overlap of the nitrogen lone pair with the half-occupied carbonyl *n* orbital.[68] Interestingly, triplet α-dialkylaminoacetophenones do *not* undergo rapid internal charge transfer; they do, however, undergo normal γ-hydrogen abstraction.[29,68] The rapid internal charge transfer in triplet γ-dialkylaminobutyrophenones does not lead to efficient product formation;[68,69] the required orbital overlap seems to enforce a restricted orientation in the exciplex that prevents proton transfer to oxygen such that CT becomes a purely competitive quenching process.

Competing Excited-State Reactions

Bimolecular hydrogen abstraction from solvent rarely competes with the rapid intramolecular process except in solvents with the most labile CH bonds and for the few ketones whose γ–CH bonds are relatively unreactive. Norrish type I α-cleavage is very competitive in the case of triplet α-alkylcycloalkanones, although the relative slowness of excited singlet state α-cleavage provides the opportunity for high chemical yields of singlet state type II cleavage in the presence of triplet quenchers. Occasionally δ-hydrogen abstraction can compete with γ-hydrogen abstraction to yield some cyclopentanols along with the normal type II products, but only in cases where the δ–CH bond is highly reactive and the γ–CH bond is relatively unreactive or when conformational rigidity inhibits proximity of the C=O and γ–CH groups.[47] A trio of such cases was mentioned above.

52.7 Biradical Behavior

Direct Spectroscopic Study of Biradicals

In 1977, Scaiano and Small[70] reported the first flash spectroscopic detection of a triplet 1,4-biradical intermediate produced from γ-methylvalerophenone. They rapidly developed two independent methods to monitor triplet-generated hydroxy-biradicals: (1) direct detection of their transient absorption, or (2) indirect detection by following the growth of the strongly absorbing paraquat radical-cation, which is produced when added paraquat oxidizes the hydroxy radical site.[71,72] Scaiano has thoroughly summarized several basic features of triplet 1,4-biradical lifetimes.[73] They are not very sensitive to substitution on the benzene ring or to steric features at the γ-carbon of the ketone, but they are increased by conjugating substituents such as γ-phenyls.[74] They are lengthened approximately threefold in Lewis-base solvents, having values in the 25- to 50-ns range in hydrocarbons and from 75 to 160 ns in alcohols.[75] They are almost independent of temperature, having activation energies for decay of 0 to 1 kcal mol^{-1}.[71] They are shortened by bimolecular interaction with paramagnetic species such as oxygen[76,77] and nitroxide radicals.[78] The most significant structurally induced change is produced by the internal oxygen atom in the biradicals formed from α-alkoxyacetophenones, which have maximum lifetimes of only a few nanoseconds.[71]

As described above, Zewail recently has reported lifetimes of 400 to 700 fs for the singlet 1,4-biradicals formed from n,π^* singlet alkanones in the gas phase.[23] DFT calculations indicated that although both

cyclization and fragmentation are essentially barrierless, cleavage of the biradical is the dominant reaction channel as a consequence of entropy effects, as conformational requirements for ring closure are more demanding than they are for fragmentation. The measured biradical decay times decreased with increasing numbers of alkyl substituents on the γ-carbon atom. Such behavior reflects relative product energies and thus suggests at least small enthalpic barriers. It also must be noted that the biradical is formed in a geometry better suited for cyclization than for cleavage. It is important to recall that almost no singlet-state cyclization occurs in solution, as the computations would predict.

Multiplicity

Overwhelming evidence has been found for the intermediacy of triplet 1,4-biradicals following internal hydrogen abstraction by triplet ketones, especially phenyl ketones. Some unquenchable cyclization reactions strongly suggest that singlet biradicals can indeed be formed; unfortunately, they appear to be too short lived to be detected by trapping or by nanosecond spectroscopy. This evanescent character of singlet biradicals helped generate one popular view of how triplet biradicals proceed to singlet products.

Based on his study of some 1,4-biradicals formed by γ-hydrogen abstraction in triplet phenyl ketones, Scaiano[79] postulated that biradical lifetimes are determined by rates of intersystem crossing (ISC) to the corresponding singlet biradicals. Moreover, he further suggested that product ratios reflect relative ISC rates for different conformations of the triplet biradicals, the singlet biradical being too short lived to convert into any other product-forming conformation.[79] Scaiano also has provided several dramatic illustrations of how paramagnetic species change the partitioning of 1,4-biradicals, presumably by inducing ISC in conformations that normally decay relatively slowly.

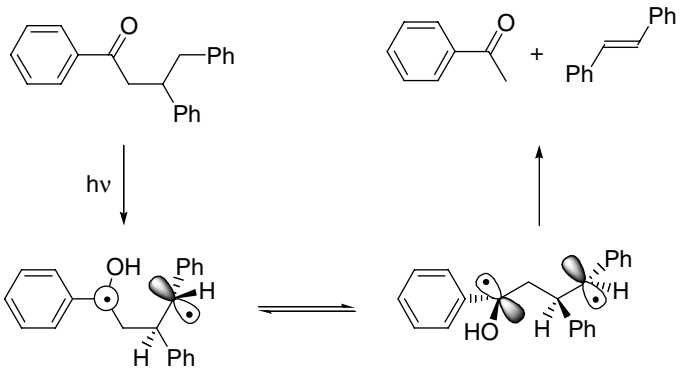
More recently, other workers have suggested an alternative view. From magnetic resonance studies of biradicals, Closs[80] suggested that triplet biradicals cyclize whenever their two ends collide, but with a low probability that reflects the amount of singlet character mixed into the biradical by spin-orbit coupling. Michl[81] has suggested a comparable picture, purely from a theoretical viewpoint, with the added feature that incipient bonding of the two ends of the biradical induces additional spin-orbit coupling through a highly stabilizing covalent interaction. As is discussed in Chapter 58, solvent effects on biradical lifetimes and product quantum yields agree with the notion that ISC and product formation are coupled.

Morita and Kato[82] theoretically examined the intersystem crossing mechanism of a Norrish type II 1,4-biradical in solution. Their calculations revealed that the energy splitting and the spin-orbit coupling element between the singlet and triplet states vary with the molecular geometry and have no apparent correlation to the distance between the radical termini, indicating that a through-bond interaction is dominant.

One thing that is clear is that cleavage of the triplet biradical is not adiabatic. Both Caldwell and Wagner[83] independently showed that only ground-state enes are formed in the type II cleavage of β,γ-diphenylbutyrophenone (Scheme 5). The α-hydroxystyrene (enol) and stilbene products have triplet energies lower than those of the ketone and the biradical, with stilbenes being the lowest. Thus, formation of triplet stilbene would have been preferred over triplet enol and would have yielded a nearly 50:50 mixture of *cis* and *trans* isomers, but the product was almost entirely *trans*, as expected from the thermodynamically preferable biradical conformation, with the β and γ phenyls *anti* to each other.

Biradical Disproportionation Back to Ketone

It cannot be overemphasized that the quantum yields for two-step triplet reactions such as those initiated by hydrogen abstraction often reflect partitioning of the intermediate biradicals more than relative rate constants for triplet reaction. This is especially true for the very rapid intramolecular hydrogen abstractions of n,π^* triplets, such as recorded in Tables 52.1 and 52.3. This fact was first demonstrated by the behavior of 2-hexanone, in which γ-deuteration *increases* the quantum yield of type II cleavage[84] and of γ-substituted butyrophenones, in which quantum yields for some type II cleavages decrease as rate constants for γ-hydrogen abstraction increase, as shown in Table 52.3.[85]



SCHEME 5

It is generally true that almost all the hydroxybiradicals formed by internal hydrogen abstraction partially revert to starting ketone by an internal radical disproportionation reaction in which the carbon-centered radical site abstracts the hydrogen from the hydroxyl group. This process often is the major reaction of the intermediate biradical, so that the overall quantum yield of product formation is low even when hydrogen abstraction by the excited state is 100% efficient. Should the efficiency of hydrogen abstraction be low because of electronic or conformational problems, then biradical disproportionation lowers quantum efficiency even further.

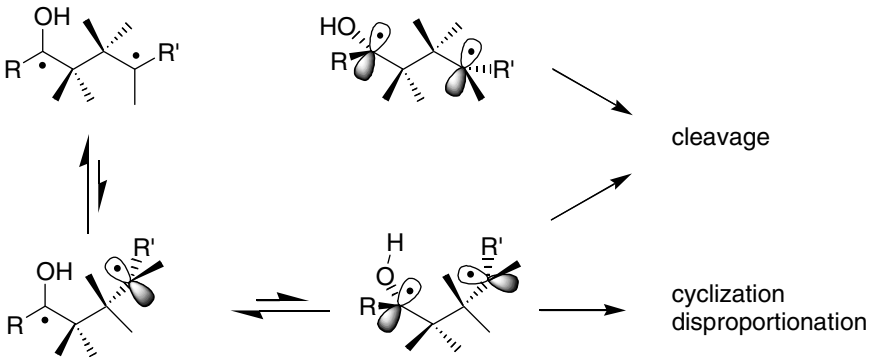
Added Lewis bases inhibit disproportionation back to ketone and thus enhance quantum yields of product formation.[15,16] In many cases, reversion to ketone is totally suppressed and quantum yields approach unity, as discussed above. This phenomenon is attributed to hydrogen bonding by the relatively acidic OH group of the biradical[86] to the Lewis base. Disproportionation requires destruction of this hydrogen bond, whereas, cleavage and cyclization of the biradical do not. The ability of different additives to solvate the biradicals, as determined by the concentration needed to maximize product quantum yields, closely matches their basicities.[16] Alcohols, water, ethers, and pyridines are commonly used for this purpose, but all Lewis bases that are not also strong electron donors work to some extent. Not every ketone reacts with 100% efficiency even in the presence of strong Lewis acids. The equilibrium between solvated and unsolvated biradical obviously varies with biradical structure. Sometimes only a fraction of the biradical is solvated; the rest still reverts to ketone.

Can a biradical undergo only disproportionation so that no product is formed no matter how fast the excited state reacts? A recent example is provided by the behavior of 1,6-cyclodecadione, which is discussed in Chapter 58. In general, cyclic and polycyclic systems with little conformational freedom, such that the two radical sites might not be able to get away from each other, seem the most likely to have this problem.

The only real difference between the reversion to ketone that occurs in both singlet and triplet hydrogen abstractions is the slowness of T-to-S ISC, such that the triplet forms a detectable biradical intermediate. In the singlet process, the molecule can slip onto the pathway for reversion to ground-state ketone directly. This singlet state decay is not suppressed by added Lewis bases,[19,24–26] further evidence that it can proceed without first forming a transient intermediate.

Factors Affecting Biradical Cleavage Efficiency

The cleavage efficiency of triplet-generated 1,4-biradicals varies widely with structure. Fortunately, the short lifetime of these 1,4-biradicals prevents several forms of disproportionation that 1,5-biradicals undergo.[4] Several factors affect the partitioning among cleavage, cyclization, and reversion to starting ketones.[87,88] Four geometries of the 1,4-biradical must be considered: two stretched-out staggered conformations and two coiled *gauche* conformations. Cleavage can occur from either *gauche* or staggered conformations, whereas cyclization and disproportionation require the latter.



SCHEME 6

TABLE 52.5 Representative Biradical Partitioning Ratios in Benzene

Ketone	Φ_{elim}	Φ_{cycl}	Φ_{disp}	τ (ns)

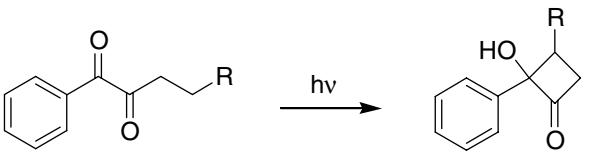
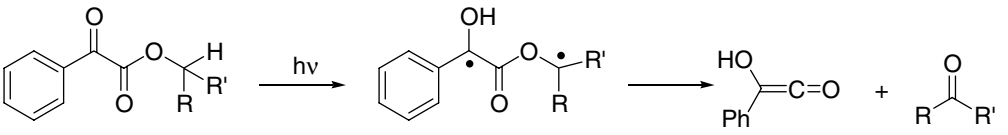


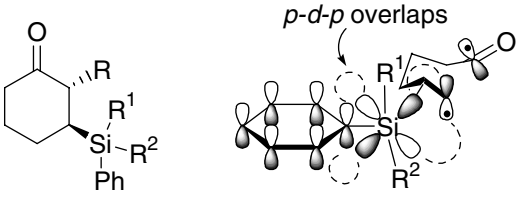
SCHEME 7

Cleavage appears to be governed by the stereoelectronic necessity for overlap of the breaking bond with both half-occupied *p* orbitals (Scheme 6).[85,89] Anything that prevents such molecular alignment retards or suppresses cleavage. In straight-chain ketones, cleavage/cyclization ratios tend to be at least 5:1. However, α-substitution by alkyl groups,[90] fluorines,[91] or rings[92] increases cyclization, primarily by destabilizing the geometry required for cleavage. α–Alkoxy ketones cyclize as much as they cleave;[43] in this case cleavage is not retarded so much as cyclization is enhanced, presumably by the oxygen relieving ring strain.

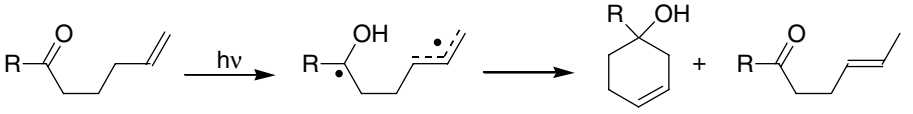
A distinction is often made between coiled and stretched conformations in order to rationalize cyclization/cleavage ratios. However, disproportionation also requires a coiled conformation; it is not at all clear what affects the competition between cyclization and disproportionation, other than that hydrogen bonding to Lewis bases dramatically inhibits the latter and changes the stereoselectivity of the former. Table 52.5 provides examples of the wide variations among cyclization/disproportionation ratios. Upon irradiation in water, valerophenone undergoes both cleavage and cyclization reactions in quantum yields of 65 and 32%, respectively,[44] which compare to the 33 and 10% yields in hydrocarbon solvents. Cases have been reported in which either cleavage or cyclization is the sole reaction of these 1,4-biradicals, apart from reversion to starting ketone. α-Diketones undergo photocyclization to hydroxycyclobutanones without undergoing any cleavage (Scheme 7).[93,94]



SCHEME 8



SCHEME 9



SCHEME 10

The opposite behavior is evident in the Norrish type II photochemistry of arylglyoxylates that Neckers and co-workers have studied (Scheme 8).[95–102] The 1,4-biradical intermediate resulting from triplet-state γ-hydrogen abstraction undergoes, exclusively, the cleavage reaction; no cyclization is observed. The Norrish type II reaction, accompanying a more efficient CO bond cleavage, has been studied also on mixed anhydrides.[103]

Pincock and co-workers have examined the Norrish type II fragmentation of various aromatic esters.[104–106] In contrast to alkyl aryl ketones, esters with lowest π,π* triplets undergo the reaction with a low quantum efficiency, which is induced by intramolecular electron transfer.

Hwu and co-workers[107] reported that the Norrish type I cleavage overwhelms the type II cleavage in the photolysis of α-alkylcycloalkanones bearing a substituted silyl group at the β-position and that the quantum yields are often greater than those of the non-silylated cycloalkanones.[107] The authors reasoned that a silyl group can stabilize a β-carboradical through a *p–d* homoconjugation in the course of the α-cleavage reactions (Scheme 9).

Competing Biradical Reactions

Apart from cyclization to cyclobutanols, type II 1,4-biradicals have been known to undergo radical cleavage from the α and δ carbons, the latter being discussed more fully later. When a vinyl group is attached to the γ-carbon, an allylic rearrangement occurs, producing a 1,6-biradical that can cyclize to a cyclohexenol and disproportionate to a 5-acyl-2-hexene as well as form normal type II products (Scheme 10).

Environmental Effects

Both the rate constants for competing triplet reactions and the partitioning of biradical intermediates may be affected by the environment. The major effects on triplet reactivity involve conformational changes induced by highly ordered media[108] and decreases in the efficiency of radical α-cleavage. The major effects on biradicals involve conformational restrictions that impede or promote coiling and solvation that inhibits disproportionation back to ketone.

Several research groups found high quantum yields and product ratios that suggest a fairly polar environment for ketones irradiated in aqueous surfactant solution.[109] It is now well accepted that the polar end of the ketones and particularly the biradicals reside mostly near the micelle–solvent interface, called the Stern layer, which has Lewis-base character. Although micelles produce negligible effects on triplet rate constants, they can improve type II/type I ratios by their "supercage" effect that enhances the recoupling of radical pairs.[110] That rate constants are not greatly affected reveals that the inside of micelles is flexible enough to allow the alkyl chain of ketones to coil.

The benzoin ethers were a mechanistic puzzle for years, as they were first reported to undergo only α-cleavage to radicals and *no* type II reaction in solution,[111] despite the high rate constants for γ-hydrogen abstraction in simple α-alkoxy ketones.[43] The use of methanol as solvent provides 5 to 10% type II reaction. Cyclization and type II elimination also occur when benzoin ethers, dissolved in micelles[112] or adsorbed on silica, are irradiated.[113] Irradiation of solid complexes of three common benzoin ethers with β-cyclodextrin produces 90% type II reaction.[114] All the "organized" media apparently force the ketone into a more reactive geometry than obtains in solution and, just as important, decrease translational mobility, thus making type I cleavage mostly revertible. Other examples have been observed of ketones that undergo mainly type I cleavage in solution but mostly or entirely type II reaction when complexed with β-cyclodextrin.[115] These high product selectivities are achieved only when the solid complex is irradiated. Aqueous solutions of ketone and cyclodextrin give more type II reaction than occurs in benzene but radical cleavage still competes strongly.

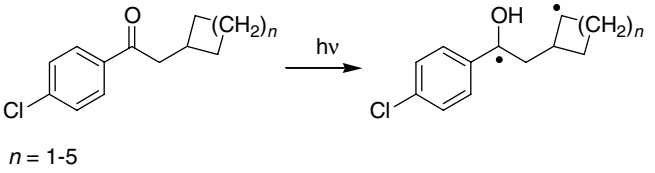
Turro and Wan[116] have looked at the effects of several zeolites on the photochemistry of α,α-dimethylvalerophenone, which undergoes competitive type I and type II reaction in solution.[117] Depending on the cavity size of the zeolite, product ratios vary substantially. Observation of mainly type I cleavage was interpreted as indicating cavities too small to allow the conformational changes required for type II reaction.

Weiss has explored the effects of liquid crystals on the type II reaction.[118] Their effects on short ketones are variable, whereas their effects on long ketones can be dramatic. His study of various *p*-alkylalkanophenones in *n*-butyl stearate reveals key aspects of how guest molecules orient themselves in liquid crystals. In short, when the carbonyl group is in the middle of the ketone molecule, very little γ-hydrogen abstraction occurs, apparently because most of the carbonyls are in the middle of a liquid crystal network and the alkyl chains are fully stretched alongside the stearate molecules. What little reaction does occur arises from random misaligned ketones. When the carbonyl group is at one end of the ketone, much more hydrogen abstraction occurs, presumably because of less rigidity in the stearate framework. Whenever the γ-radical site is part of a long alkyl group that is held in a stretched geometry, α-cleavage dominates cyclization.

Similar results have been found for crystalline *n*-alkanones that exist as layers of fully stretched molecules aligned in parallel. In the case of symmetric alkanones with the carbonyl in the middle, very little type II reaction occurs because the γ-hydrogens are constrained to remain too far from the carbonyl oxygen to be attacked.[119] However, 2-alkanones do undergo type II cleavage efficiently, as the carbonyl groups are now at a nonrigid layer interface.[120]

Whitten and co-workers[121] studied a ketone that is also a surfactant, ω-(*p*-toluyl)pentadecanoic acid. When prepared as a monolayer film in arachidic acid, this ketone undergoes only a trace of type II reaction. In benzene, it cleaves to *p*-methylacetophenone with a normal $\Phi = 0.20$; in an aqueous SDS solution, $\Phi = 0.80$. The enhanced quantum efficiency in the micelle was discussed above; it is interesting that the molecule must be looped so that both carbonyls are in the Stern layer. The lack of γ-hydrogen abstraction in the monolayer is ascribed to the linear rigidity of the monolayer environment. The monolayer would appear to allow even less molecular flexibility than does the liquid crystal.

The photochemistry of polymers containing keto groups has been studied extensively and reviewed by Guillet.[122,123] The type II reaction has been of particular interest inasmuch as it is partially responsible for the photodegradation of polymers. In this regard, temperature effects on the quantum efficiency for cleavage of ethylene-CO copolymers have been associated with glass transitions that reduce conformational mobility and the eventual freezing out of key rotations.[124] At temperatures above the glass transition,



SCHEME 11

TABLE 52.6

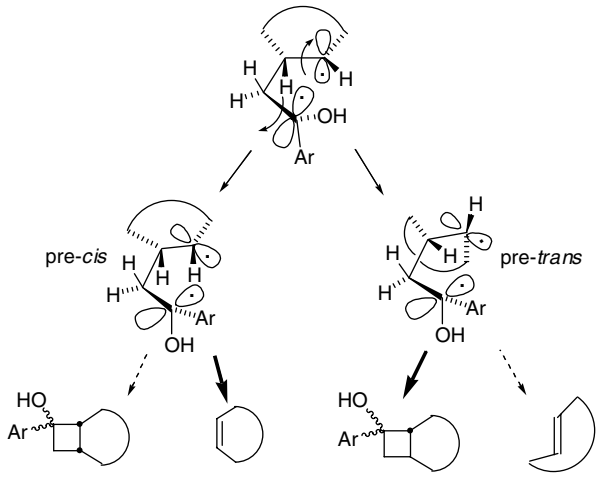
Ring Size	d (Å)	ω [°]	Δ [°]	K (10^8 s^{-1})	Cleavage (%)
4	3.1	23	78	0.3	92
5	2.8	31	96	1.2	92
6	2.6	42	90	1.2	38
7	2.7	42	82	5.7	59
8	2.7	48	77	6.7	18

the type II cleavage of both amorphous host polymers and guest ketones proceeds with efficiencies similar to those in solution. Whatever constraints the polymer places on molecular motion are not large enough to prevent the relatively small motions required for γ-hydrogen abstraction and cleavage. Golemba and Guillet[125] have carefully studied the behavior of polyacrylophenones and copolymers of styrene and phenyl vinyl ketone. Guillet has even produced a purposely photodegradable polystyrene copolymer based on type II cleavage of the backbone.

Wamser[126] has studied the photochemistry of cyclohexylacetyl groups bonded by Friedel–Crafts acylation to polystyrene beads, which provides an α-cyclohexyl acetophenone structure. The polymer-bound ketone reacts with almost the same quantum efficiency as the free ketone in pentane, 50%, but is unreactive in ethanol, which does not swell the polymer and allow the molecular motion necessary for reaction.

The crystalline state provides more unique behavior than the example described above. The *Crystal Structure–Solid-State Reactivity Correlation Method*, comprehensively formulated by Weiss and Ramamurthy,[127] has provided many experimental data about the most favorable geometric relationship between the abstracting carbonyl group and the abstracted γ-hydrogen atom. Scheffer[52,128] has studied five α-cycloalkyl-*p*-chloroacetophenones, all of which react both in solution and in the crystal (Scheme 11; Table 52.6). They give comparable product ratios in both phases. With the knowledge that organic molecules normally crystallize in their most stable conformations, examination of solution rate constants for hydrogen abstraction revealed no correlation with the geometric parameters for reaction. The rate constants do correlate well with those for bimolecular attack of various radicals on the different sized cycloalkanes, so the intrinsic reactivities of the different CH bonds appear to determine relative reactivities. Scheffer concluded that Eq. (52.3) applies, with comparable values of χ for all five. He suggests that these ketones react not from their most stable conformations but rather from higher energy ones that provide a more favorable geometry for reaction. The value of θ averages only 114° for the crystals. It is also possible that all these compounds react from their crystal geometries, in which case χ_r values are all close to one. All of the ketones except the cyclobutyl are considerably more reactive than *p*-chlorovalerophenone despite their awkward geometries. The rate enhancements probably represent the normal entropic gain associated with the ring.[63] The high observed k values cannot contain a really low value of χ_r, so any common geometric adjustment in solution must involve a relatively low-energy conformational change.

These results also provide unique insight into biradical behavior. The ketones with the smallest two rings undergo primarily cleavage, the next two examples split nearly 50:50, and the largest ring gives mainly cyclobutanol. In the last case, the 18% elimination gives mainly *cis*-cyclooctene, the *cis*/*trans* ratio



ring size				
4		92 %		
5		92 %		
6	7 %	40 %	53 %	
7	3 %	61 %	36 %	
8	5 %	14 %	77 %	4 %

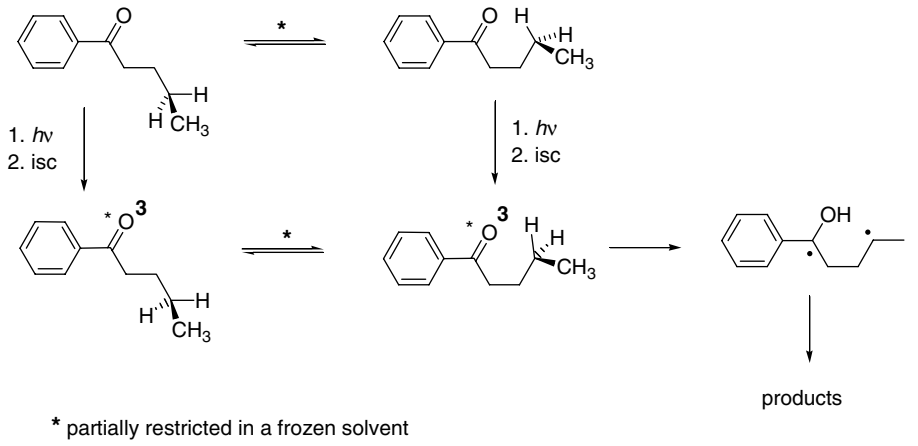
SCHEME 12

being 9:1 in benzene and 2.5:1 in the crystal. However, over 85% of the cyclization gives the *trans* ring junction. Scheffer[128] provides an intriguing explanation by noting that the *p* orbital on the ring in the biradical must twist 90 ± 45° to become parallel to the *p* orbital at the hydroxy radical site and achieve the geometry required for both cleavage and cyclization. Rotation in the direction that gives *cis* products is favored for the two smallest rings; rotation in the opposite direction, which favors formation of *trans* products, is favored for the largest ring; the two rotations are equally likely for the six- and seven-rings. Because the three largest ketones yield mostly *trans*-fused cyclization products but *cis*-cycloalkene cleavage product, Scheffer concludes that the pre-*cis* biradical undergoes mainly cleavage and the pre-*trans* biradical undergoes mainly cyclization. He further proposes that the phase-independence of the results indicates that these preferences are intrinsic to the molecules' structures. Scheme 12 depicts the proposed biradical geometries and indicates the product ratios as a function of ring size.

Experimental evidence on the relationship between structure and reactivity in Norrish type II photochemistry of spirobenzoyladamantanes in the solid state has been produced.[129] Geometric factors clearly determine partitioning between cleavage, cyclization, and hydrogen transfer reactions of the 1,4-biradical intermediate: Cleavage becomes predominant when the singly occupied orbitals overlap poorly with one another but well with the central CC bond, which, as earlier sections indicate, has been presumed for years based on ketone structure.

Methodology of how compounds are forced to crystallize in a chiral space group[130] has been developed in the concept of the ionic chiral auxiliary: The optically active salt of a ketone with a carboxylic acid functionality was prepared by the reaction with an enantiomerically pure amine.[131–133]

The Norrish type II reaction of various phenyl alkanones in zeolites has been studied by Ramamurthy and his collaborators.[134–136] The size and shape of zeolite reaction cavities control the behavior of triplet ketone as well as the 1,4-biradical intermediate that is consequently monitored as a difference in photoproduct distribution and triplet lifetimes.[137] Norrish type I and type II reactions of 2-pentanone included within cavities of various types of zeolites and the alkali metal cation-exchanged ZSM-5 zeolite have been investigated by experimental and theoretical approaches.[137–139] Ion-exchanged cations had significant effects not only on the adsorption state but also on the photochemical reactions of the ketone. The



SCHEME 13

observed infrared and phosphorescence spectra of the adsorbed ketones and the *ab initio* molecular orbital calculations of this host–guest system indicate that the ketones interact with two different adsorption sites: the surface OH groups and alkali metal cations.

The Norrish type II reaction of an aryl ketone monolayer-protected colloid was investigated by Workentin and co-workers.[140,141] Photolysis of a mercaptoalkanophenone-modified gold colloid generates free acetophenone in solution and the modified monolayer-protected clusters via the triplet excited state and the 1,4-biradical intermediate. The reaction has been developed as a probe of conformational mobility within the monolayer environment.

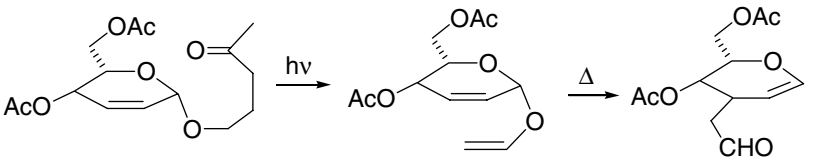
Alkyl aryl ketone photolysis has been also studied on a silica-gel surface.[142,143] Molecules in the outermost layer are responsible for the reaction, which has been consequently used for the determination of the solid support surface area.[145] The effect of the alkyl chain length on the type II photoreactivity of alkyl phenyl ketones on the surface was found to be insignificant. Based on the quantum yield measurements of valerophenone and *p*-substituted valerophenone photolysis, a silica-gel surface was reported to be as strong a polar medium as methanol; the surface might cause the inversion of the n,π^* and π,π^* triplet states.

Klán and co-workers investigated the photoreactivity of valerophenone in frozen polar and nonpolar solvents, including water.[144] Results indicated that a portion of the ketone molecules are almost unreactive due to physical restraints of the solid solvent cavity. Free rotation along the CC bonds becomes difficult inside the cavity; thus, large conformational changes are restricted (Scheme 13).

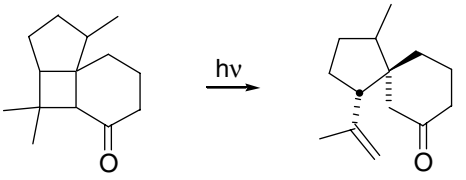
52.8 Synthetic Uses and Other Applications

The Norrish type II reaction is occasionally used in synthetic processes mostly when other procedures leading to a desired product are difficult or costly. Simple type II elimination has been put to use in several ways. Glycosides made from γ-hydroxy ketones undergo photoelimination to give *O*-vinyl glycosides, which can undergo a Claisen rearrangement in certain deoxy sugars (Scheme 14).[145] Properly alkylated bicyclo[4.2.0]-octan-2-ones formed by [2+2]-photocycloaddition of cyclohexenones to alkenes cleave to δ,ε-unsaturated ketones (Scheme 15).[146] Scharf has removed the C17 side chain in steroids by photolysis (Scheme 16).[147] Perhaps the most unusual use of type II elimination was Goodman and Berson's preparation of *m*-xylylene (Scheme 17).[147] Wirz and Kresge[149,150] have brilliantly exploited the type II elimination of various ketones induced by flash photolysis to allow kinetic studies of the transient enols photoproducts.

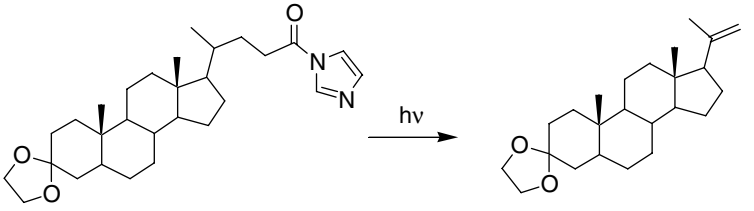
Synthesis of a new C/D synthon of vitamin D from hydrodeoxycholic acid was performed by employing the type II reaction (Scheme 18).[151]



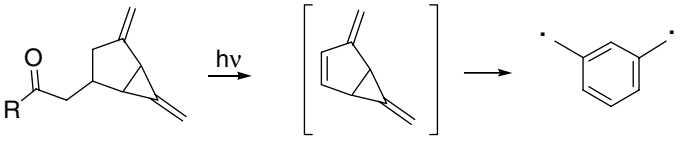
SCHEME 14



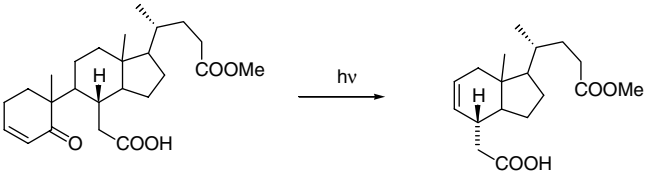
SCHEME 15



SCHEME 16

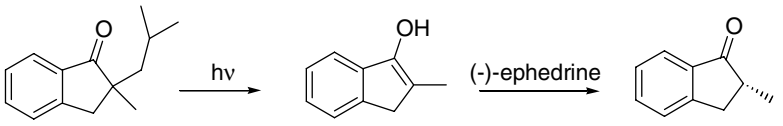


SCHEME 17



SCHEME 18

Hénin and co-workers[152,153] reported the results from the irradiation of α-disubstituted indanones, tetralones, and propiophenones bearing at least one hydrogen in the γ-position in the presence of catalytic amounts of optically active aminoalcohols. The reaction provided the Norrish type II cleavage compounds with an enantiomeric excess reaching 89% (e.g., Scheme 19). Synthesis of 3-hydroxyindene by a Norrish type II elimination as well as the mechanistic aspects of this reaction were discussed by Jefferson and



SCHEME 19

co-workers.[154] The syntheses of enediynes[155] or taxane precursors[156] utilizing the Norrish type II reaction provide additional examples.

Alkyl or aryl α-ketoesters of primary or secondary alcohols react upon irradiation in a Norrish type II fashion from the intermediate triplet state into aldehydes.[157] This research was performed in order to study a controlled release of perfumery aldehydes. Lerner, Janda, and their co-workers[158] investigated a catalytic antibody for a multistep Norrish type II photochemical reaction of α-ketoamide substrates. The single product obtained in the antibody-catalyzed reaction was not observed in the uncatalyzed reaction, suggesting that the interplay of conformational control and chemical catalysis were responsible for the high specificity. The antibody described could be a model for the evolution of light-activated enzymes and serve as a foundation for the development of light-dependent antibody catalysts for a range of even more complex photochemical reactions. Inoue and co-workers[159] studied an enantiomeric enrichment occurring by irradiation of a racemic sample of amino acids by circularly polarized light resulting from the preferential excitation/decomposition of one enantiomer over another via the Norrish type II reaction. The enantiomeric excess was found to be dependent on the degree of protonation of the aminocarboxylic acid moiety. The authors discussed the possibility that the origin of biological homochirality may be the result of the absorption of circularly polarized light. The Norrish type II reaction has been also utilized to monitor the production of HCOOH, CO_2, and CO following ultraviolet laser excitation of gas-phase formate esters in time-resolved infrared absorption spectroscopy.[160] Photolysis of *i*-pentanal and *t*-pentanal was investigated by using dye laser photolysis in combination with cavity ring-down spectroscopy.[161]

52.9 The Type II Reaction as a Mechanistic Probe

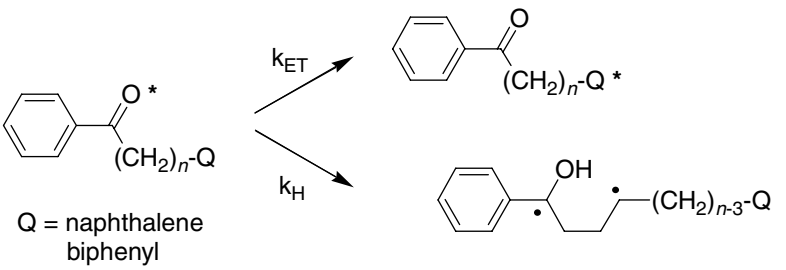
A good number of compounds have been studied whose triplets undergo both the type II reaction and one or more other processes, either physical or chemical. Because structural effects on rate constants for γ-hydrogen abstraction are well understood, the type II reaction can serve as a clock for measuring rates of the other reactions, with quantum yield measurements allowing triplet lifetimes to be divided into separate rates for the competing reactions.

A very early example is provided by the study of solvent viscosity effects on the rate constants for bimolecular quenching of triplet valerophenone by dienes.[162] Several studies by the Wagner group[163,164] on the competing type II reactions of α,ω-diacylalkanes have provided measures of the rates of internal triplet energy transfer between the two carbonyl groups.

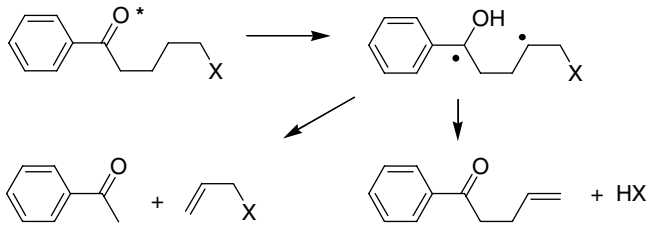
Wagner and Klán[165,166] have determined rate constants for intramolecular triplet energy transfer in various flexible ω-arylalkanophenone systems by comparing type II quantum yields and triplet lifetimes to the known rate constants of the competing γ-hydrogen abstraction reactions (Scheme 20).[165,166] The values of the energy transfer rate constants as a function of *n* provided clear evidence for the importance of through-space interactions.

Rate constants for intramolecular reactions of triplet ketones with double bonds,[167] amino groups,[168] azido groups,[169] and alkylthiyl groups[170] have been established from type II quantum yields and triplet lifetimes of appropriately substituted ketones.

Study of ring-brominated valerophenones revealed high rate constants for radical cleavage of bromine atoms from the benzene rings of the excited triplets,[171] a fact that could lead to new photoactivated chemotherapeutic compounds.[172] Likewise, the study of *p*-(3-buten-4-oxy)-substituted valerophenones revealed large rate constants for [2+2]-cycloaddition of the remote double bond to the benzene ring.[173]



SCHEME 20



X = Cl, Br, I, SR, S(O)R, SO_2R

SCHEME 21

Other studies have taken advantage of the radical-like behavior of the 1,4-biradical intermediates, such as in their earlier mentioned trapping by thiols. Of special importance was the ability to gauge rate constants for β-cleavage of radicals by the behavior of δ-substituted valerophenones: The acetophenone/4-benzoyl-1-butene ratios reveal ratio of biradical cleavage and radical cleavage rates (Scheme 21).[174]

Most recently, Klán and co-workers[175,176] utilized the type II reaction in studies of temperature-dependent photochemical reactions carried out in a microwave field. Microwave radiation is not a classical energy source but usually serves to accelerate chemical transformations. In an original project of microwave photochemistry, the Norrish type II reaction provided a reliable strategy for the estimation of the microwave superheating effects using the thermally sensitive solvation of the OH group in the Norrish 1,4-biradical intermediate.[177,178]

Photodegradation of various copolymers containing carbonyl group via the Norrish type II reaction has received considerable attention. Originally, the major interest was in preventing photodegradation of polyethylenes. Photolabile copolymers of propylene/carbon monoxide with ethylene/carbon monoxide;[179] methyl methacrylate with acrylophenone, *t*-butyl acrylophenone, or *p*-chloroacrylophenone;[180] styrene with methyl vinyl ketone or phenyl vinyl ketone;[181] or styrene with methylvinyl ketone and ethylene-propylene-diene[182] may serve as representative examples. In addition, crosslinking of poly(3,5-dimethoxyacrylophenone) caused by a hydrogen abstraction reaction between pendent phenylglyoxylate chromophores was reported.[183]

Photoinduced Electron Transfer Reactions of Oxiranes and Epoxy Ketones

Eietsu Hasegawa
Niigata University

Masaki Kamata
Niigata University

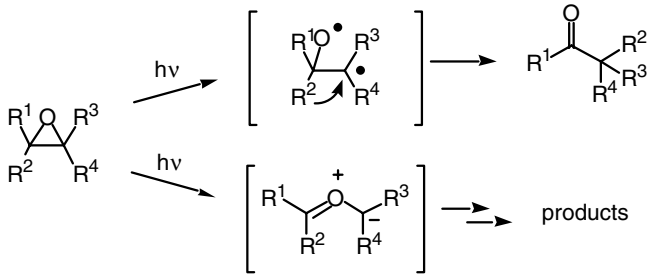
53.1 Introduction

Much attention has been focused on the photochemistry of three-membered ring compounds due to their interesting reactivities; among these compounds are oxiranes.[1–4] Irradiation of these compounds demonstrates two main types of rearrangements: (1) homolytic CO bond cleavage followed by 1,2-migration of a substituent yielding carbonyl compounds, and (2) heterolytic CC bond cleavage giving carbonyl ylide intermediates (Scheme 1). Several reviews dealing with oxirane photochemistry have already appeared. In this chapter, we will focus on the photoinduced electron transfer (PET) reactivity of oxiranes and epoxy ketones.

Over the last three decades, the PET chemistry of organic molecules has been extensively explored, and considerable advances in the understanding of the PET reaction mechanism as well as the synthetic applications of PET processes have been made.[5–7] Due to large enhancement of the electron-donating and electron-accepting ability of a molecule on irradiation, the photoexcited molecules, compared to their ground-state counterparts, more readily undergo single electron transfer (SET) with other molecules. Rehm and Weller[8,9] demonstrated that the feasibility of this SET process is estimated by Eq. (53.1).

$$\Delta G \text{ (kcal/mol)} = 23.06[E^{ox}_{1/2} - E^{red}_{1/2} + C] - E_{00} \quad (53.1)$$

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1

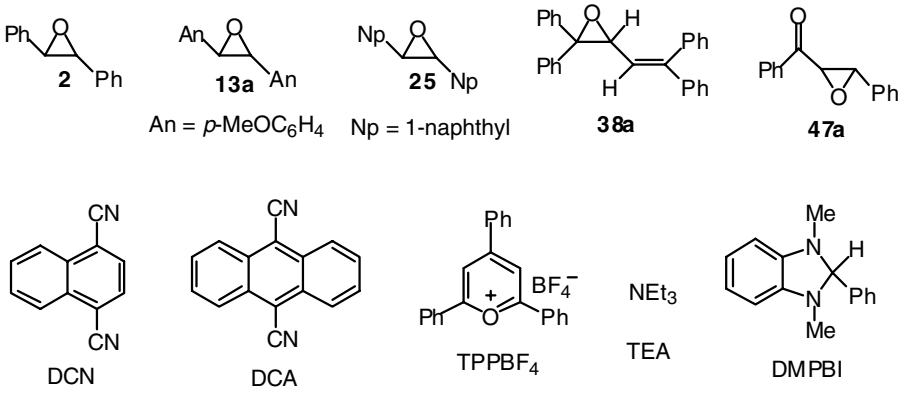


FIGURE 53.1 Representative oxiranes, epoxy ketones, and redox reagents.

The free energy change (ΔG) for the SET process between the donor molecule and the acceptor molecule, one of which is electronically excited, is calculated by using their reduction and oxidation (redox) potentials ($E^{ox}_{1/2}$, $E^{red}_{1/2}$), the excitation energy (E_{00}), and the Coulomb term (C), which depends on the solvent used. The term C is known to be –0.06 eV for a typical polar solvent such as MeCN.

The electron-donating and electron-accepting properties of oxiranes in solution are estimated by their redox potentials which are measured by the electrochemical method.[10,11] Figure 53.1 presents the representative oxiranes, epoxy ketones, and redox reagents (for which the ET reactions will be described later). Their redox properties and the thermodynamic data for their PET processes are listed in Table 53.1. In a general sense, aryl-substituted oxiranes are reasonably good electron donors that undergo PET reaction with several electron-accepting sensitizers such as 1,4-dicyanonaphthalene (DCN), 9,10-dicyanoanthracene (DCA) and 2,4,6-triphenylpyrilium tetrafluoroborate ($TPPBF_4$). On the other hand, PET reduction of oxiranes requires the substitution of certain electron-withdrawing groups such as carbonyls. Thus, the photoexcited triplets of epoxy ketones are recognized as good electron acceptors against certain electron donors such as triethylamine (TEA) and 1,3-dimethyl-2-phenylbenzimidazoline (DMPBI).

53.2 Electron Transfer Reactions involving Radical Cations

Oxirane radical cations undergo the following types of reactions: (1) CC bond cleavage and subsequent formation of carbonyl ylide radical cations which react with dipolarophiles and oxygen, affording tetrahydrofurans and 1,2,4-trioxolanes, respectively; and (2) CO bond cleavage giving the corresponding radical cations which rearrange to carbonyl compounds.

TABLE 53.1 Redox Potentials ($E^{ox}_{1/2}$, $E^{red}_{1/2}$; V vs. SCE) of Oxiranes, Electron Acceptors and Electron Donors, and Free-Energy Changes (ΔG, kcal/mol) for PET Processes Between Oxiranes and Electron Acceptors or Electron Donors in MeCN

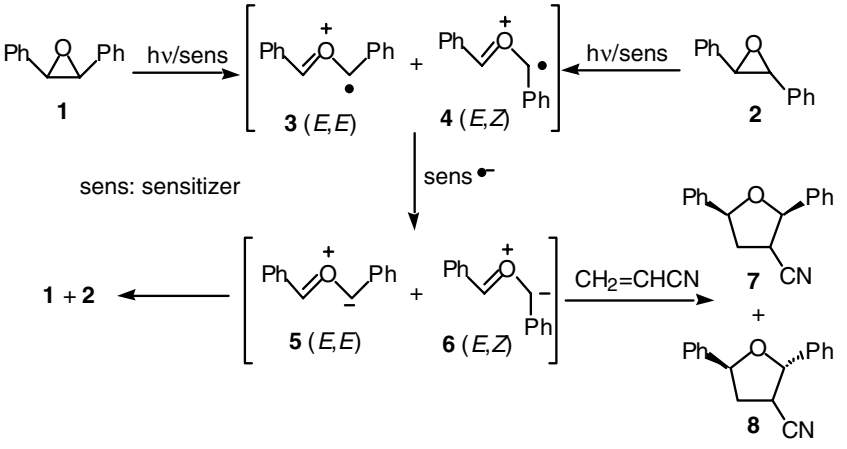
[a] Redox potentials are reported vs. $Ag/AgNO_3$.

[b] Because the reaction was conducted in CH_2Cl_2,[29] +0.16 eV is used as term *C* in Eq. (53.1).[9]

Abbreviations: DCN, 1,4-dicyanonaphthalene; $TPPBF_4$, 2,4,6-triphenylpyrilium tetrafluoroborate; DCA, 9,10-dicyanoanthracene; DMPBI, 1,3-dimethyl-2-phenylbenzimidazoline.



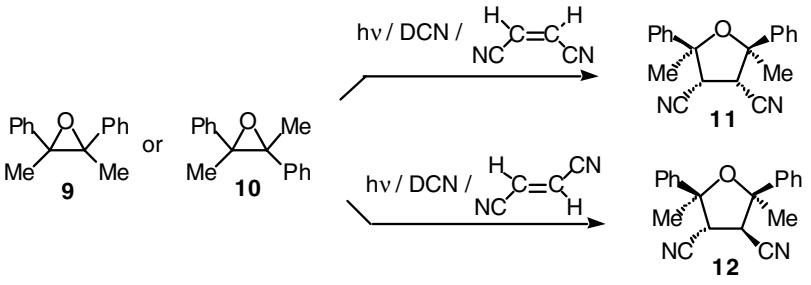
SCHEME 2

Tetrahydrofuran Formation through CC Bond Cleavage

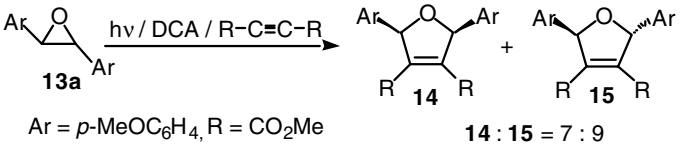
Arnold[12] first discovered that PET reactions of *cis*- and *trans*-2,3-diphenyloxiranes (**1** and **2**) with electron-accepting sensitizers such as DCN, 1,4-dicyanobenzene, dimethyl terephthalate, and methyl 4-cyanobenzoate produce the isomeric tetrahydrofuran derivatives **7** and **8** (Scheme 2). The proposed mechanism involves the CC bond cleavage of the oxirane radical cations to give ylide radical cations **3** and **4**, followed by back electron transfer (BET) to generate carbonyl ylides **5** and **6**. The resulting carbonyl ylides are trapped with dipolarophiles, such as acrylonitrile, maleonitrile, and fumaronitrile, to produce the observed products. In the absence of dipolarophiles, *cis*-/*trans*-isomerization (**1/2** = 0.19–0.28) was observed, which is consistent with the formation of carbonyl ylides **5** and **6**, as well as their radical cations **3** and **4**. This method was successfully applied to the synthesis of various tetrahydrofurans (Scheme 3)[13] and dihydrofurans (Scheme 4).[14]

1,2,4-Trioxolane Formation through CC Bond Cleavage

The PET reactions of oxiranes carried out in the presence of oxygen frequently produce oxygenated products such as 1,2,4-trioxolanes (ozonides). Futamura first reported that DCA-sensitized PET oxygenation of



SCHEME 3



SCHEME 4

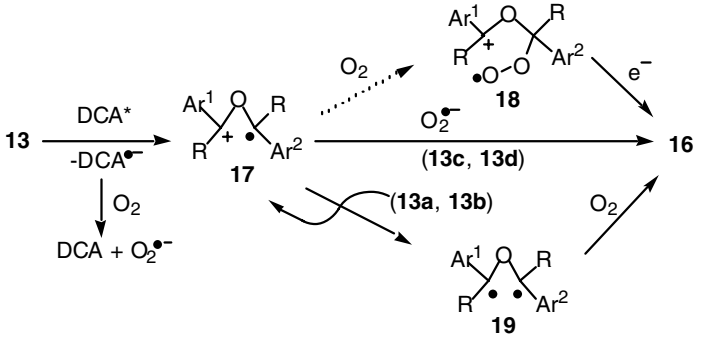
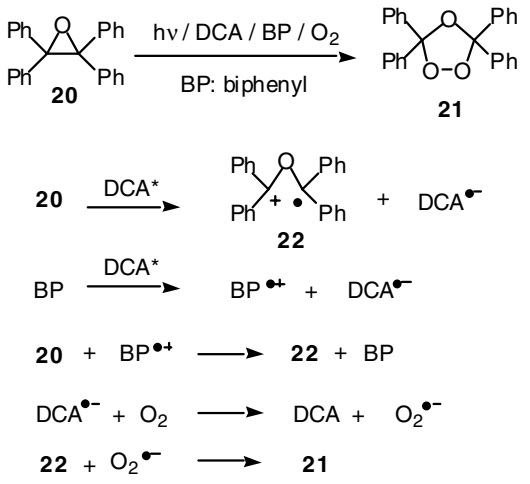
13c: $Ar^1 = p\text{-}MeOC_6H_4$, Ar^2 = Ph, R = H
13d: $Ar^1 = p\text{-}MeOC_6H_4$, $Ar^2 = p\text{-}MeC_6H_4$, R = H



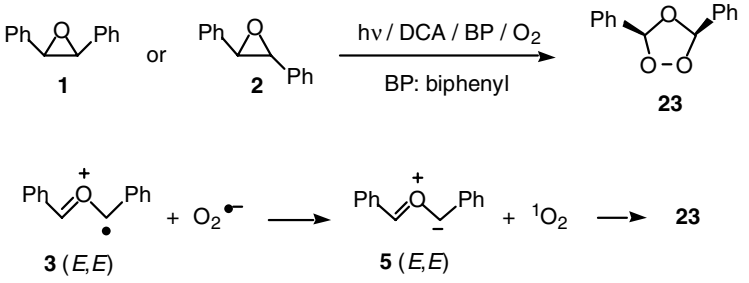
SCHEME 5

1,2-diaryloxiranes **13** possessing an electron-donating aryl group ($p\text{-}MeOC_6H_4$) produces 1,2,4-trioxolanes **16** (Scheme 5).[15,16] In the reactions of **13a** and **13b**, the quantum yields were greater than 1.0, suggesting catalytic generation of the radical cations of **13**; however, the stereochemistry of **16** and the active oxygen species (triplet oxygen, singlet oxygen, or oxygen radical anion) was unclear in the proposed mechanism.

Schaap[17] reported that DCA–biphenyl (BP)-cosensitized PET oxygenation of tetraphenyloxirane **20** produced 1,2,4-trioxolane **21** (Scheme 6). Although **20** does not efficiently quench the fluorescence of



SCHEME 6

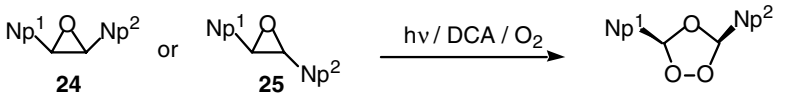


SCHEME 7

DCA, a dramatic rate enhancement of the oxygenation is observed by addition of BP. The rationalization is as follows: BP quenches the fluorescence of DCA to generate a BP radical cation and a DCA radical anion. The lifetime of the BP radical cation is long enough to accept a single electron from **20** to generate radical cation **22**, although this process is endothermic. The resulting **22** reacts with the oxygen radical anion to give **21**. The same method was applied to PET oxygenation of *cis*- and *trans*-1,2-diphenyloxiranes **1** and **2** (Scheme 7).[18] Interestingly, only *cis*-1,2,4-trioxolane **23** was obtained from both **1** and **2**. It was proposed that a more stable carbonyl ylide **5**, generated by BET from the oxygen radical anion to the radical cation **3**, reacts with singlet oxygen to give *cis*-**23**. Addition of BP was not found to be essential to control the stereochemistry of the product.

Oxygenation of 1,2-dinaphthyloxiranes **24** and **25** by PET was conducted without BP, as both **24** and **25** were able to quench the fluorescence of DCA.[19] Thus, *cis*-trioxolane **26** was isolated as the sole stereoisomer (Scheme 8). However, the Schaap mechanisms described above, involving a highly stereoselective formation of *cis*-1,2,4-trioxolanes (Scheme 7 and 8), seem to be inconsistent with the previously described Arnold mechanism (Scheme 2), where two types of radical cations (**3** and **4**) as well as carbonyl ylides (**5** and **6**) are generated by the PET oxidation of **1** and **2**, respectively.

Kamata[20–22] found that *cis*-1,2,4-trioxolanes **29** were stereoselectively produced, while a nonstereoselective [3+2]-cycloaddition (**30** and **31**) with tetracyanoethylene (TCNE) competes with 1,2,4-trioxolane formation on irradiation of the charge transfer (CT) complexes of 2,3-diaryloxiranes (**27** and **28**) with TCNE in the presence of oxygen (Scheme 9). Interesting features of this chemistry are:



$Np^1 = Np^2$ = 1-naphthyl
$Np^1 = Np^2$ = 2-naphthyl
Np^1 = 1-naphthyl, Np^2 = 2-naphthyl

38b: Ar = *p*-MeC$_6$H$_4$

39

40a

SCHEME 10

1. The amounts of TCNE did not significantly change the yields of oxygenation products **29**, indicating that TCNE is regenerated in the oxygenation cycle.
2. Addition of 1,2,4,5-tetramethoxybenzene (TMB) as a SET quencher completely suppressed the oxygenation but did not affect [3+2]-cycloaddition with TCNE.
3. The solvent polarity could control the reaction pathway, in that **28b** gave **30b** (28%) and **31b** (25%), together with a trace of **29b** in benzene, while **29b** was obtained as the sole product (66%) in acetonitrile.
4. Oxygenation occurred stereoselectively, but [3+2]-cycloaddition did not.

The fact that the same stereoselectivity was observed for photooxygenation products in the reaction with TCNE as that observed under DCA-sensitized conditions (see above) is particularly interesting. Neither an oxygen radical anion nor singlet oxygen is generated in the TCNE cases, implying that singlet oxygen may not always be responsible for the stereoselective oxygenation of oxiranes under DCA-sensitized conditions. In other words, triplet oxygen, as an active species for oxygenation, cannot be ruled out even under DCA-sensitized conditions. Related information was provided by Gollnick and Schnatterer[23] that suggested that triplet oxygen is responsible for the DCA-sensitized PET oxygenation of 1,1-di(*p*-methoxyphenyl)ethylene. It is assumed that the ring cleavage of the radical cations of **27** and **28** occurs nonstereoselectively to form **32** and **33**, both of which, in turn, can be captured by the triplet oxygen to form peroxy radical cations. In these intermediates, the barrier to rotation around the C–O–C$^+$ bond is small, so a second CO bond formation can occur through the least hindered radical **36** (not **37**) to form **29** followed by BET. The nonstereoselective formation of **30** and **31** can be explained either by a concerted [3+2]-cycloaddition of **32** and **33** with the TCNE radical anion or, more likely, by an alternative concerted addition of carbonyl ylides **34** and **35** with TCNE after a BET reaction has occurred within the solvent cage.

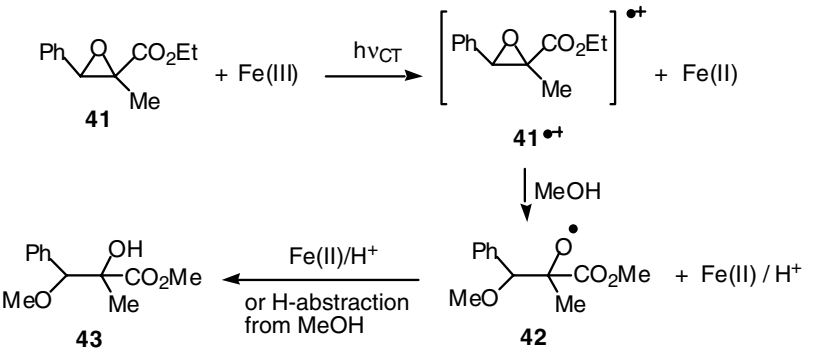
Kamata[24] recently reinvestigated DCA-sensitized PET oxygenation of vinyloxirane **38** and found that 1,2,4-trioxolane **39** was a major product without the isolation of the seven-membered 1,2,4-trioxepine **40**, although **40a** was previously reported by Futamura[25] to be the product in the same reaction (Scheme 10).

Recently, extensive efforts have been devoted to the synthesis of cyclic peroxides since the discovery of artemisinin and related antimalarial 1,2,4-trioxanes.[26,27] As described previously, PET oxygenation is a unique but effective method for the preparion of cyclic peroxides, which is also applicable to the synthesis of the peroxide structures from arylated cyclopropanes, aziridines, and olefins.[21,22]

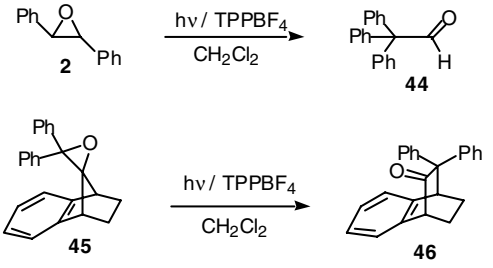
Rearrangement through CO Bond Cleavage

In the absence of dipolarophiles and oxygen, oxirane radical cations sometimes undergo CO bond cleavage to give rearranged carbonyl compounds. Reactions of a ring-opened radical cation with nucleophiles are observed to give the addition products.

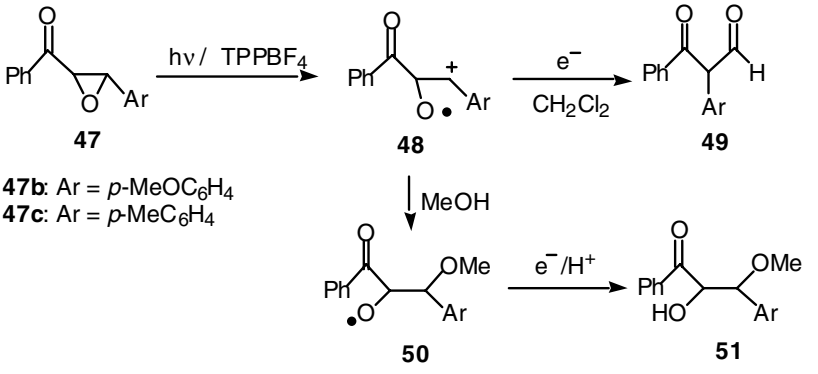
Kagan[28] reported that the methanol adduct **43** was obtained on irradiation of a methanol solution of oxirane **41** in the presence of Fe(III) (Scheme 11). The reaction is assumed to proceed through the excitation of a CT complex of **41** with Fe(III) followed by the MeOH-assisted ring-opening of the radical



SCHEME 11



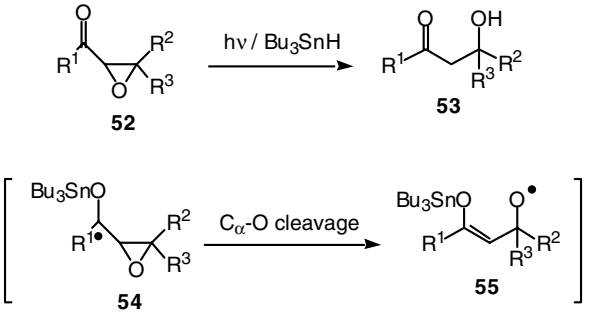
SCHEME 12



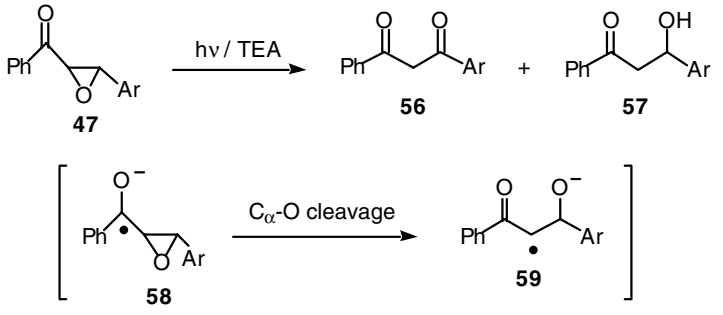
SCHEME 13

cation of **41**. The alkoxy radical **42** is produced and finally converted to **43**. Hasegawa[29] found that 2,4,6-triphenylpyrylium (TPP) salt-sensitized PET reactions of oxiranes **2** and **45** undergo rearrangement to produce carbonyl compounds **44** and **46**, respectively (Scheme 12). Similar rearrangement and methanol addition reaction were also found for the TPP-sensitized PET oxidation of epoxy ketones **47** to afford the products **49** and **51** (Scheme 13).[30] Selective $C_\beta O$ cleavage of the radical cation of **47** gives radical cation **48**, which rearrange to **49** in dichloromethane and is trapped by methanol to produce **51** through the oxy radical **50**.

While these types of reactions are synthetically useful, the understanding of the reaction mechanism is still controversial. Thus, a clear mechanistic distinction between radical cation rearrangements and rearrangements promoted by acid catalysis, presumably generated during ET processes, for the above transformations is often very difficult to make.[31]



SCHEME 14



SCHEME 15

53.3 Electron Transfer Reactions Involving Radical Anions

Photoreactions of epoxy ketones have been extensively investigated, and these studies demonstrated that several types of photochemical processes are open to these compounds.[1–4] Thus, it was often difficult to control the regioselectivity of the epoxy ring-opening because the reactivity depends on the substitution and the nature of their excited states.

Photoreactions of Epoxy Ketones with Triethylamine and Other Donors

About 10 years ago, Hasegawa discovered that oxiranyl methyl radicals such as **54** that possess an electron-donating tributylstannyloxy substituent at the radical center undergo selective $C_\alpha O$ bond cleavage to give the oxy radicals **55** in the free-radical reaction of epoxy ketones **52** with tributyltinhydride, which finally produce β-hydroxy ketones **53** in high yields (Scheme 14).[32,33]

This observation suggests that the carbonyl radical anions (ketyl radicals) of epoxy ketones, in which the negative charge builds up at the position adjacent to the epoxy ring, should also cause selective $C_\alpha O$ bond cleavage of these intermediates. As expected, irradiation of some aromatic epoxy ketones **47** with TEA produced β-diketones **56** and β-hydroxy ketones **57** in which the transformation of the ketyl radicals **58** to the ring-opened radical anions **59** was proposed (Scheme 15).[34] The product ratio of **56a** to **57a** obtained from **47a** depends on the reaction conditions as shown in Table 53.2. While both **56a** and **57a** were obtained in MeCN and MeOH, addition of $LiClO_4$ completely suppressed the formation of **57a** together with the formation of acetophenone as well as benzaldehyde (retro-Aldol products). Irradiation of epoxy ketones **60** in the presence of allyltributyltin as an electron donor produced α-allyl-β-hydroxy ketones **61**, which were presumably formed by coupling of the ring-opened radical anions **64** and an allyl radical (Scheme 16).[35] Following a mechanistic study it was demonstrated that the product ratio of β-diketone **62a** and β-hydroxy ketone **63a** was influenced by the amine used (Table 53.3).[36]

TABLE 53.2 Photoreaction of Epoxy Ketone **47a** (Ar = Ph) with Triethylamine (TEA)

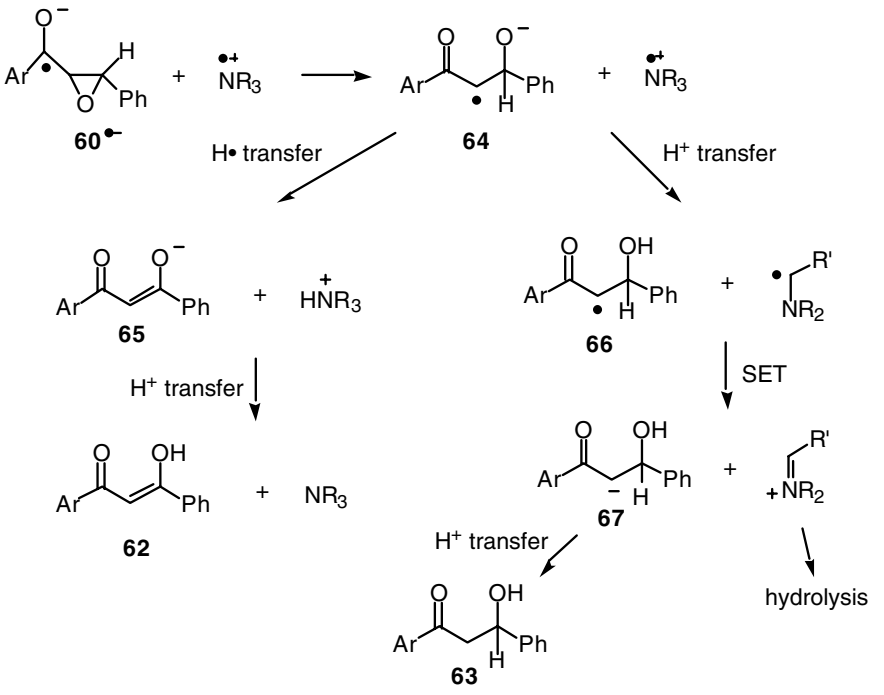
4	DEA	PhH	7	42
5	TBA	PhH	12	50

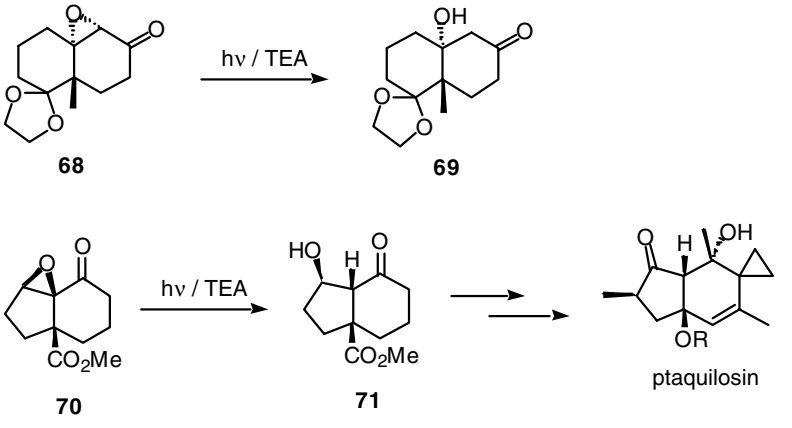
Note: Yields of **62a** and **63a** are reported on the basis of the conversion of **60a**. DABCO, 1,4-diazabicyclo[2.2.2]octane; DEA, *N,N*-diethylaniline; TBA, tribenzylamine.

A reaction mechanism in which interaction between the radical anions derived from epoxy ketones **60** and amine radical cations govern the selective pathway to the observed products **62** and **63** was proposed (Scheme 17).[36]

Such interactions should be more favorable in less polar solvents such as benzene than the more polar solvent MeCN, as this change of solvent shifts the equilibrium of the free radical ions to the radical ion pairs. Hydrogen atom transfer between radical anion **64** and the amine radical cation produces the enolate **65**, which is protonated to become **62.** The efficiency of the hydrogen abstraction by the amine radical cation is qualitatively correlated with the NH bond strength of the corresponding ammonium salt. On the other hand, proton transfer between **64** and the amine radical cation followed by SET gives the anion **67**, which is transformed to **63** by protonation. This first proton transfer step is governed by the proton-donating ability (acidity) of the amine radical cation, which is affected by the α substituents of the amine.



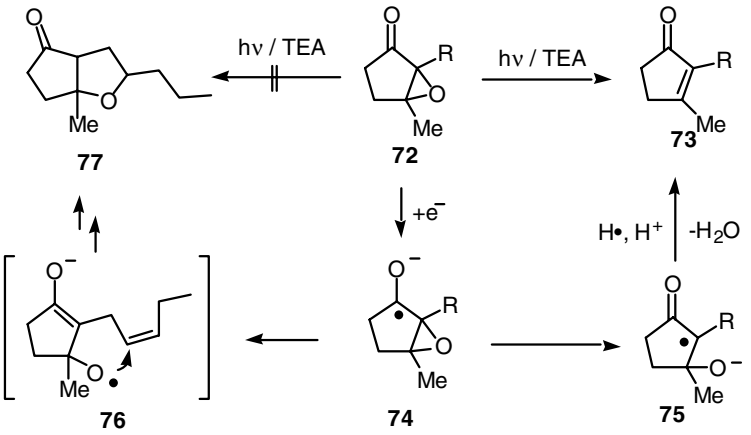
SCHEME 17



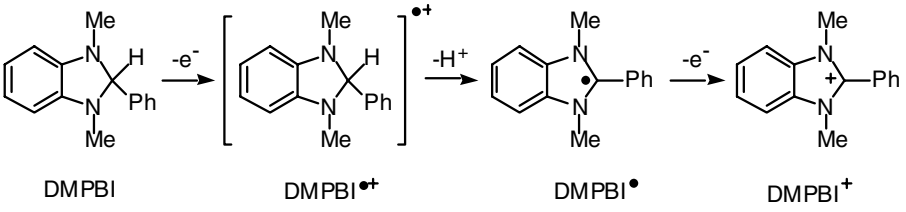
SCHEME 18

The transformation of epoxy ketones to β-hydroxy ketones is recognised as a synthetically important chemical process.;[37] thus, Cossy[38,39] reported photoreactions of several aliphatic and aromatic epoxy ketones with TEA (Scheme 18).

For example, epoxy ketone **68** was irradiated (254 nm) with TEA to give hydroxy ketone **69** (68%) at 56% conversion of **68**. This method was successfully applied to the synthesis of a bioactive compound, ptaquilosin.[40] Mattay[41] examined the photoreaction of epoxy ketone **72** with TEA in expectation of the formation of the cyclized product **77**, which presumably results from the intermediacy of **76** (Scheme 19). However, **77** was not obtained, while enone **73** was isolated in low yield. The rationalization was that



SCHEME 19



SCHEME 20

ketyl radical **74** chemoselectively rearranges to **75** instead of **76**, which is consistent with Hasegawa's proposal (see Scheme 15).

Photoreactions of Epoxy Ketones with 1,3-Dimethy-2-Phenylbenzimidazoline

In the above experiments, while the yields of β-hydroxy ketones were modest, several problems were encountered. For example, Hasegawa's experimental conditions produced β-diketones as major products.[34,36] Cossy mentioned that prolonged irradiation by quartz-filtered light caused decomposition of the β-hydroxy ketones.[39] Therefore, it was desired to discover the optimal PET conditions to produce β-hydroxy ketones in better yields. On the basis of the proposed mechanism in Scheme 17, the compounds, which act as good electron donors as well as hydrogen donors, could improve the yield of β-hydroxy ketones. As shown in Scheme 20, it was reported that 1,3-dimethy-2-phenylbenzimidazoline (DMPBI)[42,43] is first oxidized to the radical cation ($DMPBI^{+\cdot}$) followed by deprotonation to give an α-amino radical ($DMPBI^{\cdot}$) which is converted to imidazolium ($DMPBI^{+}$).[44–47] Thus, DMPBI was first applied to PET reduction of epoxy ketone **47a** (Scheme 21).[48,49] While the reaction in dry THF did not give the desired result of yielding enone **78** as a major product, the same reaction in wet THF produced **57a** in excellent yield. Following related investigations, it was finally demonstrated that DMPBI-acetic acid is an effective reagent system for photoinduced reductive transformation of α,β-epoxy ketones **52** to β-hydroxy ketones **53** (Scheme 22) (Table 53.4).[50] Irradiation of benzoyl-substituted epoxides **52a**-**d** in THF by Pyrex-filtered light produced the corresponding β-hydroxy ketones **53a**-**d** in good to excellent yields (Table 53.4, entries 1–5). On the other hand, photoreduction of acetyl-substituted epoxide **52e** to **53e** required photosensitized conditions (>360 nm) in DMF using 1,6-*bis*-dimethylaminopyrene as a sensitizer (Table 53.4, entry 5).

Photoreactions of Other Oxiranes with Triethylamine (TEA)

Photoreactions of aryl and alkyl oxiranes such as **79** and **81** with TEA were also reported by Epling[51] to give the corresponding alcohols **80** and **82** (Scheme 23). Other studies by Maruyama[52] using derivatives such as epoxy quinone **83** and by Ishii[53] using epoxy nitrile **86** were also subjected to PET reduction with TEA to produce the various reduction products **84**, **85**, **87**, and **88** (Scheme 24 and Scheme 25).

SCHEME 25

53.4 Summary

Photoinduced electron transfer (PET) reactions of oxiranes and epoxy ketones show various chemical pathways, which depend on the substrates and the conditions employed. It is hoped that further investigation on PET reactions of oxiranes and other related compounds will provide a breakthrough in our understanding of the mechanism as well as lead to new synthetically useful methods. To generate radical ions in solution, thermal methods such as reactions promoted by redox reagents as well as electrochemical reactions are perhaps more common to organic chemists. This review, we hope, has demonstrated further that the PET method is a unique but useful way to generate these active species. The reactivity of radical ions is, in general, governed by the nature of the radical ions themselves, as well as the surrounding conditions such as solvents, redox reagents, and incident light. Therefore, the PET method and traditional thermal methods should be complementary in the investigation of ion radical reactions from the mechanistic as well as synthetic viewpoints.

Crystal Structure–Solid-State Reactivity Relationships: Toward a Greater Understanding of Norrish/Yang Type II Photochemistry

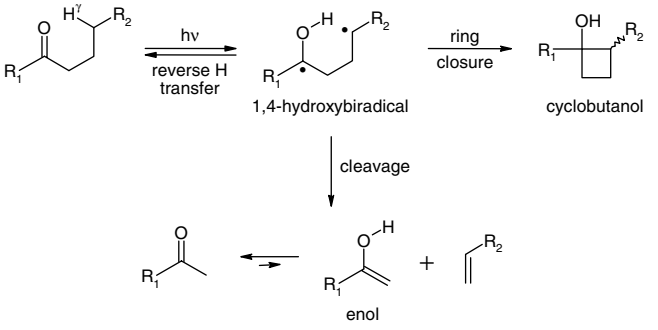
John R. Scheffer
University of British Columbia

Carl Scott
University of British Columbia

54.1 Introduction

The Norrish/Yang type II reaction, arguably the most widespread and well-studied transformation in the field of organic photochemistry, remains to this day an important source of strained, small-ring compounds as well as a vehicle for the generation and study of reactive intermediates such as enols and 1,4-biradicals.[1] In this reaction, ketones with geometrically accessible γ-hydrogen atoms undergo six-membered transition state hydrogen atom abstraction from their $n \rightarrow \pi^*$ excited states to afford 1,4-hydroxybiradicals. As shown in Scheme 1, these species have three fates: (1) reverse hydrogen transfer to

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1

regenerate ground-state starting material, (2) cleavage to form an enol and an alkene (Norrish type II cleavage), and (3) ring closure to form a cyclobutanol (Yang photocyclization).[2] In the absence of factors that render it geometrically or energetically unfavorable, cleavage is generally found to be the predominant pathway followed.

Until we began our work in 1983,[3] all studies of the Norrish/Yang type II reaction were conducted in solution or the gas phase. There are, however, several excellent reasons for investigating this reaction in the crystalline state. Chief among these is that it enables correlations to be drawn between the photochemistry observed in this medium and the crystal and molecular structure of the reactant. Put another way, it provides a method by which a three-dimensional "snapshot" of the conformation and environment of the reactant can be obtained — a detailed view of the *preorganized assembly* of reacting molecules in the crystal that is fixed on the photochemical time scale. This differs from the situation in fluid media, where an essentially infinite number of conformers and intermolecular geometries are possible. As an added bonus, if one is fortunate, a so-called "topotactic" solid-state reaction may occur. In such cases, a perfect single crystal of the reactant is continuously and quantitatively transformed into a perfect single crystal of the photoproduct. This permits the entire photochemical transformation to be mapped out crystallographically and allows direct structural correlations between reactant and product to be developed in unprecedented detail. We describe one such topotactic reaction in the pages that follow.

What can we learn about the Norrish/Yang type II reaction by studying it in the crystalline state? In this chapter, we concentrate on the following points: Does γ-hydrogen abstraction actually proceed through a chair-like, six-membered transition state as originally suggested on intuitive grounds by Wagner?[4] Over what distances can abstraction take place, and what is the preferred angular relationship between the carbon–hydrogen bond being broken and the carbon–oxygen double bond of the abstracting carbonyl group? In addressing questions such as these, our goal is to make the Norrish/Yang type II reaction more predictable. By compiling crystallographically determined geometric data for hydrogen abstraction for a large number of structurally diverse type II systems, a database of favorable reaction coordinates can be constructed. A comparison of such data with analogous data for hypothetical type II systems calculated by using molecular mechanics methods then allows predictions to be made concerning the probable success of new Norrish/Yang photoreactions.

A final impetus for investigating the Norrish/Yang photoreaction in the solid state stems from the possibility of using the crystalline medium as a template for asymmetric induction studies. Substances that crystallize in chiral space groups reside in asymmetric environments that are capable of differentiating enantiomeric transition states, and the photochemical conversion of achiral ketones into chiral cyclobutanols offers an ideal vehicle for testing the efficacy of this method of asymmetric synthesis. As we shall see in the following pages, it turns out that it is the asymmetric *conformation* of the reactant in the chiral crystal rather than the asymmetric environment of the surrounding lattice that is responsible for the enantioselectivity of cyclobutanol formation.

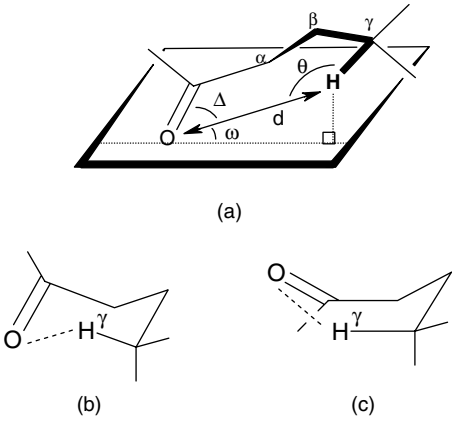


FIGURE 54.1 (a) Definition of geometric parameters *d*, ω, Δ, and θ for γ-hydrogen abstraction. (b) Chair-like hydrogen abstraction geometry. (c) Boat-like hydrogen abstraction geometry.

54.2 The Preferred Geometry of γ-Hydrogen Atom Abstraction

Definition of Geometric Parameters

For discussion purposes, it is useful to define four geometric parameters associated with γ-hydrogen atom abstraction (Figure 54.1a). The first is *d*, the distance between the carbonyl oxygen and the γ-hydrogen atom. It seems reasonable to suggest that the optimum value of *d* should be close to the sum of the van der Waals radii for oxygen and hydrogen, which is 2.72 Å.[5] The second parameter is given the symbol ω and is defined as the angle by which the γ-hydrogen lies outside the mean plane of the carbonyl group. Because hydrogen atom abstraction involves the *n*-orbital on oxygen, which lies in the plane of the carbonyl group, the most favorable angle of ω is expected to be 0°. The third parameter, Δ, is defined as the C=O···H angle, and the best value of this angle should lie between 90° and 120°, depending on the hybridization of the *n*-orbital on oxygen (2p or sp^2). The fourth parameter is θ, the C-H···O angle, which, according to theory, should have an optimum value of 180°.[6] In the discussion that follows, we also characterize the six-atom γ-hydrogen atom abstraction geometry as primarily chair-like (Figure 54.1b) or boat-like (Figure 54.1c).

A Case Study: the *cis*-9-Decalyl Aryl Ketone System

cis-9-Decalyl aryl ketones of general structure 1 (Scheme 2) offer a wealth of possible Norrish/Yang type II reaction pathways. Not only can the *regioselectivity* of hydrogen atom abstraction be probed (H2 vs. H4), but the *enantioselectivity* can be tested as well (H2 vs. H7 and/or H4 vs. H5). Each hydrogen abstraction event can in principle lead to either cleavage or cyclization and, in the latter case, because the resulting cyclobutanol can be formed with two different configurations at the hydroxyl-bearing carbon, *diastereoselectivity* can also be investigated. With these ideas in mind, we synthesized a number of *cis*-9-decalyl aryl ketone derivatives and studied their photochemistry in solution as well as the crystalline state.[7] The compounds investigated and the products formed are outlined in Scheme 2; Table 54.1 summarizes the yields in each case.

Several striking features can be noted in the results presented in Scheme 2 and Table 54.1. First of all, no Norrish type II cleavage products were formed, either in the solid state or solution. Second, small amounts of some unexpected, non-Norrish/Yang photoproducts were isolated and identified. These are the cyclopentanone derivates **8a–f**, formed only in solution, and the novel cyclopropanol derivative **7d**,

[b] Yield is reduced due to the presence of several small unidentified GC peaks.

formed exclusively in the solid state. A third notable feature of the experimental results is that cyclobutanol photoproducts **6** and **9** were formed in roughly equal amounts in solution, whereas in the crystalline state only a single cyclobutanol was observed in each case at low conversions. At higher conversions, small amounts of the other photoproducts were observed as a result of crystal breakdown and melting,

[b] Two independent molecules in the asymmetric unit.

particularly for the lower melting ketones **1a–d**. Remarkably, only one diastereomer of each cyclobutanol was formed, regardless of the reaction medium or extent of conversion.

As an aid to understanding these results and in order to obtain the hydrogen abstraction geometries (*vide infra*), the crystal and molecular structures of ketones **1a–f** were determined by single crystal x-ray diffraction. This revealed that ketone **1a** crystallizes in a conformation that is quite different from that adopted by ketones **1b–f**, all of which share the same basic conformation. Oak Ridge Thermal Ellipsoid Plot Program (ORTEP) representations of these two conformations are shown in Figure 54.2, and the corresponding line drawings are given in Scheme 2 (conformer **X** for ketones **1b–f** and conformer **Y** for ketone **1a**). Molecular mechanics calculations indicate that structure **X** represents the global minimum energy conformation for this system and that conformer **Y** lies only about 0.1 kcal/mol above the minimum. From the crystal structures of ketones **1a–f**, the values of the hydrogen atom abstraction parameters d, ω, Δ, and θ for each ketone were calculated; the data are presented in Table 54.2.

Crystal Structure–Reactivity Correlations for the *cis*-9-Decalyl Aryl Ketone System

From the experimental results presented above, a clear picture of the structure–reactivity relationships involved in the solid-state photochemistry of the *cis*-9-decalyl aryl ketone system emerges. As depicted in Scheme 2, reaction through conformation **X** leads to photoproducts of type **6** via abstraction of H4 and to photoproducts of type **7** and **8** via abstraction of H10. In contrast, reaction through conformation **Y** leads exclusively to the formation of photoproducts of type **9** via abstraction of H2. These conclusions are borne out by the geometric data presented in Table 54.2. In conformation **X** (ketones **1b–f**), the carbonyl oxygen is much closer to hydrogen atoms H4 and H10 than it is to H2. The average values of *d* (the hydrogen abstraction distances) are 2.63 ± 0.05 Å for H4, 2.39 ± 0.02 Å for H10, and 3.49 ± 0.06 Å for H2. The situation is reversed for ketone **1a**, which crystallizes in conformation **Y**. In this case, the carbonyl oxygen is close to H2 (2.65 Å) and relatively distant from H4 (3.52 Å) and H10 (3.82 Å).

The data in Table 54.2 reveal that the hydrogen atoms with the most favorable values of *d* also have relatively favorable values of the angular parameters ω, Δ, and θ. Consider ketone **1a** (d_{H2} = 2.65 Å; d_{H4} = 3.52 Å). Although the ω angle for H4, at 44°, is slightly closer to the ideal of 0° than it is for H2 (56°), the values of Δ and θ favor abstraction of H2. There is a particularly large difference in the value of Δ, which, at 84° for H2, is much closer to the ideal of 90 to 120° than for H4 (Δ = 44°). Recent work by Griesbeck et al. has highlighted the importance of the Δ angle in hydrogen abstraction reactions.[8] A similar trend is seen in the data for ketones **1b–f**, where abstraction of H4 is favored over abstraction of H2. As above, the values of ω slightly favor abstraction of the more distant hydrogen H2, but the values of θ and particularly Δ favor abstraction of H2.

An interesting aspect of the photochemistry of ketones **1b–f** is that it presents a rare example in which β-hydrogen atom abstraction competes with the normally much more favorable process of γ-hydrogen abstraction.[9] Two main factors conspire to bring this about. First of all, the β-hydrogen H10 is tertiary and therefore more susceptible to abstraction than the secondary γ-hydrogen H4.[10] Second, H10 is particularly well situated for abstraction, with an unusually short abstraction distance, *d*, of 2.39 ± 0.02 Å and a nearly ideal out-of-plane ω angle of 3 ± 2°. Despite this favorable β-hydrogen abstraction geometry, only minor amounts of photoproducts **7** and **8** are formed, a result that may reflect the relative ease of reverse hydrogen atom transfer in hydroxy biradical **3** compared to ring closure, even in hydrogen-bonding solvents such as acetonitrile.[11]

We turn next to a discussion of why the product distribution in solution is so much different from that observed in the crystal (Table 54.1). The simple answer is that, in solution, equilibrium between conformers **X** and **Y** is established and both can react to give a mixture of cyclobutanols **6** and **9**, plus small amounts of cyclopentanone **8** (Scheme 2). In contrast, equilibration between conformers **X** and **Y** is topochemically restricted in the crystalline state and reaction is limited to one or the other.

A subtler question has to do with why cyclopentanones of type **8** are observed only in solution and why cyclopropanol **7d** is formed exclusively in the solid state. We suggest the following scenario (refer to Scheme 2): Ring closure of biradical **3** to form cyclopropanol **7** is slow due to ring strain and in solution conformational isomerization to biradical **4** is faster. This places the aromatic ring in proximity to the radical at C10 and radical coupling of **4** at the *ortho* position followed by tautomerization and oxidation leads to cyclopentanone **8**.[12] In contrast, conformational isomerization of biradical **3** to biradical **4** is topochemically forbidden in the crystalline state, and cyclopentanone **8** is not formed in this medium. Formation of cyclopropanol **7** is slow in the solid state as well, and biradical **3** reverts to starting ketone rather than undergoing ring closure. The one exception to this rule is biradical **3d**, which, for reasons that we do not understand, gives 19% of cyclopropanol **7d** in the crystalline state.

The structure–reactivity relationships developed above also account very nicely for the high diastereoselectivity observed in the formation of cyclobutanols **6** and **9**. This can be understood by reference to Scheme 2, which depicts the structures of conformers **X** and **Y** in the crystalline state. In the case of conformer **X**, abstraction of H4 followed by least motion closure of biradical **2**, *with retention of configuration at the carbonyl carbon*, leads directly to the experimentally observed diastereomer **6**. Formation

of the diastereomer with the opposite configuration at the hydroxyl-bearing carbon atom would require biradical **2** to undergo a large-amplitude rotation of the hydroxybenzyl group, a process that is topochemically forbidden in the crystalline state and is evidently slow in solution as well. A similar analysis applies to the preferential formation of *endo*-arylcyclobutanol **9** rather than its *exo*-aryl diastereomer. Here, abstraction of H2 occurs from conformer **Y** to afford biradical **5**, and closure of this species with retention of configuration at the carbonyl carbon leads naturally and directly to the topochemically allowed cyclobutanol **9**. As above, formation of the unobserved diastereomer requires large-amplitude motions of the hydroxyl and aryl groups, which are prohibited by the rigid, close-packed environment of the crystal. Based on the two examples presented above, plus a number of others that will be discussed later in this review, it seems safe to conclude that 1,4-hydroxy biradical ring closure involving retention of configuration at the carbonyl carbon is a general feature of Yang photocyclization reactions in the crystalline state.

A final point in our discussion of the photochemistry of the *cis*-9-decalyl aryl ketone system concerns the question of the overall geometry of the six-membered transition state hydrogen atom abstraction process: chair-like, boat-like, or other? The unequivocal answer in the present instance is boat-like, a feature that appears to be general to the systems we have investigated in the crystalline state (*vide infra*). Although present in both conformers **X** and **Y**, the boat-like six-atom hydrogen abstraction geometry is most easily visualized in conformer **X** (Scheme 2), where the C4–H4 and C9 to carbonyl carbon bonds form the parallel sides of the boat and C10 and the carbonyl oxygen atom represent the prow and the stern. The normal eclipsing and bowsprit-flagpole interactions present in boat cyclohexane are absent in this particular arrangement.

Summary of Crystallographically Derived γ-Hydrogen Atom Abstraction Geometries for *cis*-9-Decalyl Aryl Ketones and Other Systems

The crystallographically derived geometric data compiled in Table 54.2 for *cis*-9-decalyl aryl ketones **1a–f** represent the results of just one of a number of similar studies on the Norrish/Yang reaction in the crystalline state. In Table 54.3 we summarize the values of *d*, ω, Δ, and θ for a variety of type II systems. These data are taken from our own published work as well as that of other groups working in the field. For comparison purposes, Table 54.3 also includes geometric data for intramolecular hydrogen abstraction reactions taking place through five-membered (β) and seven-membered (δ) transition states. In cases where more than one hydrogen is reasonably situated for abstraction, Table 54.3 reports data only for the hydrogen atom with the smallest value of *d*. This is based on work from our group which demonstrated that a difference in *d* of only 0.27 Å (2.72 vs. 2.99 Å) and comparable values of ω, Δ, and θ leads to exclusive abstraction of the nearer hydrogen in the crystalline state.[13]

Only crystallographically derived geometric parameters are given in Table 54.3 for compounds that actually react in the solid state; some studies report values of *d*, ω, Δ, and θ based on molecular mechanics calculations, but these are not included. In some published reports, only the abstraction distance (*d*) is given, and in others, only *d* and ω are provided. In this review, we have not attempted to calculate the value of missing parameters based on accompanying x-ray coordinates. Finally, we note that entries 1 to 5, 12, and 26 in Table 54.3 report average values for several structurally related compounds. In these cases, standard deviations are supplied along with the number of examples reported.

Discussion of Results Presented in Table 54.3

With 33 entries representing data for 115 separate compounds of widely varying structure, Table 54.3 paints a picture of the geometric requirements for intramolecular hydrogen atom abstraction that is remarkable in its internal consistency. Consider, for example, the parameter *d*, the C=O···H abstraction distance. Ranging from a low of 2.17 Å (entry 20) to a high of 3.15 Å (entry 15), most values of *d* fall within ±0.2 Å of the sum of the van der Waals radii for oxygen and hydrogen (2.72 Å), thus amply justifying our original intuition in this regard. One report of γ-hydrogen atom abstraction occurring over

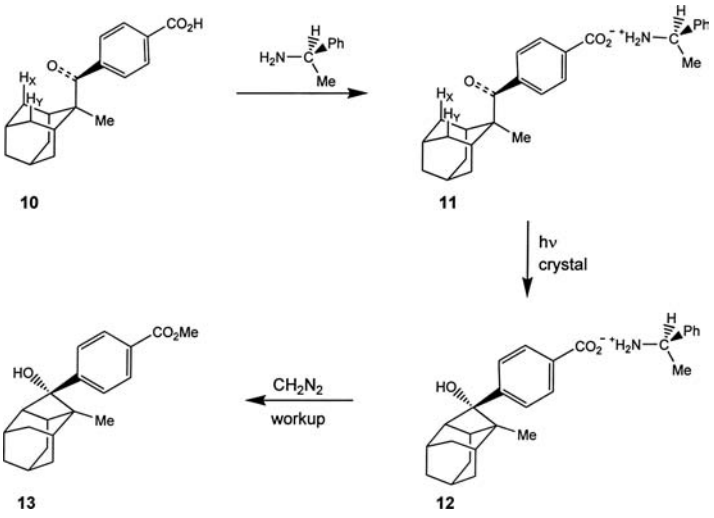
a distance of 4.45 Å is puzzling,[45] but the authors conclude that this most likely takes place at defect sites in the crystal where different conformers having shorter values of *d* are present.

Turning next to the parameter ω, the prediction that the γ-hydrogen should lie in the same plane as the *n*-orbital on oxygen (ω = 0°) is clearly contradicted by the data in Table 54.3, which includes many ω angles in the 40 to 60° range, with three even higher (66°, entry 27; 73°, entry 30; 78°, entry 31). How can this discrepancy be explained? Wagner has suggested and provided evidence for a $\cos^2\omega$ dependence on the rate of γ-hydrogen atom abstraction.[46] This means that ω can be quite large and still lead to respectable rates of abstraction. For example, when ω = 60°, $\cos^2 60 = 0.25$ and abstraction can occur at 25% of its maximum rate, more than enough for observable solid-state reactivity. In theory, abstraction should cease when ω = 90°, because at this geometry the γ-hydrogen is orthogonal to the abstracting *n*-orbital on oxygen and $\cos^2\omega = 0$. Several examples of such a situation have been noted in the literature.[47] Wagner and co-workers[40] report an interesting case in which abstraction of a methyl hydrogen with *d* = 2.53 Å and ω = 95° competes to the extent of ~15% with abstraction of a methylene hydrogen atom, with *d* = 2.63 Å and ω = 45° (entry 28). One possible explanation for this apparent anomaly is the presence of a small amount of methyl/ethyl disorder in the crystal, which is known to be common.[48] Another interesting hydrogen atom abstraction that occurs with a large value of ω is that shown in entry 31, a seven-membered, transition-state (δ) process. This reaction was first investigated in solution by DeBoer et al.,[49] who showed that it proceeds through a $(\pi,\pi^*)^3$ excited state. This means that it should have a different optimum value of ω, (i.e., 90°). In reasonable agreement with this, the experimentally determined value of ω for the reaction in the crystalline state is 78°.[43]

The data in Table 54.3 are less complete regarding the preference for boat-like or chair-like transition states and for the parameters Δ and θ, but here, too, a few comments are in order. The preference for boat-like abstraction geometries that was noted earlier for the *cis*-9-decalyl aryl ketone system is seen to carry over into entries 2 to 4, and this may prove to be a general feature of type II hydrogen atom abstraction. With respect to the angle Δ (the C=O···H angle), the experimental data are in reasonably good agreement with the hypothetical ideal of 90 to 120° and much closer on average to the former value than the latter. This could be taken as evidence for involvement of a non-bonding orbital on oxygen that is largely 2p-like in character, but more likely it is simply due to the geometric constraints inherent in a six-membered transition state process. This reasoning also applies to the parameter θ (the C–H···O angle), which cannot possibly approach its theoretical ideal of 180° within the confines of a cyclic six-membered transition state. In line with this, typical values of θ lie in the range of 115 ± 10°. On this basis, it might be expected that θ would be somewhat larger for a seven-membered transition state (δ) hydrogen atom abstraction and slightly smaller for the corresponding β (five-membered transition state) process. Entries 1 and 26 to 32 in Table 54.3 do hint in this direction, but the data are really too sketchy to draw any firm conclusions. What the data do indicate is that the values of *d* and ω for β- and δ-hydrogen abstraction are very similar to those for the corresponding six-membered transition state process, and we continue to view these parameters (particularly the former) as being most critical to the success of intramolecular hydrogen atom abstraction.

We close this section with a brief discussion of the significance of the ground state geometric parameters presented in Table 54.3 to reactions that occur in the excited state. Three main factors make the crystal structure–excited state reactivity relationships less than exact. First, n,π^* excitation lengthens CO double bonds by about 0.1 Å;[50] second, x-ray crystallography consistently underestimates CH bond lengths by approximately 0.1 Å due to the low diffraction cross section of hydrogen atoms; and, third, the carbonyl carbon atoms of aliphatic ketones tend to pyramidalize in their n,π^* excited states.[51] This last factor is not a problem for the majority of the data in Table 54.3, which come from conjugated aryl ketones whose n,π^* excited states are not significantly pyramidalized.[52] Furthermore, lengthening the CO double and CH bonds by 0.1 Å at a typical abstraction geometry of Δ = 90° and θ = 115° decreases *d* by only about 0.2 Å. It is safe to conclude, therefore, that, while the abstraction parameters measured by x-ray crystallography do not provide *exact* information on the geometry in the excited state, we have good reason to expect that the structure–reactivity relationships developed above are approximately correct and can be used in a predictive sense. It is a relatively simple matter these days to calculate reasonable estimates of



SCHEME 3

d, ω, Δ, and θ for virtually any ketone through the use of molecular mechanics methods and in this way to gauge the probable success or failure of a hypothetical Norrish/Yang type II reaction.

54.3 Asymmetric Induction in the Yang Photocyclization Reaction

As can be seen from Scheme 1, the process of Yang photocyclization produces a chiral cyclobutanol from an achiral ketone — a reaction that is ideal for testing new methods of asymmetric induction in organic photochemistry. Our goal was not the formation of optically pure cyclobutanols for their own sake (although such compounds may prove useful in mechanistic studies of carbocation rearrangements), but rather the development of asymmetric induction techniques applicable to photorearrangement reactions in general. Asymmetric synthesis is nowhere near as well developed for excited-state reactions as for ground-state processes, and this topic remains one of the major relatively unexplored areas of organic photochemistry.[53]

The Concept of the Ionic Chiral Auxiliary

It has been known for some time that chemical reactions conducted in bulk crystalline media can lead to high levels of asymmetric induction provided that the crystals adopt chiral space groups.[54] It was thus natural to extend the solid state work discussed in Section 54.2 of this review to an investigation of asymmetric induction in the Yang photocyclization reaction. To achieve this goal, two conditions must be met. First, the molecules chosen for study must crystallize in conformations that favor hydrogen atom abstraction. This rules out straight-chain aryl alkyl ketones such as valerophenone and its derivatives, which crystallize in extended conformations with inaccessible γ-hydrogen atoms. Second, the reactant molecules must crystallize in chiral space groups. This can be achieved by attaching temporary chiral auxiliaries to the substrates that can be removed once the solid state photoreactions are complete.

These concepts are best illustrated with a specific example. Ketone **10** (Scheme 3) was expected to have a minimum energy conformation in which the ketone oxygen is directed toward the enantiotopic γ-hydrogen atoms Hx and Hy and this was confirmed by molecular mechanics calculations. Because organic molecules generally crystallize in or near their minimum energy conformations, it was anticipated that

ketone **10** would undergo facile γ-hydrogen abstraction in the solid state, a prediction that was amply borne out by experiment (*vide infra*). The *p*-carboxylic acid group in compound **10** was introduced as a site to which the chiral auxiliary could be attached. This could be achieved in two ways — covalently (*via* ester formation with an optically pure alcohol or amide formation with an optically pure amine), or ionically through salt formation with an optically pure amine. For a variety of reasons, including novelty, ease of introduction and removal of the chiral auxiliary and the fact that salts form robust ionic crystals with high melting points (important for studies in the solid state), we chose to work with ionic chiral auxiliaries.

Asymmetric Induction in the Crystalline State

Several salts of general structure **11**, varying only in the nature of the ionic chiral auxiliary, were prepared and irradiated in the crystalline state.[15] The reaction mixtures were worked up with ethereal diazomethane to remove the chiral auxiliaries and form the corresponding methyl esters; this led to the anticipated cyclobutanol **12** (Scheme 3) as the sole photoproduct. Best results were obtained with the 1-phenylethylamine salt, which afforded enantiomeric excesses (*ee*s) of approximately 80% at 100% conversion. Either enantiomer of cyclobutanol **12** could be prepared by using the optical antipodes of 1-phenylethylamine and the critical importance of the crystalline state to the process was shown by the fact that irradiation of salt **11** in acetonitrile or methanol gave racemic **12**.

A remarkable feature of the photorearrangement of salt **11** in the solid state is that it proved to be of the rare single crystal-to-single crystal (topotactic) variety. In such processes, product molecules take the place of reactant molecules in all proportions in the crystal lattice with no change in space group and very little change in unit cell dimensions. This permits the *same crystal* to be analyzed by X-ray diffractometry at the initial, intermediate and final stages of reaction. Such an experiment was carried out for salt **11** and its photoproduct **12** and the results are presented in Scheme 3. Because the absolute configuration of the ionic chiral auxiliary is known, Scheme 3 depicts the absolute steric course of the photorearrangement and we can state with certainty that H_X (**d** = 2.60 Å) is abstracted in preference to H_Y (**d** = 3.59 Å) and that cyclobutanol formation is a least motion process involving "retention of configuration" at the carbonyl carbon. The reader will recall that in our investigation of the *cis*-9-decalyl aryl ketone system discussed earlier, formation of cyclobutanols **6** and **9** (Scheme 2) involved similar ring closures with retention of configuration at the carbonyl carbon.

In fact, one of the major goals of our work with the *cis*-9-decalyl aryl ketone system **1** was to apply the ionic chiral auxiliary approach to the asymmetric synthesis of cyclobutanols **6** and **9**. Like ketone **10**, ketones of general structure **1** are achiral, but unlike **10**, contain *two* pairs of enantiotopic γ-hydrogen atoms (H4/H5 and H2/H7), abstraction of which leads to enantiomeric cyclobutanols of general structure **6** and **9** (see Scheme 2). Hydrolysis of nitrile **1e** provided the corresponding carboxylic acid and reaction of this compound with (*R*)-(+)-1-phenylethylamine gave salt **1e**. X-ray crystallography revealed that this salt crystallizes in conformation **X** (absolute configuration as shown) and in this conformation only γ-hydrogen atom H4 is in position to be abstracted (**d** = 2.62 Å). In accord with this picture, irradiation of crystals of this material to 85% conversion afforded cyclobutanol **6d** in a remarkable 98% *ee*.[7a] The (*R*)-(+)-bornyl amine salt proved to be even better, yielding cyclobutanol **6d** in a particularly clean reaction with >98% *ee* at 78% conversion. Neither of these reactions proved to be topotactic, thus preventing determination of the absolute configuration of cyclobutanol **6d**, but there can be little doubt that it is as shown in Scheme 2.

Our studies on the adamantyl (**10**) and decalyl (**1**) systems are only two of several examples of the successful application of the ionic chiral auxiliary approach to asymmetric induction in the Yang photocyclization reaction. Space does not permit a full exposition of our results in this area. The interested reader may wish to consult references 17, 25, 27, 31, 35, 38 and 44 for additional examples and further details. As a note of interest, reference 44 describes the use of *anionic* chiral auxiliaries in the Yang photocyclization of a cationic counterion in the crystalline state; all of our other studies have been of the reverse type.

Molecular Conformation Determines the Enantioselectivity of Yang Photocyclization

The results presented above highlight the importance of *molecular conformation* in bringing about high levels of asymmetric induction in the Yang photocyclization reaction in the crystalline state *via* the ionic chiral auxiliary approach. In the presence of an ionic chiral auxiliary, the reactive counterions crystallize in chiral conformations in which one of the two γ-hydrogen atoms that were enantiotopic in solution is more favorably oriented for abstraction than the other. It is at this point that the importance of the crystalline state in preventing conformational equilibration becomes apparent. Without this restriction, both enantiotopic hydrogens would become available for abstraction (as they are in solution) and the enantioselectivity would be lost. The role of the ionic chiral auxiliary is therefore one of *preorganizing* the counterions in conformations favorable for the formation of only one enantiomer and the role of the crystalline state is to *immobilize* them in this arrangement. This of course predicts that should the reactant prefer to crystallize in a symmetrical conformation in which both enantiotopic γ-hydrogens are equally accessible (even in the presence of a chiral auxiliary), racemic cyclobutanol will be formed. In this interesting situation, any *ee* that is observed would necessarily be the result of anisotropic *intermolecular* interactions with lattice neighbors in the chiral crystal. We are currently designing symmetrical and conformationally immobile type II systems to test these ideas.

Thus, in comparison to the situation in most conventional, ground state asymmetric induction reactions, where the chiral auxiliary is intimately involved in the enantiodifferentiating step through its stereoelectronic effects or coordinating ability, the role of the ionic chiral auxiliary in solid state cyclobutanol formation is a relatively passive one. For example, the ionic chiral auxiliary does not need to be located close to the site of reaction and all that is required is that its attachment to the reactant *via* salt formation does not give rise to diastereomers. In addition, there is no direct correlation between the size and structure of the ionic chiral auxiliary and the extent of *ee*, nor is it possible to predict which enantiomer of the photoproduct will be favored. This would be akin to making an *a priori* prediction of crystal and molecular structure, a feat that is currently beyond the scope of modern crystal engineering.

Conformational Enantiomerism

Given the presentation of the results so far, one might expect that all ionic chiral auxiliaries would lead to high *ee*s, but such is not the case. For example, in the *cis*-9-decalyl aryl ketone system **1**, use of (1*R*,2*S*)-(−)-norephedrine as the chiral auxiliary (salt **1f**, Scheme 2) led to cyclobutanol **6d** in 30% *ee* at 55% conversion,[7a] and in the 2-benzoyladamantane system **10**, several of the salts investigated led to *ee*s in the 20-30% range.[55] As a matter of fact, for any given prochiral type II photoreactant, finding an ionic chiral auxiliary that gives a high *ee* is entirely a trial and error procedure and low *ee*s are obtained as often as not. How is this possible if the salts crystallize in conformations that permit abstraction of only one of the two enantiotopic γ-hydrogen atoms? We can rule out trivial explanations such as crystal melting in these low *ee* cases, since (a) no melting was detectable upon examination of the crystals following photolysis and (b) the results were not improved by using low temperatures and low conversions, where crystal melting should be minimal.

The origin of the low *ee*s was eventually deduced from the X-ray crystal structures of several of the salts that show this behavior.[56] In these cases it was found that half of the reactant ions crystallize in one enantiomeric conformation while the other half crystallize as its near (but not exact) mirror image. This was shown by computationally inverting one of the conformers, superimposing it on the other and calculating the root mean-square error for the overlap of the heavy atoms of the two species, which proved to very low (0.08 Å in the case of norephedrine salt **1f**). We coined the term *conformational enantiomerism* to describe this heretofore unrecognized mode of crystal packing.[56]

Armed with this knowledge, the reason for the low *ee*s observed in salts that exhibit conformational enantiomerism is straightforward: half of the molecules in the crystal react to give one photoproduct enantiomer while the other half react to form its optical antipode. The reason the *ee* is not zero is that the conformational enantiomers are in fact independent molecules that reside in structurally different

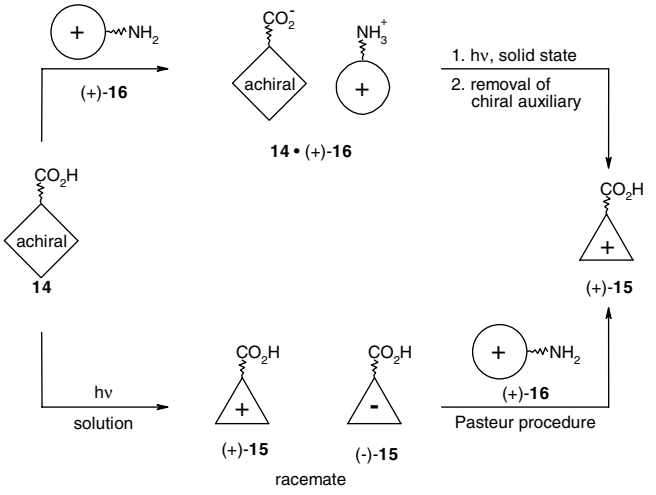


FIGURE 54.3 Comparison of the solid state ionic chiral auxiliary method of asymmetric synthesis with the Pasteur resolution procedure.

environments, thus leading to slightly different reaction rates. Put another way, the conformational enantiomers form diastereomeric salts with the common optically pure amine and should not, therefore, be expected to react at exactly identical rates. Support for this interpretation comes from the crystal structures of salts that give high *ee*s. In these cases, the reactant ions invariably crystallize in a single, homochiral conformation that react to form a single enantiomer of the photoproduct.

Comparison of the Solid State Ionic Chiral Auxiliary Method of Asymmetric Synthesis with the Pasteur Resolution Procedure

Both of the cyclobutanols discussed in this review (compounds **6d** and **13**) could have been prepared in enantiomerically pure form by irradiation of their keto-acid precursors (**1**, X = COOH and **10**) in an isotropic solvent to give a racemic mixture followed by resolution employing the classical Pasteur procedure. This method, which involves treatment of the racemate [(+)-**15**/(−)-**15**] with an optically pure amine [(+)-**16**] followed by fractional crystallization of the resulting diastereomeric salts, is outlined schematically in the bottom half of Figure 54.3. The top half of Figure 54.3 summarizes the solid state ionic chiral auxiliary method of asymmetric synthesis. The difference between this approach and the Pasteur method is one of *timing*: in the chiral auxiliary procedure, crystalline salt formation *precedes* the photochemical reaction, whereas the reverse is true for the Pasteur method. In principle, irradiation of the salt **14**/(+)-**16** can lead to a pair of diastereomeric product salts [(+)-**15**/(+)-**16** and (−)-**15**/(+)-**16**] — a reaction that takes place through diastereomeric transition states. Viewed in this way, the success of the ionic chiral auxiliary approach can be thought of as deriving from a kinetic preference for the transition state of lower energy [(+)-**15**)/(+)-**16** in the example shown in Figure 54.3]. The ionic chiral auxiliary method has an obvious advantage over the Pasteur procedure in terms of yield, since in principle and (as we have seen) in practice, the reactant (**14**) can be completely transformed into one enantiomer of the photoproduct or the other, as desired. By way of contrast, the maximum yield in which a given enantiomer can be obtained using the Pasteur procedure is 50% and in practice is often considerably less.[57]

Synthetic Potential of the Ionic Chiral Auxiliary Approach to Asymmetric Synthesis

The solid state ionic chiral auxiliary method of asymmetric synthesis is not limited to Yang photocyclization and can, in principle, be applied to any chemical reaction — photochemical or thermal — that

occurs in the crystalline state and converts an achiral reactant into a chiral product. Thermal reactions may, of course, present a problem owing to the greater chance of crystal melting, but ionic solids with their high melting points (generally > 160 °C) hold promise in this regard. Current efforts in our laboratory are aimed in this direction. It is to photochemical reactions, however, that the method is most applicable, since temperature control is a simple matter in such reactions and we have extended our studies to a wide variety of excited state processes. The following is a list of photochemical reactions (in addition to Yang photocyclization) to which the ionic chiral auxiliary approach has been applied: the di-π-methane rearrangement,[58,59,61,62] rearrangement of a benzocyclohexadienone,[63] electrocyclic ring closure,[64] *cis*,*trans*-isomerization of cyclopropane derivatives[65,66] and the Paterno-Büchi reaction.[67]

We close with a brief mention of the *scale* on which these reactions can be conducted — an important consideration when it comes to synthetic utility. For practical reasons and because modern methods of analysis do not require large sample sizes, most of our solid-state photolyses have been carried out on a microscale (< 10 mg). In one instance, however, we showed that the method could easily be scaled up to the 500 mg level with an *ee* of 99% and an isolated yield of 91%.[68] This was done by irradiating the salt crystals as a hexane suspension in a conventional immersion well apparatus — a technique that would certainly allow reactions to be conducted on the multi-gram level if desired.

54.4 Summary

The preferred geometry for photochemically-initiated intramolecular hydrogen atom abstraction has been elucidated using the crystal structure-solid state reactivity correlation method. Based on more than a hundred examples taken from our own work and that of others, it has been shown that abstraction is successful when the C=O···H distance, d, is within approximately ± 0.2 Å of the sum of the van der Waals radii for oxygen and hydrogen (2.72 Å), although d values as short as 2.17 Å and as long as 3.15 Å have been recorded. A second important geometric parameter in intramolecular hydrogen atom abstraction is the angle ω, the degree to which the hydrogen lies above or below the mean plane of the carbonyl group. Because hydrogen abstraction involves the n-orbital on oxygen, which lies in the plane of the carbonyl group, the best value of ω is predicted to be 0° and the worst ± 90°. Surprisingly, most successful hydrogen abstraction reactions were found to occur with rather unfavorable ω angles (50 ± 10°) and only when ω approaches 90° does abstraction fail, a result that supports Wagner's proposed $\cos^2\omega$ dependence on the rate of abstraction.[46] Another unexpected experimental finding was that the overall 6-atom geometry for γ-hydrogen abstraction is primarily boat-like rather than chair-like, a result that appears to fly in the face of conventional organic wisdom, but which may be understood when one realizes that two of the six atoms involved (oxygen and hydrogen) are sterically neutral in the sense that they do not possess attached groups that can raise the energy of the boat geometry through eclipsing and bowsprit-flagpole interactions (Figure 54.1c).

In many respects, the present results resemble the pioneering work of the late G. M. J. Schmidt and his co-workers at the Weizmann Institute of Science, who used crystal structure–solid-state reactivity correlations to elucidate the geometric requirements for intermolecular [2+2]-photocycloaddition.[69] In both his case and ours, distance and angular requirements for reaction were established and the structure and stereochemistry of the products were shown to be simply and directly related to the molecular structure existing in the bulk crystal.

With an excellent understanding of the relationship between structure and reactivity in the Norrish/Yang type II reaction, it was logical to use this information to carry out the reaction enantioselectively. In an approach resembling the classical Pasteur procedure for resolving racemic carboxylic acids, this was accomplished by providing the prochiral reactants with a carboxylic acid substituent to which an "ionic chiral auxiliary" was attached through an acid-base reaction with an optically pure amine. The resulting salts were then irradiated in the crystalline state. This approach is based on the fact that salts containing ionic chiral auxiliaries are required to crystallize in chiral space groups, which provide the asymmetric environment necessary for chiral induction. Using this methodology, near-quantitative optical yields could be obtained in a variety of Yang photocyclization reactions, even at very high conversions.

Furthermore, through the use of X-ray crystallography, it could be demonstrated that the high *ee*s observed in these reactions are conformationally rather than topochemically determined; i.e., they are due to the homochiral conformations adopted by the reactive ions in the crystal, which favor the abstraction of one nominally enantiotopic γ-hydrogen atom over the other.

Norrish Type II Processes of Ketones: Influence of Environment

Tadashi Hasegawa
Tokyo Gakugei University

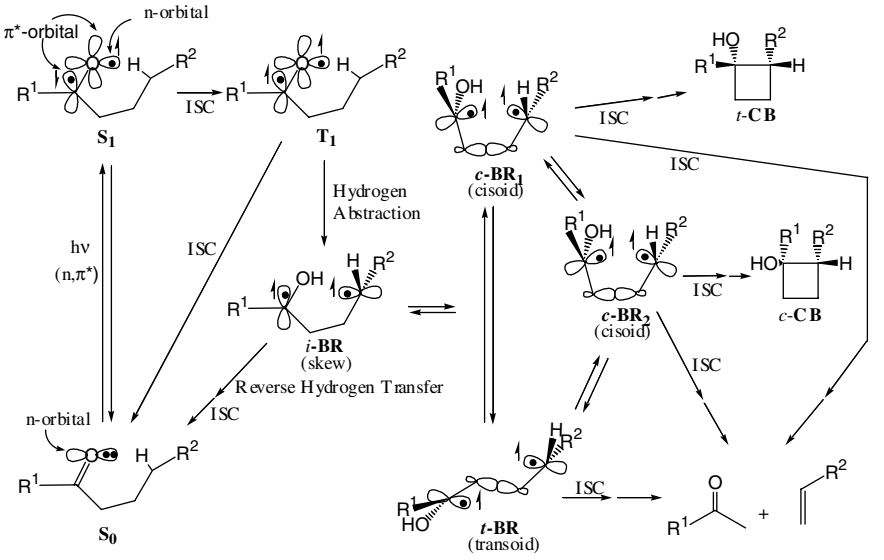
55.1 Introduction

Photolysis of a carbonyl compound having γ-hydrogen commonly gives a shorter chain carbonyl compound, an alkene, and a cyclobutanol, which are formed from a 1,4-biradical[1] produced via γ-hydrogen abstraction by the excited carbonyl. The photoreactions derived from the 1,4-biradical are termed the Norrish type II reaction,[2] and those involving intramolecular hydrogen abstraction from γ- and other positions are generically referred to as the type II family.[2b] The chemical behavior of the 1,4-biradical determines the type II reactivity of carbonyl compounds. In this chapter, the influence of environment on the formation and behavior of the 1,4-biradical from simple alkyl aryl ketones will be described. Environmental effects on the type II reaction have been reviewed.[2e,3,4]

55.2 Mechanistic Details of the Type II Reaction

The excited state responsible for hydrogen abstraction by the carbonyl group is the lowest n,π^* state. Ketones with the lowest π,π^* states are far less reactive than ketones with the lowest n,π^* states. The n,π^* transition involves excitation of an electron from a nonbonding orbital localized mainly on oxygen to an antibonding π^* orbital that covers both carbon and oxygen. The yield of intersystem crossing (ISC) from the n,π^* singlet to triplet state in alkyl aryl ketones is generally 100%, so that the type II reaction occurs from the triplet state.[5] The 1,4-biradical (*i*-**BR**) formed initially from the n,π^* triplet state is in a triplet skew form (Scheme 1). The triplet 1,4-biradical has a relatively long lifetime and transforms to the cisoid (*c*-$\mathbf{BR}_1$ or *c*-$\mathbf{BR}_2$) or transoid biradical (*t*-**BR**) via a rotation of the central σ-bond. Intersystem

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1 A detailed mechanism of the Type II reaction.

crossing changes the triplet to singlet biradicals that have very short lifetimes (sub-nanosecond)[1c] and lead immediately to products. Only elimination occurs from *t*-**BR**, while both cyclization and elimination occur from *c*-**BR**.[6] In cyclobutanol formation, the conformation of the triplet biradicals is maintained because the nascent singlet biradicals have the same conformation as that of the triplet biradicals.[1c] The reaction environment affects both the nature of the lowest excited state of ketones and the formation and behavior of the triplet 1,4-biradicals.

55.3 Environmental Effects on the Electronic States of Alkyl Aryl Ketones

The benzoyl chromophore shows a weak n,π^* band (ε = 5 to 100) in the 300- to 370-nm range and a moderately intense π,π^* band (ε = 1000 to 2000) in the 270- to 290-nm range. The lowest triplet state of phenyl alkyl ketones is n,π^* in hydrocarbon solvents. Introduction of a substituent such as a hydroxy, thiomethoxy, bromo, or phenyl group to the benzoyl phenyl group causes π,π^* states to be lowest.[7,8] The type II photoreactivity of these ketones is quite low ($\phi < 0.001$). The quantum yield for the type II reaction of *p*-methoxyvalerophenone (0.14) in benzene is, however, half of that of valerophenone (0.33), although *p*-methoxy substitution leads to the lowest π,π^* state.[7] The reactivity of ketones having the lowest π,π^* triplets decreases with an increase of the energy gap between the π,π^* and the n,π^* triplets[7] and increases with an increase of reaction temperature.[9] This indicates that the upper n,π^* and lowest π,π^* states are in thermal equilibration, and the reaction of *p*-methoxyvalerophenone occurs from the upper n,π^* triplet state.[7,9] Polar solvents destabilize the n,π^* state by lowering the energy level of the *n* orbital and stabilize the π,π^* state by lowering the level of the π^* orbital.[10] The quantum yield of *p*-methoxyvalerophenone decreases to 0.09 in methanol because of the large contribution of the π,π^* state in the equilibration.[7] The lifetime of valerophenone changes with solvent polarity and is longer in polar solvents than in nonpolar solvents (Table 55.1).[11–15] The lowest excited state of valerophenone in water is the π,π^* state.[11]

A nonreactive solid surface, such as a silica-gel surface, provides an ordered two-dimensional environment for effecting and controlling photochemical processes.[16–20] A silica-gel surface is composed of an interconnected network of polar silanol (Si–OH) and siloxane (Si–O–Si) groups[16] and therefore provides a strong polar reaction medium. Silica gel has a Kosower's *Z* value[21] of 88, intermediate between

those of water (94.6)[21] and methanol (83.6).[21,22] Indeed, the polar silica-gel surface causes the inversion of the nearby n,π^* and π,π^* triplet states of alkyl aryl ketones.[23]

Zeolites have three-dimensional pore structures in which alkyl aryl ketones are included. The triplet lifetime (τ) of valerophenone included in zeolites is affected by polarity of the zeolite interior: zeolite LiX (τ = 4 to 5 ms), NaX (τ = 0.8), KX (τ = 0.9), PbX (τ = 0.7), and CsX (τ < 0.2).[24] The interior of LiX is more polar than other cation-exchanged X zeolites and changes the lowest triplet state of valerophenone from n,π^* to π,π^*.

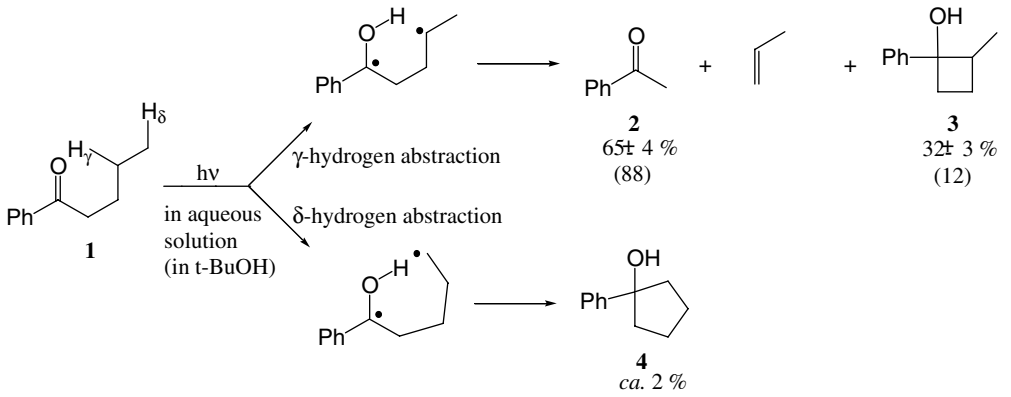
55.4 Environmental Effects on the Formation of 1,4-Biradicals

Although the quantum yield for the type II reaction of valerophenone is unity in *t*-BuOH,[5] a small amount (~2%) of phenylcyclopentanol, formed via δ-hydrogen abstraction, has been observed in a highly polar aqueous solution (Scheme 2).[11] Molecular oxygen is a ground-state triplet and dissolves in common organic solvents. The dissolved oxygen quenches the n,π^* triplet state of ketones.[25] The oxygen is also known to trap a 1,4-biradical and causes an increase of the type II product yields.[26]

The type II reaction requires close approach of a γ-hydrogen to carbonyl oxygen and effective overlap of the hydrogen *s*-orbital with the oxygen *n*-orbital responsible for abstraction. Flexible ketone molecules change their conformation freely and achieve conformational equilibrium before γ-hydrogen abstraction.[27] Conformational restriction caused by environment decreases the type II reactivity and may allow appearance of other reactivities.

Valerophenone undergoes the type II reaction in frozen benzene, but a fraction (25 to 30%) of the valerophenone remains unreacted even after prolonged irradiation.[28] This means that 25 to 30% of the valerophenone is in unreactive conformations and the unreactive conformers cannot convert to reactive ones in the frozen solution.

Conformational changes are much more restricted in a crystalline state, so that only γ-hydrogens that meet geometrical requirements can be abstracted. Four parameters have been used for prediction of the occurrence of γ-hydrogen abstraction in the crystalline state (Figure 55.1a). Parameters *d*, Δ, θ, and ω



SCHEME 2

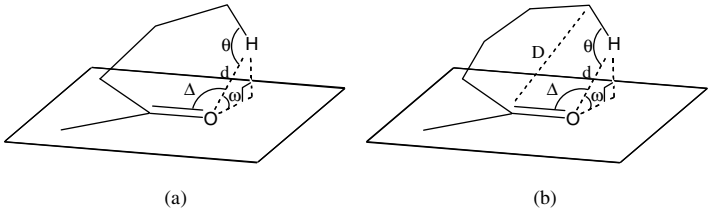


FIGURE 55.1 Definition of geometric parameters for γ-hydrogen abstraction (a) and those for δ-hydrogen atom abstraction (b).

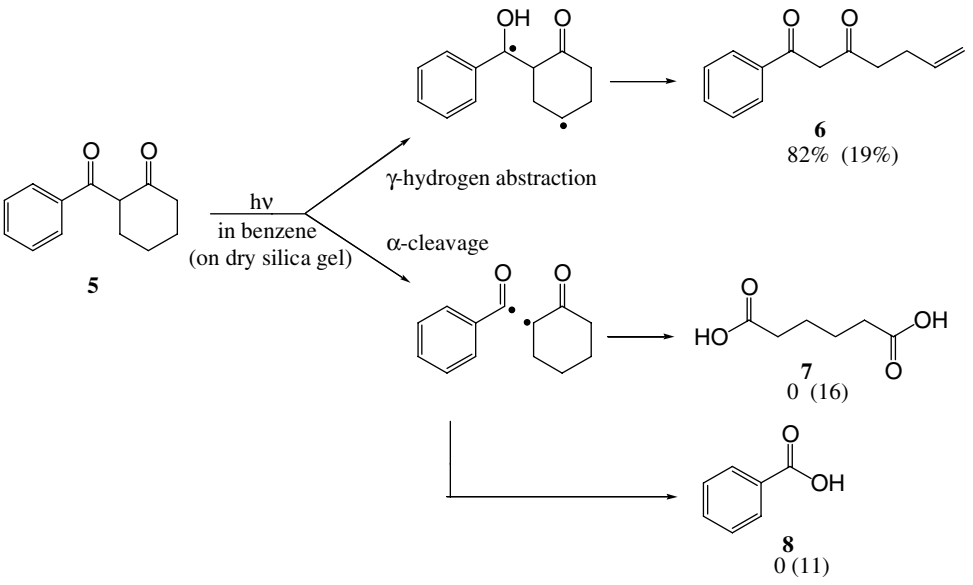
are the distance between the carbonyl oxygen and the γ-hydrogen, the C=O···H angle, the C–H···O angle, and the angle by which the γ-hydrogen atom lies outside the mean plane of the carbonyl group; their respective optimum values are 2.72 Å, 90° to 120° (depending on the hybridization of the orbitals containing the nonbonding electrons on oxygen), 180°, and 0°.[29] An additional parameter *D*, which represents the interatomic distance between the two carbon atoms and is expected to be 3.4 Å (the sum of the van der Waals radii of two carbon atoms), has been proposed for δ-hydrogen abstraction (Figure 55.1b).[30]

Conformational change might be restricted by adsorption of alkyl aryl ketones on a solid surface. Upon irradiation in benzene, 2-benzoylcyclohexanone undergoes the type II elimination to give **6** at an 82% yield (Scheme 3).[31] No cyclization products nor α-cleavage products are formed. On the other hand, the α-cleavage competes with the 1,4-biradical formation on a dry silica-gel surface.[32] A silica-gel surface may act as a possible field, bringing out the latent reactivity of dispersed molecules because of its adsorptivity and high polarity.[33] Although δ-hydrogen abstraction has been also observed on the surface,[34] remote hydrogen abstraction, which requires more conformational flexibility than γ- and δ-hydrogen abstraction, has not been observed so far.[35]

55.5 Environmental Effects on the Behavior of 1,4-Biradicals

Process Regenerating Starting Ketones

Quantum yields for disappearance of the starting material in the type II reaction of simple alkyl aryl ketones having the lowest n,π^* state in hydrocarbon solvents are usually in the range of 0.1 to 0.5.[5,8,30,36–38] The quantum yields show solvent dependency and rise to nearly unity in polar solvents.[5,6,36,38] This effect



SCHEME 3

is due to suppression of reverse hydrogen transfer, which regenerates the starting ketones from 1,4-biradicals, by hydrogen bonding between the hydroxyl group of the biradical and polar solvents.[2c,5]

In contrast to the behavior in solution, valerophenone shows equal quantum efficiencies in frozen solvents.[34] No significant interaction occurs between a solvent molecule and the OH group of a 1,4-biradical in frozen solvents. The frozen solvents provide passive cavities.[28,39] On the other hand, interfaces of micelles provide active cavities where guest molecules can be oriented through hydrophobic–hydrophilic interactions.[40,41] The quantum yield for the type II reaction of valerophenone in an aqueous hexadecyl tetramethyl ammonium chloride (HTAC) solution is unity.[40] A polar silica-gel surface also provides an active cavity[39] and would enhance the type II quantum efficiency.

Elimination vs. Cyclization

The percentage of cyclization in the type II reaction depends strongly on the structure of ketones and is in the wide range of 5 to 90%, even in simple alkyl aryl ketones.[11,30,37] The percentage increases with α-substitution, although β- and γ-substituents also exert a small influence.[30] Cyclization requires overlap of the orbitals on the ketyl and alkyl radical centers, whereas elimination requires overlap of the orbitals, with orbitals comprising the σ-bond undergoing cleavage. The 1,2-eclipsing interaction in 1,4-biradicals formed from α-substituted ketones is less severe in the transition state for cyclization than that for elimination.[30] Although polar solvents enhance the overall quantum yield of the type II reaction, the solvents decrease the total yield of cyclobutanols because of steric congestion in the solvated biradicals.[5,15] In frozen solvents, the rotation along the CC bonds becomes difficult, and large conformational changes are totally restricted. Transformation from the initially formed 1,4-biradical (*i*-**BR**) to the transoid biradical (*t*-**BR**), from which only elimination occurs, requires larger conformational changes than transformation to the cisoid biradical (*c*-$\mathbf{BR}_1$ or *c*-$\mathbf{BR}_2$). The ratio of type II elimination to cyclization (E/C) becomes lower in frozen solvents than in solution, and the ratio decreases with decreasing temperature (Table 55.2).[28]

The E/C ratio in a crystalline state is often quite different from that in solution. The cyclization predominates greatly over the elimination in the photolysis of **9** (Scheme 4, Table 55.3)[29,42] The x-ray crystallography of **9a–j** shows that all the ketones have the geometrical parameter *d* (see Figure 55.1a) nearly equal to the optimum value of 2.72 Å. The geometric data for the unreactive diketone **9a** are

virtually indistinguishable from those for reactive diketones **9c** and **9e**.[42] The lack of reactivity of **9a** in the solid state has been attributed to steric strain associated with closure to an eight-membered ring. In α-cyclohexyl-4-chloroacetophenone, the E/C ratio is 0.91 in the solid state, although the ratio is 0.37 in acetonitrile[43] and 0.64 in benzene.[44] The E/C ratios in the solid state must be determined by the geometry of the1,4-biradicals. The spiroketone **13a** undergoes type II elimination exclusively in the crystalline state to give **15**, whereas **13c** and ketone **17**[45] undergo cyclization (Scheme 5).[46] Compound **13b** shows efficient reverse hydrogen transfer in the crystalline state. The x-ray structure analysis of **13a–c** and **17** revealed that compound **13a** has favorable geometry for the elimination reaction.[46]

A silica-gel surface lowers the E/C ratio and allows only cyclization at low temperature (TLC and reverse-phase TLC in Table 55.4).[17] Inclusion of alkyl aryl ketones in zeolites and cyclodextrin (CD) changes the behavior of 1,4-biradicals. The reaction cavities of the zeolites are hard in the sense that they

are not flexible. The zeolites may be classified on the basis of pore (window) size: (1) zeolites having channel dimensions less than 6.5 Å (e.g., ZSM-5, ZSM-11, ZSM-34, and other offretites), and (2) zeolites having dimensions larger than 7 Å (e.g., X, Y, L, Ω-5, and M-5).[24] Only the type II elimination occurs in photolysis of alkyl aryl ketones in group 1 zeolites, whereas both elimination and cyclization occur in group 2 zeolites (Table 55.4). The preference for elimination in group 1 zeolites is due to suppression of cyclization. Large conformational change are not allowed in the small cavities of group 1 zeolites, although either the alkyl or aryl group must change positions when *i*-**BR**, from which the elimination would occur directly, transforms to *c*-**BR**.[24] An increase of cyclization products has been observed in photolysis of butyrophenone and valerophenone included in CD compared to photolysis in solution. Because addition of more than 1 equivalent of CD does not produce any significant variation in the product distribution, photoreactions occur from 1:1 complexes (Table 55.4).[47] Structures of the β-CD complexes with butyrophenone and valerophenone have been determined from x-ray crystallographic studies to be 2:2 β-CD/guest systems, and the complexes are regarded as reaction nanotubes.[48] Liquid crystals (LCs) are

considered to be very disturbed solids or ordered liquids.[49] Smectic and nematic LC has commonly been used as solvents for photoreactions of organic compounds. The E/C ratio in the type II reaction of valerophenone is larger in the smectic LC phase than in isotropic solvents (Table 55.4).[50] This might be due to slower interconversion between triplet biradical conformers in the smectic phase.

The type II reaction of *p*-alkylalkanophenones in *n*-butyl stearate has been studied.[51] The E/C ratio in the reaction depends on the length of their two-alkyl chains. The type II elimination occurs exclusively from alkyl aryl ketones on monolayer protected gold clusters (Scheme 6).[52] Although the ketones are not

in extremely rigid environments, but rather dynamic within the monolayer, the environment affects the equilibrium of the biradical conformers. Stringent demands must be made on the biradical to adopt *t*-**BR** over *c*-**BR** in the monolayer protected gold clusters. The type II elimination occurs in polymers of acrylophenones in solution[53a] and in the solid state.[53b] In the solid-state photoreaction of poly(4′-ethoxy-acrylophenone), the O–CH_2CH_3 bond cleavage from the lowest π,π^* state competes with the γ-hydrogen abstraction from the upper n,π^* state.[53b]

Stereochemistry of Cyclobutanols

The triplet biradicals *c*-$\mathbf{BR}_1$ and *c*-$\mathbf{BR}_2$ lead to the stereoisomeric cyclobutanols *t*-**CB** and *c*-**CB**, respectively, via ISC to the singlet biradicals that have very short lifetimes. The ratios of *trans*- to *cis*-cyclobutanol (*t*/*c*) in the type II reaction of alkyl phenyl ketones are in the range from 2 to 5 in nonpolar solvents (Table 55.5).[5,11,24,40,50] The ratios become smaller in polar solvents. The *t*/*c* ratio in the photolysis of valerophenone decreases from 3.6 in benzene to 1.35 in *t*-BuOH.[50] Formation of the *trans*-isomer, where the hydroxy group is *cis* to the γ-alkyl group, is suppressed in polar solvents because of steric interference between a hydrogen bonded solvent molecule and the alkyl group. The *t*/*c* ratio in a HTAC micellar solution is similar to that in polar solvents.[40] The average position of alkyl aryl ketones should be either on the micelle surface or in the Stern layer. The hydrogen bonding is formed between the 1,4-biradical and water on the surface or in the layer. The *t*/*c* ratio is also affected significantly by smectic LC order,

[a] **20**/(c-**19** + t-**19**)

[b] The sign of rotation of the predominant enantiomer of *c*-**19** at the sodium D-line.

whereas the ratio in the nematic phase is similar to that obtained from the type II reaction in isotropic liquid.[50] The *t*/*c* ratios in the type II reactions of the ketones included in zeolites are dependent on the cavity size of zeolites and cations within the cavities.[24]

Ketones **9a**–**j** undergo stereoselective photocyclization to give cyclobutanols in a solid state.[29,42] The *t*/*c* ratios show an increase and a decrease alternatively with an increase of the ring size of **9** (Table 55.3). Each addition of a methylene group between the two carbonyls in **9** changes the conformation around the γ-carbon. With this conformational change, the γ-hydrogen that is not abstracted alternates between being *syn* or *anti* to the carbonyl oxygen. The γ-hydrogen becomes the bridgehead methine that is either *cis* or *trans* to the hydroxy group in the **CB**.

Selective formation of an optically active cyclobutanol has been achieved in type II cyclization of salts of aminoketone **18** (Scheme 7).[54] While irradiation of the free aminoketone in benzene gives *c*-**19** (ϕ = 0.105), *t*-**19** (0.048), and **20** (0.120), little or none of *t*-**19** is produced when the salts formed between **18** and enantiomerically pure acids are photolysed in the crystalline state (Table 55.6). Enantiomeric excesses obtained for *c*-**19** are fairly good except for the *N*-Cbz-L-phenylalanine salt of **18**. The decrease in enantioselectivity with increasing conversion is due to the breakdown of the ordered crystal lattice as photoproducts replace starting material. The solid-state ionic chiral auxiliary approach may become one of general techniques for asymmetric synthesis in organic photochemistry.

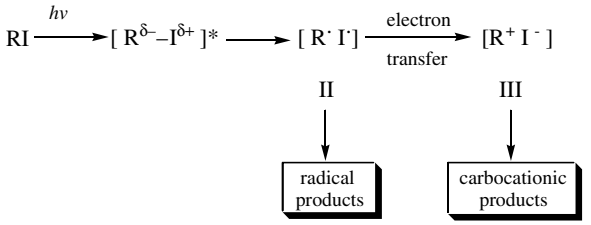
56.1 Introduction

Organic photochemical synthesis has developed to an important and pervasive field within current organic chemistry. In photochemical reactions and photobiological reactions, electron transfer, transfer of excited energy, and photoinduced intramolecular and intermolecular isomerizations are important and fundamental.[1] Photolysis, photosynthesis, photopolymerization, and photochemical isomerization arise by excited atoms and molecules under irradiation by light. These reactions are different from reactions carried out thermally, under pressure, or by catalysis.

We have been investigating an iodination method using iodine–copper(II) acetate and iodine–ammonium cerium(IV) nitrate (CAN) to synthesize iodoletones.[2] These iodoketones are more active than chloro- and bromoketones, and it was found that they are unstable and sensitive to light. From the viewpoint of green chemistry,[3] we have tried to transform these iodo compounds into useful products by photochemical methods.

After many years of investigation of the photochemistry of alkyl halides RX (X = Cl, Br, I),[4] it was found that the photochemical reaction of alkyl iodides in nonpolar solvent leads to radical products;[5] in polar solvent, to carbocationic products (Scheme 1).[6] Photoinduced alcoholysis and photodehalogenation of α-halo ketones (X = Cl, Br) in alcohols have been investigated by Tomioka et al.[7] In their interesting work on photosolvolysis of α-halo ketones, they proposed that the homolysis of CX bonds produces a

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1

radical pair, which may undergo radical reaction or electron transfer to afford an ion pair. This pair would then undergo carbocationic reactions. A little information is found in the literature concerning the photochemical reactions of α-halocycloalkanones. Orito et al.[8] reported that the photolysis of α-bromocamphor in methanol provides a dimerized α-camphorylcamphor derivative. However, the photochemical reactions of α-iodo cyclic ketones have not been reported until now.

The purpose of this study is to transform these iodo compounds into useful products using photochemistry with a high-pressure mercury lamp ($\lambda > 300$ nm). The subjects of the study are classified into five areas:

1. Irradiation of α-iodocycloalkanones in some alcohols afforded the corresponding ω,ω-dialkoxy esters by photochemical cleavage of the C(X)–C=O bond at room temperature.[9]
2. α-Iodo- and α,α′-diiodocycloalkanone were irradiated in alcohol under the presence of air to give the corresponding α-hydroxy- and α,α′-dihydroxyketones in good yields.
3. Irradiation of α-iodoketones (steroidal α-iodoketones, α-iodoketones, and α,α′-diiodoketones) in hexane under a nitrogen atmosphere at room temperature yields the corresponding α,β-unsaturated ketones.[10]
4. Cycloalkanones and 1-tetralone were irradiated in alcohol to give the corresponding pinacol-type compounds in good yields.[11]
5. Camphorquinone was irradiated under oxygen with a high-pressure mercury lamp to give camphoric anhydride in good yields.[12]

ω,ω-Dialkoxy ester derivatives are important intermediates in organic synthesis.[13] Some syntheses of ω,ω-dialkoxy ester involve regiospecific oxidative ring cleavage of cycloalkenes with ozone in various alcohols;[14] ring-opening oxygenation on treatment with lead(IV) acetate,[15] sodium periodate,[16] perbenzoic acid,[17] iron(III) salt,[18] and oxovanadium(V)[19] in alcohol under oxygen; and electrochemical oxidative cleavage of α-substituted cycloalkanones and cycloalkanone enol acetates.[20] Our co-workers reported that the reaction of α-alkylcycloalkanones with iodine–cerium(IV) salts[21] and cerium(IV) salts[22] in alcohol yields the corresponding oxo ester and ω,ω-dialkoxy ester. Most of these processes suffer from disadvantages by using toxic reagents and heavy metals; consequently, development from the viewpoint of green chemistry is needed.

The photochemistry of organic halides RX (X = Cl, Br, I) has been intensively investigated for many years, as it became clear that cationic, as well as free-radical, intermediates play an important role in the solution-phase photochemistry of these halides.[4] Competing ionic and radical photobehavior has been observed for haloalkenes and cycloalkyl halides.[6,23]

In this chapter, we report that the irradiation, under a high-pressure mercury lamp, of α-iodocycloalkanones **1** to **7** in alcohols containing a small amount of water gave the corresponding ω,ω-dialkoxy esters **1c–10c** by cleavage of a CC bond. Moreover, it was found that photochemical ring opening can take place, and 2-hydroxycycloalkanones and formyl esters are intermediates.

It is known that α-hydroxyketones are important as intermediates for organic synthesis. In order to increase the yield of an α-hydroxyketone we carried out a detailed investigation of the reaction conditions. The reaction of α-iodo- and α,α′-diiodoketone using photoirradiation in alcohols, hexane, and acetone, etc. in the presence of air afforded the corresponding α-hydroxy- and α,α′-dihydroxy ketones in good yield.

α,β-Unsaturated ketones are also important intermediates in many addition reactions involving the addition of nucleophiles at the β-position under the influence of the inductive polarization of a carbonyl group. They are usually prepared by one of the following methods in steroidal systems: dehydrobromination of α-bromoketones by the treatment of nitrogenous bases and by lithium salts,[24] dehydrogenation of a steroidal ketone using DDQ (dichlorodicyano quinone) in boiling benzene,[25] or dehydrogenation of 3-oxo steroids using selenium dioxide in *t*-butyl alcohol.[26] However, in the case of a steroidal α,β-unsaturated ketone, it is known that these reactions tend to give abnormal products (i.e., α′, β′-unsaturated ketones).[27] It is difficult to separate these isomers because they have similar properties.

We observed that the irradiation of α-iodoketones in hexane under a nitrogen atmosphere with a high-pressure mercury lamp ($\lambda > 300$ nm) at room temperature yields the corresponding α,β-unsaturated ketones, accompanied by some deiodination products. Moreover, it was shown that the reaction was dependent upon the media used, and such changes resulted in different photoproduct distribution.

During the course of our studies, we found that cyclic ketones undergo a novel self-coupling reaction brought about by irradiation using a high-pressure mercury lamp. This yields the corresponding pinacol-type compound in good yields. Moreover, we determined that camphorquinone undergoes a novel unsensitized photooxidation in polar solvents such as alcohol under oxygen to give camphoric anhydride in 85% yield.

56.2 Photocleavage of Carbon–Carbon bonds of α-Iodocycloalkanones Giving ω,ω-Dialkoxy Esters in Alcohol

The photochemical reaction of α-iodocycloalkanones **1** to **7** in methanol, brought about by irradiation with a high-pressure mercury lamp at room temperature, afforded predominantly photocleavage products, methyl ω,ω-dimethoxyalkanoates **1c** to **10c**, in good yields. These reactions did not occur under the same conditions in the absence of light. Similarly, the reaction of α-iodocyclododecanone **6** in ethanol, 1-propanol, and 2-propanol yielded the corresponding ω,ω-dialkoxyalkanoates. These results are summarized in Scheme 2 and Table 56.1.

14	**7**	MeOH	100 W	20	**10c** (73)[d]
15	**7**	MeOH	400 W	20	**10c** (75)

[a] Substrate (15.7 mmol/l) in hydrous alcohol (0.02%) was employed.
[b] Reactions were carried out with high-pressure mercury lamp as irradiation source under a nitrogen atmosphere.
[c] Isolated yields. n = no obtained.
[d] Traces of methyl 6-formylhexanoate (**4b**), methyl 7-formylheptanoate (**5b**),[25a] methyl 11-formylundecanate (**6b**), ethyl 11-formylundecanoate (**7b**), and 14-formyltetradecanoate (**10b**) were obtained, respectively.

On the basis of these results, it was found that the photochemical cleavage of the carbon–carbon bond occurred between the C1 and C2 positions of α-iodocycloalkanones to give finally ω,ω-dialkoxy esters **1c** to **10c** in 65 to 88% yields. Also, it was found that in methanol the yield of the ring-opened product, methyl 12,12-dimethoxydodecanoate **6c**,[13,19a] was higher and the reaction proceeded faster than in other alcohols (entries 6 to 11). However, isopropyl 12,12-diisopropoxydodecanoate **9c** was not obtained from the reaction in 2-propanol, and isopropyl 11-formylundecanoate **9b** and 2-hydroxycyclododecanone **6a** [19] were formed in 65 and 15% yields (entries 12, 13), respectively. It seems that acetalization of **9b** with 2-propanol is difficult due to the bulkier alkoxy group. The ^{1}H nuclear magnetic resonance (NMR) spectra exhibited the presence of a formyl group δ 9.76 (t, J = 1.83 Hz, CHO). It is particularly noteworthy that this photoreaction provides a new synthetic method for ω,ω-dialkoxy esters that is more convenient and cleaner than many methods reported heretofore.[13–21] Therefore, the new photocleavage products, **7c, 8c**, and **9b** were obtained from α-iodocyclododecanone in ethanol, 1-propanol, and 2-propanol containing a small amount of water.

In order to investigate the reaction pathway of photocleavage for α-iodocycloalkanones in alcohol, irradiation of **6** was carried out. The results are summarized in Tables 56.2 and 56.3. It was found that the relative ratios of the photochemical products depend on the reaction conditions. Irradiation of **6** for 3 hr in MeOH–H_2O (0.02%) with a 100-W, high-pressure mercury lamp gave **6a**, methyl 11-formylundecanoate **6b**,[13,28] and **6c** in 33, 38, and 7% yields, respectively. (Table 56.2, entry 1). On irradiation of **6** for 12 hr, products **6a** and **6b** were minor, and the major photoproduct **6c** was obtained in 87% yield (Table 56.2, entry 4). When a 400-W, high-pressure mercury lamp or a commercial fluorescent lamp was used, the same behavior was observed for **6** (Table 56.2, entries 5 to 9). From these results, it was found that in the cases of a high-pressure mercury lamp and a commercial fluorescent lamp as irradiation sources, the photocleavage product methyl 12,12-dimethoxydodecanoate **6c** was obtained preferentially.

From the above results, it seems that **6a** and **6b** are intermediates for **6c**. Formation of **6a** may be due to the presence of a small amount of water in methanol. In order to clarify this hypothesis, irradiation of **6** was carried out in absolute methanol and hydrated methanol. As can be seen from Table 56.3, the irradiation of **6** in absolute methanol gave the photoalcoholysis product 2-methoxycyclododecanone **6d** (65%), accompanied by the reduction product cyclododecanone **6e** (17%) and the elimination product

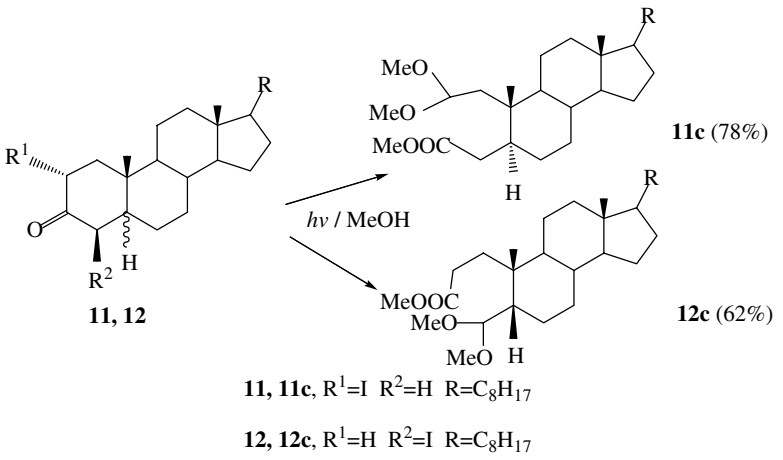
[a] A deoxygenated solution (15.7 mmol/l) of α-iodocyclododecanone (**6**) in methanol were irradiated until complete consumption of substrate **6** which was apparent by TLC.
[b] The high-pressure mercury lamp in a water-cooled quartz immersion well as irradiation source.
[c] Isolated yields after purification by column chromatography on silica gel.
[d] Reactions were carried out with a commercial fluorescent lamp.
[e] Methanol was dried completely by stored over 4A molecular sieves.
[f] The 2 ml water was added in methano (150 ml). t = trace.

2-cyclododecen-1-one **6f** (8%)[29] (Table 56.3, entry 1). However, in methanol containing 0.6 or 1.2 molar equivalents of water, the ring-opening product **6c** was obtained in 84 and 85% yields, respectively (Table 56.3, entries 4 and 5), while with methanol containing water (0.01%), the reduction product **6e** and the elimination product **6f** were obtained (Table 56.3, entry 3). From these results, the influence of water on the photochemical reaction of α-iodocycloalkanones is clear.



SCHEME 3

2α-Iodo-5α-cholestan-3-one (**11**) and 4β-iodo-5β-isomer (**12**) were also irradiated with a high-pressure mercury lamp under the same conditions, and the results are shown in Scheme 3. From these results, it was determined that the reaction of **11** and **12** gave methyl 2,2-dimethoxy-2,3-seco-5α-cholestan-3-oate (**11c,** 78%) and methyl 4,4-dimethoxy-3,4-seco-5β-cholestan-3-oate (**12c,** 62%),[4,30] respectively. These results show that the photocleavage reaction is also operative with steroidal α-iodoketones. Moreover, the photocleavage reaction is preferred to the oxidative ring cleavage reaction.[4]

Kropp and his co-workers[6] reported competing ionic and radical photobehavior for a number of alkyl halides. Photolysis of α-halo ketones (ROCCX) is understood to proceed via competing homolysis of CC and CX bonds as the primary processes.[4] Tomioka et al.[7] also proposed that irradiation of α-halo ketones in alcohols brings about competition between ionic and radical reaction paths with the formation of photoalcoholysis and photoreduction products. During the course of our studies, it was found that irradiation of α-iodocycloalkanones in the nonpolar solvents (e.g., hexane) afforded mainly the elimination product, an α,β-unsaturated cyclic ketone, accompanied by a small amount of photoreduction product.[10] Therefore, it is considered that this photochemical behavior can be explained as shown in Figure 56.1 on the basis of the results mentioned above.

As can be seen from Figure 56.1, irradiation of α-iodocycloalkanones generates the radical pair (I) via a process involving light-induced homolytic cleavage of the CI bond.[6,22] In polar solvents, electron transfer competes efficiently to produce an ion pair (II) and then photosubstituted product **6a** is formed preferentially. This product is formed by nucleophilic trapping of the ion pair (II). Under the present irradiation conditions, the ring opening of **6a** by cleavage of the C1C2 bond gives secondary photoproduct, the formyl ester, which probably arises from the biradical pair (III) by electron transfer and intermolecular addition of alcohol. It seems that these formyl compounds undergo ready acetalization to afford stable products.

Suginome et al.[31] reported that the irradiation of α-hydroxy cyclic ketones with mercury(II) oxide and iodine in benzene gives CC bond cleavage products. On the basis of our results, it is considered that this reaction proceeds through photocleavage of the C(OH)–C=O bond of **6a** after displacement of iodide by hydroxide ion, followed by acetalization (Scheme 4). Although the reason has not yet been clarified, it seems that α-iodo groups of cycloalkanones are essential for the cleavage reaction of the CC bond.[32] Thus, in the case of **6a** in methanol containing iodine and HI, the methyl ω,ω-dimethoxy ester was obtained. This fact apparently supports the validity of **6a** as intermediate (Figure 56.2).

In order to investigate the photochemical behavior of iodo-substituted aromatic compounds, 2-iodo-1-tetralone **17** was chosen as a model. The irradiation of **17** in methanol gave 1-naphthanol **17g** and 1-tetralone **17e**. These results are summarized in Table 56.4. From these results, it was found that the photochemical behavior is quite different compared to α-iodocycloalkanones. Moreover, the photochemical products are not affected by the polarity of the solvents used. It seems that **17** undergoes aromatization

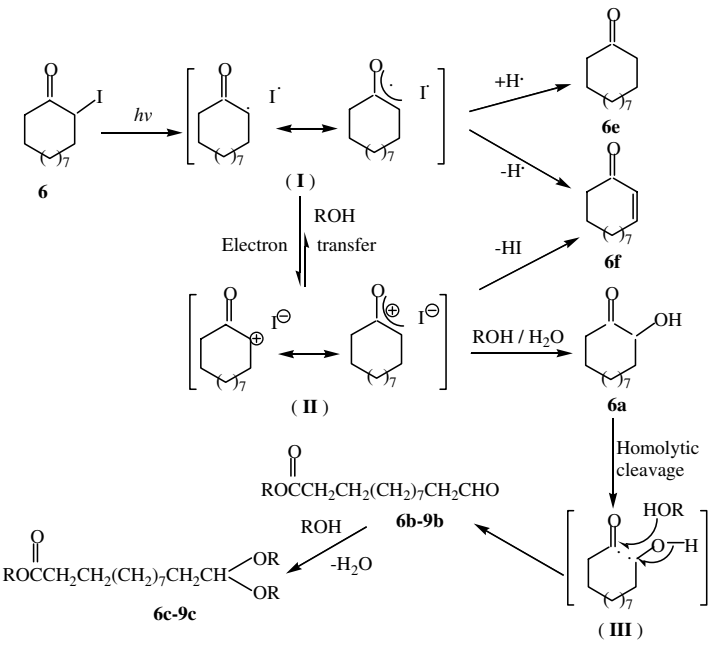


FIGURE 56.1 Photochemical cleavage behavior of α-iodocyclododecanone.

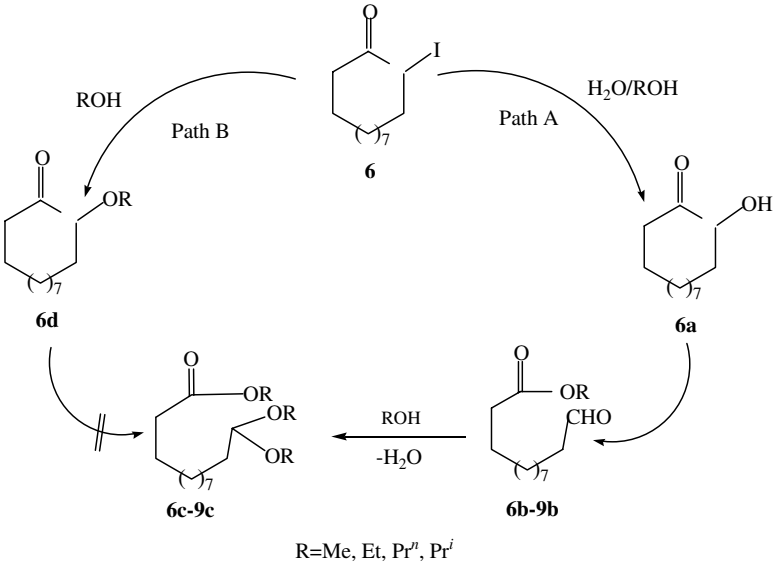

SCHEME 4 Photochemical process of α-iodocycloalkanones.

rather than CC bond cleavage. In the presence of 1 molar equivalent of triethylamine, the formation of the aromatized product **17g** is greatly enhanced (Table 56.4, entry 3).[7f]

For comparison, the reactivity of the α-iodo cyclic ketone was compared with that of the corresponding chloro and bromo derivatives, and the results are summarized in Table 56.5. On the basis of these results, it was found that irradiation of 2-chloro- (**13**) or 2-bromocyclohexanone (**14**)[33] afforded mainly acetalization

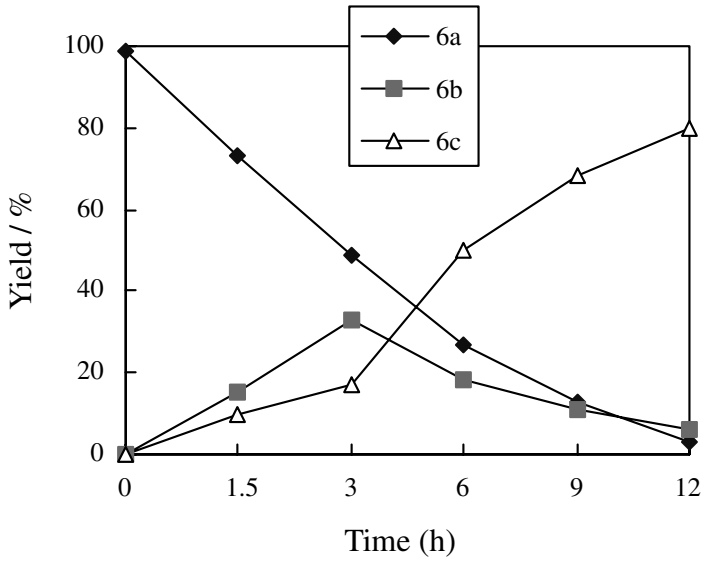

FIGURE 56.2 Yields of **6b** and **6c** during irradiation of **6a** in degassed methanol.

[b] Isolated yields.

products 2-chloro- (**13h**) or 2-bromo-1,1-dimethoxycyclohexane (**14h**)[2d] in 90 and 85% yields, respectively. It is suggested that the difference in the reactivity of the iodo compound, compared with the bromo and chloro derivatives, is due to the weaker CI bond and the ease with which this undergoes photochemical reaction.

In conclusion, we have encountered a novel photochemical cleavage reaction of α-iodocycloalkanones in alcohols using a high-pressure mercury lamp and a commercial fluorescent lamp. This reactivity results in an efficient and direct synthesis of ω,ω-dialkoxyalkanoic esters. It is noteworthy that the present photocleavage reaction affords a new synthetic method that is more convenient and cleaner than methods used previously.

56.3 Synthesis of α-Hydroxy- and α,α′-Dihydroxyketone from α-Iodo- and α,α′-Diiodoketone Using Photoirradiation[34]

α-Hydroxy ketones are usually prepared by one of the following methods: α-hydroxylated by treatment of their enolate forms with a molybdenum peroxide reagent in THF-hexane at –70°C,[35] transformation of enamine derivatives of ketones to α-hydroxy derivatives by molecular oxygen,[36] and α-hydroxylation of silyl enol ethers with *m*-chloroperbenzoic acid[37] or with other oxidizing agents.[38]

Considerable interest has been expressed in the development of direct methods for the synthesis of α-hydroxy ketones using nontoxic hypervalent iodine reagents and which involve the following methods: reaction of a ketone with iodobenzene diacetate in the presence of potassium hydroxide in methanol and then hydrolysis of the dimethylacetals;[39] oxidation of the enol silyl ether of acetophenone using the system iodosobenzene/boron trifluoride etherate/water in methylene chloride at –40°C;[40] and reaction of ketones with [*bis*(trifluoroacetoxy)]iodobenzene and trifluoroacetic acid in acetonitrile–water under acidic conditions.[41]

We have found that the photocleavage of the CC bond of α-iodocycloalkanones in alcohol gives ω,ω-dialkoxy esters via the intermediacy of α-hydroxy ketones. In order to increase the yield of the α-hydroxyketone, we carried out a detailed study of the reaction conditions employed. The reaction of α-iodo- and α,α′-diiodoketone using photoirradiation in, for example, alcohols, hexane, and acetone in the presence of air afforded the corresponding α-hydroxy- and α,α′-dihydroxy ketone in good yield.

The irradiation of α-iodoketones (**1**, **4**, **5**, **6**) in a solvent at room temperature under an atmosphere of air with a 400-W mercury lamp for 2 to 20 hr gave the corresponding α-hydroxy ketones (**1a, 4a** to **6a**) in good yields. These results are summarized in Table 56.6, which shows that the α-hydroxy ketones are formed preferentially when triethylamine is added. Moreover, this reaction affords hydroxydiosphenol present in buchu oil obtained from the leaves of *Barosma betulina* Bartl. (mountain buchu) (Table 56.7).

It is interesting that, in the case of α,α′-diiodoketones, α,α′-dihydroxyketones were obtained in good yields. The reaction of α,α′-diiodoketones (**23** to **26**) in acetone afforded the corresponding α,α′-dihydroxyketones (**23a′** to **26a′**) in good yield. These results are summarized in Table 56.8. On the basis of these results, it is interesting that, for the first time, we have succeeded in developing a novel and convenient synthesis of α,α′-dihydroxyketones.

56.4 Synthesis of α,β-Unsaturated Ketones from α-Iodoketones Using Photoirradiation

The photochemical reaction of steroidal α-iodo ketones **11**, **12**, **27**, **28**, and **29** in hexane under a high-pressure mercury lamp gave the corresponding steroidal α,β-unsaturated ketones **11f**, **12f**, **27f**, **28f**, and **29f** under a nitrogen atmosphere at room temperature. These results are summarized in Table 56.9, where it is seen that 5α-steroidal α-iodo ketone derivatives **11**, **28**, and **29** gave α,β-unsaturated ketones **11f**, **28f**, and **29f** in higher yield than the 4β-iodo-5β-isomer (**12**) under the same conditions (Table 56.9, entries 3, 5, 7, and 8). It is considered that the difference is due to the stereochemical structure of the 5α- and the 5β- isomers.[42] In the presence of a 1 molar equivalent of triethylamine[6c] in hexane, a marked increase of 5α-cholest-1-en-3-one (**11f**) for 2α-iodo-5α-cholestan-3-one (**11**) could be observed (Table 56.9, entries 1 and 2). In the absence of light, the reaction did not occur.

Extension of the reaction to α-iodocycloalkanones (**1** to **6**) also demonstrated that these compounds reacted to give α,β-unsaturated ketones (**1f** to **6f**). These results are summarized in Table 56.10, where it can be seen that the medium-sized ring α-iodocycloalkanones (**1** to **5**) gave the α,β-unsaturated ketones (**1f** to **5f**) in higher yield (72 to 80%) than the macrocyclic α-iodoketone (**6**). Similarly, the irradiation of α-iodo acyclic ketones (**19** and **30**) and α,α′-diiodoketones (**24** and **26**) gave the corresponding α,β-unsaturated ketones (**19f** and **30f**) and α,β,α′,β′-dienone derivatives (**24f′** and **26f′**) (Table 56.11). Thus, we have demonstrated that this method is applicable to the synthesis of α,β-unsaturated ketones from α-iodocycloalkanones, α-iodo acyclic ketones, and α,α′-diiodoketones.

Reaction conditions: Substrate (0.1 mmol) in solvent (10 ml) was irradiated by High Pressure Mercury Lamp (400 W) under air.

[a] Yields were determined by GLC.

α-Iodocyclododecanone (**6**) was chosen as a model compound to study the effect of solvents on the photochemical reaction of α-iodoketones, as we have sought to decrease the formation of the reduced ketones. It was thought that the α-iodoketone is reduced by hydrogen iodide. In order to justify this explanation, we carried out a reaction in the presence of an amine to remove HI from the reaction mixture. The reaction of **6** in hexane containing triethylamine (1 molar equivalent) at room temperature under a nitrogen atmosphere with a 400-W high-pressure mercury lamp for 2 hr gave 2-cyclododecen-1-one (**6f**) and cyclododecanone (**6e**) in 70 and 30% yields, respectively. These results are summarized in Table 56.12, and it is obvious that the presence of triethylamine and pyridine increased the yield of α,β-unsaturated ketone (**6f**) (Table 56.12, entries 1 and 2). Entry 4 in Table 56.12 shows that the use of hexane containing hydrogen iodide increases the yield of the reduced product. These observations support the proposal that HI is involved in the formation of the reduced ketone.

Irradiation of alkyl iodides in solution is a powerful and convenient method for the generation of carbocations via a process thought to involve light-induced homolytic cleavage of the carbon–iodine bond followed by electron transfer within the initially formed caged radical pair.[7f,43] Kropp et al.[6] reported that irradiation of 1-iodooctane in a variety of solvents affords mainly 1-octene accompanied by small amounts of octane and substituted octane. It appeared that α-iodoketone would be a more reactive substrate than the alkyl iodide. The reaction containing benzophenone (Table 56.12, entry 3) preferentially gave ketone **6e** due to hydrogen abstraction and protonation. In the case of benzene or acetonitrile, it was found that ketone **6e** is increased (Table 56.12, entries 11 and 12).

competition of both substitution and elimination reactions. Similarly, irradiation of **6** in hexane containing a small amount of water for 576 hr under a commercial fluorescent lamp as the irradiated light source gave predominantly **6a** in 50% yield. Therefore, it seems that dried hexane is an excellent solvent for the photosynthesis of α,β-unsaturated ketones from α-iodocycloalkanones.

In nonpolar solvents, electron transfers become unfavorable, and the escape of intermediates from the solvent cage leads to radical products.[5] In polar solvents, electron transfer competes efficiently with escape from the solvent cage to produce an ion pair and ultimately products derived from carbocations.[6] During the course of our studies, it was found that irradiation of α-iodoketones in hexane mainly afforded the elimination product α,β-unsaturated ketones. In the presence of a small amount of water in hexane, an α-substituted product was also obtained; therefore, the general photochemical behavior of α-iodoketones can be explained in Figure 56.1 on the basis of the results described above.

Figure 56.1 shows that irradiation of α-iodoketones involves light-induced homolytic cleavage of the CI bond proceeding to the radical pair (I) in solvents. When hexane is used, α,β-unsaturated ketone **6f** and reduced product **6e** are obtained by elimination and reduction. These processes involve free radicals.[5] However, in the presence of a small amount of water in hexane, the radical pair (I) can undergo subsequent electron transfer to afford the ion pair (II); ultimately, the substituted product 2-hydroxycyclododecanone is formed.[6]

In conclusion, this method is very clean, simple, and convenient for the synthesis of α,β-unsaturated ketones. It is particularly noteworthy that this reaction affords a new synthetic method for the synthesis of steroidal α,β-unsaturated ketones. The reaction is more convenient than the methods described previously.

[j] 2-Hydroxycyclododecanone(**11c**) was obtained.
[k] Contained 0.1 molar equiv. of 57% hydroiodic acid.

56.5 A Novel Self-Coupling Reaction of Cyclic Ketones Under High-Pressure Mercury Lamp

Pinacol type 1,2-diols can be synthesized by reduction of ketones and aldehydes with active metals (sodium, magnesium, or aluminum),[44] Mg–MgI_2,[45] SmI_2,[46] Ce–I_2,[47] Yb,[48] and a reagent prepared from $TiCl_4$ and Mg amalgam.[49] Again, some of these methods use toxic reagents and heavy metals. However, it is known that the dimerization of ketones to 1,2-diols can be accomplished by photochemical methods. These are usually the irradiation of aromatic aldehydes and dialkyl ketones in the presence of a hydrogen donor such as 2-propanol, toluene or amines.[50]

The pinacol-type 1,2-diols of cycloalkanone are usually prepared by one of the following methods: reduction of ketone in THF with [Mg–Hg]/$TiCl_4$,[51] reaction of magnesium atoms with cycloheptanone,[52] pinacolization of cyclohexanone using samarium(II) bromide,[53] and reductive coupling of carbonyl compounds to pinacols using low-valent cerium;[47] however, these methods are not applicable to cyclododecanone. Nickon and Zurer[54] reported that reductive coupling of cyclododecanone with $TiCl_4$ and Zn in THF and pyridine gave 1,1-bicyclododecanol (16%).

We have observed that the irradiation of cycloalkanones (cyclohexanone **1e**, cycloheptanone **4e**, cyclooctanone **5e**, cyclodecanone **5′e**, cyclododecanone **6e**, 2-methylcyclohexanone **31e**, 2-phenylcyclohexanone **32e**, α-tetralone **17e**, 5α-cholestan-3-one **11e**, and 5β-cholestan-3-one **12e**) in methanol under a nitrogen atmosphere with a high-pressure mercury lamp ($\lambda > 300$nm) at room temperature yields the corresponding pinacol 1,2-diols. The irradiation of cyclododecanone **6e** in methanol at room temperature under nitrogen atmosphere with a 400-W mercury lamp for 4 hr gave 1,1-bicyclododecanol **6l** (84%) and cyclododecanol **6k** (8%). These results are summarized in Table 56.13, where it can be seen that the

2-Phenylcyclohexanone (**32e**)	MeOH	100 W	30	Dimethyl Acetal (**32h**) (33)
4-Methylcyclohexanone (**33e**)	MeOH	100 W	18	Dimethyl Acetal (**33h**) (91)
5?-Cholestan-3-one (**11e**)	MeOH	400 W	12	Dimethyl Acetal (**11h**) (87)
5?-Cholestan-3-one (**12e**)	MeOH	400 W	10	Dimethyl Acetal (**12h**) (85)

[a] Substrate (3.23 mmol) in alcohol (200 ml) was employed.
[b] All products displayed satisfactory spectral data (IR, ^{1}H-NMR, ^{13}C-NMR, and MS).
[c] Isolated yield.
[d] MeOH: H_2O = 20:1.

method is applicable to some cycloalkanones. There are limitations, however, and cyclohexanone **1e**, 2-methylcyclohexanone **31e**, 2-phenylcyclohexanone **32e**, 4-methylcyclohexanone **33e**, 5α-cholestan-3-one **11e**, and 5β-cholestan-3-one **12e** do not form the corresponding pinacols. Instead, the dimethyl acetals **31h**, **32h**, **33h**, **11h**, and **12h** are formed in 92, 76, 33, 87, and 85% yields, respectively. Also, cyclodecanone (**5′e**) affords cyclodecanol in 65% yield. Moreover, when 2-propanol is used as the solvent, **1e** is transformed to cyclohexanol **1k** but not to the diisopropyl acetal. The reaction of benzaldehyde **34** in methanol at room temperature under the same conditions gave pinacol **34m** (31%) and phenyl-1,2-ethanediol **34n** (69%). These results are summarized in Table 56.14.

The photoreduction of benzophenone in methanol and ethanol gives benzopinacol and a cross-coupled product.[55] Moreover, Weiner reported that photoreduction of benzophenone in 2-propanol yields a pinacol-type compound and the mixed pinacol $(C_6H_5)_2C(OH)C(OH)(CH_3)_2$.[56] These reactions occur by the free ketyl radicals.

The reaction of benzaldehyde **34** in methanol gave the cross-coupling diol, phenyl-1,2-ethanediol **34m** (69%) and pinacol **34a** (31%); however, due to the bulkiness of the alkoxyl group (methanol, ethanol, 1-propanol and 2-propanol), it is difficult to form the cross-coupled product.

In conclusion, the present method, while not widely applicable, has a notable characteristic that was not observed previously.[4,11] This reaction affords a new simple synthetic method for the pinacols of cycloheptanone, cyclooctanone, and cyclododecanone. It is particularly noteworthy that this reaction is a new, clean method.

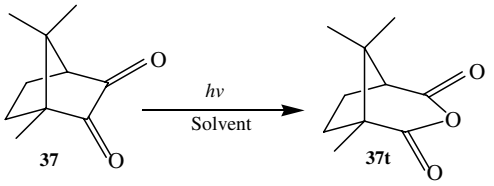
[a] All products displayed satisfactory spectral data (IR, ^{1}H-NMR, ^{13}C-NMR, and MS).
[b] Almost quantitative yields of the pinacol and the cross-coupling diols were obtained. The composition of the reaction mixture was determined from the peak area ratio of the NMR spectrum.

56.6 Synthesis of Camphoric Anhydride Via Unsensitized Photooxidation of Camphorquinone

The photochemical reactions of carbonyl compounds has been thoroughly investigated and the behavior is well established.[57] Some ketones show different photochemical behavior on a silica gel surface from that in solution as reported by Hasegawa et al.[58] Scheffer et al.[59] reported that the irradiation of an

TABLE 56.15 Irradiation of Camphorquinone (**37**) Under an Oxygen Atmosphere at Room Temperature[a]



Entry	Condition	Method[b] (W)	Time (h)	Yields[c] (%)
1	MeOH/Ar	100	12	N.R.

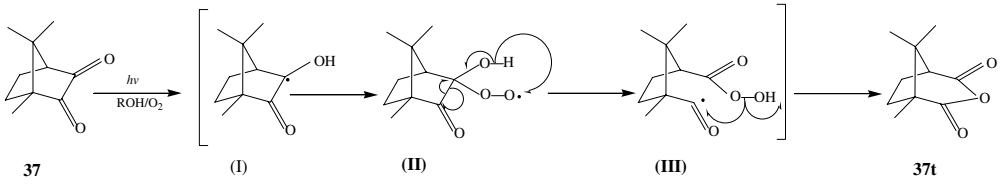
8	CH_2Cl_2/O_2	100	14	N.R.

[a] Camphorquinone (3.14 mmol) in solvent (200 ml) was employed.
[b] Reaction was carried out with a high-pressure mercury lamp in a water-cooled quartz immersion well as the irradiation source.
[c] Isolated yields after purification by column chromatography on silica gel and was identified by satisfactory spectral data (IR, NMR, and HRMS). N.R. = did not react.
[d] n-Hexane was dried completely by storing over 4A molecular sieves.

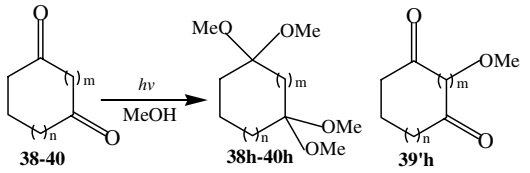


SCHEME 5 Reaction mechanism of camphorquinone (37).

α-diketone brought about a novel photorearrangement in the crystalline state that is different from the Norrish/Yang type II photocyclization process observed in solution. We have observed that direct irradiation of camphorquinone under oxygen with a high-pressure mercury lamp afforded the camphoric anhydride in good yield in a novel reaction. The unsensitized photooxidation of (1*R*)-(−)-camphorquinone gave (+)-*cis*-camphoric anhydride in 85% yield. These results are summarized in Table 56.15. The photoreaction is very simple, clean, and convenient for the synthesis of camphoric anhydride. In the case of methanol and ethanol as solvents, irradiation of camphorquinone **37** gave the camphoric anhydride **37t**[31] in 80 to 85% yields, respectively (Table 56.15, entries 1–4, 7); however, the product **37t** was not obtained under an atmosphere of argon (entry 1). When hexane was used as the solvent under oxygen, the product **37t** was not formed (entry 5). These results indicate that solvent-polarity is important for the success or failure of the unsensitized photooxidation of camphorquinone.

Suginome et al.[31] reported that the irradiation of α-hydroxy cyclic ketones with mercury(II) oxide and iodine in benzene gives camphoric anhydride.[31] On the basis of our results, it is considered that anhydride **37t** can be formed through an intermediate (III) that is formed through the cleavage of a CC bond in radical (II). This is followed by migration of hydrogen. The polar solvent is important role for the generation of radical (I) (Scheme 5). The reactivity of the cyclic diketone was compared with that of the

TABLE 56.16 Irradiation of Cyclic Diketones in Methanol at Room Temperature[a]



38-40 **38h-40h** **39'h**

Entry	Substrate	Method (W)	Time (h)	Product	Yield[b] (%)

[b] Isolated yield and all products were identified by satisfactory spectral data (IR, NMR, and HRMS).

cyclohexanedione derivatives, and the results are summarized in Table 56.16. These results show that the photochemical behavior, under identical conditions, is quite different compared with camphorquinone (**37**). The influence of stereochemistry could be important in this case. In conclusion, we have observed that camphorquinone undergoes a novel unsensitized photooxidation, which provides a more efficient, simple, and clean method for the synthesis of camphoric anhydride than the method used heretofore.

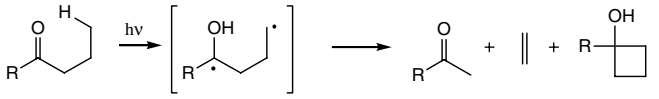
Regioselective Photochemical Synthesis of Carbo- and Heterocyclic Compounds: The Norrish/Yang Reaction

Pablo Wessig
Humboldt University Berlin

57.1 Introduction

Photochemical reactions of the carbonyl group are among the most extensively investigated areas of organic photochemistry. In this chapter, the regioselective route to a variety of carbocyclic and heterocyclic compounds by means of the Norrish/Yang reaction are discussed. The main emphasis is on preparative applications. First, the history of this reaction is briefly outlined. In 1934, Norrish and Appleyard observed, upon irradiation of aliphatic ketones, a cleavage reaction providing products whose alkyl chain was cleaved between the α- and the β-carbon atom with respect to the carbonyl group.[1] Today, this cleavage reaction is referred to as *Norrish type II cleavage*. As a result of the limited analytical capabilities almost 70 years ago, Norrish and Appleyard did not identify any cyclization products that are formed in competition with the cleavage process. Yang and Yang were the first to recognize, in 1958, the formation of cyclobutanes as well as the Norrish type II cleavage products.[2] This discovery was the basis of a very versatile and valuable ring-closure reaction that is referred to as the *Norrish/Yang reaction* (Scheme 1).

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1

Mechanistic details of the Norrish/Yang reaction have been reviewed in many excellent articles[3] and are duplicated in this chapter only as necessary for the understanding of a specific reaction outcome. Nevertheless, two fundamental facts should be mentioned here. The initial step of the Norrish/Yang reaction is a n,π^* excitation of the carbonyl group followed by an intramolecular hydrogen migration from an sp^3-carbon atom to the oxygen atom of the carbonyl group to provide a biradical. In this context, the spin multiplicity of the excited carbonyl group is of great significance for the outcome of the reaction. From a preparative point of view, phenomena of regio- and stereoselectivity are of particular importance and therefore receive special attention. The aim is to show that, in spite of the apparently low structural flexibility of the original Yang reaction (formation of cyclobutanes), it is possible to influence regio- and stereoselectivity and thus gain access to a variety of cyclic products. It should be noted that the Yang reaction itself will be discussed only briefly in this chapter, and the reader is referred to other articles in this volume.

57.2 Cyclopropanes

The precondition for the synthesis of cyclopropanes as products of a Norrish/Yang reaction is the formation of 1,3-biradicals and consequently a hydrogen abstraction from the β-position with respect to the carbonyl group. (Unless otherwise stated, the terms α-, β-, etc. always refer to sites adjacent to the carbonyl carbon atom.) The geometrical parameters of the corresponding five-membered transition state, especially the O–H–C bond angle, differ substantially from the ideal parameters reported by Scheffer et al.[4] Therefore, it is not surprising that only few syntheses of cyclopropanes via the Norrish/Yang reaction are known.[5,6] In most of these cases, it was either proven or it is very likely that the initial step is a photoelectron transfer (PET). In addition, the hydrogen atom is transferred not homolytically but by a proton shift that occurs after PET. These conditions limit the preparative value because the electron-rich functional groups responsible for the PET cause a great sensitivity of the cyclopropanes to oxidative ring opening.

A recently developed method utilizes a leaving group attached to a carbon adjacent to one of the radical centers that is formed following the hydrogen transfer process. This is shown in **1**, where the leaving group X is attached to the carbon atom adjacent to the carbonyl group. Once the initial biradical is formed, an elimination of the acid HX occurs at the stage of biradicals **2**, which proceeds fast enough to compete with the "classic" Norrish/Yang processes (cleavage, cyclization). As a result, the left half of biradicals **2** (hydroxy radical) is converted into an enolate radical (oxoallyl radical), and the spin density is shifted to the adjacent atom. In fact, 1,4-biradical **2** is transformed into 1,3-biradical **3**. This approach has been named the *spin center shift* of biradicals.[7] After intersystem crossing (ISC), biradicals **3** cyclize to acyl-cyclopropanes **4**. (Scheme 2, Table 57.1)

The method tolerates a wide range of functional groups. Although the lifetimes of biradicals **3** have not yet been measured, the experimental results strongly suggest that the lifetimes are very short (<25 ns). This can be concluded especially from irradiation of the cyclopropyl-substituted compound **1f**, which cyclized in good yields to *bis*-cyclopropylketone **4f** without any detectable opening of the cyclopropyl ring. In general, cyclopropylcarbinyl radicals undergo very fast ring opening to butenyl radicals ($k = 4.0 \times 10^7\ s^{-1}$) and this reaction is often used to determine radical lifetimes (the *radical clock*).[8]

The cyclopropane synthesis is also suited for the preparation of highly strained bicyclic hydrocarbons such as [2.1.0]bicyclopentanes **6** and spiropentanes **8**.[7,9] The formation of spiropentane **8** is particularly remarkable in that it is the result of a homolytic hydrogen abstraction from a cyclopropane ring, which is very rarely observed. (Scheme 3).

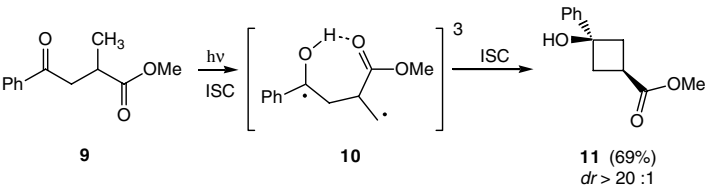
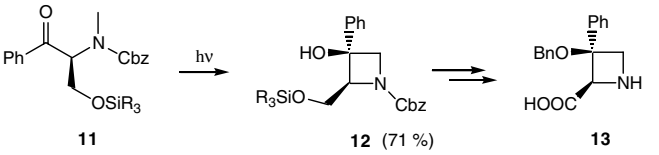
57.3 Four-Membered Rings

Cyclobutanes

The synthesis of cyclobutanes is the classical area of application of the Norrish/Yang reaction. It has been discussed comprehensively elsewhere.[3a,b,10] Here, only two special aspects are addressed. The main drawback of Yang cyclization from a practical point of view is the Norrish type II cleavage, which almost always competes with the cyclization and is often the only observed process. Nevertheless, the cleavage can be suppressed if the overlap of both radical p_z orbitals with the breaking C–C bond is disturbed by



SCHEME 4



SCHEME 5

steric or electronic factors. This is exemplified in the irradiation of oxoester **9**. On irradiation of α-methyl-γ-oxoester **9**, cyclobutane **11** is formed in good yield as only one diastereomer. The explanation for the low extent of Norrish type II cleavage is that biradical **10** is conformationally fixed by a hydrogen bond, thus preventing the overlap of the benzylic radical with the breaking bond and causing the exclusive formation of the *cis*-configured product (Scheme 4).[11]

Azetidines and Oxetanes

Another approach to repress the cleavage is to replace the β-carbon atom by a nitrogen atom. The mesomerism between the γ-radical center and the nitrogen lone pair forces a conformation unfavorable for Norrish type II cleavage. This concept was used in the stereoselective synthesis of the highly functionalized azetidine **12**, which was subsequently converted into azetidine carboxylic acid **13**, an unnatural α-amino acid. Interestingly, no Norrish type II cleavage was observed, and, due to an intramolecular hydrogen bond, only one diastereomer was obtained (Scheme 5).[12]

β-Lactams play an important role both as versatile building blocks and as compounds, often exhibiting interesting biological activity such as antibiotic activity. In the course of Sheehan's penicillin synthesis, the construction of the β-lactam ring was the most striking and challenging task.[13] In this regard, it is noteworthy that β-lactams can also be prepared using the Norrish/Yang reaction. Thus, upon irradiation of α-ketoamides **14**, the excited carbonyl group abstracts a hydrogen atom from one of the nitrogen-bound alkyl groups forming 1,4-biradicals, which cyclize to β-lactams **19** (Scheme 6). It was shown that the observed range of products depends remarkably on the substituents and the solvent used during photolysis. A thorough discussion of the complex reaction course would go beyond the scope of this chapter; therefore, only the most important facts are mentioned. α-Ketoamides **14** first form biradicals **15**, which should exist, at least partially, in the singlet state.

In contrast to the examples presented thus far, the appearance of zwitterionic intermediate **18** was proven unambiguously. This intermediate may be formed either directly from the singlet biradical **15** or by recombination of Norrish type II products **16** and **17**. The zwitterion may then cyclize to β-lactams **19**. It seems that this ring closure is limited to radical stabilizing substituents (Ph) when performed in solution, whereas less stabilizing substituents preferentially afford oxazolidin-4-ones.[14a] Interestingly, the product ratio can be altered substantially in favor of β-lactams **19**, if amides **14** are irradiated as inclusion complexes with desoxycholic acid or cyclodextrin (Scheme 6, Table 57.2).[14b,c] Very recently, this ring closure approach was applied by Griesbeck and Heckroth[14d] to derivatives of amino acids. In this way, enantiomerically pure β-lactams were synthesized.

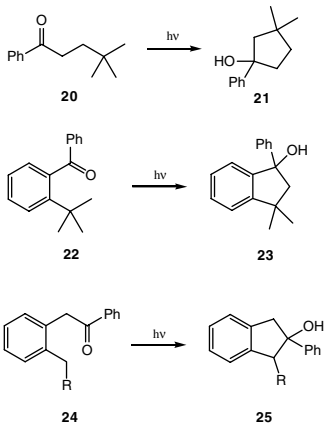
The photochemical preparation of oxetanes is the domain of the Paternò–Büchi reaction, but only a few examples have been published where these heterocycles were prepared in the course of a Norrish/Yang reaction. This is presumably due to the remarkable tendency of the corresponding 1,4-biradicals to undergo Norrish type II cleavage. Lewis and Turro[15] explored the photochemical behavior of α-alkoxyacetophenones as early as 1970 and found that oxetanes are generally formed as minor products only.

57.4 Five-Membered Rings

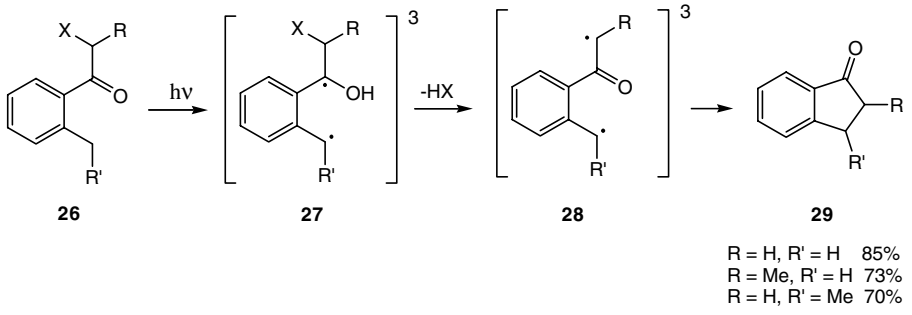
Cyclopentanes and Indanes

Usually, the regioselectivity of the Norrish/Yang reaction may be described by a simple rule. If sp^3–CH bonds are present in the γ-position with respect to the carbonyl group 1,4-biradicals are formed that undergo Norrish type II cleavage or cyclization to four-membered rings. This reaction path may be circumvented by decreasing the CH bond energy in the δ-position or by blocking the γ-position with quaternary carbon atoms or heteroatoms or by spin center shift. The first approach is not very convenient, because it rarely succeeds in suppressing the γ-hydrogen abstraction completely. On the other hand, blocking the γ-position has been used several times. In Scheme 7, three different types of molecular framework are depicted that fulfill this concept; thus, cyclopentane **21**[16] and indenes **23**[17] and **25**[18] were prepared from the corresponding *t*-butyl-substituted ketones **20** and **22** and phenacyl ketone **24**, respectively (Scheme 7).

The idea of spin center shift, which was successfully applied to the preparation of cyclopropanes (see Section 57.2) can be extended to five-membered rings. Accordingly, *o*-alkyl-substituted aryl ketones **26** bearing a leaving group in the α-position undergo γ-hydrogen abstraction, giving 1,4-biradicals **27**, which quantitatively eliminate HX, providing 1,5-biradicals **28**. After ISC, the 1,5-biradicals cyclize to indanones



SCHEME 7



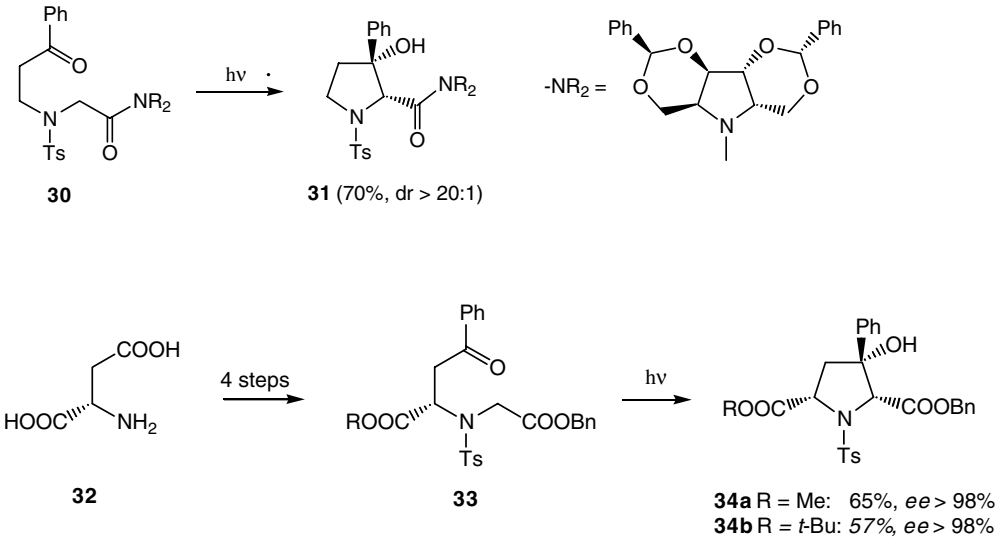
SCHEME 8

29 in good yields (Scheme 8).[19] This elimination process reaction was originally developed for photochemically removable protective groups[20] and has not been used in the preparation of such compounds. This is all the more surprising given that the indanone moiety is regularly found in natural products (e.g., in the cytotoxic pterosines).[21]

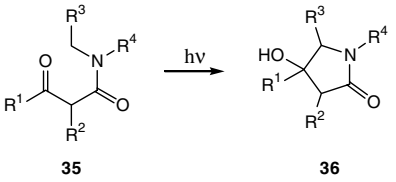
Pyrrolidines and Indoles

In 1981, Henning and co-workers[22a] developed a synthesis of pyrrolidines from β-aminopropiophenones. It should be noted that the introduction of an electron-withdrawing group at the nitrogen atom retarded the formation of cyclopropanes. In due course, Henning investigated thoroughly the influence of various substituents and developed a diastereoselective route to substituted prolines.[22b,c] Based on this work, enantiomerically pure prolines were prepared. Thus, *N*-substituted glycine amide **30** bearing a C_2-symmetric chiral auxiliary gave, on irradiation, proline amide **31** in high yields and in a fully diastereoselective manner.[23] Besides the chiral auxiliary controlled asymmetric synthesis, utilization of the chiral pool of natural products is widespread and was also applied to the photochemical synthesis of prolines. Starting from aspartic acid **32**, glycine esters **33** were prepared and cyclized stereoselectively to pyrrolidines **34**, which are recognizably L- and D-prolines (Scheme 9).[24] Remarkably, the three protective groups in **34b** are orthogonal to each other and could be removed independently, which makes this pyrrolidine derivative a very attractive building block for peptide synthesis.

The necessity of protecting the nitrogen atom by an electron-withdrawing group to avoid PET can also be carried out by the introduction of a carbonyl group in the β position, affording β-ketoamides **35**. On irradiation, they provided an access to γ-lactams **36** (Scheme 10, Table 57.3).[25]



SCHEME 9



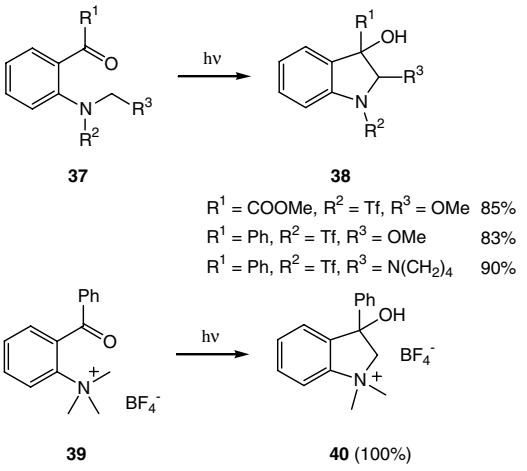
SCHEME 10

TABLE 57.3 Yields of γ-Lactams **36**

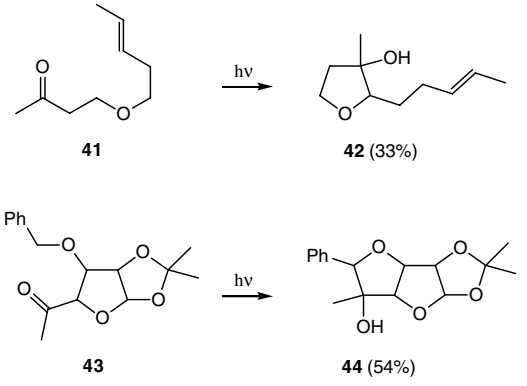
Entry	R^1	R^2	R^3	R^4	Yield (%)	Ref.
a	COOMe	H		$-(CH_2)_3-$	44	25a
b	Ph	H	Ph	CH_2Ph	83	25c
c	Ph	Et	Me	Et	66	25d
d	Ph	*i*Bu	Ph	CH_2Ph	86	25e

The reaction possesses considerable flexibility with respect to the substituents R^1 to R^4, as shown with the examples summarized in Table 57.3. Notably, δ-hydrogen transfer proceeds even in those cases where γ-hydrogen atoms are present (**35c,d**).

A special case exists if the two carbon atoms between the carbonyl group and the nitrogen atom are members of an aromatic ring. Due to the strong electron-donating character of the nitrogen atom, the lowest excited state of these compounds is π,π* in character; consequently, barely any Norrish/Yang reactivity is observed. But, the introduction of electron acceptor groups also introduces pitfalls. Taking into account that the nitrogen atom is part of the chromophore, it is not surprising that the photochemical behavior of compounds **37** (R^2 = Tosyl) is mainly characterized by a homolytic cleavage of the N-S bond. Such reactions were described previously for *N*-tosyl-β-amino-α,β-unsaturated ketones.[26] Only the trifluoromethanesulfonyl group (Tf) facilitates formation of 2,3-dihydro indoles **38**.[27] Another interesting approach to suppressing the electron-donating character of the nitrogen atom exists if this atom is a part of a quaternary ammonium salt, as in **39**, which cyclizes upon irradiation to give indoline **40** (Scheme 11).[28]



SCHEME 11



SCHEME 12

Furans and Benzofurans

Taking into consideration the widespread occurrence of molecules containing the tetrahydrofuran substructure, it is amazing that we have only a few examples of synthesis of these heterocycles by means of the Norrish/Yang reaction.[29] Interestingly, aliphatic ketones were used as exemplified by the photocyclization of ketones **41**[29b] and **43**[29c] (Scheme 12). Despite the moderate yields, these examples illustrate the huge potential of the Norrish/Yang reaction for natural product syntheses.

The replacement of the two sp^3 carbon atoms between the oxygen atom and the carbonyl group ring furnishes *o*-alkoxy-alkyl-aryl ketones **45**, the photochemical behavior of which have been intensively studied. The variability of substituents, both at the two side chains and at the aromatic core, tolerated by the photocyclization is remarkable. Furthermore, in many cases only one diastereomer of benzofurans **46** is obtained upon irradiation of **45** (Scheme 13, Table 57.4).[30]

57.5 Six-Membered Rings

Naphthalenes

Synthesis of six-membered rings by means of the Norrish/Yang reaction is rather rare;[31] nevertheless, with the appropriate choice of molecular framework these rings may be prepared in good yields. The

47 **48**

SCHEME 14

essential prerequisite is to block both the γ- and δ-position with respect to the excited carbonyl group. In addition, a restriction of the molecular flexibility is necessary in order to obtain six-membered rings.

Blocking of the γ- and δ-positions may be achieved either by an aromatic ring or an amide group (see Section 57.4). The former approach is taken by compounds **47**. The preparative applicability of compounds bearing two sp^3-carbon atoms between the carbonyl group and the aromatic ring (**47a**) is limited, because the quantum yield of product formation is very low (**Φ** = 0.0012 in MeOH for **47a**). The low reactivity is attributed to a rapid internal CT quenching as a result of an efficient interaction between the β-aryl and the carbonyl group in the excited state.[31c] The behavior of diketones **47b–d** is surprising because they bear two carbonyl groups, and one would expect, taking into account both enthalpic and entropic considerations, that we should observe a preference for the carbonyl group adjacent to the aromatic ring to react, affording benzocyclobutenes. Indeed, these products were isolated if irradiation is performed in hexane, whereas the utilization of methanol as solvent furnished benzocyclobutenes in trace amounts only. The unusual outcome of the reaction was explained either by a hydrogen shift from a primarily formed hydroxy benzyl radical to the aliphatic carbonyl group[31d] or by a radical attack of the *o*-benzyl radical onto the aliphatic carbonyl group forming an alkoxy radical[31e] (Scheme 14, Table 57.5).

SCHEME 15

δ-Lactams

The second approach (i.e., the introduction of an amide group) was successfully used for the synthesis of γ-lactams (see Section 57.4). An extension of the concept to γ-keto amides provides not only a method attractive from a synthetic point of view but also a molecular system that has potential for a better understanding of the Norrish/Yang reaction. Thus, γ-keto amides **49** cyclize on irradiation to δ-lactams **50** in good yields.[32] It should be noted that the reaction outcome strongly depends on the solvent used. The irradiation in dichloromethane gives δ-lactams **50**, while the only products formed in diethyl ether were pinacols.[33] Earlier work describing the formation of cyclopropanes from **49**[34] was shown to be in error.[33]

The δ-lactams have two newly formed stereogenic centers, thus two diastereomers may be formed. The ratio of these diastereomers depends on the ring size of the cyclic secondary amine in **49**, on the substituents, and on the solvent. It has been shown that small rings and substituents at the carbon atom adjacent to the nitrogen atom increase the diastereoselectivity in favor of **50a** (Scheme 15, Table 57.6); this preference could be substantiated by consideration of different triplet biradical conformers.[32]

β-Ketoamides such as **49** not only are versatile reactants for the synthesis of δ-lactams but also are valuable for studying the mechanism of the Norrish/Yang reaction. If β-ketoamides with two different residues at the nitrogen atom of the secondary amine are used, the question of regioselectivity arises. In this connection, the photochemical behavior of sarcosine derivative **51** is very instructive. In the ground state, **51** consists of the two rotamers **51-A** and **51-B** in ratios of 2:1 to 4:1, depending on the solvent. Bearing in mind the relatively high barrier for the rotation around the amide bond (18 to 20 kcal/mol[33]), one would expect the product ratio of **52**:**53** to reflect the ground-state ratio. Surprisingly, the irradiation of **51** in aprotic solvents provides only the product **52**; however, if **51** is irradiated in protic solvents, a product ratio of 2.8:1 for **52**:**53** is observed, which is very close to the rotamer ratio of the ground state. Obviously, the product ratio in aprotic solvents is dominated by an exclusive back hydrogen transfer of the biradical **BR**2. The frequently observed phenomenon that the regioselectivity of the Norrish/Yang reaction is decided by neither relative rates of hydrogen transfer nor ground-state conformational equilibria but solely by back hydrogen transfer was originally recognized by Sauers and Huang,[31a] and its importance must not be underestimated (Scheme 16).

The stereochemical situation is more complicated if a chirality center is already present in the reactant. In such cases, two features must be considered: the simple diastereoselectivity and the asymmetric induction. Commencing with aspartic acid, the enantiomerically pure benzoylalanine amides **54** were prepared in a fashion similar to that described for **33** (see Section 57.4) and irradiated to give the ornithine lactams **55** (Scheme 17);[35] similar results were later also recorded by Griesbeck, who employed differently substituted compounds.[36]

TABLE 57.6 Yields of δ-Lactams **50**

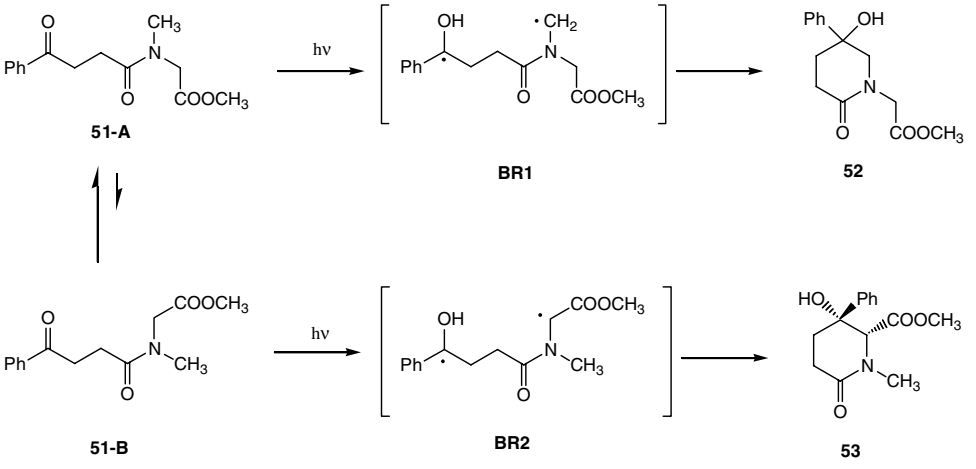
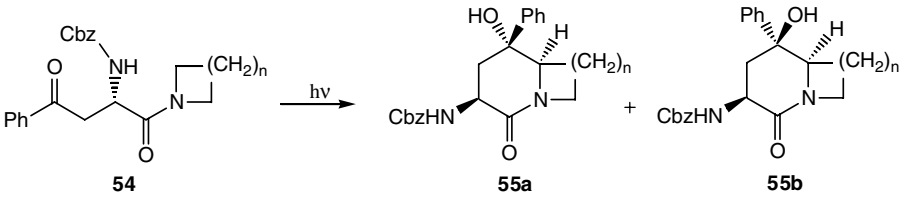
	55	0	>99
	33	8	61
	34	8	61
	48	6	78

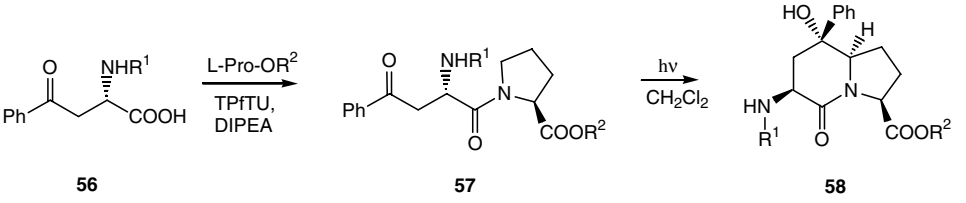


SCHEME 16

Despite the fact that the asymmetric induction from the chirality center C3 on C6 proceeds with high selectivity (>99%), the simple diastereoselectivity with respect to the C5–C6 bond is only moderate. For this reason, it is not very promising to complicate the system by the introduction of additional chiral centers. In view of that proposal, the photochemical behavior of dipeptides **57** is surprising. Prepared from *N*-protected benzoylalanines **56** by peptide coupling with proline esters, they cyclize photochemically in good yields to "bicyclic β-turn dipeptides" **58**, which are potential peptide mimetics. The high



SCHEME 17



SCHEME 18

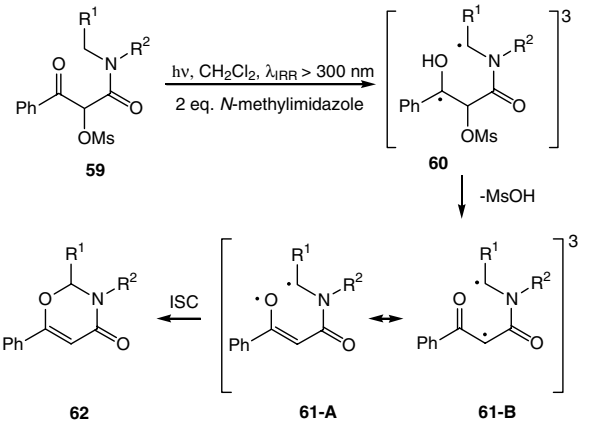
stereoselectivity can be explained by a synergistic effect of the two chiral centers at the triplet biradicals stage (Scheme 18; TPfTU, *O*-pentafluorphenyl-*N*,*N*,*N*,*N*-tetramethyluronium tetrafluoroborate).[37]

Oxazines

The idea of a spin center shift was already discussed twice in this chapter as a means of broadening the synthetic scope of the Norrish/Yang reaction. A third example applies to the preparation of six-membered rings. Thus, by treating of β-ketoamides **35** (Section 57.4) with hypervalent iodine(III) reagents, α-methanesulfonyloxy-β-ketoamides **59** are obtained in excellent yields. On irradiation, 1,5-biradicals **60** are formed, which are converted into biradicals **61** by elimination of methanesulfonic acid. In the methods described previously for preparation of cyclopropanes and indanones, the enolate radical moiety reacts as a carbon radical. Such reactivity is in agreement with the higher spin density at the carbon atom. Surprisingly, the enolate radical moiety of biradicals **61** reacts solely as oxygen radicals **61-A**, giving the oxazinones **62**. This result could be explained considering the relative energy of different biradical conformers (Scheme 19, Table 57.7).[38]

Chromenes

In 1985, Meador and Wagner[39] described the photocyclization of α-(*o*-benzyloxyphenyl)acetophenone **63**, which may formally be derived from ketones **45** by insertion of a methylene group between the keto group and the aromatic ring. The 3-hydroxychromene **64** was obtained in 80% yield as a 1.6/1 mixture of the two diastereomers (Scheme 20). It is instructive to draw attention to the fact that, despite the huge importance of oxygen-containing heterocycles in biological context, considerably fewer examples of syntheses of these ring systems by means of the Norrish/Yang reaction have been observed compared with those of nitrogen-containing heterocycles. As revealed in the preceding sections, the hydrogen abstraction from a definite position often demands the blocking of two positions in the chain between



SCHEME 19

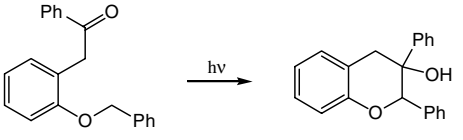
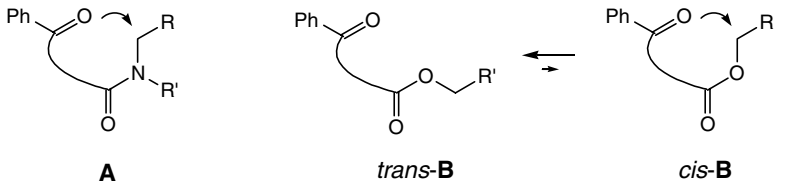
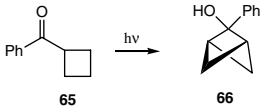


SCHEME 20

the excited carbonyl group and the position from which abstraction should take place. In many cases, this was accomplished by introduction of an amide bond. Surprisingly, secondary amides (R′ = H in **A**, Scheme 21) have not been used. The simple reason for this is that secondary amides exclusively adopt the *trans* conformation, thus the alkyl group (RCH_2 in **A**) is unreachable by the carbonyl oxygen. Tertiary amides consist of an equilibrium mixture of rotamers that can be converted into each other (see



SCHEME 21



SCHEME 22

Scheme 16). Esters almost entirely adopt the *trans* conformation (*trans*-**B**); therefore, it is not surprising that no hydrogen abstraction can occur. The energy difference between *trans*-**B** and *cis*-**B** amounts to more than 8 kcal/mol; consequently, the *cis* conformer is not populated at room temperature.[40] It should be noted that, if the chain between the excited carbonyl group and the ester group is long enough, a hydrogen abstraction from the alkoxy group could be observed; however, macrocyclizations are not a topic for this chapter.

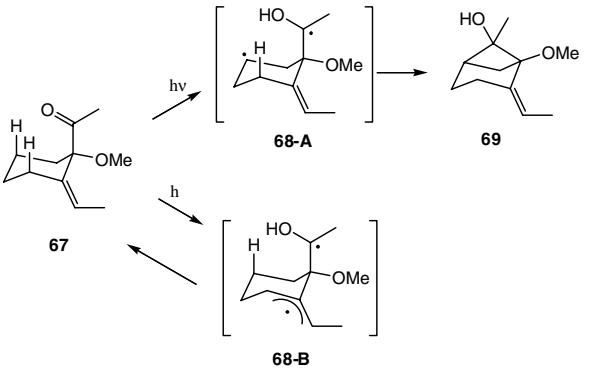
57.6 Bi- and Tricyclic Compounds

This last section deals with such applications of the Norrish/Yang reaction furnishing bi- and tricyclic compounds. It seems to be justifiable to dedicate a separate section to this topic because often the regioselectivity rules may be circumvented if the conformational flexibility of the molecules is reduced. In fact, a rigid molecular framework is an alternative to the hitherto presented concept of blocking positions with heteroatoms or quaternary carbon atoms. Naturally, it is not possible to structure the reactions according to ring size and type of ring; furthermore, vastly different examples are known. In this section, then, only some representative examples are discussed, and the selection does not claim to be complete.

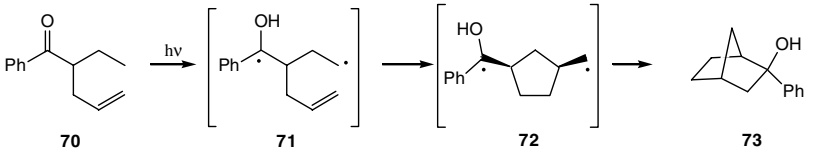
Presumably, the most popular example of a transannular hydrogen abstraction giving a bicyclic molecule is Padwa's bicyclo[1.1.1]pentane synthesis, published in 1967.[41] By virtue of the considerable ring strain of bicyclo[1.1.1]pentanes, the formation of **66** from **65** demonstrates impressively the synthetic scope of the Norrish/Yang reaction (Scheme 22).

Two other examples for the synthesis of bicyclic compounds whose skeleta bear only carbon atoms are shown in Schemes 23 and 24, each of which is instructive in its own way. Upon irradiation of cyclohexane derivative **67**, one tends to expect a hydrogen abstraction from the allylic position, but bicyclo[3.3.1]heptane **69** was obtained by cyclization of the less stable biradical **68-A**.[42] The reason for this unusual reaction course is the exclusive back hydrogen transfer of the more stable biradical **68-B** (Scheme 23).

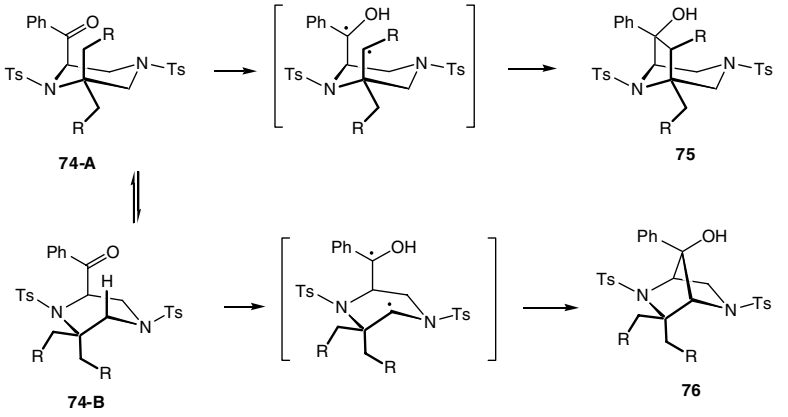
Bicyclo[2.2.1]heptane **73** is not directly formed in the course of a Norrish/Yang reaction, but the primarily formed 1,4-biradical is trapped intramolecularly by a vinyl group in a kind of 1,5-*exo*-cyclization of a hexenyl radical, well known from monoradical chemistry.[43] Compared with the concept of acid elimination from hydroxy radicals bearing a leaving group at the adjacent carbon atom (see preceding sections), the cyclization of **71** to **72** can also be regarded as a spin center shift. Unfortunately, cyclization of alkenyl radicals in most cases proceeds too slowly[44] to compete with the "normal" reactions of the Norrish/Yang biradicals, thus this concept seems not to be commonly applicable (Scheme 24; byproducts not shown).



SCHEME 23



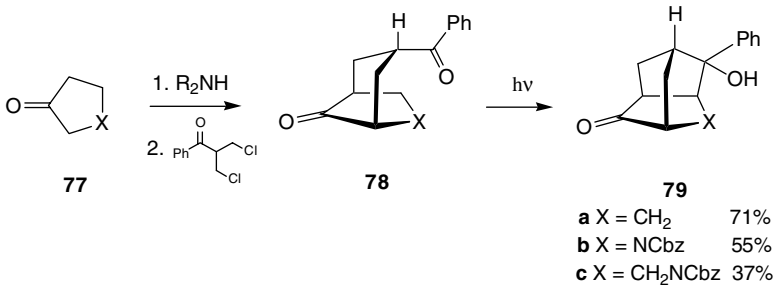
SCHEME 24



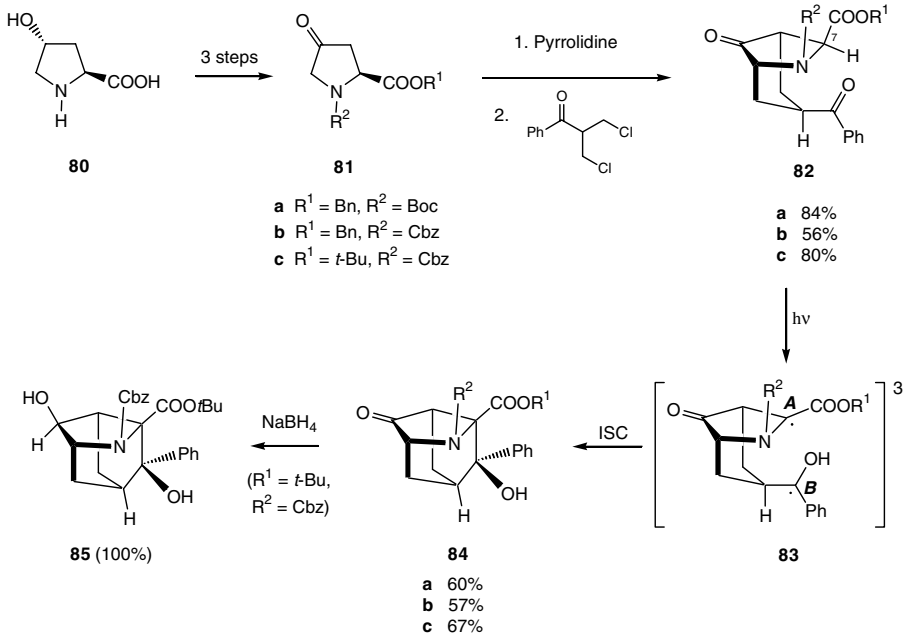
SCHEME 25

Different CH bond energies as well as different ring conformers of the reactant may be responsible for the photochemical reaction course of 1,4-ditosylpiperazines **74**. From the chair-like conformer **74-A**, the 3,8-diazabicyclo[3.2.1]octanes **75** are formed by a hydrogen abstraction from one of the alkyl groups affixed to the 6-position of the piperazine ring in yields between 3 and 6%, whereas 2,5-diazabicyclo[2.2.1]heptanes **76** are formed from conformer **74-B** in yields between 15 and 29% (Scheme 25).[45]

Undoubtedly, the regioselective attack at non-activated CH bonds by an excited carbonyl group is one of the most remarkable features of the Norrish/Yang reaction. This will be demonstrated with the transannular cyclization of bicyclic diketones **78**, which can be easily prepared from cyclic ketones **77**, according to Stetter et al.[46] The α,α′ fusion to **78** proceeds fully diastereoselectively and furnishes, fortunately, the diastereomer that fulfills the structural requirements for the subsequent photochemical step. Upon irradiation, the selectively excited benzoyl group abstracts a hydrogen atom from the formal



SCHEME 26



SCHEME 27

δ-position, because the γ-position is unreachable due to the rigid molecular framework. Whereas noradamantane **79a** was obtained as a mixture of diastereomers, heterocyclic compounds **79b** and **79c** were, despite lower yields, formed fully diastereoselectively with respect to the newly formed C–C bond. This result was substantiated by the directing effect of intramolecular hydrogen bonds at the triplet biradical stage (Scheme 26).[47]

The strategy outlined in Scheme 26 was extended to enantiomerically pure tricyclic α-amino acids. The synthesis commences with the natural amino acid *trans*-4-hydroxyproline **80**, which was converted in a straightforward manner in three steps into the 4-oxo-prolines **81**. Application of Stetter's α,α′ fusion afforded bicyclic diketones **82**. Interestingly, in the photochemical key step, the chirality center at C7 is destroyed by the hydrogen abstraction. But, naturally, the radical center **A** can only be attacked by radical center **B** from the underside of the pyrrolidine ring; therefore, no racemization can take place. In the final step, the keto group is stereoselectively reduced, affording the highly functionalized compound **85**. It should be noted that in the course of the discussed reaction sequence, five new chiral centers were selectively set up originating from one chiral center in **81** (Scheme 27).[48] Tricyclic compound **85** may be

regarded as a "chimerical" amino acid because it bears the substructures of a whole lot of natural and unnatural amino acids. Its preparation impressively reveals the synthetic scope of the Norrish/Yang reaction in the construction of complex molecules.

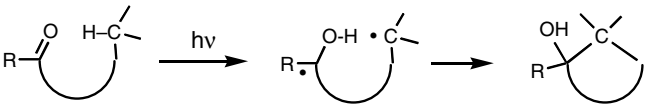
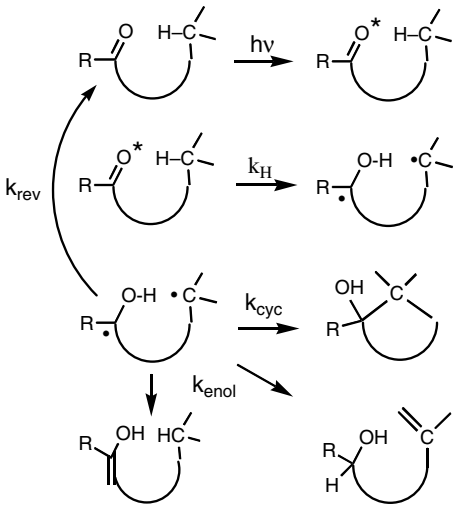
58.1 The Yang Photocyclization Reaction



58.2 Mechanism



58.3 Byproducts

enol of reactant
reduction of carbonyl to alcohol, oxidation of CC bond to double bond

58.4 History

A wide variety of carbonyl compounds undergo photoinduced intramolecular hydrogen atom abstraction to form 1-hydroxy-1,*x*-biradicals, which then undergo two common competing reactions: (1) coupling to produce cyclic alcohols and (2) disproportionation back to ketone or to various enols. The overall process closely parallels the well-known bimolecular photoreduction of ketones, the most common products of which are formed by radical coupling. These intramolecular hydrogen abstraction processes have been widely studied, and several reviews are available.[1–6]

The first and still best known example of such intramolecular hydrogen abstraction is the type II photoelimination discovered by Norrish,[7] who found that ketones with γ–CH bonds cleave to methyl ketones and alkenes. Later, the Yangs found that cyclobutanols accompany cleavage and suggested that both processes arise from a common 1,4-biradical intermediate formed by γ-hydrogen abstraction of the excited ketone,[8] although at the time type II cleavage was generally considered to be a concerted reaction. At about the same time, Barnard and Yang[9] reported that irradiation transforms cyclodecanone to bicyclo[4.4.0]decan-1-ol, the cyclization product of a 1,6-biradical formed by ε-hydrogen abstraction. As realization of this intramolecular hydrogen abstraction process grew, other workers, for both synthetic and mechanistic purposes, investigated a variety of carbonyl compounds that form different kinds of biradicals and cyclic alcohols, with δ-hydrogen abstraction drawing the most attention. In the meantime,

it had become clear that Norrish type II cleavage proceeds via the intermediacy of 1,4-biradicals, as Yang had suggested, and that their cleavage and cyclization are linked mechanistically (see Chapter 52).[10] Consequently, it became common to also refer to the more general cyclization reaction as Norrish, although Norrish himself studied only the cleavage reactions. Because only 1,4-biradicals can cleave to give Norrish type II products, it seems most proper to name cyclic alcohol formation initiated by any mode of intramolecular hydrogen abstraction after its actual discoverers, as Breslow did in 1969.[11]

58.5 Quantum Efficiency

As the above description indicates, the mechanism for Yang photocyclization reactions involves at least two consecutive intermediates: first an excited state and then a biradical. (As with most excited carbonyl reactions, both singlet and triplet states can react.) The quantum efficiency for cyclization, as described by Eq. (8.1), depends on how many competitive reactions *each* intermediate undergoes:

$$\Phi\mathrm{II} = \alpha^1 k_\mathrm{H}\tau_\mathrm{S} + P_\mathrm{cyc}\Phi_\mathrm{ISC}{}^3 k_\mathrm{H}\tau_\mathrm{T} \tag{58.1}$$

where α is the percentage of singlet reaction that forms biradical; k_H is the rate constant for hydrogen abstraction; τ is the excited state lifetime; P_cyc is the percentage of triplet biradical that cyclizes; and Φ_ISC is the percentage of excited singlet that crosses to triplet state. Consequently, it is necessary to understand how structure and environment affect the behavior of each species separately.

It cannot be overemphasized that the quantum yields for two-step reactions such as those initiated by hydrogen abstraction often reflect partitioning of the intermediate biradicals more than relative rate constants for triplet reaction. This is especially true for the very rapid intramolecular hydrogen abstractions of n,π^* triplets. This fact was first demonstrated by the behavior of 2-hexanone, for which γ-deuteration *increases* the quantum yield of type II cleavage,[12] and of γ-substituted butyrophenones, for which quantum yields for type II cleavage decrease as rate constants for γ-hydrogen abstraction increase.[13]

58.6 Excited-State Reactivity

Most of the characteristics that allow excited carbonyl compounds to abstract hydrogen atoms have been determined by studies of bimolecular photoreductions and Norrish type II elimination reactions (see Chapter 52). The following sections provide abbreviated descriptions of various aspects that are more fully covered in Chapter 52.

Nature of Excited State

The lowest excited states of most ketones are n,π^* in nature; the C=O double bond is effectively broken into a 1,2-biradical, thus conferring on the electron-deficient oxygen atom radical reactivity that closely parallels that of alkoxy radicals.[1,14] Both singlet and triplet n,π^* states thus are highly reactive in abstracting hydrogen atoms.

Singlet vs. Triplet

Aliphatic ketones have n,π^* lowest singlets that undergo intersystem crossing (ISC) to their n,π^* lowest triplets slowly enough that both singlet and triplet reaction products can be formed. The singlet reactions generally occur in low quantum efficiency due to partial radiationless decay directly back to reactant at the point of a forbidden crossing between ground and excited singlet surfaces along the hydrogen abstraction reaction coordinate.[15] Triplet reaction occurs exclusively via biradicals. The rapid ($>10^{10}\,\mathrm{s}^{-1}$) intersystem crossing in most phenyl ketones usually produces exclusive triplet reactivity. A few intramolecular hydrogen abstraction reactions of aryl ketones have been shown to involve excited singlets at least partially.[16,17] This pattern occurs when the n,π^* singlet reaction is fast enough to compete with intersystem crossing. Exclusive singlet reactions can occur if the triplet reaction is so slow that it is totally suppressed by added quenchers.

Substituent Effects: n,π^* vs. π,π^*

Aryl ketones can have either n,π^* or π,π^* lowest triplets; the former being far more reactive than the latter. Ketones with π,π^* lowest triplets do undergo hydrogen abstraction reactions and display two quite different forms of reactivity. In systems with π,π^* triplets, only a few kcal/mol below their n,π^* triplets, most of the measured reactivity arises from low concentrations of the n,π^* triplet in thermal equilibrium with the lower π,π^* triplet.[18–20] Equation (58.2) describes observed rate constants for hydrogen abstraction, with the n,π^* state providing most or all of the reactivity when ΔE ($E_{n,\pi} - E_{\pi,\pi}$) < 4 kcal/mol:

$$k_{\text{obs}}^{\text{H}} = \chi_{n,\pi} k_{\text{H}}^{n,\pi} + \chi_{\pi,\pi} k_{\text{H}}^{\pi,\pi} \tag{58.2}$$

$$\chi_{n,\pi} = \left(1 - \chi_{\pi,\pi}\right) = e^{-\Delta E/\text{RT}} \Big/ \left[1 + e^{-\Delta E/\text{RT}}\right] \tag{58.3}$$

Table 52.2 (Chapter 52) lists rate constants for triplet-state γ-hydrogen abstraction in ring-substituted valerophenones. These values reflect variations only in excited-state reactivity, as the CH bond being attacked is fixed; therefore, their *relative* values should hold for more remote hydrogen abstractions as well and thus provide a guide to predicting relative reactivities of aryl ketone triplets. Electron-donating groups (RO, alkyl, Cl, RS), as well as conjugatively electron-withdrawing groups (CN, RCO) *para* to the carbonyl, decrease reactivity by promoting π,π^* lowest triplets.

The second type of π,π^* reactivity occurs in polynuclear aryl ketones with large $E_{n,\pi} - E_{\pi,\pi}$ values. The observed triplet reactivity of some naphthyl ketones is only 0.01 to 0.001% that of an n,π^* triplet.[21,22] This large rate difference reflects the distinct spin localization on the carbonyl oxygen in an n,π^* triplet as opposed to the delocalized spin in a π,π^* triplet.

Substituent Effects: Inductive

Inductively, electron-withdrawing ring substituents (F, CF_3, N, N^+) enhance the reactivity of n,π^* triplets, magnifying the electron deficiency of the carbonyl oxygen (groups on the α-carbon of ketones increase excited state reactivity). Cyano and carbonyl substituents *ortho* or *meta* have the same effect, as they are not conjugated to the benzoyl carbonyl in the triplet state. Electron-withdrawing groups on the α-carbon of ketones likewise increase reactivity.

Solvent Effects

For ketones with n,π^* lowest triplets, significant intrinsic solvent effects on k_{H} values are not apparent, although solvation of other functionalities in the molecule can affect conformational kinetics. Also, when the π,π^* triplet is of lower or comparable energy, polar solvents reduce overall reactivity by lowering the excitation energy of the π,π^* triplet and raising that of the n,π^* triplet, thus decreasing $\chi_{n,\pi}$ values.[18,19]

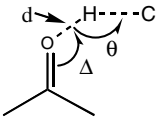
Energetics

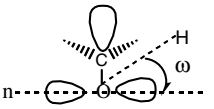
Generally speaking, hydrogen abstraction rate constants for singlet n,π^* states are an order of magnitude greater than for the corresponding triplet states. The higher reactivity of n,π^* singlets relative to triplets most likely reflects the greater exothermicity of the singlet reaction. Abstraction of even primary hydrogens is exothermic; both aliphatic and phenyl ketone triplets display similar rate constants for attack on a given type of CH bond.[1,23]

Nature of Hydrogen Atom

C–H bond Energy Effects

Tables 52.3 and 52.4 (Chapter 52) list how different substituents on or near the γ-carbon affect the rate constants for triplet-state γ-hydrogen abstraction. γ-Substituents affect intrinsic CH bond energies and the electron density of the CH bonds, both of which affect k_{H} values. Substituents one or two carbons away create inductive effects that generally lower reactivity, as most substituents (aside from alkyl groups)





ideal: Δ = 90-120°	θ = 180°	ω = 0°	d ≤ 2.7
actual: Δ = 73-110°	θ = 85-120°	ω = 20-70°	d < 3.1

SCHEME 1

are inductively electron withdrawing. The relative effects of comparably situated substituents should hold for any type of hydrogen abstraction by n,π^* triplets.

Geometric Effects

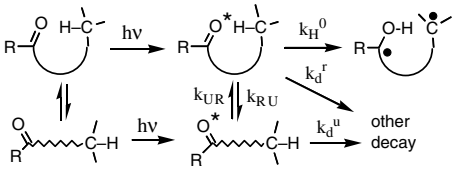
CH and CO Double-Bond Orientation

For a bifunctional reaction to occur, two geometric factors must be optimized: the distance between the two reacting groups and their orientation with respect to each other. In the case of hydrogen abstraction, the distance between the carbonyl and the CH group and the orientation of the CO double bond and CH bonds determine reactivity. Whereas the reactive functional groups of the two molecules in a bimolecular reaction are free to diffuse to the van der Waals contact distance and to rotate into all possible relative orientations, in an intramolecular reaction intervening bonds and structure limit the orientations and proximity available to two separate functional groups. The resulting conformational equilibria and kinetics affect rate constants for hydrogen abstraction and thus determine both reaction rates and regioselectivity.

What are the orientational features required for hydrogen abstraction by ketone n,π^* states? Scheffer[24,25] has studied a variety of ketones that undergo γ-hydrogen abstraction in their crystalline states. In analyzing their reactivity, Scheffer considered the four ground-state parameters depicted in Scheme 1 to be the most important in determining reactivity: *d*, the distance between O and H; θ, the O–H–C angle; Δ, the C=O–H angle; and ω, the dihedral angle that the O–H vector makes with respect to the nodal plane of the carbonyl π system. Such a comparison of triplet reactivity with ground-state geometries is valid because n,π^* excitation is known to be so highly localized on the carbonyl group that geometric changes in the rest of the molecule are negligible and further are suppressed by the crystal lattice.

Scheffer suggested the theoretically "ideal" values for these parameters noted in Scheme 1, and theoretical approaches to answering these orientational questions have confirmed the "ideal" values of Scheme 1.[26,27] The values actually observed in over two dozen examples in which x-ray crystal structures were obtained for reactive ketones are summarized in the scheme. The most important parameter appears to be *d*; whenever two hydrogens at different distances <3.1 Å are available, the closer one is abstracted. Whenever a hydrogen is positioned this close to the carbonyl in the ground state, minimal molecular motion is required for reaction, and minimal motion is all that most crystal lattices allow. The value of θ obviously can vary greatly from the linear arrangement thought to be preferable. Likewise, the value of ω can depart significantly from the "ideal" 0°. Both of these deviations from ideality have long been known from the reactivity of many steroidal ketones.[3,28] The meaning of Δ is the least clear, as n,π^* excitation lengthens carbonyl bonds.[29]

For some time, it has been commonly believed that the hydrogen atom being abstracted must lie along the long axis of the carbonyl *n*-orbital. This notion recognizes the directionality of *p* orbitals and the fact that n,π^* radical reactivity is centered on this particular *p* (or sp^2) orbital; however, to augment Scheffer's evidence, several examples are described later in this chapter in which efficient hydrogen abstraction takes place, with the developing HO bond making a fairly large angle with respect to the nodal plane of the carbonyl π system.[28,30–32] It has been pointed out that such reactivity probably demonstrates a $\cos^2$ dependence on this angle,[3] that being the electron density function for a *p* orbital. Several experimental



SCHEME 2

observations suggest zero reactivity when ω = 90°.[33,34] All of these involved rigid polycyclic ketones or crystalline media, where the reactants are constrained to maintain their ground-state geometry. This lack of conformational mobility maximizes the possibility that a biradical formed by either α-cleavage or hydrogen abstraction might revert to starting ketone with 100% efficiency. This very problem affects cyclodecanone in solution. Yang[8] originally found that it provides only the product of ε-hydrogen abstraction in benzene. However, Sauers and Huang[35] have since found that products of both γ- and ε-hydrogen abstraction are formed in *t*-butyl alcohol, despite the fact that the ε-hydrogen lies at an angle ω of 90°, whereas ω is only 56° for the γ-hydrogen.

It appears that hydrogen abstraction becomes slow as ω approaches 90°, but, without systematic measurements of rate constants as a function of ω, no generalization is possible. One example has been reported for some sterically congested ketones whose triplets undergo δ-hydrogen abstraction. For hydrogens held at nearly identical distances from the oxygen, those with ω = 20–30° react three to four times faster that those with ω = 65–70°, the difference being predicted by a $\cos^2$ relationship.[35] More such measurements are needed for compounds that cannot undergo revertible competing photoreactions. In particular, more ways to measure rate constants for solid-state reactions need to be developed.

Conformational Effects

Rate constants for intramolecular hydrogen abstraction reflect conformational effects,[3,36] as depicted in Scheme 2. It is assumed that interconversion among the various conformers of a given excited state competes with reaction and decay. One or more conformations may have geometries close to that required for reaction and are dubbed *favorable* or *reactive*. Also, *unreactive* geometries are usually present in which the two functional groups are too far apart for reaction; these must be able to rotate into reactive conformations if they are to react rather than decay to ground state or undergo a competing reaction such as α-cleavage. Molecules that react as solids must have lowest energy conformations that are reactive. Many acyclic ketones exist primarily in unreactive conformations, such that they do not react in the solid state. The lowest energy conformations of cyclic systems may have either reactive or unreactive geometries.

Molecules can be classified both structurally and dynamically in terms of their intramolecular reactivity. The three structural classes are (1) those with a reactive geometry as the most stable or only conformation, (2) those with a reactive geometry that interconverts with other more stable but unreactive conformations, and (3) those with no reactive conformations populated. Dynamically, the three classes of excited states are (1) those in which interconversion among conformers is much faster than decay reactions of the individual conformers, such that conformational equilibrium is established before reaction; (2) those in which conformational interconversions are all slower than decay, such that ground-state conformational preferences control photoreactivity; and (3) those in which unreactive conformers undergo irreversible rotation into a reactive conformer, which reacts faster than it can rotate back into the unreactive geometry. In this third case, reaction of the excited state is subject to rotational control, the intramolecular equivalent of intermolecular diffusion control.

Intramolecular hydrogen abstraction can be subject to any of these different dynamic boundary conditions.[39] The first dramatic example of ground-state control of triplet reactivity was provided by Lewis' study[37] of the Norrish type II reaction of benzoylcyclohexanes. Photoenolization of *ortho*-alkyl ketones was the first reaction recognized to show rotational control of triplet reactivity.[38] Conformational equilibrium is much more common; an early example is the type II reaction of benzoylcyclobutanes.[39] Scheme 3 defines observed k_H values for each of the three cases. For systems in which the excited state

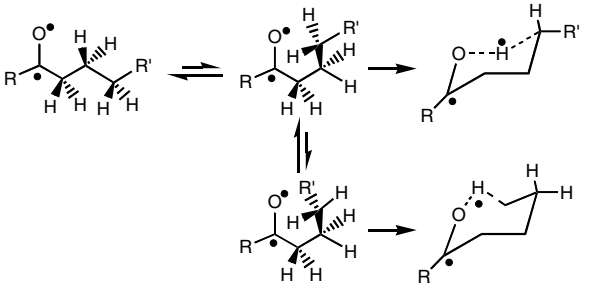
Conformationalequilibrium $$\left[1/\tau = \Sigma\chi_u/k_d^u + \Sigma\chi_r/\left(k_H^o + k_d^r\right)\right] \quad (58.4a)$$

$$\left[k_H^{obs} = \Sigma\chi_r k_H\right] \quad (58.4b)$$

Ground-state control $$\left[k_H^{obs} = k_H^o\right] \quad (58.5)$$

Rotational control $$\left[k_H^{obs} = \chi_u k_{ur} + \chi_r k_H^o\right] \quad (58.6)$$

SCHEME 3



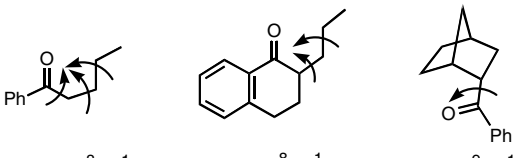
SCHEME 4

establishes conformational equilibrium before decay, only one excited state lifetime exists and is determined by the weighted decay rates of all conformers. If more than one conformer is reactive, then the observed rate constant for reaction is the sum of possibly different rate constants k_r weighted by their individual equilibrium populations χ_r ($\Sigma\chi_r + \Sigma\chi_u = 1$). When ground-state or rotational control obtains, different excited states have different lifetimes whether they undergo the same or different reactions.

Several general comments can be made about different classes of structure. In acyclic ketones, the regioselectivity of hydrogen abstraction reflects different rate constants for cyclic transition states of different sizes, which are closely related to χ_r values. Normally, the largest α-substituent eclipses the carbonyl in ketones, with the lowest energy conformation being fully staggered. No internal hydrogen abstraction is possible except in higher energy conformers that contain some *gauche* conformations. The α,β-CC bond must become *gauche* for γ-hydrogen abstraction to occur, as must the β,γ-CC bond for δ-hydrogen abstraction, as Scheme 4 depicts. Needless to say, more remote hydrogen abstractions require even more twists between carbonyl and the target CH bond which can be provided by rings and *cis* double bonds.

When the carbonyl and CH bond are part of a ring or substituents on a ring, the conformational limitations of the ring may either increase or decrease the population χ_r of favorable conformations. Lewis demonstrated how incorporation of rings between the carbonyl and the γ-carbon can increase rate constants for γ-hydrogen abstraction.[40] Scheme 5 shows some ketones in which the activation energy for abstraction of a secondary hydrogen remains the 3.5 kcal/mol for bimolecular reaction,[41] but the entropy of activation becomes less negative as rings freeze intervening CC bond rotations. Each such frozen rotation increases the rate constant by a factor of ~8, which corresponds to 4 EU. In all three cases, the major conformation is either reactive or of comparable energy, and the rings limit the number of unreactive conformers.

In general, however, no constant factor exists by which rings change intramolecular reactivity**.** They may decrease population of a reactive conformation, as Alexander and Uliana[39] showed for benzoylcyclobutane;[39]



SCHEME 5

limit reaction to one site, as exemplified by the selective δ-hydrogen abstractions in the synthesis of dodecahedrane by Paquette and Balogh;[42] or prevent population of a reactive conformer, as Turro and Weiss[43] reported for cyclohexanones with axial α-alkyl groups.

Regioselectivity

Competing intramolecular reaction rates are determined by differences in the energy required for the molecule to rotate and/or twist into different geometries that bring the excited carbonyl and a remote CH bond into the proper distance and orientation for reaction. Regioselectivities are determined by such energy and rate differences.

Acyclic Systems

The predominance of γ-hydrogen abstraction by excited straight-chain ketones is so pronounced that for years it was thought that no ketone containing γ-hydrogens would react at any other position. A few notable exceptions were eventually found; δ-methoxyvalerophenone[44] and γ-benzoylbutyraldehyde[45] undergo both γ- and δ-hydrogen abstraction with comparable rate constants, because both possess a highly reactive δ–CH bond and an inductively deactivated γ–CH bond. From these results, it was deduced that the intrinsic γ/δ selectivity in triplet ketones is 20:1, the same as that already established for alkoxy radicals.[28]

Houk has published several theoretical studies of intramolecular hydrogen transfer that accurately reproduce the preference for 1,5- vs. 1,6-hydrogen transfers in triplet ketones.[27] Much of the preference is entropic, as expected, but little enthalpy difference exists between the two modes. A chair-like transition state was originally suggested for γ-hydrogen transfers.[28] The calculations predict a strong preference for a linear C–H–O arrangement ($\theta = 180^\circ$), which is more easily accommodated in a seven-atom transition state than in a six-atom one. Thus, relative enthalpies of activation reflect both ring size strain and orbital orientation in the transition state. It must be reiterated that actual ketones react even when θ approaches 90° in the ground state and may adopt a chair-like transition state.

In summary, ketones react preferentially at γ–CH bonds but, as Schemes 4 and 5 show, only if the nearby bonds are free to rotate. Substituents that reduce γ–CH bond lability can allow more remote hydrogen abstraction to compete, but the only way to eliminate γ-hydrogen abstraction is to eliminate γ-hydrogens. Reaction occurs at more remote positions only if the overall structure of a compound allows remote carbons to rotate within a few angstroms of the carbonyl.

Cyclic Systems

The interposition of even one ring between the carbonyl and potentially reactive CH bonds imposes conformational restrictions that limit the molecular geometries possible. Consequently, regioselectivity becomes dominated by frozen rotations such that only certain CH bonds get close enough to the carbonyl to react.

Charge Transfer Followed by Proton Transfer

Bimolecular photoreduction of ketones by good electron donors often proceeds by either electron transfer or charge transfer complexation, followed by a proton transfer. Intramolecular hydrogen transfers sometimes follow this pathway as well. There is good evidence from the behavior of aminoketones that tight

overlap of the donor lone pair with the half-empty *n* orbital is necessary for triplet CT reaction. Rate constants for internal quenching in ω-dimethylaminoalkyl phenyl ketones are maximum for β- and γ-amino ketones, in which five- or six-atom rings can be formed by overlap of the nitrogen lone pair with the half-occupied carbonyl *n* orbital.[46] How the separation between amino and carbonyl groups affects the efficiency of biradical formation is described in several sections that follow.

Competing Reactions

Obviously the most efficient photocylizations occur when rate constants for internal hydrogen abstraction are faster than those for bimolecular hydrogen abstraction from solvent and those for α-cleavage. Thus, the more remote hydrogen abstractions generally work best at low ketone concentrations and in solvents such as benzene and acetonitrile that are very poor substrates for hydrogen atom abstraction. One would not want to attempt photocyclizations by irradiating ketones in strongly electron-donating solvents such as amines and certain alkenes. When irradiated in solution, ketones with significant α-substitution often undergo competing type I cleavage to radicals. Fortunately, various groups have shown that such compounds primarily form the products of intramolecular hydrogen abstraction in the solid state as well as in other confining environments such as micelles, zeolites, and cyclodextrins. When the two radicals formed by α-cleavage cannot diffuse apart, they rapidly recouple to regenerate the ground state of reactant; in contrast, the biradicals produced by hydrogen abstraction are born in a geometry appropriate for cyclization.

Chapter 52 describes the competition between cyclization and cleavage unique to the 1,4-biradicals formed by γ-hydrogen abstraction. Examples of this competition are included later in this chapter.

58.7 Biradical Behavior

Chapter 52 presents a thorough description of the general properties and behavior of the hydroxybiradicals formed by n,π^* hydrogen abstraction as well as the history of their detection. This chapter focuses on how biradicals of different sizes differ in behavior and how these differences affect our general understanding of biradical behavior.

Overwhelming evidence has been found for the intermediacy of triplet biradicals following internal hydrogen abstraction by triplet ketones, especially phenyl ketones. Some unquenchable cyclization reactions indicate that singlet biradicals can indeed be formed in dialkyl ketones.

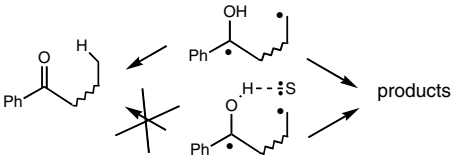
In most cases, the biradicals formed by intramolecular hydrogen abstraction can both cyclize and disproportionate. In the case of Norrish type II 1,4-biradicals, reversion to starting ketone is the sole result of disproportionation, but biradicals with more connecting atoms between the two radical sites can disproportionate to various enol structures, as is described below. It appears that singlet 1,4-biradicals undergo little if any cyclization or disproportionation. It is not known to what extent larger singlet biradicals partition between cyclization and disproportionation.

Direct Study of Triplet Biradicals

In 1977, Small and Scaiano[47] reported the first flash spectroscopic detection of a triplet 1,4-biradical intermediate from γ-methylvalerophenone. Scaiano[48] has thoroughly summarized several basic features of triplet 1,4-biradical lifetimes (described in Chapter 52). They are lengthened approximately threefold in Lewis base solvents, having values in the 25- to 50-nsec range in hydrocarbons and 75- to 160-nsec range in alcohols.[49] They are almost independent of temperature, having activation energies for decay of 0 to 1 kcal/mol.[50] They are not very sensitive to substitution on the benzene ring or to steric features at the γ-carbon of the ketone, but they are increased by conjugating substituents such as γ-phenyls.[50] They are shortened by bimolecular interaction with paramagnetic species such as oxygen[51] and nitroxide radicals.[52] These general features have been observed for some 1,5-biradicals as well, as shown in Table 58.1. Thus, they may hold for even longer biradicals.

TABLE 58.1 Lifetimes and Product-Forming Efficiencies of Some Hydroxy-Biradicals

Biradical	E_a, kcal	τ, ns		$\Phi_{H\text{-abs}}$	
		CH_3OH	Alkane	Polar	Hydrocarbon
	0	100–200	30–70	1	0.3
	1	30	25	1	1
	0	43	≤4	1	0.05
	?	5	1	0.20	0.023



A biradical's lifetime is the reciprocal of its overall rate of decay by both product formation and reversion to ketone. Because the biradicals are formed as triplets in the majority of cases, they must convert to singlets in order to form ground-state products and ketone. Thus, biradical decay involves both physical and chemical changes. These two processes can occur in two ways: one after the other or concurrently. For many decades, it generally has been believed that T ∅ S intersystem crossing of triplet biradicals precedes product formation.

$$\tau = 1/(k_{cyc} + k_{rev}) \tag{58.7}$$

Based entirely on his study of 1,4-biradicals formed by γ-hydrogen abstraction in triplet phenyl ketones, Scaiano postulated that biradical lifetimes are determined by rates of irreversible ISC to the corresponding singlet biradicals. Moreover, he further suggested that product ratios reflect relative ISC rates for different conformations of the triplet biradicals, the singlet biradical being too short-lived to convert into any other product-forming conformation.[53] This view is supported by the temperature independence of some of the biradical lifetimes, ISC not having any enthalpic barrier, but assumes that conformational interconversions are fast enough that conformational equilibrium is established before ISC occurs. Such kinetics are likely in the case for acyclic systems but not for cyclic ones.

It must be emphasized that 1,4-biradicals are unique in being able to form a product from almost any conformation, because they alone can cleave to form two double bonds. Although it is possible that little if any conformational change can occur after ISC in such short, relatively constrained biradicals, larger

biradicals that cannot undergo any chemical reaction in stretched conformations must rotate into cyclic geometries before any products can be formed.

More recently, other workers have suggested an alternative view. From magnetic resonance studies of biradicals, Closs and Redwine[54] suggested that triplet biradicals cyclize whenever their two ends collide, but with a low probability that reflects the amount of singlet character mixed into the biradical by spin-orbit coupling. Michl[55] has suggested a comparable picture, purely from a theoretical viewpoint, with the added feature that incipient bonding of the two ends of the biradical induces additional spin-orbit coupling through a highly stabilizing covalent interaction.

The behavior of the biradicals shown in Table 58.1 suggests that attainment of product-forming geometries does indeed induce ISC so that product ratios reflect normal (small) barriers to bond rotation and product formation.[4] As Table 58.1 shows, the solvent effect on the lifetimes of several biradicals parallels the solvent effect on product quantum yields, indicating that rates of biradical decay are linked to product formation. (The lifetimes of biradicals that do not contain a hydroxy group are not affected by protic solvents.[56]) Inasmuch as hydrogen bonding of the biradical to solvent prevents the disproportionation that regenerates starting ketone, it must lower the rate of biradical decay and thus lengthen biradical lifetime.

Thus, two apparently contradictory experimental facts regarding triplet biradical lifetimes can be identified: Zero or near-zero temperature effects suggest a physical rather than chemical rate-determining step for decay, whereas the solvent effects suggest that the rate-determining step involves product formation. These can be reconciled with the premise that the triplet state rises only slightly in energy along product-forming reaction coordinates before it interconverts with the singlet state, in accord with the Closs and Michl proposals.

Biradical Cyclization

Inasmuch as this chapter covers the cyclization of hydroxy-biradicals, it is important to remember that excited-state hydrogen abstraction forms a biradical with its two radical sites initially very close to each other. Unless some of the connecting bonds rotate very rapidly, disproportionation back to ketone would be all that happens. One would think that rather simple conformational changes are all that is required for cyclization to take place. In order to predict cyclization quantum efficiency, the challenge is to understand the kinetics of those bond rotations as well as other conformational changes that lead to competing disproportionations and cleavage (only 1,4-biradicals).

Because cyclization is of great synthetic interest, the factors that determine stereoselectivity are of major importance. It is only in the past decade that significant interest has developed in understanding the stereoselectivity of biradical cyclizations. Interestingly, renewed interest in the stereoselectivity of bimolecular radical coupling has also developed. The photoreduction of acetophenone to pinacol forms both diastereomers in comparable yields, with the coupling of two prochiral 1-phenyl-1-hydroxyethyl radicals being stereorandom. In the case of biradicals with two prochiral radical sites, selectivity can be determined by nonbonded interactions that occur during cyclization or by pre-existing nonbonded interactions built into the molecule.[57] Therefore, the question that must be addressed is how and to what extent the intervening structure may affect diastereoselectivity in biradical cyclization. Both the relative energy of isomeric conformers and their relative interconversion rates must play a role.

Biradical Disproportionation

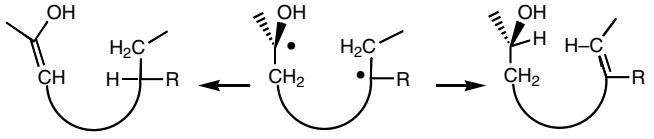
It is generally true that almost all the hydroxy-biradicals formed by internal hydrogen abstraction partially revert to starting ketone by an internal radical disproportionation reaction in which the carbon-centered radical site abstracts the hydrogen from the hydroxyl group. This process often is the major reaction of the intermediate biradical, so that the overall quantum yield of product formation is low even when hydrogen abstraction by the excited state is 100% efficient. Should the efficiency of hydrogen abstraction

be low because of electronic or conformational problems, then biradical disproportionation lowers quantum efficiency even further.

Added Lewis bases inhibit disproportionation back to ketone and thus enhance quantum yields of product formation.[58] In many cases, reversion to ketone is totally suppressed and quantum yields approach unity. This phenomenon is attributed to hydrogen bonding by the relatively acidic OH group[59] of the biradical to the Lewis base. Disproportionation entails breaking this hydrogen bond, whereas all other reactions of the biradical do not. The ability of different additives to solvate the biradicals, as determined by the concentration needed to maximize product quantum yields, closely matches their basicities.[58b] Alcohols, water, ethers, and pyridines are commonly used for this purpose, but all Lewis bases that are not also strong electron donors work to some extent. Not every ketone reacts with 100% efficiency even in the presence of strong Lewis acids. The equilibrium between solvated and unsolvated biradicals obviously varies with biradical structure. Sometimes only a fraction of the biradical is solvated; the rest still reverts to ketone.

Occasionally, intramolecular hydrogen bonding of the hydroxyl group to a Lewis base substituent in the biradical can be quite effective in suppressing reversion to ketone. In any event, it is important to remember that disproportionation back to ketone is a chemical reaction of these triplet hydroxy-biradicals and must be taken into account when analyzing structural and kinetic factors that determine product ratios. It usually is the major cause of low quantum yields for product formation. In fact, in some cases disproportionation and reversion to starting ketone is the only biradical reaction.

These biradicals can also disproportionate by attack of one radical site on a CH bond next to the other radical site. As mentioned above, such behavior is limited to biradicals with three or more atoms connecting the two radical sites, as shorter biradicals are unable to twist into the necessary geometry for such a hydrogen transfer.



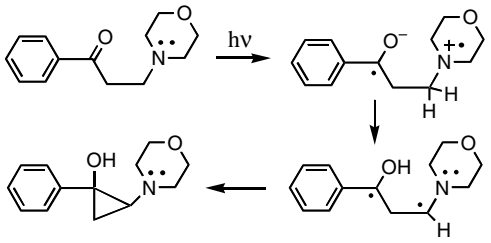
58.8 Environmental Effects

Both the rate constants for competing triplet reactions and the partitioning of biradical intermediates may be affected by the environment. The major effects on triplet reactivity involve conformational changes induced by highly ordered media and decreases in the efficiency of radical α-cleavage. The major effects on biradicals involve conformational restrictions that impede or promote coiling and solvation that affects disproportionation back to ketone. Quite thorough studies have been conducted on systems that undergo γ-hydrogen abstraction (described in Chapter 52). Only a few such studies have been applied to more remote hydrogen abstraction reactions.

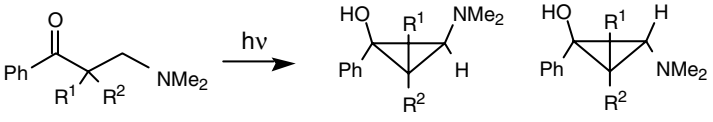
58.9 Formation and Behavior of Biradicals of Different Sizes

1,3-Biradicals: β-Hydrogen Abstraction

Even though β-hydrogen atom abstraction could proceed through a five-atom transition state, which normally is not a bad thing, it rarely occurs, probably because the necessary alignment of atoms discussed above is not possible. The rapid internal charge transfer that occurs in certain triplet β-dialkylamino ketones is followed by β-proton transfer to oxygen, and the resulting 1,3-biradicals cyclize to cyclopropanols.[60] Why can a β-hydrogen be transferred to the carbonyl oxygen as a proton, but not as a neutral atom? Presumably, the charge-transfer exciplex geometry draws the donor entity fairly close to the carbonyl to maximize overlap of the donor and acceptor orbitals, in so doing dragging a β-proton within striking distance of the oxygen.



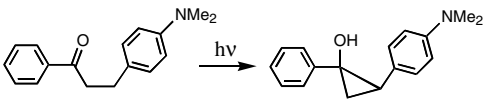
There are some confusing aspects of this reaction. Protic solvents lower the quantum yield of cyclization, for reasons that are not fully understood, while ether and hydrocarbon solvents promote different cyclization diastereoselectivity. Hydrogen bonding to the amino nitrogen decreases its basicity and electron-donating potential. The hydroxy-biradicals most likely hydrogen-bond to ether solvents, a fact known to alter stereoselectivity.[58] Equally interesting is the strong deactivating effect of α-methyl groups; the quantum yield drops from 0.59 to <0.02 when two α-methyls are present on β-dimethylaminopropiophenone. Steric interactions probably impede proton transfer rather than electron transfer.



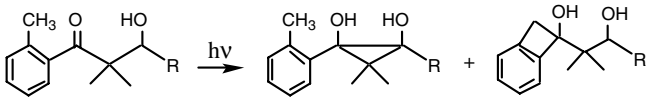
$R^1 = R^2 = H$	Benzene	>95%	<5%
$R^1 = R^2 = H$	Dioxane	50%	50%
$R^1 = Me$; $R^2 = H$	Either	<5%	>95%

Henning and co-workers[61] have found that in other β-alkylamino ketones proton transfer takes place partially or exclusively from a δ-carbon to generate a 1,5-biradical that cyclizes to a pyrrolidine. More about these reactions is provided in the 1,5-biradical section. Differing regioselectivities are thought to be due to differing geometries of the intermediate exciplexes.

More recently this form of cyclopropanol formation was found to occur with β-(*p*-aminophenyl)propiophenones, in which the aniline electron donor promotes a β-proton transfer and 1,3-biradical formation.[62] This study was particularly interesting in that phosphorescence of the intermediate exciplex was detected. Various structural modifications led to interesting diastereoselectivity in the products.

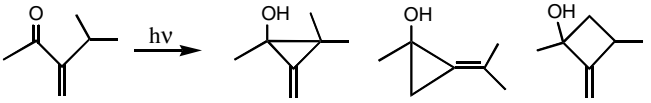


One of the few examples of apparently straightforward β-hydrogen abstraction is afforded by the reaction below, in which Yang photoenolization competes depending on the size of R.[63] The larger R groups cause the ketone to adopt a conformation with the β–CH bond neatly aligned for abstraction, which is not the case for small R's. This behavior presents strong evidence for the proximity of a CH to the carbonyl oxygen being the major factor driving H-abstraction.



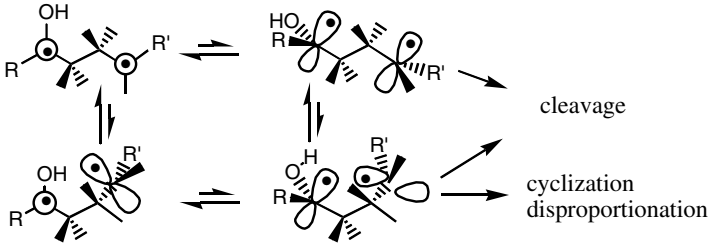
R = ^{i}Pr, ^{t}Bu, Ph, *o*-tolyl R = Et, Me, H

Another instance of direct β-hydrogen abstraction is provided by the behavior of α-methylene ketones, which form both cyclopropanols and methylenecyclobutanols.[64] The reaction appears to occur only from excited singlet states.



1,4-Biradicals: γ-Hydrogen Abstraction

Chapter 52 covers this topic thoroughly, but, because that chapter focuses on type II cleavage products, cyclobutanol formation is covered mainly as a competing byproduct. Here, the cleavage and disproportionation that compete with cyclization are byproducts. The cyclization efficiency of triplet-generated 1,4-biradicals varies widely with structure. Fortunately, the short length of 1,4-biradicals prevents several forms of disproportionation that 1,5-biradicals undergo. Several factors affect the partitioning among cleavage, cyclization, and reversion to starting ketones.[65,66] Four geometries of the 1,4-biradical must be considered: two stretched-out, staggered conformations and two coiled *gauche* conformations. Cleavage can occur from either *gauche* or staggered conformations, whereas cyclization and disproportionation require the latter.



Cleavage appears to be governed by the stereoelectronic necessity for overlap of the breaking bond with both half-occupied *p* orbitals.[66,67] Anything that prevents reasonably parallel alignment of the two half-occupied *p* orbitals and the central CC bond retards or suppresses cleavage. In straight-chain ketones, cleavage/cyclization ratios tend to be at least 5:1. However, α-substitution by alkyl groups,[68] fluorines,[69] or rings[70] increases cyclization, primarily by destabilizing the geometry required for cleavage. α-Alkoxy ketones cyclize more than they cleave;[71] in this case, cleavage is not retarded so much as cyclization is enhanced, presumably by the oxygen relieving ring strain.

Because various bonds in biradicals are free to rotate in solution and thus to allow population of several different conformers, some of which can cyclize and some not, cleavage/cyclization ratios tend to be higher in solution than they are in more rigid environments. Biradicals formed from crystalline ketones tend to maintain shapes very similar to those of the ground-state ketones, which means that the two ends of the biradical remain close enough to cyclize but may not be properly aligned for cleavage. Thus, irradiation of solid ketones presents the best chance of getting good yields of cyclobutanols following γ-hydrogen abstraction.

3-Benzoylpropanal is unique in that it yields only a 2-hydroxycyclobutanone at low conversions but mostly acetophenone at high conversions when irradiated with wavelengths of ~300 nm.[45] The problem is that the cyclization product undergoes photo-induced α-cleavage back to the 1,5-biradical, only a small fraction of which cleaves to the enol, with most reverting to ketoaldehyde, which then repeats the cycle. Fortunately, irradiation at wavelengths greater than 354 nm provides high yields of cyclobutanone, which does not absorb light above 330 nm. This case is a rare example of Yang photocyclization products undergoing secondary photochemistry, a common phenomenon in many photoreactions.

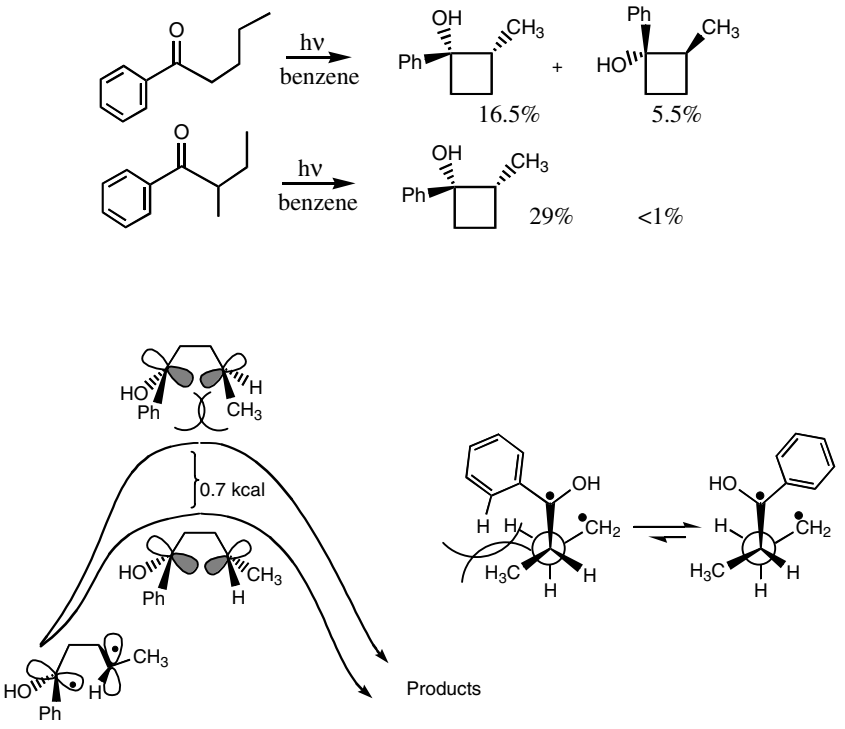
Acyclic Ketones

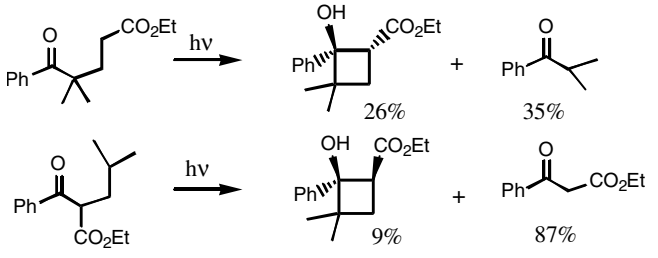
A distinction is often made between coiled and stretched conformations in order to rationalize cyclization/cleavage ratios; however, disproportionation also requires a coiled conformation, and it is not at all clear what affects the competition between cyclization and disproportionation, other than that hydrogen bonding to Lewis bases dramatically inhibits the latter and changes the stereoselectivity of the former. The bond rotations needed to initiate both cyclization and disproportionation must be different, but they likely are quite small and thus not very different. Examples of the wide variations among cyclization/disproportionation ratios are provided in Table 58.2. Inasmuch as conformer populations determine product ratios, cyclobutanol yields are determined primarily by how well cyclization competes with disproportionation.

Table 58.2 also indicates diastereomer ratios for the cyclobutanols formed from some of the ketones. One particularly interesting case involves α-methylbutyrophenone (αMeBP) and valerophenone (VP) forming the same 2-methyl-1-phenylcyclobutanol but with much different stereoselectivity. αMeBP forms a single isomer with the methyl and phenyl groups *trans*, whereas VP forms a 3:1 ratio favoring that isomer. VP exemplifies stereoselectivity induced by nonbonded interactions created as the two radical sites approach each other, whereas αMeBP exemplifies stereoselectivity induced by pre-existing nonbonded interactions in the biradical. In the former case, selectivity appears to mirror relative product energies; in the latter, it mirrors relative biradical conformational preferences. Scheme 6 illustrates both types of selectivity.



SCHEME 6 Left: nonbonded interactions created during cyclization of valerophenone. Right: pre-existing nonbonded interactions in α-methylbutyrophenone.

A more recent study[72] displayed intriguing variations in both cleavage/cyclization ratios and *cis*/*trans* stereoselectivity. The γ-dimethyl-γ-benzoyl ester, true to form, undergoes significant cyclization, but with the phenyl and carboxyethyl groups *cis*; the α-keto ester, however, undergoes just a little cyclization, but the phenyl and carboxyethyl groups stay *anti*, as in α-methylbutyrophenone.[72] The low cyclization/cleavage ratio undoubtedly reflects the low radical coupling proclivity of tertiary radical sites.

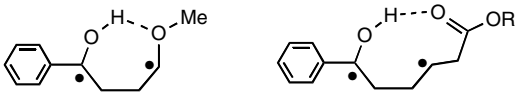


Because polar solvents usually improve quantum efficiency and thus actual rates, they also can affect the diastereoselectivity of cyclization, presumably because hydrogen bonding to solvent enlarges the steric bulk of the OH groups. In many cases, *cis*/*trans* ratios become 50:50, and no stereoselectivity is observed.

Ketones Containing Heteroatoms

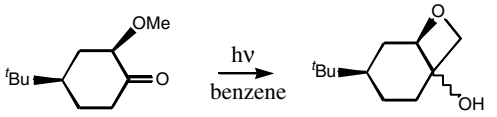
γ-Methoxybutyrophenone and δ-methoxyvalerophenone both show very high selectivity in forming mainly the cyclobutanol, with the phenyl and methoxy groups *trans*. This behavior most likely represents an early example of intramolecular hydrogen bonding holding the biradical in a geometry with the OH and OMe necessarily *syn*. Ethers being quite weak bases, internal hydrogen bonding is apparently not

sufficient to prevent a large percentage of reversion to ketone. In contrast, ketones with carboxyl groups at their γ and δ positions display unusually high quantum yields for product formation, presumably because the internal hydrogen bonding to carbonyl oxygens is strong enough that the majority of biradicals are protected from reversion to reactant.



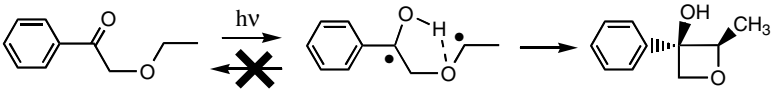
γ-Thioalkoxybutyrophenones undergo Norrish type II cleavage and also form about 10% cyclobutanols, both in very low quantum yield due to rapid internal charge transfer quenching of the triplet ketones.[73]

The behavior of α-alkoxy ketones has been of great interest for years, first because of their unusually high cyclization yields, next because of their very short biradical lifetimes, and more recently for their synthetic potential in making oxetane rings, for which case one attempt to model the oxetane of the D ring of Taxol is shown in the following.[74] Unfortunately, no one has figured out how to induce stereoselectivity in this particular biradical cyclization, although more successful examples in other biradical systems are described later.



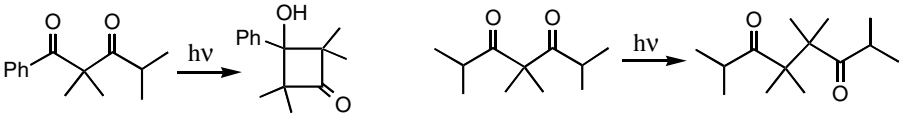
cis/trans = 3

α-Ethoxyacetophenone produces an oxetane not only in high yield but with over 90% diastereoselectivity. It and other α-alkoxy ketones also have the unique feature of reacting in lower quantum efficiency in alcohol than in hydrocarbon solvents, the opposite of most ketones. Both effects might be due to internal hydrogen bonding by the hydroxyl group to the ether carbon in the β position. However, the very short lifetime of the intermediate biradical indicates that cyclization happens much faster than in biradicals not containing heteroatoms; thus, rapid kinetics of product formation may induce both regio- and stereoselectivities.



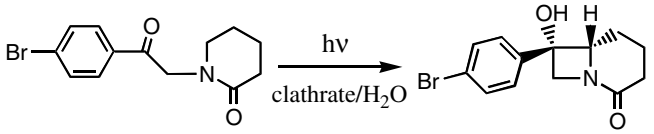
α-Thioalkoxy ketones undergo γ-hydrogen abstraction in competition with radical cleavage of the α-CS bond. The 1,4-biradical cleaves but does not cyclize.

Nonenolizable 1,3-diketones photocyclize to hydroxycyclobutanones, which requires that the two carbonyls be aligned in opposite directions so that the γ–C–H bonds are within reactive distance of the excited carbonyl.[75] As shown below, phenyl ketones cyclize, whereas aliphatic ketones undergo only type I α-cleavage instead.

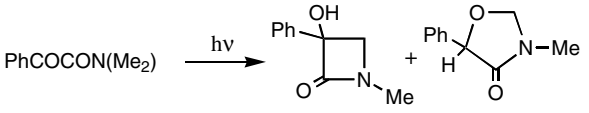


Unlike β-aminopropiophenones, triplet α-dialkylaminoacetophenones do not undergo rapid internal charge transfer; they do, however, undergo singlet state γ-hydrogen abstraction that leads only to cleavage.[17,76]

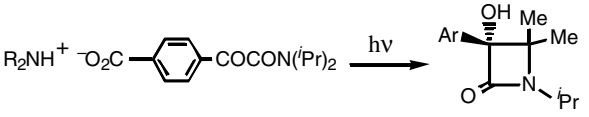
Gold[77] later discovered that α-(*N*-alkylamido)acetophenones undergo γ-hydrogen abstraction to produce azetidinols, revealing the fact that acylation of nitrogen makes electron transfer less competitive by weakening the electron donating ability of nitrogen. Below are three recent examples.



Irradiation of an *N*-phenacyl-δ-lactam in water containing a chiral clathrate produced a single diastereomer of the bicyclic lactam in >90% enantiomeric excess.[78]



Irradiation of a phenylglyoxylamide as a solid inclusion complex formed a β-lactam as well as a oxazolidinone rearrangement product.[79]

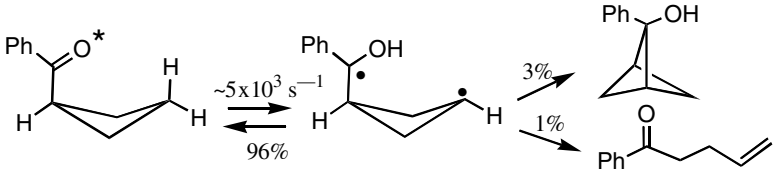


Irradiation of a *para*-substituted phenylglyoxylamide as a suspension of crystals in hexane also formed a β-lactam in >91% yield and 99% enantiomeric excess, the selectivity induced by a chiral ammonium cation paired with the carboxylate anion.[80]

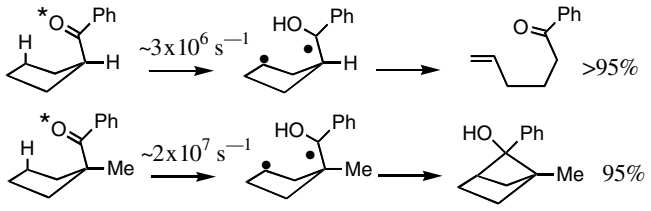
The rapid internal charge transfer in triplet γ-dialkylaminobutyrophenones does not lead to efficient product formation;[46,81] the required orbital overlap seems to enforce a restricted orientation in the exciplex that prevents proton transfer to oxygen, such that CT becomes a purely competitive quenching process. However, simple γ-hydrogen abstraction does compete and forms a 1,4-biradical that cleaves but undergoes very little cyclization.

Acylcycloalkanes and Cycloalkanones

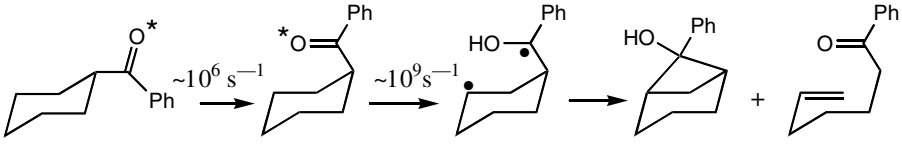
Table 58.2 includes the behavior of the three 4- to 6-carbon cycloalkyl phenyl ketones, all of which undergo γ-hydrogen abstraction with quite different results.[82] Early evidence for the ability of light to convert a reactant into a higher energy isomer was provided by the very low quantum yield photocyclization of benzoylcyclobutane to a bicyclo[1.1.1]-pentanol.[83] That it undergoes more cyclization than cleavage is similar to the behavior of the α,α-dialkyl acyclic ketones. The rate constant for γ-hydrogen abstraction is very low, presumably because of a low population of reactive conformers. Partitioning of the biradical apparently is determined by the poor alignment of its SOMOs for cleavage and by a barrier to twisting the cyclobutadiyl ring enough for radical coupling, leaving disproportionation as the fastest reaction.



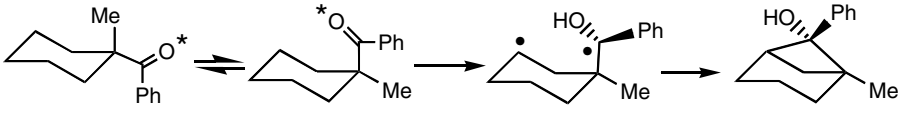
Benzoylcyclopentane undergoes much faster triplet hydrogen abstraction, but the 1,4-biradical does not cyclize, instead cleaving with 22 to 40% efficiency.[82] The k_H value is 1/50th that of valerophenone, indicating the modest barrier required for transannular bond stretches. The 5-benzoyl-1-pentene product undergoes Norrish type II cleavage and also forms a cyclic alcohol, as will be discussed below. An α-methyl group enhances k_H sixfold, most likely by increasing population of the conformer with the benzoyl group in a pseudo-axial position. More important, the 1,4-biradical undergoes only a few percent cleavage and cyclizes with 19% efficiency,[70] paralleling the effect already discussed for acyclic ketones.



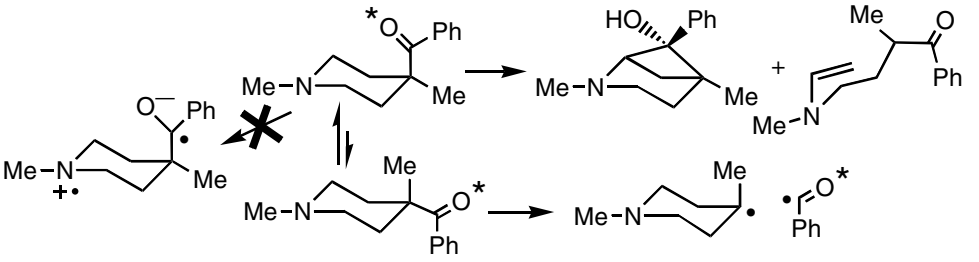
The behavior of benzoylcyclohexane took a while to figure out, as quantum yields for products are extremely low. Lewis and co-workers[84] discovered that the compound has two kinetically distinct triplet conformers, both of which give products. The axial conformer reacts ten times faster than valerophenone, indicating an ideal geometry for reaction as discussed above. The equatorial conformer cannot react directly but undergoes an irreversible chair inversion as the rate determining step to form the highly reactive conformer. The stereochemistry of the cyclobutanol ring was not ascertained, but more recent work indicates that the phenyl is *endo* to the six-ring.



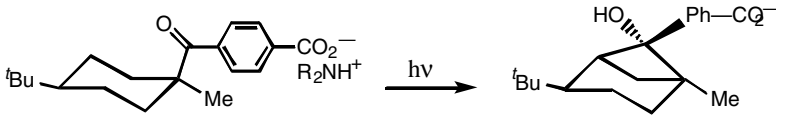
Lewis solved this conformational problem by adding a methyl group to the carbon bearing the benzoyl group, which enhances population of the chair conformer with the benzoyl axial and thus within abstraction range of an axial γ-hydrogen.[84] Its triplet abstracts a hydrogen much faster than it can undergo α-cleavage. The other conformer cannot abstract a hydrogen but, because of the α-methyl, undergoes type I cleavage faster than chair inversion. Quenching studies showed that the two types of reaction occur from kinetically distinct triplets, providing one of the first clear examples of ground-state control of reactivity. The bicyclic alcohol is formed predominately with the phenyl ring *endo*, because H-abstraction occurs with the phenyl twisted away from the α-methyl, where it stays until the biradical cyclizes. As usual, the α-methyl decreases the amount of type II cleavage by the biradical.



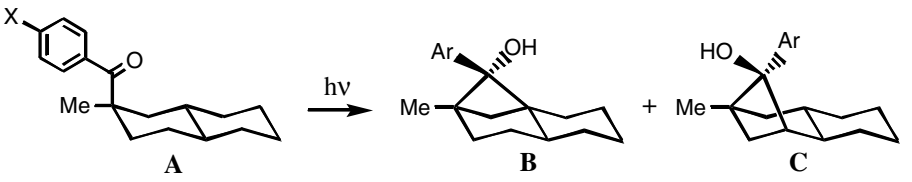
A similar study of 4-methyl-4-benzoyl-*N*-methylpiperidine provided comparable results and the important conclusion that no charge-transfer quenching of the triplet ketone occurs as it does with acyclic γ-amino ketones, proving that the charge transfer does not occur through bonds but requires close through space contact.[85]



Several studies have explored environmental effects on the stereoselectivity of this photocyclization. One particularly nice example is provided by the solid-state photocyclization shown below, in which the counter-ion of the benzoate is a chiral ammonium ion, which results in formation of a single enantiomer of the bicyclic alcohol, presumably by inducing a tilt of the benzoyl group that leads to preferable abstraction from one of the two γ carbons.[86]

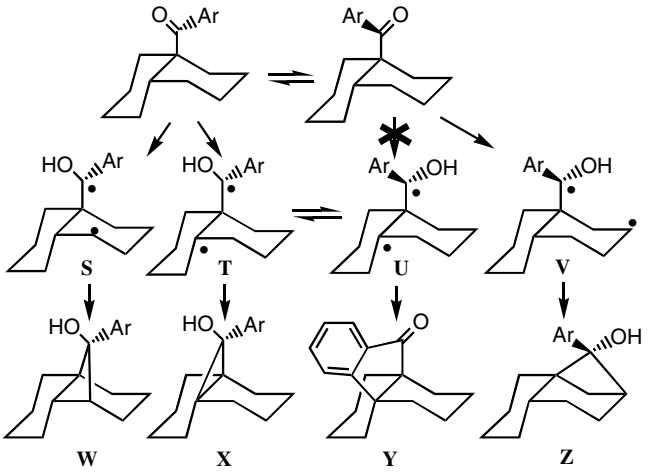


A recent study of benzoyldecalins revealed how the regioselectivity of photocyclization is enhanced in the crystalline state compared to solution.[87] Irradiation of **A** (X = CO_2Me) in CH_3CN results in 42% each of **B** and **C**, with only 6% total of the opposite two diastereomers. Irradiation of crystals produces more **B** than **C** — 2:1 for racemic **A** and 4.6:1 for optically pure **A**. The differences appear to represent conformer populations, there being but one in the crystal but three of similar energies in solution. In the crystal, the benzoyl group is aligned so as to favor abstraction of the tertiary bridgehead hydrogen, whereas the three lowest energy conformers in solution are all aligned differently and thus allow abstraction of both methylene and methine hydrogens. Interestingly, when X is COOH, the **B**:**C** selectivity is reversed to favor **C** both in solution and crystal, probably due to the effect of dimer formation on conformation.

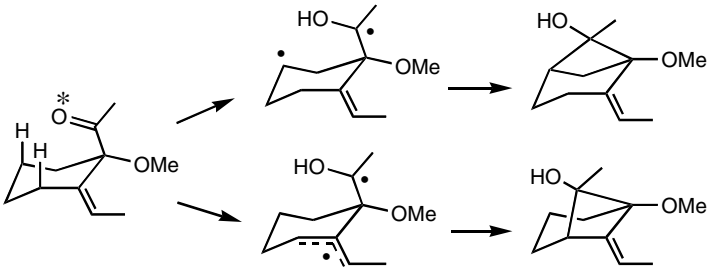


An earlier study of 9-benzoyl-*cis*-decalins produced some unexpected results.[88] Irradiation in acetonitrile solution produces **W**, **Y**, and **Z** in yields of 47, 6, and 47%, respectively. With both pictured conformers of the ketone about equally populated, hydrogens at carbons 4, 10, and 2 are abstracted, and biradical **T** is free to rotate into **U**, which cannot be formed by direct H-abstraction. Compound **Y** was not anticipated, but its formation by radical addition *ortho* to a benzylic radical site would represent a

well-precedented mechanism. The crystalline ketone exists only in the leftmost geometry, with the carbonyl oxygen pointed over the shared CC bond such that only hydrogens on carbons 4 and 10 are close enough for abstraction. Thus, irradiation forms only biradicals **S** and **T**, which form **W** and **X** in 84 and 19% yields, respectively. With an ammonium carboxylate ionic chiral auxiliary attached *para* to the benzene ring, **W** is formed in 99% yield and 91% EE from the crystalline ketone.[89]

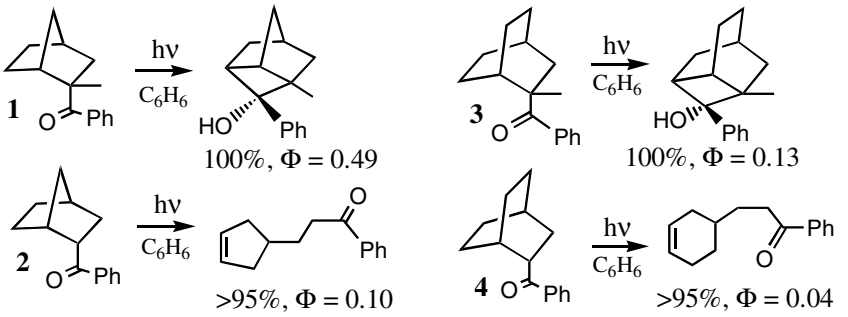


An early example of regioselectivity was provided by the behavior of an acetyl-2-methylenecyclohexane, which photocyclizes primarily via what would appear to be the less readily formed biradical. Only traces of product were found from the allylic biradical, which should be formed at least as fast or faster than the one leading to the observed product.[90]



Several studies of benzoylbicycloalkanes indicate that the *endo*-isomers undergo very rapid triplet-state γ-hydrogen abstraction, with k_H values of 9×10^7, 7×10^9, 3×10^8, and 1×10^{10} s^{-1} for **1**, **2**, **3**, and **4**, respectively.[70] It is noteworthy that the *exo* 2-methyl groups on **1** and **3** slows hydrogen abstraction by two orders of magnitude, presumably because of eclipsing interactions between the methyl and phenyl groups in the transition state for hydrogen abstraction. However, these same eclipsing interactions in the 1,4-biradicals enhance product quantum yields by destabilizing the rotamer, with the OH aimed at the distance radical site and thus minimizing disproportionation. They also must destabilize the geometry required for type II cleavage, because tricyclic alcohols are the only products. In contrast, the 1,4-biradicals from ketones **2** and **4** without methyl groups do not cyclize and cleave with very low efficiency, presumably

because the phenyl group is now free to extend outward and stabilize the geometry required for disproportionation but not cyclization. Interestingly, the biradical geometries required for both cleavage and cyclization are so similar with and without the methyl group that the cyclization/cleavage ratios may be determined by product energies.

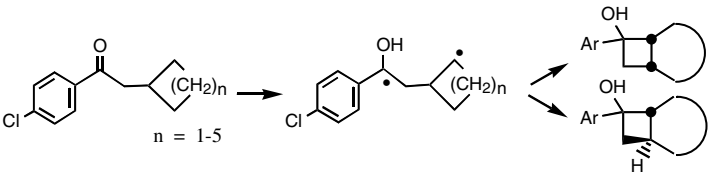


The isomers of **1** and **2** with the benzoyl group *exo* do not photocyclize. Their triplets coincidentally react with the same 1×10^7 s^{-1} rate constant for two different reactions: (1) *exo*-**1** undergoes only type I α-cleavage, the 10^7 rate constant being the same as that for other *t*-alkyl phenyl ketones; and (2) *exo*-**2** does abstract a methylene hydrogen, thus accounting for its low rate compared to *endo*-**2**, while the biradical so produced undergoes only type II cleavage.

Scheffer[25,91] has conducted a thorough study of five α-cycloalkylacetophenones that provide unique insight into biradical behavior. All of them react both in solution and in the crystal and give comparable product ratios in both phases. With the knowledge that organic molecules normally crystallize in their most stable conformations, examination of solution rate constants for hydrogen abstraction revealed no correlation with the geometric parameters for reaction. The rate constants do correlate well with those for bimolecular attack of various radicals on the different sized cycloalkanes, so the intrinsic reactivities of the different C–H bonds appear to determine relative reactivities. Scheffer concluded that Eq. (58.4) applies, with comparable values of χ for all five α-cycloalkylacetophenones. He suggests that these ketones react not from their most stable conformations but rather from higher energy ones that provide a more favorable geometry for reaction. The value of θ averages only 114° for the crystals. It is also possible that these compounds all react from their crystal geometries, in which case χ_r values are all close to one. All of the ketones except the cyclobutyl are considerably more reactive than *p*-chlorovalerophenone despite their awkward geometries. The rate enhancements probably represent the normal entropic gain associated with the ring.[40] The high observed k_H values cannot contain a really low value of χ_r, so any common geometric adjustment in solution must involve a relatively low energy conformational change.

The two ketones with the smallest rings undergo primarily cleavage, the next two split nearly 50:50, and the largest ring gives mainly cyclobutanol. In the last case, over 85% of the cyclization gives the *trans* ring junction. Scheffer provides an intriguing explanation by noting that the *p* orbital on the ring in the biradical must twist 90 ± 45° to become parallel to the *p* orbital at the hydroxy radical site and achieve the geometry required for both cleavage and cyclization. Rotation in the direction that gives *cis* products is favored for the two smallest rings; rotation in the opposite direction, which favors formation of *trans* products, is favored for the largest ring; the two rotations are equally likely for the six- and seven-rings. Because the three largest ketones yield mostly *trans*-fused cyclization products but *cis*-cycloalkene cleavage product, Scheffer concluded that the pre-*cis* biradical undergoes mainly cleavage, and the pre-*trans*

biradical undergoes mainly cyclization. He further proposed that the phase independence of the results indicates that these preferences are intrinsic to the structure of the molecules.



n	*d* (Å)	ω	Δ	k_H (10^8 s^{-1})	% Cleavage	% Cyclization (*t*/*c*)
1	3.1	23	78	0.3	92	8

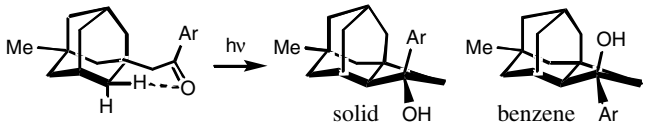
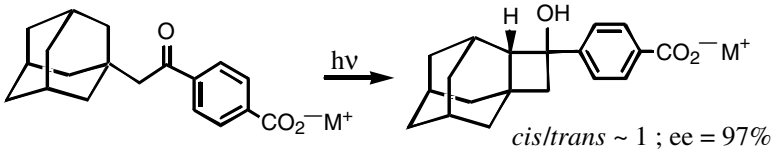
3	2.6	42	90	1.2	40	60 (7.5:1)
4	2.7	42	82	5.7	61	41 (12:1)
5	2.7	48	77	6.7	18	82 (15.4:1)

Study of adamantylacetophenones has revealed several types of selectivity. In a chiral (methyladamantyl)acetophenone, hydrogen abstraction takes place only across the ring from the bridgehead methyl group, and the biradical cyclizes to opposite diastereomers in benzene and the solid state.[92] Under topological control in the rigid crystal, the biradical maintains its initial pre-*cis* geometry and cyclizes to a single isomer in 82% EE. In solution, the biradical is free to rotate into a less crowded geometry and forms a racemic epimer as major product. Attachment of a chiral auxiliary via a carboxylate group provides very high EE but no diastereoselectivity in the alcohol products of a skeletally achiral compound irradiated in solution.[93]





Lewis and Hirsch[94] studied four α-cycloalkoxyacetophenones, in which the ring is even farther away from the carbonyl and the γ-hydrogen is tertiary.[94] Table 58.3 lists the results, which consist of oxaspiro[3,*n*]alkanol and cycloalkanone formation, via normal cyclization and cleavage of the 1,4-biradicals. Simple isopropoxyacetophenone is included for the sake of comparison to acyclic compounds. As with other α-alkoxy ketones, overall quantum yields are quite high and cyclization yields are reasonable, except for the cyclopropyloxy ketone. Hydrogen abstraction rate constants are very high and decrease as expected as the rings get smaller.

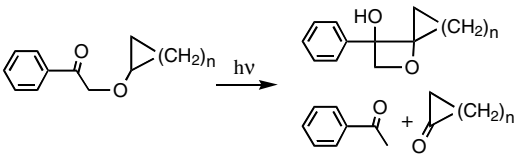


TABLE 58.3 Product Quantum Yields from α-Cycloalkoxy Ketones

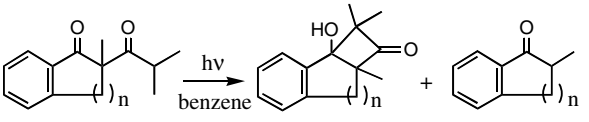
Ketone	Φ_{cyc}	Φ_{elim}	k_H (10^9 s^{-1})
Isopropoxy	0.40	0.59	8.2
$n = 4$	0.20	0.38	8.9
$n = 3$	0.28	0.33	6.9
$n = 2$	0.42	0.40	3.3
$n = 1$	0.06	0.02	0.24

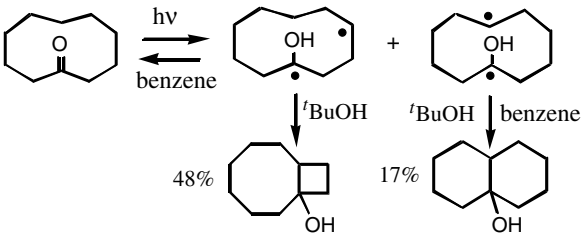
Cycloalkanones themselves undergo photoinduced α-cleavage to produce biradicals that disproportionate in various ways. Both singlet and triplet excited states of simple α-alkylcycloalkanones undergo γ-hydrogen abstraction, but the 1,4-biradicals mainly cleave to cycloalkanone and alkene. Yields are very low due to very rapid competing α-cleavage of the ring; consequently, cyclobutanol formation occurs at best in small amounts.

Yoshioka and co-workers[95] have studied several 1,3-diketones that undergo γ-hydrogen abstraction to yield primarily hydroxycyclobutanones. The behavior of three benzocyclohexenones reveals how the competition between cyclization and cleavage of the 1,4-biradicals varies with ring size. As shown in Structure 33, the percentage of cyclization decreases as ring size increases from 6 to 8, while the yield of type I α-cleavage increases from 0 to 50%.

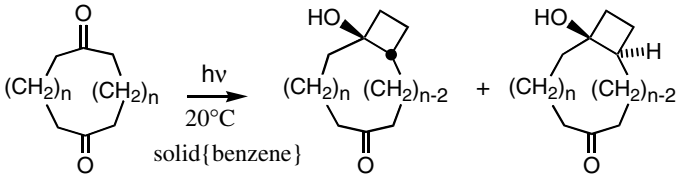


n		
2	65%	1%
3	47%	4%
4	7%	10%

The larger cycloalkanones can undergo cross-ring hydrogen abstraction, the first example of which was provided by cyclodecanone, which is now known to undergo both γ- and ε-hydrogen abstraction, such that both bicyclo[6.2.0]- and bicyclo[4.4.0]decanols are formed.[35] The fact that only the 1,4-biradical reverts to ketone in benzene must be a subtle conformational effect, although it is not clear why the two biradicals would differ enough in geometry that only one would disproportionate. It cannot be due to differences in cyclization rates: Cyclization to six-membered rings should be thermodynamically favored over cyclization to an eight/four bicycle, but both biradicals manage to cyclize when solvated by alcohol, with three times as much cyclobutanol as hydroxydecalin being formed. The nearly 3:1 preference strongly suggests that γ- is faster than ε-hydrogen abstraction in this molecule, but not by as large a ratio as would occur in an acyclic ketone.



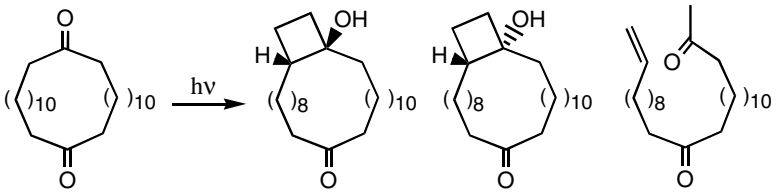
Scheffer's group has extended investigation of the conformational aspects of cycloalkanone photochemistry to a group of macrocyclic diketones. An early study is shown in Structure 35.[96] Four symmetric cyclic diketones photocyclize with the same sort of phase dependent stereoselectivity noted for monoketones. Cyclohexadecane-1,9-dione and cycloeicosane-1,11-dione undergo photocyclization in the crystal primarily to *cis*-cyclobutanols. In contrast, cyclooctadecane-1,10-dione and cyclodocosane-1,12-dione produce mainly *trans*-cyclobutanols in the crystal. Each compound has two pairs of symmetry-related γ-carbons, one of which has a γ-hydrogen closest to the carbonyl (~2.7 Å). Each additional methylene between the two carbonyls causes the ring puckering to alternate such that, on the carbon attacked, the hydrogen that is *not* abstracted is alternately *syn* or *anti* to the carbonyl oxygen. This hydrogen becomes the bridgehead methine that is either *cis* or *trans* to the hydroxy group in the cyclobutanols. The few percent type II elimination in the crystal increases to 45 to 50% in solution, and the *trans*/cis cyclobutanol ratio is 2.5–3:1 for all four diketones; obviously, topological control is not present in solution. The stereoselectivity shown by these diketones is temperature dependent because of solid-state phase transitions.



n = 5 or 7	85%	{12%}	13%	{43%}
n = 6 or 8	3%	{13%}	88%	{37%}

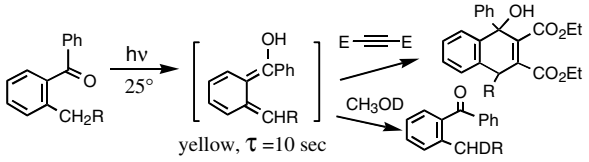
Two other symmetric cyclic diones show unique behavior. Cyclodecane-1,6-dione is photoinert, both as a solid and in solution.[97] Evidence indicates that it undergoes excited-state γ-hydrogen abstraction, but the biradical does nothing except revert to ground-state reactant, presumably for the same reasons as the 1,4-biradical from cyclodecanone. Unlike the monoketone, the dione has no ε-hydrogens to abstract.

A much bigger symmetric macrocycle, crystalline 1,14-cyclohexacosanedione exists as both plates and needles. When irradiated as crystals, the former yields only a *cis*-cyclobutanol, while the latter form gives the *trans*-cyclobutanol with >90% selectivity; neither undergoes type II elimination. In solution, type II cleavage accounts for half the products, the other half are cyclobutanols in a 2.3:1 *trans/cis* ratio. These results provide another example of how crystal lattices enforce conformationally driven stereoselectivity, which can vary with the exact crystal morphology.[98] A full paper has been published that provides details for a wide range of symmetric and unsymmetric cycloalkanediones.[99]

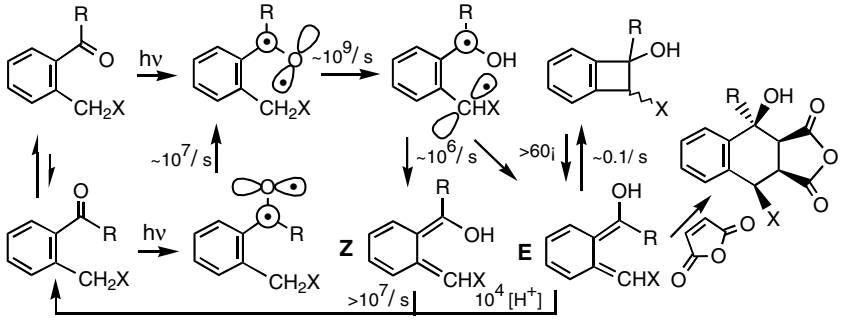


o-Alkylphenyl Ketones: Yang Photoenolization

In 1961, Yang and Rivas[100] discovered that some *o*-tolyl and *o*-benzylphenyl ketones undergo γ-hydrogen abstraction to form *o*-xylylenes that are trapped by dienophiles to form benzocyclohexenols. In CH_3OD, the benzylic carbon of the starting ketone is deuterated, additional evidence that a dienol intermediate (an *o*-xylylenol) is involved.

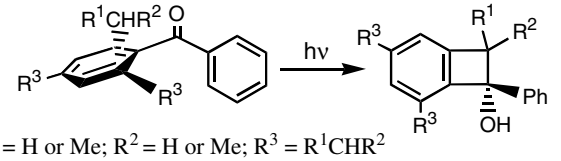


Over the intervening decades, various details of this enigmatic reaction have been clarified, as shown in Scheme 7. First came the realization that the initially formed triplet biradical is an excited state of the product xylylenol and its decay to ground state requires bond rotations, which partially answered the puzzle as to why Diels–Alder adducts are generated stereospecifically from a single dienol isomer (labeled E in Scheme 7).[101] Wagner and Chen[38] then found that the two rotamers of *o*-alkylacetophenones have kinetically distinct triplets, with rotation to the reactive geometry being the pathway for decay of the unreactive rotamer. Laser flash kinetics soon identified the two isomeric xylylenols in Scheme 7 and found that the *Z*-isomer undergoes very rapid reversion to starting ketone via a 1,5-sigmatropic hydrogen transfer, leaving only the *E*-isomer to form new products.[102]



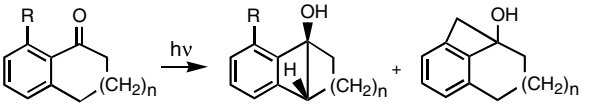
SCHEME 7 Intermediates and alcohol products formed from *o*-alkylphenyl ketones.

Meanwhile, and most relevant to this chapter, Matsuura and Kitaura[103] reported the formation of benzocyclobutenols from 2,4,6-trialkylphenyl ketones. Matsuura et al.[104] studied these photocyclizations quite extensively, including the photocyclization by crystalline 2,4,6-triisopropylbenzophenone, which occurs cleanly despite a 76° value for ω.[30] Until recently, only two examples had been reported of benzocyclobutenol formation from simple *ortho*-alkyl ketones.[101,105]



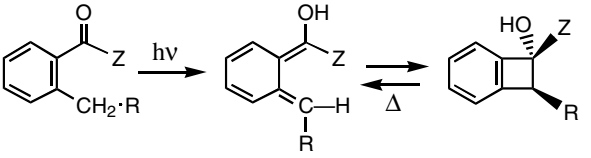
R^1 = H or Me; R^2 = H or Me; $R^3 = R^1CHR^2$

Carré and co-workers[106] studied a group of benzocycloalkenones that form tricylic benzocyclobutenols. As might be expected, transannular γ-hydrogen abstraction competed with *o*-methyl abstraction only for ring sizes of 10 or more carbons, and again ω was nowhere near 0°. The *cis* geometry of the [4,*n*+1]bicycles formed is explained below.



R = H ; n = 4 - 6 R = Me ; n = 3 - 6
R = Me ; n = 5 - 9

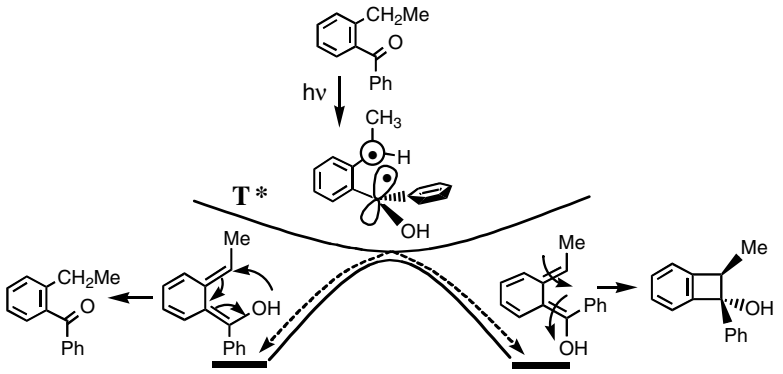
Eventually it was found that many *o*-alkylphenyl ketones not only undergo photocyclization to benzocyclobutenols but do so stereoselectively; a few early examples are shown in Structure 40.[107] Acids quench the photocyclization, indicating that the *o*-xylylenols are the precursors to the cyclobutenols and form them by thermal electrocyclization. The reason for their not having been discovered earlier is their thermal instability above 60 to 80°C.



Z = CH_3 : R = OCH_3 or $OCH_2CH{=}CH_2$
Z = Ph : R = H, CH_3 or Ph

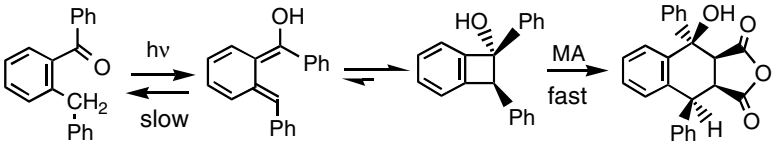
The stereochemistry for the electrocyclization of one of these *o*-xylylenols is explained by Scheme 8; the lowest energy conformer of the triplet biradical is the one that decays to two xylylenols, one with the OH pointed out forming the cyclobutenol by conrotatory motion, and any Diels–Alder cycloaddition occurs by disrotatory motion.[108] More specific examples are described in Reference 108.

Thus, this form of γ-hydrogen abstraction does produce cyclic alcohols, but it does not do so in two simple steps, as the initial biradical converts to ground-state *o*-xylylenols, which then undergo thermal pericyclic reactions. As noted earlier, the thermal equilibrium between *o*-xylylenol and benzocyclobutenol generally favors the latter. Because heating regenerates *o*-xylylenol, doing so in the presence of a dienophile can produce Diels–Alder adducts quite cleanly, thus giving these cyclobutenols significant synthetic potential. *ortho*-Benzylbenzophenone displays unique behavior in that the equilibrium between its



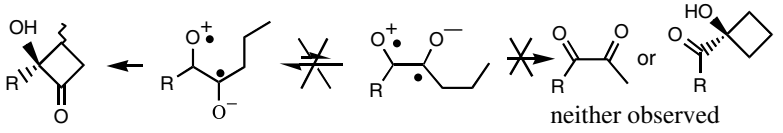
SCHEME 8

o-xylylenol and cyclobutenol photoproducts keeps small amounts of the xylylenol populated at room temperature, so that addition of dienophiles produces Diels–Alder products.[109]



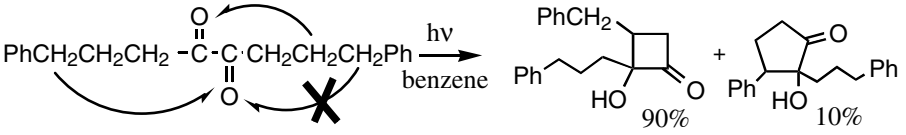
α-Diketones

In the early 1960s, Urry and Trecker[110] discovered that aliphatic α-diketones undergo photoinduced cyclization to α-hydroxycyclobutanones. Most interestingly, they do not form any acylcyclobutanols and, unlike α-ketoesters, do not undergo any type II cleavage. One of the carbonyl groups abstracts a hydrogen only from the alkyl group attached to the other carbonyl.

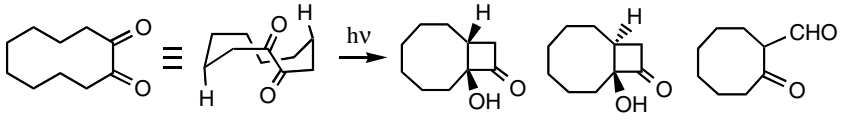


This regioselectivity originally was ascribed to the preferred geometry of the excited triplet being *anti*. The *syn* geometry could not possibly produce the observed products, but it is not obvious why an alkyl group next to either carbonyl could not be aligned in a reactive position; however, it is the unusual nature of the n,π^* excited state that causes the observed regioselectivity, with through-bond coupling splitting the *n* orbitals such that radical-like reactivity appears to be greatest on the inner lobe of the oxygen *n* orbitals. The structurally symmetric 1,8-diphenyloctan-4,5-dione provided an impressive early example of this selectivity, with simple methylene γ-hydrogen abstraction being preferred over benzylic.[111] Interestingly, some 10% of a 3-phenyl-2-hydroxycyclopentanone was also formed. Given the creed of the times, only γ-hydrogen abstractions were considered possible, so it was suggested that the **X**-ed out forbidden γ-hydrogen transfer had occurred; however, current knowledge recognizes this as an early demonstration of the ~20 γ/δ rate ratio, as abstraction of a secondary benzylic hydrogen is only three

times faster than abstraction of an unactivated methylene hydrogen. This new interpretation is consistent with the nonreactivity of the outer lobe of the *n* orbital.



One cyclic α-dione has been studied — 1,2-cyclodecanedione. As in the nonconjugated diketones described previously, one of its carbonyls abstracts a γ-hydrogen, but from across the other carbonyl, like acyclic diketones.[112] When irradiated as crystals, it forms only the *cis*-cyclobutanol product. In benzene, both isomers are formed in a 7:1 *cis*/*trans* ratio; a cleavage product, 2-ketocyclooctanecarboxaldehyde, is also formed, either by direct cleavage of the reactant's O=C–C=O bond or by α-cleavage of a product's HOC–C=O bond, followed by disproportionation of the resulting biradical in either case. It does not appear as though as much attention has been given to the stereochemistry of the products formed from most other α-diketones.



Rate constants for hydrogen abstraction by α-diketone triplets are only 0.1% as large as those for comparable monoketones, although relative rates toward primary, secondary, etc. hydrogens are similar for both mono- and diketones.[113,114] The low rate constants for triplet reaction allow phosphorescence to compete, something that almost never occurs for monoketones. Phenyl alkyl diketones undergo another competing reaction: enolization of the β-carbonyl in diketones with α-hydrogens. The mechanism is not known but could involve β-hydrogen abstraction. It definitely affects the efficiency of cyclization. However, slight amounts of acid catalyze the enols back to diketone and should maximize cyclobutanol formation, as long as irradiation is done at wavelengths long enough to be absorbed only by the diketone.

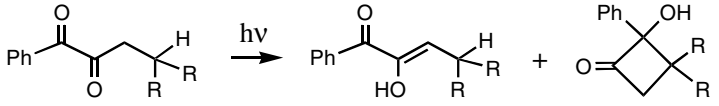


Table 58.4 lists kinetic parameters for a group of phenyl alkyl diketones.[114] When R is neopentyl there are no γ-hydrogens (just three γ-methyls) but nine δ-hydrogens, none of which is abstracted by either carbonyl group. The analogous monoketone, γ-dimethylvalerophenone, undergoes triplet δ-hydrogen abstraction with a rate constant ~4×10^5 s^{-1}. That indicates a rate ~1×10^3 s^{-1} for the diketone, less than 1% the rate of enolization, which explains the lack of photocyclization of this compound.

The electronic asymmetry of the phenyl alkyl diketones prompts, as a possible explanation for the regioselectivity that they show, the idea that reactivity is localized on the benzoyl carbonyl, but the regioselective behavior of the symmetric aliphatic diketones refutes that notion. Moreover, no distal γ-hydrogens are present on the phenyl diketones for the β-carbonyl to abstract.

TABLE 58.4 Kinetic Parameters for 1-Phenyl-1,2-Diones PhCOCOR in Benzene

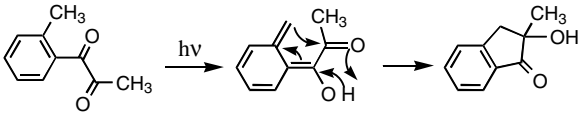
[c] *p*-Methoxy.

Another reaction of aryl α-diketones originally was thought to involve γ-hydrogen abstraction from an *ortho*-alkyl group, although the product is a hydroxyindanone.[111,115] The quantum yield in methanol for the *o*-tolyl compound was 83%, but only a few percent when the *ortho*-alkyl group was bulky. At the time this reaction was discovered, it was still generally assumed that internal hydrogen abstraction occurred only from γ-carbons. Thus, several hypotheses were advanced for rearrangement following abstraction from an *ortho*-carbon. One is shown in Structure 46 and is plausible but no longer considered too likely. The fact that no benzylic deuteration occurred when the reaction was run in methanol-*O*-d did provide a warning that a dienol may not have been formed. Likewise, an 83% quantum yield for a Yang enolization seems unlikely given that half the *o*-xylylenols usually revert to starting ketone. More details, together with some stereochemistry, appear later in the section on δ-hydrogen abstraction.

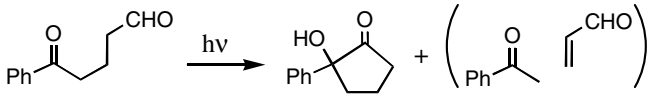


1,5-Biradicals: δ-Hydrogen Abstraction

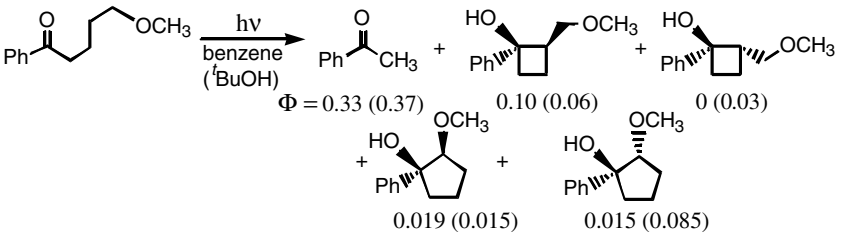
As noted above, efficient δ-hydrogen abstraction requires the absence of reactive γ-hydrogens, where the definition of "reactive" involves both CH bond strength and proximity to the carbonyl. Several classes of compounds fulfill these requirements, and many papers have been published describing a wide variety of reactants. Paquette's synthesis of dodecahedrane is the model for overall geometry being more important than intrinsic reactivities, excited cyclopentanone units undergoing hydrogen abstraction only at δ-carbons and faster than the very rapid type I α-cleavage of cyclopentanones.[42]

Acyclic Ketones

Two ketones were mentioned above that undergo both γ- and δ-H-abstraction because their structure enhance δ-reactivity and lower γ-reactivity. 4-Benzoylbutanal forms both an α-hydroxycyclopentanone and acetophenone in a 2:1 ratio.[45]



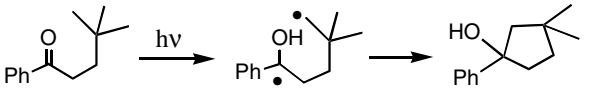
δ-Methoxyvalerophenone behaves similarly; quantum yields are shown below.[44] Product yields from the 1,4-biradical are much greater than cyclopentanol yields, although the rate constants for hydrogen abstraction are each ~2.6×10^7 s^{-1}.



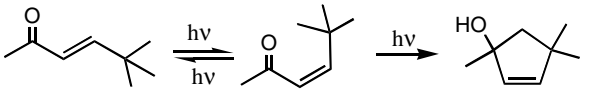
Quantum yields for cyclization of hydroxy biradicals formed from acyclic ketones in general are low because of rapid reversion to ketone, especially so for 1,5-biradicals, the cause for which is explained below and in Scheme 9. It is noteworthy that the alcohol solvent enhances formation of the cyclic alcohols with the OH and methoxymethyl groups *trans* to each other and lowers yields of the *cis*-isomers. It also should be noted that no 1,8-hydrogen transfer competes with the δ-hydrogen abstraction, even though the methoxy group possesses highly reactive CH bonds except for their distance from the carbonyl.

δ-Thioalkoxyvalerophenones form cyclobutanols but no measurable cyclopentanols for two reasons: (1) internal charge transfer quenching by the sulfide causes 78% of the triplet decay; and (2) the δ-alkylthiyl group activates δ–CH bonds and deactivates γ–CH bonds less than does a δ-alkoxy group, so that no more than 5% of the triplets undergo δ hydrogen abstraction and only 10% of them cyclize (as is the case for the δ-methoxy compound).[73]

The simplest example of δ-hydrogen abstraction is provided by γ-dimethylvalerophenone, which has no γ-hydrogens. It forms a 3,3-dimethylcyclopentanol in high yield but low quantum efficiency (0.04 in benzene). Its measured triplet lifetime of only 500 nsec indicates a rate constant for δ-hydrogen abstraction only 1/30th the rate constant for γ-hydrogen abstraction by triplet β-dimethylbutyrophenone.[28]

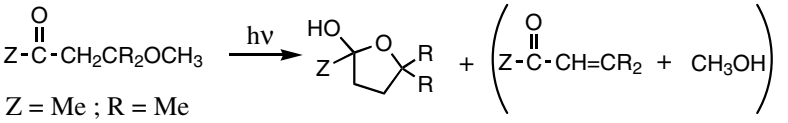


Photocyclization of 5,5-dimethyl-3-hexen-2-one provides an aliphatic example, with the added twist that the α,β-unsaturated ketone undergoes photoinduced *cis*/*trans* equilibration, which allows the *cis*-isomer to undergo δ-hydrogen abstraction.[116]

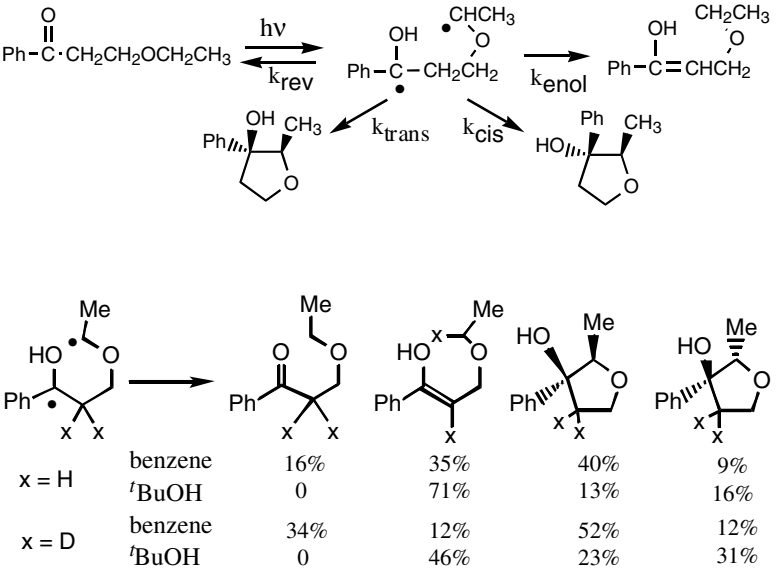


β-Alkoxy Ketones

Photocyclization of β-alkoxy ketones provided the earliest examples of δ-hydrogen abstraction in acyclic ketones.[117] Some of the compounds studied had readily abstractable γ-hydrogens but no oxetanes or type II cleavage products were formed. Instead, oxacyclopentanols and α,β-unsaturated ketones were formed. Originally it was thought that only δ and no γ-hydrogen abstraction occurred. Later it was suggested that γ-hydrogen abstraction must have occurred but that the 1,4-biradical eliminated methanol rather than cyclize.[44]

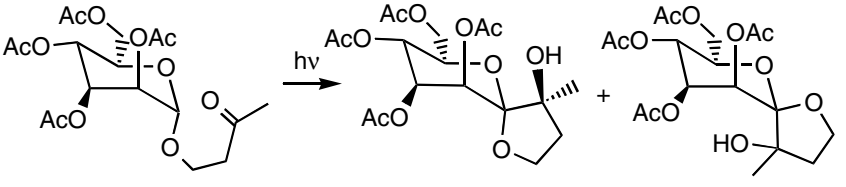


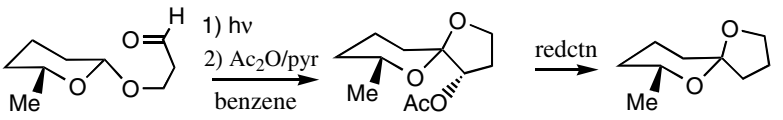
Irradiation of β-ethoxypropiophenone produces oxacyclopentanols in good yield and reveals the surprising fact that most of the biradical reversion to ketone involves a 1,4-hydrogen transfer to produce the enol of starting ketone.[118] It is this second path for reversion of the biradical to ketone, which is twice as fast as the one that transfers an OH hydrogen, which causes the low quantum yields for cyclization in many other 1,5-biradicals. In this case, as with α-alkoxy ketones, cyclization quantum yields are quite high and indicate again that biradical reactions are affected by energies of the products being formed; in this case an oxygen eliminates eclipsing interactions in the developing oxacyclopentanols. Scheme 9 shows how the 1,5-biradical partitions between reversion and cyclization. As usual, an alcohol solvent, by solvating the biradical OH group, lowers the yields of cyclization and reverses the *trans*/*cis* ratio of the diastereomeric products. α-Deuteration of the ketone raises the cyclization yields because of a primary isotope effect on the rate of enolization. The rate constant for triplet δ-hydrogen abstraction is 1.4×10^7 s^{-1}, much smaller than the $\sim 5 \times 10^9$ for the equivalent α-ethoxy ketone.



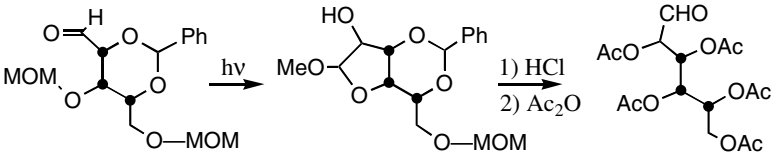
SCHEME 9

Following are a few examples of photoinduced δ-hydrogen abstraction in β–alkoxy ketones as a synthetic method. Descotes has studied the photoreactions of ketones tethered to sugars as 4-hydroxy-2-butanone glycosides.[119] In Structure 53, one isomer is formed as a single diastereomer, likely due to hydrogen bonding of the biradical OH to the axial acetate group. In Structure 54, a simple synthesis of a pheremone is displayed.[120] Descotes also has reviewed many aspects of sugar photochemistry.[121]

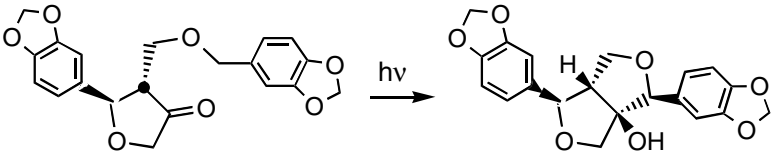




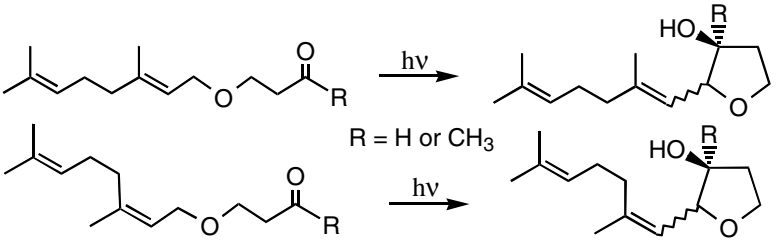
Kraus and Schwinden[122] utilized protecting groups, especially methoxymethyl (MOM), which allowed the pentose xylose to undergo photoinduced δ-hydrogen abstraction, which produces a cyclic acetal. Acid catalysis converts the acetal carbon to an aldehyde, such that the overall process produces two epimeric hexoses, gulose and idose. The same paper provides a short review of other sugar photochemistry.



Kraus and Chen[123] have reported the completely stereospecific synthesis of racemic paulownin based on δ-hydrogen abstraction by a β-alkoxy ketone. It is particularly interesting that only one of four possible diastereomers is formed during cyclization of the 1,5-biradical intermediate, the one that would arise if coupling occurs only on the same face of the initial five-membered ring as hydrogen abstraction took place and with the substituents at the δ-radical site maintaining the same relative configuration they had before hydrogen abstraction. Further such examples follow.



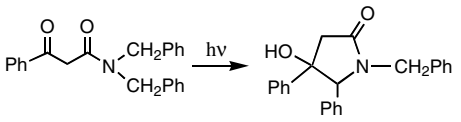
Carless and co-workers[124] tested the ability of β-allyloxy ketones to maintain the original geometry of the allyl double bond upon formation of the 1,5-biradical. In the examples below, the biradicals cyclize faster than the allyl radicals can interconvert between their *cis* and *trans* geometries. Both diastereomers of the oxacyclopentanols are formed in this case, unlike the Kraus example.[123]



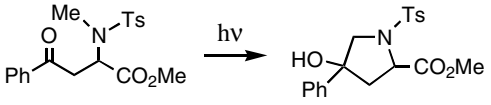
β-Amido Ketones

As mentioned above, *N*-acylation of amino ketones suppresses the basicity of the nitrogen lone pair and thus its electron-donor potential. That being the case, β-amido ketones operate much like β-alkoxy

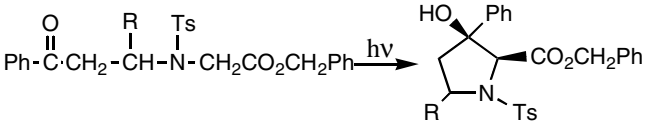
ketones, in that δ-hydrogen abstraction is possible and γ-hydrogens may be absent. The nitrogen atom in *N*-alkyl-acylacetamides is also in a β position with respect to the ketone carbonyl. Thus, irradiation of *N*-alkyl-2-acylacetamides produces γ-lactams, as shown below.[125]



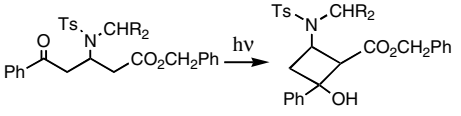
Henning's group was the first to show that δ-hydrogen abstraction by photoexcited *N*-(2-acylethyl)-*N*-tosyl aminoacid derivatives produces substituted prolines with high diastereoselectivity.[125] Since then, a large number of remotely acylated *N*-tosyl aminoacid derivatives have been studied, primarily by the groups of Wessig and Giese. Below are three reactions that exemplify different modes of hydrogen abstraction.[127] The first shows a proline synthesis from a *N*-alkyl alanine ester with the β–benzoyl group part of the aminoacid itself. Both diastereomers are formed and the S configuration of the alanine is maintained, because hydrogen abstraction takes place from an *N*-alkyl group.



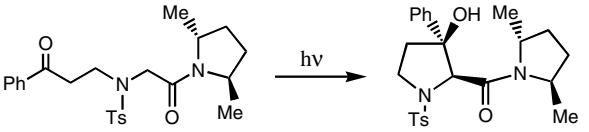
In the next reaction, the acylethyl group is attached to the nitrogen and the δ-hydrogen abstracted is on the stereocenter of the amino acid. CH bonds α to a carboxyl group normally are not highly reactive, but in this case they are modestly activated by the amide nitrogen. The OH and carbobenzyloxy groups are *cis* in the racemic major products, due to internal hydrogen bonding in the biradical.



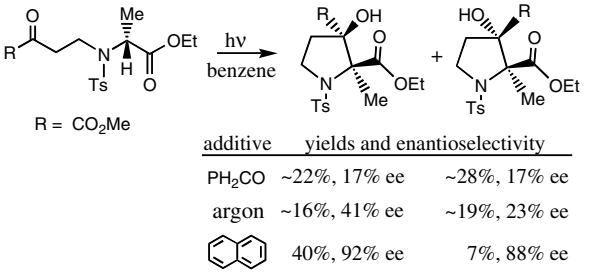
The third reactant, a γ-benzoyl-β-(*N*-alkylamido)butanoate ester, is a one-carbon homolog of the first reactant; its reaction exemplifies the greater reactivity of γ relative to δ-hydrogens. Triplet γ-benzoylbutanoate esters undergo γ-hydrogen abstraction with rate constants of only 1×10^7 s^{-1}, so the k_H values for CH bonds next to amide nitrogens must be considerably lower than those for δ-hydrogens in β-alkoxy ketones, which are also in the 1×10^7 range.



With a pyrrolidine chiral auxiliary, the *N*-(2-benzoylethyl)-*N*-tosylglycinamide below undergoes δ-hydrogen abstraction to enantioselectively form two proline diastereomers, the one with OH *cis* to the carboxamide group favored 4:1.[128] The major product has the S configuration shown as the pyrrolidine structure induces the hydrogen abstraction to occur mainly from the top face (as drawn) of the molecule, from which the biradical cyclizes. With even larger groups on the pyrrolidine, the EE for product formation actually rises to 100%.



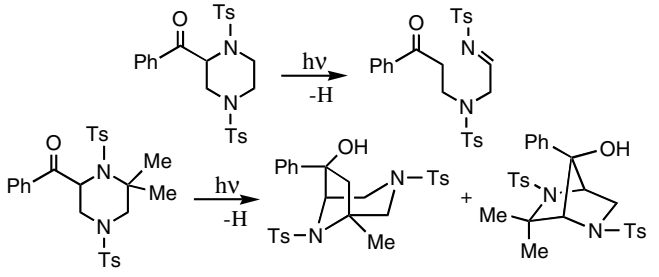
With *N*-(2-acylethyl)-*N*-tosyl-alanine esters, the proline products retain the configuration of the α-carbon of the alanine to various degrees depending upon conditions, as shown in Scheme 10.[129] With added benzophenone, which sensitizes triplet reaction of the ketoester, a triplet biradical is formed and there is little stereoselectivity. With air replaced by argon, both singlet and triplet states react and selectivity is higher. Addition of 1-*M* naphthalene greatly enhances both enantio- and diastereoselectivity. The naphthalene sensitizes excited singlet formation and quenches all triplet reaction so that only singlet biradicals are formed.[130] The selectivity trends illustrate the varying speeds with which singlet and triplet biradical coupling competes with conformational changes. Thus, the triplet biradicals clearly approach conformational equilibrium before cyclizing in this quite flexible molecule, whereas only a little bond rotation occurs before singlet biradicals cyclize. When R = phenyl, as in the above examples, only triplet reaction occurs.



SCHEME 10

Giese has summarized the different approaches to achieving enantioselective photocyclization of remotely acylated aminoacids as follows: With triplet ketone reactions, asymmetric induction via chiral auxiliaries is needed to coax the long-lived biradicals into appropriate geometries, as triplet biradicals tend to live long enough to assume several conformations before cyclizing; with singlet ketone reactions, molecular chirality such as that of alanine can induce the triplet carbonyl into an appropriate geometry for hydrogen abstraction from which the singlet biradical can cyclize quite rapidly.[131]

Henning and co-workers[132] earlier studied the photocyclization of some cyclic amides, such as the tosylated piperazines shown below. With no alkyl groups on the piperazine ring, only γ-hydrogen abstraction and type II elimination occur, just as with acylcyclohexanes. With an alkyl group on the γ-carbon, two things happen: In the chair conformation, δ-hydrogen abstraction from that alkyl group generates a bicyclo[3.2.1]octanol product; in a twist-boat conformation, cross-ring abstraction of a δ-hydrogen occurs to yield a bicyclo[2.2.1]heptanol product.



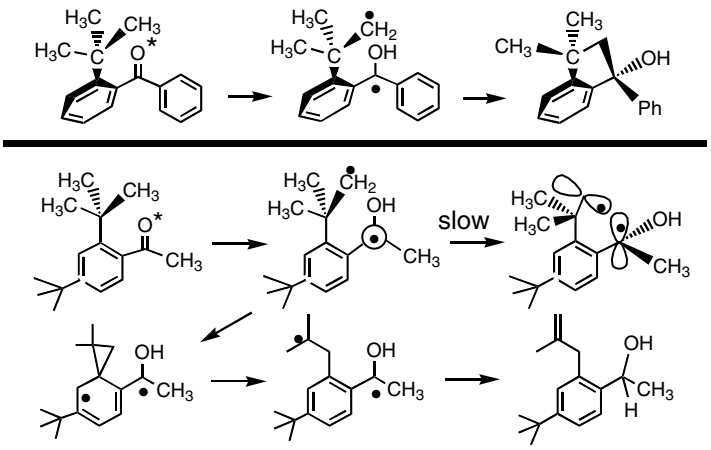
o-t-Alkylphenyl Ketones

Triplet *o-t*-butylbenzophenone does not undergo bimolecular photoreduction but instead undergoes rapid intramolecular δ-hydrogen abstraction to form an indanol both in solution and as crystals.[133] The quantum yield for cyclization is only 5% in hydrocarbon solvents, a value that leaps to 100% in alcohol solvents. It is not clear why the unsolvated 1,5-biradical undergoes disproportionation so much more than cyclization, but its 4-ns lifetime (Table 58.1) indicates that it disproportionates back to ground-state ketone some ten times faster than do 1,4-biradicals. This ketone provides the best evidence that rates of hydrogen abstraction in solution are determined by the distance, not the number of connecting atoms, between a hydrogen and the carbonyl. Hydrogens on two of its methyl groups are within 2.5 Å of the oxygen, and its k_H of 10^9 s^{-1} is close to the value for γ-hydrogen abstraction by triplet *o*-methylbenzophenone. The temperature dependence of its triplet lifetime revealed an E_a value of 2.5 kcal/mole and an A value of 10.6.

The high rate constant and the low activation energy for abstraction of a plain methyl hydrogen raised the question of whether hydrogen abstraction in these molecules involves tunneling. Measurement of the activation parameters for 2,4-di(*t*-butyl-h_9) and di(*t*-butyl-d_9) benzophenones revealed identical $\Delta S^{\ddagger}$ values for the two and a 1.1-kcal/mol higher $\Delta H^{\ddagger}$ for the deuterated ketone.[134] This behavior is exactly what is predicted for primary isotope effects driven by zero point energy differences and rules out tunneling as a mechanism for hydrogen transfer in these compounds.

	k_H 22 C		
R = Ph	1×10^9 s^1	99%	< 1%
R = CH_3	~2×10^8 s^1	5%	95%

For analogous acetophenones, the major product is not an indanol but an *ortho*-alkenylbenzyl alcohol, which is formed by internal rearrangement.[135] It is believed that the 1,5-biradical formed by δ-hydrogen abstraction forms a spiro-triene, possibly as a triplet, which can reopen to a rearranged biradical that disproportionates so as to yield an alcohol rather than a ketone. The reason for this reverse form of disproportionation has yet to be found, but that the rearranged biradical disproportionates rather than cyclizes is normal for the interaction of two tertiary radicals. However, the different behavior of the benzophenone- and acetophenone-derived biradicals is readily explained by the different geometries of the two ketones. The coplanar alignment of the acetyl group and benzene ring in the triplet state is transferred to the biradical, maintaining benzylic π-conjugation; the bond rotation required for biradical cyclization is slow, as it weakens benzylic conjugation. In contrast, the *t*-butylphenyl ring is twisted over 70° out of coplanarity with the carbonyl, such that the 1,5-biradical is formed in a geometry ideal for coupling of its two radical sites, which explains its efficient cyclization in crystals. Thus, what little rearrangement may compete could not be detected.



Irradiation of *o-t*-amylbenzophenone produces indanols with varying regio- and diastereoselectivity depending on conditions.[136] The former is of particular interest because one hydrogen on the methylene and one on a methyl group, both 2.5 Å from the oxygen, have dihedral angles ω of 45° and 90°, respectively, in relation to the carbonyl. That 30% or more of the products are formed by abstraction of an intrinsically less reactive primary hydrogen at a theoretically terrible angle supports the view described previously that distance is more important than alignment. The shift in regioselectivity as solvents get more polar probably reflects differences between the ease with which biradicals **BR**1 and **BR**2 can disproportionate back to ground-state reactant. This question requires more study, especially because total product quantum yields are only 0.034 in hydrocarbon solvents and 0.43 in methanol.

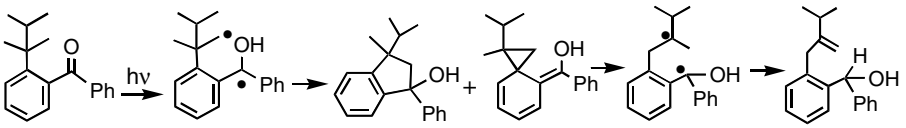
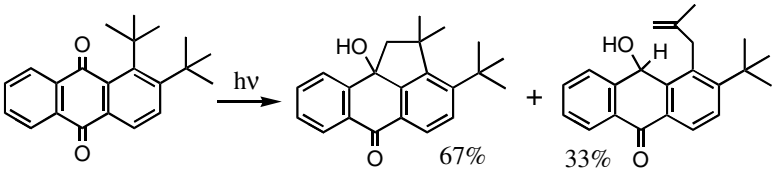
Some recent, yet to be published work revealed that **otAmBP** forms a small amount of a rearranged benzhydrol similar to that formed by *o-t*-butylacetophenone. Even more is formed by irradiation of 2′-(2,3-dimethyl-2-butyl)benzophenone, which undergoes δ-hydrogen abstraction from both a methyl and the isopropyl group to yield three indanols in a total quantum yield of 0.07 in benzene and 0.36 in methanol.[137] It is noteworthy that a single hexenylbenzhydrol isomer is formed. The rearranged biradical disproportionates at the methyl group in preference to the isopropyl group, the opposite of bimolecular radical behavior but understandable in an intramolecular process where the large isopropyl group is pointed away from the body of the biradical structure in order to minimize steric interactions.



The carbonyls on naphthoquinones and anthraquinones also can abstract hydrogens from *ortho* substituents. One such example is a 1,2-di-*t*-butylanthraquinone, which undergoes the same photocyclization as the similarly substituted benzophenones and acetophenones as well as some butyl rearrangement.[138] Interestingly, the ratio of cyclization to rearrangement and disproportionation is 2:1, with neither reaction of the biradical intermediate dominating, unlike the simple monoketone cases.



o-Alkoxyphenyl Ketones

Studies of the photocyclization of various *o*-alkoxyphenyl ketones provided some of the earliest examples of δ-hydrogen abstraction.[139–141] More recent studies of these compounds have dealt with structure–reactivity relationships, stereoselectivity, and biradical behavior. Horaguchi[142] has reviewed the synthetic potential of the reaction. Although the formation of benzofuranols following δ-hydrogen abstraction seems straightforward enough, the low reactivity of the triplet is what attracted mechanistic interest. One factor fueling this interest was the report that photoexcited 2,4-dimethoxy-6-t-butylbenzophenone cyclizes by abstracting a hydrogen only from the *t*-butyl group,[143] even though methoxy methyl hydrogens are intrinsically far more labile than simple methyl hydrogens.

Wagner and co-workers[144] studied the photokinetics of a variety of *o*-alkoxyphenyl ketones. Table 58.5 lists the data for some of the ketones studied. Cyclization quantum yields for the five benzophenones are all normal, but the value for the acetophenone is quite low. Ketones **2**, **3**, **4**, and **6** cyclize with high diastereoselectivity in benzene, which as shown below is diminished in polar solvents. The dihydrobenzofuranol products readily undergo acid-catalyzed dehydration to benzofurans.

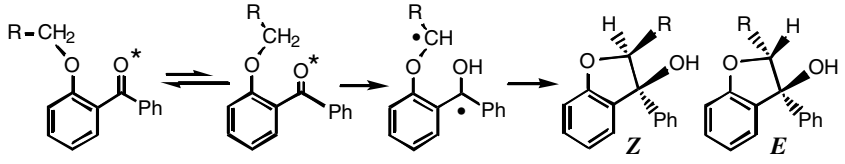
[a] From Reference 146.
[b] *o*-Isopropoxybenzophenone.

Rate constants k_H for δ-hydrogen abstraction are extremely low for ketones **1** and **2**. The *o*-benzyloxy **3** reacts faster, but **4** with partial π,π^* character is only 1/10 as fast as **3**. The key results are the **6/3**, **5/1**, and **7/4** rate constant ratios of 8:1, 13:1, and 12:1, respectively. Compounds **5**, **6**, and **7** were studied to address the suspicion that the low rate constants for the simple *o*-alkoxy ketones are due to the alkyl part of the alkoxy groups being pointed away from the *o*-carbonyl in their most populated equilibrium conformations. Ketones **5** to **7** obviously have their methyl and benzyl groups pointed toward one of the benzoyl groups, and their high k_H values confirm the idea that k_H values reflect conformational populations, in accord with Eq. (58.4).



The early findings that polar solvents lower the yields and the diastereoselectivity of cyclization prompted a thorough study by Horaguchi and co-workers.[145] They varied both solvents and the groups attached to the δ-carbon. Tables 58.6 and 58.7 list their results together, with those of Kim and Park.[146]

The results in Table 58.6 are quite informative. In benzene, yields approach 100%, and, with two exceptions, over 90% of the benzofuranols consist of the isomer with R and phenyl *trans*. Diastereoselectivity this high

likely involves biradical conformational preferences more than steric interactions between the two radical sites as they couple. The change to acetonitrile lowers yields only slightly but drastically lowers diastereoselectivity, possibly due to trace water solvating the biradicals. Methanol just about eliminates diastereoselectivity, as it does for many hydroxy-biradicals. Its major effect, however, is to lower yields significantly, probably because low k_H values allow bimolecular hydrogen abstraction from solvent to dominate, except for the benzyloxy and allyloxy ketones, where the δ-hydrogens are activated. The most intriguing result is the inversion of diastereoselectivity by strong electron-withdrawing groups. Park has suggested that a captodative effect alters the electrostatics of the biradical such that the partially positive OH and the partially negative CN or CF_3 interact enough to force the phenyl and R groups *cis* during cyclization.

Table 58.6 includes data for *o*-isopropoxybenzophenone, which cyclizes in lower yield than the others, despite the fact that triplet δ-hydrogen abstraction in it is sufficiently faster than in many of the others that its cyclization yield is not lowered in methanol. It turns out that it undergoes a competing reaction that was reported in 1971[139] and is described below.

Horaguchi's team also studied some α-substituted (2-benzoylphenoxy)acetate esters, which have a moderately electron-withdrawing carboxy group on the δ-carbon. Table 58.7 shows the same kind of data for these compounds as did Table 58.6 for the others. Interestingly, product yields and *Z/E* ratios in both benzene and acetonitrile are much the same as for the other ketones in which R is not electron-withdrawing. Apparently, the alkyl substituent also on the δ-carbon negates any electron withdrawal and activates the δ-hydrogen sufficiently that yields are high even in methanol. However, for the two largest R groups, diastereoselectivity is inverted from their acetonitrile values, with only the phenyl-substituted compound maintaining high *Z/E* selectivity. One would have thought that in aprotic solvents hydrogen bonding would hold the OH and carboxy groups together sufficiently that they would end up *cis* and that methanol would solvate the hydroxy group sufficiently to allow the R and phenyl groups to be *trans*. As shown below, in polar solvents an additional product was found in 6 to 8% yield for R = Et. The process whereby such byproducts are produced is discussed below.

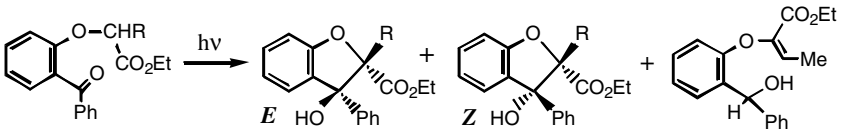


TABLE 58.7 Photocyclization of Ethyl α-(*o*-Benzoylphenoxy)Carboxylates

	% Yield (*Z*/*E*)		
α-R in *o*-OCHR-CO_2Et	Benzene	Acetonitrile	Methanol

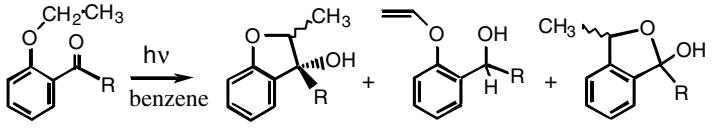
As mentioned, Pappas[141] was one of the first investigators of *o*-alkoxyphenyl ketone photochemistry. He studied exclusively *o*-alkoxyphenylglyoxylate esters, which cyclize only by δ-hydrogen abstraction, and acquired some interesting early results about solvent effects that have since been found to affect many other ketones. The k_H values were found to be $\sim 3 \times 107 s^{-1}$, faster than for γ-hydrogen abstraction in phenylglyoxylates. In later work it was found that lowering the temperature to 0° doubles the *trans*/*cis* ratio and that brominated solvents raise it even more.[147] Both would seem to indicate forced cyclization of the initially formed biradical geometry.

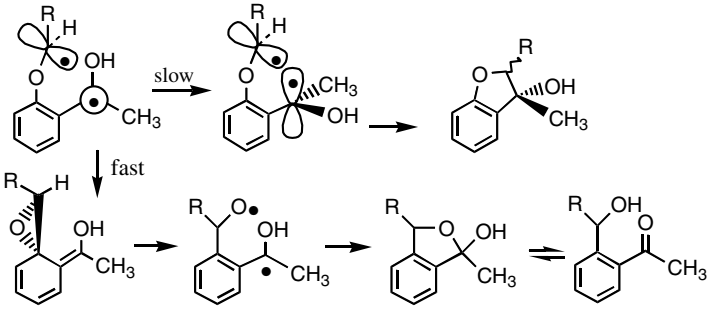
	Φ_{cyc}	*t/c*
benzene	0.89	6.7
CH_3CN	0.56	1.9
^tBuOH	0.47	1.0

As already mentioned, some byproducts are formed from these *o*-alkoxyphenyl ketones, one of which resembles the rearrangement that the *o*-*t*-alkylphenyl ketones undergo. The scheme below depicts these byproducts for *o*-ethoxy ketones; the benzophenone undergoes only cyclization, whereas the acetophenone rearranges to a hemiketal and to a vinyloxybenzyl alcohol.

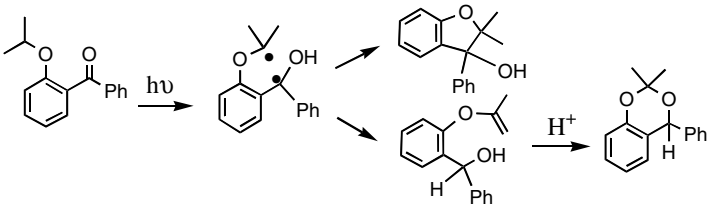


R = Ph	100% (11:1 *Z*/*E*)	0	0
R = CH_3	12% (all *Z*)	19%	69%

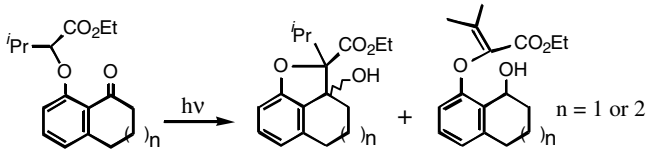
The O-C switch presumably occurs for the same reason that a similar switch does in the *o*-*t*-alkylacetophenones, namely that the coplanarity of the carbonyl and benzene ring in excited acetophenone is transferred to the 1,5-biradical, slowing its cyclization and favoring spiro-enol formation, subsequent opening of the epoxy group, and either direct coupling to the hemiketal or disproportionation followed by addition of the alcohol to the ketone.



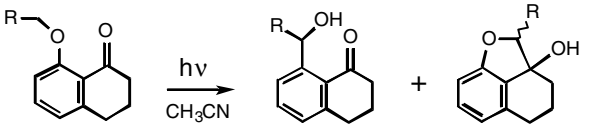
The rearrangement to vinyloxybenzhydrol involves disproportionation of the original 1,5-biradical to a compound with a vinyl ether and an alcohol *ortho* to each other, thus providing a perfect geometry for acid-catalyzed addition of the alcohol to the vinyl ether. The following shows the mechanism developed by Wagner and Laidig[148] that explains the earlier observed formation of a dioxane from *o*-isopropoxybenzophenone. When the ketone is irradiated in benzene, a 2:1 ratio of benzofuranol and *o*-propenoxybenzhydrol is formed. Addition of just a trace of acid causes the vinyl and hydroxy groups of the latter to disappear. When the ketone was made from acetone-d_6, the benzylic hydrogen in both vinyl ether and dioxane was replaced by deuterium.



Horaguchi's group[149] provided another example of competition between cyclization and an internal redox process in some *ortho*-substituted benzocyclohexenones. These compounds have the electronic nature of comparable acetophenones, with rings of different sizes providing variable amounts of flexibility to the carbonyl group. Vinyl ether formation occurs only in the six- and seven-membered rings, which remain fairly rigid compared to larger rings, which allow enough twisting of the phenyl–C(OH) bond for the biradical to cyclize rapidly.

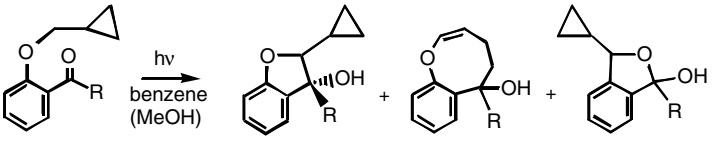


A similar study of simple 8-alkoxytetralones highlighted the effect of coplanarity in that a rearranged 8-hydroxyalkyltetralone is formed in 5 to 12 times the amount of a benzofuranol, depending on the size of R.[150] The corresponding *o*-alkoxybenzosuberones undergo only cyclization, just like simple *o*-alkoxybenzophenones.



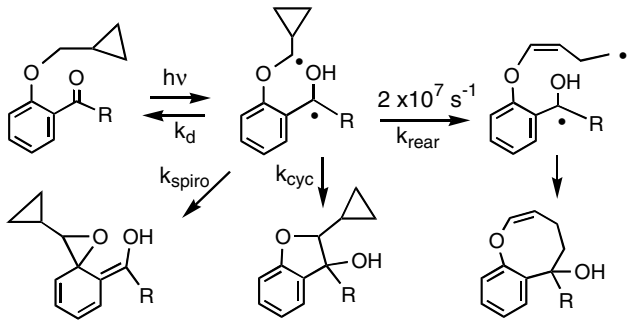
R = H	36%	34%
Me	62%	5%
Et	43%	8%
^{i}Pr	69%	11%
^{t}Bu	71%	9%

As described previously, β-alkoxyketones form 1,4-biradicals with lifetimes of only a few nanoseconds, values which are now generally understood as reflecting high through bond spin-orbit coupling. An obvious question arises as to what effect the extra atom might have on lifetimes of 1,5-oxabiradicals. Because triplet hydrogen abstraction rate constants are slower than the decay rate of most biradicals, the cyclopropylcarbinyl radical clock was employed to provide 1,5-biradical lifetimes.[151] The following scheme shows the products formed from *o*-cyclopropylmethoxy ketones.



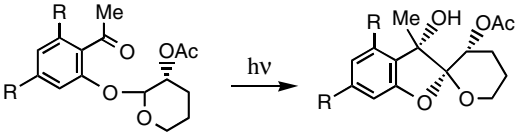
R = Ph	Φ = 0.26	92% (8:1 *Z*/*E*)	8%	
R = CH_3	Φ = 0.02	7% (all *Z*)	13%	80%
		(35% (1:2 *Z*/*E*)	15%	50%

As with other *o*-alkoxyphenyl ketones, the benzophenone forms mainly a benzofuranol, while the acetophenone forms mainly a hemiketal, its yield being lessened by methanol in favor of the benzofuranol. (This change of solvents could possibly be a general way of minimizing unwanted byproduct.) Both ketones gave small amounts of a benzocyclooctadienol, the cyclization product of the 1,8-biradical formed by opening of the cyclopropyl ring of the original 1,5-biradical. From the product ratios, quantum yields, and known rate constants for cyclopropylethyl radical ring opening, the rate constants shown below could be estimated for the various reactions of the 1,5-biradical (the hemiketal comes from the spiroepoxide), which add up to much the same decay rates as measured for the 1,4-oxabiradicals. Their values may be smaller if the oxygen stabilizes the δ-radical site enough to slow opening of the cyclopropyl ring.

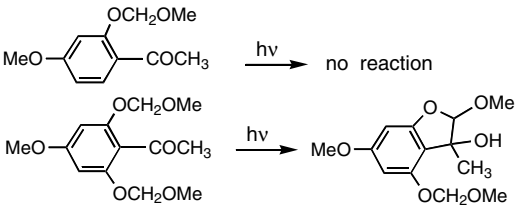


R	k_{spiro}	k_{cyc}	k_d	$1/\tau_{BR}$
Ph	$< 1 \times 10^7$	2.5×10^8	7.5×10^8	$10 \times 10^8\ s^{-1}$
CH_3	1.2×10^8	1×10^7	$4—40 \times 10^7$	$2—5 \times 10^8\ s^{-1}$

Descotes et al.[152] reported an approach to the synthesis of crombénine that involves δ-hydrogen abstraction from an acetal to generate the required spiroketal structure. Unfortunately the required 2,4-dioxy substituents lower the yield from 87% when R = H to 20 and 0% when R = OAc and OMe. Because *p*-methoxy groups deactivate triplet phenyl alkyl ketones by causing the lowest triplet to become π,π*, electronic and conformational effects apparently combine to lower k_H values so much that they barely compete with phosphorescence. Moreover, the bulk of the cyclic ether very likely worsens the conformational problem common to *o*-alkoxyphenyl ketones.

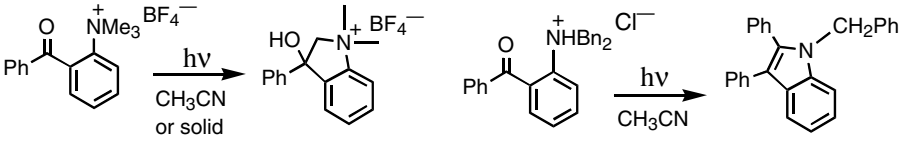


Kraus et al.[153] have reported several uses of intramolecular hydrogen abstraction for synthetic purposes. One example used *o*-alkoxyphenyl alkyl ketones to prepare an aflatoxin precursor. In the process the substituent problem encountered by Descotes was partially solved. Elaboration of the dihydrobenzofuranol photoproduct to aflatoxin required the presence of a methoxy group *para* to the acyl group in the original ketone reactant. The result was no reaction for 4-methoxy-2-alkoxyphenyl alkyl ketones. However, 2,6-dialkoxyphenyl ketones undergo photocyclization even with a *p*-methoxy group. It turns out that, with both *ortho* positions occupied, the acyl group twists out of conjugation with the benzene ring to avoid nonbonded interactions, providing a much better geometry for δ-hydrogen abstraction and likely increasing the population of *n*,π* triplets.



o-Amino phenyl ketones have excited states with mainly charge transfer character and are not reactive as hydrogen atom abstractors, providing rather messy mixtures of photoproducts that include very small yields of indoles.[154] Although acyclic amidoketone excited states readily undergo hydrogen abstraction, as described above, Hasegawa and co-workers[154] reported that irradiation of *N*-(*o*-benzoylphenyl)-*N*-methylacetamide causes only deacylation in polar solvents and dealkylation in nonpolar solvents. Though acylation lowers the electron-donating potential of amines, the lowest excited states of *ortho*-amidophenyl ketones retain charge transfer character.

Two examples of *o*-acyl-*N*-alkylanilines being activated by conversion to anilinium salts have been reported.[155] *o*-Benzoyl trimethylanilinium tetrafluoroborate, as either crystals or in acetonitrile solution, undergoes quantitative photocyclization to an *N*,*N*-dimethylindolium salt. The reactant *o*-benzoyl anilinium cation has the same structure as *o*-*t*-butylbenzophenone and undergoes δ-hydrogen abstraction followed by cyclization of the resulting 1,5-biradical. In acetonitrile, the quantum yield is 0.56; k_H is 1/30 as large as k_H for the *t*-butyl ketone, as would be anticipated for hydrogen abstraction from carbons bonded to positively charged atoms (see Chapter 52). The temperature dependence of the triplet decay of the *o*-trimethylammonium benzophenone revealed the same 2.36 kcal/mol activation energy already measured for *o*-*t*-butylbenzophenone, but a 7.6 EU more negative entropy of activation.[134] Thus, the entire factor of 30 difference in their rate constants for δ-hydrogen abstraction is entropic or at least nonenthalpic.



The hydrochloride salt of *o*-benzoyl-*N*,*N*-dibenzylaniline also photocyclizes and then dehydrates to an indole, although with low quantum efficiency; the free base exists in equilibrium with its conjugate acid and acts as both a quencher and an internal filter.

Giese's group has now activated *o*-acylanilines by converting them to triflamides, which undergo photocyclization to indolinols in high yield. The reaction shows high, solvent-mediated stereoselectivity, with R mainly *cis* to the OH when R = CO_2Me and *trans* when R = phenyl.[156]

	cis/trans

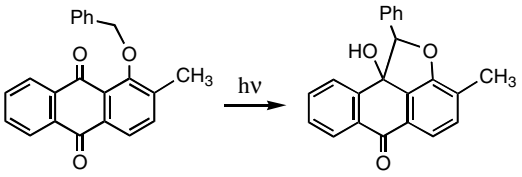
Alkoxy-substituted naphtho- and anthraquinones undergo δ-hydrogen abstraction to form a variety of products. Kraus et al.[157] have studied some naphthoquinones, and Blankespoor et al.[158] have studied some anthraquinones. The addition of a methyl next to the alkoxy group has the beneficial effect of

increasing the population of the conformer with the benzyl group tilted toward the carbonyl, thus increasing k_H and the quantum yield for cyclization.



α-(*o*-Alkylphenyl) Ketones

Reactivity

Prompted by the behavior of *N*-(*o*-tolyl)phthalimide, Meador and Wagner[159] found that α-(*o*-tolyl)acetophenone photocyclizes to 2-phenyl-2-indanol quantitatively and with a quantum yield of 1.0. Follow-up studies by Wagner et al.[160,161] have revealed an interesting array of structure–reactivity relationships as substituents add to the steric congestion of the molecules. These α-aryl ketones provide unique examples of kinetic competition between conformational change and product formation as well as potential for indanol synthesis. Table 58.8 lists rate constants for triplet δ-hydrogen abstraction from representative α-aryl ketones and quantum yields for both cyclization and Norrish type I α-cleavage when it competes with hydrogen abstraction. Rate constants for triplet α-cleavage are 0.2, 2, and 12 × 10^7 s^{-1}, respectively, for α-phenyl acetophenone, propiophenone, and isobutyrophenone. Thus, cleavage competes with cyclization in the α-aryl propiophenones and totally dominates in α-dialkyl ketones.

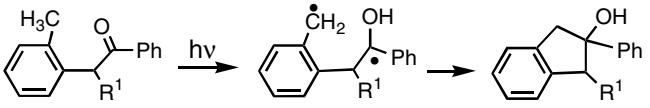


TABLE 58.8 Photokinetics of ArCHR¹R²COPh in Benzene

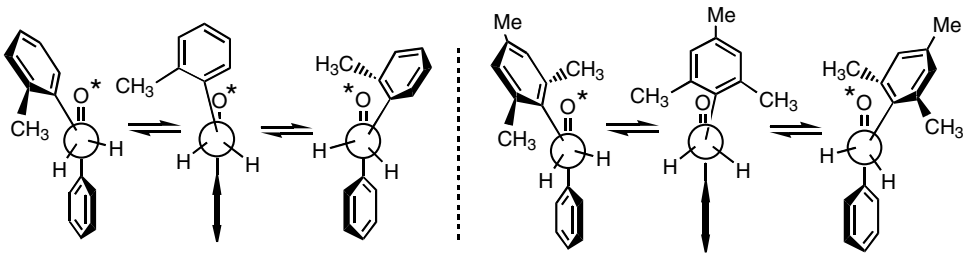
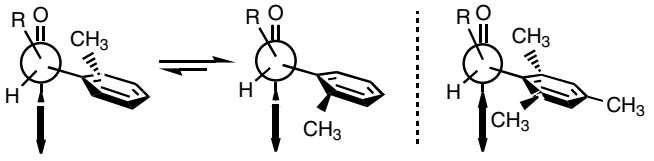
That hydrogen abstraction rate constants range from 1.6–8.5 × 10^8 s^{-1} indicates a molecular geometry, with the δ–CH bonds quite close to the carbonyl. Structure 86 illustrates why the mesityl acetophenone reacts 3.5 times faster than the *o*-tolyl. The α-aryl groups are oriented perpendicular to the CH_2–CO bond and eclipse the carbonyl group. For hydrogen abstraction to take place, the ring must rotate a little to get a methyl close to the carbonyl, but the opposite rotation is favored for an *o*-tolyl group. In the mesityl ketones, rotation in either sense delivers a methyl to the carbonyl.



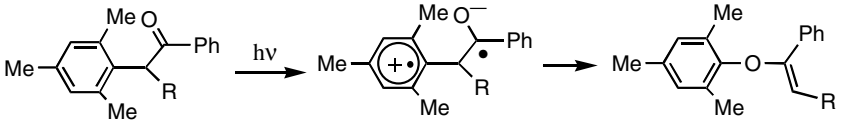
Flash kinetic measurements of biradical decay rates revealed average lifetimes of 20 nsec in toluene and 30 nsec in methanol when the α-aryl group of the ketone has *o*-methyl groups, 40 nsec in toluene, and 45 nsec in methanol when the α-aryl group has *o*-isopropyl groups. How lifetimes and quantum yields are increased by Lewis-base solvents was discussed earlier. That lifetimes vary with substituents on the *ortho*-carbon, with tertiary radical sites coupling more slowly than primary radical sites, adds evidence that ease of product formation contributes to biradical lifetimes.

Acetophenones react with much larger rate constants compared to propiophenones with the same α-aryl group — a 64:1 ratio for *o*-tolyl and 3.8:1 for mesityl. Scheme 11 illustrates the reason, which is due to the different geometry of α-disubstituted ketones. The α-alkyl group nearly eclipses the carbonyl, forcing the α-aryl ring to twist off to the side. In the mesityl case, one of the *ortho* methyls is close to the oxygen at the time of photoexcitation, but at a dihedral angle ω of some 66°, the cosine of which would predict a fivefold lowering of k_H, almost as observed. In the *o*-tolyl case, the methyl group can be tilted toward the oxygen in much the same position as a mesityl methyl, but more often it is tilted away from the carbonyl. The low k_H thus is due to a combination of an unfavorable conformational equilibrium and an imperfect CH alignment relative to the carbonyl in the lowly populated reactive conformer.

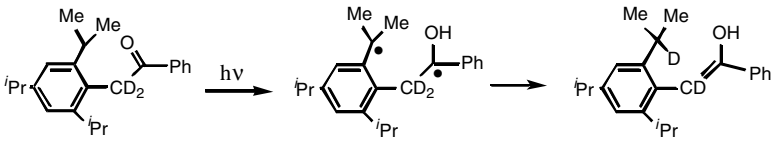


SCHEME 11 Preferred geometries of some α-arylpropiophenones.

Two other reactions besides α-cleavage compete with cyclization, but only from the most sterically crowded compounds. A 1,3-shift of α-mesityl groups forms enol ethers in low chemical and quantum yields (1 to 2%).[162] This reaction may be initiated by charge transfer from mesityl to excited carbonyl.



Another example of 1,5-biradicals disproportionating to enols is provided by *o*-(2,4,6-triisopropylphenyl)acetophenone, which forms an enol that is long lived due to its steric congestion.[163] Table 58.8 indicates that the cyclization yield of the compound is larger for the α-deuterated form, thanks to a primary isotope effect on the biradical disproportionation. However, Lewis-base solvents greatly diminish cyclization yields, probably because the solvated OH group presents a steric barrier to cyclization.



Stereoselectivity

When the biradicals from most α-aryl ketones cyclize, the carbon holding the phenyl and hydroxy groups becomes a stereocenter. An additional α-substituent and/or an *ortho* CH_2R group on the α-aryl ring provide extra stereocenters and introduce the possibility of two to four diastereomeric indanol products. Table 58.9 lists the stereoselectivity of cyclization for several ketones as well as the quantum yields for any competing α-cleavage. One column lists the *trans*/*cis* ratios for the *ortho* R relative to the phenyl; the other lists *trans*/*cis* ratios for α-methyl relative to the phenyl. Two of the ketones have both methyls so two *trans*/*cis* ratios are listed.

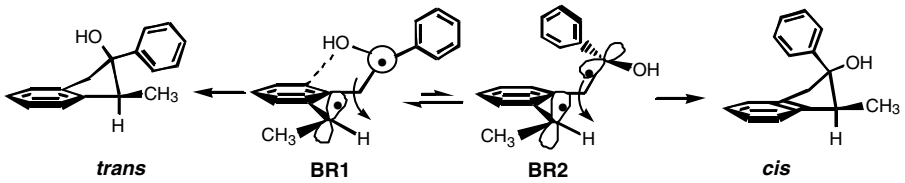
[a] Values in methanol in parentheses.
[b] *ortho*-CH_2–R vs. Ph.
[c] α-Me vs. Ph.

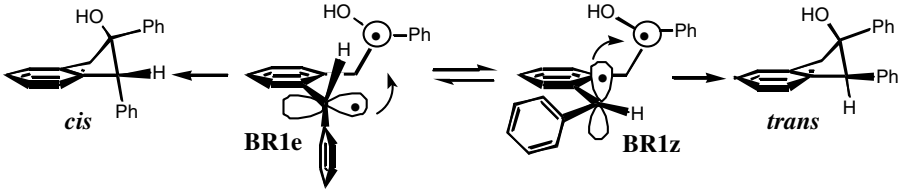
In all but one case the α-methyl group ends up predominately *trans* to the phenyl, the exception being one of the two diastereomeric products from the triethylphenylpropiophenone. As described earlier, the α-methyl of these α-arylpropiophenones is oriented *anti* to the benzoyl phenyl and stays so in the triplet and the initially formed 1,5-biradical. Thus, its predominantly *trans* position relative to the phenyl in the indanols is a result of a not easily changed pre-existing conformational preference.

For the four ketones with *ortho*-ethyl groups, at ambient temperatures the ethyl-derived methyl group also is predominantly *trans* to the phenyl in the indanol products, but the predominance fades in methanol as solvent and disappears at low temperatures and for the solid state. In contrast, the indanol products from the α-(*o*-benzylphenyl) ketones are formed with almost no diastereoselectivity in any solvent.

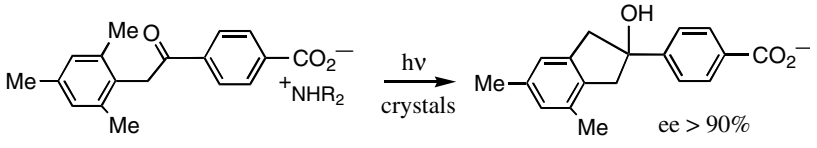
The photocyclization of α-(*o*-ethylphenyl)acetophenone in benzene or as a solid occurs with 90 to 100% diastereomeric excess, favoring the isomer with the methyl and phenyl groups *trans*.[164] Analysis indicates that conformational preferences in the 1,5-biradical determine this selectivity. Hydrogen abstraction creates the biradical **BR**1 in a geometry from which simple disrotatory rotation of the two radical sites produces the major product. the same rotation forms the isomeric product in a higher energy conformer, **BR**2. A **BR**1-to-**BR**2 conversion cannot occur in the solid, so only *trans*-indanol is formed. What is most interesting is that **BR**1 is lower in energy because its OH group hydrogen-bonds to the benzene ring which prevents the normal reversion to ketone that causes low quantum yields in many Yang photocyclizations and Norrish type II eliminations, thus allowing these biradicals to cyclize in high quantum yields. Stereoselectivity drops to 5:1 in dioxane and 2:1 in methanol, mainly because solvation of the OH destabilizes **BR**1 and allows a larger population of **BR**2.



The lack of stereoselectivity in the photocyclization of α-(*o*-benzylphenyl) ketones most likely is due to the fact that δ-hydrogen abstraction creates a benzhydryl radical site that does not allow both phenyl groups to be fully conjugated with the half-occupied *p* orbital. Although conformers exist that are analogous to the **BR**2 above, they remain less populated than **BR**1e and **BR**1z, which are roughly equally populated and maintain the hydrogen bonding that stabilizes **BR**1. It is the fact that their individual least-motion pathways to cyclize require rotations in the opposite sense (**BR**1z disrotatory like **BR**1 and **BR**1e conrotatory) that removes stereoselectivity.



Although most of the indanols formed from these α-aryl ketones are chiral, they are all produced racemic by simple irradiation. However, Scheffer et al.[165] have shown that his method for inducing enantioselectivity with ionic chiral auxiliaries works well for *para*-carboxylated α-mesitylacetophenone in the solid state, which produces one enantiomer in 90% EE. The twisting of the mesityl ring required to bring an *o*-methyl group close enough to the carbonyl, as described above, normally can occur both clockwise and counterclockwise, thus allowing either *o*-methyl group to be attacked by the excited carbonyl. The twisting motion amounts to a form of helical chirality and in the presence of an outside chiral force one methyl is favored.



Wagner et al.[166] have studied temperature effects on the cyclization diastereoselectivity of the ketones shown in Table 58.9. The ketones were irradiated in toluene at various temperatures from –78°C to 110°C, and the product isomer ratios provided linear Arrhenius plots. A graphical table of the results includes the differential activation parameters for formation of *cis*- and *trans*-isomers of each indanol. The results are analyzed in Table 58.10.

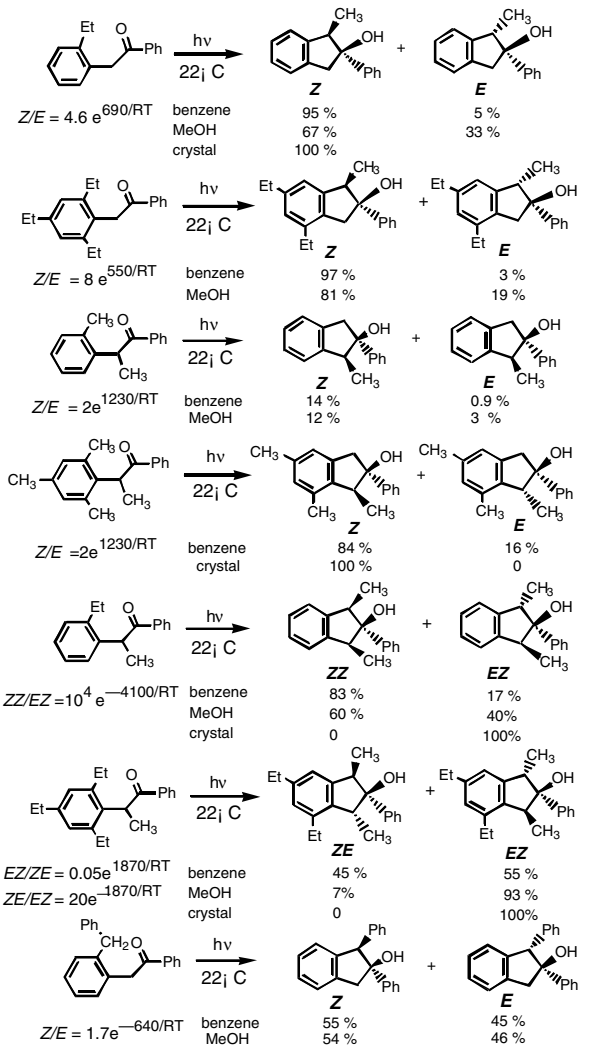


TABLE 58.10 Range of Indanol Diastereoselectivities from ArCHRCOPh

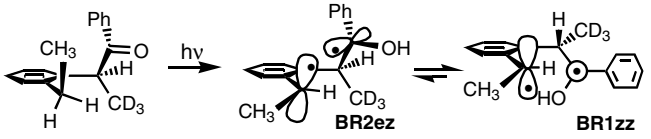
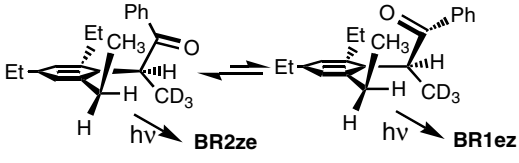
The two *o*-ethylphenyl acetophenones display very similar behavior: similar small $\Delta\Delta E_a$ values and non-zero A factors indicating nonenthalpic effects favoring formation of the *Z* product from **BR**1. Because the half-occupied *p* orbitals of **BR**1 and **BR**2 are aligned differently, **BR**1 apparently enjoys more spin-orbit coupling, converts from triplet to singlet more efficiently, and thus cyclizes more. In solution, the biradicals displays conformational equilibrium in their cyclization selectivity.

The two *o*-methylphenyl propiophenones show nearly identical temperature effects. (The low yields for the *o*-tolyl compound reflect the large amount of competing cleavage.) They each have both enthalpic and entropic preferences for keeping the α-methyl *anti* to the phenyl group. The latter again probably reflects different spin-orbit coupling in the biradical conformers that cyclize. The cyclization selectivity reflects primarily ground-state control, as the initial **BR**2-like geometry has a difficult time converting to a **BR**1-like geometry, which can form the *E*-isomer.

The *o*-ethylphenyl propiophenones do not mimic any of the above four ketones. They both could yield four diastereomers, but each forms only two. The simple *o*-ethylphenyl compound forms one isomer (*ZZ*) that keeps both methyls *trans* to the phenyl and that is favored at room temperature, but at low temperatures and as crystals it forms only the *ZE*-isomer, in which the ethyl-derived methyl is *cis* to the phenyl. Under the conditions favoring the *ZE* product, ground-state control determines selectivity, but at higher temperatures in solution rotational control takes over with regard to the ethyl-derived methyl. The large $\Delta\Delta E_a$ and A values can only represent a bond rotation, not a conformational equilibrium or a spin-orbit coupling difference. As described previously, the geometry of the ketone is such that hydrogen abstraction produces **BR**2ze; in order for it to convert to a **BR**1-like geometry (**BR**1zz), two bond rotations are required to keep the α-methyl and phenyl groups apart. At temperatures above 20°C, the rise in *ZZ*/*ZE* ratios slows and Norrish type I cleavage lowers cyclization yields.



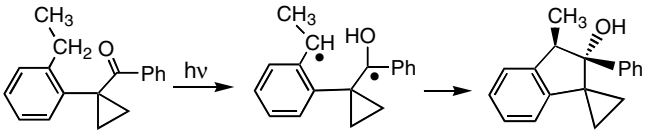
The triethylphenyl propiophenone also forms only two indanol isomers, each of which has one of the two methyls *cis* to the phenyl. Again, the *EZ*-isomer is favored under conditions that retard rapid bond rotations. The favored ground-state geometry produces a biradical with a **BR**2ez shape, but with the extra *ortho*-ethyl group it cannot rotate to a **BR**1zz geometry and has a difficult time rotating to a **BR**1ze geometry. That the $\Delta\Delta E_a$ and A factors favor opposite isomers is intriguing. The 20-fold entropic preference for the *ZE*-isomer could again be a spin-orbit effect. The 1.9-kcal $\Delta\Delta E_a$ could represent conformational equilibrium between either biradical or ground-state conformers.



Finally, α-(*o*-benzylphenyl)acetophenone not only shows little diastereoselectivity but also starts to favor the *E*-indanol as the temperature decreases. Its *Z*/*E* ratio ranges from 1.2:1 to 1:1.2 over the temperature range. Nonetheless, its A factor still favors cyclization to the *Z*-indanol, again most likely due to different *p* orbital orientations.

Park et al.[167] recently added an interesting twist to known photoreactivity by studying the behavior of acylcyclopropanes such as 1-benzoyl-1-(*o*-ethylphenyl)cyclopropane. It does not undergo any Norrish

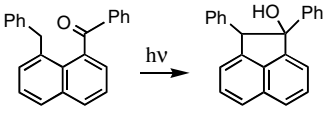
type I cleavage as α-dialkyl ketones do, but its cyclopropane ring takes the place of two methyls in affecting biradical geometries. It undergoes normal photocyclization to an indanol, and the intermediate biradical obviously does not undergo a cyclopropyl ring opening which might have produced a benzoyltetralin. What is most interesting is that the *Z*/*E* indanol ratio ranges from 1:19 to 1:2.5 from –72° to 90°C in toluene and goes as low as 1:99 in methanol at 25°C. As in the *o*-ethylphenyl propiophenones, the initially formed biradical cyclizes to the *E*-indanol but faces a large barrier to rotation into a *Z*-forming geometry.



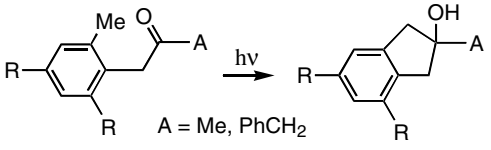
Park's group[168] has also studied the effect of zeolites on diastereoselectivity. When the model (*o*-ethylphenyl)acetophenone was irradiated in X and Y zeolites, *Z*/*E* indanol ratios were much lower than in solution.

Excited States Other Than Simple n,π* Triplets

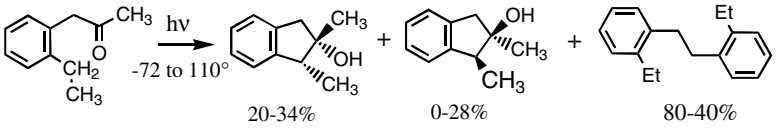
An early and unique example of δ-hydrogen abstraction was provided by 8-benzyl-1-benzoylnaphthalene (BBN), which undergoes photocyclization despite having a π,π* lowest triplet.[22] (Most naphthyl ketone reactions involve excited singlet states.) Its ground-state geometry is almost perfect for hydrogen abstraction and resembles that of α-(*o*-benzylphenyl) acetophenone. Its measured triplet hydrogen abstraction rate constant of 7×10^3 s^{-1} is 0.001% as large as k_H for the *n*,π* triplet of the *o*-benzylphenylacetophenone. This ratio provides a rare measure of the intrinsic reactivity of π,π* ketone triplets in hydrogen atom abstraction. Measurements of the temperature dependence of the BBN triplet lifetime revealed an E_a of 4.7 kcal/mol and a log A of 7.25. These numbers indicate that the low reactivity is mostly entropic in origin.



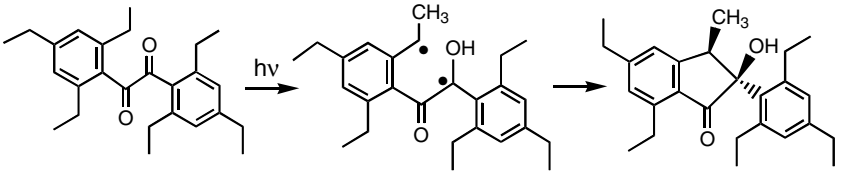
Turro and co-workers[169] discovered that the excited singlet states of *o*-tolyl acetones, but not their triplets, undergo cyclization to indanols, another example of *n*,π* singlet hydrogen abstraction in aliphatic ketones competing with intersystem crossing while triplet hydrogen abstraction is slower than α-cleavage. Quantum yields are very low as described above for singlet-state hydrogen abstraction in general.



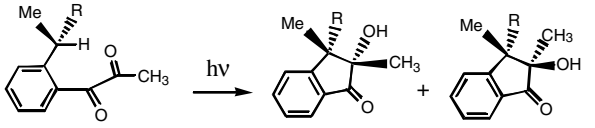
There have been few studies of stereoselectivity in the cyclization of singlet biradicals formed by intramolecular hydrogen abstraction. Zand and Wagner[170] have studied α-(*o*-ethylphenyl)acetone, which photocyclizes to a mixture of both the *cis*- and *trans*-1,2-dimethyl-2-indanols, suggesting that singlet biradicals do undergo some bond rotations before cyclizing. Interestingly, over a 182°C range, the cyclization yield increases with temperature at the expense of cleavage, as singlet hydrogen abstraction becomes faster relative to ISC.



Benzils may be considered 2-aryl-2-keto-1-arylethanones (i.e., slightly modified α-arylacetophenones. The photochemistry of several symmetric 2,4,6,2′,4′,6′-hexaalkyl benzils has been studied in depth[171] in order to ascertain whether the rather puzzling photocyclization of *o*-alkylphenyl diketones to hydroxyindanones is initiated by γ- or δ-hydrogen abstraction, as discussed above. The hexa-methyl, -ethyl, and -isopropyl benzils all photocyclize cleanly to 2-hydroxyindanones in modest quantum yields, the hexaethyl benzil even showing some diastereoselectivity, especially as a solid, where only the pictured *Z*-isomer was formed. It now seems certain that the reaction proceeds only through a 1,5-biradical intermediate, as rearrangement of a benzocyclobutenol in a crystal seems doubtful. More important, in excited diketones one carbonyl abstracts hydrogen only from the moiety attached to the other carbonyl.

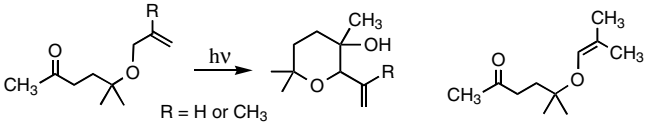


Returning to the methyl *o*-alkylphenyl diketones, Hamer et al.[115] reported that two chiral diketones form hydroxyindanones in methanol with retention of configuration and with modest diastereoselectivity, but in quantum yields of only 1–5%.[115] Remarkably, the stereochemistry parallels that of the α-(*o*-alkylphenyl)acetophenones, with OH preferentially *cis* to an ethyl group but showing only slight selectivity when R is phenyl. This fact further supports the idea that a 1,5-biradical is the precursor to the products.



1,6-Iradicals: ε-Hydrogen Abstraction

A few systematic studies of ε-hydrogen abstraction, which generally requires the absence of both γ- and δ-hydrogen atoms, have been performed. Carless and Fekarurhobo[172] provided one of the earliest examples in γ-allyloxy ketones and aldehydes, which photocyclize to roughly equal amounts of diastereomeric tetrahydropyranols. The ε-allylic radical site can disproportionate at each end to generate both starting ketone and a vinyl ether.



Meador and Wagner[173] found that α-(*o*-benzyloxyphenyl)acetophenone photocyclizes to a dihydrobenzopyran. Park and Wagner[174] have studied a few more examples, as listed in Table 58.11, with an average $k_H \sim 4 \times 10^7\ s^{-1}$, significantly faster than k_H for δ-hydrogen abstraction in *o*-alkoxy phenyl ketones. The difference is due to the very favorable orientation of the α-phenyl ring relative to the carbonyl, as in the α-(*o*-alkylphenyl) ketones. Quantum yields are low, in the 3 to 18% range, but type I α-cleavage accounts for only 25% of the products. The pyranol isomer with R and phenyl *cis* is favored, a sharp departure from normal diastereoselectivity, but that is reversed in the products from 1-benzoyl-1-(*o*-alkoxyphenyl)cyclopropanes.[174]

[c] Half of cyclopropyl CH_2CH_2.

Another class of compounds that undergo ε-hydrogen abstraction is the β-(*o*-tolylphenyl) propiophenones.[175] As Table 58.12 shows, quantum yields and rate constants are much smaller than in the *o*-alkoxyphenyl acetophenones, the former because CT quenching of triplet carbonyls by β-aryl groups is very rapid; the latter because of conformational issues.

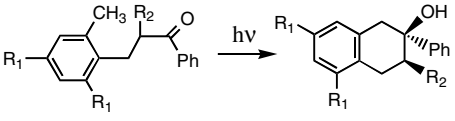

TABLE 58.12 Photochemistry of β-(*o*-Tolyl)Propiophenones

R_1	R_2	Φ (C_6H_6)	Φ (MeOH)	k_H ($10^7 s^{-1}$)

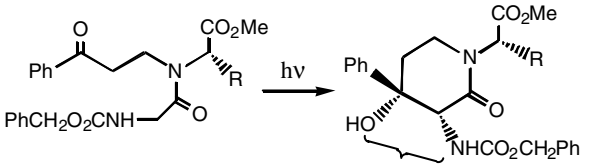
H	CH_3	0.0003	0.0012	0.026
CH_3	CH_3	0.002	0.012	0.18

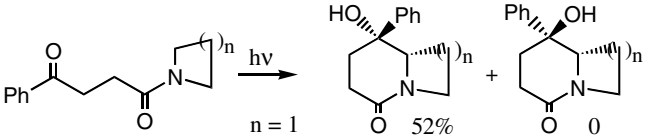
Giese et al.[176] have reported a case in which an *N*-benzoylethyl dipeptide undergoes ε-hydrogen abstraction in preference to δ-hydrogen abstraction. The ε/δ ratio was 8:1 for R = H and 20:1 for R =

benzyl, suggesting a steric reason for the selectivity. The diastereoselectivity of cyclization also depended on the size of R.



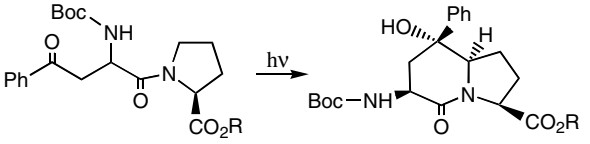
8/1, R = Bn ; 1:1, R = H *cis/trans*

Wessig et al.[177] have explored the effect of amine ring size on the diastereoselectivity of photocyclization of 3-benzoylpropanoamides.



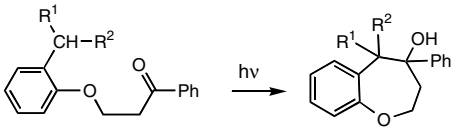
n = 1	52%	0
n = 2	54%	0
n = 3	33%	6%
n = 4	48%	8%

Following a similar theme, Wessig[178] has also synthesized an indolizinone by stereoselective photocyclization of an *N*-protected β-benzoylalanyl proline ester. The product was formed in 60% yield and simulates a β-turn dipeptide.

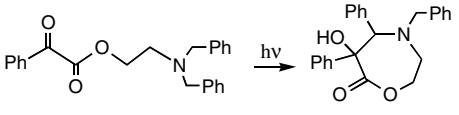


1,7-Biradicals: ζ-Hydrogen Abstraction

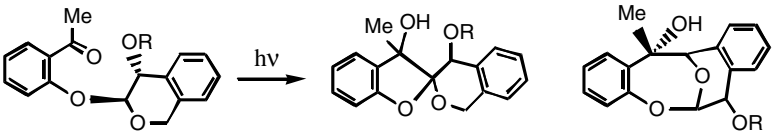
Carless and Mwesigye-Kibende[179] provided a rare example with the photocyclization of some β-(*o*-alkylphenyl)propiophenones. With R^2 = Ph or allyl and R^1 = H, the isomeric benzoxipenols were formed in a 2:1 ratio, in rather low quantum yields.



Hasegawa and Yamazaki[180] have reported ζ-hydrogen abstraction in some 2-(alkylamino)ethyl phenylglyoxylates, initiated by electron transfer. No products of γ- or δ-hydrogen abstraction were formed.



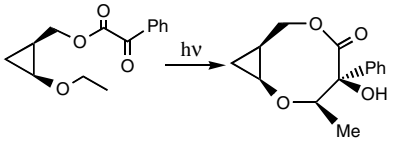
In Descotes' synthetic efforts toward making crombénine that were described above, the desired δ-hydrogen abstraction did not occur unless a bulky OR substituent was present to block the ζ-hydrogen abstraction that otherwise was the major reaction and that led to a bicyclic ether.[152]



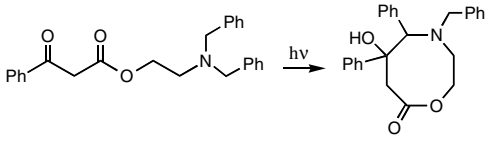
R = H	0	41%
Ac	10%	24%
$Me_2(^tBu)Si$	70%	14%

1,8-Biradicals: η-Hydrogen Abstraction

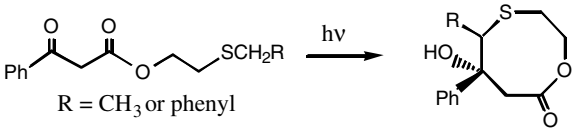
Kraus and Wu[181] has achieved the synthesis of an eight-atom lactone via η-hydrogen abstraction by a cyclopropyl phenylglyoxylate. The *cis* geometry of the cyclopropyl ring places the ethoxy group closer to the carbonyl than the ester γ-carbon.



Yoshioka and co-workers[182] have studied the photochemistry of a variety of 2-aminoethyl benzoylacetates, which cyclize to η-lactones, likely by electron transfer followed by proton transfer to generate a 1,8-biradical. It is noteworthy that no δ-hydrogen abstraction occurs.



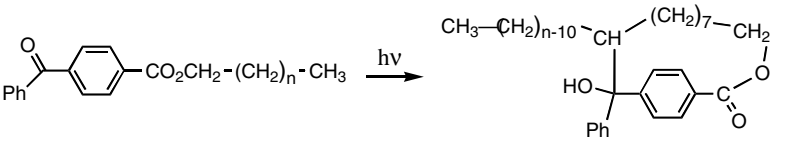
In a similar study, some β-thioalkoxyethyl α-benzoylacetate esters also were shown to undergo photocyclization to lactones.[183] A charge-transfer process again is thought to initiate the reaction, with a proton on the more remote α-carbon being the one transferred to oxygen. The CT nature of the reaction is upheld by the fact that the sulfone version of the compound does not react. Triplet quenching by 2,5-dimethyl-2,5-hexadiene indicates a 2.7×10^7 s^{-1} rate of triplet decay in acetonitrile, an order of magnitude faster than the analogous reaction of the phenylglyoxylate esters. Both the ethyl and benzyl sulfides cyclized in good yield, but for R = Ph only the lactone isomer with the two phenyls *cis* was formed, whereas for R = Me both isomers were formed equally. There is no explanation for such disparate stereoselectivity.



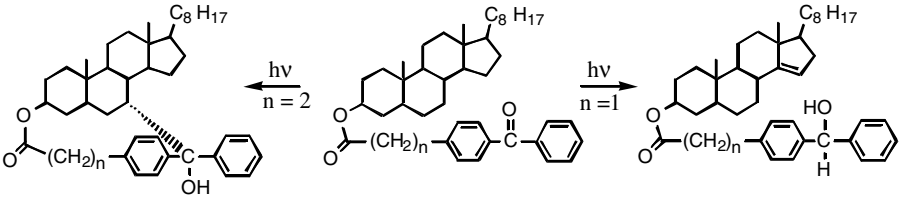
R	%yield	*c/t*
Me	55	1:1
Ph	65	1: 0

Very Remote Hydrogen Abstraction

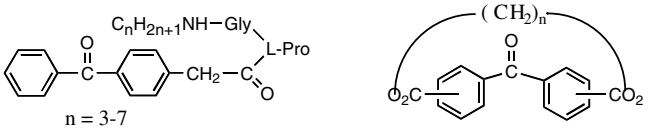
Breslow[185] and Winnick et al.[184] really opened the field of remote intramolecular hydrogen abstraction with their study of *n*-alkyl *p*-benzoylbenzoates, with the alkyl group containing from 14 to 20 carbons.[11] The ketones photocyclize by hydrogen abstraction from methylene groups between C9 and C17, showing preference for ones between C11 and C15. Quantum yields ranged from 4 to 17%. Values of k_H are in the 0.1 to 5.4×10^5 s^{-1} range, increasing by roughly 1×10^5 with each additional methylene beyond C9.[184]



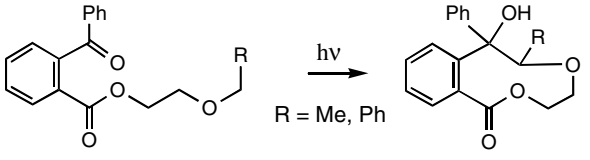
Breslow[185] showed that chaining benzophenone to the A ring of a steroid could lead to regioselective hydrogen abstraction depending on chain length. For example, when $n = 2$, cholestanol undergoes hydrogen abstraction on its α-face from both C7 (shown) and C12 that results in cyclic alcohols; when $n = 1$, hydrogen abstraction is from C14 and the biradical disproportionates instead of cyclizing, as tertiary radical sites tend to do. The ability of Yang hydroxybiradicals to disproportionate to unsaturated alcohols and the promise of high stereoselectivity of cyclization within chiral molecules have been rediscovered in the past decade.

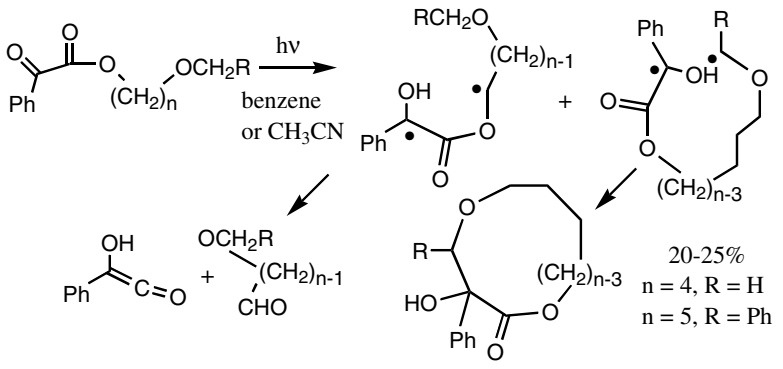


Recent elaborations of the early Winnik work with dipeptides has tethered remote alkyl groups to benzophenone and induced regioselective hydrogen abstraction[186] and hydrogen abstraction from the polymethylene part of a benzophenone embedded in a cyclophane.[187]



Attaching a 2-alkoxyethyl carboxylate group *ortho* rather than *para* on benzophenone provides an example of θ-hydrogen abstraction and cyclization of the 1,9-biradical to a lactone.[188]





SCHEME 12

Chapter 52 describes the Norrish type II cleavage of alkyl phenylglyoxylate esters; the 1,4-biradicals formed by γ-hydrogen abstraction cleave to yield an aldehyde and a ketene but do not cyclize. Neckers and Hu[189] performed much of this work and have since found that some ω-alkoxyalkyl esters undergo remote hydrogen abstraction to produce macrocyclic lactones. Scheme 12 shows what happens in a group of eight compounds with *n* ranging from 2 to 6 and R being methyl, ethyl, or phenyl.

All eight ketoesters undergo type II cleavage, but only the two ketoesters indicated form cyclic lactones in modest yields, stereochemistry not determined. No compounds with $n < 4$ cyclize, including two ω-ethoxy and one ω-benzyloxy, nor do ω-methoxy esters with $n = 5$ and 6. Thus, no δ-hydrogen abstraction occurs in the ketoesters with $n = 2$, unlike the case for δ-alkoxyketones. Moreover, *t*-butyl phenylglyoxylate is photoinert, unlike the β-*t*-butylpropiophenone described above. The conformational requirements for remote hydrogen abstraction are not stringent, but factors promoting coiling of the alkyl group are needed to allow remote hydrogen abstraction to compete with the type II reaction. It has not been established whether the scantiness of cyclization is due to slow triplet hydrogen abstraction or rapid biradical disproportionation. The measured triplet lifetimes indicated overall rates of reaction in the range of 2 to 5×10^6 s^{-1}, values that likely represent mainly γ-hydrogen abstraction.[190] The fact that rates for abstraction of methyl and benzyl hydrogens are within a factor of two of each other indicates that the rate-determining step involves conformational change.

Analogous ω-thioethoxy ketoesters also undergo photocyclization.[191] Unlike the case for the ω-alkoxy ketoesters, nine of the ten sulfide-containing compounds studied, with *n* ranging from 2 to 11, formed cyclic lactones. In this case, remote hydrogen transfer is due to prior charge transfer from sulfur to triplet carbonyl, with subsequent proton transfer coming exclusively from the carbon on the far side of the sulfur atom. The fact that β-thiophenoxyethyl phenylglyoxylate undergoes no photocyclization emphasizes the lack of δ-hydrogen atom abstraction as well as the nonavailability of a proton on the near side of the positive sulfur in the charge transfer complex.[192]

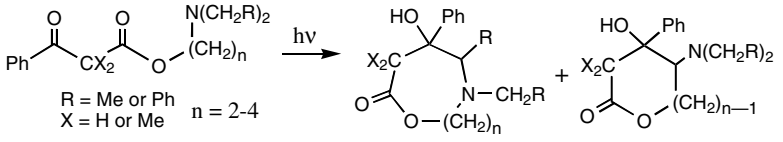
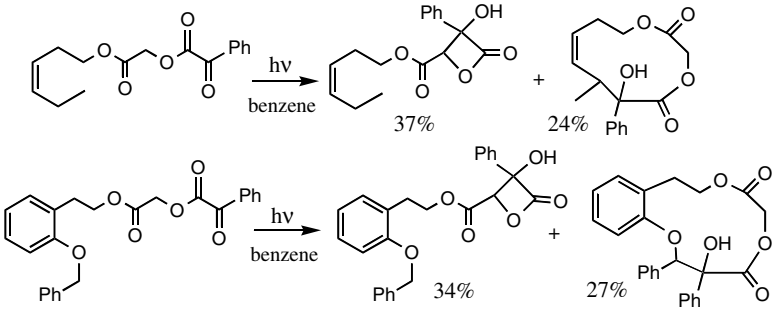
[a] Of lactone.
[b] Of type II cleavage and bimolecular photoreduction.
Source: Adapted from Hu and Neckers.[191]

As Table 58.13 indicates, both chemical and quantum yields decrease as n gets larger. For $n = 2$ and 3, cyclization was quantitative, but as n increases products resulting from bimolecular and internal γ-hydrogen abstraction compete more. The total range of triplet ketone decay rates increase from 1.5×10^6 to 3.2×10^7 s^{-1} as n increases, but it is not clear why competing triplet reactions get faster as n increases. Not surprisingly, the diastereomeric (*t*/*c*) ratio is small, varies slightly with n, and favors the phenyl being *trans* to the methyl. The flexibility of the relatively long chains connecting the two radical sites apparently allows stereochemistry to be dominated by nonbonded interactions in the transition state for cyclization. The low quantum yields for cyclization are partially due to the competing reactions of the triplet ketoester as well as nonradiative decay associated with the charge transfer interaction. The extent of any biradical reversion to ketone cannot be deduced from the data.

Some (ω-dialkylamino)alkyl benzoylacetate esters undergo remote hydrogen abstraction probably initiated by electron transfer to form 1,8, 1,9, or 1,10 biradicals and their azalactone cyclization products.[193] Contrary to most other such reactions, a hydrogen gets transferred from an internal methylene next to nitrogen to produce aminolactones.



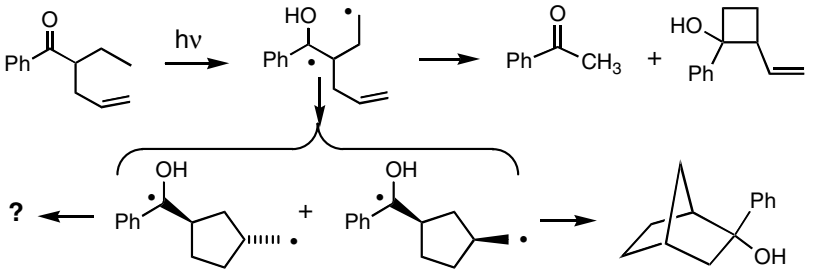
Kraus et al.[194] have reported examples of triplet phenylglyoxylate esters undergoing 1,12- and 1,13-hydrogen transfers leading to macrocyclic lactones. In this case, even a *cis*-hexenyl group and an *ortho*-substituted phenyl group do not prevent competition from simple γ-hydrogen abstraction, as β-lactones are also formed.



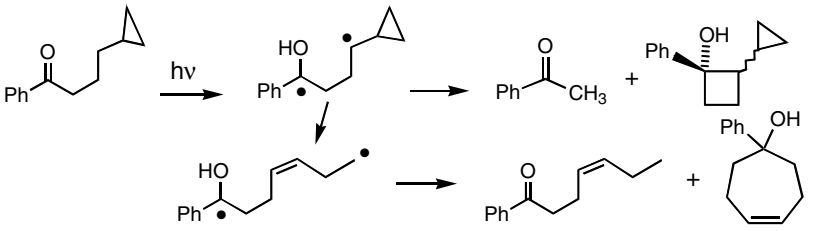
Hydrogen Abstraction Followed by Biradical Rearrangements

The most obvious case involves abstraction of an allylic hydrogen, such that the biradical can react at either end of its allyl radical site. Thus, γ-vinylbutyrophenone forms more cyclohexenol than 2-allylcyclobutanol.[4,82] In contrast, *o*-allyloxyphenyl ketones photocyclize without any allylic rearrangement,[140,145] and several β-allyloxy ketones[195] behave similarly. It is not clear why 1,5-biradicals behave differently than 1,4-biradicals in this regard. If any group attached to the γ-carbon undergoes a radical rearrangement, then the lifetime of the 1,4-biradical is shortened due to that rearrangement competing with its normal cyclization, disproportionation, and cleavage reactions.

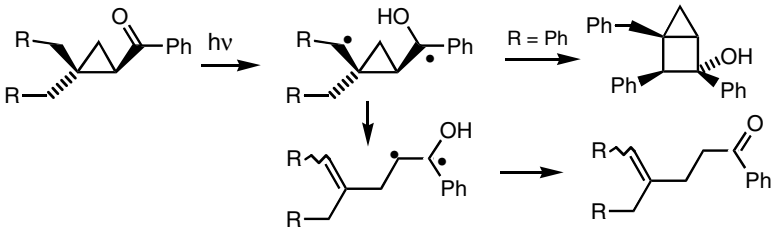
An early example involved a 1,4-biradical that underwent a hexenyl-radical cyclization to a 1,5-biradical that cyclized to a hydroxynorbornane.[196]



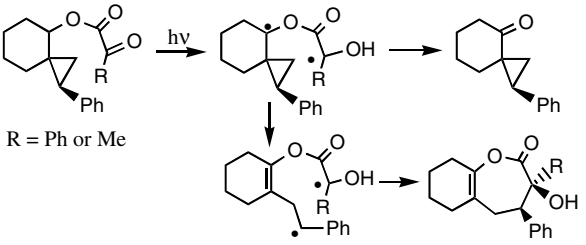
A later example presented a 1,4-biradical undergoing a cyclopropyl-carbinyl ring opening to a 1,7-biradical that both cyclizes to a cycloheptenol and disproportionates to a 1-benzoyl-3-hexene.[197]



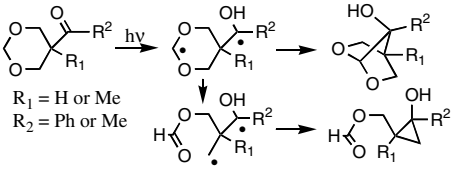
A different example involving cyclopropyl ring-opening is provided by a benzoylcyclopropane which cyclizes normally and ring-opens as a type II cleavage to generate a 5,6-unsaturated ketone.[198]



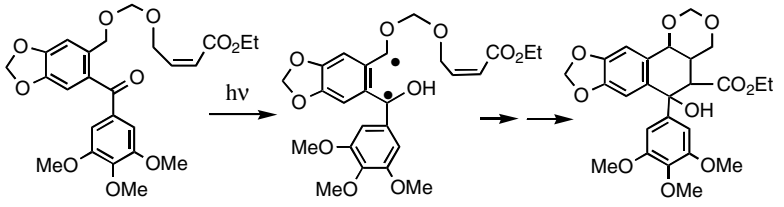
Kraus and Wu[181] put cyclopropyl ring-opening to use as a synthetic method to make ε-lactones without requiring a 1,8-hydrogen transfer. With R = phenyl, only ring-opening occurs, but with R = methyl, both type II cleavages also occur, probably because of some singlet γ-hydrogen abstraction. Without the phenyl group on the cyclopropane ring, only type II cleavage to cyclohexanone occurs.



A rather unique example is provided by a δ-hydrogen abstraction of an acetal hydrogen; the 1,5-biradical so formed both cyclizes and undergoes β-elimination at the dioxy radical site to produce a 1,3-biradical that cyclizes to a cyclopropylmethyl formate ester.[199]



As described earlier, *o*-alkylphenyl ketones undergo γ-hydrogen abstraction, and the *o*-xylylenols so formed are highly reactive towards dienophiles. Quite a few tricyclic structures have been synthesized by such photoinduced intramolecular Diels–Alder reactions. Below is an example provided by Kraus and Wu.[200]



Finally, Hasegawa and co-workers[201] have reported an interesting method to separate two carbonyl groups via photocyclization of a 2-alkyl-1,3-diketone, with the 2-acylcyclobutanol product readily undergoing a retro-Aldol reaction. Note that the carbonyl with the lower triplet excitation energy is the one that reacts.

Oxetane Formation: Stereocontrol

Axel G. Griesbeck
University of Cologne

Samir Bondock
University of Cologne

59.1 Introduction

The combination of two prostereogenic substrate molecules, the carbonyl and the alkene component, in the course of a Paternò–Büchi reaction leads to a photoadduct with three new stereogenic centers. Control of the relative and absolute configuration of these stereogenic centers is a challenge for synthetic chemistry in that many interesting products could in principle be derived from oxetane precursors. A detailed knowledge of the photophysical properties of the electronically excited compound (which in most cases is the carbonyl addend) is necessary to understand (and predict) the stereochemical result of such a [2+2]-cycloaddition reaction. Therefore, the configuration of the excited state, its lifetime, and IC as well as intersystem crossing (ISC) properties should be known. For clean transformations, the carbonyl group should be the only absorbing chromophore in the reaction mixture (i.e., the product should not absorb at the wavelength used), the solvent should not interfere with the cycloaddition step by competing reactions (e.g., hydrogen abstraction), and the polarity influence of the reaction medium on biradical or photoinduced electron transfer (PET) steps ought to be carefully investigated.

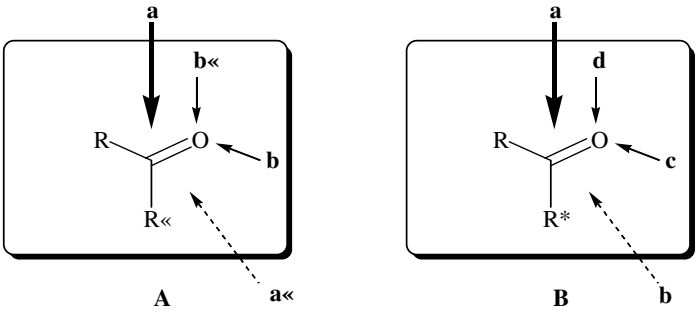
59.2 The Carbonyl Part

Parallel and Perpendicular Approach



enantiotopic faces a,a«and b,b« *diastereotopic* faces a,b and c,d

Considering the simple model for the spatial distribution of electron density in the n,π^* state, a non-prostereogenic n,π^* excited carbonyl compound (**A**) has two pairs of enantiotopic faces for interaction with an alkene addend. Analogous to the ground-state nucleophilic addition reaction, and considering the *Umpolung* effect, electron-deficient alkenes should preferentially interact with the nucleophilic π^* orbital. Such an orientation has been named the *parallel approach*. On the other hand, electron-rich alkenes should preferentially interact with the electrophilic *n*-orbital perpendicular to the π-plane; consequently, such an orientation has been named the *perpendicular approach*. Analyses of the product stereochemistry cannot uncover these primary orientation phenomena. A study of Stern–Volmer kinetics of several 2-norbornanones with the electron-rich *cis*-diethoxyethylene (*c*-DEE) and the electron-poor *trans*-dicyanoethylene (*t*-DCE) as quenchers did corroborate this model.[1] In these cases, the carbonyl compounds are chiral (**B**) and exhibit two pairs of diastereotopic faces for interaction with the alkene addends. The 2-norbornanone skeleton could be attacked by *t*-DCE via a parallel approach from the *exo*- or *endo*-face. From the fluorescence quenching data in Table 59.1, it can be seen that *exo*-blocked compound **2** is quenched with a five-times-lower rate constant than parent compound **1**. The quenching by *c*-DEE, however, is not affected by groups blocking the π-plane of the carbonyl group. If the two diastereotopic faces of the perpendicular *n* plane are additionally blocked by methyl groups (e.g., in compound **3**) the rate constant for *c*-DEE quenching drops by a factor of >50, whereas the rate constant for *t*-DCE is now not affected.

In an additional paper it was shown by Turro and Farrington[2] that the *t*-DCE addition is a highly stereoselective process, indicating an exclusive interaction with the first excited singlet state of the carbonyl compound. An increase in steric hindrance toward the approach from the *exo*-side reduced the rate of fluorescence quenching; however, the efficiency of oxetane formation was increased. Therefore, it was interpreted that for sterically more hindered ketones a possible exciplex intermediate is much more effectively transformed into the photoproduct. This may be due to a puckering effect of the n,π^* excited carbonyl group, which leads to enhanced efficiency of photoproduct formation from the exciplex intermediate.

Non-Prostereogenic Carbonyls

Ketones with homotopic faces have been widely used to determine the stereoselectivity in Paternò–Büchi reactions with *E*- and *Z*-isomers of electron-rich and electron-poor olefins. The photocycloaddition of

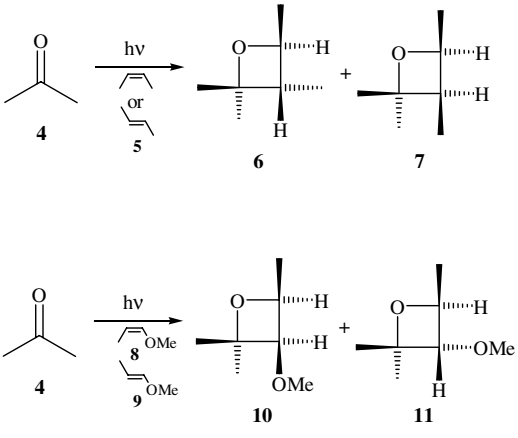
acetone **4** to *cis*- or *trans*-2-butene **5** leads to a mixture of diastereomeric oxetanes **6** and **7** in a constant ratio of 64:36 (±2%) independent of the substrate configuration.[3] No isomerization of the alkene substrates could be detected at low to medium conversion. The photocycloaddition of acetone **4** to *cis*- and *trans*-1-methoxy-1-butene **8** and **9** has been studied in order to show the divergent stereoselectivity of singlet and triplet excited carbonyl states.[4] By use of piperylene as triplet quencher and investigation of the concentration (quencher as well as substrate) dependency of the stereoselectivity of the Paternò–Büchi reaction, a consistent mechanism was established. At high concentrations of the alkene or the triplet quencher maximum diastereomeric ratio, values of 82:18 and 27:73 were found for the oxetanes from **8** and **9**, respectively. Therefore, it was concluded that the stereochemistry of the initial butene is retained in oxetanes **10** and **11** (regioisomers ignored) when singlet excited acetone attacks the alkene, whereas a scrambling effect is obtained for the triplet case indicating a long-lived triplet biradical intermediate.



In some cases, however, a high degree of stereoselectivity could be obtained even with "pure" triplet excited carbonyl compounds. In these cases (e.g., the photocycloaddition of benzophenone to several methyl vinyl sulfides **12**), the intermediary triplet 1,4-biradical preferentially undergoes one of two possible cyclization modes after intersystem crossing.[5] The nonstereospecific (using Zimmerman's definition)[6] nature of this reaction has been demonstrated by the use of stereoisomeric substrates that lead to oxetanes **13** in identical diastereomeric ratios. Another possibility for obtaining stereoisomerically pure oxetanes is the use of alkenes that simultaneously serve as quenchers for the carbonyl triplets (e.g., dienes). The photocycloaddition of acetone **4** and 2-methyl-2,4-hexadiene **14** represents such a process leading to the two regioisomeric oxetanes **15** and **16** where the substrate configuration is retained in **16**.[7]

4 **14** **15** **16**

Prostereogenic Carbonyls: Product Stereoselectivity

Simple (non-induced) diastereoselectivity in general describes a selection process where two stereogenic elements (or more) are generated in a chemical process without stereogenic elements present already in the starting materials, whereas induced diastereoselectivity describes a selection process where stereogenic elements are generated in a chemical process from substrates with at least one stereogenic element already present. Thus, in the case of Paternò–Büchi reactions, the combination of two prostereogenic substrate molecules leads to a photoadduct with a maximum of three new stereogenic centers with a characteristic simple diastereoselectivity.

Simple Diastereoselectivity

In contrast to the results with acetone (*vide infra*), the photoaddition of acetaldehyde **17** with the 2-butenes **5** is highly stereoselective (or stereospecific[6]).[8] Aromatic carbonyl compounds such as benzaldehyde **18** show low stereoselectivities independent of their concentrations (in contrast to aliphatic ketones) due to fast intersystem crossing into the triplet manifold of the carbonyl substrate. If, however, the configuration of the triplet excited state switches from n,π^* to π,π^*, the product stereoselectivity rises again. In these cases (e.g., 2-naphthaldehyde **19**), the carbonyl singlet is the reactive state in photocycloaddition reactions involving the carbonyl group. Obviously, the quantum yields for such a process are low (about 5% of triplet reactivity) because of efficient deactivation via the triplet π,π^* states. Jones et al.[9] have published another concentration study where they describe the photocycloaddition of aliphatic aldehydes to medium ring cycloalkenes. The variation in photoadduct distribution is due to stereospecific addition of the aldehyde singlet (dominant at high alkene concentrations) accompanied by a more stereorandom triplet pathway at lower concentrations of the cycloalkenes.[9]

In the case of Paternò–Büchi reaction of cycloalkenes with prostereogenic aromatic carbonyl compounds (which show rapid ISC to the triplet excited carbonyl), less clear results were obtained. The reaction of cyclohexene **20** with benzaldehyde **18** was reported in the literature,[10] and the spectral data of the main product **21** (35%) was described as "consistent with the unusual assignment of *endo*-stereochemistry."[11] A detailed study of the photocycloaddition of (triplet) benzaldehyde with several cycloalkenes revealed that *endo* stereoselectivity is an inherent property for these processes.[12] The addition of **18** to 2,3-dihydrofuran **22** was especially significant; only one regioisomer, **23** (analogous to the reaction with acetone),[13] is formed in a diastereomeric ratio of 88:12. Increasing steric demand of the carbonyl addend leads to an increase in diastereoselectivity; for example, for mesityl aldehyde **24** only the *endo*-diastereomer **23b** could be detected.[14] Substituent effects have also been described for methyl-substituted cycloalkenes that were in accord with the postulated principle for control of stereoselectivity in triplet reactions.[15] This selectivity effect could be explained by the assumption of certain 1,4-biradical conformers that fulfill the prerequisites (Salem rules)[16] for rapid intersystem crossing to form the 1,4-singlet biradicals. These can interconvert without spin barrier into the products and thus exhibit a "conformational memory". In contrast to the triplet pathway, singlet excited carbonyl compounds such as 1- or 2-naphthaldehydes **25** do add with high *exo* stereoselectivity to 2,3-dihydrofuran.[17] Both singlet- *and* triplet excited carbonyl compounds underwent photocycloaddition to furan **26** with high *exo* selectivity to give adducts **27**. Additionally, only one regioisomer is formed in these reactions, which show high efficiency and proceed with excellent yields.[18] The oxetanes formed in these reactions are acid-labile compounds and can be converted into the corresponding aldol products. Schreiber and Satake[19] used this property for the synthesis of several key compounds as substrates for the synthesis of natural products by the "photo–Aldol reaction".[19] Besides the addition of aldehydes to furan, ketones and esters as well as substituted furans have been used as starting materials.[20,21] In most cases, the locoselectivity (for furans with unsymmetric substitution pattern) is moderate,[22] but the regioselectivity (exclusive formation of the acetal product) and the stereoselectivity stay high (>500:1 in some cases).[23] The same degree of regio- and

stereoselectivity has been observed for other heterocyclic substrates, such as thiophenes, oxazoles, pyrazoles, and many more.[24] A somewhat lower degree in stereoselectivity was reported for the photocycloaddition of carbonyl compounds to 1,3-cyclopentadiene (with propanal, *exo*/*endo* = 80:20)[25] and 1,3-cyclohexadiene (with acetaldehyde, *exo*/*endo* = 88:12).[26] Another group of highly efficient carbonyl addends are α-keto esters such as alkyl pyruvates, alkyl glyoxylates, and esters of phenylglyoxylic acid. Photocycloaddition with electron-rich cycloalkenes such as dioxoles and furans have been reported to proceed highly regio- and diastereoselectively. The Paternò–Büchi reaction of 2,2-diisopropyl-1,3-dioxole **28** with ethyl pyruvate **29** leads to an 80:20 mixture of diastereomeric oxetanes **30**.[27] Zamojski and Kozluk[28] have reported a highly selective reaction of triplet excited *n*-butyl glyoxylate **31** with furan **26**. Similar to the reactions with aromatic aldehydes,[18] only the *exo*-photoproduct **32** is formed.

The simple diastereoselectivity of the photocycloaddition of electronically excited carbonyl compounds with electron rich olefins was studied as a function of the substituent size – at identical starting conditions ignoring the electronic state involved in the reaction mechanism.[29] The [2+2]-photocycloaddition of 2,3-dihydrofuran (**22**) with different aldehydes in the nonpolar solvent benzene resulted in oxetanes **23** with highly regioselectivity and surprising simple diastereoselectivities: the addition to acetaldehyde resulted in 45:55 mixture of *endo* and *exo* diastereoisomer, with increasing the size of the α-carbonyl substituent (Me, Et, *i*-Bu, *t*-Bu), the simple diastereoselectivity increased with preferential formation of the *endo* stereoisomer.

The benzaldehyde addition, which was most intensively investigated, gave a 88:12 mixture of *endo*- and *exo*-diastereoisomers. Thus, the thermodynamically less-stable stereoisomers (>1.5 kcal/mol, from *ab initio* calculation) were formed preferentially. To further enlarge the phenyl substituent, *o*-tolyl and mesitaldehyde, as well as 2,4-di-*t*-butyl-6-methylbenzaldehyde, were applied, and the diastereoselectivity did actually further increase.

In contrast to the diastereoselectivity of the 2,3-dihydrofuran photocycloaddition, the photocycloaddition of furan **26** with aromatic as well as aliphatic aldehydes proceeded with unusually high *exo*-diastereoselectivity to give the bicyclic oxetanes **27** in good yield.[29] The diastereoselectivity of reaction of furan with acetaldehyde, propionaldehyde, and benzaldehyde (*exo*/*endo*) were 19:1, 82:1, and 212:1, respectively. The exchange of the hydrogen in benzaldehyde by a methoxy group completely inverted the diastereoselectivity in the photocycloaddition with furan. Further modification of the α-substituent in the benzoyl substrates disclosed a distinct dependence of the *exo*/*endo* ratio on the size of this substituent. The photocycloaddition of acetophenone with furan gave only one product, whereas a 77:23 mixture of diastereoisomers resulted from the addition of benzoyl cyanide. Increasing the size of the aryl group from phenyl to mesityl in aroyl cyanides led to an increase in *exo*-diastereoselectivity from 3.7:1 up to 16:1.

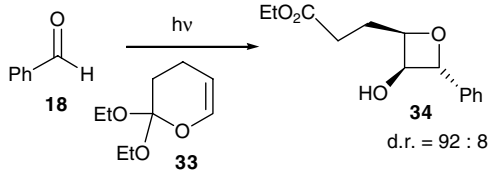
Steric hindrance can also reach a critical value during bond formation and might favor the formation of thermodynamically more stable product. In a report by Park and co-workers,[30] the photocycloaddition of benzaldehyde **18** to 2,2-diethoxy-3,4-dihydro-2*H*-pyran **33** is described to give preferentially the *exo*-phenyl product **34**.[30]



18 **33** **34**

d.r. = 92 : 8

Bach and Schröder[31] investigated the photocycloaddition of electron-rich *N*-acyl enamines **35** with benzaldehyde.[31] The 3-amidooxetanes **36** were formed with excellent regioselectivity (analogous to reactions with enol ethers, *vide supra*) and good diastereoselectivity.

Bn	89 : 11
Pr	90 : 10

Silylenol ethers **37** were also investigated by Bach and Jödicke[32] in the last decade. A series of photocycloaddition reactions of benzaldehyde with these substrates showed a trend in stereoselectivity which at first sight was in contradiction to the rules described above; that is, the thermodynamically more stable *trans*-diastereoisomers **38** (with respect to the substituent at C2 and C3) were formed preferentially and the *trans*/*cis* ratio increases with increasing size of the C3 substituent. This peculiar stereoselectivity might be attributed to a memory effect from the approach geometry between the triplet excited benzaldehyde and the alkene.

Recently, Bach and Schröder[34] reported the photocycloaddition of α-alkyl-substituted enecarbamates **41** to benzaldehyde affording 3-aminooxetanes **42** in moderate to good yields (46 to 71%). The α-phenyl-substituted enecarbamate did not lead to a photocycloaddition product presumably due to rapid energy transfer (triplet sensitization) from the electronically excited aldehyde. An increase in steric bulk of the alkyl substituent R shifted the diastereomeric ratio *cis*/*trans* in the direction of the thermodynamically more stable *cis* product.

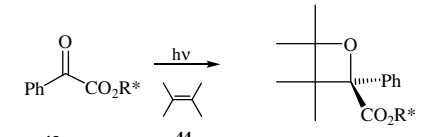
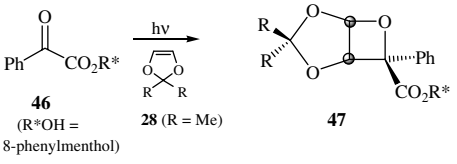
Induced Diastereoselectivity

The first report concerning an "asymmetric" Paternò–Büchi reaction with a chiral carbonyl component was made in 1979 by Gotthardt and Lenz.[35] The photocycloaddition of the enantiomerically pure menthyl ester of phenylglyoxylic acid **43** with 2,3-dimethyl-2-butene **44** gave the oxetane **45** with a diastereomeric excess of only 37%. The corresponding chiral glyoxylates gave, with furan, even lower diastereomeric excesses of 5 ± 2%.[36] The unique behavior of chiral phenyl glyoxylates was later demonstrated by Scharf and co-workers.[37] Despite the fact that in all cases the stereogenic centers are localized in the alcohol part of the α-keto ester and therefore remarkably far away from the reactive (triplet excited) carbonyl group, the (induced) diastereoselectivities were exceedingly high (>96% in many cases) with 8-phenylmenthol as chiral auxiliary.[37] The same group has studied the temperature dependence of the auxiliary-induced diastereoselectivity.[38] As substrates for the photoaddition of phenyl glyoxylates several electron-rich cycloalkenes were used that had already been studied with α-keto esters.[39] Besides normal isoselectivity effects, in most cases an *inversion* of the induced diastereoselectivity was found at certain temperatures. Consequently, this effect was named the *isoinversion principle* and has been demonstrated to be a general phenomenon for many two-step reactions.[40] The inherent (non-induced) diastereoselectivity for these photoadditions (e.g., oxetane **47** from the dioxole **28** and 8-phenylmenthyl phenyl glyoxylate **46**) was >96%, with the phenyl group being directed into the *endo*-position. The applications of Cram-like model compounds such as isopropylidene glyceraldehyde[41] or acyclic α-chiral ketones[42] did not, however, lead to high stereoselectivities.





Effect of Temperature on Diastereoselectivity

Recently, Adam and Stegmann[43] reinvestigated the Paternò–Büchi reaction of *cis*- as well as *trans*-cyclooctene (**48**) with electronically excited benzophenone (**49**). They reported an unprecedented temperature-dependent diastereoselectivity, where the more stable substrate diastereoisomer (*cis*-cyclooctene) leads, with increasing reaction temperature, to increasing amounts of the less stable product diastereoisomer **50** (*trans*-oxetane). Adam rationalized the unprecedented experimental facts for the

[2+2]-photocycloaddition of the diastereoisomeric cyclooctenes with benzophenone in terms of a consistent mechanism:[44] (1) The *cis*-**48** displays a remarkable temperature dependence in that the *trans*-2-oxetane is favored with increasing temperature; (2) for *trans*-**48** the *trans* geometry is preserved in *trans*-cycloadduct over a broad temperature range of 180°C; (3) the extent of *trans* to *cis* isomerization in the cycloaddition with the *trans*-cyclooctene increases with temperature.

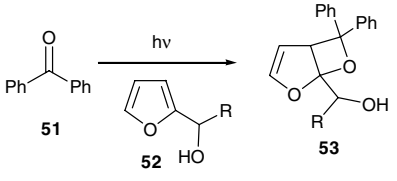
59.3 The Alkene Part

Inherent Diastereoselectivity

A huge number of acyclic and cyclic alkenes and alkadienes have been used as addends for Paternò–Büchi reactions with carbonyl compounds, and many of them are mentioned in other chapters. Dioxoles[45] and 2,3-dihydrooxazoles[46] have been found to be remarkably effective addends. These alkenes are highly electron-rich compounds with low ionization potentials and also serve as potent electron-donor substrates. This property makes the application of electron-rich alkenes sometimes critical because PET reactions can interfere with the normal photocycloadditions via triplet 1,4-biradicals. The use of nonpolar solvents is therefore recommended; however, an analysis of the energetics (Rehm–Weller relationship) should always be included.[45] Intensive investigations of the diastereofacial selectivity of ketone photocycloaddition to norbornene and norbornadiene have been reported. The biacetyl (**51**) addition to norbornene **52a** is highly (>24:1) *exo* selective, whereas the *syn*-7-*t*-butyl derivative (**52b**) showed inverted (<1:30) *exo* selectivity.[48] Introduction of a hydroxy group at the 7-*syn*-position of norbornene (**52c**) reinverts the diastereoselectivity; in this case, the *exo*-adduct **53c** is formed, with the diastereomeric excess > 97%. The latter effect could be due to hydrogen bonding, which pre-complexes the excited carbonyl species. A similar photoreaction has been reported for norbornadiene.[49] As was shown by Gorman et al.,[50] ketone triplets do not add to but interconvert norbornadiene into the quadricyclane isomer that serves as the substrate for the subsequent Paternò–Büchi reaction.

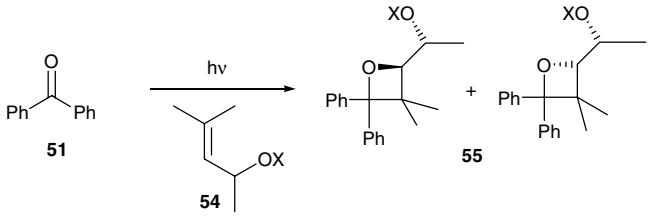


R = Et, ^{i}Pr

Effect of Hydrogen Bonding on Diastereoselectivity of Paternò–Büchi Reaction

The Paternò–Büchi reaction of 2-furylmethanol derivatives **54** with benzophenone was recently investigated by D'Auria and co-workers.[51] The regio- and stereoselectivity of the reaction was exceedingly high

and rationalized by assuming a decisive hydroxy bonding interaction favoring the approach of the electronically excited carbonyl group toward one of the diastereotopic faces of the furan ring and formation of only one diastereoisomeric oxetane **55**. When the OH group was masked by means of a methyl ether, the reactivity dropped remarkably.



X =	solvent	d.r. (threo : erythro)

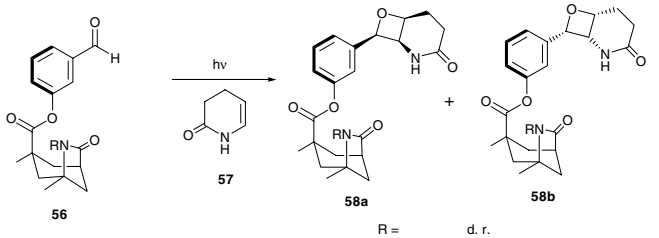
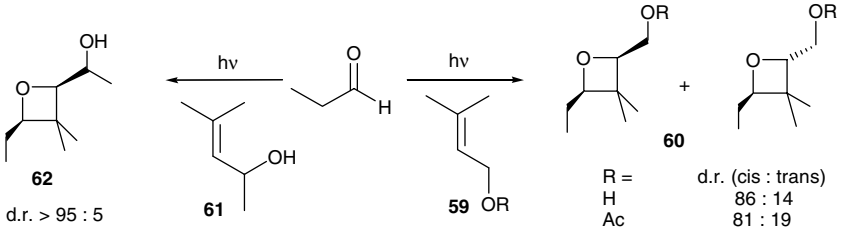
Hydrogen bonding is also a possible reason for the diastereoselectivity of the [2+2]-photocycloaddition of benzophenone in the case of acyclic chiral allylic alcohols **56**. These substrates afforded only one regioisomer of the diastereomeric *threo*, *erythro* oxetanes **57** with a preference for the *threo* isomer.[52] The diastereoselectivity was remarkably reduced in the presence of a protic solvent (methanol as a competitive intermolecular hydrogen bonding substrate) and totally disappeared in case of the silylated substrate **56**.[53]



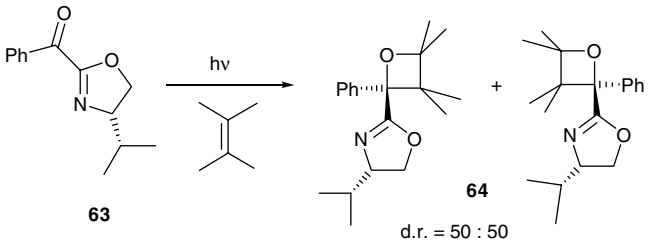
R =	d. r.
H	83 : 17
Me	50 : 50

Bach and co-workers investigated the effect of *ground-state* hydrogen bonding interactions in a complex between a rigid chiral host **58** that assists the control of enantiofacial- and diastereofacial selectivity.[54] Irradiation of this chiral host with 3,4-dihydro-1*H*-pyridino-2-one **59** in benzene gave the oxetane **60** with high selectivity, with attack of the electronically excited aldehyde occurring exclusively on one of the enantiotopic faces of the alkene. The *N*-methylated chiral host that is no longer hydrogen-bond active gave no significant diastereomeric excess.



R =	d.r. (cis : trans)
H	86 : 14
Ac	81 : 19

Recently, Griesbeck and Bondock[55] compared the effect of hydrogen bonding in the first excited singlet vs. the first excited triplet state of aliphatic aldehydes in the photocycloaddition to allylic alcohols and acetates (**61**). The simple diastereoselectivity was nearly the same, but the presence of hydrogen bonding interactions increases the rate of the Paternò–Büchi reaction. Moreover, the effect of hydrogen bonding for simple diastereoselectivity was completely different than that for the induced diastereoselectivity. This was confirmed by comparison with the mesitylol (**63**)-photocycloaddition to aliphatic aldehydes.



Induced Diastereoselectivity

Asymmetric Induction Via Chiral Carbonyl Compounds

Numerous applications were developed by the Scharf group[37–40,45,46] using chiral α-keto esters in [2+2]-photocycloadditions to electron-rich cycloalkenes that have already been mentioned in the text. An optically active acetal was used as substrate in the synthesis of prostaglandins. The induced (*anti*) diastereoselectivity was high (>90%); the inherent diastereoselectivity was not reported.[56] An interesting solvent dependency of the face selectivity was reported for 3,4,6-tri-*O*-acetyl-D-glucal as carbohydrate substrate.[57] Oppenländer and Schönholzer studied the diastereoface differentiation in the Paternò–Büchi reaction using the 4-(*S*)isopropyl-2-benzoyl-2-oxazoline **65** (prepared from condensation of phenylglyoxylic acid with (*S*)-valinol) as a chiral auxiliary.[58] The [2+2]-photocycloaddition gave a mixture of diastereoisomeric *l*- and *u*- (*like* and *unlike*) oxetanes **66** in equal amounts.

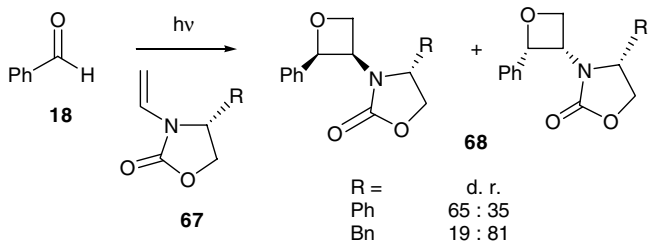
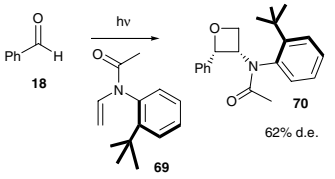
Asymmetric Induction Via Chiral Alkenes

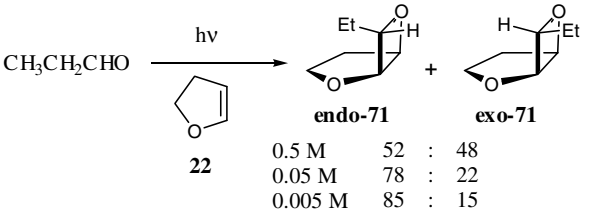
The induced diastereoselectivity in a Paternò–Büchi reaction resulting from a stereogenic center in the alkene part was recently described by Bach and co-workers[59] in the photocycloaddition of chiral silylenol ethers **67** with benzaldehyde **18**. The substituents, R, at the stereogenic center were varied in order to evaluate the influence of steric bulk and possible electronic effects. In accord with the 1,3-allylic strain model, the facial diastereoselectivity was at a maximum with large (R = *t*-Bu, $SiMe_2Ph$) and polar (R = OMe) substituents at the γ-position of silyl enol ether (diastereomeric ratio of oxetanes **68** > 95:5).



Several efforts were also made by the same group to achieve chiral auxiliary control in *N*-acyl enamines **69**, but only moderate diastereoselectivities for the 3-amido oxetanes **70** were reported.[60]



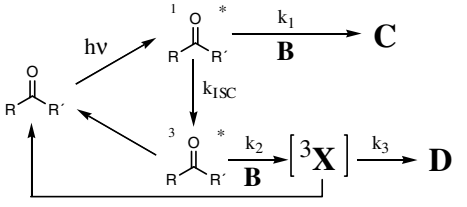
The photocycloaddition of an axial chiral *N*-acyl enamine **71** with benzaldehyde resulted in oxetane (**72**) formation with moderate diastereomeric excess.[61]



The stereogenic center in a dihydropyrrole derivative was used as the key directing element in the synthesis of natural product (+)-preussin via a [2+2]-photocycloaddition with benzaldehyde.[62]

Effect of Concentration on the Stereoselectivity of the Paternò–Büchi Reaction

The difference between the simple diastereoselectivities in photocycloaddition reactions following the singlet vs. the triplet route were studied by determination of the concentration dependence of the Paternò–Büchi reaction.[63] Carbonyl substrates that have both reactive singlet and triplet states exhibit one characteristic substrate concentration where a 1:1 ratio of singlet and triplet reactivity, (i.e., *spin selectivity*) could be detected. The shape of these concentration/diastereoselectivity correlations reflects the different kinetic contributions to this complex reaction scenario. The mixtures of diastereoisomers formed in the singlet and triplet pathway, respectively, are termed C and D.



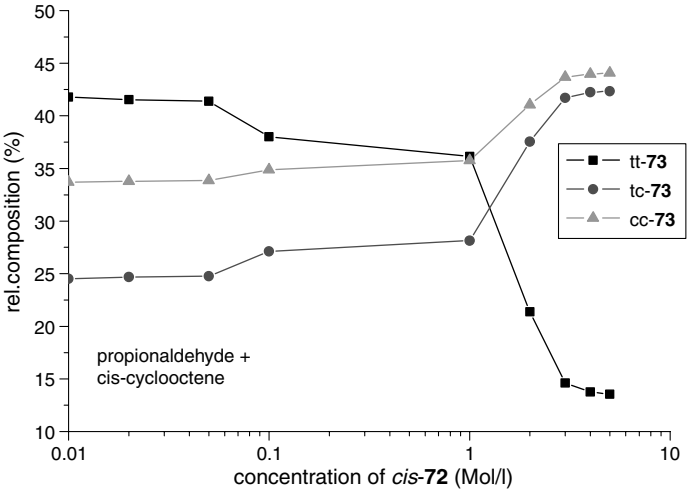


FIGURE 59.1

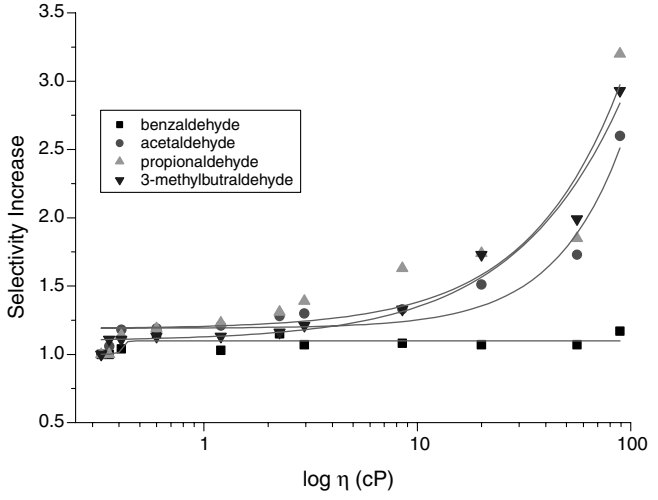

FIGURE 59.2 Viscosity dependence (normalized) of the Paternò-Büchi reaction of 2,3-dihydrofuran with aldehydes (1M) at 293 K.

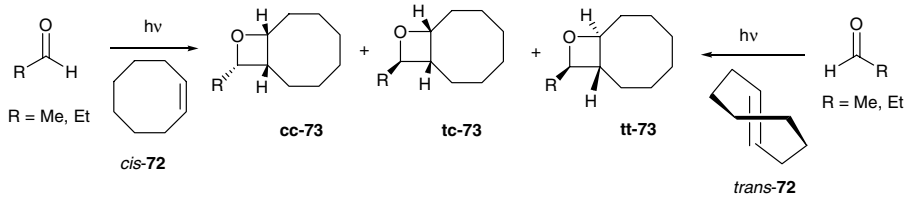
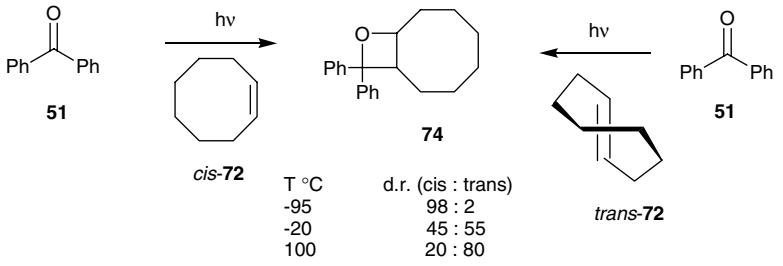
The selectivity (C/D) is controlled by the geometry of the conical intersection for the singlet reaction and by the optimal ISC geometry of the 2-oxatetramethylene biradical (^{3}X) for the triplet reaction. The situation is described for the propionaldehyde/2,3-dihydrofuran photocycloaddition reaction. At low concentrations (0.005 *M*, triplet conditions), the diastereoselectivity approaches a maximum *endo*/*exo* value of 85:15. At high concentrations (0.5 *M*, singlet conditions), the diastereoselectivity decreased to 52:48.



The concentration dependence of the photocycloaddition of *cis*- and *trans*-cyclooctene **48** with aliphatic aldehydes was studied in order to test the spin selectivity with respect to the *cis*/*trans* oxetane ratio and/or the *endo*/*exo* selectivity relevant for the *cis*-photoadduct.[64] The results depicted in Figure 59.2 indicate a moderate but still significant spin correlation effect in the Paternò–Büchi reaction of cyclooctene with aliphatic aldehydes. The *exo*-diastereoisomers **tc**-**74** were formed with similar probability as the *endo*-diastereoisomers **cc**-**74** in the singlet carbonyl manifold, whereas the triplet excited aldehydes preferred the formation of the *endo*-diastereoisomer and *trans*-fused products **tt-74**.



Effect of Temperature and Solvent Viscosity on the Stereoselectivity of the Paternò–Büchi Reaction

As an extension of the work on the temperature dependence of the induced diastereoselectivity in α-keto ester photocycloadditions by Scharf et al.,[38,40] the temperature dependence of spin-selective reactions (singlet vs. triplet photocycloaddition) was determined and a characteristic nonlinear behavior was detected.[65] Prior to these experiments, solvent viscosity effects were studied in order to separate these influences from temperature effects. The photocycloaddition of benzaldehyde **18** with 2,3-dihydrofuran **22** was investigated as a typical triplet reaction with concentration-independent diastereoselectivity. Variation of the solvent viscosity over a large effective range (η = 0.3 to 1500 cp) resulted in a weak but significant increase in *endo* selectivity from 82 to 91% (see Figure 59.2).

More pronounced effects were detected for reactions of aliphatic aldehydes with **22**. In all cases, the diastereoselectivity increased with increasing solvent viscosity. In the context of the mechanistic model above, an increase in solvent viscosity favors the triplet channel due to a reduction in the diffusion rate limit (about 4 orders of magnitude in the experimental range). The temperature dependence of the *endo*/*exo* selectivity with aliphatic aldehydes RCHO (R = Et, Me, *i*-Bu) showed characteristic nonlinear curves with inversion points from which activation parameters for the singlet as well as the triplet photocycloaddition were determined.

Samir Bondock
University of Cologne

60.1 Introduction and Definition of the Reaction

The first intermolecular photocycloaddition of an aromatic carbonyl compound (benzaldehyde) to an alkene (2-methyl-2-butene) was reported by Paternò and Chieffi: "*In una prima esperienza abbiamo esposto un miscuglio equimolecolare di amilene (gr. 43) e di aldeide benzoica (gr. 67) in un tubo chiuso, dal 5 dicembre 1907 al 20 marzo 1908, cioè per circa tre mesi e mezzo della stagione invernale*".[1] When this prolonged experiment (104 days!) was repeated by Büchi and co-workers in the mid-1950s, they confirmed the oxetane structure of the main product.[2] The regioselectivity of this specific transformation, however, was not correctly established until a publication by Yang et al.,[3] and still today no exact analysis of the stereoselectivity has been reported. Several special features about this reaction are worthwhile for discussion; for example, the influence of the *state properties* of the electronically excited species (which normally is the carbonyl compound) and of the alkene properties on rate, efficiency, and selectivity of the oxetane formation. Furthermore, a detailed discussion of diastereo- and enantioselective modifications and of intramolecular variants is given in Chapter 59. This chapter describes applications of intermolecular Paternò–Büchi reactions. After discussion of the features of the carbonyl addends, the olefinic counterparts are discussed. A number of extensive reviews about special features of this reaction type have appeared in the last 15 years and are recommended for those seeking further information.[4]

60.2 Mechanism of the Paternò–Büchi Reaction

Theoretical Models

Considering orbital interactions between alkenes and n,π^* excited carbonyls, Turro et al.[5] have classified two possible primary trajectories: (1) the nucleophilic attack of the alkene toward the carbonyl half-filled *n* orbital, characterized as the *perpendicular approach*, and (2) the nucleophilic attack of the carbonyl by its half-filled π^* orbital toward the empty π^* orbital of the alkene, characterized as the *parallel approach*. First-order orbital correlation diagrams are in line with this model and predict the formation of a carbon–carbon bonded 1,4-biradical for the parallel approach and a carbon–oxygen bonded biradical

0-8493-1348-1/04/$0.00+$1.50

for the perpendicular approach.[6] Which approach dominates is controlled by the relative positions of the alkene HOMO and LUMO. For interaction between electron-rich alkenes with carbonyl compounds, the perpendicular approach is favored; for electron-deficient alkenes, the parallel approach. Several *ab initio* calculations have been published.[7] A recent MC-SCF study resulted in the prediction that intersystem crossing (ISC) from triplet to singlet leads to the same biradical ground-state pathways that are entered via singlet photochemistry.[8] Following this line of argument, the product-determining molecular geometry is expected to be similar either from the first excited singlet or triplet state of the carbonyl reactant.

Experimental Results

The biradical model has been in vogue for at least three decades to describe chemo- and regioselectivity phenomena. At least for triplet 1,4-biradicals (2-oxatetramethylenes or preoxetanes), this assumption has been confirmed by experimental facts. Trapping experiments (triplet oxygen and sulfur dioxide),[9] as well as the application of radical clocks,[10] have demonstrated that short-lived (1- to 10-ns) triplet 1,4-biradicals are formed when triplet excited carbonyl compounds interact with alkenes. Spectroscopic evidence for these species came from laser flash photolysis of electron-rich olefins with benzophenone.[11] In this case, also, the radical anion of the ketone was detected, demonstrating that electron transfer processes can interfere with the formation of oxetanes. The existence of an exciplex as precursor of the 1,4-biradicals as well as of the radical ion pair was deduced from a comparison of oxetane formation with the fluorescence quenching of singlet excited ketones by electron-rich and electron-deficient alkenes.[12] A series of experiments on substrate diastereoselectivity have been undertaken to differentiate between reactive states (n,π^* vs. π,π^*) and multiplicities (singlet vs. triplet). Simple rules have been deduced that could be used as first approximations; for example, triplet n,π^* carbonyls show much less stereoselectivity than singlet n,π^* carbonyls.[13] More details are given in the preceding chapter, which covers stereoselectivity in oxetane formation.

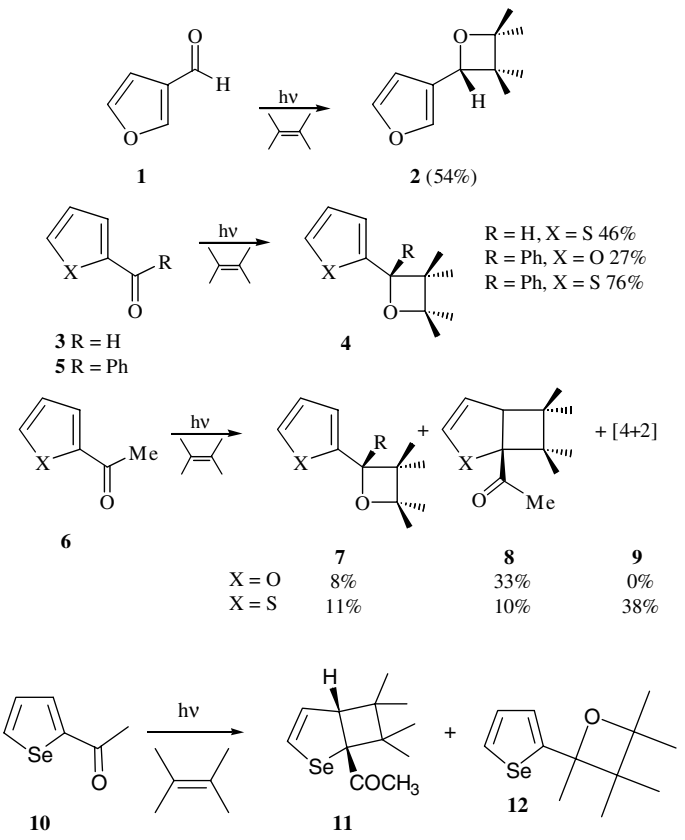
60.3 Substrates for the Paternò–Büchi Reaction

Carbonyl Compounds

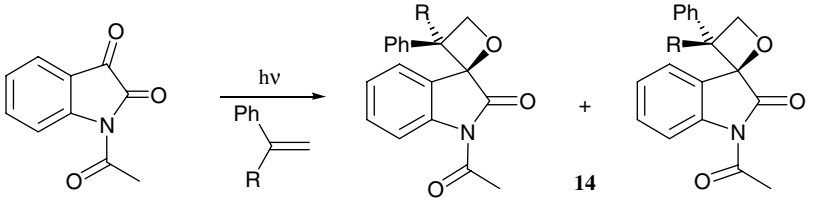
Aromatic Ketones and Aldehydes

An impressive number of Paternò–Büchi reactions have substituted benzophenones or benzaldehydes. Some of these reactions are discussed in context with their olefinic reaction partners. A special group of aromatic carbonyl reagents are heteroaromatic substrates such as acyl derivatives of furan and thiophene which could in principle undergo [2+2]-cycloaddition toward the C=O group as well as toward one of the ring C=C groups. The reaction periselectivity is controlled by the heteroatom and the substitution pattern, which influences the nature of the lowest excited triplet state.[14] Cantrell[15] has published a series of experiments with 2- and 3-substituted benzoyl-, acetyl-, and formylthiophenes and furans. The aldehydes **1** and **3** (X = S, O) gave, with high selectivity, the oxetanes **2** and **4**, with 2,3-dimethyl-2-butene as the alkene addend. Similar results were reported for 2-benzoylfuran and 2-benzoylthiophene **5** (X = S, O), whereas the corresponding 2-acetyl substrates **6** gave mixtures of [2+2]- and [4+2]-photoproducts **7** to **9**.[16]

Vargas and Rivas[17] reported the photocycloaddition of acetylselenophene **10** to tetrasubstituted alkenes, resulting in two [2+2]-photoadducts, one of them, **11**, involves the C=C bond of the monoalkene and the β,γ-double bond of the selenophene. The second product, **12**, is a Paternò–Büchi photoadduct involving the carbonyl group of the selenophene and the C=C bond of the monoalkene. In contrast to 2-acetylthiophenone, which also yields a [4+2]-cycloaddition product, no such adducts were found with 2-acetylselenophene. This was rationalized by the difference in size of the heteroatom, which might disfavor a Diels–Alder approach for the selenium compound in contrast to the corresponding sulfur and oxygen heterocycles.



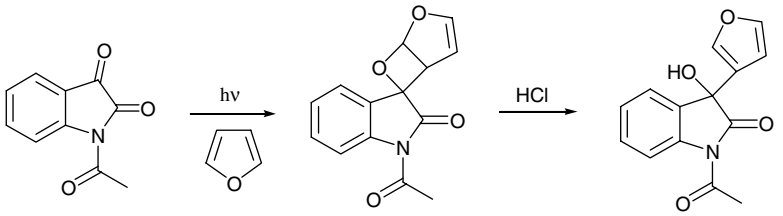
Photoinduced [2+2]-cycloadditions of [1]H-1-acetylindole-2,3-dione **13** with alkenes gave spirooxetanes **14** in moderate to high yields, displaying the typical triplet n,π^* reactivity of acetylisatin.[18] The regioselectivity and diastereoselectivity of these reactions depend on the reaction mechanism; reactions involving alkenes with high oxidation potential exclude single electron transfer (SET) processes, thus the regioselectivity can be rationalized by considering frontier molecular orbital interactions of the two addends and the diastereoselectivity by applying the Salem–Rowland rules for triplet-to-singlet biradical intersystem crossing (*vide infra*).



R =	solvent	syn : anti	yield (%)
H	benzene	1.42 : 1	96
H	acetonitrile	2.57 : 1	98
Me	benzene	1.00 : 1	96
Me	acetonitrile	2.19 : 1	96

As an extension of this work, photoinduced [2+2]-cycloadditions of 1-acetylisatin **13** with cyclic enol ethers (furan, benzofuran, 2-phenylfuran, 8-methoxypsoralen) and acyclic enol ethers (*n*-butyl vinyl ether and vinyl acetate) were investigated which afforded the spirooxetanes in high yields (82 to 96%)

and with high regio- and diastereoselectivity.[19] Treatment of the furan-derived oxetane **15** with acid resulted in oxetane ring opening and yielded the 3-(furan-3-yl)indole derivative **16**.

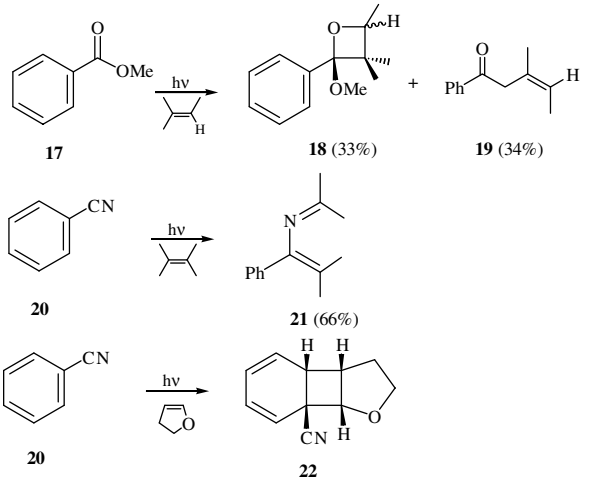


13 **15** **16**

Carboxylic Acid Derivatives and Nitriles

Coyle[20] has summarized the photochemistry of carboxylic acid derivatives. For arene carboxylic acid esters it has been shown that [2+2]-cycloaddition competes with hydrogen abstraction by the excited ester from an allylic position of the alkene. The addition of methyl benzoate **17** to 2-methyl-2-butene gave a 1:1 mixture of the Paternò–Büchi adduct **18** and the coupling product **19**.[21] Less electron-rich alkenes (e.g., cyclopentene) did add preferentially toward the benzene ring of **17** in an *ortho*- and *meta*-cycloaddition manner. Furans could also be added photochemically to methyl benzoate and other arenecarboxylic acid esters. The resulting bicyclic oxetanes could be transformed into a series of synthetically valuable products.[22] [2+2]-Cycloadducts and/or their cleavage or rearrangement products have also been described for photoreactions of alkenes with diethyl oxalate,[23] benzoic acid,[24] and carbamates.[25]

The site selectivity of alkene addition to benzonitrile **20** has been studied with a series of cyclic and acyclic olefins. Again, two reaction modes could be observed: [2+2]-cycloaddition to the nitrile group leading to 2-azabutadienes, deriving from the primarily formed azetines, (e.g., **21** from 2,3-dimethyl-2-butene),[26] and *ortho*-cycloaddition to the benzene ring (e.g., **22** from 2,3-dihydrofuran).[27]

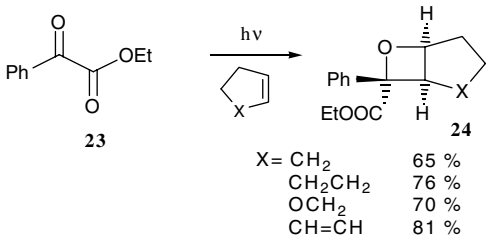


17 **18** (33%) **19** (34%)

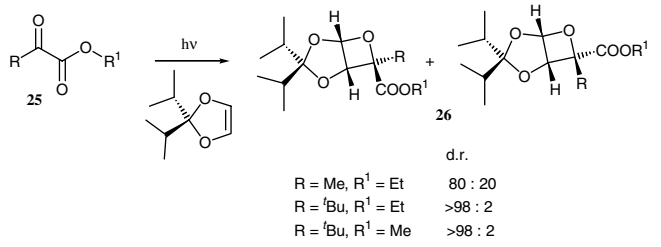
20 **21** (66%)

20 **22**

Recently, Hu and Neckers[28] reported that triplet excited states of alkyl phenyl glyoxylates react rapidly and with high chemical yields with electron-rich alkenes forming oxetanes **24** with high regio- and stereoselectivity. The intramolecular γ-hydrogen abstraction (Norrish type II) cannot compete with intermolecular reactions in most cases. When less electron-rich alkenes were used, the Norrish type II reaction became competitive.

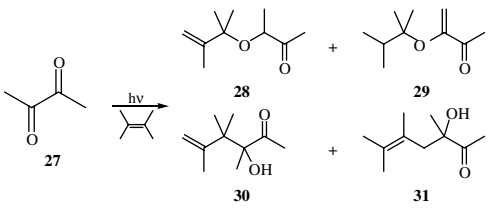


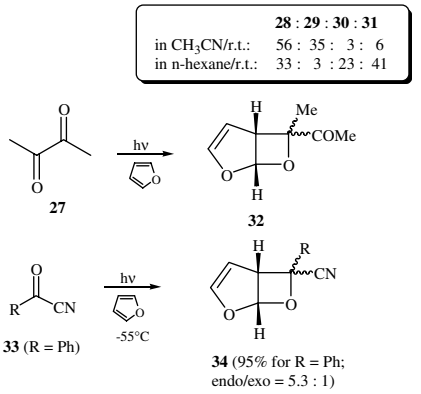
Buhr et al.[29] described the photocycloaddition of methyl and ethyl trimethyl pyruvates (**25**) with diisopropyl-1,3-dioxole. In contrast to the reaction with ethyl pyruvate, the bicyclic oxetane **26** was formed with very high (>98%) diastereoisomeric excess. An x-ray analysis revealed the unusual *endo-t*-butyl configuration. Semi-empirical calculation indicated that this clearly is the kinetic product formed by a biradical combination reaction, which might be controlled by favorable spin-orbit coupling geometries.



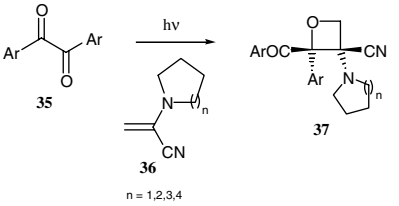
α-Ketocarbonyl Compounds, Acyl Cyanides

α-Diketones undergo primary photochemical addition to olefins to form [4+2]- and [2+2]-cycloadducts in competition to hydrogen abstraction, α-cleavage, and enol formation. The product ratios (**28**:**29**:**30**:**31**) of the biacetyl (**27**)/2,3-dimethyl-2-butene photoreaction strongly depend on the solvent polarity and reaction temperature, indicating an exciplex intermediate with pronounced charge separation and possibly free radical ions from a photoelectron transfer (PET) step.[30] Similar product ratios were reported for the methyl pyruvate/2,3-dimethyl-2-butene photoreaction. In this case, however, a state selectivity effect is responsible for the formation of the different ether and alcohol products.[31] Obviously, the existence of allylic hydrogens favors the formation of unsaturated acyclic products via hydrogen migration steps at the triplet biradical level. More electron-rich alkenes without (or with unfavorable) allylic hydrogens do give oxetanes with excited α-dicarbonyl compounds. Furan, indene,[32] as well as isopropenyl ethyl ether,[33] were converted to the corresponding [2+2]-cycloadducts (e.g., **32**) with biacetyl **27** and methyl pyruvate, respectively. Chiral phenyl pyruvates have been investigated intensively as carbonyl addends with medium to remarkably high diastereoselectivities (*vide infra*). Benzoyl cyanide **33** gives mixtures of cycloaddition and coupling products with 2,3-dimethyl-2-butene,[34] whereas the addition of **33** and a series of other acyl cyanides to furan is chemoselective and leads to bicyclic oxetanes **34** with variable *endo*/*exo* ratios.[35]

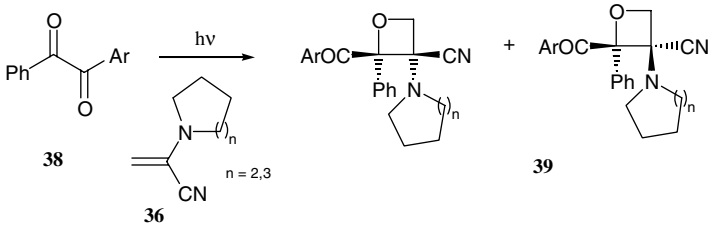




Symmetric $^3n,\pi^*$ excited 1,2-diarylethanediones (**35**) undergo highly regio- and stereoselective head-to-head additions to various captodative-substituted alkenes (2-aminopropenenitriles **36**), forming oxetanes **37** in moderate to good yield.[36]



Also, unsymmetric 1,2-diarylethanediones **38** undergo addition, resulting in the formation of cycloadducts **39**.[37] Only one regioisomer of the *a priori* conceivable regioisomers has been detected for each case. The connectivity and the preferred configuration of the products are rationalized in terms of the geometry of the more stable (including captodative stabilization) 1,4-biradical intermediate. In all cases, the cyclic amino substituent in the major diastereoisomer is oriented *cis* to the aryl moiety of the participating aroyl group, whereas the nonparticipating aroyl group is *cis* to the nitrile function.

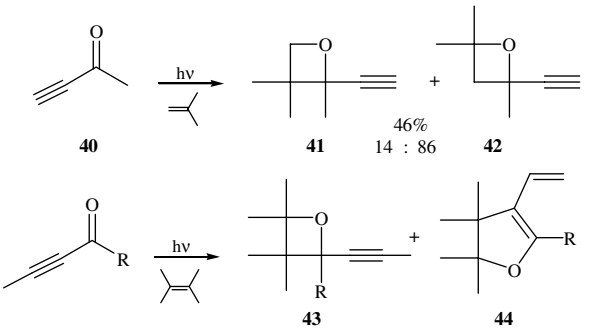


Whereas 2-naphthyl-substituted diones form oxetanes, 1,1′-naphthyl- and 1-(1-naphthyl)-2-phenyl ethanedione are unreactive, an effect that probably reflects the $\pi\pi^*$ nature of the lowest excited triplet state of these diones.

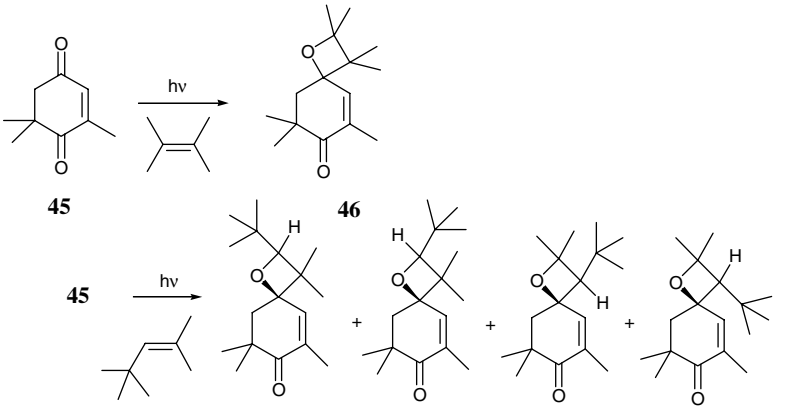
Enones and Ynones

A striking difference exists between the photochemical reactivity of α,β-unsaturated enones and the corresponding ynones. Whereas many cyclic enones undergo [2+2]-cycloaddition to alkenes at the CC double bond of the enone (probably from the triplet π,π^* state) to yield cyclobutanes, acyclic enones easily deactivate without radiation by rotation about the central CC single bond. Ynones, on the other hand, behave much more like alkyl-substituted carbonyl compounds and add to (sterically less encumbered) alkenes to yield oxetanes.[38,39] The *regioselectivity* of the Paternò–Büchi reaction is similar to that

of aliphatic or aromatic carbonyl compounds with a preference for primary attack at the less substituted carbon atom (e.g., **41** and **42** from the reaction of but-3-yne-2-one **40** with isobutylene). A serious drawback is the low *chemoselectivity*. For most substrates, a (formal) [3+2]-cycloaddition is the major reaction path that constitutes a possible rearrangement at the preoxetane biradical level.[40] A detailed kinetic and spectroscopic investigation of the reaction showed that the [2+2]-adducts **43** are formed from the singlet biradical precursors, whereas the [3+2]-adducts **44** derive from the corresponding triplet biradicals.[41]



Catalani and co-workers[42] reported the first examples of exclusive oxetane formation upon olefin photoaddition to the cyclohexen-1,4-dione 4-oxoisophorone **45**, leading to two novel 2-substitited 1-oxaspiro[3.5]non-5-en-7-ones **46** and **47**, respectively. They demonstrated that the chemoselectivity of the olefin–enone photochemistry could be directed to exclusive oxetane formation when sufficient steric hindrance inhibits cyclobutane formation.

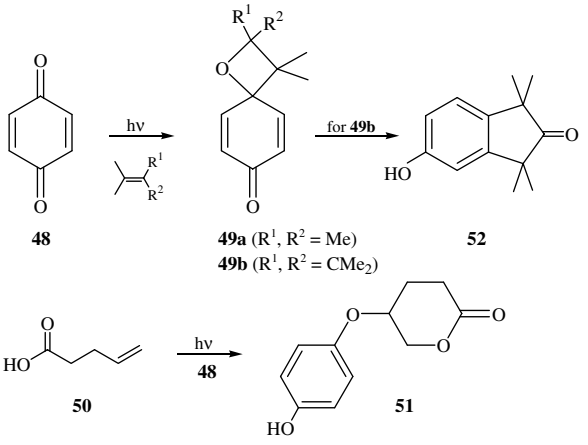


47 (9.8 : 5.1 : 3.6 : 81.5)

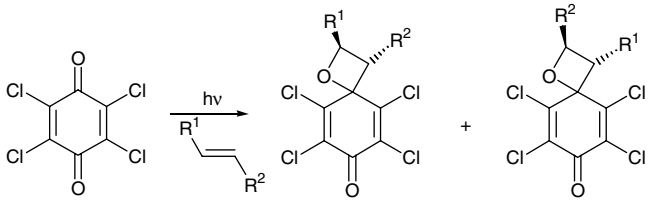
Quinones

The photoaddition of 1,4-benzoquinone **48** to electron-donor-substituted alkenes is an efficient process that leads to spirooxetanes (e.g., **49a**) in high yield.[43] The use of quinones as carbonyl compounds is advantageous because of their long-wavelength-shifted n,π^* transitions (430 to 480 nm). Most reactive are strained alkenes, such as norbornene or norbornadiene, for which rearrangement products are also formed.[44] Due to their convenient absorption behavior, benzoquinones have been used to study trapping reactions of intermediates. Wilson and Musser[45] reported the first oxygen trapping experiments using the 1,4-benzoquinone **48**/*t*-butylethene system. Whereas a triplet 1,4-biradical was assigned as the most probable intermediate at that time, later work on intramolecular trapping reaction favored the assumption of radical ion pairs.[46] An efficient lactonization reaction to form **51** during irradiation of pent-4-enoic acid

50 and **48** accounts for an olefin radical cation that undergoes electrophilic addition toward the carboxyl group. Another type of rearrangement has been detected in the photoreaction of tetramethylallene and **48**.[47] 5-Hydroxy-indan-2-ones **52** are formed in high yields, probably via unstable spirooxetanes **49b** as intermediates.



Kochi and co-workers[48] reported the photochemical addition of various stilbenes to chloroanil **53**, which is controlled by the charge-transfer (CT) activation of the precursor electron-donor/acceptor (EDA) complex. The [2+2]-cycloaddition products **54** were established by an x-ray structure of the *trans*-oxetane formed selectively in high yields. Time-resolved (fs/ps) spectroscopy revealed that the (singlet) ion-radical pair is the primary reaction intermediate and established the electron-transfer pathway for this Paternò–Büchi transformation. The alternative pathway via direct electronic activation of the carbonyl component led to the same oxetane regioisomers in identical ratios. Thus, a common electron-transfer mechanism applies that involves quenching of the excited quinone acceptor by the stilbene donor to afford a triplet ion-radical intermediate, which appears on a nanosecond/microsecond time scale. The spin multiplicities of the critical ion-pair intermediates in the two photoactivation paths determine the time scale of the reaction sequences and also the efficiency of the relatively slow ion-pair collapse ($k_c \cong 10^8\ s^{-1}$) to the 1,4-biradical that ultimately leads to the oxetane product **54**.

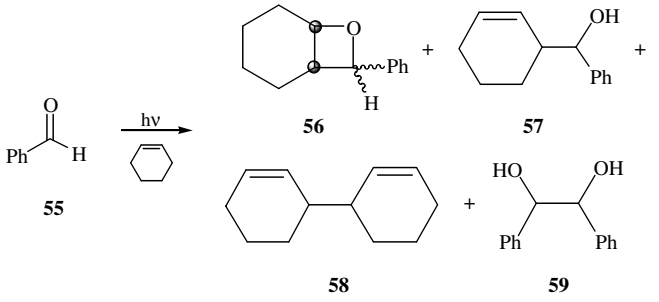


Olefin Compounds

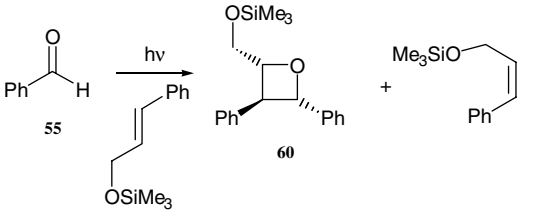
Alkenes, Alkyl-, and Aryl-Substituted

Arnold and co-workers reported a series of reactions between benzophenones and monoalkenes. In most cases, the oxetanes were the major products and could be isolated in good yields.[49] Benzaldehyde **55**, which has a triplet n,π^* as the reactive state,[50] is less chemoselective and, with cyclohexene and the oxetane **56**, gave the hydrogen abstraction and radical coupling products **57** and **58**.[51] Clear evidence for a long-lived

intermediate came from investigations of the stereoselectivity of the Paternò–Büchi reaction with *cis*- and *trans*-2-butene as substrates. When acetone[52] or benzaldehyde[53] was used as carbonyl addends, complete stereorandomization was observed. Acetaldehyde and 2-naphthaldehyde showed stereoselective addition reactions, which accounts for the singlet n,π^* as the reactive state.[43]

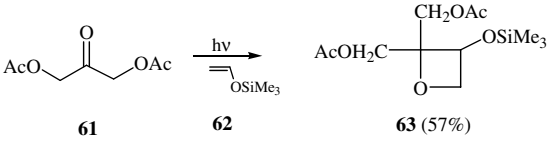


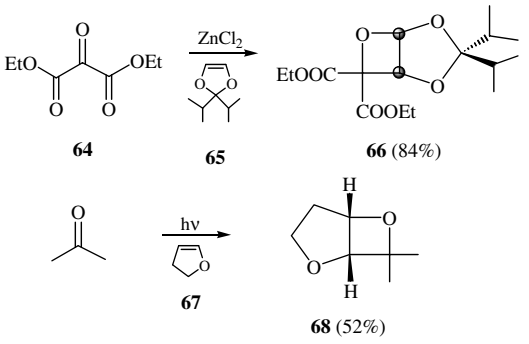
Fleming and Gao[54] reported that the photocycloaddition of the trimethylsilyl ether of phenylpropenol with benzaldehyde proceeds with high stereoselectivity to give the *trans*-oxetane **60** in 20% yield. In competition to the Paternò–Büchi reaction, *cis*/*trans* isomerization leads to *cis* and *trans* isomers of the substrate in a 1.6:1 ratio.



Alkenes, Electron-Donor-Substituted

The regioselectivity of the Paternò–Büchi reaction with acyclic enol ethers is substantially higher than with the corresponding unsymmetrically alkyl-substituted olefins. This effect was used for the synthesis of a variety of 3-alkoxyoxetanes and a series of derivatives.[55] The diastereoisomeric *cis*- and *trans*-1-methoxy-1-butenes were used as substrates for the investigation of the spin state influence on reactivity and regio- and stereoselectivity.[56] The use of trimethylsilyloxyethene **62** as an electron-rich alkene is advantageous, and several 1,3-anhydroapiitol derivatives such as **63** could be synthesized via photocycloaddition with 1,3-diacetoxy-2-propanone **61**.[57] Branched erythrono-1,4-lactones are accessible from the oxetane **66** that was derived thermally from diethyl mesoxalate **64** and 2,2-diisopropyl-1,3-dioxole **65**.[58] An impressive improvement in the regioselectivity of oxetane formation was discovered with 2,3-dihydrofuran **67** as the alkene addend. For the acetone/2,3-dihydrofuran cycloadduct **68**, a >200:1 ratio of the two possible regioisomers was found.[59] Acyclic thioenol ethers also have been investigated in their photocycloaddition behavior with benzophenone. In contrast to acyclic enol ethers, these substrates exhibit high regioselectivity, with almost exclusive formation of the 3-alkylthio oxetanes.[60]





Photocycloaddition reactions of aromatic aldehydes with cyclic ketene silylacetates have been investigated by Abe and co-workers.[61] Regio- and diastereoselective formation of the bicyclic 2-alkoxyoxetanes **69** was observed in high yields. Hydrolysis of these acid-labile cycloadducts with neutral water efficiently gave aldol-type adducts **70** with high *threo* selectivity.

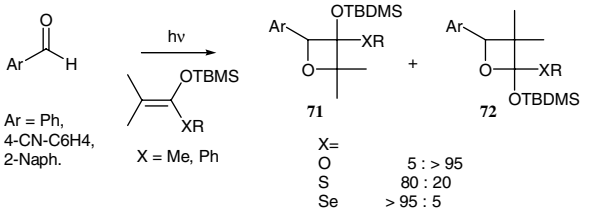
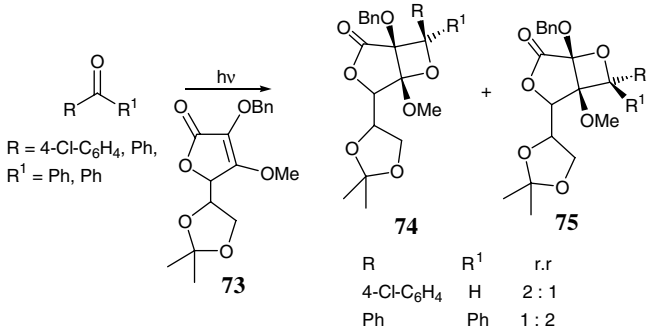
The Paternò–Büchi photocycloaddition of silyl O,X-ketene acetals (with X = O, S, Se) and aromatic aldehydes was intensively investigated by Abe and co-workers in the last decade.[62] The regioselectivity of the reaction (**69** vs. **70**) is highly affected by the heteroatom.[63,64] The regioselectivity is rationalized by: (1) the relative stability of the 1,4-biradicals, and (2) the relative nucleophilicity of sp^2-carbons in the respective O,X-ketene acetal.

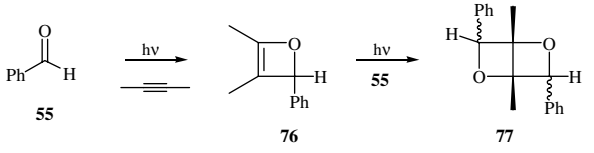


Thopate et al.[65] described the photocycloaddition of L-ascorbic acid derivatives **73** with 4-chlorobenzaldehyde and benzylmethyl ketone, which led to preferential attack on the less hindered α-face of the enone to give the oxetanes **74** and **75**, respectively, with approximately 2:1 regioselectivity (33% diastereomeric excess each). When the substrate was changed to benzophenone, the regioselectivity was reversed, even though the facial selectivity remained the same (35% diastereomeric excess). This was proposed to be the result of a mechanistic switchover, from a 1,4-biradical process for benzophenone to a photoinduced electron transfer process for the other substrates.



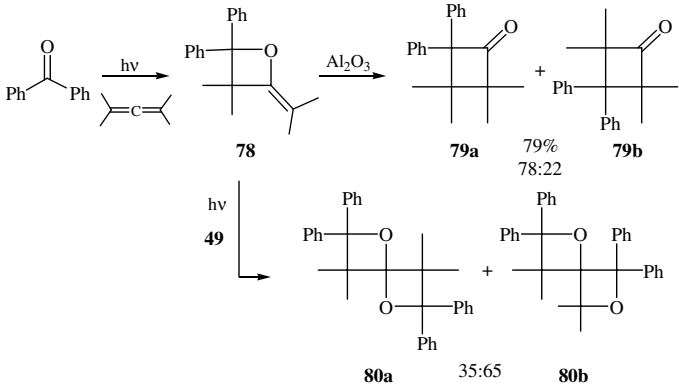
Alkynes

Oxetenes (oxetes) have been postulated as primary photoadducts between carbonyl compounds and alkyl- and aryl-substituted alkynes and alkylthioacetylenes.[66] The first evidence for an unstable intermediate with a lifetime of several hours at –35°C was reported for the benzaldehyde **55**/2-butyne-photoproduct **76**.[67] On further irradiation in the presence of excess benzaldehyde, a *bis*-oxetane **77** was formed. At elevated temperatures, rapid ring opening to α,β-unsaturated ketones occurs; these are the major products for photocycloaddition of alkynes with carbonyl addends at room temperature. The parent oxetene has been prepared from 3-hydroxyoxetane.[68]



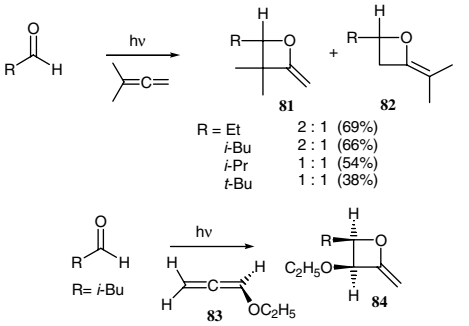
Allenes and Ketenimines

The photocycloaddition of a variety of carbonyl compounds with methyl-substituted allenes has been reported to proceed with high quantum yields (0.59 for acetophenone/tetramethylallene)[69] to give 1:1 and 1:2 adducts.[70] The 2-alkylideneoxetanes are useful precursors for cyclobutanones (e.g., **79a**,**b** from the benzophenone/tetramethylallene-cycloadduct **78**).[71] Upon prolonged irradiation in the presence of excess ketone, the monoadducts are converted into 1,5- and 1,6-dioxaspiro[3.3]heptanes (e.g., **80a**,**b**).[53] The regioisomeric 2- and 3-iminooxetanes could be prepared by photolysis of ketenimines in the presence of aliphatic or aromatic ketones.[72]



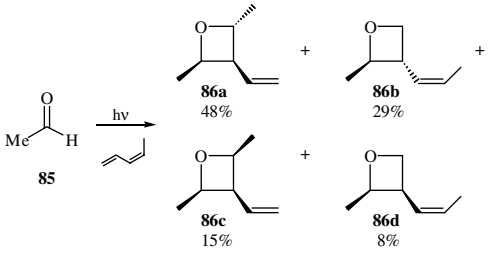
The photocycloaddition of aliphatic aldehydes to 1,1-dimethylallene was investigated by Howell et al.[73] The major products, the 2-alkylidene oxetanes **81** and **82**, were obtained in a ratio of 2:1. This low degree

of regioselectivity was rationalized by both steric and electronic factors. On the other hand, the allene **83** with an enol ether structure reacted with isovaleraldehyde with a high degree of regioselectivity to give the 2-methylene oxetane **84**.



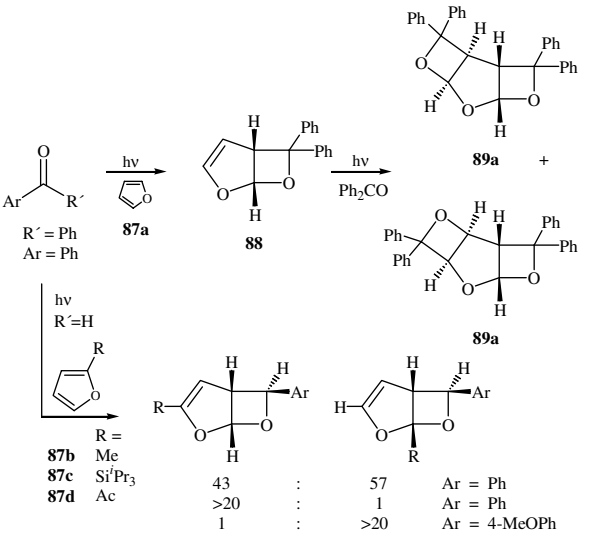
Dienes and Enynes

Because of their low triplet energies (55 to 60 kcal/mol), 1,3-dienes are often used as quenchers for excited triplet states of carbonyl compounds. Besides physical quenching, however, cycloaddition leading to oxetanes can also occur as a side reaction, as demonstrated for benzophenone.[74] Chemical yields are low because of competing diene dimerization and hydrogen abstraction reactions. The corresponding photoreactions with aliphatic ketones[75] or aldehydes[76] are much more effective in the sense that oxetanes are formed with high quantum yields and good chemical yields by a mechanism involving the singlet excited carbonyl addend. Carless and Maitra[77] have shown that the photocycloaddition of acetaldehyde **85** to the diastereomeric *E*- and *Z*-penta-1,3-dienes is highly regio- and stereoselective (e.g., oxetanes **86a–d** are obtained from the *Z* isomer) which also accounts for a singlet mechanism.[77] A locoselective reaction has been reported for the benzophenone cycloaddition to a 1,3-enyne with exclusive addition to the CC double bond.[78]

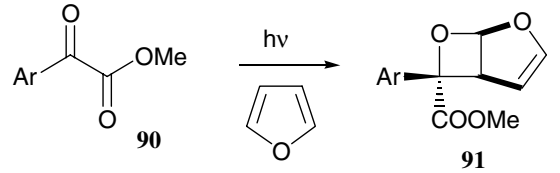


Furans

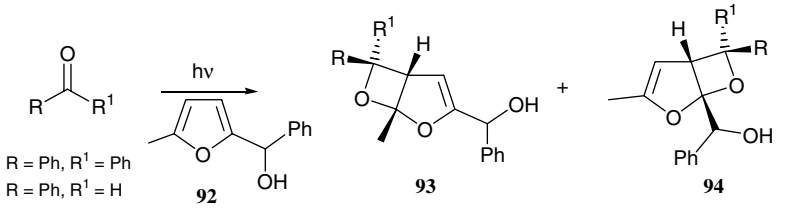
The photocycloaddition of benzophenone to furan **87a** was originally described by Schenck et al.[79] In addition to the 1:1 adduct **88**, two regioisomeric 2:1 adducts **89a**,**b** were also isolated[80] and the structure of **89a** was revised.[81] All prostereogenic carbonyl addends when photochemically added to furan showed regioselectivities >99:1 in favor of the bicyclic acetal product. This is also the case for 2-substituted furans; however, mixtures of acetal- and ketal-type oxetanes (e.g., for **87b**) were obtained.[82] The use of furans with steric-demanding substituents (e.g., **87c**)[66a,83] or an acetyl substituent (e.g., **87d**)[66b] at the 2-position greatly improves the regioselectivity. A huge number of carbonyl compounds have been investigated in the last 10 years by, for example, Zamojski[84] and especially by Schreiber,[85] who used furan–carbonyl adducts as intermediates in total synthesis of natural products. Acid-catalyzed rearrangement of these adducts is a useful method for the synthesis of 3-substituted furans.[86]



The photocycloaddition of methyl arylglyoxylates **90** with cyclo-1,3-dienes was investigated by Hu and Neckers.[87] These reactions proceed with high regioselectivity, whereas the diastereoselectivity strongly depends on the nature of the aryl substituent. Oxetanes **91** (shown with furan as the diene component) were formed with high *endo*-aryl selectivity with bulky aryl groups, while insignificant stereoselectivity was observed with glyoxylates containing sterically less demanding aryl groups. This observation was rationalized by the stability of the intermediate triplet 1,4-biradical geometries during the ISC process. The rates of the competing *ortho*-hydrogen abstraction (for *ortho*-methylated aryl groups) varied significantly among the substrates.



D'Auria and co-workers[88] investigated the photocycloaddition of 5-methyl-2-furyl-phenylmethanol **92** with benzophenone, which resulted in two adducts **93** and **94** in a 1:1 ratio; the addition to 4,4′-dimethoxybenzophenone, benzaldehyde, or 4-methoxybenzaldehyde gave only the adducts **93**.



The photocycloaddition of carbonyl compounds with 2-siloxyfurans **95** has been investigated in detail by Abe and co-workers.[89] The stereoselective formations of *exo*-oxetanes **96** and **97** were observed in high yields. The regioselectivity was found to be largely dependent upon the nature of the carbonyl component,

the substituents at the furan ring, and the excited state of the carbonyls (singlet vs. triplet). Aldehydes resulted in bicyclic oxetanes **96** and **97**, respectively, with low regioselectivity independent of the nature of the excited states and the substituents at the furan. Triplet excited ketones gave, regioselectively, the *exo*-oxetanes, except for 4-methyl-2-siloxyfuran.

Other Heteroaromatic Substrates

Methyl-substituted thiophenes afford oxetanes with high regioselectivity when reacted with excited benzophenone.[90] Pyrroles, imidazoles, and indoles behave similarly when substituted at the nitrogen atom with electron-acceptor groups.[91] Pyrroles, when alkyl-substituted at the nitrogen atom, however, gave rearranged pyrroles, probably via an oxetane intermediate.[92] The photocycloaddition of 2,4,5-trimethyloxazole **98** to carbonyl compounds afforded the bicyclic oxetanes **99** with high regio and excellent (*exo*) diastereoselectivity.[93] Hydrolytic ring opening of bicyclic oxetane yielded *erythro* α-acetamido-β-hydroxy ketones **100**.

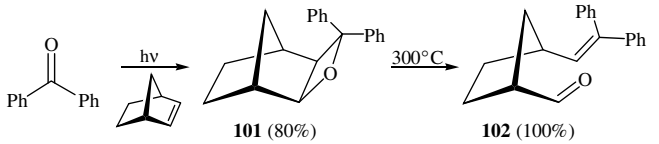
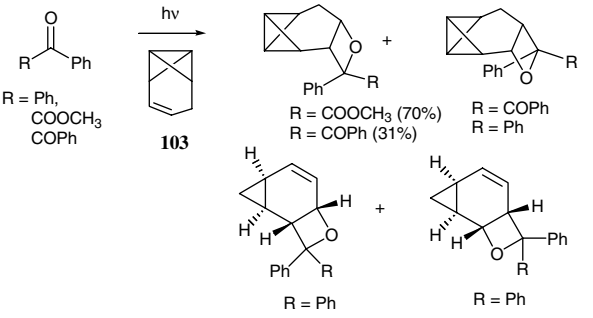
Strained Hydrocarbons

The photocycloaddition of triplet benzophenone to norbornene was originally reported by Scharf and Korte.[94] The photoproduct **101** that is formed in high *exo*-selectivity could be thermally cleaved to the δ,ε-unsaturated ketone **102**, an application of the carbonyl–olefin metathesis (COM) concept.[95] The 1,4-biradical formed in the interaction of norbornene with *o*-dibenzoyl-benzene was trapped in an intramolecular fashion by the second carbonyl moiety.[96] A highly regioselective reaction of triplet benzophenone was reported with 5-methylenenorborn-2-ene, with preferential attack toward the *exo* CC double bond.[97] A number of publications have discussed the photocycloaddition reactions of triplet carbonyl compounds to norbornadiene and quadricyclane, as well as the competition between the Paternò–Büchi reaction and the sensitized norbornadiene/quadricyclane interconversion.[98] Oxetane formation has also been reported for the photoreaction of biacetyl and *para*-quinones with benzvalene.[99]



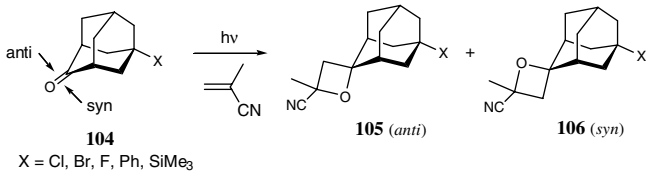
101 (80%) **102** (100%)

The irradiation of methyl phenylglyoxylate, benzil, benzophenone, and 1,4-benzoquinone in the presence of homobenzvalene **103** gave, as products of the Paternò–Büchi reaction, oxetane derivatives that contain the tricyclo[4.1.0.0^{2,7}]heptane subunit as well as ring-opened products.[100] In the case of benzophenone, the cycloaddition competes with the isomerization of **103** to cycloheptatriene. Exclusive isomerization was observed with acetophenone and acetone. Carbonyl compounds with triplet energies lower than 69 kcal/mol prefer the cycloaddition path. Cyclopent-2-en-1-one is an exception to this rule; in spite of its triplet energy of 74 kcal/mol, [2+2]-cycloadducts were formed rather efficiently.



Alkenes, Electron Acceptor-Substituted

In contrast to photocycloaddition reactions of carbonyl compounds to electron-rich alkenes (which proceed with a low degree of stereoselectivity in the case of triplet excited carbonyls), reactions with electron-deficient alkenes, such as cyanoalkenes, are highly stereoselective, although rather inefficient.[101] Kinetic analysis showed that these reactions involve the interaction with the singlet excited carbonyl via a parallel approach.[102] An important side reaction is that the photosensitized geometrical isomerization of the alkene CC double bond (e.g., *cis*-1,2-dicyanoethylene) and acetone gives the *cis*-oxetane and *trans*-1,2-dicyanoethylene. 2-Norbornanone was used as a model reagent for investigation of the influence of steric hindrance on the face selectivity of oxetane formation with electron-donor- and electron-acceptor-substituted alkenes.[103] Chung and co-workers[104] have reported that the photocycloaddition of methacrylonitrile to 5-substitiuted adamant-2-ones **104** produces two geometrically isomeric oxetanes **105** and **106**, respectively, with the oxetane-ring oxygen and the substituent at C5 in *anti* or *syn* positions. This selectivity is discussed for the *syn*-face attack in terms of transition-state hyperconjugation.



Exocyclic Alkenes

The photochemistry of ketones in the presence of exocyclic olefins has not yet been systematically studied. Chung and Ho[105] reported the photochemistry of acetone in the presence of several exocyclic olefins. Surprisingly, homoalkylation occurred, resulting in a series of 4-cycloalkylbutan-2-ones (with quantum yields of 0.14 ± 0.01) rather than the expected Paternò–Büchi reaction. With perdeuterated acetone, the photocycloaddition path increased due to the primary kinetic isotope effect (as shown for products **108** and **109**, respectively, from 2-methyleneadamantane **107**). Similar effects were obtained for methylenecycloalkanes **110** with preferential formation of the photo-Conia products **111**. Increasing ring size in **110** as well as H/D exchange favored the formation of the Paternò–Büchi products **112**.

Enantioselective Photocycloaddition Reactions in Solution

Benjamin Grosch
Technische Universität München

Thorsten Bach
Technische Universität München

61.1 Introduction

By definition, enantioselective reactions are transformations in which a prochiral substrate is converted into a chiral product such that one of the two enantiomers is formed in significant excess. The degree of enantioselectivity is given by the enantiomeric excess (*ee*). Schematically, such a transformation is depicted in Scheme 1, with the triangle (substrate S) representing a prochiral unit and the two tetrahedrons (products P and *ent*-P) representing two enantiomeric chiral products.

In photocycloaddition reactions, the degree of enantioselectivity depends on the effectiveness with which the enantiotopic faces of a prochiral olefin can be distinguished (enantioface-differentiation). The conventional way to achieve this goal is to covalently attach a chiral auxiliary (see Section 61.2) to the prochiral substrate. The consecutive reaction is diastereoselective, and the auxiliary has to be removed afterwards. The degree of diastereoselectivity in the selectivity-determining step is measured by the diastereomeric excess (DE), which is defined by analogy to the enantiomeric excess, and the *ee* corresponds to the DE after removal of the auxiliary. The auxiliary-based process consequently consists of three steps, two of which are, in principle, superfluous as they are not concerned with the reaction under scrutiny.

In recent years, efforts have been made to achieve enantioselective photocycloaddition reactions in the true sense (i.e., going from S directly to either P or *ent*-P with high *ee*). The main goal of this account is to summarize these developments. The subject has been divided into three sections according to the method used for the enantioface-differentiation: asymmetric induction by chiral complexing agent (Section 61.3), asymmetric photosensitization (Section 61.4), and asymmetric induction by circularly polarized light (Section 61.5). Results published before mid-2002 were taken into consideration. Reviews related to this area have been previously published by Rau[1] and by Inoue et al.[2,3] Finally, it should be mentioned that this account deals exclusively with solution-phase photochemistry. Reviews summarizing recent achievements in enantioselective solid-state photochemistry can be found elsewhere in this book.

Arene *ortho*-photocycloaddition	16, 26–28, 30	26, 27

61.2 Asymmetric Induction by Chiral Auxiliary

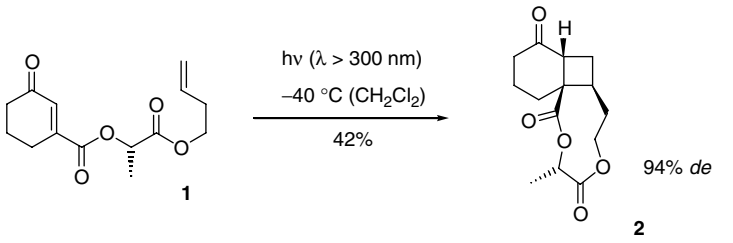
Diastereoselective photocycloaddition reactions, especially intra- and intermolecular [2+2]-photocycloaddition and Paternò–Büchi reactions, are established tools in organic synthesis. Their use and applicability have been proven in the framework of natural product syntheses and in the preparation of many other compounds. In this context, auxiliaries well established in conventional chemistry[4–6] have been employed to prepare enantiomerically pure substrates for further elaboration. The tremendous amount of work that has been done in the area of auxiliary-induced photocycloaddition reactions is by far beyond the scope of this review. More detailed information on a specific auxiliary-induced photochemical reaction can be found in individual chapters of this book which in turn deal with the corresponding transformation in a broader context. In addition, we have compiled topical reviews on photocycloaddition reactions (Table 61.1). These reviews have been roughly divided according to their focus and their relevance to auxiliary-induced diastereoselective reactions.

Despite what has been said in the previous section, three more recent developments are mentioned here, as they have not been extensively reviewed in the above-mentioned articles. This treatment is not comprehensive but rather tries to give the reader a flavor of the modern trends in the area.

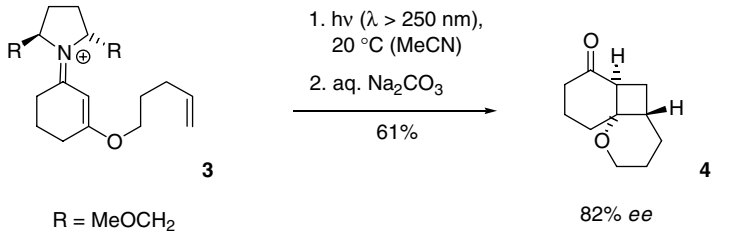
Piva et al.[31,32] have established removable chiral tethers that attach an alkene to an enone and render the intramolecular [2+2]-photocycloaddition between these groups highly diastereoselective. Chiral α- and β-hydroxy acids such as (*S*)-lactic acid, (*S*)-phenyllactic acid, or (*S*)-mandelic acid proved to be highly effective auxiliaries. Butenyl lactate **1** was converted regioselectively to the straight adduct **2**. The diastereoselectivity reached 94% DE at –40°C, albeit with a reduction in yield. At –20°C, 92% DE and 78% yield were obtained (Scheme 2).

After separation of the diastereoisomers, cleavage of the tether afforded the cyclobutane lactones in good yield and in enantiomerically pure form. This strategy has been applied in a synthetic approach to (–)-italicene and (+)-isoitalicene.[33]

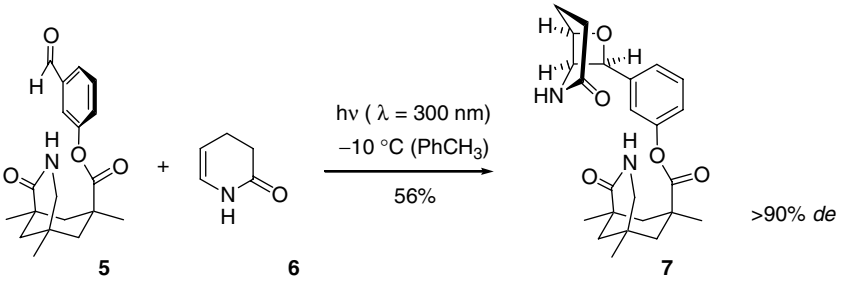
Mariano and co-workers[34] have employed chiral eniminium salts as surrogates for enones to control the stereoselectivity of the enone-olefin [2+2]-photocycloaddition. Eniminium salts have only π,π^* excited states and intersystem crossing to triplet excited states is therefore slow. As a consequence, the photocyclization should occur from the singlet state via a concerted mechanistic pathway. The chiral iminium salt **3**, accessible by condensation of the corresponding ketone with an enantiomerically pure *trans*-2,5-disubstituted pyrrolidine, cyclized in good yield. After removal of the chiral auxiliary, the tricyclic ketone **4** was obtained in enantiomeric excesses of up to 82% *ee* (Scheme 3).



SCHEME 2



SCHEME 3

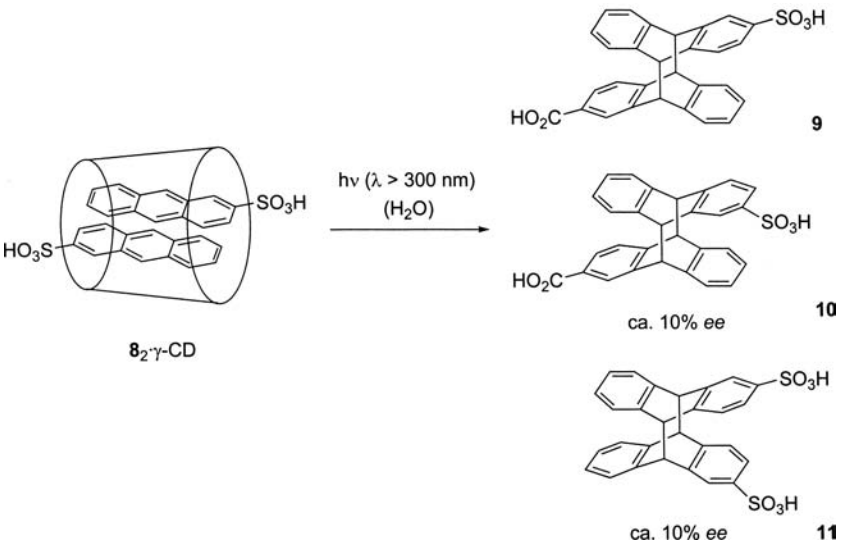


SCHEME 4

A highly diastereoselective Paternò–Büchi reaction by a new approach was reported by Bach et al.[35,36] The chiral auxiliary bound to *m*-hydroxybenzaldehyde **5** offers a binding site to which the reaction partner can be attached by two hydrogen bonds. In the complex, the two enantiotopic faces of the alkene **6** become diastereotopic and can be differentiated. The dihydropyridone **6** approaches the aldehyde from one face only (Scheme 4). Because the reaction within the complex is presumably faster than the reaction with unbound dihydropyridone, the face selection is enhanced by this rate acceleration. In toluene at –10°C, lactam **5** was converted with high diastereoselectivity to diastereoisomer **7** (>90% DE). The oxetano[2,3-*b*]piperidone fragment could be cleaved from the auxiliary by transesterification (NaOMe in MeOH).

61.3 Asymmetric Induction by Chiral Complexing Agent

Chiral complexing agents transfer the chiral information to a non-covalently bound substrate molecule as it undergoes photochemical conversion. In the enantiodifferentiating process, a complex equilibrium is set up between both species in their ground state, in contrast to enantiodifferentiating sensitized photochemical reactions (Section 61.4), where the excited states of both species are involved. Hydrogen or electron-donor/acceptor complexes with the ground-state substrate or the photochemically produced

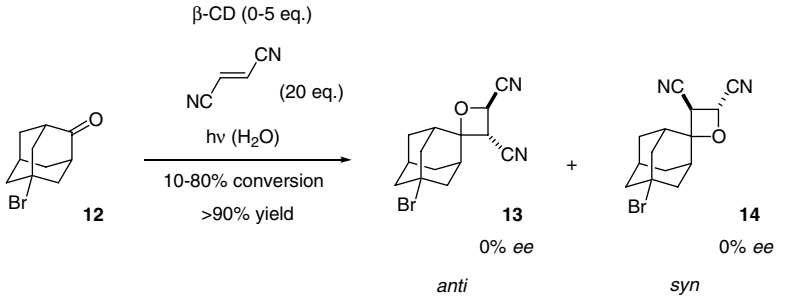


SCHEME 5

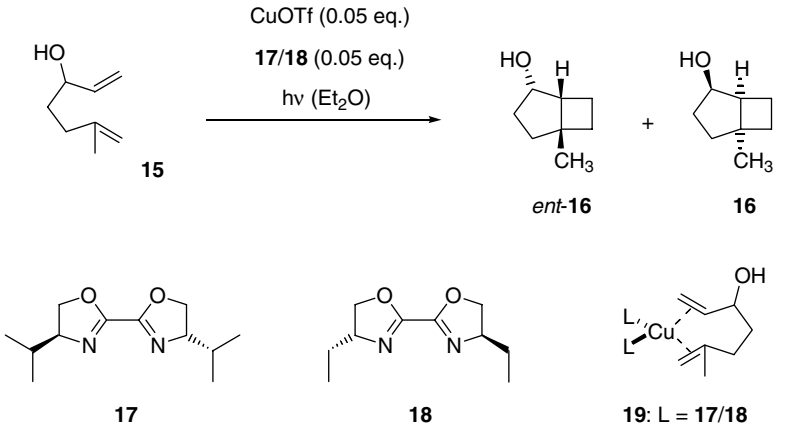
reactive intermediate have been employed to differentiate diastereotopic transition states. Ideally, the association constant of the chiral complexing agent with the photoproduct is significantly lower than that with the starting material. Then, after chiral induction and dissociation of the product, the host is available for the next chirality transfer. In this case of catalytic turnover, only substoichiometric amounts of the chiral complexing agent are necessary. For high enantioselectivity at a substoichiometric level, another prerequisite must be met. The photochemical reaction must be significantly accelerated in the complex with the chiral host, because unbound starting material is converted unspecifically and dilutes the enantiomeric excess of the product. The acceleration can be accomplished through electronic or steric effects. Even if chiral amplification is not achieved through catalytic use, a photostable chiral complexing agent used in stoichiometric or excessive amounts can be recovered and reused. Generally, the complexing agent should be readily separable from the reaction mixture without an additional and possibly damaging cleavage step, as in the case of a covalently bound auxiliary.

In the last decade, three main approaches have been employed to direct a photocycloaddition reaction enantioselectively by chiral complexing agents: host–guest complexes using chiral cyclodextrins as host molecules, catalysis by transition metal complexes with a chiral ligand sphere, and host–guest complexes using a rationally designed host compound. A variety of photoreactions such as photopinacolization, photocyclization, photorearrangement, photodeconjugation, and photoisomerization have been examined in the presence of chiral complexing agents. The results obtained have been reviewed thoroughly by Inoue[3] and by Everitt and Inoue.[2] Several photocycloaddition reactions have been conducted in complexes with cyclodextrins, and the results have been reviewed.[37–39] Studies have essentially focused on how the rate, regioselectivity, and diastereoselectivity of photoreactions are influenced by the cyclodextrin complexation of the starting material. The photodimerization of anthracene derivatives[40,41] and the [2+2]-cycloaddition of adamantan-2-ones[42] have been tested to examine the possibility of enantiocontrol of photocycloaddition reactions by cyclodextrin complexes.

An aqueous solution of 2-anthracenesulfonate **8** was irradiated in the presence of γ-cyclodextrin. The cyclodextrin accelerated the photodimerization to dimers **9**, **10**, and **11** by almost one order of magnitude (Scheme 5). Even at dilute concentrations, a sandwich complex of two anthracene molecules in the host cavity (8.5 Å) is formed which accelerates the cycloaddition reaction. In the presence of γ-cyclodextrin, the relative yields of the three isomers did not significantly change, suggesting that the guest molecules are nonspecifically trapped in the cavity.



SCHEME 6



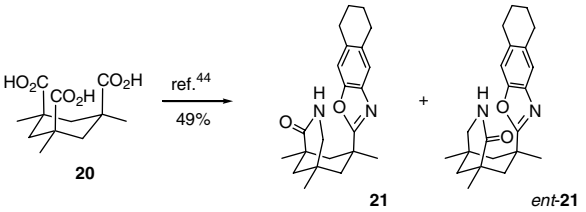
SCHEME 7

In the presence of γ-cyclodextrin, the dimers **10** and **11** were obtained with about 10% *ee*.[40] The absolute configuration of the predominating enantiomer was not identified, but CD-spectra indicated that the two anthracenes prefer *R*-helicity in the complex. From the two *R*-helical complexes that lead to the enantiomers of **10**, one seems to be sterically favored over the other because of fewer interactions between the substituents and the cyclodextrin.

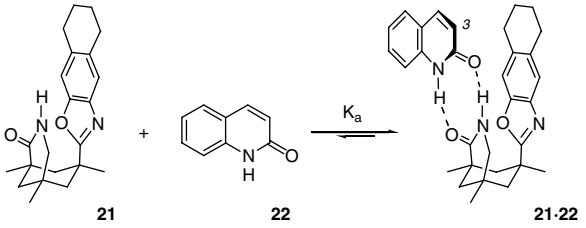
The presence of β-cyclodextrin led to no significant enantiomeric excess in the [2+2]-photocycloaddition of fumaronitrile to 5-bromoadamantan-2-one (**12**) in D_2O (Scheme 6).[42] The facial diastereoselectivity, however, changed from *anti*/*syn* of 59/41 with no cyclodextrin to 20/80 in the presence of five equivalents of β-cyclodextrin upon irradiation in water.

Asymmetric copper(I)-catalyzed intramolecular [2+2]-photocycloaddition reactions were examined by Mattay et al.[43] In a synthetic approach to (+)- and (–)-grandisol, racemic dienol **15** was irradiated in the presence of CuOTf and a chiral ligand to yield mainly cyclobutanes **16** and *ent*-**16** as a mixture of enantiomers. Other 1,6-dienes were also employed. The effectiveness of a number of chiral, nitrogen-containing bidentate ligands were tested, the most successful of which, (4*S*,4′*S*)-4,4′-diisopropyl-2,2′-bisoxazoline **17** and (4*R*,4′*R*)-4,4′-diethyl-2,2′-bisoxazoline **18**, ensured a minor enantiomeric excess of <5% *ee* (Scheme 7). As the coordination of the diene to the chiral Cu(I)-complex **19** was proved by CD analysis, the authors suggest a lower reactivity of the chiral complex compared to the copper ion coordinated to solvent molecules as the reason for the low enantioselectivities observed.

A major step toward synthetically useful enantioselectivities induced by chiral complexing agents was achieved by the introduction of rationally designed hosts. These chiral hosts serve as stoichiometric complexing agents, which differentiate the enantiotopic faces of the starting material by binding to it in



SCHEME 8



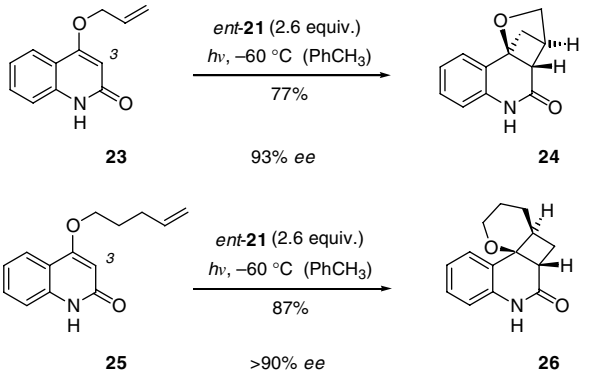
SCHEME 9

a defined orientation via hydrogen bonds. The conformational flexibility is constrained by a rigid backbone that offers an easily accessible binding site and at the same time exhibits an effective sterically demanding shield. The best results were obtained by chiral lactams **21** and *ent*-**21**, in which the hydrogen acceptor and hydrogen donor site define a plane parallel to the flat tetrahydronaphthyl residue. This shield is photochemically stable in contrast to further extended aromatics. The required spatial alignment is provided by Kemp's triacid **20**, from which racemic host *rac*-**21** is accessible in 49% overall yield (Scheme 8). The optical resolution to chiral benzoxazoles **21** and *ent*-**21** is readily achieved via the *N*-(–)-menthyloxycarbonyl derivative by column chromatographic separation.[44]

The effectiveness of these chiral host compounds has been shown in highly enantioselective [2+2]- and [4+4]-cycloadditions of prochiral lactams. Prochiral lactams such as 2-quinolone derivatives are expected to coordinate to lactam **21** with its NH-group as the hydrogen donor and the carbonyl group as the hydrogen acceptor, as depicted in Scheme 9. In this complex, any intra- or intermolecular attack at the quinolone double bond can occur exclusively from the *Re*-face relative to carbon atom C3. The other face of the molecule is shielded by the bulky tetrahydronaphthalene unit. Following ^{1}H nuclear magnetic resonance (^{1}H-NMR) titration experiments, the association constant of 2-quinolone **22** and host **21** in toluene was determined as $K_a \cong 500\ M^{-1}$ at 30°C, and a 1:1 complex stoichiometry was proved.[45] Because the complex formation was found to be exothermic, an enhanced association was expected at lower temperatures.

Upon irradiation with $\lambda > 300$ nm, the 4-alkenyloxy-2-quinolones **23** and **25** cyclized in an intramolecular [2+2]-photocycloaddition diastereoselectively to the crossed and straight cycloadducts **24** and **26**, respectively. In the presence of 2.6 equivalents of host compound **21** or *ent*-**21**, high enantioselectivities were achieved in a nonpolar solvent at low temperatures.[45,46] At –60°C in toluene, **24** and **26** were obtained with >90% *ee* (Scheme 10). Higher temperatures (84% *ee* at –15°C, 39% *ee* at 30°C) and more polar solvents (4% *ee* at 30°C in acetonitrile) significantly reduced the enantioselectivity under otherwise identical conditions.

The absolute configuration of photoproducts **24** and **26** was proved by single crystal x-ray crystallography and is in accordance with the *Si*-face attack with respect to C3, as the *Re*-face is shielded in the complex with chiral host *ent*-**21**. The observed enantioselectivities can be satisfactorily rationalized by a simple model that postulates perfect face differentiation of the complexed guest and no face differentiation if the starting material is not coordinated to the host. Therefore, the achievable enantioselectivities are



23 **24** **25** **26**

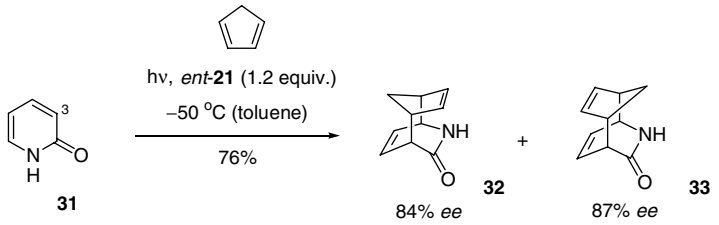
SCHEME 11

determined by the association equilibrium. The host is photostable under the irradiation conditions ($\lambda \geq 300$ nm) and was recovered after each irradiation by column chromatography in >95% yield.

The scope of this approach was widened by the observation of excellent enantioselectivities in intermolecular [2+2]-photocycloaddition reactions with various alkenes.[45,47] 4-Methoxy-2-quinolone **27** was converted with high chemo- and regioselectivity to cyclobutanes **29** and **30** in the presence of an excess of alkene. With 4-penten-1-ol **28a**, allyl acetate **28b**, methyl acrylate **28c**, and vinyl acetate **28d**, the *exo*-diastereomers **29a–d** were formed with high simple diastereoselectivity and high yields (80 to 89%). Under optimized irradiation conditions (2.4 eq. of host **21** or *ent*-**21**, –60°C), high enantiomeric excesses were achieved in all instances, as depicted in Scheme 11; these enantiomeric excesses are unprecedented for an intermolecular photochemical reaction. As in the intermolecular case, host **21** induced *Re*-attack at carbon C3, and host *ent*-**21** induced a *Si*-attack.

The applicability of the developed complexing agent was further demonstrated by differentiating the faces of 2-pyridones. In this context, the [4+4]-photocycloaddition of 2-pyridone (pyridine-2(1H)-one, **31**) with cyclopentadiene was examined.[48] Irradiation of 2-pyridone at –50°C in the presence of host *ent*-**21** and cyclopentadiene led to a 3:2 mixture of *exo* and *endo* products **32** and **33**. Both diastereoisomers were obtained in high enantiomeric excess, *exo*-cycloadduct **32** with 84% *ee* and *endo*-cycloadduct **33** with 87% *ee* (Scheme 12). The absolute configuration of the predominating enantiomer was elucidated by single x-ray crystallography. As expected, the photoexcited 2-pyridone was attacked by cyclopentadiene from the *Si*-face relative to the prostereogenic carbon atom C3, because the *Re*-face is shielded following complexation with host *ent*-**21**.



31 **32** 84% *ee* **33** 87% *ee*

SCHEME 12

The asymmetric induction achieved in the reactions examined suggests that host compounds **21** and *ent*-**21** are highly versatile and effective complexing agents when employed in enantioselective photocycloaddition reactions of prochiral, flat lactams. The complexing agents are restricted to lactams or amides as guest compounds. High enantioselectivities are achieved if the reaction center is in the vicinity of the binding site and the photoreaction is conducted at low temperatures in nonpolar solvents.

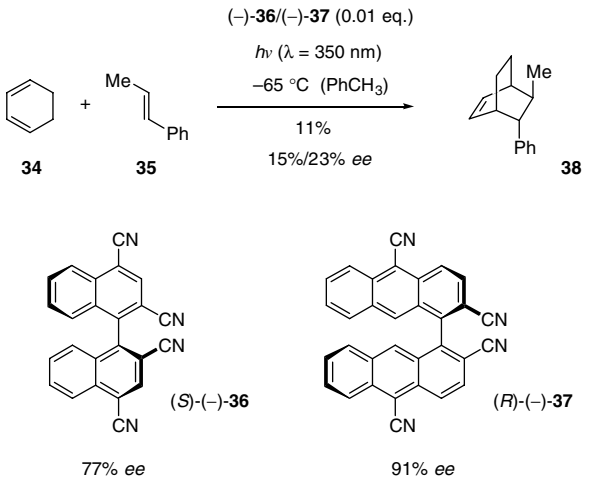
61.4 Asymmetric Photosensitization

Photosensitized enantiodifferentiating reactions are synthetically attractive and mechanistically interesting photochemical processes. The chiral information of the sensitizer is transferred to the substrate by short-lived interactions in the excited state (i.e., during the lifetime of an exciplex of a reaction intermediate and the chiral sensitizer that is involved in the reaction mechanism); hence, the chirality is multiplied, and only catalytic amounts of the optically active sensitizer are required. The stabilization energy of an exciplex compared to the locally excited state and its lifetime are often found to be strongly dependent on both electronic and steric properties of its components. Chiral induction can be achieved by different stabilization energies or lifetimes of the exciplex between the sensitizer and the intermediates that lead to the enantiomeric photoproducts. The absence of other reaction pathways without intimate contact to the sensitizer and of racemization processes in the further course of the reaction mechanism is an additional requirement to ensure effective chirality transfer.

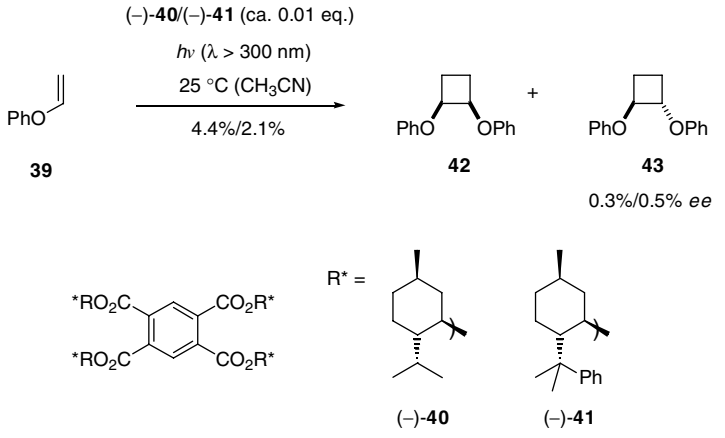
Since the first report on the asymmetric photosensitization (7.7% *ee*) of the isomerization of *trans*-1,2-diphenylcyclopropane by Hammond and Cole,[49] attention has been focused on enantiodifferentiating photosensitized isomerization reactions.[1–3] The observed asymmetric induction was limited, until Inoue et al. achieved remarkable enantiomeric excesses of up to 64% *ee* in the photoisomerization of *Z*-cyclooctene to the optically active *E*-cyclooctene, sensitized by chiral benzenepolycarboxylates at –89°C. Valuable insights into the mechanism (e.g., the entropy influence) were gained from the temperature and pressure dependence of the observed enantioselectivities.[50–52]

In contrast, until very recently only a few studies of asymmetric photocycloadditions by chiral sensitizers have been reported. Kim and Schuster[53,54] achieved enantiomeric excesses of up to 23% *ee* in the sensitized [4+2]-cycloaddition of *trans*-β-methylstyrene **34** with cyclohexa-1,3-diene (**35**), which represents the first reported enantioselective photocycloaddition reaction. This reaction is called the *triplex Diels–Alder reaction*, as it was shown to occur by formation of a ternary complex of the singlet excited sensitizer, (–)-1,1′-*bis*(2,4-dicyanonaphthalene) **36**, with the diene and the dienophile. The Diels–Alder product **38** is formed in up to 11% chemical yield (Scheme 13); other products are the dimers of cyclohexa-1,3-diene (83%) and [2+2]-cycloadducts of **34** and **35** (5%).[55]

In the presence of enantiomerically enriched sensitizer **36** (77% *ee*), the observed enantiomeric excesses increased from 1% *ee* at room temperature to 15% *ee* at –65°C.[53] With the enantiomerically enriched anthracene derivative **37** (91% *ee*), the enantioselectivity was enhanced to 23% *ee* at –65°C, favoring the opposite enantiomer. Based on fluorescence quenching experiments and the concentration dependence of the observed enantioselectivities, the authors suggest the formation of diastereomeric exciplexes by complexation of the different prochiral faces of the styrene to the chiral surface of the sensitizer. The



SCHEME 13

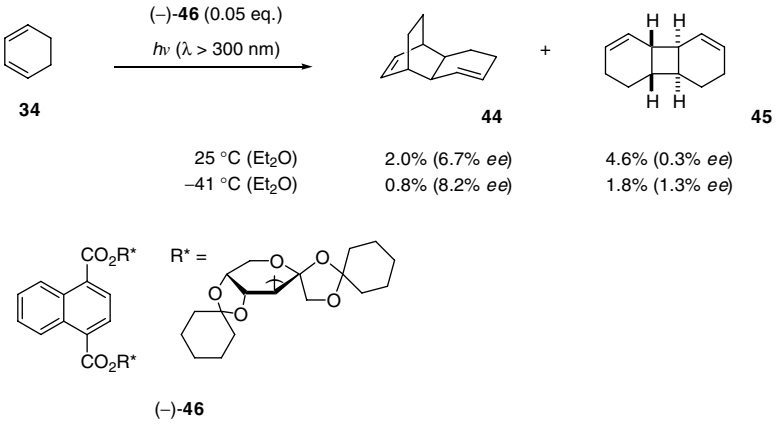


SCHEME 14

enantiomeric excess results from differential lifetimes of these exciplexes and therefore unequal capture by the cyclohexa-1,3-diene.[54]

For the sake of completeness, the synthesis of chiral 1,1′-binaphthalene derivatives as sensitizers for the photochemical dimerization of cyclohexa-1,3-diene by Vondenhof and Mattay should be mentioned.[56] However, only the racemic sensitizers were employed in the photoreactions, and their potential in asymmetric induction was not examined.

Inoue et al.[57] have performed the enantiodifferentiating [2+2]-photocyclodimerization of phenyl vinyl ether **39** in the presence of optically active menthyl or 8-phenylmenthyl arene(poly)carboxylate sensitizers (**40** and **41**). The reaction yielded the corresponding dimers **42** and **43** in a ratio of about 3:2 (Scheme 14). The highest enantioselectivity for dimer **43** (0.5% *ee*) was obtained with the sterically congested 8-phenylmenthyl ester (–)-**41**, albeit in low yields. The less congested menthyl ester (–)-**40** gave a lower optical yield (0.3% *ee*) but a slightly higher chemical yield. The asymmetric induction was not improved by irradiation at lower temperatures. The dimerization of 4-methoxystyrene gave better yields of up to 60%, but the enantioselectivities remained low (≤0.2% *ee*).



SCHEME 15

With similar chiral sensitizers enantiomeric excesses of up to 8.2% *ee* were observed in the photosensitized cyclodimerization of cyclohexa-1,3-diene **34** to the *exo*-[4+2]-cyclodimer **44** and the *anti*-[2+2]-cyclodimer **45**.[58] The *endo*-[4+2]-adduct and *syn*-[2+2]-adduct were obtained as minor components. Polymenthyl benzenepolycarboxylates similar to **40** yielded dimers **44** and **45** in low yield and with enantioselectivities of up to 2.5% *ee* at room temperature and 4.0% *ee* at –41°C. Protected saccharides as chiral substituents of the photosensitizer **46** enhanced the asymmetric induction in dimethyl ether up to 8.2% *ee*, but only in the case of the [4+2]-dimer **44** (Scheme 15).

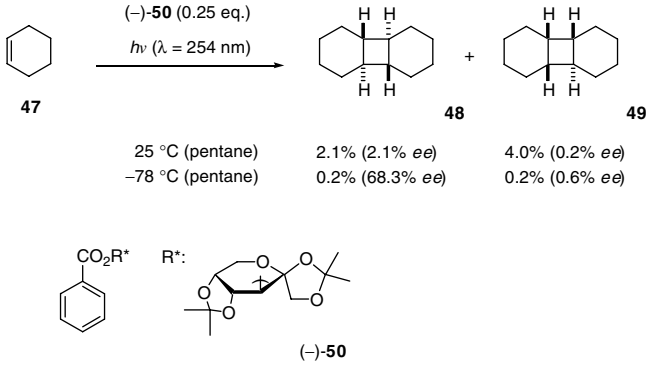
This effect is attributed to the increased microenvironmental polarity around the sensitizer chromophore that stabilizes the exciplex or contact ion pair in nonpolar solvents. As a result of this effect, the stereochemical interaction between the sensitizer and the substrate is more intimate. Because significant enantioselectivities were only observed for dimer **44**, an independent cyclodimerization pathway to **44** via an exciplex or contact ion pair of cyclohexadiene and the chiral sensitizer was suggested. Dimer **45** gave much lower *ee* values even at low temperatures, but the product chirality was inverted within the tested temperature range in favor of enantiomer *ent*-**45**. Similar temperature switching of product chirality has been reported in the enantiodifferentiating photoisomerization of cycloalkenes and in the polar addition of alcohols to 1,1-diphenylalkenes.[59] This effect has been rationalized by a non-zero differential activation entropy of the same sign as the differential activation enthalpy.

The asymmetric induction of chiral saccharide substituents was more effective in the cyclodimerization of cyclohexene **47**.[60] *Trans–anti-trans* dimer **48** was obtained in low enantioselectivity (2.1% *ee*) at 25°C, but in much higher enantioselectivity (68% *ee*) at –78°C in pentane with the chiral sensitizer (–)-**50** (Scheme 16); this represents the highest *ee* value reported for an enantiodifferentiating-photosensitized cyclodimerization.

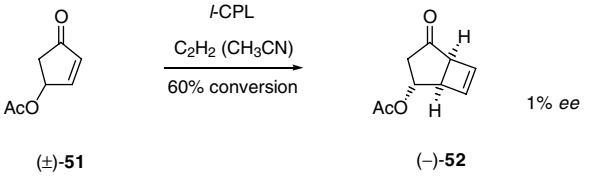
Cis/*trans* cyclodimer **49** is produced with almost no enantioface differentiation. The authors of the original publication suggest that dimer **48** is produced through the concerted $[2\pi_s + 2\pi_a]$-cycloaddition of *Z*-cyclohexene to *E*-cyclohexene that is initially formed by an asymmetric photosensitization process retaining its chiral information. Dimer **49**, however, arises from a nonconcerted process from *E*-cyclohexene with concurrent loss of its optical activity.

61.5 Asymmetric Induction by Circularly Polarized Light

Asymmetric photoreactions by circularly polarized light (CPL) are induced through the preferential excitation of one enantiomer. The chiral information is introduced by a physical source of chirality that renders this approach most effective in terms of chiral amplification. Asymmetric photodestruction causes a racemic mixture to be enantiomerically enriched when one enantiomer is consumed more rapidly by CPL. Photoderacemization creates an enantiomerically enriched reaction mixture when one enantiomer



SCHEME 16



SCHEME 17

is interconverted to the other more effectively. Another possible way is the asymmetric fixation of thermally equilibrating enantiomers. The critical parameter in these processes is the anisotropy factor *g*, defined as the relative difference of the molar extinction coefficients of an optically pure compound toward *l*- or *r*-CPL at a given wavelength: $g = (\varepsilon_1 - \varepsilon_2)/\varepsilon = \Delta\varepsilon/\varepsilon$). The *g* factor for most compounds is very low ($<10^{-2}$). Only some carbonyl compounds with a partially forbidden n,π^* transition show high *g* factors of up to 0.30.[3] Because *g* is wavelength dependent, a highly monochromatic light source is a prerequisite for effective asymmetric induction by CPL to avoid a reduction of *g* by averaging over several wavelengths.

Enantioselective photoreactions induced by CPL have received considerable interest, particularly in regard to answering the question of how enantiomerically enriched material in the universe has been generated.[61,62] From a synthetic point of view, however, this method has seen limited success. In the few asymmetric fixation reactions examined (in most cases, photocyclizations), only low enantiomeric excesses were achieved.[2,3,63] A single example of an asymmetric photocycloaddition has been reported.[64,65] By preferential excitation of the (–)-antipode of racemic cyclopentanone (±)-**51** by *l*-CPL (351- to 363-nm laser) in the presence of acetylene, enantiomerically enriched (1% *ee*) (–)-**52** was obtained (Scheme 17). The unreacted starting material **51** was optically enriched in the (+)-enantiomer. This method provided product of sufficient optical purity to examine the chiroptical data.

61.6 Conclusion

Major improvements directed towards enantioselective generally applicable photocycloaddition reactions have recently been made. With regard to chemoselectivity and stereoselectivity, the use of chiral complexing agents is currently most promising. In several cases, high chemical yields and enantioselectivities (up to 98% *ee*) have been reported. In terms of synthetic efficiency, the use of chiral sensitizers is most appealing. In this field, significant progress toward a catalytic process is likely in the near future. The achieved enantioselectivies are not yet satisfactory. The use of CPL will most likely not be widely applicable in photocycloaddition reactions, as the *ee* values are very small. It is safe to say that the topic of enantioselective photochemical reactions will remain, for many years to come, one of the most challenging and most intriguing subjects in organic photochemistry.

Photochemical Oxetane Formation: Addition to Heterocycles

Manabu Abe
Osaka University

62.1 Introduction

Photochemical [2+2]-cycloaddition of alkenes with carbonyls, the so-called Paternò-Büchi reaction, is one of the important photochemical processes to give oxetanes (Scheme 1); Paternò and Chieffi first reported the oxetane formation in 1909, almost 100 years ago.[1] The predicted structure of the oxetane was confirmed by further research carried out by Büchi et al.[2] Since their discovery, the importance of the photochemical process has been recognized and many examples have appeared in the literature. The generally accepted mechanism for the formation of oxetane rings (**OX**) is a stepwise cycloaddition via intermediate 2-oxa-1,4-diradicals (**1,4-DR**), that can be generated by the attack of the n,π^*-carbonyl oxygen at the sp^2 carbon of the alkene (Scheme 1).[3–15]

Among the photochemical cycloadditions, the reactions with heterocyclic alkenes have attracted considerable attention from both the synthetic[16–35] and biological[36–39] points of view, and a number of reviews have been published in literatures;[26,31,40–42] however, a systematic description of the mechanism that explains the observed inherent selectivities (*regioselectivity* and *stereoselectivity*) in the photochemical reactions has not been described elsewhere. This chapter concentrates on an explanation of the current understanding of this addition reaction that leads to the observed selectivities. For this purpose, the Paternò–Büchi reaction of furan derivatives is considered as a good example to illustrate the general mechanism (Scheme 2). The mechanism of the photoaddition within this system used to explain the observed selectivities should be applicable to other cases. A good mechanistic understanding will be beneficial in the design of reactions for the preparation of synthetically and/or biologically important oxetanes.

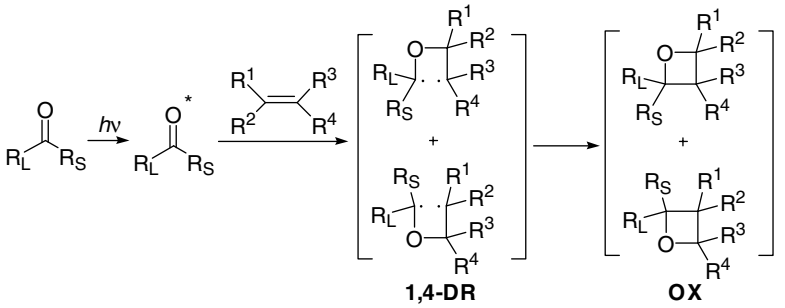
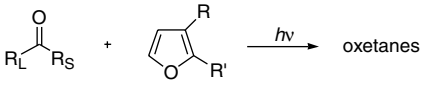
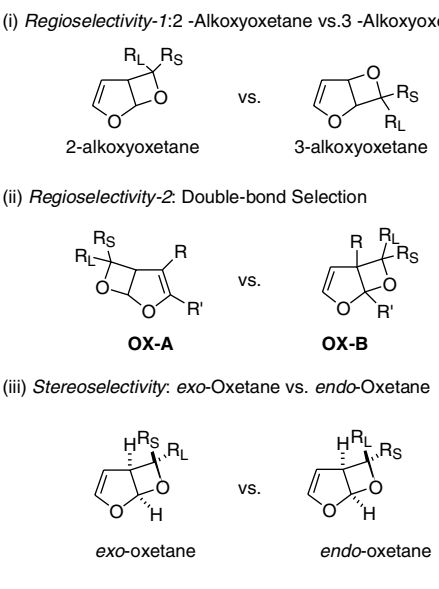


SCHEME 1



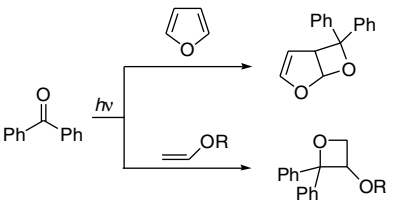
SCHEME 2



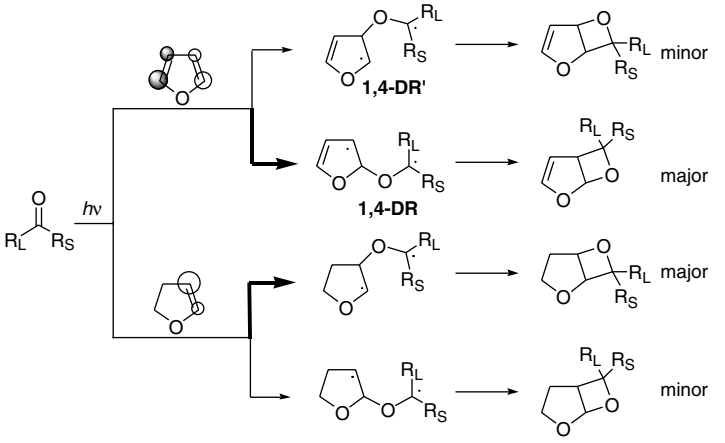
SCHEME 3

62.1 Selectivities Observed in the Paternò–Büchi Reaction of Furans

In principle, the three inherent selectivities in the reactions with furan derivatives (Scheme 3) are (i) regioselectivity (2-alkoxyoxetane vs. 3-alkoxyoxetane); (ii) double-bond selection (R, R′ ≠ H) (**OX-A** vs. **OX-B**); and (iii) stereoselectivity ($R_L \neq R_S$) (*exo*-oxetane vs. *endo*-oxetane). In the following sections, the origins for the selectivities observed in the experiments are rationalized.



SCHEME 4



SCHEME 5

62.3 Regioselectivity-1: Formation of 2-Alkoxyoxetanes vs. 3-Alkoxyoxetanes

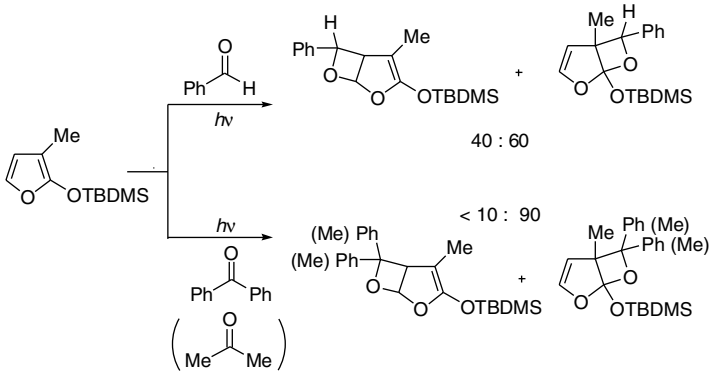
Schenck first reported the exclusive formation of 2-alkoxyoxetane in the reaction of furan with benzophenone (Scheme 4).[43] The generality of such regioselectivity (> 98: 2) was confirmed by Shima and coworkers in the photoreaction of furan with a variety of carbonyl compounds including aliphatic ketones and aldehydes.[44] At first glance, the almost exclusive formation of the 2-alkoxyoxetanes seems to be unusual, since the preferred formation of 3-alkoxyoxetanes is known in the reaction of carbonyl compounds with acyclic and cyclic vinyl ethers (Scheme 4).[45–50] This mechanistic dilemma can be readily rationalized when we consider the character of the n,π^* excited-state carbonyls and the intermediate 1,4-diradicals. First, as suggested by Hammond,[51] the excited state of carbonyls has electrophilic radical character at the oxygen. Thus, the carbonyl oxygen will attack the alkenes preferably at the site of higher frontier electron density. As can be easily imagined from the orbital coefficients of their HOMOs (Scheme 5), the oxygen will attack preferably at the β-position of the vinyl ethers and at the 2-position of furan.[52] The orbital interaction is one of the reasonable explanations for the contrasting regioselectivity observed in the experiments of vinyl ethers. Secondary, the almost quantitative regioselectivity for the furan reaction can be also explained by considering the relative stability of the intermediate 1,4-diradicals (**1,4-DRs**).[2, 3, 15] Namely, the diradical (**1,4-DR**), which afford 2-alkoxyoxetane, is relatively stabilized in terms of the allylic delocalization of the spin, compared with the regioisomeric diradical (**1,4-DR′**).

62.4 Regioselectvity-2: Double-bond Selection

When unsymmetrically substituted furans such as 2-methylfuran and 3-methylfuran are used for the photochemical reactions another regioselectivity is apparent: i.e., double-bond selection (**OX-A** vs. **OX-B**). The

TABLE 62.1 Regioselectivity-2: Double-Bond Selection

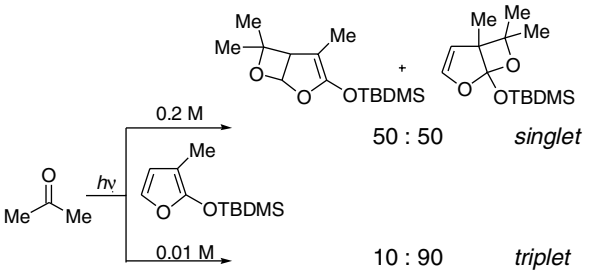
		
	44 : 56 (R' = Me, ref. 53)	52 : 48 (R = CH_2OH, ref. 56)
	< 2 : 98 (R' = Me, ref. 54) < 2 : 98 (R' = CH_2OH, ref. 55)	< 2 : 98 (R = Me, ref. 54)



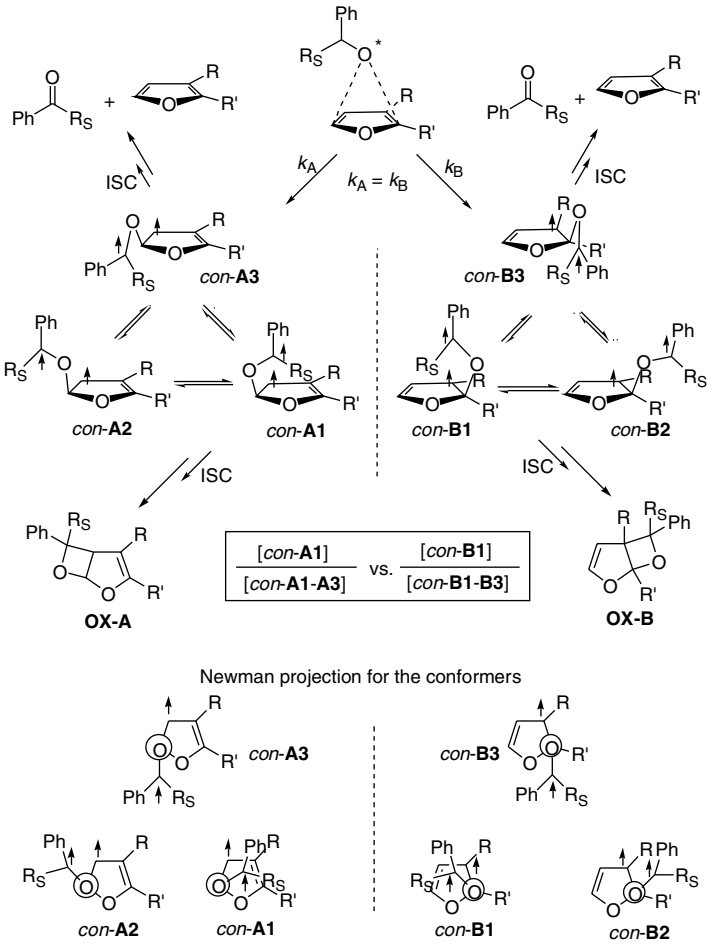
SCHEME 6

experimental data are summarized in Table 62.1. In contrast to the product mixture of the two isomeric oxetanes from the reaction with benzaldehyde (E_T = 71 kcal/mol, E_T = excited-triplet energy), the benzophenone (E_T = 69 kcal/mol) invariably adds to the double bond having the alkyl substituent at the C2 or the C3 position on the furan ring.[53–56] A similar trend is reported for the 2-siloxyfuran derivatives in the synthetic approach to γ-butyrolactones (Scheme 6).[57]

In this example the aldehyde adds to both double bonds in a regio-random fashion to give the two isomeric oxetanes. However, the sterically congested oxetanes are selectively formed in the reaction with ketones, i.e., benzophenone and acetone (E_T = 79 kcal/mol). Apparently, the selectivity is not due to the energetic difference of the excited carbonyls. What is the origin for the dramatic difference in the selectivity? Informatively, in the reaction with acetone, the regioselectivity is reported to be largely dependent upon the concentration of the furan derivative (Scheme 7). Namely, in contrast to the regioselective formation of the oxetane at the lower concentration of the 2-siloxyfuran (0.01 M), the two isomeric oxetanes are observed at higher concentration of the furan (0.2 M). The results clearly suggest that the triplet state (low concentration of the furan) gives higher selectivity and the low selectivity arises from the singlet state (high concentration of the furan).

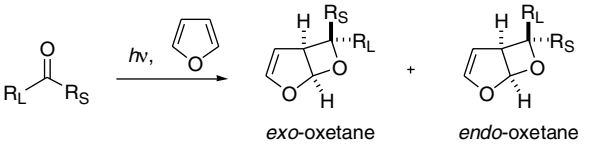


SCHEME 7

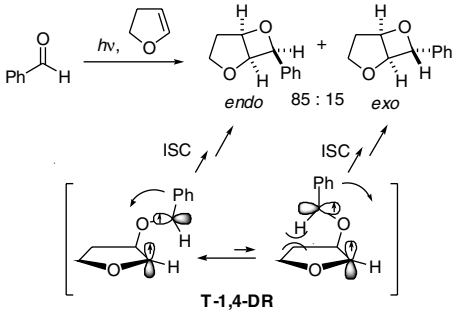


SCHEME 8

As judged by the reported experimental results mentioned above, the intermediate triplet 1,4-diradicals play an important role in the control of selectivity. A reasonable explanation is depicted in Scheme 8 (R, R′ ≠ H). In this scheme I propose that the high-energy excited carbonyls will attack both double bonds equally to give the regioisomeric triplet diradicals, i.e., $k_A = k_B$. There are three possible conformers in each diradical, i.e., productive conformers *con*-**A1,** *con*-**A2,** *con*-**B-1** and *con*-**B2** and non-productive conformers *con*-**A3** and *con*-**B3** that go back to the starting materials. The product ratio of **OX-A**/**OX-B**



SCHEME 9



SCHEME 10

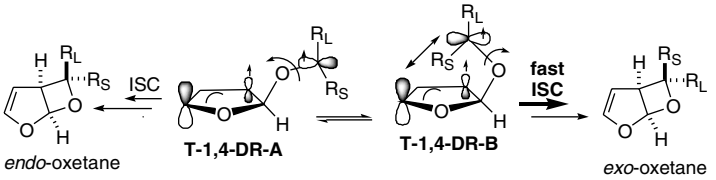
should be reflected by the population of the productive conformers in the possible triplet 1,4-diradicals. When R_S = Ph, the population of the productive conformer *con*-**B1** in *con*-**B1-B3** is higher than the conformer *con*-**A1** in *con*-**A1-A3**. This arises as a result of the steric repulsion between R_S and R, R′ in the conformers *con*-**B2** and *con*-**B3**. Such a non-bonded interaction is negligible for the **type A** conformers. Thus, the regioselectivity in the reaction with triplet-excited ketones is not only determined at the first stage of the reaction (k_A vs. k_B), but also the population of the productive conformers of the triplet diradicals, i.e., [*con*-**A1**]/[*con*-**A1-A3**] vs. [*con*-**B1**]/[*con*-**B1-B3**]. In the case of the aldehyde (R_S = H), such a steric repulsion is quite small and the population of the productive conformers would be the same for the each type of the diradicals, i.e., **OX-A/OX-B** = k_A/k_B.

62.5 Stereoselectivity: Formation of *exo*-Oxetanes vs. *endo*-Oxetanes

When unsymmetrical carbonyls ($R_L \neq R_S$) are used for the photochemical cycloaddition with furans, the inherent stereoselectivity should be considered, i.e., *exo*-oxetanes vs. *endo*-oxetanes (Scheme 9). Shima initially investigated the photocycloaddition reaction in 1965[53] and an NMR study by Whipple and Evanega[58] later provided evidence for the preference of the *exo*-selective cycloaddition. The *exo*-selective formation of the bicyclic oxetanes and their chemical transformations are now accepted as powerful tools for preparing the synthetically and biologically important materials.[16–35]

The mechanistic rationalization of the highly *exo*-selective formation of oxetanes has been exemplified by Griesbeck et al.[59] The idea was originally used for rationalization of the *endo*-selectivity in the reaction with 2,three-dimensionalihydrofuran derivatives (Scheme 10).[60–67] Namely, the stereochemical outcome is proposed to come from the relative stability of the intermediary triplet 1,4 diradicals (**T-1,4-DR**), whose conformations are suitable for the spin-orbit coupling (SOC) induced intersystem crossing (ISC) process. The "Conformational Memory Effects (Griesbeck Model)" in the stereoselectivity can be applicable to the stereochemical outcome for the reaction with furan (Scheme 11).

Among the possible conformations (**T-1,4-DR-A,B**) of the intermediary triplet 1,4-diradicals, the conformer (**T-1,4-DR-B**), that is expected to lead to the *exo*-isomer, has the most appropriate orientation of the two singly occupied p-orbitals for the SOC-induced ISC process, as judged by the perpendicularity and the distance between the spins.[68]



SCHEME 11

Griesbeck's proposal excellently explains the preferred formation of the *exo*-isomers reported so far in the experiments and predicts the stereochemistry for the related reactions.[69, 70]

62.6 Summary

In this chapter, I have summarized the important role of the triplet diradicals in the regio- and stereoselectivity for the Paternò-Büchi oxetane formations that have been reported so far. Since triplet diradical species are quite common intermediates in a variety of photochemical processes, the concept would be helpful to understand the selectivities and design the reactions for a synthetic purpose.

Carlos Rivas
Instituto Venezolano de Investigaciones Científicas

63.1 Introduction

The number and variety of phototoxic compounds are large. Furthermore, for most phototoxic xenobiotics, a correlation between structure and photoreactivity is not easily found. It is obvious that, in general, a relationship must exist between photochemical behavior and phototoxicity. This chapter discusses the role of type II reactions involving the photoactivated drug in its triplet state transferring energy to molecular oxygen to generate singlet oxygen, superoxide anion, or hydroxyl radical, causing oxidation or peroxidation of membrane lipids. In the last 10 years, we have examined the photolysis of diuretic drugs under mild conditions, similar to those encountered in biological systems — namely, neutral, oxygenated media or under argon atmosphere and irradiation carried out with visible light. These investigations were performed keeping two main goals in mind: (1) to establish the nature of the different photoproducts, and (2) to obtain evidence of the role of oxygen in these photoprocesses and in the *in vitro* phototoxicity.

63.2 Photochemistry of Diuretic Drugs

Thiazide Derivatives

The photosensitized reactions due to thiazide, chlorothiazide, and hydrochlorothiazide were described in the 1950s, soon after their introduction in the field of medicine for the treatment of hypertension. Many of these substances in different systems have been shown to induce *in vitro* phototoxicity, just as phenothiazines and tetracycline do, but few derived from oral administered sulfonamides have been studied from the standpoint of their phototoxic properties (Figure 63.1).

Diuretic Agents Photosensitizer (Sulfonamides): Furosemide, Acetazolamide, Chlorthalidone, Glipizide, and Triamterene

Furosemide and chlorthalidone are considered potent diuretics, as they are capable of bringing about the elimination of more than 15% of the filtered load of salt and water. This property is primarily due to their action on the upward branch of the Henle handle of the kidney. Although powerful, this action has a short duration (4 to 6 hours). Although it is not a benzothiadiazine, furosemide is structurally similar to hydrochlorothiazide. Many adverse effects on the skin have been reported for this substance, such as exfoliative dermatitis, among others. Cases have been reported on adverse effects caused by carbutamide, the first sulfonylurea derivative to show photosensitization among the various sulfonamides used as antidiabetic agents. Afterwards, tolbutamide, chlorpropamide, and, more recently, glipizide and glibenclamide were reported to cause reactions of skin photosensitization in patients under antidiabetic treatment (Figure 63.2).

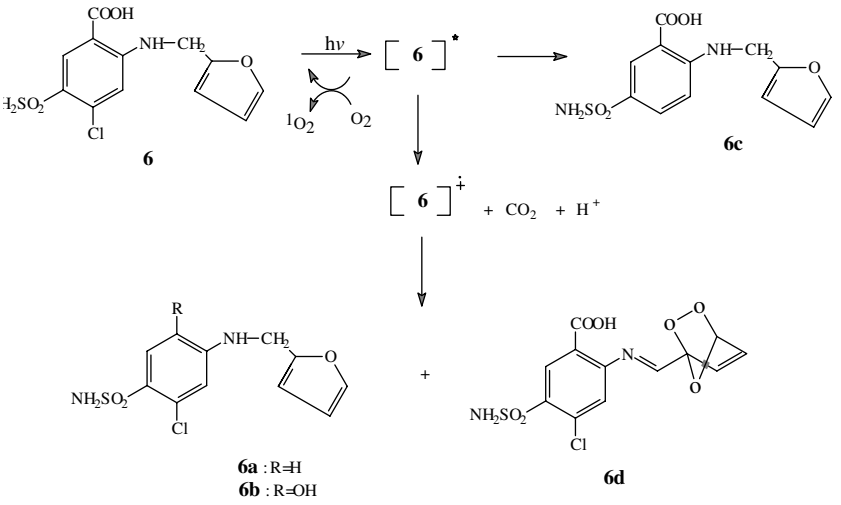

FIGURE 63.3 Mechanism of photodegradation of furosemide.

The phototoxic diuretic drug furosemide **6**, a 5-(aminosulfonyl)-4-chloro-2-[(2-furanylmethyl)-amino] benzoic acid, is photolabile under aerobic and anaerobic conditions. Previous studies have established that furosemide causes adverse photosensitizing effects *in vivo* and has a high *in vitro* photosensitizing capability. In this context, it is capable of initiating both energy transfer and free radical reactions.[1–4] Irradiation of a methanol solution of **6** produces under an oxygen atmosphere photoproducts such as **6a**, **6b**, **6c**, as well as singlet oxygen, while under an argon atmosphere only the photoproducts **6a** and **6c** have been isolated. Furthermore, a peroxidic, unstable photoproduct has also been detected during photolysis under an oxygen atmosphere. In another investigation, a photocycloaddition process of singlet oxygen to the furan group of furosemide (compound **6d**) was detected by Zanocco et al.[5]

The mechanism of this reaction under aerobic conditions proceeds presumably via decarboxylation of **6** (Figure 63.3), forming in this way a free-radical intermediate, as has already been proposed for carboxylic acids. One process leads to the hydrogen abstraction product **6a**. The formation of **6a** and **6c** does not require oxygen, as was demonstrated by its detection under argon atmosphere. A second process is photodechlorination of **6**, generating photoproduct **6c**, which was detected under anaerobic conditions.

Furosemide was screened *in vitro* at different concentrations for UV-Vis-induced phototoxic effects in a photohemolysis test, in the presence and absence of different radical scavengers, singlet oxygen, and hydroxyl radical quenchers. Furthermore, furosemide photosensitized the peroxidation of linoleic acid.[6] Data obtained in these studies show that the furosemide photodynamic action can be related, at least partially, to the ability of the drug to produce biologically significant quantities of singlet oxygen in polar and nonpolar media. Several authors have proposed that the adverse photosensitivity effects of furosemide can be related to photoproducts arising from direct photolysis or to those coming from type I photoreactions.

Acetazolamide (5-acetamido-1,3,4-thiadiazole-2-sulfonamide, **7**) is a drug commonly used as a diuretic. Cutaneous adverse reactions mediated by light have been described after oral intake of acetazolamide.[7] Phototoxic properties of this drug and related similar diuretics were determined *in vitro* by means of a photohemolysis test.[6,8–10] The photosensitivity *in vitro* of these drugs was inhibited by antioxidants and under nitrogen atmosphere.[11] These findings indicate an oxygen dependence of the phototoxic action of this drug *in vitro*.[12]

The phototoxic diuretic drug acetazolamide **7** is photolabile under aerobic and anaerobic conditions in methanolic solution as well as in buffered aqueous medium (pH = 7.2). The quantum yield under aerobic conditions was $\Phi = 0.24$, and the reaction led to the formation of photoproducts **7a** (yield 75%) and **7b** (yield 25%) (Figure 63.4). The results indicate that O_2 is directly involved in the photolysis of acetazolamide. The study of the influence of oxygen radicals on the decomposition of acetazolamide (irradiations in the presence of singlet oxygen quenchers) indicate that $^1O_2$ may lead to degradation of **7** by oxygenation.

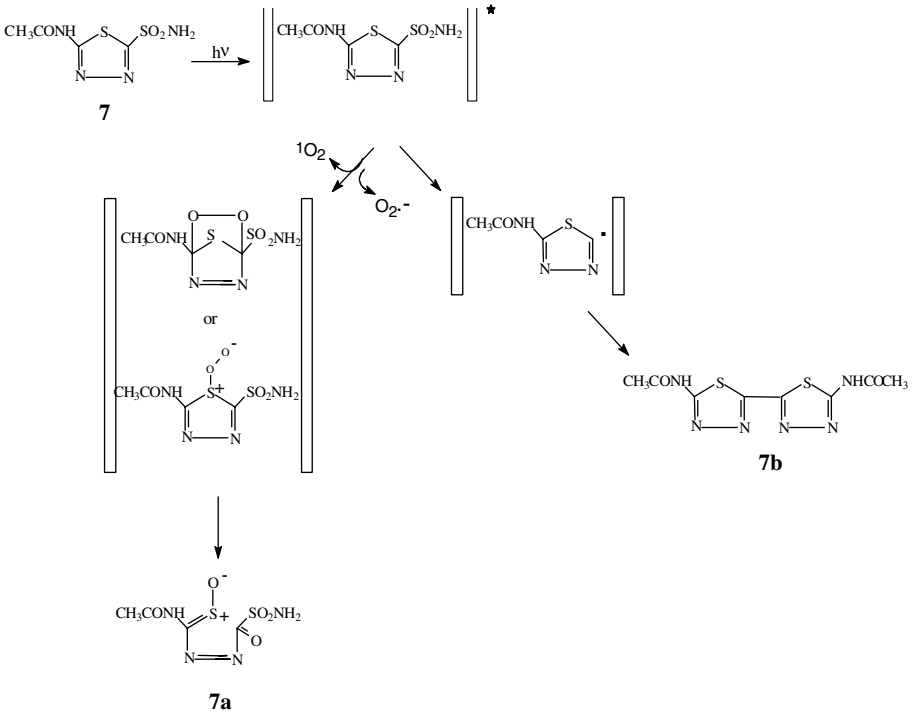

FIGURE 63.4 Mechanism of photodegradation of acetazolamide.

Although the oxygenated product **7b** may also be formed by reactions with molecular oxygen (O_2 or $O_2^{\cdot-}$), this reaction pathway was discarded as a consequence of the results obtained from the addition of singlet oxygen quenchers and superoxide dismutase (SOD) as superoxide scavenger during irradiation. Being aware of the fact that the photodegradation process was also efficient under an oxygen atmosphere and is essential to produce photoproduct **7a** is necessary to understand the mechanism of the oxygen-dependent photobiological effects of **7**.

With the determination of $^1O_2$ and $O_2^{\cdot-}$ in the photolysis of **7** and its participation in the photodegradation of acetazolamide, we can look forward to a better understanding of the role of singlet oxygen generated in photoreactions of this type of drugs in biological systems. Another photochemical process that appears to compete with the latter is the formation of the free-radical intermediate from the cleavage of the sulfonamide group in the thiadiazole ring. This intermediate produces a dimerization to yield compound **7b** and does not require oxygen.

The phototoxic diuretic drug chlorthalidone **8** is photolabile under aerobic conditions and UV-B (290- to 320-nm) light. Irradiation under an oxygen atmosphere of a phosphate-buffered saline solution of **8** produces photoproducts **8a** to **8c** and singlet oxygen (Figure 63.5). Its photolability under UV-B (290- to 320-nm) irradiation was followed by a progressive decrease in its main absorption bands at 220 and 280 nm.[13,14] The isolation of the photoproducts suggests that the photodegradation occurs via the intermediacy of radicals and with oxygen participation.

Glipizide **9** induced phototoxicity in cell cultures when irradiated with broadband UV. The phototoxic antidiabetes drug glipizide, a benzenesulfonamide derivative, is photolabile under aerobic conditions and UV-B (290- to 320-nm) light. The photolysis of **9** was followed by monitoring the disappearance of the 280-nm band and the appearance of a new band at 230 nm. Irradiation of a phosphate-buffered solution of **9** under an oxygen atmosphere produces four photoproducts as well as singlet oxygen. Incubation of this pre-irradiated drug with the cell cultures revealed no phototoxic effects.[15] The photochemistry of **9** involves cleavage of the sulfon–amine and the sulfonamine–R bonds.[11,16,17]

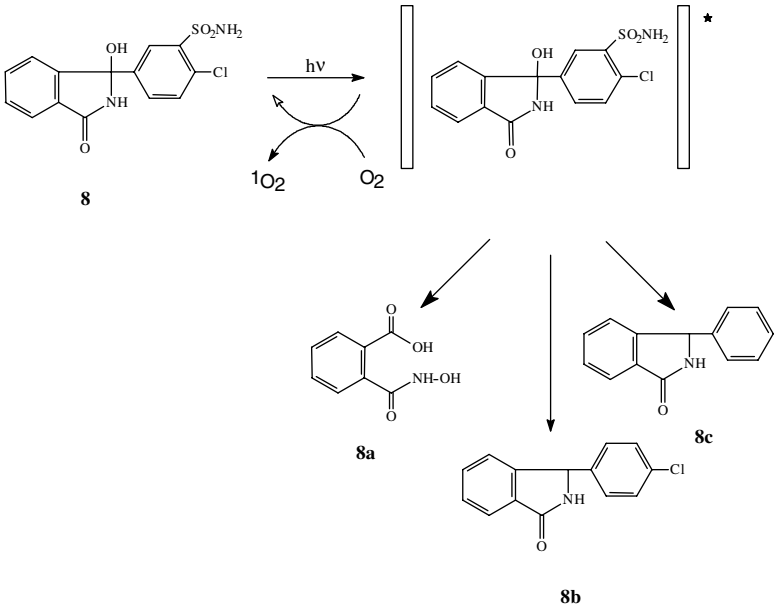

FIGURE 63.5 Mechanism of photodegradation of chlorthalidone.

Triamterene (2,4,7-triamino-6-phenylpteridine, **10**) is a drug commonly used as a potassium-sparing diuretic that inhibits sodium resorption and potassium secretion in the distal tubule in the treatment of antiarrhythmic activity. Cutaneous adverse reactions mediated by light, developing photosensitive non-scarring skin eruptions, and the onset of subacute cutaneous lupus erythematosus after intake of triamterene have been reported.[18] As an isolated clinical case, a diagnosis of photodermatitis from triamterene has been demonstrated.[19] Clinical manifestations in association with hydrochlorothiazide **11** photosensitivity include lichen planus, erythema, and acute eczema, as well as phototoxicity *in vitro*.[20,21] Photodecomposition studies of triamterene **10** in methanol, phosphate-buffered saline solution, and human serum in the presence of oxygen were followed by UV spectrophotometry and high-performance liquid chromatographic (HPLC) analysis using a sensitive HPLC method. Photodegradation was observed only under irradiation with UV-B (290- to 320-nm) light to produce the photoproduct **10a** (Figure 63.6). No photodecomposition was detected under UV-A irradiation, yet singlet oxygen ($^1O_2$) was generated.[22] The UV spectra showed a progressive decrease (under UV-B irradiation) in the main absorption bands at 235 and 375 nm, also a high quantum yield for its fluorescence was measured ($\Phi_{Fl} = 0.54$).

Hydrochlorothiazide, as shown in Figure 63.6, is completely dechlorinated upon irradiation with a medium-pressure mercury arc lamp through a glass filter in deaerated aqueous or alcohol solution with a quantum yield of 0.18.[14]

Amiloride **12**, another potent diuretic drug, shows a similar behavior under irradiation in the UV-A–Vis region, producing dechlorination products, and the photoreaction is pH dependent.[23] Presumably, the strong absorption at 360 nm in the UV-A is responsible for its phototoxic properties (Figure 63.7).[24]

63.3 Reactive Oxygen Species (ROS) Generation and Phototoxicity

Clinical photosensitization has been recognized to result from a number of pharmacological agents. The mechanism of type II reactions involves the photoactivated drug in its triplet excited state photosensitizing molecular oxygen to generate singlet oxygen that causes oxidation or peroxidation of membrane lipids, or strand breaks. Oxidation of purine or pyrimidine bases has been discussed.

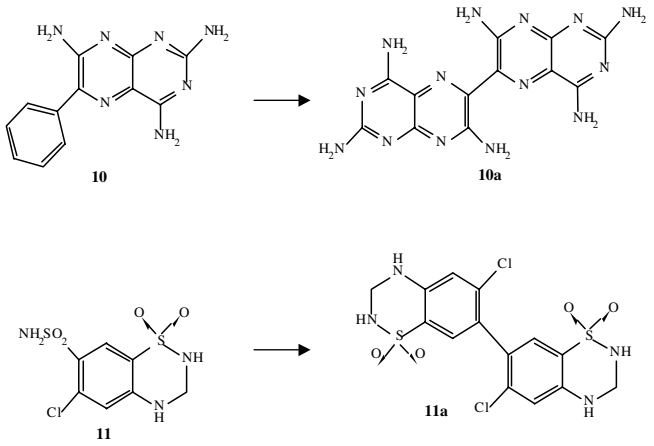

FIGURE 63.6 Photodegradation of triamterene (**10**) and hydrochlorothiazide (**11**).

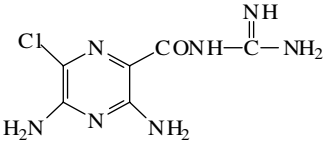

FIGURE 63.7 Structure of amiloride (**12**).

In the case of reactions when oxygen is present, the triplet state of these drugs (photosensitizer) sensitizes molecular oxygen, producing $^1O_2$, which then reacts with the biological substrate. This has been verified by trapping tests with 2,5-dimethylfuran, furfural, and 1,3-cyclohexadiene-1,4-diethanoate, as well as testing for the oxidation of histidine.[13,22,25]

Lipid peroxidative potency of thiazide diuretics has been demonstrated using squalene as the substrate, and participation of $^1O_2$ in the lipid peroxidation is possible.[26] Irradiation by UV-A of squalene in the presence of penflutizide **1**, hydrochlorothiazide **2**, methylchlorothiazide **3**, benzylhydrochlorothiazide **4**, or trichloromethiazide **5** induced *in vitro* peroxidation, as measured by production of the hydroperoxides and thiobarbituric acid-reactive substances. An especially high intensity has been observed in the penflutizide-sensitized photohemolysis with the production of ever-increasing amounts of hydroperoxides in lipids of red blood cell membranes. This fact strongly supports the idea that lipids are one of the subcellular targets of the phototoxicity.

We have extensively examined the family of diuretic-related drugs such as furosemide, acetazolamide, triamterene, and chlorthalidonem, which can induce phototoxicity through the generation of singlet oxygen. This family of diuretic drugs is capable of producing singlet oxygen through photosensitization via a type II mechanism. This process was detected by trapping the oxygen with 2,5-dimethylfuran during photolysis of these drugs in oxygenated media. The formation of $^1O_2$ was also confirmed by trapping with furfuryl alcohol (determined by HPLC) and by the histidine test. An alternative method for measuring the amount of singlet oxygen photogenerated in aqueous solution was necessary because of ambiguity about the specificity of the simple traps, such as 2,5-dimethylfuran, furfuryl alcohol, and histidine. This method is the specific chemical trapping of $^1O_2$ with 1,3-cyclohexadiene-1,4-diethanoate. The measurements with this compound were determined in water using the phosphorescence method; quantum yields with values of 0.047 and 0.078 were determined for singlet oxygen formation by furosemide photosensitization in acetonitrile and benzene, respectively. This method is much more reliable than the indirect trapping methods with, for example, diphenylisobenzofuran. [27]

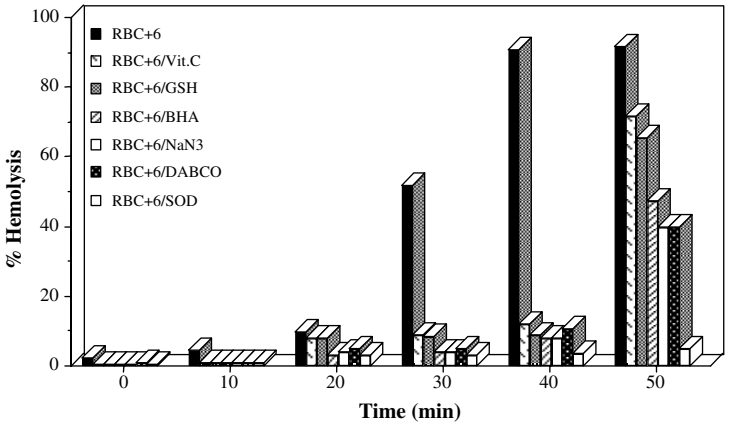

FIGURE 63.8 Photohemolysis of RBC sensitized by Furosemide (**6**) in the absence and presence of radical scavengers and singlet oxygen quenchers.

Sulfonamides and diuretics such as furosemide and chlorthalidone were the first chemotherapeutics reported to exert unwanted side effects.[28–29] Patients sensitized to diuretics after their use run the risk of generalized eruptions. One of the side effects reported in patients taking thiazide diuretics is photosensitivity. Brown and Deng,[30] as well as Darken and McBurney[18] and De Fernandez et al.,[19] have reported patients who developed lupus-like lesions (erythematous scaling papules, patches and plaques on the upper extremities, multiple flesh-colored urticarial plaques on the trunk) during treatment with diuretics and up to one year after beginning the therapy. Phototoxic compounds with different molecular structures can also produce singlet oxygen by energy transfer. The variety and number of phototoxic compounds are large. Furthermore, for most phototoxic xenobiotics, a relationship between structure and photoreactivity *in vivo* cannot be determined.[8,11,21,31–33]

Furosemide was screened *in vitro* at different concentrations for UV-Vis-induced phototoxic effects in a photohemolysis test in the presence and absence of different radical scavengers and singlet oxygen and hydroxyl radical quenchers. Furosemide-photosensitized peroxidation of linoleic acid was monitored by the UV detection of dienic hydroperoxides. The mechanism of phototoxicity for this drug probably involves reactions of singlet oxygen and superoxide ion with cellular components rather than reactions of a free radical intermediate or stable photoproducts (Figure 63.8).

Acetazolamide **7** and chlorthalidone **8** photosensitize the oxidation of either 2,5-dimethylfuran (an efficient trap for $^1O_2$ independently of the pH of the system) or histidine. This result demonstrates that compounds **7** and **8** possess type II photodynamic activity and are themselves susceptible to photosensitized oxidation. This observation is consistent with the fact that the photodegradation of this drug under aerobic conditions is affected by the addition of singlet oxygen and oxygen superoxide quenchers such as vitamin C and sodium azide and also of superoxide dismutase.[12,13] Drugs **7** and **8** were screened *in vitro* at different concentrations for UV-Vis-induced phototoxic effects in a photohemolysis test in the presence and absence of different radical scavengers, singlet oxygen traps, and hydroxyl radical quenchers. Both drugs showed a positive photohemolytic effect on human erythrocytes.

Acetazolamide and chlorthalidone have also been shown to photosensitize the reduction of nitro blue tetrazolium in phosphate-buffered saline solution. The reaction is more efficient under deoxygenated conditions and in the presence of superoxide dismutase. These results indicate that direct electron transfer occurs from either the excited state of **7** or **8** to the substrate, especially oxygen. No doubt, superoxide ion could be involved as an intermediate when oxygen is present. On the basis of these results, a photochemical reaction mechanism of acetazolamide and nitro blue tetrazolium is postulated as shown in Figure 63.9.

Red blood cell lysis, photosensitized by glipizide **9**, and the products of its aerobic photolysis were demonstrated. The photohemolysis rate was lower for **9** than for its photoproducts. Inhibition of this

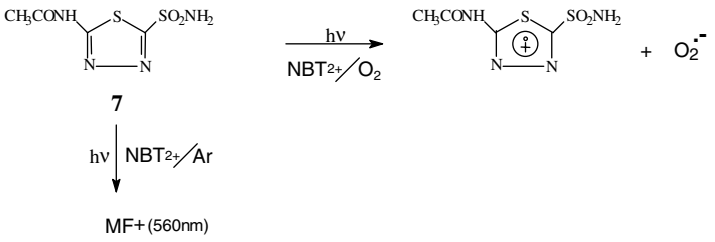

FIGURE 63.9 Photosensitized reduction of nitro blue tetrazolium (NBT) by acetazolamide.

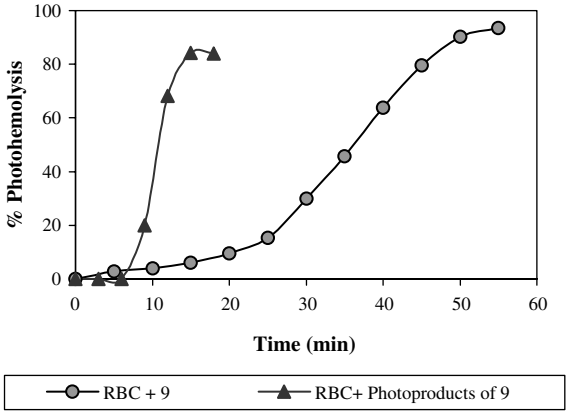

FIGURE 63.10 Photohemolysis of RBC sensitized by glipizide (**9**).

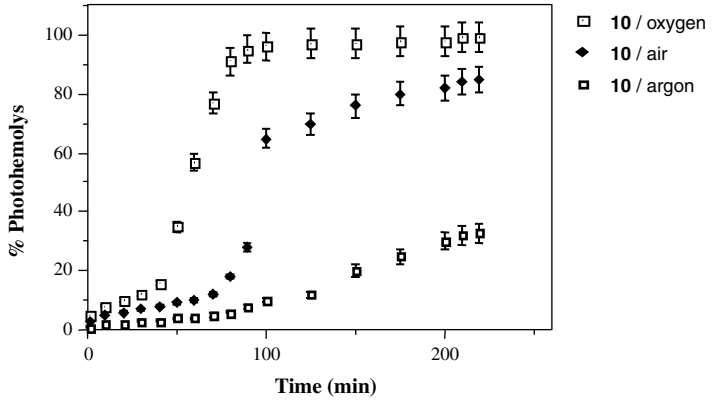

FIGURE 63.11 Photohemolysis of RBC sensitized with **Triamterene** (**10**) in the presence of oxygen, air, and argon ([**Triamterene**] = 50 mg · mL^{-1}; [**RBC**] = 3.3 × 106 cells · mL^{-1}])

process upon addition of 1,4-diazabicyclo[2.2.2]octane, glutathione, vitamin C, sodium azide, superoxide dismutase, and α-tocopherol confirmed the possibility of singlet oxygen, superoxide ion, or free-radical participation. The degree of phototoxicity induced by glipizide could depend on the balance between the generation of singlet oxygen, radical oxygen, and free-radical species and the effectiveness of the defense systems against toxic radicals.[17] Figure 63.10 shows the photohemolysis of red blood cells sensitized with **9** (2.5×10^{-4} *M*) in the presence of oxygen.

The UV-A-excited (320 to 400 nm) triamterene molecule transferred its energy to molecular oxygen, with subsequent formation of $^1O_2$; however, photodegradation was not observed. Triamterene itself shows a photohemolytic effect and photoinduced lipid peroxidation.

In the presence of oxygen, triamterene was able to induce photohemolysis of human erythrocytes. The same process was observed under an inert atmosphere, although at a significantly lower rate. The photoreactivity of triamterene *in vitro* is amply demonstrated by its capability to photosensitize the hemolysis of erythrocytes, lipid peroxidation, and decreasing cell viability of lymphocytes and neutrophils (polymorphonuclear cells).[22] The mechanisms of phototoxicity for this drug most probably involve reactions of a free-radical intermediate and/or of singlet oxygen with cellular components.

To determine the mechanism of triamterene-induced photohemolysis, the above studies were repeated in the presence of singlet oxygen quenchers sodium azide and 1,4-diazabicyclo[2.2.2]octane and the radical scavengers butylated hydroxyanisole and reduced glutathione. The photohemolytic effect was efficiently inhibited by the singlet oxygen quenchers; in contrast, the radical scavengers used produced no significant inhibition of this process.

63.4 Conclusions

The studies of phototoxicity carried out in this work may help explain the damage produced in proteins and organs. Radical-mediated damage to protein may be initiated by electron leakage and photoinduced oxidation of lipids and amino acids. As a consequence, protein oxidation can also be oxygen dependentm and it is often functionally inactive.[34] These observations may contribute to elucidate the observed accumulation and damaging activity of oxidized proteins during aging and in pathologies such as diabetes, atherosclerosis, and neurodegenerative diseases such as Alzheimer's disease.[35] The results obtained may also be very useful from the medical standpoint in elucidation of the biological action of many pharmaceutical products *in vitro* and *in vivo*.

64.1 Mechanisms and Applications of the Photodecarboxylation of Carboxylic Acid and Lactones

The decarboxylation of carboxylic acids is a photochemical process of significance in several areas of study; thus, photodecarboxylation reactions are used in synthetic chemistry to generate radical intermediates or in agriculture to produce pesticides. In the case of pharmaceuticals, this process is responsible for a decreased stability of some compounds and seems to be directly or indirectly involved in adverse photosensitizing side effects.

In the presence of light, organic compounds containing a carboxylic group can extrude carbon dioxide. This process can occur either from the free acid or from the dissociated carboxylate form. In general, photodecarboxylation of non-dissociated acids involves direct homolytic cleavage of the C–C bond α to the carboxyl group. By contrast, in the carboxylates formal heterolytic and/or homolytic mechanisms can participate. Photoionization or photoinduced electron transfer (PET) reactions can also be involved (see Scheme 1).[1,2]

Most of the studies on photodecarboxylation of simple aliphatic carboxylic acids and lactones (such as formic, acetic, or pyruvic acids; β-propiolactone; or δ-valerolactone) were summarized by Calvert and Pitts in 1966,[3] and different aspects of the photodecarboxylation of organic compounds were analyzed in the 1970s;[4,5] however, a full review of photodecarboxylation reactions did not appear until 1992.[1] A chapter in the first edition of this *Handbook of Organic Photochemistry and Photobiology* summarized the literature existing up to 1992 on the loss of carbon dioxide from photoexcited aliphatic and aromatic acids and lactones.[2] For this reason, although some earlier work will be cited here, the literature coverage will in general be limited to the work published during the last decade.

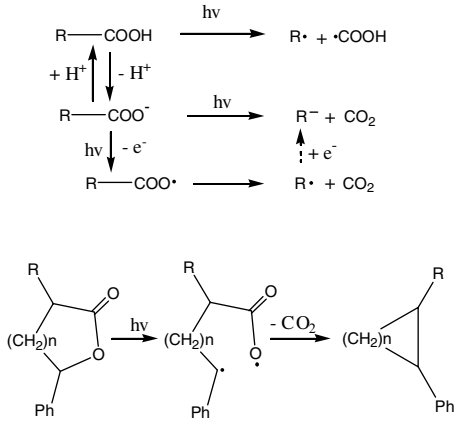
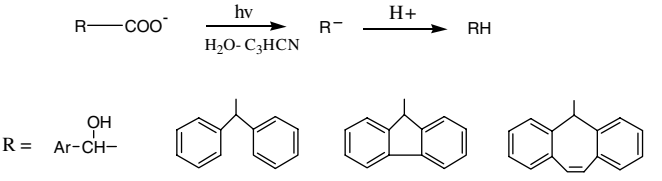


SCHEME 1

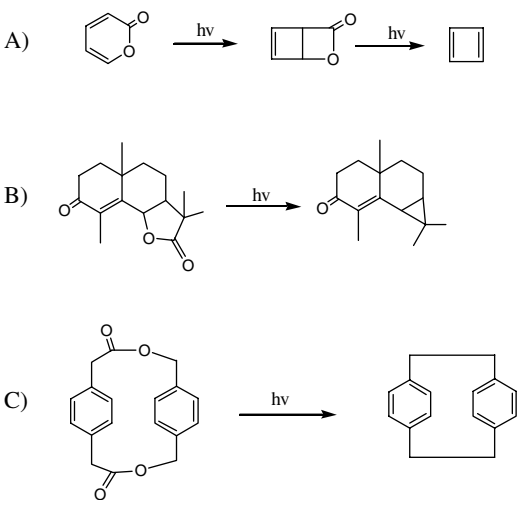


SCHEME 2

The photodecarboxylation mechanism of simple arylacetic acids is not completely understood due to the relatively low quantum yields of reaction ($\Phi < 0.06$). The formation of benzylic radicals (which show a transient absorption spectrum, with λ_{max} ~315 nm) has been taken as evidence for the homolytic cleavage of the undissociated acid. By contrast, photolysis of carboxylate forms gives rise to carbanion intermediates (λ_{max} ~350 nm) via heterolytic cleavage (Scheme 1). However, the possibility of initial electron photoejection and subsequent homolytic decarboxylation (eventually followed by recombination of the electron with the benzyl radical) cannot be ruled out, as the hydrated electron has been observed as a transient species.[6,7]

Within the cavities of cation-exchanged Y faujasites (where the carboxylate ion is the predominating species), benzyl radicals are formed and generation of benzyl anions is highly dependent on the hydration state of the zeolite.[8] Other studies in basic faujasites have shown some diastereoselectivity in the formation of 2,3-diphenylbutanes by photodecarboxylation of 2-phenylpropionic acid.[9,10]

Photodecarboxylation of the dissociated form of α-hydroxy-substituted arylacetic acids and related substrates occurs from the singlet excited state (S_1) and leads to the corresponding benzyl alcohols with high quantum yields (Φ = 0.2 to 0.7) via a heterolytic mechanism (Scheme 2).[1] Photodecarboxylation of some diarylacetic acids (Scheme 2) also proceeds from S_1 via heterolytic mechanism. It is remarkable that these compounds show dramatic differences in their relative photodecarboxylation efficiency (Φ = 0.04 to 0.6). The reaction is enhanced when a cyclic delocalized carbanion with $4n$ electrons is formed.[1] By contrast, photodecarboxylation of *m*- and *p*-nitrophenylacetic acids in aqueous solutions occurs via a heterolytic mechanism from T_1.[11] The photodecarboxylation of pyruvic and benzoylformic acids takes place with high quantum yields ($\Phi > 0.6$) in aqueous solutions, to give acetaldehyde and benzaldehyde, respectively as the primary photoproducts.[1,12,13] On the other hand, 2-, 3-, and 4-pyridinylacetic acids undergo photodecarboxylation in aqueous solutions via a heterolytic mechanism from their zwitterionic forms.[14]



SCHEME 3

The photodecarboxylation of lactones usually involves homolysis of the OC bond β to the carbonyl group, to generate a biradical after loss of CO_2 (see Scheme 1).[1,2] This process has been used to make strained ring systems (such as cyclopropanes, cyclobutenes, and cyclophanes) via intramolecular CC coupling of the biradicals formed. Some applications of this reaction are shown in Scheme 3. Thus, upon irradiation of α-pyrone, cyclobutadiene is formed by a two-step decarboxylative process (Scheme 3A).[15] Likewise, the natural product aubergenone has been synthesized from α-santonin using the photodecarboxylation of a γ-lactone to a cyclopropane as the key step (Scheme 3B).[16] Photolysis of lactones has also been used for the preparation of cyclophanes (Scheme 3C).[17,18]

In general, photodecarboxylation of lactones arises upon cleavage of an ester bond from an excited chromophore.[1,2] However, when a naphthalene is the main light-absorbing moiety, the decarboxylation requires absorption of two photons (one to produce the T_1 triplet excited state and another one to promote the T_1 to a higher energy triplet state).[19]

64.2 Photodecarboxylation of the Antiinflammatory 2-Arylpropionic Acids and Analogous Compounds

During the last decade, a large number of photochemical studies have appeared regarding the photoreactivity of non-steroidal antiinflammatory 2-arylpropionic acids. These studies have been aimed at establishing the molecular bases of their phototoxic properties[20–39] and have contributed significantly to insight into the general photodecarboxylation mechanisms of arylalkanoic acids, which are classified into two different groups, depending on the ability of the aryl ring to act as an electron-acceptor moiety (ketoprofen, suprofen, tiaprofenic acid, tolmetin, and benoxaprofen) or as an electron-donor moiety (naproxen, carprofen) (Figure 64.1).

The most important common features in the photodecarboxylation of ketoprofen, suprofen, tiaprofenic acid, tolmetin, and benoxaprofen in neutral aqueous solutions are the following: (1) All of them produce carbanion intermediates, which upon protonation give rise to the decarboxylated photoproducts (Scheme 4), and (2) the photodecarboxylation quantum yields are much higher from the carboxylate forms than from the non-dissociated acids.[20–35] However, there are also some differences. Thus, while photodecarboxylation of benoxaprofen is produced from its singlet excited state, in the case of the benzophenone derivatives (ketoprofen, suprofen, tiaprofenic acid, tolmetin), the process seems to take place from the triplet excited states.[20,21,35] Clear evidence for the participation of these states has been provided by laser flash photolysis studies.[21,35] Thus, picosecond laser excitation of ketoprofen in aqueous

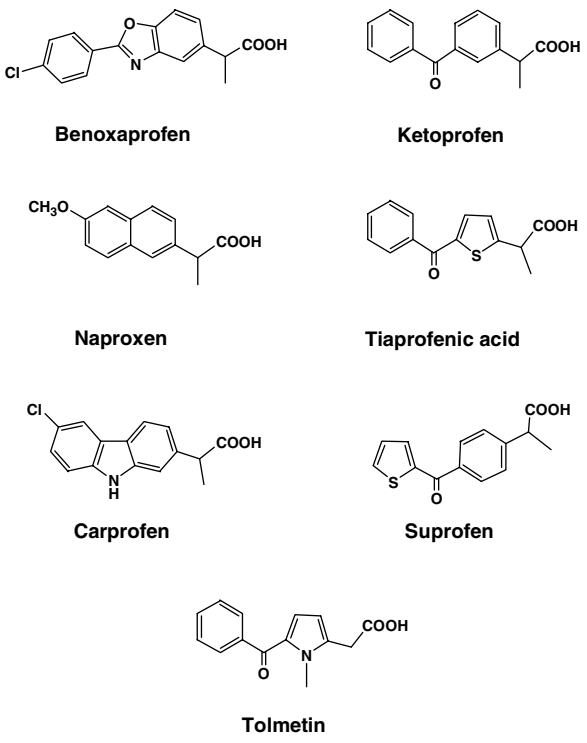


FIGURE 64.1

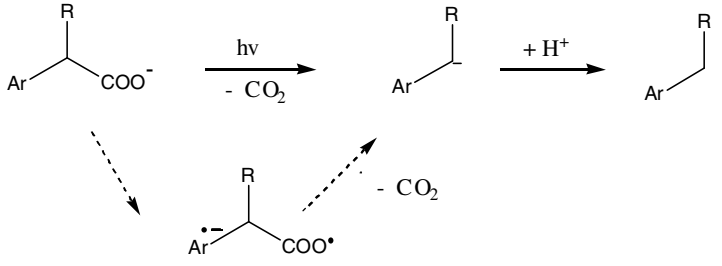
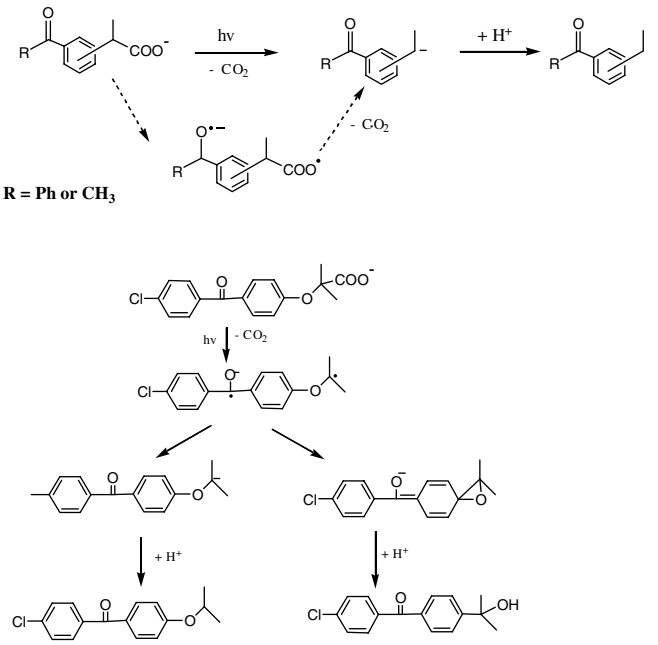


SCHEME 4 Photodecarboxylation process for benoxaprofen, ketoprofen, tiaprofen acid, suprofen and tolmetin.

solutions gives rise to its triplet excited state (λ_{max} ~525 nm, with a lifetime of ~250 ps) and subsequently to the decarboxylated ground-state carbanion (lifetime of 200 ns, λ_{max} at 330 and 600 nm). Photolysis of the carboxylate form of ketoprofen in methanol also generates the carbanion; however, a typical benzophenone-type photochemistry (ketone photoreduction) rather than decarboxylation is observed for the non-dissociated acid.[21] Nanosecond laser excitation of tolmetin in aqueous solution does not allow observation of the initial triplet excited state; instead, the triplet decarboxylated carbanion (lifetime of 6.6 μs, λ_{max} of 640 nm) that results is detected.[35] Laser flash photolysis of aqueous solution of suprofen and tiaprofenic acid in the nanosecond time scale leads to observation of the triplet excited states (transient absorption spectra with two bands at λ_{max} ~360 and 600 nm, lifetimes of 1.2 and 0.8 μs, respectively).[30,34] The decarboxylated carbanions of these drugs are also observed (λ_{max} of 380 and 600 nm for the triplet excited-state carbanions, and 380 nm for ground-state carbanions). Suprofen and tiaprofenic acid undergo photodecarboxylation less efficiently than the other benzophenone derivatives due to the activation energy of 10 kcal mol^{-1} associated with promotion of these drugs from T_1 (π,π^*) to the "reactive" T_2 (n,π^*).[30,31,34] In the cases of tolmetin and ketoprofen (typical T_1 [n,π^*]), the process



SCHEME 5

is not activated.[25,27,35] Photolysis of several other aroyl-substituted phenylacetic acids in aqueous solutions has also been reported to produce the typical photodecarboxylated compounds (see Scheme 5).[40] All the above results suggest that photodecarboxylation can be initiated by electron transfer from the carboxylate to the electron-deficient ring system. Very clear evidence for the involvement of such electron transfer reaction has been found in the photolysis of fenofibric acid in aqueous solution, where two compounds are formed by photodecarboxylation through the intermediacy of a common biradical anion generated by intramolecular electron transfer (see Scheme 5).[41,42]

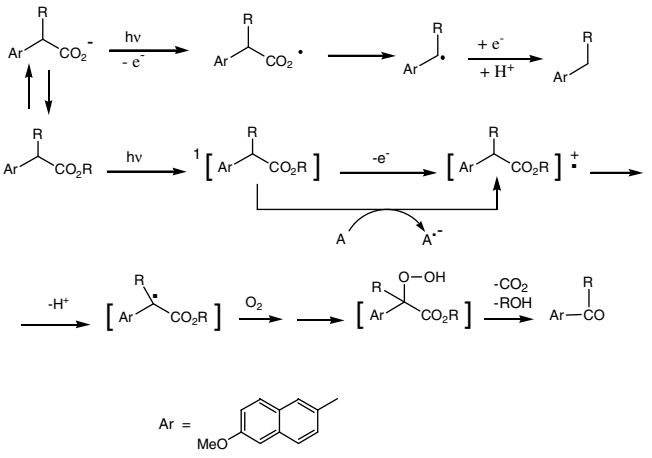
On the other hand, 2-arylpropionic acids with electron-rich aryl rings, such as naproxen, its demethyl analog 6-methoxy-2-naphthylacetic, carprofen, or its dechlorinated photoproduct, have a very low photodecarboxylation efficiency, both from the free acids and the carboxylate forms.[21,36–39] In the case of the naphthalene derivatives, decarboxylation is enhanced in the presence of oxygen and appears to proceed by photoionization of their singlet excited states (Scheme 6).

In this context, laser flash photolysis studies have provided clear evidence for the generation of naphthalene radical cations (λ_{max} of 380 and 600 nm). Addition of increasing amounts of CCl_4 in the photolysis of 6-methoxy-2-naphthylacetic acid results in fluorescence quenching, together with enhanced generation of the radical cation and a higher efficiency of the photodecarboxylation process.[39]

64.3 Photosensitized Decarboxylation

Photodecarboxylation of organic carboxylic acids in solution can be achieved via photoinduced electron transfer using electron acceptors such as aza aromatic compounds, dyes, or polycyanoaromatics as photosensitizers.[1,2,43–50] This methodology induces photodecarboxylation through generation of radical intermediates which can be useful in organic synthesis.[1,2]

Recent advances in laser spectroscopy (femtosecond time scale) have made it possible to determine the rate constants for decarboxylation (k_{dc}) and back-electron transfer (k_{bet}) in the photolysis of electron donor/acceptor salts such as methylviologen/benzilates ($MV^{2+}/Ar_2C(OH)CO_2^-$) and methylviologen/arylacetates ($MV^{2+}/ArCH_2CO_2^-$) (Scheme 7). The k_{dc} values are much higher for the benzilates ($2–8 \times 10^{11}$ s^{-1}) than for the arylacetates ($1–2 \times 10^9$ s^{-1}).[44,45] Decarboxylation of these donors is thus almost a barrier-free



R = CH_3, H and A = CCl_4, O_2 or other electron acceptors

SCHEME 7

unimolecular reaction; its real time monitoring allows direct observation of the transition state for CC bond scission.

In general, the PET decarboxylation of carboxylic acids exhibits low product selectivity, due to the subsequent radical coupling in solution; however, the PET reaction between potassium propionate and the methyl ester of *N*-methyltrimellitic acid imide is highly regioselective to the *para*-addition product. This contrasts with other intramolecular and intermolecular PET reactions of quinolinic acid imides, which do not show a high degree of regioselectivity (Scheme 8).[46]

A possible way to induce selectivity in the photodecarboxylation process could be through photosensitized reactions in the solid state. In fact, when a two-component molecular crystal of phenanthridine and 3-indoleacetic acid is irradiated at low temperature (–70°C), 3-methylindole is formed in high yield as the sole product; by contrast, when the same reaction is carried out in acetonitrile solution, four products are obtained.[47] Furthermore, irradiation of two-component molecular crystals of arylalkyl carboxylic acids with stoichiometric amounts of electron acceptor causes decarboxylative condensation between the two components with important selectivities.[48–51] Thus, irradiation of (*S*)-naproxen in a chiral crystal with 1,2,4,5-tetracyanobenzene produces a decarboxylated condensation product retaining the initial chirality.[48] Photolysis of an enantiomorphous bimolecular crystal of acridine with the R or S enantiomer of 2-phenylpropionic acid causes stereoselective condensation to give three optically active products.[49] An absolute asymmetric synthesis has also been achieved by the enantioselective decarboxylative condensation of a chiral molecular crystal formed from achiral diphenylacetic acid and acridine (Scheme 9).[50]

64.4 Summarizing Remarks

During the last decade, the major contributions to the field of photodecarboxylations have been associated with two areas: (1) the mechanistic studies to gain insight into the molecular basis of the photosensitizing side effects of non-steroidal antiinflammatory drugs, and (2) the application of electron transfer photosensitizers to achieve selective photodecarboxylation. The extensive use of time-resolved techniques (mainly laser flash photolysis), both in homogeneous solutions and in heterogeneous organized systems, has allowed us to establish the nature of the involved excited states and transient intermediates (benzylic radicals vs. anions) in the different media. Moreover, the possibility of obtaining high product yields and selectivities (including stereoselectivities) by the adequate selection of reaction conditions and photosensitizers opens the door for using photodecarboxylation as a reasonable alternative in organic synthesis.

Madurai Kamaraj University

65.1 Introduction

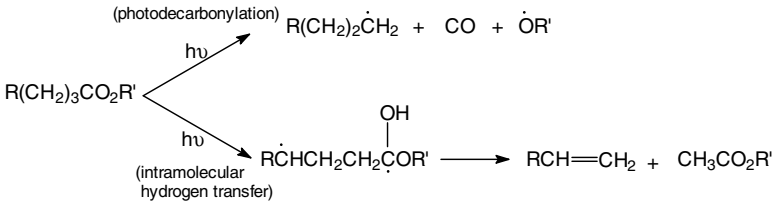
Decarboxylation, particularly by the thermal route, plays a major role in a number of biological processes such as the thiamine-mediated decarboxylation of pyruvic acid to acetaldehyde and CO_2 and the pyridoxal-phosphate-mediated decarboxylation of amino acids[1] that involves radical intermediates. Most of the earlier studies on photodecarboxylation were carried out in the gas phase and are accompanied by a large number of competing reaction channels. This factor coupled with the high energy absorption of a carboxylic group (less than 250 nm) has resulted in the photochemistry of the carboxylic group receiving less attention than aldehyde and ketones. Only recently has the reaction attracted wide academic interest and synthetic utility, and excellent reviews have appeared on this topic.[2,3]

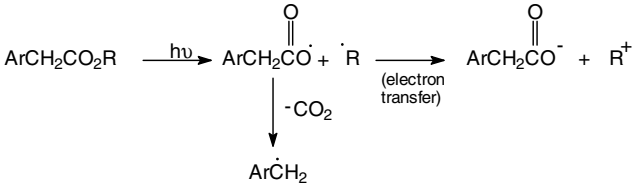
Photodecarboxylation is used to prepare radical intermediates in synthetic organic chemistry.[4] In the fields of agriculture and pharmaceuticals photodecarboxylation also plays a major role,[5–9] as many drugs, pesticides, and herbicides possessing a carboxylic group extrude CO_2 upon exposure to sunlight, leaving behind toxic components. Photodecarboxylation also has relevance in the study of techniques for solar energy conversion (photovoltaic cells), photoelectrosynthesis, and the photo-Kolbe reaction.

65.2 Mechanism

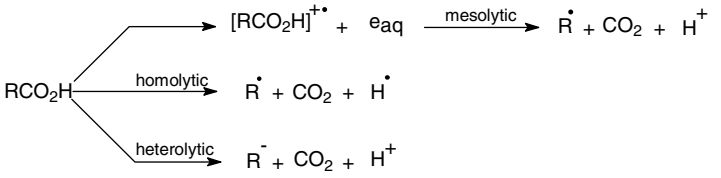
The mode of bond cleavage in carboxyl groups depends on the conditions of photolysis, and often other processes such as photodecarbonylation, intramolecular hydrogen transfer,[10] or electron transfer[11] compete with photodecarboxylation. The first two are observed in alkyl carboxylic acids and the last in aryl

0-8493-1348-1/04/$0.00+$1.50





SCHEME 1



SCHEME 2

esters (Scheme 1). Photodecarboxylation results when the CC bond α to the carbonyl group is cleaved with loss of either a proton or a hydrogen atom from the carboxyl group. Subsequent cleavage of the α-CC bond may occur via homolytic, mesolytic, or heterolytic pathways (Scheme 2).[2]

In homolytic cleavage, the OC bond in anhydrides and esters, β to the carbonyl, is cleaved first to form an acyloxy radical, which then undergoes decarboxylation via homolytic cleavage of the α-CC bond. For example, phenylacetic acid in methanol undergoes homolytic cleavage as evidenced by the identification of benzyl radicals in laser flash photolysis and formation of bibenzyl and a polyacid.[12] Homolytic photodecarboxylation is also induced by electron transfer which occurs in some aryl alkyl carboxylates in aqueous solution.[13,14] Other carboxylic compounds, such as acyl peroxides, anhydrides, and esters, also undergo photodecarboxylation via a homolytic route.[15] The first step is the homolytic cleavage of the OO bond (in peroxides) or the OC bond (in anhydrides and esters) β to the carbonyl group to form an acyloxy radical, which decarboxylates via homolytic cleavage of the α-CC bond in the second step and thus is a biphotonic process. Ibuprofen undergoes photodecarboxylation via homolytic cleavage in methanol.[8] Laser flash photolysis[12] and deuterium exchange studies[16] reveal that the photodecarboxylation of phenylacetic acid follows predominantly homolytic cleavage in solvents such as methanol.

In heterolytic cleavage, an ion pair is formed by the complete transfer of both the bonding electrons to one of the fragments. Photodecarboxylation of sodium phenylacetate in a 1% $(CH_3)_2CDOH/H_2O$

mixture or in methanol involves heterolytic cleavage on irradiation.[14] Similarly, sodium *p*-nitrophenylacetate, diphenylacetic acid, and heteroaryl acetic acids such as pyridylacetic acid undergo photodecarboxylation heterolytically.[17]

Mesolytic cleavage involves an initial photoionization leading to the formation of a radical ion, which cleaves further to give a radical and an ionic fragment.[18] 1-Naphthylacetic acid, naproxen, ketoprofen, pyruvic acid etc. are some of the well-known examples that undergo photodecarboxylation via mesolytic cleavage. Naphthylacetic acid[19–21] undergoes photodecarboxylation via mesolytic cleavage to give naphthaldehyde in aqueous medium. The ionization of the aryl portion prior to decarboxylation to form the naphthylmethyl radical has been proposed. Among the non-steroidal antiinflammatory drugs (NSAIDs), naproxen[8] and benoxaprofen[22] are found to undergo photodecarboxylation through mesolytic cleavage in a similar manner. Pyruvic acid is found to undergo photodecarboxylation via mesolytic cleavage in the presence of electron acceptors such as naphthalene.[23] Similarly, ketoprofen undergoes photodecarboxylation in the presence of methyl viologen again by a mesolytic process.[7]

Photolysis of aroyl-substituted phenylacetic acid and *p*-acetylphenylacetic acid in aqueous solution leads to efficient decarboxylation through the formation of the arylmethyl carbanion.[24] *ortho*-Acetyl- or *ortho*-benzoyl-substituted phenylacetic acids undergo efficient photodecarboxylation in benzene solution whereas the *meta*- and *para*-isomers do not undergo this process.[25] Several α-hydroxyarylacetic acids,[26,27] such as mandelic acid and benzilic acid, photodecarboxylate readily via α-hydroxyarylmethyl carbanions to give arylmethanols in high quantum yields. The photodecarboxylation of chromone-2-carboxylic acid[28] (containing a heterocyclic ring) in deaerated ethanol produces 2-(1′-hydroxyethyl)chromone by recombination of ketyl and 1-hydroxyethyl radicals formed with the release of CO_2.

The photoinduced electron transfer (PET) reactivity of phthalimidoacetic acid and the corresponding acetates has been studied in their photodecarboxylation reactions.[29] A variety of medium- and large-ring compounds are synthesised from ω-phthalimidoalkanoates using a triplet sensitized photodecarboxylation reaction initiated by intramolecular photoelectron transfer.[30] Photodecarboxylation of *N*-phthaloyl[31–33] and *N*-benzoyl esters of α-amino acids[34] has also been reported.

65.3 Photodecarboxylation of NSAIDs

The photochemistry of 2-arylpropionic acid[35] has received considerable attention in recent years as this is the basic skeleton of NSAIDs such as naproxen, ketoprofen, tiaprotenic acid, caprofen, and suprofen (Scheme 3a, NSAIDs with a 2-PPA skeleton; Scheme 3b, NSAIDs without a 2-PPA skeleton). They are the most frequently prescribed therapeutic agents for the alleviation of minor aches and pains and for the treatment of rheumatic fever, rheumatoid arthritis, and osteoarthritis.[36]

These NSAIDs are photolabile and are known to exhibit phototoxicity, causing a number of side effects such as dizziness, drowsiness, nausea, and gastrointestinal tract irritation. Many of them can also induce skin photosensitivity in some patients. In addition, ketoprofen, one of the commonly prescribed NSAIDs, produces photohemolytic activity toward red blood cells and is also capable of causing photocleavage of DNA.[37,38] The photosensitization of NSAIDs can be traced to their photochemistry and, upon excitation, decarboxylation is the major reaction pathway.[39] The aryl methyl radical can then react with molecular oxygen to yield a peroxide radical. It can also undergo coupling and other related radical reactions.

Photodecarboxylation of 2-(3-benzoyl)phenylpropionate, the ketoprofen anion, was studied[40] in water by time-resolved, laser-induced optoacoustic spectroscopy (LIOAS). The various transient species involved in the title reaction were identified and their lifetimes measured. The intrinsic photoreactivity of the 2-benzoylthiophene chromophore of the photosensitizing drug, tiaprofenic acid, was also studied.[41] The observed photoprocesses account readily for the biological photosensitization reactions such as membrane damage and protein modification. The transient photochemistry in photodecarboxylation of rufloxacin (a fluoroquinolone antibacterial drug),[42] fenofibric acid (used in the treatment of hyperlipidemia),[43] and tolmetin[44] has also been reported.

65.4. Photodecarboxylation in Confined Spaces and Induced Diastereoselectivity

The mesoporous silica FSM-16 has been found to catalyze oxidative photodecarboxylation of α-hydroxy acids and phenylacetic acid derivatives[27] to yield the corresponding carbonyl compounds. It also promotes the oxidative photodecarboxylation of *N*-acyl-protected α-amino acids to afford the corresponding imides.[45]

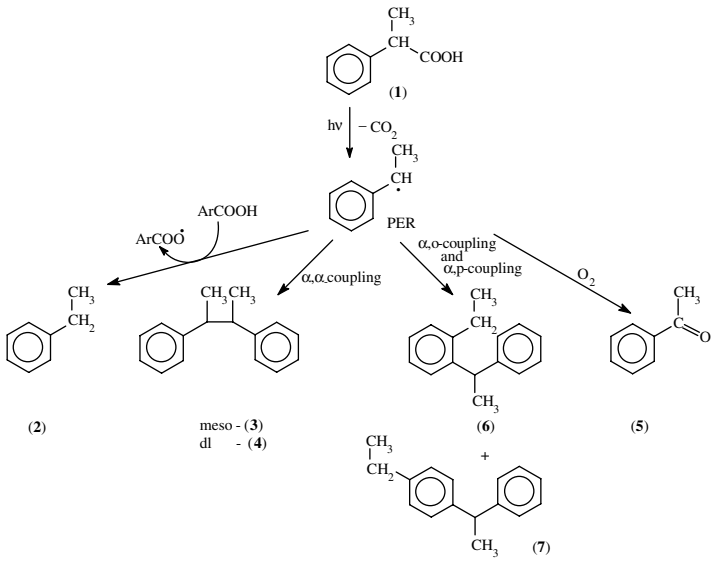
Photodecarboxylation in the presence of photocatalysts such as TiO_2 has also been studied.[46] For example, the photodegradation of (4-chloro-2-methylphenoxy)acetic acid, a herbicide, in an aqueous solution of TiO_2 involves elimination of carbon dioxide from the initially formed radical species on the catalyst surface.[46] The templating of carboxylic acids with polyethylene films has been found to enhance the photodecarboxylation at the expense of the photo-Fries rearrangement in simple aryl esters such as phenyl and 1-naphthyl esters.[47]

Irradiation of a chiral bimolecular crystals formed from acridine with diphenylacetic acid[48] and R/S-2-phenylpropionic acid (2-PPA)[49] results in enantioselective photodecarboxylation, which is followed by stereoselective condensation between the ·CHMePh radical and the hydroacridine radical species (Scheme 4, enantioselective photodecarboxylation in a chiral bimolecular crystal). The radical coupling occurs in the crystal lattice to give the optically active products II to IV. On the other hand, photolysis in solution phase results in the formation of the optically inactive II and biacridine IV.

Solid-state irradiation of two component molecular crystals of thienylacetic acids with aza aromatic compounds (acridine and phenanthridine)[50] results in photodecarboxylation and gives decarboxylated and condensation products. Two-component molecular crystals of the above azo aromatic compounds with 3-indolepropionic acid and 1-naphthylacetic acid, upon solid-state irradiation,[51] give radical intermediates via electron transfer and ultimately afford decarboxylated compounds in near quantitative yield. Irradiation of crystalline charge-transfer complexes of 3-indoleacetic acid and 2-naphthylacetic acid with 1,2,4,5-tetracyanobenzene[52] gives methylnaphthalene (decarboxylation) and naphthyl(2,4,5-tricyano)methane (dehydrocyanating condensation) in the solid state.

Photodecarboxylation of NSAIDs Inside Cyclodextrin

Photolysis of 2-phenylpropionic acid in solution (acetonitrile/methanol/benzene) under a nitrogen atmosphere produces ethylbenzene **2**, the *meso*- (**3**) and *dl*- (**4**) forms of 2,3-diphenylbutane, 1-(2-ethylphenyl)-1-phenylethane **6**, 1-(4-ethylphenyl)-1-phenylethane **7**, and acetophenone **5**, involving homolytic cleavage of the CC bond α to the carboxyl group affording 1-phenylethyl radical (PER) as the key intermediate. In solution, the radical is not stereoselective and can be converted to a mixture of *meso*- and *dl*-diphenylbutane. Acetophenone is the major product in the presence of oxygen (Scheme 5, photolysis of 2-PPA in solution).[35]



SCHEME 5

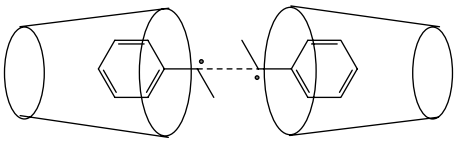


FIGURE 65.1

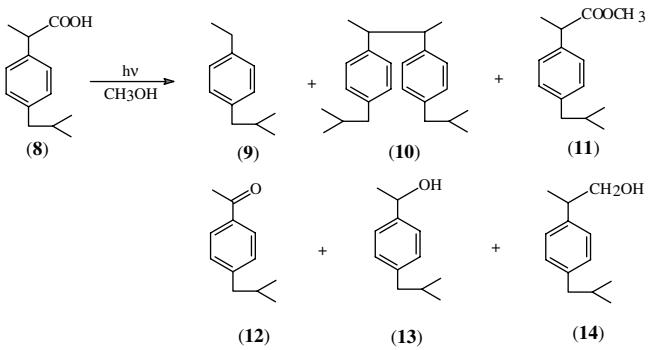
Upon complexation with β-cyclodextrin, a marked stereoselectivity is observed in favor of the *meso*-isomer **3**.[35] This stereochemical control in photodecarboxylation of 2-phenylpropionic acid is attributed to the chiral nature of cyclodextrin, which imposes translational and rotational constraints on the photochemically generated 1-phenylethyl radical. It is also reported that the lifetime of the phenylethyl radical within β-cyclodextrin is extremely long (up to several days).[53] Also, identical *meso* selectivities are achieved starting from optically active R or S enantiomers of 2-phenylpropionic acid. All these observations are rationalized by proposing that the more preferred geometrical arrangement for the approach of two phenyl ethyl radical–CD units has antiperiplanar methyl groups (Figure 65.1), and this is the precursor for the *meso*-diastereomer. CD complexation is also reported to cause considerable changes in the photochemistry of NSAIDs. For example, with ketoprofen and naproxen, the photohemolysis is inhibited by addition of β-cyclodextrin.[54] The photodecarboxylation of suprofen in the carboxylate form was studied in aqueous medium and as its β-CD complex.[55] The precursor state is the lowest (π,π^*) triplet, and in the β-CD inclusion complex an additional photoreaction involving the macrocycle as reactive species is also observed. Photolysis of naproxen in the presence of β-CD produces photodecarboxylated products with ethyl, 1-hydroxyethyl (major), and acetyl side chains (Scheme 6). Interestingly, β-CD causes a more rapid disappearance of the drug, rather than offering protection against photodegradation. The reduced photohemolytic activity in β-CD is attributed to the sequestering and stabilization of the radical intermediates by complexation.[54] The protective effect of CD is attributed to a reduction in the quantum yield of decarboxylation in CD-included drug molecules, with a resulting decrease in the amount of radical products.[56] It is also likely that cyclodextrin complexation might reduce the amount of singlet oxygen produced in the system by protecting the excited drug molecule from endogenous oxygen. Suppression of photodecarboxylation by cyclodextrin complexation is also observed in the case of ketoprofen[57] and tolmetin.[58] In their studies on tolmetin, Scaiano and Monti have suggested



SCHEME 6

that the observed reduction in biodamage cannot be entirely attributed to a decrease in NSAID photoconversion in the presence of cyclodextrin. The inhibition in phototoxicity may be due in part to cyclodextrin complexation of toxic photoproducts (rendering them inactive) and also to the possibility of cyclodextrin trapping of radical species formed during tolmetin photolysis. A decrease in photodecarboxylation and suppressed benoxaprofen-photosensitized hemolysis is also reported[59] upon CD complexation. However, recent studies on the role of CDs as phototoxicity inhibitors in drug formulation with naproxen as model systems[39] in the presence of alcohols or protein (bovine serum albumin, BSA) have cautioned that cyclodextrin complexation of drugs will be significantly weaker *in vivo* than *in vitro*. As the reduction in phototoxicity cannot be attributed solely to the ability of cyclodextrin to complex the drugs or their photoproducts, additional work both on model systems and *in vivo* seems desirable.

Diastereoselective Photodecarboxylation of 2-Phenylpropionic Acid in Zeolite Medium

2-Phenylpropionic acid loaded into various cation-exchanged Y zeolites[60] (Si/Al ratio 2.43) was irradiated as a hexane slurry, and in all the cation-exchanged zeolites a remarkable diastereoselectivity can be observed. The *dl*-2,3-diphenylbutane is the major product, with a small amount of the meso-isomer. Ethylbenzene is also formed as one of the products, and the amount of ethylbenzene increases with an increase in cation size. A decrease in cage free volume with an increase in the cation size prevents the loading of two molecules/cage that facilitates the unimolecular reaction pathway, namely, hydrogen abstraction to yield ethylbenzene. The formation of ethylbenzene may be due to the abstraction of proton by the α-methylbenzyl anion, which is likely to be formed along with α-methylbenzyl radicals. The *ortho*- or the *para*-coupled products of the α-methylbenzyl radical are not formed in the zeolite-mediated reactions.

The data in Table 65.1 show an interesting dependence of reactivity (unimolecular/bimolecular) on the loading level. With LiY, NaY, and KY, about two molecules can be accommodated inside the super cage, whereas in RbY and CsY the loading level decreases to 1.5 and 1.3, respectively. The mobility of the α-methylbenzyl radical inside the cages of LiY and NaY is also greater compared to RbY and CsY. This higher mobility inside the smaller LiY and NaY zeolites coupled with the higher loading level leads to a faster α,α-coupling with another radical as is evident by the higher percentage conversions in LiY and NaY in relation to RbY and CsY. Correspondingly, in the case of larger cations, the lower loading level and decreased mobility of the α-methylbenzyl radical promotes, in addition to coupling, significant unimolecular hydrogen abstraction to give ethylbenzene and oxidation to acetophenone.

In an oxygen atmosphere, acetophenone is the only product due to the reaction of oxygen with the α-methylbenzyl radical;[35] however, in the photolysis of 2-PPA in a zeolite slurry and as a solid complex under an oxygen atmosphere, only a minor amount of acetophenone is obtained along with considerable

amounts of the *dl*-isomer **4**. This observation is presumably due to the preassociation of the 2-PPA molecules inside the cage in such a way that the radicals are not completely free. The *dl*/*meso* ratio is very high compared to that obtained in the irradiation of 2,4-diphenylpentan-3-one (~2.0),[61] where the same α-methylbenzyl radical is identified as the intermediate.

The predominant formation of the *dl* form of 2,3-diphenylbutane over the *meso*-isomer is explained on the basis of steric and electronic factors. Binding to the walls of the zeolite cage takes place through the more polar carboxyl groups, and this pushes the hydrocarbon part into the interior of the zeolite cavity. This factor, along with the higher electrostatic field present in LiY and NaY zeolites, results in hydrophobic association between the phenyl rings of adjacent 2-PPA molecules (Figure 65.2). Thus, the preferred geometrical arrangement in zeolite cages is one in which the methyl groups are *anti*- to each other (Figure 65.2a,b). As the *syn*- arrangement of methyl groups will have considerable steric hindrance (Figure 65.2c), it may not be energetically favored. Dimeric association, which is commonly encountered in carboxylic acids, may not be significant here due to (1) the spatial constraints imposed by the cavity on the formation of the eight-membered ring in the dimer, and (2) the intrinsic polarity of the inner walls of the zeolite, which attracts the carboxyl group toward them (more pronounced in a hydrocarbon solvent, as in the present study). With RbY and CsY zeolites, a combination of lower loading and decreased electrostatic field results in a weaker preassociation (hydrophobic interaction) between the adjacent aryl rings which leads to a decrease in diastereoselective induction.

It is relevant to note here that the chemistry of benzylic radicals from the steady-state photolysis of dibenzyl ketones inside cavities of pentasil zeolites have been reported.[61,62] From a study on the lifetime of simple benzyl radicals generated inside the zeolite cages in the photolysis of phenylacetic acid using nanosecond diffuse reflectance spectroscopy, it has been concluded that the benzyl radicals decay rapidly by a coupling reaction with a second benzyl radical, and the mobility decreases within the series from LiY to CsY.[63]

Turro et al.[61,62] have reported the generation of benzyl radicals and α-methylbenzyl radicals (from diastereomeric dibenzyl ketone and 2,4-diphenylpentan-3-one, respectively) inside the cages of cation-exchanged faujasites X and Y. In the case of LiY and NaY, which show greater diastereoselectivity, the *dl*-isomer of 2,3-diphenylbutane is the major product (the *dl*/*meso* ratio for LiY is ~1.8 and for NaY is ~1.9; the ratio decreases in the case of KY) compared to that of LiX and NaX. The magnitude of diastereoselectivity is a function of the substrate configuration inside the zeolite cavity, and the observed zeolite-induced diastereoselection is more significant compared to other organized media such as micelles and

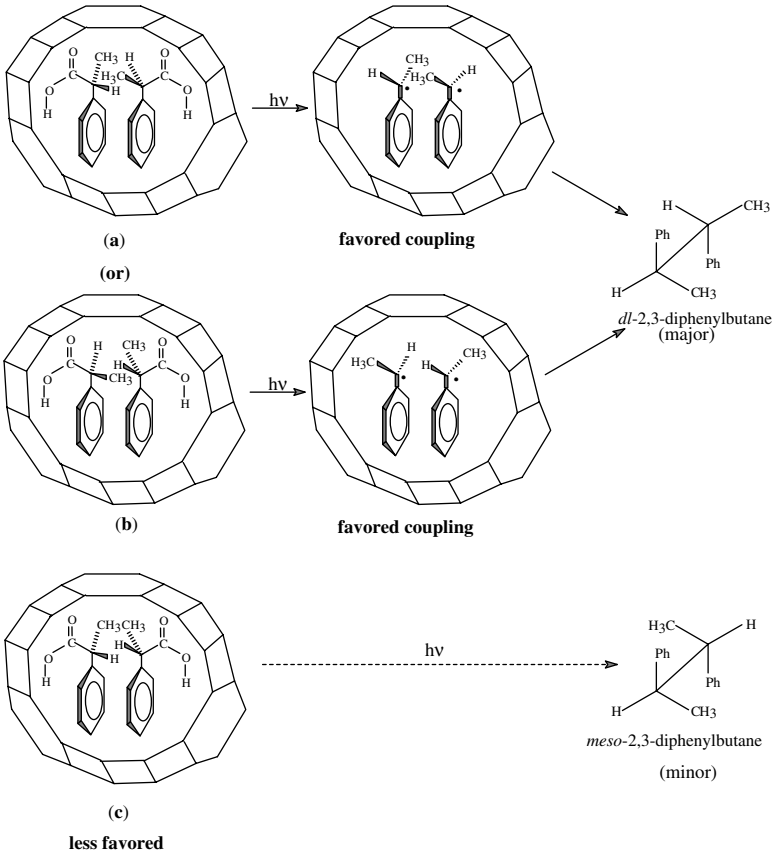

FIGURE 65.2 Packing of 2-PPA molecules inside the faujasite cage and the preferred modes of coupling of α-methylbenzyl radicals.

porous glass.[61,62] It is also interesting to note that the zeolites have preferentially retained the *dl*-isomer of both 2,3-diphenylbutane and 2,4-diphenylpentan-3-one.[61] Cozens et al.,[63] using nanosecond photolysis, have reported the direct observation of benzyl radicals inside cation-exchanged zeolites.

When the results are compared with the photolysis of 2,4-diphenylbutan-3-one (which also involves the generation and subsequent coupling of a similar α-methylbenzyl radical) the induced diastereoselectivity is very high, which may be attributed to preassociation of the 2-PPA molecules in a preferred geometrical arrangement inside the zeolite cavities (Figure 65.2). The results are also remarkable in that the dramatic diastereoselectivity is achieved from a racemic mixture of 2-PPA. A closer look at Figure 65.2 points out an interesting observation. Preassociation of a *d*-isomer with another *d*-isomer (Figure 65.2a) is sterically favored, while with an *l*-isomer it leads to considerable repulsion (Figure 65.2c). Similarly an *l*-isomer associates only with another *l*-isomer (Figure 65.2b), and this enatioselection is largely responsible for the observed zeolite-induced diastereoselectivity in decarboxylation.

It is interesting to note that, while the *meso*-2,3-diphenylbutane **3** is the predominant product in β-cyclodextrin[35] (with a hydrophobic cavity), the corresponding *dl*-isomer (**4**) is the exclusive product in zeolite cages. This striking reversal of diasteroselectivity, in comparison to β-CD, is attributed to (1) the polar environment inside the zeolite cage, wherein more efficient binding by the carboxyl moiety may be visualized, and (2) the larger cage size in the zeolite, which ensures packing of approximately two 2-PPA molecules, thereby facilitating preassociation. Thus, it is obvious that the photodecarboxylation of 2-PPA is controlled not only by the confining spaces inside the zeolite cages/cyclodextrin cavities but also by their polarities.

In a typical experiment, activated zeolite is added to a solution of the substrate in hexane and stirred overnight. The solid complex is filtered, washed with hexane to remove the substrate present on the surface, and then made into a slurry with about 5 ml of hexane. This slurry is stirred and irradiated using a 400-W, medium-pressure mercury vapor lamp. After completion of irradiation, the hexane portion is filtered. The zeolite framework is broken with ~4-*M* Hcl, and the acidic solution is extracted with diethyl ether. After drying over anhydrous sodium sulfate, the ether is removed. The hexane and the ether portions are combined and analyzed by gas chromatography using an OV-1 (10% phenylmethylsilicone) column and a flame ionization detector. A bulk solution of 2-phenylpropionic acid is irradiated, and the *dl*- and *meso*-isomers of 2,3-diphenylbutane are separated by column chromatography and identified by their characteristic nuclear magnetic resonance (NMR) spectra.[64] The NMR resonances for the *dl*-isomers are $\delta = 1.26$ (*m*, 6, $2CH_3$–), 3.14 (*m*, 2, 2CH–), and 7.27 (*m*, 10, $2C_6H_5$); for the *meso*-isomers, $\delta = 1.05$ (*m*, 6, $2CH_3$–), 2.80 (*m*, 2, 2CH–), and 7.25 (*m*, 10, $2C_6H_5$).

Photolysis of Ibuprofen and the Methyl Ester of Naproxen

Castell et al.[6] have demonstrated that the photolytic degradation of ibuprofen (2-[4-isobutylphenyl]propionic acid, **8**) in methanol results in photodecarboxylation followed by secondary reactions (Scheme 6, photodecarboxylation of ibuprofen), giving products of hydrogen abstraction, dimerization, incorporation of methanol, or reaction with oxygen (**9** to **14**). With a view to achieving induced diastereoselectivity, ibuprofen entrapped in various cation-exchanged zeolites has been irradiated, and the results of the photolyses are shown in Table 65.2. In all the cation-exchanged faujasites, a decreased photoreactivity (~2 to 3% photoconversion) is observed, indicating that the zeolite microenvironment offers better protection to this drug against the action of light. Due to an increase in the size of the arylalkanoic acid, even when a high concentration of the guest is employed, only a loading level of about one molecule per super cage is observed in all the three zeolites. This rules out the formation of a dimer. Though the irradiation is carried out under a nitrogen atmosphere, only the oxygenated products **12** and **13** are formed in small amounts. The presence of trace amounts of zeolite-bound oxygen may contribute to their formation.

Significant results obtained in photodecarboxylation of 2-phenylpropionic acid have prompted a study of naproxen. The molecular mechanism of photosensitization of naproxen (2-[6-methoxy-2-naphthyl]propionic acid, **15**) in red blood cells has been reported.[8] In aqueous buffered solutions, photodegradation of naproxen leads to decarboxylated products with ethyl (**16**), 1-hydroxyethyl (**17**), and/or acetyl (**18**) side chains (Scheme 7, photodecarboxylation of naproxen).[54,65] When the methyl ester of naproxen complexed with LiY, NaY, and CsY zeolites is irradiated as hexane slurries under a nitrogen atmosphere for 6 h, no photoproducts are formed, and the methyl ester is photostable under the conditions employed, indicating that the zeolite environment also offers better protection to naproxen against the action of light.

SCHEME 7

64.5 Conclusion

Photodecarboxylation reactions have great relevance in synthesis, mechanistic studies, and a wide range of biological applications, especially in the area of drugs such as NSAIDs. Considerable attention has been paid in recent years to utilize the confined spaces of a host matrix to control the photochemistry of these drugs with a view to improve their photostability. In many instances, a very significant diastereoselective induction is observed in these reactions, unlike the corresponding solution-phase processes. Detailed studies in cyclodextrins as host matrices have been carried out, and inorganic hosts such as zeolite can also offer a wide scope of application in this area. Further exploration in these domains will provide valuable insight and exciting prospects in a variety of areas such as drug stability, skin photosensitivity, and chiral applications in photoprocesses, as well as mechanistic insights into these processes.

The Photochemistry of Esters of Carboxylic Acids

James A. Pincock
Dalhousie University

66.1 Introduction

This topic was reviewed in 1995 in Chapter 32 of the first volume of the *CRC Handbook of Organic Photochemistry and Photobiology* and in several earlier reviews on carboxylic acid esters[1] and photodecarboxylation.[2] Reviews on phosphate[3] and sulfonate ester[4] photochemistry have also appeared. In addition, a recent review on the photochemistry of arylmethyl esters[5] and on benzylic cleavage reactions in general[6] provides useful background. Two excellent reviews[7,8] of photolabile protecting groups in general have appeared very recently, parts of which discuss the ester photochemistry covered below. Finally, the *Chemical Society Reports* continues to be a valuable resource. This chapter covers material more recent than 1995 and up to mid-2002 and, rather than being exhaustive, focuses on a few recent, well-referenced papers.

Aliphatic esters have only a weak n,π^* transition (λ_{max} 212 nm; $\varepsilon = 48\ M^{-1}\ cm^{-1}$ for ethyl acetate);[1] therefore, their photochemistry cannot be examined by the usual solution techniques that use Hg or Hg/Xe light sources. Consequently, essentially all of the photochemistry reported in any detail is that of substrates with other chromophores (almost exclusively aromatic rings) that allow reactivity of the ester functional group. A considerable amount of this research has been aimed at "phototriggers" or photolabile protecting groups, which allow spatial and temporal control of the release of the carboxylic acid functional group, often as a probe of biological pathways. The review that follows is divided into seven sections: arylmethyl esters, phenacyl esters, benzoin esters, *ortho*-nitrobenzyl esters, orthogonal deprotection of diesters, radical anions of esters generated by single electron transfer (SET), and miscellaneous.

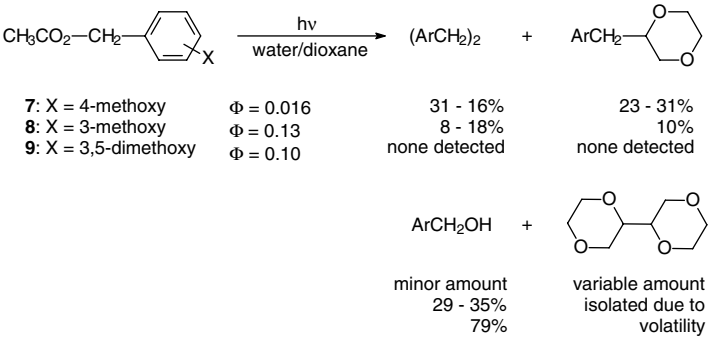
66.2 Arylmethyl Esters

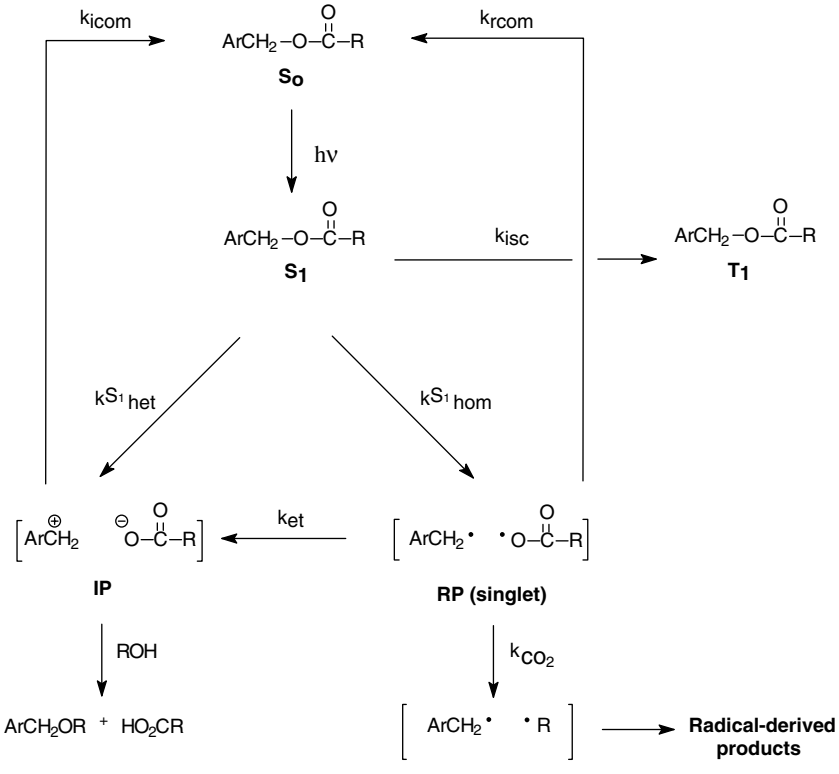
Benzylic Esters

Since the pioneering study by Zimmerman and co-workers on substituted 4-methoxy, 3-methoxy and 3,5-dimethoxybenzyl acetate in aqueous dioxane,[9] the photochemistry of arylmethyl esters has attracted considerable attention:



(66.1)

Of particular interest has been the pathway for formation of ion-derived products and the observation of high yields of these from the 3-methoxy and 3,5-dimethoxy substrates (originally called the *meta* effect but now recognized as *ortho*/*meta*). A generalized mechanism is shown in Scheme 1. This scheme



SCHEME 1

would be even more complicated if the triplet state was also reactive, but sensitization and quenching studies for 1-naphthylmethyl esters[10] and quenching studies for arylmethyl esters[11] indicate that it is not. In this scheme, no distinction has been made between the possible forms of radical (in cage, separated) and ion (contact, solvent separated, separated) pairs. Esters have the added advantage for mechanistic studies that radical pair intermediates have a built-in radical clock, the decarboxylation of the acyloxy radical (k_{CO2}). Rate constants for this process vary from around 10^6 s^{-1} for aromatic cases ($ArCO_2\cdot$)[12] to 10^9 s^{-1} for aliphatic cases ($RCO_2\cdot$)[13] and up to 10^{12} s^{-1} for cases that lead to highly stabilized radicals ($Ph_2C(OH)CO_2\cdot$)[14] after decarboxylation.

A considerable body of experimental work, mainly from our own laboratory and including product yields, quantum yields, and fluorescence studies indicates that the major pathway in ester photochemistry is homolytic cleavage (k_{hom}) from S_1 to give singlet radical pairs. We examined nine structurally different sets of substituted arylmethylesters: **1**,[13,15] **2**,[16] **3**,[16] **4**,[17] **5**,[15] **6**,[11,18] **7**,[19] **8**,[20] and **9**[21] (73 compounds in all). Decarboxylation of the acyloxy radical then competes with electron transfer (k_{et}) for formation of ion pairs. The rates of electron transfer for both substituted 1-naphthylmethyl **2** and benzyl substrates **6** follow Marcus' theory in both the normal and inverted region when correlated with the oxidation potential of the arylmethyl radical.[22,23] The *meta*-methoxy compounds give high yields of ion-derived products because the oxidation potentials of their arylmethyl radicals place them near the maximum on the Marcus plot; therefore, k_{et} is competitive with k_{CO2}. This work has been reviewed in the previous volume of this Handbook and in other places.[5,6]

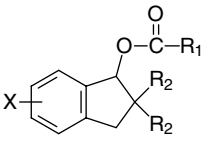
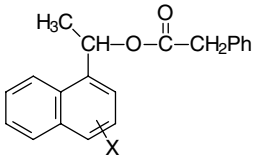
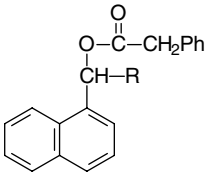
6: R = methyl, *t*-butyl
X = 4-cyano, 4-trifluoromethyl, hydrogen, 4-methyl, 3-methyl, 4-methoxy, 3-methoxy, 3,4-dimethoxy, 3,5-dimethoxy, 3,4,5-trimethoxy



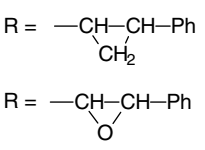
7: R_1 = methyl, R_2 = hydrogen, X = hydrogen
R_1 = *t*-butyl, R_2 = hydrogen, X = hydrogen
R_1 = methyl, *t*-butyl, R_2 = methyl, X = hydrogen,
5-methoxy, 6-methoxy

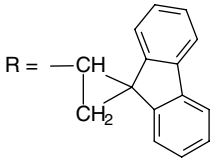


8: X = 4-cyano, hydrogen, 4-methoxy,
4,7-dimethoxy



9: R = CH_2Br, CH_2-(SO)-CH_3, CH_2-(SO)-C_6H_5



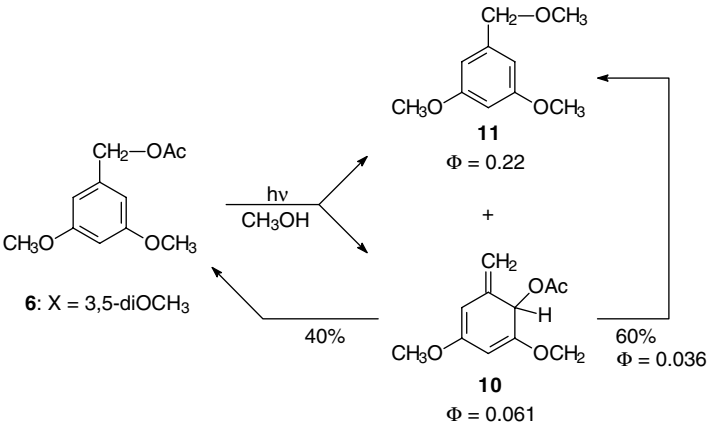


In contrast to this conclusion, high-level MO calculations by Zimmerman[24,25] suggest that ion pairs are formed directly from S_1 (k_{het}) and that this process is accelerated by *meta*-methoxy substitution. The heterolytic σ-bond cleavage proceeds directly from S_1 through a conical intersection to the ion pair. In agreement with the initial SHMO calculations,[9] the 3-methoxybenzyl cation in the excited state is more stable than the 4-methoxy one at these higher levels of theory.

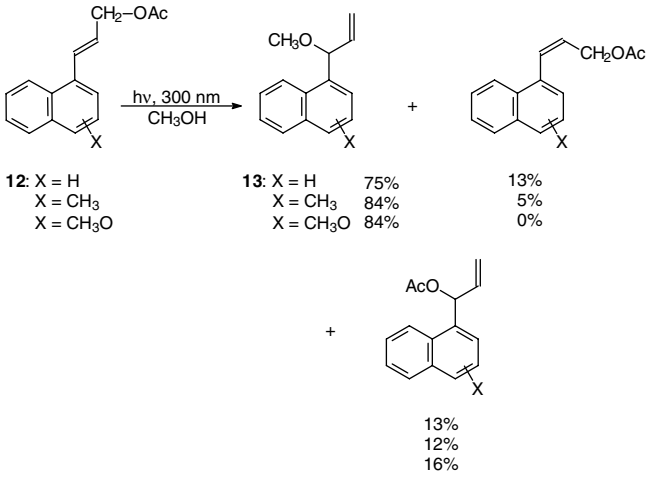
The observation that the chromophore in **6** (X = 3,5-dimethoxy) results in particularly high reactivity for σ-bond cleavage has resulted in it being advocated as a particularly useful one for photolabile protecting groups. In fact, this substrate gives a much higher yield of ion-derived product (56%) than predicted (32%) from the Marcus plot established by the remaining isomers in set **6**.[18] However, as shown in Scheme 2, the photo-Claisen type product **10** is formed as a primary photoproduct on irradiation in methanol.[26] Its half-life in methanol is only 2.7 minutes, with a 40% return to starting material and 60% to the solvolysis product **11**. The quantum yield for the formation of **10** is 0.061; therefore, the efficiency of formation of **11** via **10** is 0.036, and $(0.036/0.22) \times 100 = 16\%$ of the photosolvolysis product is formed by a pathway that does not involve direct formation of ion pairs from **6**. Therefore, at least for this substrate, the high yield of ion-derived products is a result of two pathways. A similar observation was made for diethylphosphate and triethylamine as leaving groups.

Allyl Esters

A recent report[27] on the photochemistry of the 3-(1-naphthyl)propenyl acetate derivatives **12** (Scheme 3; yields normalized to 100%) is clearly related to the arylmethyl ester reactivity. Along with rearranged acetate and *E* to *Z* isomerization, photosolvolysis in methanol results in the ethers **13**. Two observations are surprising: First, no ethers resulting from trapping of the allylic cation at the terminal end were reported, and, second, no products derived from allylic radical intermediates were observed.



SCHEME 2



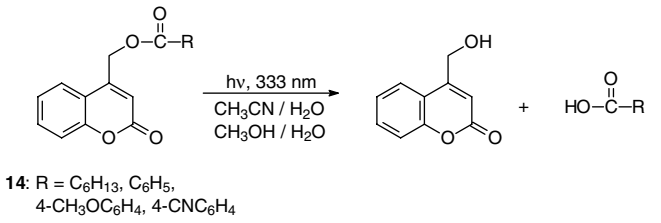
SCHEME 3

Coumarinyl Esters

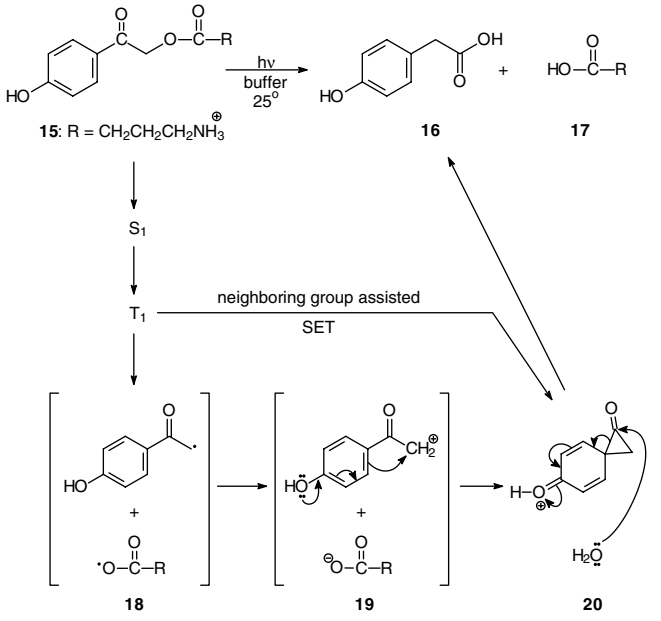
Coumarin derivatives **14** are a special class of arylmethyl compounds that are unusual in that the photochemistry yields products that are exclusively ion pair derived, Scheme 4.[28] The quantum yields for product formation increase and the fluorescence quantum yields decrease systematically as the leaving group ability of the carboxylate anion increases (lower pK_a of the corresponding acid). This suggests that ion pairs are formed directly from S_1, but the intervention of precursor radical pairs was not ruled out.

66.3 Phenacyl Esters

Considerable effort has been made recently to develop photochemically removable protecting groups based on phenylacyl (i.e., $PhCOCH_2$–) chromophores, particularly as "phototriggers" for the study of physiological pathways. The focuses of this research have been to develop systems that allow the phototrigger to be activated efficiently at longer wavelengths (>300 nm) to avoid competitive absorption by the usual biomolecules (proteins), to improve solubility and thermal ground-state stability in aqueous media, to yield byproducts that do not absorb at long wavelengths and that are also physiologically benign, and



SCHEME 4

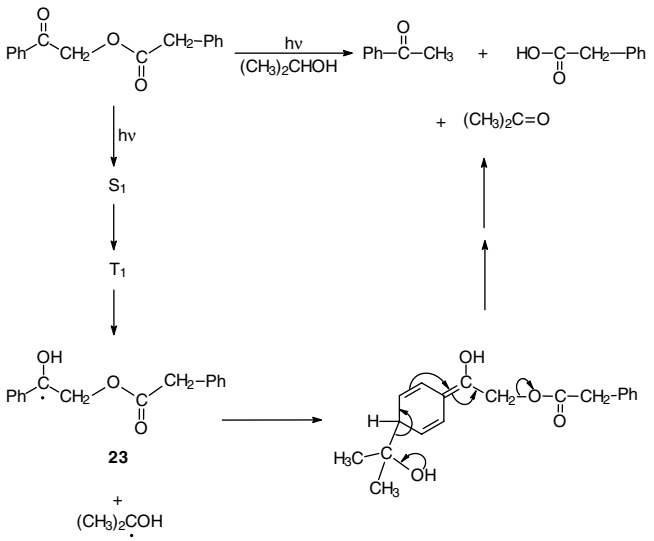


SCHEME 5

to give rapid photorelease (shorter than microseconds). The use of these new chromophores/functional groups will probably supercede the more traditional σ-nitrobenzyl derivatives, which have disadvantages because of the relatively slow deprotection rate (a ground-state process following the excited-state process) and the undesirable reactivity with biomolecules of the aromatic nitroso compounds generated. A recent manuscript describing the photorelease of a cage protein kinase is an excellent example.[29]

para-Hydroxyphenacyl

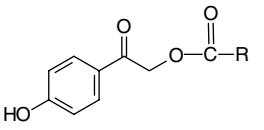
The example[30] shown in Scheme 5 is based on the preliminary research on phosphate release by the Givens group.[31] The yield of amino acid **17** on irradiation at $\lambda > 300$ nm is quantitative, and the disappearance of the precursor **15** has $\Phi = 0.35$. By Stern–Volmer quenching results, the rate constant for release from the excited triplet state of **15** was 7×10^7 s^{-1}. The ester **15** does not hydrolyze in buffered aqueous media over a period of 24 hours at room temperature. The mechanism originally proposed involves homolytic cleavage of the excited triplet state to give a radical pair **18** followed by rapid electron transfer to give the ion pair **19**. Rapid cyclization gives the spiroketone **20**, which is then hydrolyzed to the acid **16**. Because acyloxy radicals decarboxylate so rapidly (~10^9 s^{-1}, for this case), a mechanism involving radical pairs is problematic because it cannot correctly explain a high yield for the carboxylic acid released. An alternate proposal was, therefore, that the excited triplet state proceeded directly to the



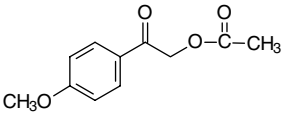
SCHEME 6

spiroketone and the carboxylate anion by electron transfer from the π^* aromatic orbital to the σ^* orbital of the reacting σ bond (neighboring group assisted SET). In either case, the role of the *p*-hydroxy group is critical. Givens and co-workers[32] have more recently extended this approach for the photorelease of small peptides (ala-ala and bradykinin) and to a longer wavelength chromophore by introduction of 3-methoxy (λ_{max} = 350 nm) and 3,5-dimethoxy (λ_{max} = 370 nm) substituents.[33]

Because the phenolic –OH group is critical for the photoactivity of these compounds, a mechanism involving excited-state proton transfer has been suggested.[34] Particularly important in this regard is the observation that, on irradiation in 1:1 D_2O–CD_3CN at 300 nm, carboxylic acids were formed in >90% yield for all members of the set of esters **21**, even though the rate of decarboxylation of the potential acyloxy radicals generated would vary over more than two orders of magnitude (~10^9 s^{-1} to ~10^{12} s^{-1}). Therefore, radical pairs are highly improbable. Also, the *p*-methoxy compound **22** gave no observable reaction under the same conditions. In this water/acetonitrile medium, the reactions only occur efficiently between pH 2 and 10. On the basis of these observations and the properties of the transients observed by laser flash photolysis (LFP), a mechanism involving excited-state proton transfer (either intramolecular [ESIPT] or intermolecular [ESPT]) in the excited singlet state was proposed. The conflict between this mechanism and the triplet-state mechanism proposed above seems to have been resolved in favor of the latter by LFP results.[35]



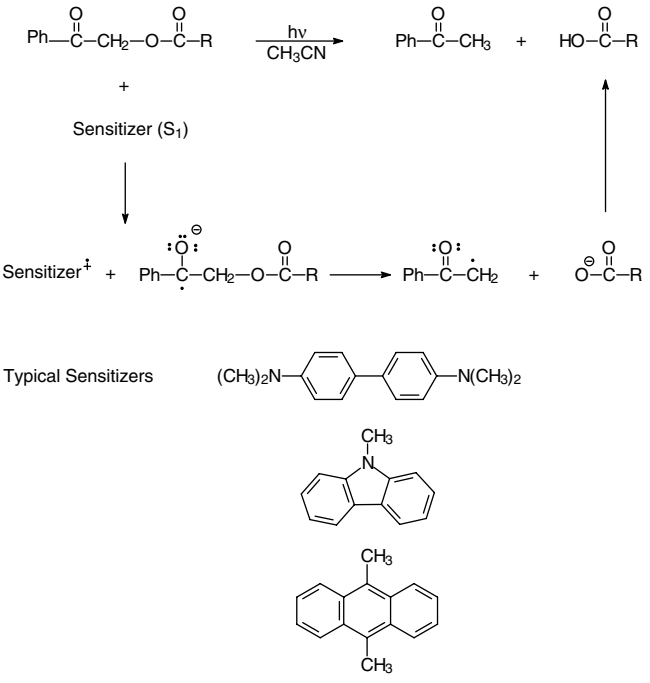
21: R = CH_3, CH_2Ph, $C(CH_3)_3$, $C(OH)Ph_2$



22

H-Atom Transfer

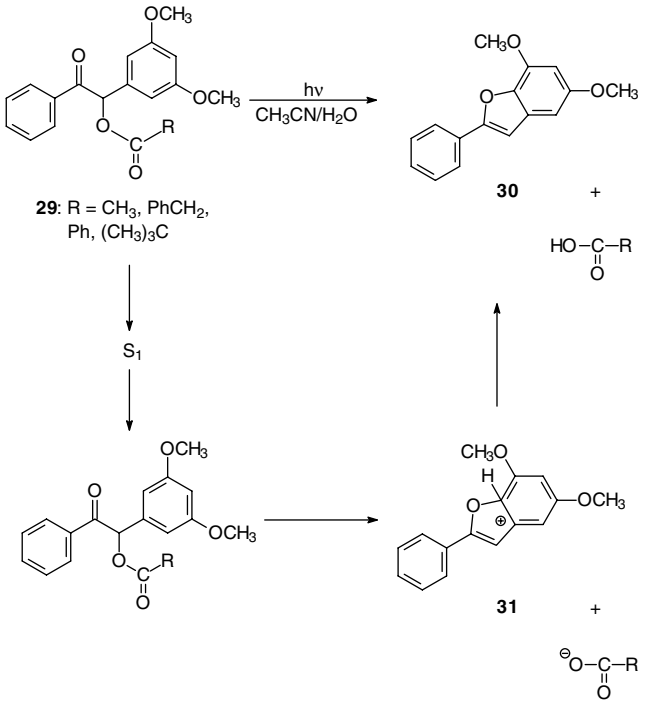
An important observation by Banerjee and Falvey[36] related to the mechanism of phenacyl photochemistry is that, in the presence of H-atom donors, the excited triplet state of the ketone chromophore is quenched to give ketyl radicals **23** clearly observed by LFP. As shown in Scheme 6, carboxylic acids are photoreleased but, again, originally as carboxylate anions, not acyloxy radicals.



SCHEME 8

their low solubility in aqueous media and hydrolytic instability. The 3,5-dimethoxy derivatives **29** (Scheme 9) have been of particular interest because, on photolysis in 1:1 water/acetonitrile, they release carboxylic acids (along with the furan **30**) in high yield with little indication of radical derived byproducts.[45] The fact that the potential acyl radicals from these substrates span several orders of magnitude in their rate of decarboxylation indicates that the product acids must be released as carboxylates. Initial suggestions that this observation was a consequence of activation of the carbon–oxygen bond to heterolytic cleavage by the *meta*-methoxy groups seem to be incorrect. A mechanism involving intramolecular charge/electron transfer in the excited singlet state is more reasonable as it takes into account the easily oxidized electron-rich aromatic ring. Rearrangement and fragmentation of this intermediate gives the carboxylate anion and **31** (detected by LFP), which is nicely stabilized as a carbocation by the methoxy groups.

Rock and Chan have reported[46]that the low water solubility of benzoin derivatives can be overcome by replacement of the methoxy groups in **29** by $-OCH_2CO_2H$ groups (**32**). Photolysis in aqueous media releases acetic acid and gives the expected furan (30% yield) along with **33** resulting from trapping of a carbocation intermediate. Products resulting from nucleophilic trapping of benzoin-ester-derived carbocations had not been reported previously. The biradical **34** in Scheme 10 has been proposed as the critical intermediate. Finally, an important recent result in benzoin photochemistry has been reported for phosphate (not carboxylate) release.[47] The LFP evidence indicates that benzoin phosphate does react from its excited triplet state. The triplet state then partitions between two pathways — cyclization to the usual benzofuran and adiabatic heterolytic cleavage of the carbon–oxygen bond of the phosphate — to give the excited triplet state of the α-keto carbocation. This species is long lived and does not react with solvent before intersystem crossing to the singlet state. This surprising result, which may be more general than previously thought, should be considered in future mechanistic proposals.



SCHEME 9

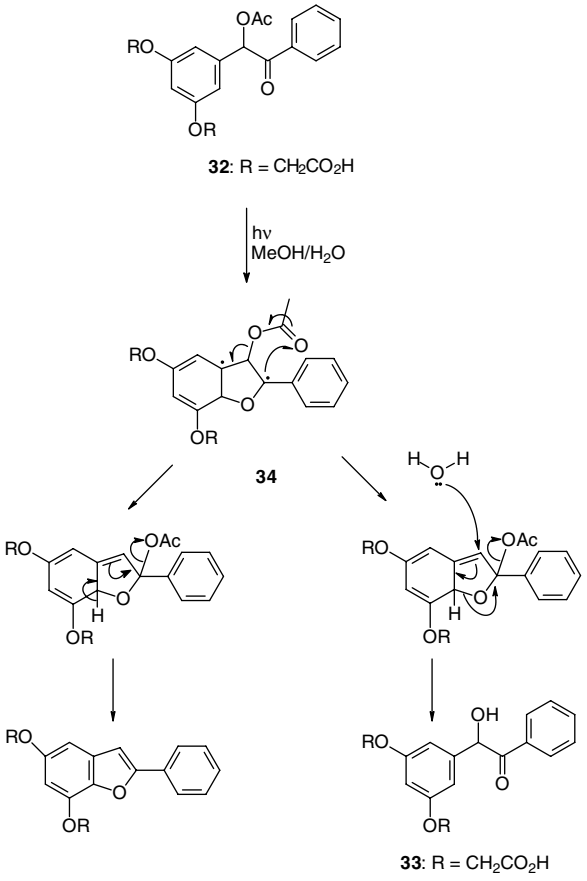
66.5 *ortho*-Nitrobenzyl Esters, Orthogonal Deprotection of Diesters

For photodeprotection, the wavelength of incident light required is often critically important in order to avoid competitive absorption by other chromophores. o*rtho*-Nitrobenzyl chromophores, particularly when methoxy substituted, allow long-wavelength/low-energy (up to 420 nm) excitation. An interesting "chromatic" orthogonal protocol for the selective deprotection of dicarboxylic acids has been developed (Scheme 11) that takes advantage of both σ-nitrobenzyl and benzoin photochemistry.[48]

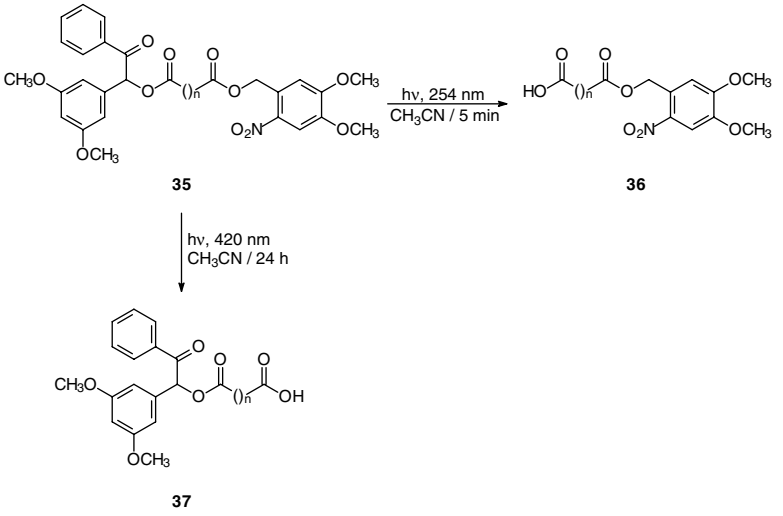
Irradiation of the bichromophoric molecule **35** ($n = 5$) in CH_3CN at 254 nm resulted in deprotection of the benzoin carboxylate to give **36** (92% yield). In contrast, irradiation at 420 nm gave *ortho*-nitrobenzyl deprotection, (**37**; 70% yield). The latter reaction occurred some two orders of magnitude more slowly. Remarkably, this same chromatic orthogonality was maintained as the linker between the two chromophores was decreased from $n = 5$ to $n = 0$. The surprising feature of this observation is that normally bichromophoric molecules rapidly transfer excitation energy to the lowest energy chromophore. Perhaps, as discussed above (Section 66.4), the higher energy benzoin excited state undergoes very rapid electron/charge transfer from the excited singlet state that is faster than the exergonic energy transfer to the *ortho*-nitrobenzyl chromophore.

66.6 Radical Anions of Esters

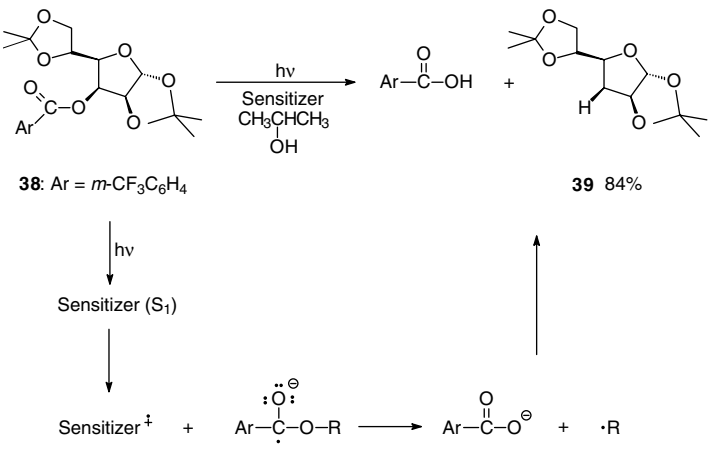
As discussed above (Section 66.3), phenacyl ester radical anions fragment readily to phenacyl radicals and carboxylate anions. The radical anions of benzoate esters also fragment to carboxylate anions and alkyl radicals, and this process is faster if the alkyl radical is stabilized (3°, benzylic).[49] This concept has been applied successfully to the deoxygenation of carbohydrate alcohols by photoinduced electron transfer (PET) sensitization.[50,51] For instance, irradiation of **38** in water/2-propanol, using a substituted



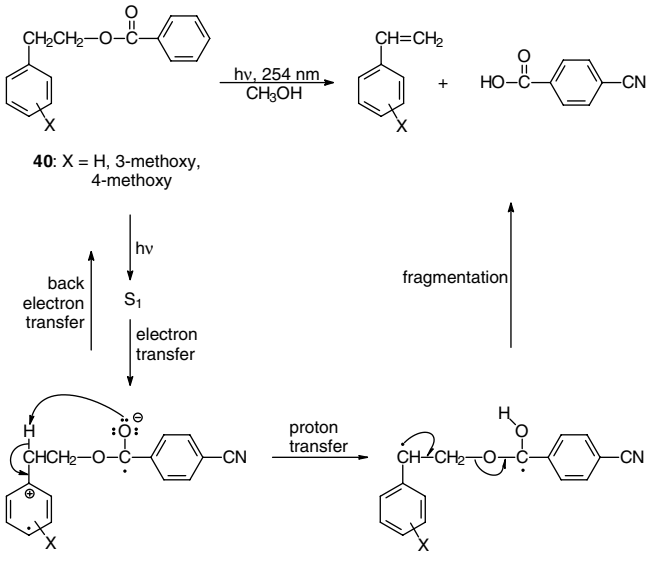
SCHEME 10



SCHEME 11



SCHEME 12



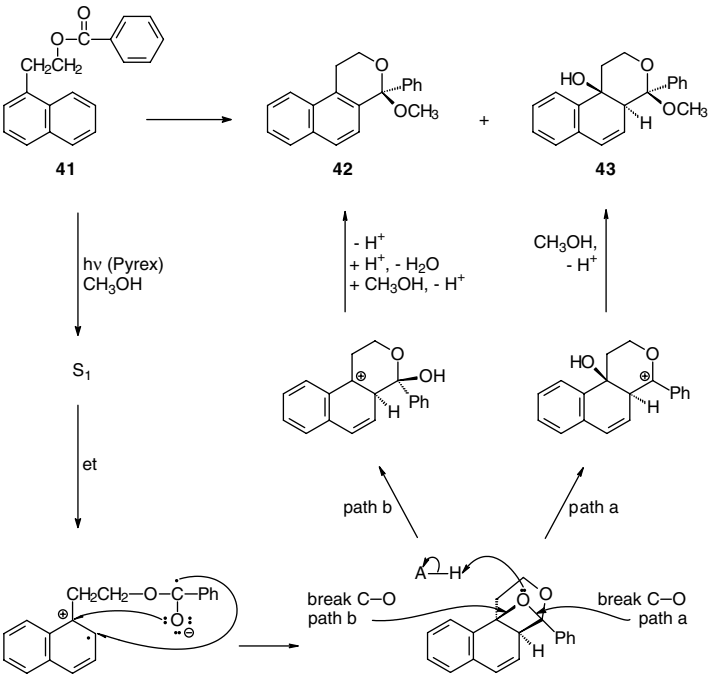
SCHEME 13

carbazole as a sensitizer, gave the deoxygenated derivative **39** (84% yield).[51] The proposed mechanism is outlined in Scheme 12.

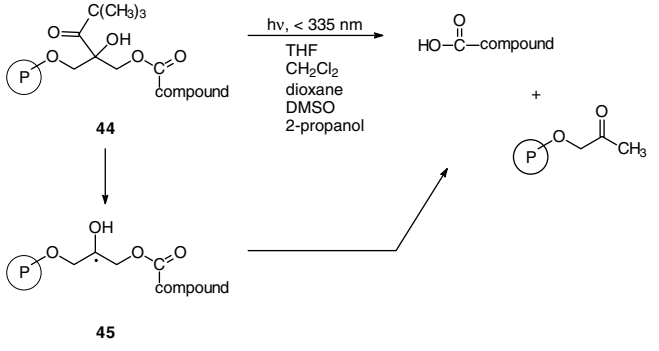
Intramolecular Electron Transfer and Norrish Type II Fragmentation

Normally esters do not undergo the classic Norrish type II reaction of aromatic ketones because their lowest energy exited state is not of the n,π^* configuration required for efficient intramolecular H-atom transfer. The reactions are known but with quantum yields less than 0.01. Recently, we have observed that the process can be 5 to 50 times more efficient if induced by intramolecular electron transfer (Scheme 13).[52]

Irradiation of esters **40** in methanol gives the styrenes and 4-cyanobenzoic acid. The mechanism proposed involves excitation to S_1 and efficient intramolecular electron transfer (as indicated by redox



SCHEME 14



SCHEME 15

potentials and fluorescence spectra), followed by proton transfer in the intramolecular radical ion pair. The driving force for proton transfer is the enhanced acidity of the arylmethyl hydrogen in the radical cation and the enhanced basicity of the carbonyl radical anion. The result is formation of the 1,4-biradical required for fragmentation. Thus, the usual H-atom transfer of the Norrish type II process occurs by sequential electron and proton transfer. The styrenes formed are not isolated in high yield because they are rapidly degraded by secondary photochemistry.

In an attempt to study these reaction at longer wavelengths, particularly for fluorescence experiments, substrates with naphthalene chromophores **41** were examined, (Scheme 14).[53] Again, intramolecular electron transfer was clearly demonstrated by fluorescence, but the products formed, **42** and **43**, resulted from an unusual [2π+2π]-cycloaddition of the ester carbonyl to the aromatic π system of the naphthalene ring. Intermolecular cycloadditions of ester carbonyls to aromatic rings are known, but only for furan.[54,55]

66.7 Miscellaneous

Deprotection of esters induced by Norrish type I has been suggested as a possible photochemical method of fragmenting a linker in solid-phase peptide synthesis (Scheme 15).[56] The linker with this chromophore cleaved more efficiently than an *ortho*-nitrobenzyl one by a factor of three to four, and, moreover, high-level conversions occurred with greater efficiency. The mechanism proposed is via Norrish type I α-cleavage of **44** at the carbonyl group of the *t*-butyl ketone. Decarbonylation gives the C2 glyceryl radical **45**, which fragments to the carboxylic acid (presumably avoiding intervention of an acyloxy radical). PTOC (pyridine-2-thioneoxycarbonyl) esters (e.g., **46**; Eq. (66.2)) are only mentioned here because, although they are not alcohol-derived esters of carboxylic acids, they have been important in both the generation and the study of reactivity of acyloxy radicals.[57,58] Rapid decarboxylation then gives the alkyl radical.

The Photochemistry of Barton Esters

Peter I. Dalko
Centre National de la Recherche Scientifique

67.1 Introduction

The third part of the 20th century witnessed a spectacular advancement in free-radical chemistry. This progress had a major impact on organic synthesis. Among the number of methods developed, one of the mildest and most flexible ways of generating "disciplined radicals" is by using thiohydroxamates, usually known as Barton esters.[1] Due to the remarkably simple experimental conditions required for both the preparation and the subsequent radical reaction and, also, to the environmentally friendly "green" aspect of this chemistry,[2] this class of compounds has received considerable interest.[3,4] The broad potential of this chemistry has been described in a number of excellent reviews, books, and chapter of books, and it ultimately found application in the synthesis of biologically relevant compounds.

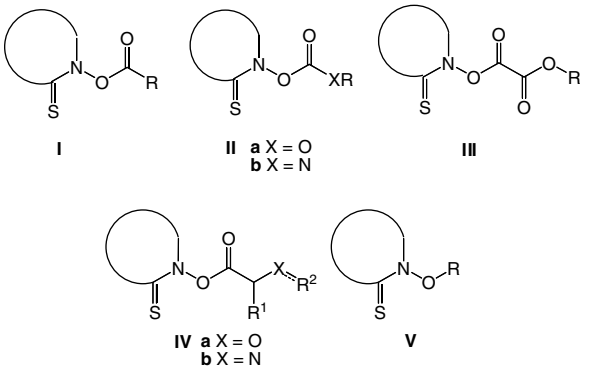
67.2 Structure and Reactivity

According to the classical definition, Barton esters are mixed anhydrides of carboxylic acids with thiohydroxamic acid such as I (Scheme 1).[5] This class of compound was originally developed to allow the transformation of carboxylic acids to a convenient source of radicals for synthetic application. Even now, they are one of the most important entries to *C*-radicals. Over time, the scope of the reaction was broadened, allowing the generation of heteroatom-centered radicals, particularly oxyl-, aminyl-, and iminyl radicals of synthetic interest. For these transformations, carbonates and carbamates (II), acetates (IV), and ethers (V) were developed (Scheme 1). Finally, oxalates (III) were used for deoxygenation of secondary and tertiary alcohols. The radical fragmentation reaction of these compounds can be carried out either by irradiation or by thermal activation. Both methods are discussed here briefly.

PTOC Esters

Among the most popular chromophores that usually offer the mildest and highest yielding radical-forming reaction is the *N*-hydroxypyridine-2(1*H*)-thione **1** (Scheme 2). It is interesting to notice the

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1

SCHEME 2

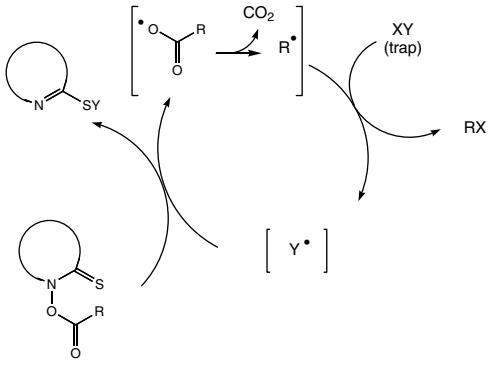
structural similarity between **1** and the *N*-hydroxy-2-pyridone **2** developed earlier by the Taylor group for photolytic generation of oxyl radicals.[6]

The free acid **1** (R = H; *N*-HPT; Scheme 2) undergoes homolytic fragmentation under ultraviolet (UV) irradiation[7] and produces ·OH radicals in aqueous media[8] as well as in organic solvents,[9] with concomitant formation of the 2-pyridylthiyl (PyS·) radical.[10] The fragmentation is pH dependent. In neutral aqueous media, photoionization occurs, generating highly reactive solvated electrons (e^-_{aq}) in a relatively efficient process ($\Phi_{e^-} = 0.1$ using $\lambda_{exc} = 308$ nm).[11] In addition to ·OH and e_{aq}^-, *N*-HPT generates two distinct thiyl radicals, an excited triplet state and an *N*-oxide radical, under various conditions. The primary homolytic process of the *N*-HPT fragmentation displays similar photochemical behavior under nonaqueous media conditions (i.e., NO bond scission generating ·OH and PyS· radicals and triplet-state formation). This fragmentation has low selectivity due to the simultaneous generation of several highly reactive species. This fact spoils the potential use of this compound as a simple photolytic source of hydroxyl radicals.

In contrast, esters derived from **1** (R = acyl; pyridine-2-thioneoxycarbonyl [PTOC] esters)[12] have been the focus of considerable attention (Scheme 3). These compounds are usually stable at room temperature or below when shielded from light and can be eventually heated up to 60 to 80°C with no special precautions taken. Compounds derived from **1** undergo radical chain reactions above ~80°C by irradiation at room temperature or even below, with a convenient light source or by ultrasound. The absorption spectra of **1** recorded between 250 and 450 nm displays two absorption bands with maxima around 300 and 375 nm in benzene (Table 67.1).[14] These bands are blue shifted in acetonitrile ($\Delta\lambda = 8$ nm). The wavelength absorbance extends into the visible range, giving the compounds a characteristic light yellow color. These broad absorption bands allow irradiation under a variety of conditions, including irradiation in the visible spectrum by using a simple tungsten tube, discharge lamp, sunlight, halogen (xenon) spotlight, or laser beam. A radical initiator is not required for this process, as Barton esters can ensure both the initiation and propagation steps.

Generation of radicals by irradiation has been proven to occur via an initial photoexcitation of the thiocarbonyl group, resulting ultimately in cleavage of the NO bond (Scheme 3, Table 67.1).[13,14] The initial homolysis gives an acyloxyl radical and the 2-pyridinethiyl radical, the latter having a long wavelength absorbance (λ_{max}, ~500 nm). No long-lived excited states are produced during preparation of the radical species.[13] The UV spectrum of the reaction is characterized by a marked negative band with a

maximum at 375 nm due to ground-state depletion resulting from the photoinduced decomposition of the starting material by NO bond cleavage and by a secondary bleaching process corresponding to the reaction of PyS$^{\bullet}$ with the ground state of the starting ester.[14] Irrespective of the R group, the quantum yield of photoinduced NO bond cleavage Φ_{NO} was found to be around 0.5.[14]



SCHEME 3

TABLE 67.1

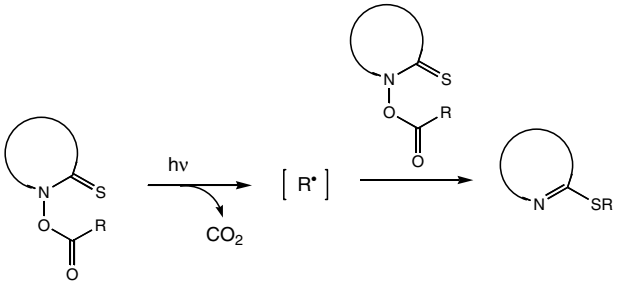
The generated alkylacyloxyl radicals are unstable under the reaction conditions and undergo decarboxylation, giving rise to the corresponding alkyl radicals almost instantly (i.e., in less than 1 ns) (Scheme 3).[15–18] In contrast, the decarboxylation of arylcarbonyloxyl or vinylic acyl radicals is reasonably slow below 100°C,[17] and the intermediate carboxyl radicals can be trapped at room temperature by electron-rich olefins such as vinyl ethers[7b,18] or alkynes.[19] In the absence of added trap, such radicals eventually afford acid anhydrides. When decarboxylation occurs, excess of good trap XY can immediately react with the carbon radical R$^{\bullet}$, resulting in formation of the trapped product RX and the chain carrier radical Y$^{\bullet}$. The radical chain sequence is perpetuated by the addition of radical Y$^{\bullet}$ to the sulfur center of the starting thione, thus reforming the acyloxyl radical. The chain length varies sensitively with the reaction conditions and typically is 10 to 30, although it can be as high as 60 (as observed in halogenation reactions) or 600 (as seen in phosphonylation reactions under photolytic conditions).[3g] The efficiency depends on the concentration and reactivity ratios of the Barton ester and of the trap XY.

The driving forces for the reaction are the formation of a strong C=O bond at the expense of the weak thiocarbonyl bond and the aromatization of the heterocycle. Compounds having non-aromatizable cycles undergo thermal rearrangement reluctantly, although the UV photolysis remains efficient in generating radicals.[20] The fragmentation reaction also makes the reaction favored from an entropy point of view, and the loss of CO_2 renders the entire process irreversible. The chain propagation is assured by the affinity of the thione toward sulfur-centered or, alternatively, tin- or silicon-centered radicals and the weakness of the NO bond.

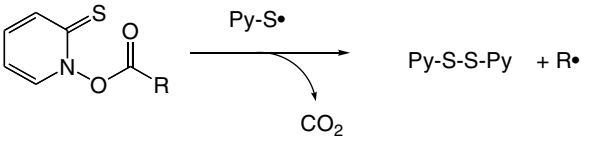
In the absence of external traps, Barton esters undergo decarboxylative rearrangement in which the formed carbon-centered radicals add to their precursor, affording alkyl 2-pyridyl sulfides (Scheme 4).[21a] Competitive

studies have determined rate constants of 2×10^6 (50°C) and 4.6×10^5 (30°C) M^{-1} s^{-1} for the addition of primary and tertiary carbon radicals to their precursor, respectively. This is the simplest and most characteristic reaction of this type of chemistry. Even in more complex reactions and independently of the nature of the radical trap used, this rearrangement occurs as a competing background reaction. The rearrangement becomes dominant when the trapping reaction (by an olefin, for example) is otherwise too slow.



SCHEME 4

In some cases, the reaction affords a non-negligible amount of dipyridyl-disulfide and dialkyl dimers, particularly when the photolysis is run at the lower temperature of 80°C. One explanation can be the recombination of the thiopyridyl radicals and the stabilized (alkyl) radicals, respectively, suggesting that this process competes or even supplants the chain pathway at low temperature.[22,23a] Evidence was found, however, that bisulfide formation is rather the consequence of chain reactions of the type depicted in Scheme 5, in which the PyS· reacts with its precursor and leads to further production of R·.[14] Arguably, this process is even more dominant where the steady-state concentration of the radicals are lower and the concentration of the starting ester is higher. Yet, increasing the temperature (to 110°C) is sufficient to simplify the reaction course to the normal radical chain process.[22]



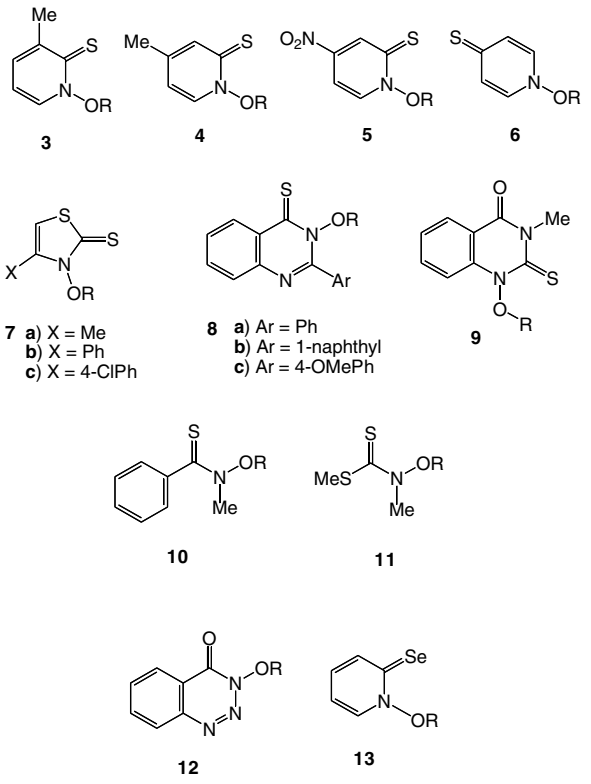
SCHEME 5

Related Thiohydroxamate Systems

In the wake of efficient free-radical chemistry by means of PTOC esters, a number of related hydroxamate systems have been devised and tested (Scheme 6).[18a,20–24,61] The influence of the substitution pattern of the thiopyridone moiety (**3** to **6**) as well as the nature of the heterocycle (**7** to **9**) and the effect (absence) of the aromatizable cycle (**10** and **11**) have been addressed.[18a,20,23,61] Related compounds having no thiohydroxamate backbone, such as compound **12** and the seleno-derivative **13**, have also been prepared.[21,23a]

Similar to esters derived from *N*-hydroxypyridine–2(1*H*)-thione **1**, the *O*-esters of 4-methyl and 4-phenyl *N*-hydroxythiazoline-2-thiones (**7a** and **7b**) undergo smooth thermal decarboxylative rearrangement in refluxing toluene but require UV photolysis at ~320 nm (medium mercury pressure) for the photochemical reaction.[18a,61]

In contrast, the 2-substituted *N*-acyloxyquinazoline-4-thione derivatives **8a–c** are highly light-sensitive products and rearrange easily. Varying the substituents on the aromatic side chain of **8**, however, changes only ε, but does not shift λ_{max}, which is around 356 nm.[23a] The reactivity and light sensitivity of these compounds are also reflected in their half-lives. The half-life of the photolytic rearrangement (tungsten light, 300 W) of **8a** is 14 s, the shortest ever observed in this type of Barton chemistry. For comparison,



SCHEME 6

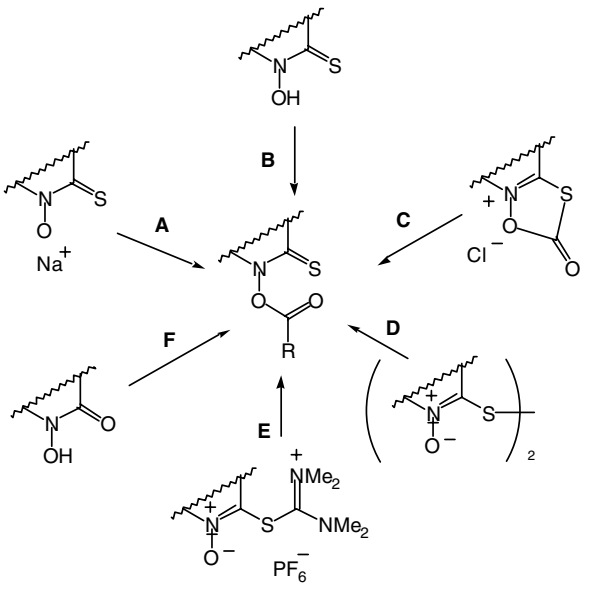
the half-life of compound **12** is 19 s under similar conditions, which is one magnitude shorter than half-lives usually observed for thiopyridone derivatives such as **1** (200 s). Although compounds **3** to **7** can be stored at –25°C in a dark vial without decomposition, **8** is too unstable at this temperature and rearranges within a few hours to the corresponding thioether.

The thione function of the Barton ester **1** can be replaced by other elements such as Se (**13**) without significant alteration of the reactivity (Scheme 6).[21] Although the starting esters are more air sensitive than the analogous *N*-hydroxypyridine 2-thione derivatives (**1**), the method has some advantages; for example, the adducts of the free-radical fragmentation reactions of *N*-hydroxypyridine-2-selenone derivatives **13** (i.e., alkylpyridylselenides) can usually be more easily modeled and transformed to other chemical functions than thioethers.

Recently, solid-supported reagents were proposed.[24] This technique may allow easier separation of the radical end product and also open the way for automated parallel synthesis of products arising from CC, CN, and CO bond-forming radical chain reactions.

Preparation of Barton Esters

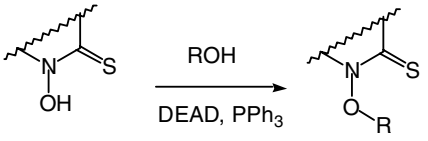
In addition to the general usefulness of this class of compounds, the popularity of this chemistry is largely due to the facile preparation of the starting materials (Scheme 7). The most straightforward method of preparation of Barton esters of types I to IV is acylation by activation of the corresponding carboxylic acid (paths A and B). Accordingly, the hydroxamic acid sodium salt can be *O*-acylated with the acyl chlorides or, alternatively, the free hydroxamic acid can be condensed with primary carboxylic acids in the presence of *N,N′*-dicyclohexylcarbodiimide and dimethylaminopyridine (DMAP).[25] Likewise, condensation of the free thiohydroxamic acid or the corresponding sodium salt with the mixed anhydride formed from the acid and isobutyl chloroformate in the presence of *N*-methylmorpholine has proven to



SCHEME 7

be the most useful method in the activation of amino acids.[26] In some cases, this activation fails, but addition of phosphonic acid anhydride (PPAA) to a solution of thiohydroxamic acid, acetic acid, and pyridine or DABCO® may overcome this difficulty.[27] A conceptually different approach is when the thiohydroxamic acid is activated and condensed with the carboxylic acid. Cyclic carbonate salt (path C), which is prepared from 2-mercaptopyridine-*N*-oxide with phosgene, was used to prepare *O*-acyl thiohydroxamates. Also, the use of disulfide in the presence of tributylphosphine is a particularly mild activation methodology that can be used in connection with easily epimerizable substrates (path D).[28] The use of HOTT (*S*-(1-oxido-2-pyridinyl)-1,1,3,3-tetramethyl thiouronium hexafluorophosphate) salt is a recent alternative. The activated ester is a stable crystalline solid, which allows esterification even with hindered carboxylic acids (path E).[29] A third type of approach consists of transforming the *O*-acyl hydroxamates to *O*-acyl thiohydroxamates by Lawesson's reagent, although this method is reputedly low yielding (path F).[30]

The preparation of *N*-alkoxy derivatives (i.e., type V) is somewhat more difficult. They can be prepared by treatment of the sodium salt of 2-mercaptopyridine-N-oxide with 1 molar equivalent of the suitable alkyl halide in DMF at 80°C.[80] By using this coupling reaction, alkylation occurs at sulfur rather than at oxygen, and the reaction affords pyridyl sulfides as the major product. In such cases, the Mitsonobu method using diethyl azodicarboxylate and triphenylphosphine may provide a solution (Scheme 8).[31]



SCHEME 8

67.3 Elementary Reactions

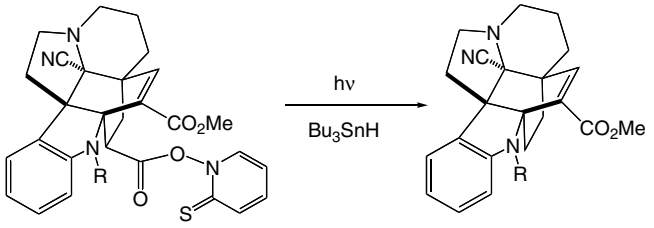
Formation of C-Centered Radicals

Barton esters were used in a number of standard and also in more complex free-radical transformations including substitution, fragmentation/elimination, and addition reactions. Some representative examples are collected in the following sections.

Free-Radical Substitution Reactions

Reductive Decarboxylation

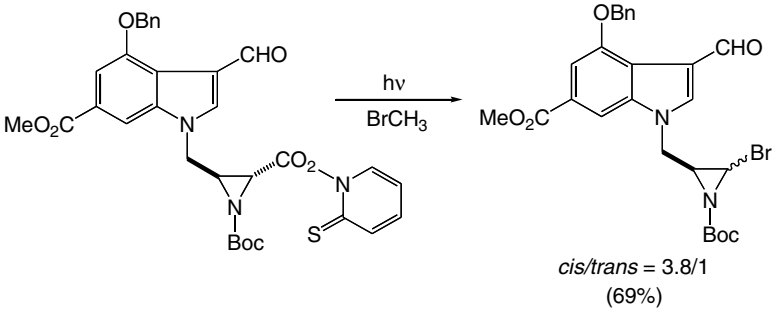
The photolysis or thermolysis of *O*-acyl-thiohydroxamates in the presence of appropriate H-donors gives rise to reductive decarboxylation via a free-radical mechanism. Hydrogen donors can be tin hydrides such as Bu_3SnH or Ph_3SnH, silicon hydrides such as $(TMS)_3SiH$, or more generally thiols such as Me_3CSH or PhSH. The general usefulness of the reaction has been validated in a number of syntheses.[32] The scope of the reaction is illustrated in Scheme 9, which shows the reduction of a key intermediate in the synthesis of the (±)-kopsidasine.[33]



SCHEME 9

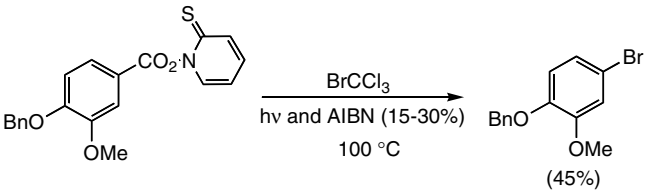
Decarboxylative Halogenation

The free-radical halogenation reaction using Barton chemistry has proved to be particularly mild and selective.[34–36] The radical chain is relatively long in the case of bromination (up to 60) by using $CBrCl_3$. Halogen donors can be CBrCl3, CCl4, CH3I, or CHI3. Scheme 10 shows decarboxylative halogenation on the aziridine cycle in the synthesis of the antitumor agent FR-900482;[35] it is worth pointing out the chemoselectivity of the transformation and the absence of the intramolecular alkylation reaction in the presence of activated indole.



SCHEME 10

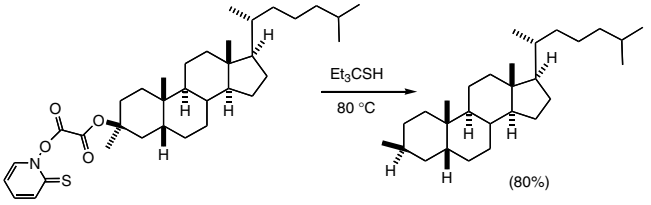
Aryl carboxylic acids can be halogenated conveniently under free-radical conditions.[34a–c,36] This transformation offers an alternative to the Hunsdiecker reaction. Under the classical conditions, the substrate undergoes a parasite electrophilic (Friedel–Crafts) halogenation reaction, which is translated in decreased yields. The radical variant of this transformation allows the use of very strong electrophiles and can be performed in the absence of heavy metals. The reaction is performed at high temperatures (~100 to 130°C) in order to favor the unimolecular decarboxylation step of the intermediate acyloxyl radical. Even under such drastic conditions, the sluggish decarboxylation may hamper the efficiency of the radical chain process, causing a buildup of ester concentration. The addition of external initiator such as AIBN may circumvent this difficulty by increasing the number of radical chains in operation (Scheme 11).



SCHEME 11

Deoxygenation of Tertiary Alcohols

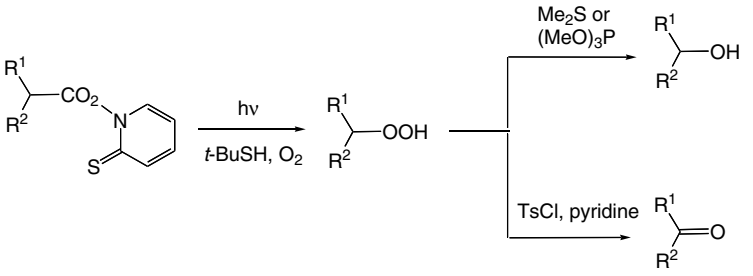
A conceptually different fragmentation reaction is the homolytic fragmentation of mixed oxalate esters such as III.[37] This reaction offers an alternative to the more frequently used Barton–McCombie deoxygenation reaction.[38] The fragmentation requires thermal activation. Reactions produced by using tertiary alcohols as substrates are usually performed in refluxing benzene and are heated in PhCl (132°C) for deoxygenation of secondary alcohols. Deoxygenation of tertiary alcohols is of interest when the Barton–McCombie reaction offers only limited utility due to competing Tsugaev olefination reactions. The intermediate transient free radical can be reduced in the presence of hindered H-donors, such as 1,1-dimethylethane-thiol or, better, 1,1-diethylpropane-thiol, or alternatively can be captured by simple Michael acceptors (Scheme 12).[38] The corresponding alkyl halide can be obtained when the reaction is carried out in refluxing carbon tetrachloride.[39]



SCHEME 12

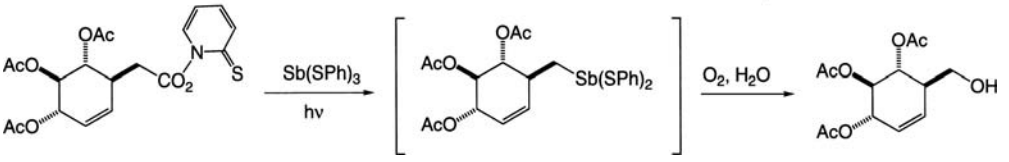
Free-Radical nor-Hydroxylation and Peroxide Formation

Basically, two standard methods are used to obtain nor-hydroxy or hydroperoxy compounds by free-radical decarboxylative fragmentation of Barton esters, either under photochemical or thermal conditions. The trapping of the intermediate radicals by triplet oxygen (bubbling) is a simple reaction both from a mechanistic and preparative standpoint (Scheme 13).[41] The reaction gives rise, in the presence of *t*-butyl-mercaptan, to the corresponding hydroperoxides. The kinetic basis of this reaction is the fact that the capture of the molecular oxygen is some ten thousand times faster than the competitive hydrogen atom abstraction from a thiol. The hydroperoxide can be isolated or alternatively can be transformed either into alcohol by using reductive work-up[41] or can be transformed into a ketone in the presence of TsCl and pyridine (Scheme 13).



SCHEME 13

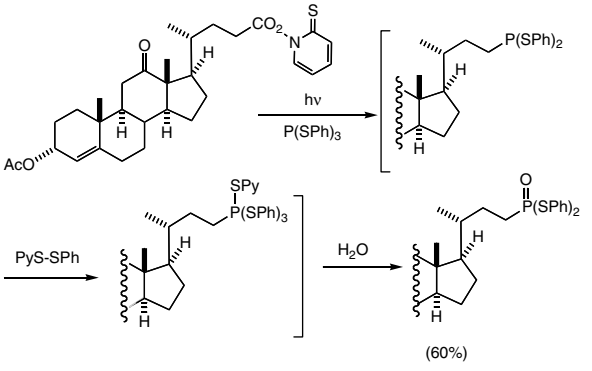
The nor-hydroxylation reaction by using *tris*(phenylthio)antimony was developed later.[42] In this reaction, the organoantimony reagent traps the intermediate free radical. The formed organoantimony derivative is air sensitive and undergoes oxygen insertion into the C-Sb bond in the presence of air. The corresponding alcohol is obtained after aqueous hydrolysis. Scheme 14 is represents the synthesis of a carbocyclic analog of glucose.[43]



SCHEME 14

Decarboxylative Phosphonylation

Analogous to the free-radical hydroxylation using *tris*(phenylthio)antimony, the trapping of radicals derived from *O*-acyl-thiohydroxamates with *tris*(phenylthio)phosphorous proceeds via a free-radical chain process (Scheme 15).[44] The formation of the thiophosphonate end product is the result of a consecutive rearrangement of a pentavalent intermediate under the reaction condition and hydrolysis under aqueous work-up.

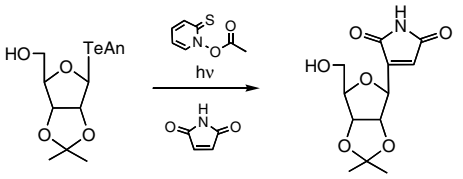


SCHEME 15

A conceptually different and even more elegant method was to convert carboxylic acids into phosphonates by the use of elemental white phosphorous (P_4) as a trap.[45] The reaction can be initiated by light in a CH_2Cl_2/CS_2 binary mixture or in the dark by traces of oxygen by using tetrahydrofurane (THF) as solvent. Oxidation of the intermediary products provides a convenient synthesis of phosphonic acids.[43]

Substitution on Selenium, Tellurium, and Boron

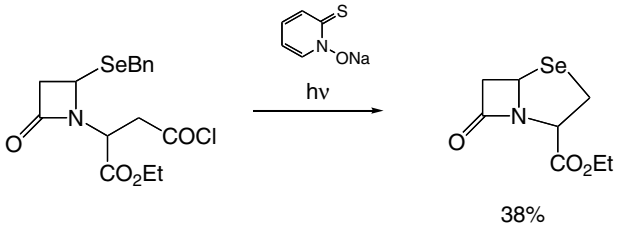
Aryl-tellurides undergo radical fragmentation reactions in the presence of methyl radical generated by photochemical decarboxylation of *O*-acetyl thiohydroxamate.[46] The driving force of this reaction is the formation of the relatively strong methyl-tellurium bond at the expense of the R-tellurium bond. Conventional radical traps can react with the formed alkyl radical. Scheme 16 shows an application of this reaction in the synthesis of *showdomycin*.[46a]



SCHEME 16

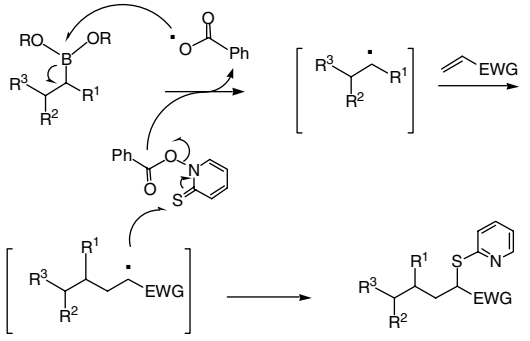
Another application concerns the preparation of selenides and tellurides from diaryl diselenides[40] or ditellurides.[47] While selenide formation is carried out in refluxing toluene by using a large excess of diselenides, diaryl ditellurides give the best results by utilizing visible irradiation at 35°C. Aryl, benzyl, methyl, and dicyanogen selenides can be prepared in this way.

The substitution reaction can also be carried out under intramolecular conditions.[48] Scheme 17 illustrates synthesis of the selenopenam. When a solution of the acid chloride in benzene was slowly added to a water-cooled, irradiated (250-W tungsten lamp) suspension of the sodium salt of *N*-hydroxypyridynethione in benzene, the selenopenam analog was isolated in 38% yields as a 7:3 mixture of diastereoisomers.[48a]



SCHEME 17

The use of PTOC esters under photochemical conditions offers a logical solution to the lack of reactivity and to the chain propagation problems, usually encountered in free-radical fragmentation of organoboranes (Scheme 18).[49] In the postulated mechanism of the reaction, the formed arylcarbonyloxyl radical[49b]



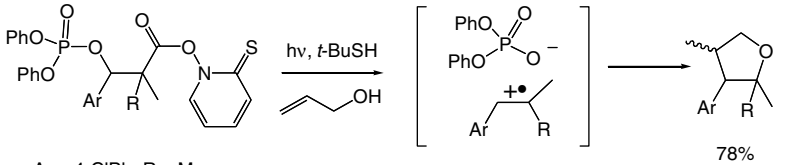
SCHEME 18

or eventually alkoxy radical[49c] reacts with the boronic ester, resulting in selective fragmentation of the weak B-alkyl bond (Scheme 18). Best results were obtained by using catechol boronates, with $(RO)_2$ = catechol. Under these conditions, the alkylation reaction can be extended to a seemingly unrestricted array of Michael acceptors.

Free-Radical Fragmentation/Elimination Reactions

Homolytic vs. Heterolytic Fragmentation Problem of the Transient Radical

When a radical is generated in a position adjacent to a homolytically easily fragmenting function (such as a thioether, nitro-group, halogen, epoxide, or other strained cycles), the radical intermediate can be stabilized by fragmentation and may evolve toward the formation of olefins.[50] In some cases, the dissociation of the radical intermediate occurs by a heterolytic path, giving rise to radical ionic intermediates. This radical/polar crossover sequence occurs in the fragmentation of β-phosphatoxyalkyl radicals. Because of the biochemical relevance of this reaction and because of the synthetic/mechanistic potential of this transformation, the study of β-phosphatoxyalkyl radicals has moved into the spotlight. The intermediate radical may evolve toward either the elimination or phosphate-migration product.[51] Dissociation occurs with the formation of a radical-cation intermediate that can be intercepted by conveniently chosen nucleophiles. Scheme 19 illustrates a short application in the synthesis of substituted tetrahydrofurans.[52]



Ar = 4-ClPh; R = Me

SCHEME 19

Photoinduced Nucleic Acid Cleavage

Hydroxyl radicals are known to cleave DNA in a variety of ways, including direct hydrogen atom abstraction from the backbone and nucleobase modification. One of the main H-abstraction pathways occurs by generating nucleotide C4′ radicals. This transformation is implicated in the cleavage of DNA by antitumor antibiotics such as bleomycin, a process that is blamed for related DNA degradation reactions under anaerobic conditions. In these reactions, the C4′ radicals formed are thought to undergo initial heterolysis, producing enol-ether radical cations and phosphate anions.[53] Evidence of heterolysis of C4′ radicals has been reported by the Giese group.[54,55] As was discussed earlier, the heterolysis produces a contact ion pair (CIP) that can collapse back to a radical or solvate to give a solvent-separated ion pair (SSIP) evolving toward the diffusively free species.[56]

Such "artificial" photonucleases can be generated by UV excitation of *N*-hydroxypyridinethiones (*N*-HTP) **1** and **6** (R = H) and *N*-aroyloxypyridine-2-thiones (**1**, R = $ArCO_2$), which can photocleave DNA through release of hydroxyl or aryloyloxyl radicals, repectively.[7,10,11,14,57–59] Some more complex structures based on Barton esters were also prepared. Recent efforts are focused on combining these highly efficient DNA-cleaving families with an intercalative moiety (Scheme 20).[60]

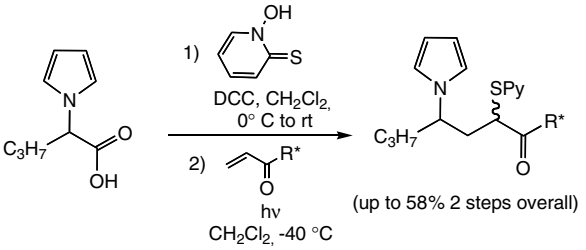
Y = H, F, Cl, CH_3, OCH_3,

SCHEME 20

Free-Radical Addition Reactions

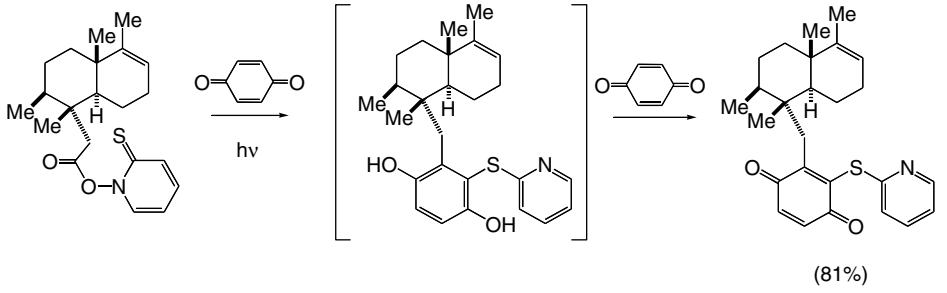
Alkylation Reactions

Carbon-centered radicals generated from **1** add preferentially to electron-deficient olefins in a regioselective manner.[61,62] The reaction follows the classical trend observed for free-radical reactions (Scheme 21). A characteristic feature of this reaction is the incorporation of a thiopyridyl unit in to the β-position. This bonus reaction may open the way for further functionalization of the molecule. Eventually, the thiopyridyl moiety can be removed by using Zn/acetic acid,[63] $NiCl_2/NaBH_4$ or Raney Ni,[64] Na_2Te reduction,[63f] catalytic hydrogenation over Pd/C, or by reductive cleavage of the corresponding pyridyl sulfone in the presence of SmI_2.[49a] Activated terminal alkenes (e.g., β-unsubstituted Michael acceptors) afford moderate to good yields in intermolecular alkylation reactions. A great variety of activating groups, such as ketones, esters, amides, phosphonates, sulfones, nitriles, and nitro compounds were tested and shown to afford high yields for alkylation.[65] The following example was taken from the stereoselective synthesis of indolizidine 167B (Scheme 21).[63a]



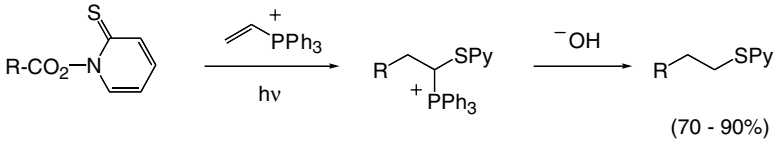
SCHEME 21

In contrast, β-substituted olefins generally reacted too slowly to afford synthetically useful yields of the alkylated product. In these reactions, the main reaction path is the rearrangement of the Barton ester affording thiopyridyl ethers. The use of the strongly electron-withdrawing nitro-group as the activating group or *bis*-activation as in maleates, fumarates, and quinones may allow such alkylation.[61,66] An elegant example of this type of alkylation reaction is presented in the synthesis of avarol and its structural analog avarone (Scheme 22).[67] The transformation involves photochemical activation at 350 nm of the thiohydroxamic ester and *in situ* trapping of the generated carbon radicals by benzoquinone. The reaction affords the hydroquinone, which is further oxidized with the excess of benzoquinone.[68]



SCHEME 22

The free-radical alkylation is not restricted to the use of classical Michael acceptors. Vinylphosphonium salts are also good radicophiles, allowing the formation of the corresponding pyridyl-sulfide after basic hydrolysis (Scheme 23).[3d]

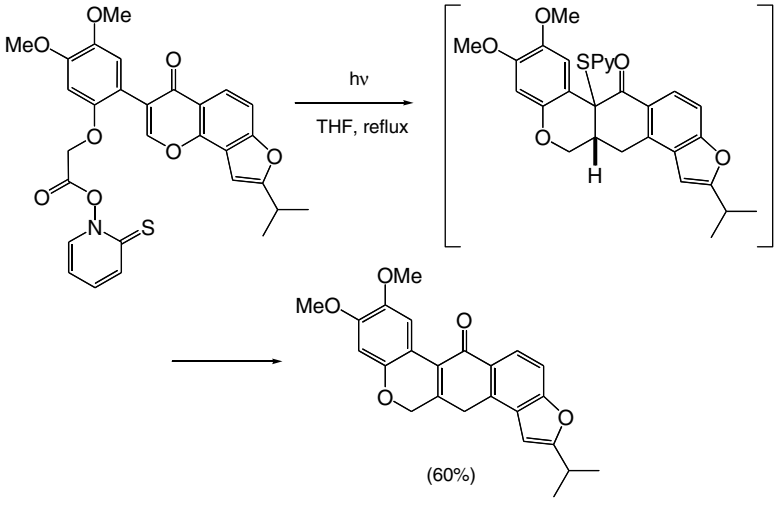


SCHEME 23

Likewise, protonated heteroaromatic bases are also good acceptors. Addition of alkyl radicals derived from Barton esters to pyridinium salts leads to the mixture of 2- and 4-substituted pyridines, in which the 2-isomer form predominates.[69]

Related free-radical alkylation reactions include the trapping of isocyanides[70] and the decarboxylative cyanation reaction.[71] Both methods allow entry to the preparation of labeled carboxylic acids.

Remarkably, only a small number of intramolecular reactions utilize Barton esters;[41a,61,72] likewise, the use of the Barton chemistry in making CC bonds in tandem or domino reactions is far less exploited compared to the tin-hydride-mediated free-radical sequences.[73] The following example is taken from the biomimetic conversion of isoflavone to the rotenoid, where the reaction affords the 6-*endo* product (Scheme 24).[72a]



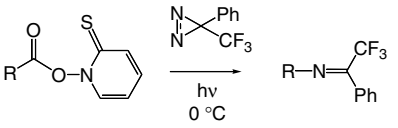
SCHEME 24

Sulfonation

A large excess of sulfur dioxide (i.e., a mixture of sulfur dioxide and dichloromethane at –10°C) can overcome the problem of the competing rearrangement, which is the result of the sluggish addition of the carbon-centered radical to the SO double bond.[74] The reaction allows entry to the preparation of sulfones.

Amination and Nitrosation

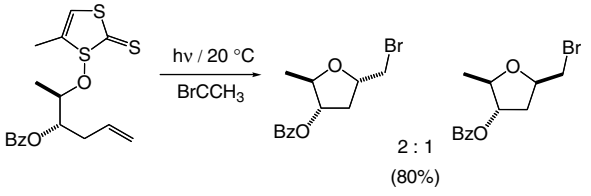
Free radicals generated under photochemical conditions from thiohydroxamates add readily to the NN double bond of diaziridines and in particular to the 3-bromo or 3-trifluoromethyl-3-phenyldiazirine to produce diaziridinyl radicals (Scheme 25);[75] these intermediates undergo dimerization and fragmentation to yield the corresponding imines, which can be hydrolyzed to the corresponding amines. Barton esters can also be used for the direct preparation of nitroso compounds.[76] From a synthetic standpoint, the yields are moderate and the method is limited to primary and secondary carboxylic acids, which form dimers as an end product. Tertiary nitroso compounds do not dimerize and further react with the radical present under the reaction conditions.



SCHEME 25

Generation of Heteroatom-Centered Radicals

Hydroxyl radicals can be generated by photolysis of thiohydroxamic acid **1** (Scheme 2, R=H) and its derivatives (Barton esters of type **I**).[9] Likewise, the photo- or thermolysis of mixed carbonates (IIa), carbamates (IIb),[77] and α-substituted acetates (IV)[78] may give rise to *O*- and *N*-centered radicals, respectively.[7b;65e,g;77b;79] Analogously, pyridinethione *O*-ethers, such as V have also been shown to give alkoxy radicals.[80,81] Although the original *N*-(alkenoxy)pyridine-2(1*H*)-thiones and in particular the *N*-benzyloxy derivatives are usually rather unstable, modified derivatives were proposed.[82] These *N*-(alkoxy)thiazolethiones (**7**, Scheme 6) are less sensitive to visible light than the corresponding pyridinethiones and require irradiation at $\lambda \leq \sum$ 350 nm. When *N*-cyclopentoxy- or carbohydrate-derived thiazole-2(3*H*)-thiones are photolysed in the presence of a hydrogen donor, the product of the reaction is the corresponding substituted aldehyde formed via highly regioselective radical fragmentation.[82] Primary oxyl radicals are more stable toward fragmentation.[31b] Usually, electron-donating substituents can improve the stability of oxygen and, in a larger sense, heteroatom-centered radicals, while electron-withdrawing substituents do not.[83] In the presence of a suitable intramolecular trap, the formed oxyl radical undergoes fast cyclization, forming tetrahydrofurans and tetrahydropyrans, respectively, often with remarkably high regio- and stereoselectivity.[84] The key 6-*exo trig* cyclization in the synthesis of (+)-*allo* muscarine illustrates the synthetic potential of this transformation (Scheme 26).[85] The cyclization reaction can be run also in water by using *N*-alkoxy-(*p*-chlorophenyl)thiazole-thione **7c** as an activator (see Scheme 6) and irradiation at 350 nm.[86]



SCHEME 26

67.4 Kinetic Measurements: Radical Clocks

The PTOC method in kinetic studies was originally developed to avoid the inherent boundary and precursor instability encountered at the upper limit of the tin-hydride method. This technique relies on the generation and simultaneous competitive trapping of the radicals by convenient radical traps, such as thiols or tin-hydrides, and on the analysis of the product distribution. PTOC esters are excellent radical sources for LFP studies because they have a strong long-wavelength absorbance at λ_{max} of about 360 nm and are efficiently cleaved either by 355-nm light from a Nd:YAG laser[13,72,87] or at 308 nm by using XeCl excimer laser over a large temperature range (–40 to 50°C). For the LFP studies, a dilute solution of the starting ester in a static cell or, more frequently, in a flow-cell assembly is used. It should be noted that complete chain collapse resulting from highly dilute solution of PTOC esters could be accommodated by extended photolysis, because Barton esters are not only chain carriers but also radical initiators. It is technically advantageous that the 2-pyridinethiyl radical formed during the course of the homolytic fragmentation reaction has a long-wavelength absorbance with λ_{max} at 490 nm but does not absorb strongly between ~3l0 and 350 nm.

67.5 Alternative Reactions

Hypervalent iodine compounds, especially (diacetoxyiodo)arenes, have been used for the generation of C-centered radicals through thermal or photochemical fragmentation of carboxylic acids.[88] The reaction works well to generate carbon-centered radicals by β-cleavage of alcohols. The reaction, which is usually known as the Suàrez reaction, was extended to oxygen- and nitrogen-centered radicals. The radicals were employed in oxidative addition, substitution, β-fragmentation, Hofmann–Löffler–Freytag reactions, and reductive addition reactions were used successfully for functional group transformation, formation of new skeletons, and synthesis of natural products.[89] Depending on the reaction conditions, the intermediate radical can be oxidized to the corresponding carbocation. Scheme 27 shows this transformation in the synthesis of gibberellins.[90]

Photochemically Induced Tautomerism of Salicylic Acid and Its Related Derivatives

Minjoong Yoon
Chungnam National University

68.1 Introduction

Salicylic acid (SA) and its derivatives such as methyl salicylate (MSA) have strong hydrogen bonds between the phenolic hydroxy groups and the nearby carbonyl proton-accepting groups, which become, respectively, more acidic and more basic in the excited state. Consequently, in aprotic solution, this gives rise to a dual emission with a large Stokes shift, as observed initially by Weller,[1,2] which has been attributed to an excited-state intramolecular proton transfer (ESIPT), as shown in Scheme 1. The proton transfer is driven by a pK change of –6 in the phenolic oxygen and a pK change of +8 in the carbonyl oxygen of the carbonyl group upon excitation.[3]

The dual emission has been attributed to double-well potentials arising from the proton transfer in the excited state as well as in the ground state, as shown in Figure 68.1. The primary form (I) in the ground state is more stable than the tautomeric form (T), whereas the tautomeric form in the excited state (T*) is more stable than the excited primary form (I*). According to Weller, the initially excited phenol form (P*) is in equilibrium during its lifetime, with the proton-transferred tautomer form T* resulting from ESIPT. The anomalous large Stokes-shifted fluorescence (blue fluorescence) is assigned to the formation of the tautomer T*, while the ultraviolet (UV) component of the fluorescence was attributed to the fluorescence of the phenol form (II*).

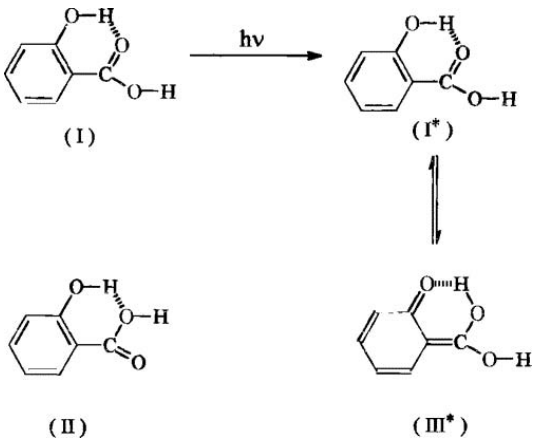

SCHEME 1

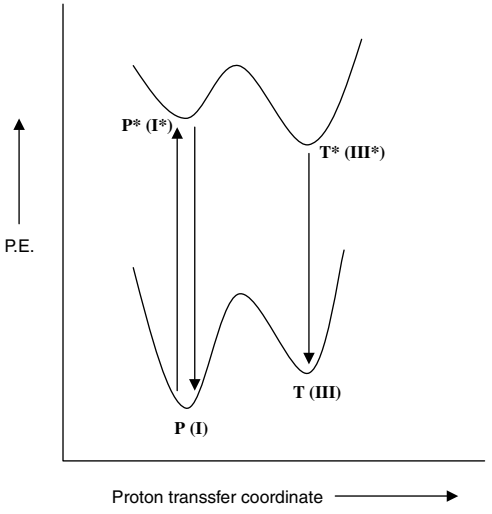

FIGURE 68.1 Schematic diagram of asymmetric double well potentials proposed by Weller for the ground and excited state of salicylic acid.

The excited-state equilibrium is sometime broken, depending on the substituents (R and R′) or the environment of the media employed. For example further work on methyl salicylate[3,4] has demonstrated the different excitation spectrum for the two emission species, indicating that the excited species are not in equilibrium but originate from different ground-state species. In this case, there are two different conformers (open form or closed form) depending on the hydrogen bonding strength due to intermolecular hydrogen bonding with solvent molecules. These findings have been confirmed in the spectroscopic study of several derivatives of salicylic acid in a supersonic jet.[5,6] This has been explained in terms of a single minimum distorted potential energy surface along the tautomerization coordinate, as confirmed by the Zewail group by real-time measurements of the proton-transfer reaction.[7] The time for the process was reported to be 60 fs.

Earlier investigations have shown that in certain derivatives, such as aminosalicylates[8–14] and salicylideneanilines,[15–18] a twisted intramolecular charge transfer (TICT) state is formed and is followed by the ESIPT. These compounds show multiple fluorescence.

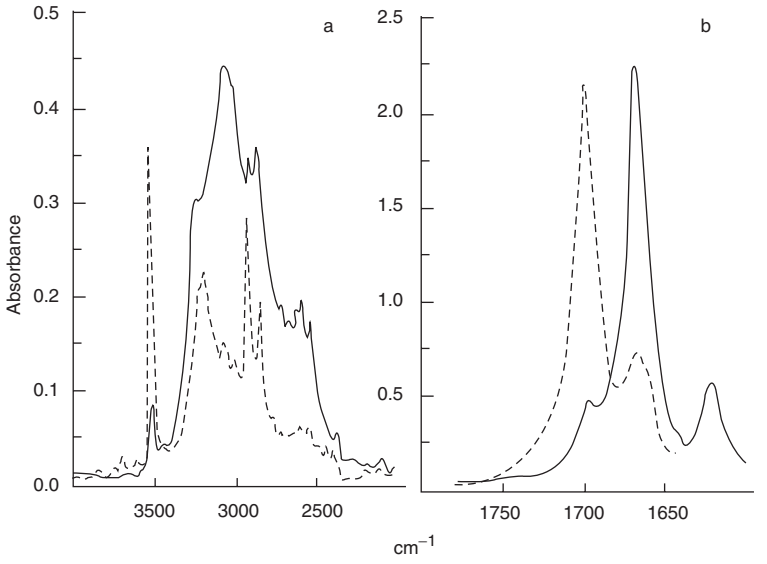

FIGURE 68.2 IR spectra of SA solutions in CCl_4 (10^{-2}mol/l(———), 5×10^{-5} mol/l (•••••••) in ν OH (a) and ν C=O (b) regions.

The excited-state dynamics of these complex molecules have also been studied by ultrafast time-resolved spectroscopy[19,20] to elucidate the mechanistic details. The potential energy (PE) function of the first excited singlet state of the ESIPT process in salicylic acid has been calculated by *ab initio* MO calculations using the 6–31G** basis set at the restricted Hartree–Fock and configuration interaction single excitation (CIS) levels, as well as the semi-empirical method AM1.[21,22]

68.2 Fluorescence Spectroscopic Evidences of Excited-State Intramolecular Proton Transfer of Salicylic Acid and Methyl Salicylate

In Solution

Weller[1,2] observed the dual emission in the fluorescence spectrum of SA and MSA in methylcyclohexane (10^{-4} mol/L), characterized by a strong emission with a maximum at 450 nm and a shoulder at 350 to 370 nm. The features of the emission spectrum of salicylic acid and its derivatives in solution are sensitive to the concentration of the solute and the solvent composition. This effect could be due to self-dimerization[23,24] or the existence of intermolecular hydrogen bonds formed by the carboxylic acid influencing the intramolecular hydrogen bond, C=O···HO in salicylic acid providing ESIPT.

The self-dimerization of salicylic acid in nonpolar aprotic solvents is also the cause of its dual emission.[23] Similar emission has been found for heterodimers formed by salicylic acid with other carboxylic acids such as 2,6-dihydroxybenzoic acid.[25] In this case, a weakening of the intramolecular hydrogen bond is caused by the intermolecular hydrogen bond with another acid, followed by an increase of the UV component with a decrease of the blue emission from the ESIPT. The concentration dependence of intra- and intermolecular hydrogen bonds of SA and its related compounds has been proved by NMR and IR studies in CCl_4 or in solvents such as hexane.[25–27] The typical example of dimerization has been confirmed by observation of the relative change of intensities of the two bands for the C=O stretch at 1697 and 1660 cm^{-1} (23) with concentration variation (see Figure 68.2). From this study, it was shown that the two bands at 1697 and 1660 cm^{-1} originate from the monomer and the dimer, respectively. Simultaneously similar changes in the OH stretching bands at 3200 to 3540 cm^{-1} were also observed. Usually, the

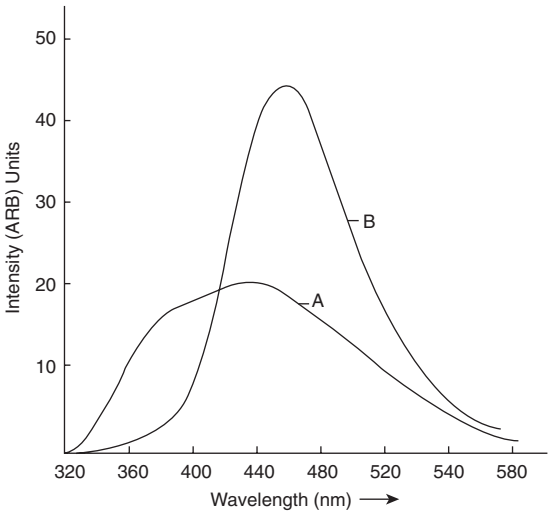

FIGURE 68.3 Emission spectra of SA (10^{-3}M) in hydrocarbon at 290K in the presence of Et_2O (A) 0.0M and (B) 0.9M.

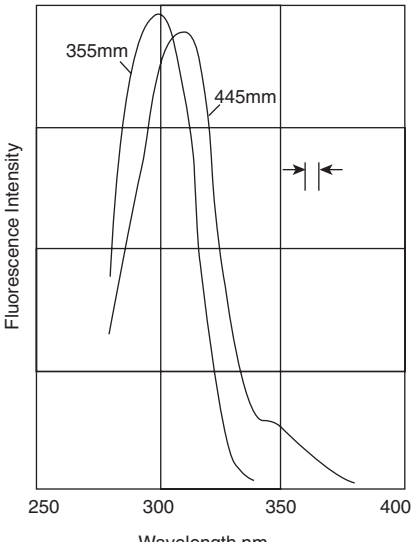

FIGURE 68.4 Fluorescence excitation spectra of MSA, 10^{-4}mol/l in methanol, corrected for equal photon intensity; emission wavelengths and excitation slit width indicated.

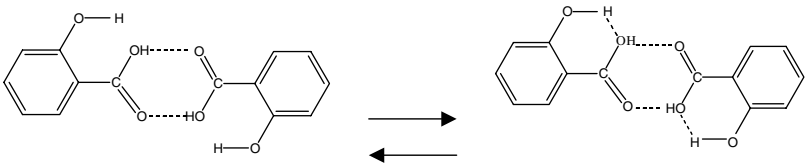
dimerization of SA and its derivatives in nonpolar solvents at room temperature is negligible when the total concentration is less than 10^{-6} mol/L. The early observations of dual emission of SA and MSA (1, 2) have been performed at higher concentrations in nonpolar solvents ($>10^{-5}$ mol/L). Under such conditions, the relative intensity ratio of the UV emission to the blue emission increases as the concentration increases (Figure 68.3). The excitation spectrum of the visible emission of SA or MSA at 445 is shifted by ~10 nm to the blue of the UV excitation maximum (355 nm) either in cyclohexane or in methanol (Figure 68.4). These indicate that the ESIPT is inhibited by self-dimerization or intermolecular hydrogen bond in the ground state, as described above. However, at very dilute concentrations less than



(D) (T)

SCHEME 2

TABLE 68.1 Shift of the Emission Band of Solid Salicylic Acid at 10 K with the Excitation Wavelength

λ_{exc} (nm)	λ_{em} (nm)	Shift (cm^{-1})
351	390	2849
355	397	2980
360	400	2777
370	410	2636
375	415	2570

10^{-6} mol/L, the hexane solution of SA shows a fluorescence emission maximum in the blue region (410 to 450 nm) with no pronounced maximum in the UV region (380 nm). The excitation spectra of both the blue and UV emissions are identical, indicating that the species from which the blue emission originates is the same as that of the small UV emission. The blue emission, peaking at 450 nm, exhibits a large Stokes shift (9000 cm^{-1}) and appears to be associated with the monomer rotamer form I (Scheme 1) undergoing ESIPT, in accordance with other works.[1–3,24–26] In other words, in the diluted nonpolar solution, the rotamer (Scheme 1, I) is stabilized by the intramolecular hydrogen bond, and it is relatively dominant in the ground state. Thus, the initially excited rotamer P* emits UV fluorescence, and consequently it is in equilibrium during its lifetime with the proton-transferred form T*, which emits the blue fluorescence.

When the intramolecular hydrogen bond is weakened by intermolecular hydrogen bonding with solvent or by esterification of the carboxylic acid, another rotamer (Scheme 1, II) in which the ESIPT is not accessible, becomes dominant. Further work on methylsalicylate[26–27] has shown two different excitation spectra in aprotic nonpolar solvent. The existence of two different excitation spectra implies that two different ground species, such as rotamers I and II (Scheme 1), are also involved. The relative population of rotamer I/rotamer II is expected to increase as the strength of intramolecular hydrogen bonding increases.

On the other hand, with the intermolecular hydrogen bonding formed by self-dimerization in the concentrated solutions, a double proton transfer is known to take place converting dimer D to tautomer T, as shown in Scheme 2; this is confirmed by observing the cryogenic effects (10 to 293 K) on the steady-state and time-resolved fluorescence spectroscopic techniques.[23]

The fluorescence emission obtained by excitation at energies lower than the 0–0 band of the dimer absorption (351 to 380 nm) exhibits a maximum around 390 nm, which shifts toward the red with increasing wavelength (see Table 68.1), indicating that the red-edge effect results from different distorted forms of dimers. However, with higher energy excitation (343 to 265 nm), the tautomeric blue emission (430 nm) is also observed as well as the dimeric UV emission (Figure 68.5).[23] The tautomeric emission bands at 428 and 455 nm are shifted by 5125 and 6,512 cm^{-1}, respectively, from the 0–0 band of the dimer at 28,490 cm^{-1}. These shifts are well in accord with the jet-cooled studies[5,6] and correspond to the C=O and OH stretch assigned for the tautomer of the SA monomer (see below). The excitation spectral feature

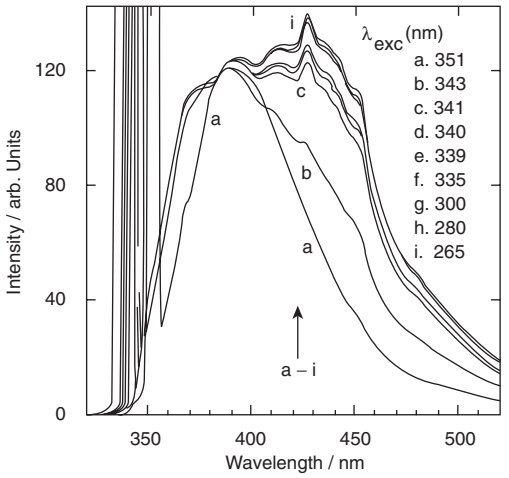


FIGURE 68.5 Emission spectra of solid SA at 10K with different excitation wavelengths shorter than the (0-0) band as indicated in the figure. The truncated sharp peak in each spectrum is the scattered excitation light.

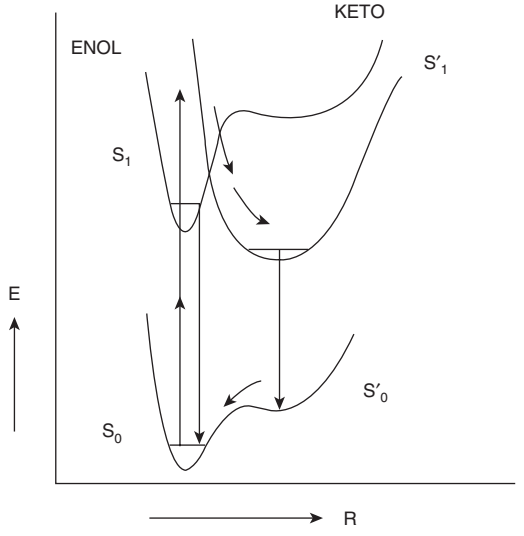

FIGURE 68.6 Schematic diagram of the double potential minimum for the proton transfer reaction in the SA dimer Enol and keto represent the D and T forms of the SA dimer respectively.

of the UV emission and the blue emission show differences at 10 K, but both excitation spectra become identical at higher temperatures, indicating the loss of the identity of the two potentials in the excited state at higher energies (Figure 68.6). The barrier height (1050 cm^{-1}) is calculated by the energy difference between the two-excitation spectra peaks and is sensitive to the temperature variation.

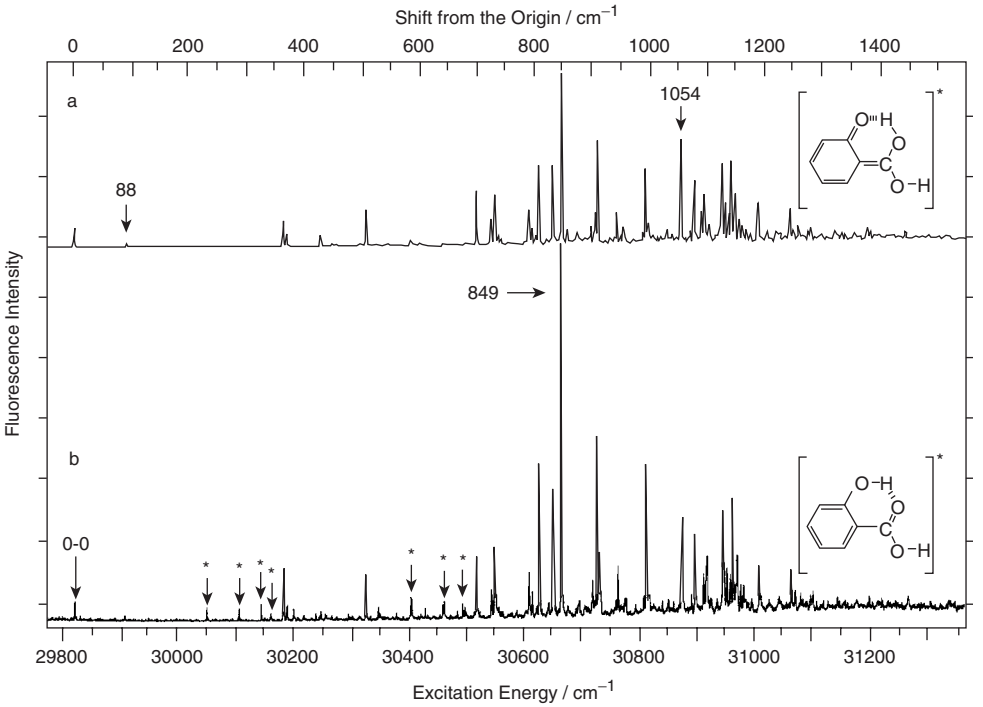

FIGURE 68.7 The fluorescence excitation spectra of the rotamer I on monitoring (a) BLUE fluorescence, (b) UV fluorescence. Asterisk (*) indicates the bands due to the SA dimer. The spectra are normalized at the origin.

In a Supersonic Jet

Figure 68.7 shows the fluorescence excitation spectra of rotamer I of SA in a supersonic jet obtained by adjusting the reservoir temperature between 35 and 100°C. The fluorescence excitation spectra were measured by monitoring separately the UV (340 to 370 nm; Figure 68.7a) and the blue (380–480 nm; Figure 68.7b) emissions.[6] The same supersonic jet excitation spectra were also measured for MSA by monitoring the light emitted above 420 nm.[5] The frequencies of the main vibronic bands for the SA and MSA are summarized in Table 68.2. The excitation spectrum of SA shows the first weak feature at 29,820 cm^{-1}, which is assigned to the 0–0 transition, while those of MSA shows the origins at 30,052, cm^{-1}. Due to the methoxy group, MSA has additional bands, and the density of vibrational states is significantly higher, but the general shape of the spectrum is similar to that of SA. This indicates that rotamer I, having a strong OH···O=C hydrogen bond, is dominant enough to exhibit the ESIPT in the S_1 state.

The excitation spectrum monitored by the UV emission shows several very weak bands that appear in the 0- to 1000-cm^{-1} region (Figure 68.8) and are due to the dimer, as shown in Scheme 3.[5,6] This is contrast to the fluorescence excitation spectrum monitored by the blue emission. The frequencies of the main vibronic bands for the dimer are summarized in Table 68.3. The 364 and 511 cm^{-1} modes correspond to the doubly degenerate, in-plane breathing modes of benzene and are commonly found in benzene derivatives such as MSA, phenol, and benzoic acid dimer.[30–32] These two modes may originate from the OH in-plane bending mode. The 704-cm^{-1} mode of SA is not observed from MSA, which shows the 569 or 595 cm^{-1} bands instead, indicating that these modes involve the motion of the –COOH group or –COOMe, respectively. It is noted that the transitions in the 800- to 1100-cm^{-1} region are the most intense for both SA and MSA. The intensities for SA are lower than for MSA, especially the 849 cm^{-1} band, which is about 2.2 times more intense in the UV than in the blue fluorescence excitation spectra. These differences in the relative intensities may be due to different Franck–Condon factors or to a large

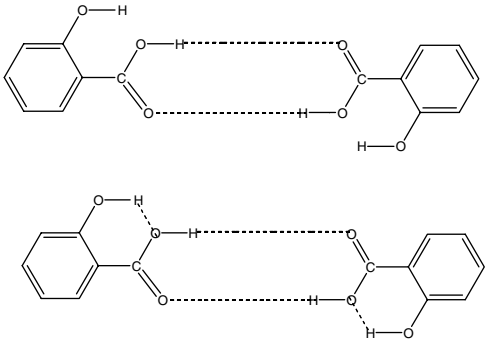

SCHEME 3

vibronic-state dependence of fluorescence quantum yields. However, the lack of vibronic-state dependence of the lifetime, the quantum yields for both molecules, and the differences in relative intensities are attributed to different molecular structures of the dimer of rotamer I, in which a double proton transfer takes place, as shown in Scheme 3, supporting the interpretation of the fluorescence spectroscopic results obtained from solution (*vide infra*).

Studies of SA and MSA in the gas phase[6] and in free jet systems[7] also support the existence of a different rotamer II in addition to rotamer I. In vapor at room temperature, rotamer II of MSA is estimated to be 1/70 the concentration of rotamer I.[6] The UV emission usually originates from both rotamers I and II, but the blue emission does not involve rotamer II, as this rotamer has no ESIPT. In solution, the UV emission of MSA excited at 33,131 cm^{-1} (UV region) is observed, in addition to the blue emission in a supersonic jet, indicating the presence of two rotamers. The intensity ratio of these two emissions (I_{UV}/I_{blue}) depends on the temperature, giving rise to the enthalpy change associated with the ground-state conversion of the two rotamers, 10.5 kJ/mol.[6] Rotamer II of SA probably is similar to that of MSA; the fluorescence excitation spectrum of rotamer II of SA up to 1300 cm^{-1} above the origin could be observed

by monitoring the UV emission (320 to 360 nm; Figure 68.9).[6] The vibrational shifts and intensities for rotamer II are listed in Table 68.4. The spectrum is considerably weaker than that for rotamer I. This is due to a larger contribution from the n,π^* transition because the open form lacks the internal hydrogen bond as suggested for MSA.[5] The original band corresponding to the 0–0 vibrational transition is observed at 32,101 cm^{-1} (~2280 cm^{-1} above the origin of rotamer I). For comparison, the origin of the rotamer II spectrum of MSA is 32,303 cm^{-1}. The phenolic OH and COOH vibrational modes appear at 240, 363, 403, and 521 cm^{-1} above the origin, a finding that is similar to the corresponding bands of rotamer I at 364, 431, and 531 cm^{-1}. The fluorescence excitation of SA dimer measured in a supersonic jet provides the vibrational assignment of a ground state (see Table 68.3).

68.3 Excited-State Dynamics of ESIPT of Salicylic Acid and Methyl Salicylate

Ultrafast studies of the excited-state proton transfer dynamics of molecules have been performed both in solution[32–34] and in a gas matrix.[35] About three decades ago, Smith and Kaufmann[19] performed the picosecond studies of ESIPT of MSA in nonpolar solvent such as methylcyclohexane at different temperatures. They found that the fluorescence decay time of the blue (450-nm) emission of MSA is about 280 ps at room temperature. They also measured the rise time of the blue emission and estimated the ESIPT rate as $>10^{11}$ s^{-1}.

The lifetime is independent of temperature between 40 and 160 K; however, above 160 K the lifetime becomes shorter, with the relative quantum yield decreasing as the temperature increases (see Table 68.5). These data make it possible to calculate the temperature-dependent nonradiative rates, which yield an activation energy of 3.7 kcal/mol, implying the existence of the excited zwitterions as well as the tautomer form. Nevertheless, interpretation of these experiments is complicated by thermal and solvent effects, thus a proper description of the formation of the blue emission has not been unambiguously established. In order to eliminate these problems, supersonic jet excitation spectroscopy was found to provide new information regarding the spectra of the isolated molecule and dynamics at different excess vibrational

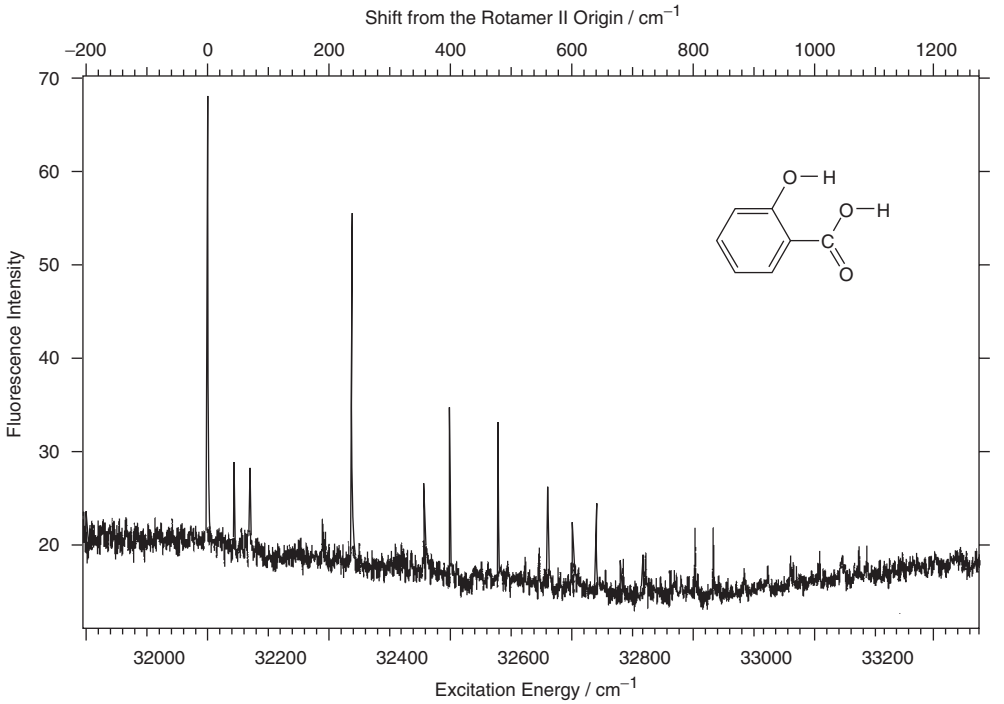

FIGURE 68.9 Fluorescence excitation spectrum of rotamer II on monitoring UV fluorescence.

energies.[7] Felker et al.[7] have observed a dispersed fluorescence of jet-cooled MSA excited at 332.75 nm. This fluorescence shows long progressions from the excitation original to 3220 cm^{-1}, with frequency intervals of 180 cm^{-1} that correspond to a ground-state, out-of-plane bending motion of the ring, including the intramolecular hydrogen bond. The fluorescence decay rate of MSA as a function of the excess vibrational energy is shown in Figure 68.8. As the excitation energy increases, the decay rate is observed to decrease markedly (from 12 ns to 160 ps), with a threshold at ~1300 cm^{-1}. This is in good agreement with the presence of the nonradiative process in solution with the activation energy (3.7 kcal/mol) as described above. The nonradiative process involves low-frequency torsions and bends as supported by the prominence of the 180-cm^{-1} progression leading to formation of zwitterions in the excited state.

The fluorescence spectrum and fluorescence lifetime of SA are strongly dependent on the solvent conditions, as shown in Table 68.6, because of the presence of several forms of the molecule in different solvent conditions; furthermore, SA has a much greater tendency to form dimers than MSA. Thus, it is difficult and complicated to analyze the dynamics of SA in solution at room temperature.

Bisht et al.[6] observed cryogenic effects (10 to 293 K) on time-resolved fluorescence spectroscopy, confirming the ESIPT in the dimeric state of crystalline SA. The time-resolved fluorescence decay curves for solid SA at 10 K observed at 410 nm with different excitation wavelengths are shown in Figure 68.9, and the analyzed data are summarized in Table 68.6. The emission decays are bi-exponential and are resolved into two lifetime components: the first one shows a shorter and constant lifetime (3.0 ns), and the other one shows longer and variable lifetimes (7.95 to 4.7 ns), depending on the excitation wavelength. The relative amplitude also changes and is greater for the longer component in the long-wavelength region. This red-edge effect (REE) at 10 K is due to various distortions of sites/oligomers. The decays of both the UV and blue emissions show single exponential behavior as the temperature increases above 160 K. These results indicate that a ground- and an excited-state double proton transfer, as well as the simultaneous intramolecular fast proton transfer, take place.[23]

Yoshihara's group[6] has also measured the lifetimes of SA rotamers in a supersonic free jet expansion. The fluorescence decays of rotamer II were too fast to measure with their experimental time resolution (<1 ns); however, the excitation energy dependence of decay rates of rotamer I fluorescence could be observed. At low energy, the fluorescence decay was measured to be single exponential with a lifetime of 9.6 ns (12.0 ns for MSA). On the other hand, at higher energies above ~1100 cm^{-1}, the decay curves show bi-exponential behavior with lifetimes decreasing to ~4.3 ns due to an efficient intramolecular nonradiative decay process, as observed in solution, which may be attributed to the proton transfer. The 9.6-ns component is nonlinearly dependent on SA concentration and is attributed to the dimer.

68.4 Substituent Effects on the ESIPT in Salicylic Acid and Its Derivatives

ESIPT in 5-Methyl- and 5-Methoxysalicylic Acid

Modification of the excited-state acidity of the phenolic OH of SA and MSA has been observed to exhibit the possibility of modulating the ESIPT process and the excited-state equilibrium between enol and keto forms.[36] The proton-donating ability of the phenolic OH is known to be reduced by introducing an electron-donating group such as a CH_3 or an alkoxy in the 5-position (*para*) to the OH of MSA. The effect of an ethoxy substituent in the 5-position of MSA was first investigated by Weller[37] 40 years ago and studied further in by Acuna et al.[38] for the 5-methoxy derivative in the gas phase and in solution. The fluorescence of the 5-methoxy MSA exhibits a strong maximum at 400 nm and a shoulder at 490 nm. Both emissions have the same excitation spectrum, indicating that they originate from the same ground-state species. The 400-nm emission observed in 5-MSA deviates from the usual UV emission of other SA derivatives (~380 nm). This may be attributed to the emission from the initially excited rotamer I (Scheme 1) in its enol form, while the 490-nm shoulder originates from the ESIPT process, indicating a keto-enol equilibrium mechanism involved in the excited state.

Lahrmani and Zehnacker-Rentien[36] have investigated the influence of methyl and methoxy substitution in a position *para* to the phenolic OH group on the intramolecular proton-transfer properties of the electronically excited of SA (ESIPT), both in different solvents and in the isolated gas-phase condition provided by supersonic cooling. The absorption spectra and the emission of 5-MeSA and 5-MeOSA in cyclohexane at a concentration of ~$2–3 \times 10^{-5}$ *M* are shown in Figure 68.10. The substitution with methyl- and methoxy groups in the 5-position induces a bathochromic shift of the absorption with respect to the non-substituted SA (310 nm). The fluorescence of 5-MeSA is weak and consists of two bands with two distinct maxima in the UV at 380 nm and in the blue at 450 nm. On the other hand, the fluorescence from 5-MeOSA exhibits a strong band at 400 nm and a shoulder at about 430 nm. The relative intensity of the UV/blue emission of 5-MeSA increases with concentration but is independent of concentration in 5-MeOSA. The excitation spectrum of 5-MeSA for the UV emission is red-shifted by ~10 nm from that of the blue emission; however, those two emissions for 5-MeOSA show identical excitation spectra (Figure 68.11). These results indicate that MeSA and MeOSA behave differently. The increase of UV emission with increased concentration of 5-MeSA and the emission wavelength-dependent excitation

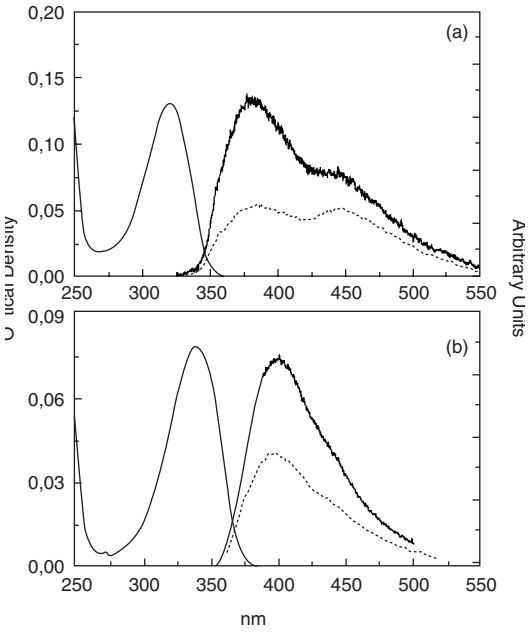

FIGURE 68.10 Absorption and emission spectra of 5-MeSA and 5-MeOSA in cyclohexane solutions: (a) 5-MeSA, $c = 3 \times 10^{-5}$ M (continuous line), $c = 0.9 \times 10^{-5}$ M (dotted line); (b) 5-MeOSA, $c = 2.13 \times 10^{-5}$ M (continuous line), $c = 0.5 \times 10^{-5}$ M (dotted line).

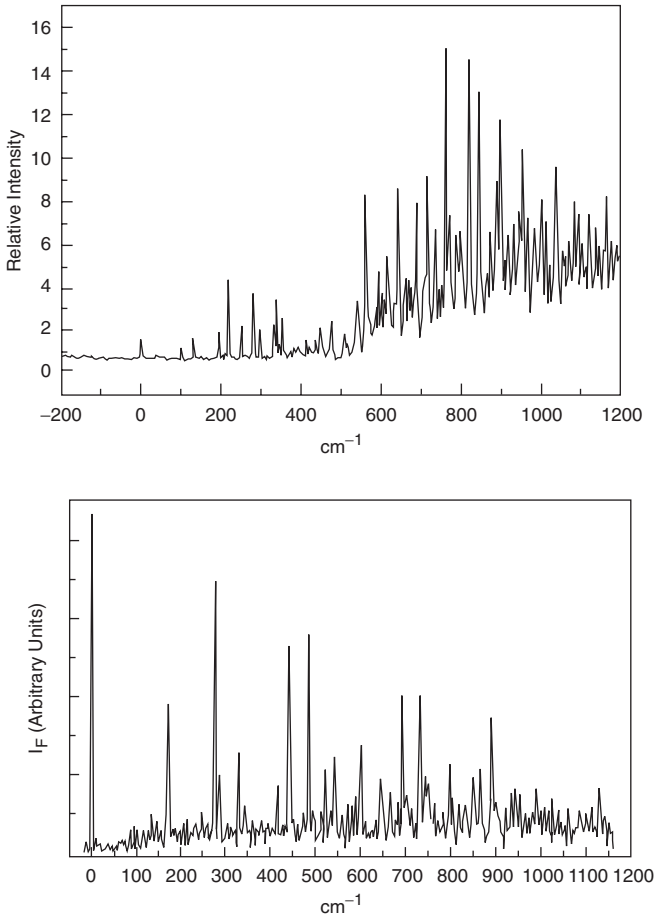

FIGURE 68.12 (a) Fluorescence excitation spectrum of jet-cooled 5-MeSA (T = 80°C, WG 420 Schott filter). The 0-0 transition is at 29,040 cm^{-1} (b) Fluorescence excitation spectrum of jet-cooled 5-MeOSA (T = 80°C) observed at 400 nm through a low-resolution monochromator ($\Delta\lambda$ = 20 nm). The 0-0 transition is at 28,615 cm^{-1}.

spectrum can be related to the equilibrium between the monomer and the dimer as observed for SA;[23] however, no evidence for a dimeric form can be found in the case of 5-MeOSA. Nevertheless, it is very difficult to characterize unambiguously the excited-state properties of SA derivatives in solution as described above. This is because several species including monomers in different conformations (rotamers I and II) and the dimer coexist in the SA derivatives depending on the solvent and the concentration. In order to isolate molecules and elucidate the photophysical properties selectively, a supersonic jet experiment is helpful.

The fluorescence excitation spectra of jet-cooled 5-MeSA and 5-MeOSA heated at 80°C, obtained by monitoring the light emitted at 400 nm and longer wavelengths, are shown in Figure 68.12. The first weak features at 29,040 cm^{-1} and 28,615 cm^{-1} are assigned to the 0–0 transition. The frequencies of the main vibrational bands are listed in Table 68.7. The density of vibrational bands is significantly larger in 5-MeSA then in SA (Figure 68.12A), but the general shape of the spectrum looks similar to that of SA. Thus, it can be assigned to the S_0–S_1 transition of the rotamer involving the strong OH···O=C hydrogen bond. The fluorescence excitation spectrum of jet-cooled 5-MeOSA shows a red shift of ~1200 cm^{-1} relative to that of SA. The spectrum at the origin of 5-MeOSA is stronger that that of SA or MSA, indicating that the Franck–Condon distribution of 5-MeOSA is different from that of SA or MSA. Thus,

the excited-state potential surface is deeply modified and the intramolecular proton transfer in the isolated molecule is inhibited in 5-MeOSA, while the ESIPT takes place in the isolated 5-MeSA, as confirmed by the difference in the low-resolution dispersed fluorescence spectra of jet-cooled 5-MeSA (Figure 68.13A) and 5-MeOSA (Figure 68.13B). In nonpolar solvent, no ESIPT process takes place in 5-MeOSA, in agreement with the conclusions of the isolated jet-cooled, gas-phase results. Nevertheless, the presence of diethyl ether or of a stronger proton acceptor such as triethylamine promotes the ESIPT reaction in 5-MeOSA. These results show that intermolecular hydrogen bonding of the solvent to the carboxylic OH does not break the intramolecular hydrogen bond but rather reinforces it, thus allowing the ESIPT reaction to occur by increasing the electron density on the C=O group. This effect can be interpreted in terms of the charge transfer within the intermolecular hydrogen bond from the electron-rich ligand to the carboxylic group, which in turn results in a strengthening of the intramolecular hydrogen bond. Consequently, such ESIPT has also been demonstrated to enhance the intramolecular charge transfer in the *N*,*N*-dialkyammonium substitution of SA.[13,14]

ESIPT in *p*-Aminosalicylic Acid and Its Derivatives

Molecular structures of *p*-aminosalicylic acid and its derivatives are shown in Scheme 4, which shows the molecular structures of 2-methoxy-4-aminobenzoic methyl ester (MABAE, I), 2-methoxy-4-dimethylaminobenzoic acid methyl ester (MDABAE, II), *p*-aminosalicylic acid (PASA, III), *p*-aminosalicylic acid methyl ester (PASE, IV), *p*-dimethyl-aminosalicylic acid (PDASA, V) and *p*-dimethylaminosalicylic acid methyl ester (PDASE, VI). In these molecules, the hydroxy group, when hydrogen bonded to the ester or acid carbonyl group, permits an ESIPT fluorescence. Simultaneously, the *p*-amino group permits the so-called twisted intramolecular charge transfer (TICT) fluorescence to be observed when activated

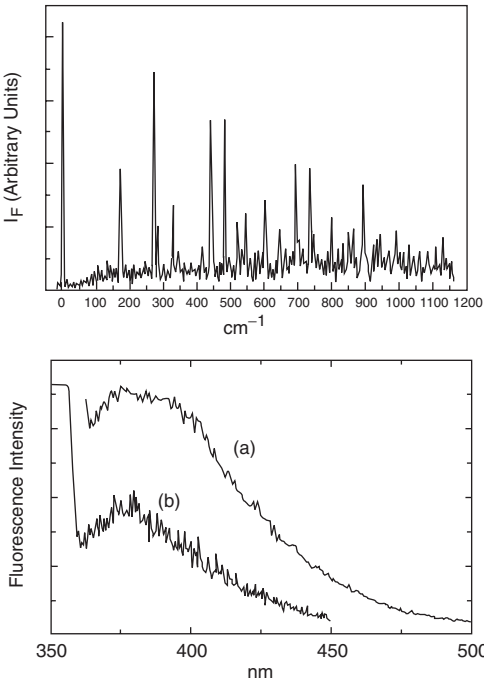

FIGURE 68.13 (a) Low-resolution dispersed fluorescence spectra ($\Delta\lambda$ = 20 nm) of jet-cooled 5-MeSA: (a) ν_{exc} = 0-0 + 217 cm^{-1}; (b) ν_{exc} = 0-0 + 556 cm^{-1} (b) Low-resolution ($\Delta\lambda$ = 20 nm) dispersed fluorescence from jet-cooled 5-MeOSA excited (a) on the 0-0 transition at 28 615 cm^{-1} and (b) the first vibronic level at 170 cm^{-1}.

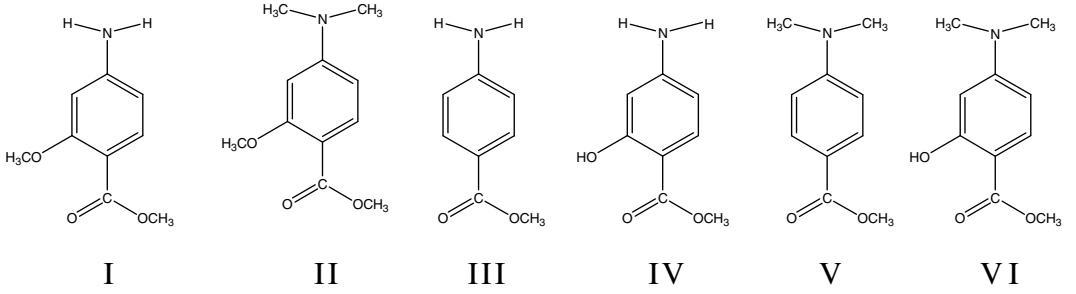

SCHEME 4

in a suitable dielectric media. Kasha et al.[9,10] have observed the ESIPT, which is competitive with the excited-state ICT. However, they proposed that the absence of double alkyl substitution of the amino group and α-hydroxy group *ortho* to the ester carbonyl, as shown in structure I, does not exhibit either ESIPT or the excited-state ICT. These molecules are observed to exhibit only normal $S_1 \rightarrow S_0$ fluorescence emission at 332 nm, as shown in Figure 68.14.

On the other hand, structure II exhibits the usual dual fluorescence as well as TICT emission at 350 and 423 nm, but no ESIPT is observed. This is due to the lack of a hydroxy group *ortho* to the ester carbonyl. The bulky *p*-amino-substituted molecule is known to exhibit TICT. Structures III and IV show the dual emissions similar to that of structure II. Kasha et al.[9,10] interpreted this dual emission as the normal and ESIPT emission, as it does not include bulky *p*-amino-substituents.

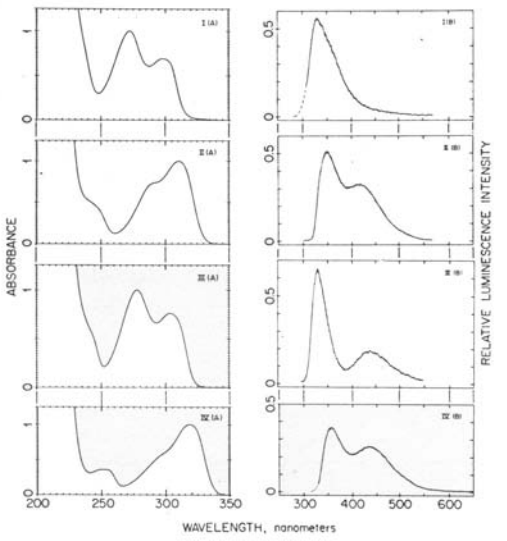

FIGURE 68.14 The absorption and fluorescence emission spectra of compounds I, II, III and IV in methylene chloride at 298K C ≈ 2×10^{-5} M. Excitation wavelength: I (B) = 297, II (B) = 287, III (B) = 277 and IV (B) = 318nm

Structures V and VI exhibit intramolecular proton transfer originating from the OH group and a TICT state emission as a result of the dimethylamino substituent. The second emission band is broadened, indicating the existence of the two emission components originating from the ESIPT and TICT, which are relaxed from the emission originating from the initial excited state. The intensities of these two emissions are competitively changed depending on the polarity of the solvent used. As the polarity increases, the TICT emission is stronger than the ESIPT emission. Such competitive relaxation channels involved in normal emission (i.e., TICT and ESIPT reactions) have been investigated by Gomin and Kasha[9,10] based on the observation of multiple fluorescences from various selected aminosalicylates. As a prototype, *p*-dimethylaminomethylsalicylate (PDASE) exhibits ESIPT emission in nonpolar solvents, while multiple emissions from normal TICT states are observed in polar, aprotic solvents. According to the steady-state fluorescence measurements of the PDASE in different solvent conditions, the excited-state processes were assigned as the normal emission ($S_1 \rightarrow S_0$). The TICT emission (S_1[TICT] $\rightarrow S_0$[FC]) and the ESIPT emission (S_1'[ESIPT] $\rightarrow S_0$[FC]) are shown in Figure 68.15; however, these two emissions overlap more closely at longer wavelengths (F_2) than the normal emission band (F_1), and it is difficult to resolve them into the two bands by steady-state fluorescence techniques. Thus, in order to confirm this assignment, Gormin[11] has measured the picosecond transient absorption spectra of PDASE, PASE, and MDABAE in methylene chloride and cyclohexane at 50-ps time delay. The transient absorption spectra of MDABAE (panel A), PASE (panel B), and PDASE (panel C) are shown in Figure 68.16. Because MDABAE has the phenolic OH replaced by methoxy, no ESIPT is expected; however, a broad transient absorption is exhibited at ~470 nm for MDABAE in methylene chloride. In cyclohexane, this transient is not observed, indicating that the transient observed in methylene chloride originates from the TICT because of the bulky amino group as observed for the *p*-dimethylaminobenzoate.[39] In contrast to MDABAE, PASE is known to be a molecule capable of exhibiting ESIPT-type and not TICT-type behavior as a result of the poor electron-donating ability of the amino group to induce TICT. Consequently, the comparative dynamics between ESIPT and TICT are dependent on the substituent and solvents used. Thus, the Kasha and Gormin groups proposed that the ESIPT can be tuned by changing the charge-transfer functional groups.

Chou et al.[12] have also observed dual emission bands from *p-N,N*-diethylamino salicylic acid (PEAS) that appear in ratios dependent upon the excitation wavelength, consistent with the results of Shabestary

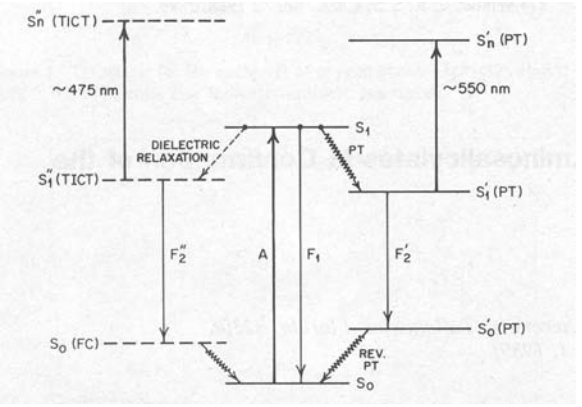

FIGURE 68.15 Energy level diagram indicating the origins of the three competitive fluorescence transitions and two possible transient absorption transitions. The dashed level (S_1") represents a 90 twist between the planes of the donor and acceptor protons of structures II and III.

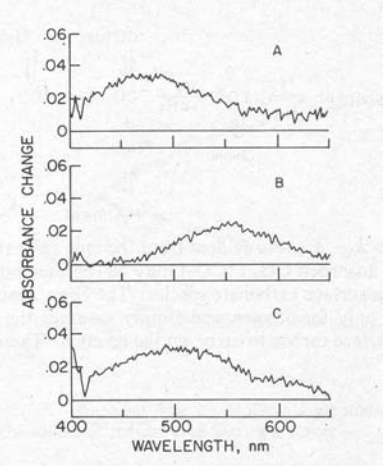

FIGURE 68.16 Room temperature picosecond transient absorption spectra of structure I (panel A), structure II (panel B) and structure III (panel C), in methylene chloride solution at a 50-ps time delay. The concentrations used are 0.722, 0.317 and 0.902 mM for A, B and C, respectively.

and El-Bayoumi;[8] however, they found that these two emission bands also showed significant concentration dependence in heptane (Figure 68.17). In combination with the concentration-dependent absorption spectra (Figure 68.18), they concluded that no emission results from the amino-*N*-charge-transfer state. Instead, the normal Stokes-shifted emission is assigned to the emission from a dimer (Figure 68.19c) overlapping the normal emission of conformer b or b′.

These controversial results were obtained using a limited number of aprotic solvents such as methylene chloride or cyclohexane. Such a limited solvent system does not provide full information of the complex excited-state reactions including TICT and ESIPT. When one considers the ICT and ESIPT together, specific solvent effects such as hydrogen bonding should be considered in addition to the polarization effects. Thus, Yoon's group has attempted to explore the hydrogen bonding effects more systematically on the excited-state process of PASA and its derivatives by observing the steady-state and time-resolved fluorescence properties in various protic and aprotic solvents[13] as well as aqueous cyclodextrin solutions.[14] The concentration effects on the fluorescence spectral properties were also observed. The fluorescence

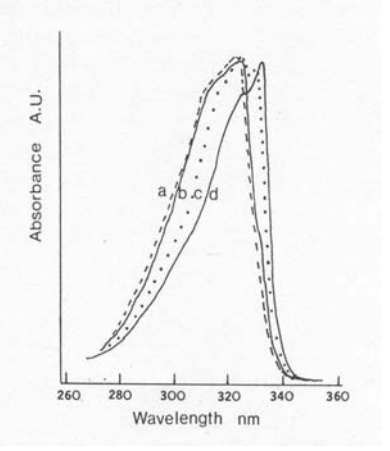

FIGURE 68.18 Room-temperature absorption spectra of PEAS in n-heptane at various concentrations: (a) 5.0×10^{-7}M, (b) 2.0×10^{-5}M, (c) 1.0×10^{-4}M and (d) 1.27×10^{-3}M. Since the spectra have been normalized the absorbance is in arbitrary units.

emission spectra of PASA (1.0×10^{-5} *M*) in various aprotic solvents are shown in Figure 68.20. Upon increased solvent polarity, the large Stokes-shifted emission at 440 nm is quenched and broadened. This is accompanied by an increase in the normal emission band at 330 nm; however, no absorption spectral change is observed as the solvent polarity increases. These results indicate that the normal excited state is relaxed into two different excited states, which are related to solvent polarity. This is consistent with the fact that the large Stokes-shifted band is resolved into 430 nm and 470 nm by band analysis (Figure 68.21). Table 68.8 shows the fluorescence lifetimes of PASA in various aprotic solvents. In non-polar aprotic solvents, the decay profile of the 430-nm emission is single exponential and its decay time is within ~300 ps. This is attributed to the ESIPT state of PASA, in agreement with result obtained by Kasha et al.[9,10] However, as the solvent polarity increases, the decay of the large Stokes-shifted emission at ~430 nm exhibits a bi-exponential behavior with two lifetime components, ~300 ps and ~150 ps. Furthermore, the relative amplitude of the 150-ps component is observed to increase with increasing

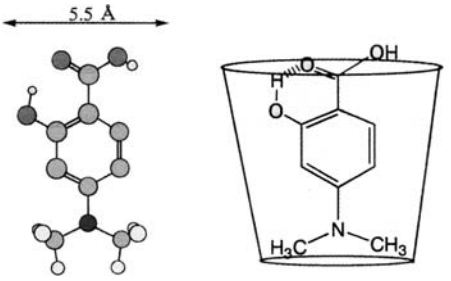
TABLE 68.8 Fluorescence Lifetimes of AS in Various Aprotic Solutions

	Wavelength	
Solvent	430 nm	465 nm
THF	330 ps (1)	330ps (1)
Ethyl acetate	270 ps (0.85)	280 ps (0.73)
	160 ps (0.15)	150 ps (0.27)
	Rise time: 40 ps	Rise time: 40 ps
Acetonitrile	270 ps (0.09)	270 ps (0.02)
	150 ps (0.91)	150 ps (0.98)
	Rise time: 40ps	Rise time: 40 ps

solvent polarity, while that of the 300-ps component decreases. These results contrast with the kinetics observed for PASA by Kasha et al.,[9,10] who suggested the existence of the ESIPT state only in aprotic polar solvents. It is also noteworthy that a rise component (~40 ps) is observed in polar solvents in contrast to its absence in nonpolar solvents. The rise time is too large to be the rate of ESIPT and its origin, we believe, is due to the forward conformational relaxation of the excited PASA followed by the polar solvent reorganization to facilitate the formation of the ICT state. Thus, the 150-ps component should be originated from the excited ICT state.

Previous work revealed that the hydrogen bonding plays an important role in the excited ICT of PDASA;[40–42] thus, the excited-state ICT in PASA could also be coupled with the inter- and intramolecular hydrogen bonding. In order to clarify this possibility, the influence of concentration effects on the fluorescence decay kinetics of PASA in ethanol were investigated by Kim and Yoon.[13] In dilute concentrations (0.005 m*M*), the decay of the large Stokes-shifted emission is bi-exponential (1.2 ns and 420 ps); however, in concentrated solutions (0.1 m*M*), an additional lifetime component of ~200 ps was observed in addition to the two components observed in the dilute solutions. In conclusion, this new lifetime component is solvent polarity dependent, and the ESPT is a prerequisite to form the ICT state even in the case of the PASA. In other words, the ICT is feasible when a closed conformer is formed by intramolecular hydrogen bonding which makes ESIPT feasible.



SCHEME 5

Yoon's group has also attempted to explore systematically the effect of hydrogen bonding on the excited-state processes of PDASA by observing the steady-state and time-resolved fluorescence spectral properties in aqueous cyclodextrin (CD) solutions. CD forms a hydrophobic and restrictive cavity with hydrophilic external walls in aqueous solution, providing two different microenvironments with an incorporated guest molecule. Thus, CD is an ideal system for controlling the relative microenvironment of each functional group of PDASA. This helps to distinguish the hydrogen bonding and polarity dependence of the electron-donating group from the inter- or intramolecular hydrogen bonding effect of the carboxylic acid. Actually, many scientists have employed the CD system to control the ICT process of various ICT molecules.[43–46] According to the absorption and fluorescence studies of FDASA in the aqueous β-CD solutions, the optimized structure of PDASA and the proposed pattern of inclusion complex with β-CD has been proposed, as shown in Scheme 5.

A single emission at 400 nm is observed for 0.05-m*M* PDASA in aqueous solution. This originates mostly from excited-state intermolecular hydrogen bonding. Upon addition of β-CD, the 400 nm emission band is diminished, accompanied by broadening of the bandwidth along with an appearance of a new band at 350 nm (Figure 68.22). These spectral changes were further confirmed by band analysis using the Gaussian distribution function (Figure 68.23). Even in CD-free aqueous solution, the emission band of PDASA was found to be composed of two different bands at 390 and 420 nm, indicating that two different conformers exist even in aqueous solution (one a closed-form conformer due to intramolecular hydrogen bonding between the OH and COOH group, and the other an open conformer formed by intermolecular hydrogen bonding). As the concentration of CD increases, two additional emission bands appear at 350 and 460 nm, indicating the presence of two corresponding excited species in addition to the open and closed conformers formed by the CD complex formation. These two emission are considered as originating from the ESIPT and ICT process, respectively. Consistent with these steady-state spectroscopic results, the picosecond time-resolved fluorescence study unraveled three decay components corresponding to two different proton transfer processes (5.6 ns, 160 ps) and the excited ICT (1.5 ns) (see Table 68.9).[14] It is noteworthy that the relative amplitude of the 1.5-ns component, attributable to the ICT state, is enhanced in parallel with an increase in the 160-ps ESIPT component. These results are interpreted in terms of the proton transfer with charge-coupling processes. Based on these experimental and theoretical observations, the excited-state potential surface for the reaction of PDASA in CD has been proposed as shown in Figure 68.24.

ESIPT in Salicylideneanilines and Related Compounds

The salicylideneaniline (SAN) molecule and related molecules are highly useful model compounds for the investigation of the role of structural flexibility in light-induced structural transformations. This photochromic transformation is connected with adiabatic ESIPT OH→NH in the S_1 state of the structure (E, Scheme 6), which is the origin of the fluorescence anomalous Stokes shift.[16–18,47] The anomalous Stokes-shifted fluorescence and absorption spectral maxima of SAN observed under several conditions are listed in Table 68.9. The anomalous Stokes-shifted emission was found to be observed only in rigid matrices, especially in a glassy solvent at 77 K, as well as in crystals.[17] This implies that the necessary step

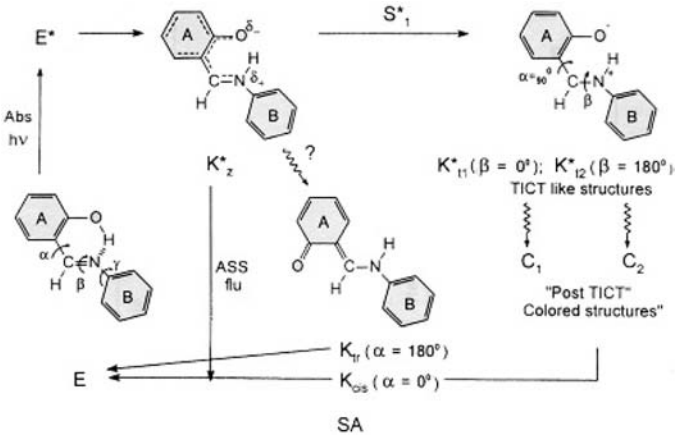
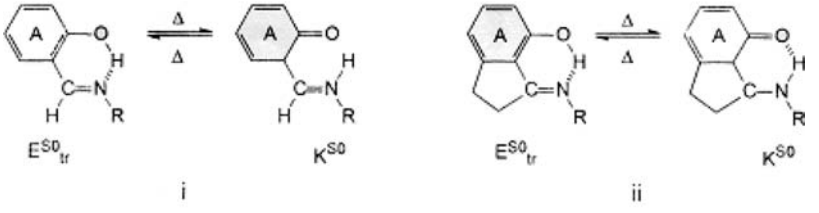
for the phototautomerism may be connected with NH···O bond and disruption due to the ring A twist around the CC double bond (K_{tr}) in the ground-state structure (NH, Scheme 6). In other words, the ring A rotation may inhibit the reverse general ground state NH→HO proton transfer and secure the metastability of the colored NH structure formed by the ESIPT, leading to the adiabatic formation of the intermediate S_1-zwitterionic NH structure (K_z^*). The ESIPT is followed by adiabatic disruption of the intramolecular hydrogen bond NH–O with the formation of a colored, metastable, ground-state keto structure having *trans* configuration with respect to the CC double bond (K_{tr}).



SCHEME 6



SCHEME 7

In earlier papers,[17,18] rather different interpretations of the anomalous Stokes-shifted emission have been presented. Luminescence spectral[48] and quantum chemical[17,47] methods applied to model compounds such as salicylidene methylimine (i_a in Scheme 7) revealed that the longest wavelength transition in the SA molecule responsible for photochromism is localized mainly on the A–C=N– moiety of the SAN molecules, as in i_a. Intramolecular charge transfer (ICT) from *o*-hydroxy (OH) into the azomethine (C=N) group is also proposed to be involved in the ESIPT by the participation of the N-ph π-electron system.[48] It is certain that the twist in ring A plays a crucial role in ESIPT and the photochromic phenomenon. Thus, in order to elucidate the role of ring A rotation in the ESIPT more directly, Knyazhansky et al.[47] have recently performed comparative studies of the derivatives (i and ii, Scheme 7) by using PNMR, x-ray crystallography, and fluorescence techniques, as well as quantum chemical calculations. A comparison of the spectroscopic characteristics obtained from these derivatives is listed in Table 68.9. Quantum chemical studies by semiempirical and *ab initio* methods were carried out to obtain the necessary information of the structural mechanism and the energetics of the photoinduced processes. The semiempirical calculations were carried out by PM3 using the Mopac program;[50,51] the *ab initio* calculations used the restricted Hartree–Fock method in the STO-3–21G basis set (for detailed results of these calculations, see references 47 and 52).

The simplified scheme (Figure 68.25) for the photoinduced processes in salicylideneaniline molecules is based on spectroscopic work and quantum chemical calculations, together with well-known kinetic data for the excited state of molecule i. The primary photoinduced process, a fast ESIPT, takes place in the S_1 state, leading to the formation of the planar NH structure (I*), which is responsible for the anomalously large Stokes-shifted (ASS) fluorescence displayed only in rigid media. Two processes then compete with the ASS fluorescence; adiabatic ring A twisting occurs only in liquids and leads to the TICT state [(I*), $\tau = 90°$] in the *Z*-structure of the NH form. This structure makes a considerable contribution

to the ASS fluorescence quenching. The process is completely reversible via the ground state but is inhibited in rigid media (viscosity barrier) in the S_1 state. In both liquid and rigid media, in spite of a viscosity barrier in the latter, the concerted diabatic process — including *Z,E*-isomerization about the C=N bond and ring A 70° rotation around the CC double bond — may be the origin of the feebly fluorescent colored form (i_{col}). This is assumed to have a nonplanar structure as the result of steric interaction between the *N*-aryl and keto A rings solely in the *E*-isomer with respect to the C=N bond.

The photochromic reaction may be an additional efficient channel of ASS fluorescence quenching. In liquid solvents, bleaching occurs in the ground state ($t = 10^{-7}$). In rigid media, the bleaching is drastically delayed ($t = 10$ s in poly[methyl methacrylate] at T = 290 K and depends on temperature and viscosity)[22] and was found to be virtually absent in the glassy solvent at liquid-nitrogen temperature due to the viscosity barrier in the ground state. The scheme is proposed to be qualitatively valid for crystals also.

68.5 Applications

The ESIPT of aminosalicylate derivatives is the primary process for the photochromic phenomenon. The development of useful photochromic systems is very promising for high-resolution imaging systems and for the storage of information in computers. The theoretical spatial resolution of a photochromic imaging or storage system is of the order of molecular dimensions, as the photochemical process itself takes place at the molecular level. The very high spatial resolution of photochromic systems implies a very low sensitivity, so these systems are most useful in conditions of high light intensity (flash or laser light). Thus, a potential application of such photochromic materials could be the protection of eyesight against light pulses of extremely high intensity, such as flashes from nuclear explosions. The photochromic material must respond instantly and must recover very quickly. It has also been suggested to make Plexiglas by dispersing the photochromic material into the polymer. The Plexiglas can act as a rapidly reversible photochromic material through triplet–triplet absorptions in the visible region. The photochromic material can be used to protect the polymer material by femto- or picosecond dissipation of the UV energy absorbed so that oxidation of polymer is inhibited.
