Foreword

The second edition of the *Handbook of Organic Photochemistry and Photobiology* has sought to give extensive coverage within the broad area of organic photochemistry and photobiology. Although the cover is not encyclopedic, the editors have ensured that the articles included will give a good idea of the advances that are being made within the various subject headings. The authors who have contributed are all international authorities at the forefront of their research areas and they all have produced well-written articles that are extensively referenced and should be of value to the beginner or to the specialist.

From its humble beginnings more than a century ago organic photochemistry has become an interdisciplinary science. In its early days the studies could only examine what happened on the exposure of organic molecules to light. Now, with the added sophistication of photophysics, the breadth of our understanding has increased dramatically. Our knowledge of what can be achieved from a given reaction has increased dramatically over the last decade. This has led us to situations where control can be exercised on the outcome of many photoprocesses. Many of the articles included in this Handbook deal with these new methods such as photoelectron transfer, irradiation of compounds in the solid, as crystals or contained with supramolecular cages. All of these techniques have changed the specificity of the reactions being studied. The use of chiral auxiliaries has also provided paths to molecules with high enantio or diastereoselectivity. All of these techniques provide more ammunition to the synthetic organic chemist. Indeed there is every hope that the new techniques will open more doors to the development of reactions that will provide new paths to molecules of biological and pharmacological interest.

Such a handbook could not have been compiled without the good will and cooperation of all the contributors and I am truly indebted to everyone who has given of their valuable time in writing for this text. I express my sincere thanks to Professor Francesco Lenci for his unstinting help in identifying and securing manuscripts from the authors for the photobiology section. I would also like to thank the members of the editorial staff at CRC Press for their great help and encouragement throughout the compilation of this magnum opus.

William M. Horspool
Dundee, Scotland

Introduction to Photobiology Section

This second edition of the *CRC Handbook of Organic Photochemistry and Photobiology* reports updated and extended chapters on topics already described and discussed in the first edition as well as chapters on new emerging subjects. As Pill-Soon Song mentioned in his foreword to the first edition, photobiology is a profoundly interdisciplinary science, and to properly face any photobiological problem a variety of skills and professional qualifications are needed: from photophyscis and photochemistry to biochemistry and molecular biology, from optical spectroscopy to genetic engineering, from structural biology to medicine and biomedicine to environmental sciences. This makes clear why most research groups active in photobiology include physicists, biologists, and chemists. The synergistic connection of different cultural backgrounds, in fact, not only allows the research group to successfully use different theoretical and experimental approaches, but also contributes to the form of photobiology as a new frontier of science. All photobiological phenomena originate from a single first act, the absorption of a photon, but the cascades of molecular, cellular, and biological events following this step end in a variety of phenomena, which is as large as life itself. Indeed, without light, life as we know it on our planet would not exist. Solar radiation, in fact, is a fundamental source of energy for all photosynthetic organisms and microorganisms, and photosynthesis is one of the most important biological processes on earth, which, by consuming carbon dioxide and liberating oxygen, has made the world into the livable place we know today. Light is also a sensory stimulus which provides vital information on the environment to all living beings, terrestrial and aquatic, diurnal and nocturnal, preys and predators, to creatures provided with "eyes" and nervous system as well as to aneural life forms like plants, fungi, and unicellular microorganisms. Both ultraviolet and visible radiation are also responsible for a number of damaging effects on biological systems and the deep knowledge of these processes has allowed us to develop promising concepts and set up efficient procedures in photomedicine. Last, but not least, the detailed understanding of the molecular mechanisms operating in biological photoreceptors has brought about studies in biomolecular electronics with the aim of using biological molecules or biomimetic systems in electronic or photonic devices by taking advantage of the fact that natural selection has already evolved materials with key properties desired for device applications.

Not all fields of photobiology have been covered in this book and I do apologize for not being able to cover all the vast area of modern photobiological sciences. All the authors are among the most active and authoritative researchers in the different fields and I hope this Handbook will serve to advance our understanding in some areas of photobiology. Working and corresponding with Professor William Horspool has always been a pleasure and a great experience, both from the cultural and the human point of view. I wish to sincerely thank all the authors for their efforts and patience and gratefully acknowledge the precious collaboration of all the CRC staff, with specially warm thanks to Debbie Vescio, Editorial Assistant, for her long-lasting support and graciousness.

Certainly editing a large book like this is a special experience: I had the opportunity of staying in touch and corresponding with colleagues from different countries and different cultures. I think and I hope that our common work has favored cooperation, mutual confidence and trust, not only among us, but also among the many different countries in which we live, thus giving a small contribution toward making our world closer to the open world Niels Bohr called for.

Francesco Lenci
Pisa, Italy

Dedication

In memory of all those whom we have loved and who have donated to us the precious gift of their love and friendship.

Francesco Lenci

The Editors

William M. Horspool was a reader in organic chemistry in the Department of Chemistry at the University of Dundee in Scotland, where he taught from 1965 up to his retirement in 2001.

He obtained his Ph.D. from the University of Glasgow in 1964 and his D.Sc. from Dundee University in 1976. His undergraduate studies were carried out at the University of Strathclyde in Glasgow.

Dr. Horspool has carried out research in organic photochemistry for his entire professional career and has published extensively in this area. He has been a regular contributor (for the past 34 years) to *Photochemistry,* a publication of the Royal Society of Chemistry. In addition to these reviews, he has written two textbooks on the subject and has edited another, in addition to editing the first edition of this Handbook.

He is a Fellow of the Royal Society of Edinburgh and of the Royal Society of Chemistry.

Francesco Lenci, a physicist working in biophysics, is research director of National Research Council (CNR). From October 1990 to April 2002, he was director of the Istituto Biofisica in Pisa. His research specialties are in photosensory biology/photobiophysics, with particular attention to photosensory transduction in microorganisms, spectroscopic studies of natural and synthetic photoreceptor pigments, and photochemical reactivity of natural pigments. He has served as associate editor for *J. Photochem. Photobiol. B: Biol.* (1989–1995) and for *Photochem. Photobiol* (2000–present). He is a member of the Italian (SIFB), European (ESP), and American (ASP) Societies for Photobiology and has served as SIFB president (1992–1998), as a member of the ASP Council (1998–2001), as chairman of the ESP Education Committee (1999–present), and as one of the vice-presidents of the International Union for PhotoBiology (IUPB). Organizer and chair of several symposia at international congresses and conferences and director of NATO-ASIs, in 2001 Francesco Lenci was awarded the Medal of the European Society for Photobiology.

Photobehavior of Alkyl Halides

Paul J. Kropp
University of North Carolina

1.1 Photochemical Behavior

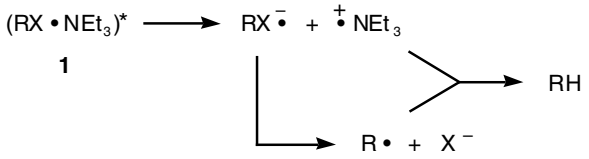
Principal Pathways

Alkyl iodides afford mixtures of radical- and ion-derived photoproducts in solution, with the latter usually predominating. Indeed, this is a powerful method for generating carbocations, including many that cannot be readily prepared by other methods. Alkyl bromides display similar photobehavior, but with a lower proportion of ionic products. Analogous behavior has also been observed for phenyl thioethers and selenoethers,[1] as well as some organosilicon iodides.[2] In a process related to the formation of ionic intermediates, irradiation of dihalomethanes in the presence of alkenes results in cyclopropanation, a synthetically useful procedure that complements traditional methods. This chapter, which is concerned with alkyl halides, is a major expansion of an earlier review.[3] The solution-phase photobehavior of aryl, benzylic, and homobenzylic halides has been reviewed, along with that of alkyl systems.[4] The photobehavior of alkyl halides in the gas phase has also been reviewed.[5]

Spectroscopic Properties

Alkyl iodides have a long wavelength absorption arising from an $n \rightarrow \sigma^*$ transition that is red-shifted with increasing substitution about the iodine-bearing carbon atom, ranging in λ_{max} in hydrocarbon solvents from 258 nm for CH_3I to 269 nm for tertiary iodides (ε 375–675).[6] It is slightly blue-shifted with increasing solvent polarity, ranging in λ_{max} from 254 nm for CH_3I to 267 nm for tertiary iodides in CH_3OH (ε 380–735). There is also a strong shorter wavelength band at 194 nm arising from an $n \rightarrow R(6s)$ transition. The $n \rightarrow \sigma^*$ absorption in bromides is less intense and occurs at much shorter wavelengths, ranging in λ_{max} from 202 nm for CH_3Br to 215 nm for tertiary bromides in hydrocarbon solvents (ε 200–300). Alkyl chlorides have little or no absorption above 200 nm, rendering them difficult to study photochemically. The absorption spectra of geminal dihalides are more complex and extend to longer wavelengths due to mutual interaction of the two halogen atoms. For example, CH_2I_2 has absorptions at 212 (ε 1580), 240 (ε 600), and 290 (ε 1300) nm. These arise from four $n \rightarrow \sigma^*$ transitions, with the highest wavelength absorption consisting of two unresolved peaks.

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1

Irradiation Procedures

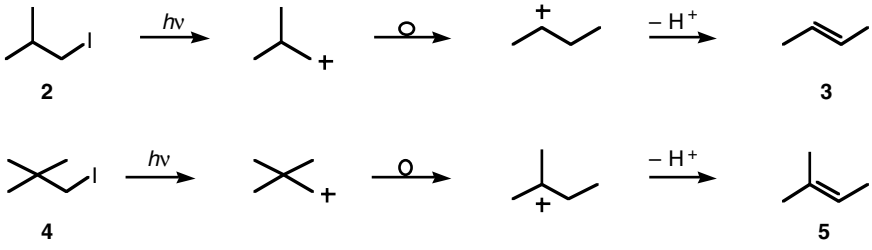
Since alkyl iodides have maximum absorption near the principal mercury line at 254 nm, they can be easily irradiated with a low-pressure mercury lamp and quartz or Vycor optics. Bromides, on the other hand, require light of shorter wavelengths, such as that emitted by a medium-pressure mercury arc.

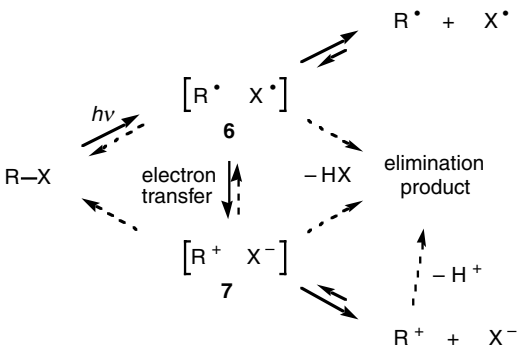
The byproduct HX can frequently influence the course of reaction, by both re-adding to elimination products and serving as an efficient hydrogen atom donor, and is best removed from the irradiation mixture as it is formed. Triethylamine can be used as a scavenger in nonpolar solvents. In polar solvents, however, it leads to increased formation of the reduction product RH because of competing reaction via the amine–halide exciplex **1** (Scheme 1). The poorer electron donor HO^- has been found to be a suitable HX scavenger in alcoholic solvents.[7]

1.2 Mechanisms

It has long been recognized that absorption of light by the carbon–halogen chromophore results in homolytic cleavage of the bond. Not only is the antibonding sigma orbital occupied in the lowest lying excited singlet state, but also more than sufficient energy is available for bond cleavage. For example, the 0,0 energy levels of a typical tertiary iodide and bromide, estimated from the onsets of absorption at 315 and 250 nm, are 380 and 476 kJ/mol, respectively — substantially higher than the bond dissociation energies of 226 and 284 kJ/mol, respectively. It should be noted, however, that although the excited state is dissociative, it does not cleave with unit efficiency. The quantum yield for dissociation of ethyl iodide, for example, has been determined to be 0.30–0.32 in the gas phase, in the pure liquid, and in hexane.[8]

Early studies on the photobehavior of alkyl halides were usually conducted in the gas phase and interpreted in terms of radical intermediates.[5] Similar thinking carried over to early solution-phase studies.[4a] However, several "anomalous" products appeared in the solution phase that require skeletal rearrangements appropriate for carbocations but not typical of radical intermediates. These include the formation of (*E*)-2-butene (**3**) from iodide **2**[9] and the rearranged alkene **5** from iodide **4**,[10] which could readily arise via the ionic intermediates shown. In view of the formation of such products, an extensive study of the solution-phase photobehavior of alkyl iodides was undertaken, which provided firm evidence for the involvement of cationic intermediates and led to the proposal that they arise via initial homolytic cleavage followed by electron transfer within the resulting radical pair cage (**6**), as outlined in Scheme 2.[11] As discussed below, the resulting carbocations display behavior typical of other "free" cations generated by high-energy processes with little or no solvent participation.[12]



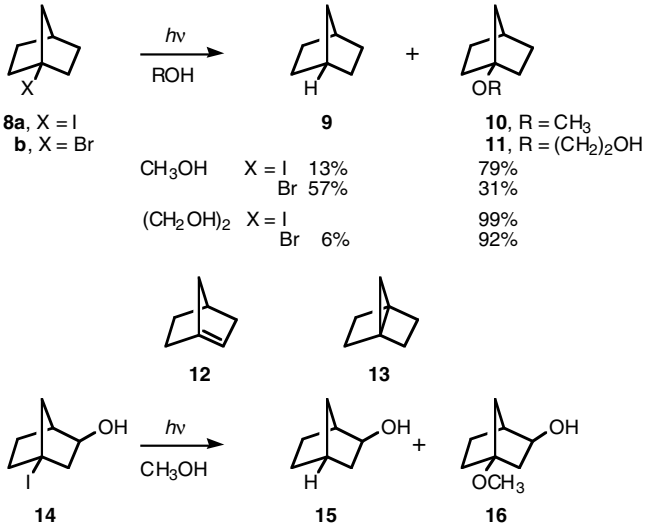


SCHEME 2

The initial studies centered on the 1-norbornyl halides **8**. On irradiation in CH_3OH, they afford a mixture of the reduction product norbornane (**9**) and the ether **10**, with the former predominating from bromide **8b** and the latter from iodide **8a**.[11,13] The reduction product **9** arises via abstraction of a hydrogen atom by 1-norbornyl radical from the medium and ether **10** via nucleophilic trapping of the 1-norbornyl cation. Irradiation of either halide in CH_3OD afforded ether **10** with no detectable incorporation of deuterium, indicating that it does not arise via acid-catalyzed addition of the alcohol to an initially formed unsaturated intermediate such as the bridgehead alkene **12** or the propellane **13**.

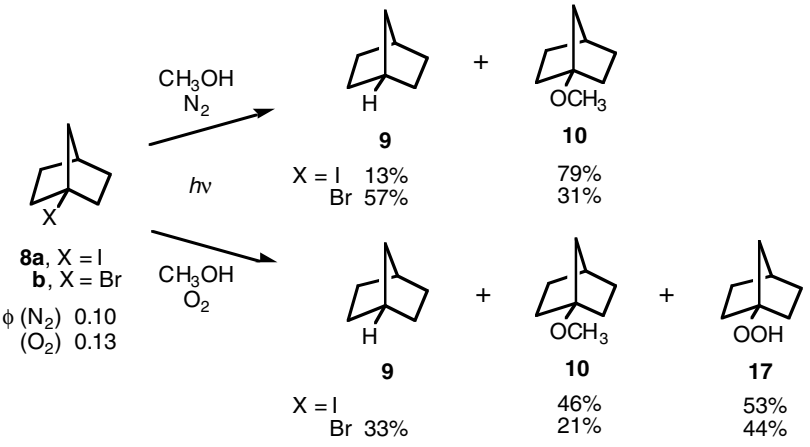
The higher ratio of ionic to radical products from iodide **8a** has proven to be general for iodides compared with the corresponding bromides. It is surprising since the more electronegative Br• might be expected to undergo electron transfer to the ion pair more readily than I• (Scheme 2). The observed trend apparently reflects a higher rate of diffusion from the radical pair cage relative to the rate of electron transfer for the lighter bromine atom.

As expected, the ratio of ionic to radical products is also dependent on the ionization potential of the alkyl radical R•. For example, in contrast with 1-iodonorbornane (**8a**), the 3-hydroxy derivative **14** afforded more of the reduction product **15** than ionic product **16** in CH_3OH.[14] Apparently the electron-withdrawing OH group impedes electron transfer. It has been proposed that the ionization potential of R• must be ≤200 kcal/mol for electron transfer to occur.[15]



Consistent with the proposed mechanism, the ratio of ionic to radical product is dependent on the viscosity of the medium. Thus irradiation of halides **8** in $(CH_2OH)_2$, which is only slightly more polar than CH_3OH but is substantially more viscous, resulted in almost exclusive formation of the nucleophilic trapping product **11** from both the bromide and the iodide.[11,13] The extended lifetime of the radical pair in the more viscous medium permits electron transfer to compete more effectively with diffusion of the radical components from the cage.

The quantum yield for disappearance of iodide **8a** in CH_3OH at 254 nm is 0.10.[13] The low value is probably due, at least in part, to recombination of the radical and ion pairs **6** and **7**. The quantum yield was somewhat higher in CH_3OH saturated with O_2, with formation of the radical product **9** almost totally quenched and that of the ionic product **10** substantially reduced.[13] This was accompanied by the formation of a new product, hydroperoxide **17**, arising from trapping of R·. Bromide **8b** displayed similar behavior except that formation of norbornane (**9**) was not totally quenched. Quenching of the ionic product **10** by O_2 is consistent with the proposed coupling of the radical and ionic pathways by electron transfer (Scheme 2).



1.3 Examples

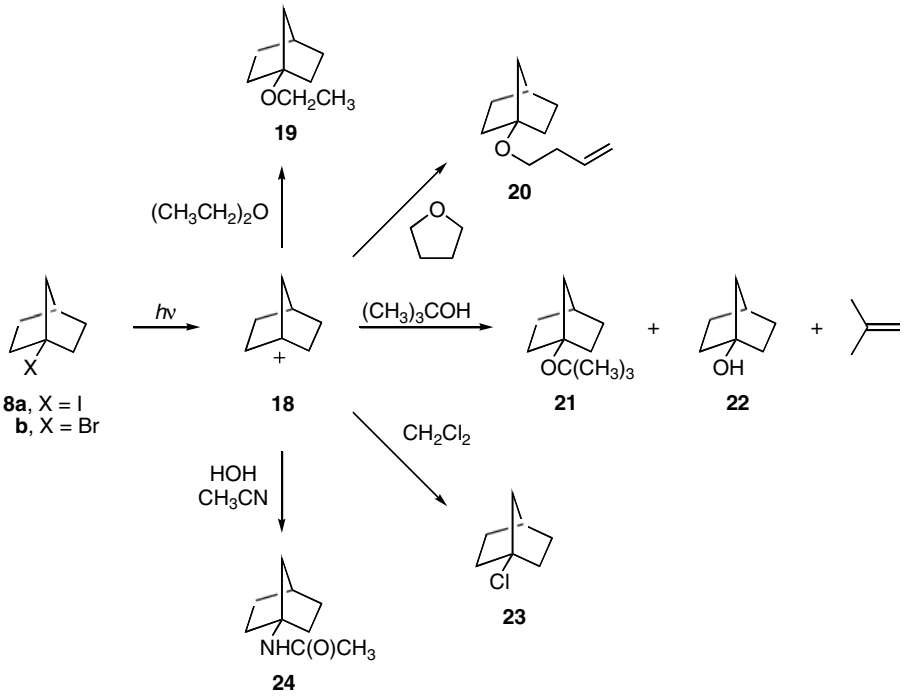
Monohalides

The photobehavior of alkyl halides varies with structure, depending on the ease of β-elimination.

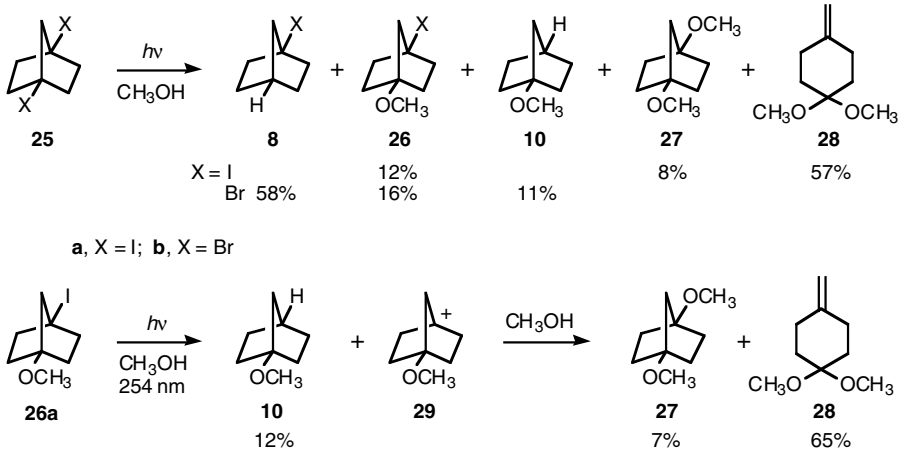
Bridgehead and Related Halides: Nucleophilic Trapping vs. Reduction

Irradiation of bridgehead halides is thus a convenient method for generating bridgehead carbocations, which are readily trapped nucleophilically. Even though tertiary, these cations are difficult to form by conventional methods because bridgehead carbon atoms are structurally inhibited from relaxing to a planar geometry to provide the sp^2 hybridization preferred by carbocations. Thus iodide **8a** was recovered quantitatively from treatment with CH_3OH in the dark for 24 h — even in the presence of silver ion, which normally facilitates solvolysis of alkyl iodides.[13] By contrast, a methanolic solution of **8a** readily afforded ether **10** on exposure to ultraviolet light.

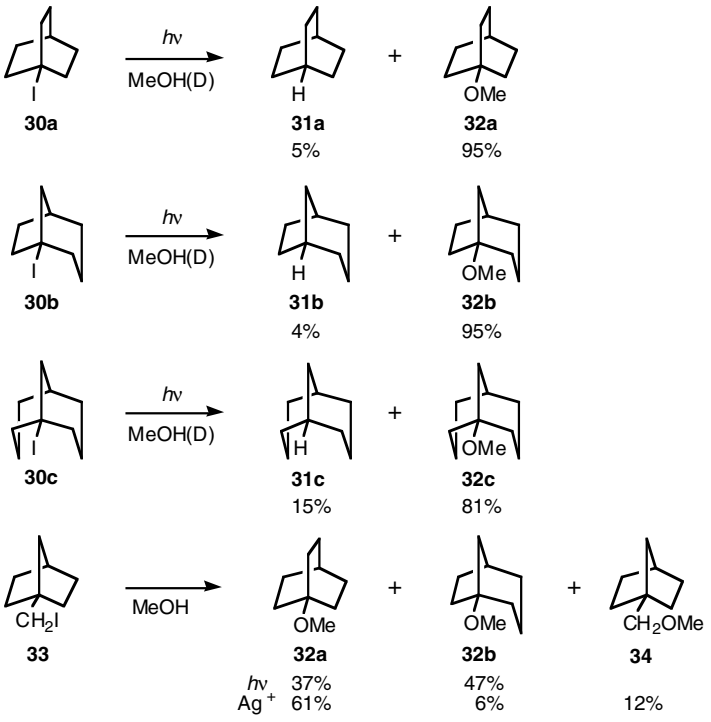
Since they are difficult to form, bridgehead cations are highly reactive. Irradiation of halides **8** in a variety of media provided a convenient means of exploring the remarkable reactivity of the 1-norbornyl cation (**18**).[13] It was efficiently trapped by diethyl ether and THF to afford the ethers **19** and **20**. Even in aqueous THF, a substantial portion of the butenyl ether **20** was obtained. Trapping by *t*-butyl alcohol afforded some of the ditertiary ether **21** but was accompanied by formation of 1-norbornanol (**22**) and 2-methylpropene. Cation **18** was trapped by CH_2Cl_2 to afford chloride **23**, and in aqueous CH_3CN the Ritter product **24** was formed. It should be noted that radical abstraction from CH_2Cl_2 occurs at H and ionic abstraction at Cl.



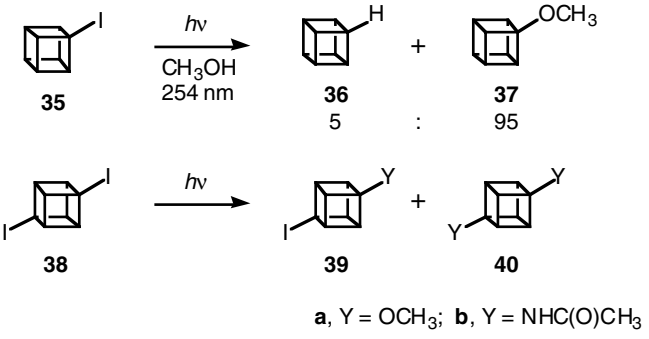
Interestingly, the 1,4-diiodide **25a** afforded mainly the acetal **28** rather than the dimethoxy product **27**.[16] Acetal **28** apparently arises from fragmentation of the 4-methoxy cation **29** prior to trapping with CH_3OH since it was also the principal product from separate irradiation of the 4-methoxy iodide **26a**. In contrast with diiodide **25a**, the 1,4-dibromide **25b** afforded predominantly the reduction product **8b**.



In analogy with 1-iodonorbornane (**8a**), the bridgehead iodides **30** afforded the corresponding ethers **32**, along with small amounts of the reduction products **31**.[17] Once again, irradiation in CH_3OD afforded ethers **32** with no detectable deuterium incorporation. The bicyclo[2.2.2]- and bicyclo[3.2.1]octyl cations were also obtained by irradiation of 1-(iodomethyl)norbornane (**33**) in CH_3OH to afford ethers **32a** and **32b** in a ratio approaching the kinetic ratio of 1:2.[13] By contrast, silver ion assisted methanolysis of iodide **33** afforded predominantly ether **32a**, arising from the thermodynamically more stable bicyclo[2.2.2]octyl cation, along with small amounts of the bicyclo[3.2.1]octyl ether **32b** and unrearranged ether **34**.

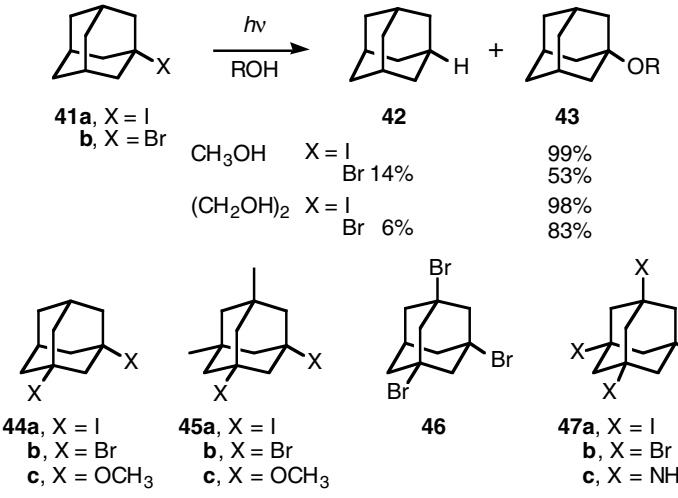


Irradiation of iodocubane (**35**) afforded the methyl ether **37** accompanied by a small amount of the reduction product cubane (**36**).[18] The high ratio of ionic to radical product indicates that the cubyl cation is easier to form than the 1-norbornyl cation, in agreement with solvolysis data and *ab initio* calculations showing stabilization of cubyl cation by cross-ring bonding to the β carbon atoms.[19] The 1,4-diiodide **38** afforded the mono- and disubstituted derivatives **39** and **40** in CH_3OH and wet CH_3CN.



Irradiation of the 1-adamantyl halides **41** in a variety of alcohols afforded the ethers **43** along with a small amount of the reduction product adamantane (**42**).[13,20] The greater ease of forming the 1-adamantyl, compared with the 1-norbornyl, cation is reflected in the higher ratio of ionic to radical product from both the iodide and bromide. Once again, use of the viscous solvent $(CH_2OH)_2$ greatly increased the amount of ionic product **43** from the bromide **41b** compared with CH_3OH.[13] Adamantyl bromides are significantly more sensitive to the presence of electron-withdrawing substituents than are the corresponding iodides. Thus the 1,3-diiodides **44a** and **45a** afforded the corresponding diethers **44c** and **45c** in high yield, whereas the dibromides **44b** and **45b** afforded principally the corresponding monoether **43** (R = OCH_3) and its 3,5-dimethyl derivative.[20] Similarly, the tribromide **46** afforded mainly the diether **44c** in CH_3OH,[20] and the tetrabromide **47b** afforded only 1-acetamido-3,5,7-tribromoadamantane in wet

CH_3CN.[21] By contrast, the tetraiodide **47a** afforded the tetraamide **47c** in 51–60% yield under similar conditions.[21]

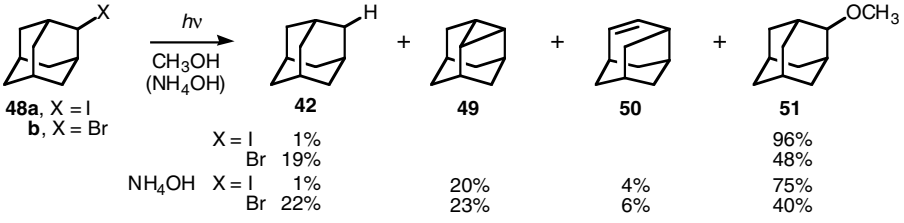


Nonbridgehead Halides: Elimination vs. Nucleophilic Trapping and Reduction

Except for systems such as the preceding bridgehead halides that are strongly inhibited from undergoing elimination, alkyl halides undergo competing elimination and trapping in nucleophilic solvents. The product ratio depends on the degree of structural inhibition to elimination and the nucleophilicity of the solvent, but there is a strong propensity for undergoing elimination that is characteristic of "free" cations formed by high-energy processes without substantial solvent participation.[12] Cationic rearrangements frequently precede elimination and nucleophilic trapping. Competing radical behavior is also usually observed.

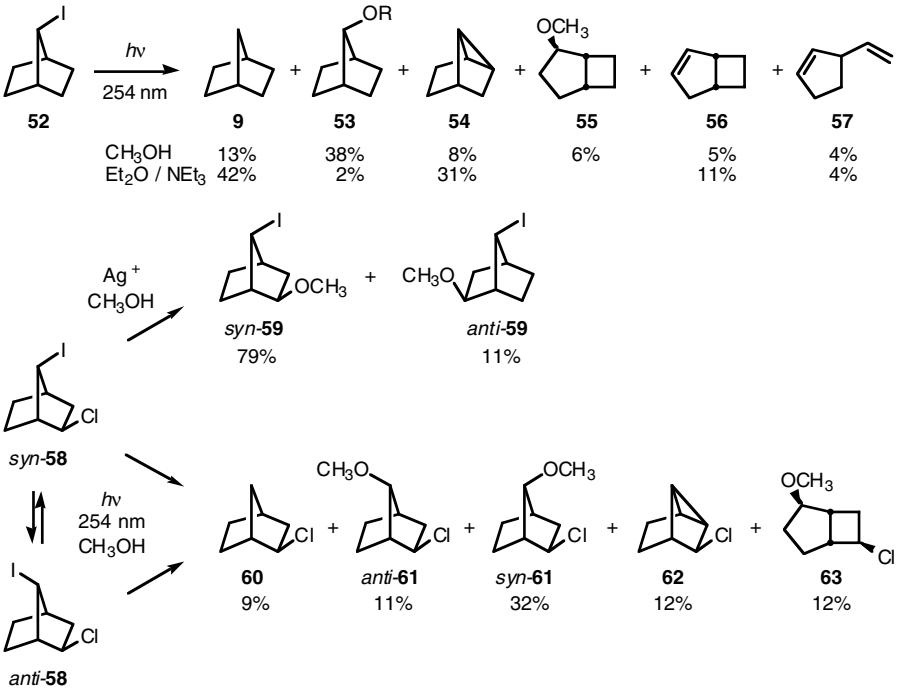
1,2- and 1,3-Elimination

Irradiation of the 2-adamantyl halides **48** in CH_3OH afforded principally the 2-adamantyl ether **51**, along with the reduction product adamantane (**42**).[13,20] However, when the irradiation was conducted in the presence of NH_4OH as a HX scavenger, the 1,3-elimination product **49** and rearranged elimination product **50** were also obtained.[7,22] In the absence of scavenging, these latter products undergo addition of HX to reform the starting halides **48**. Irradiation of iodide **48a** in the nonnucleophilic solvent ether containing triethylamine as a scavenger afforded principally the 1,3-elimination product **49**.[22]

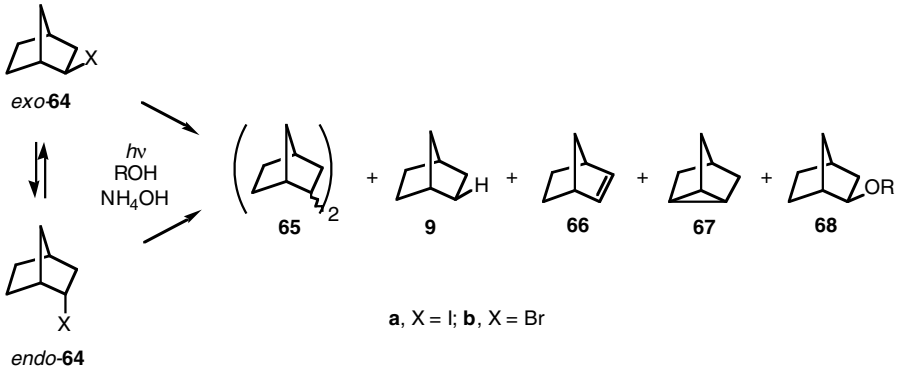


Another cation that, like bridgehead cations, is difficult to form by conventional methods is the 7-norbornyl cation. The problem in this case is angle strain. Thus, extended treatment of 7-iodonorbornane (**52**) with methanolic $AgNO_3$ afforded only a trace of ether **53** (R = CH_3).[23] By contrast, irradiation in CH_3OH readily afforded ether **53** (R = CH_3), along with smaller amounts of the reduction product norbornane (**9**), the unprecedented 1,3-elimination product **54** and the rearrangement products **55**–**57**. The 2-chloro derivatives **58** underwent *syn,anti* interconversion in competition with formation of the reduction product **60**, the ethers **61** and **63**, and the 1,3-elimination product **62**. By contrast, treatment

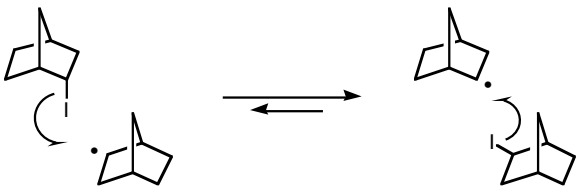
with methanolic $AgNO_3$ resulted in ionization of the more reactive chlorine substituent to afford ethers **59**. Thus, irradiation at 254 nm is a simple method for inducing selective reaction by the iodine substituent.



By contrast, the 2-norbornyl cation is easily formed. Moreover, the 2-norbornyl system can readily undergo elimination. On irradiation in CH_3OH or $(CH_3)_3COH$, the 2-norbornyl iodides **64a** underwent *exo,endo* equilibration and afforded the 1,2- and 1,3-elimination products **66** and **67**, along with the nucleophilic trapping product **68**.[7,24] The corresponding bromides **64b** each afforded the same products, along with small amounts of the radical products **65** and **9**, but underwent no detectable interconversion.



Clearly, the ethers **68** and the 1,3-elimination product nortricyclene (**67**) are ionic in origin. However, the 1,2-elimination product 2-norbornene (**66**) might, in principle, arise via either hydrogen atom transfer within the radical pair **6** or proton transfer within the ion pair **7** (Scheme 2). Deuterium labeling studies revealed that it arises by both paths, with the percent ionic pathway being 36% for iodides **64a** and 64–69% for bromides **64b**.[7] These distributions, combined with the yields of the ionic products

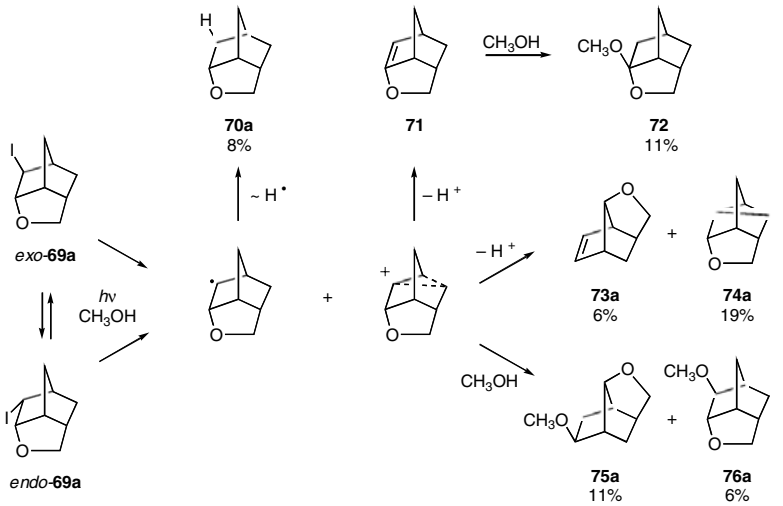


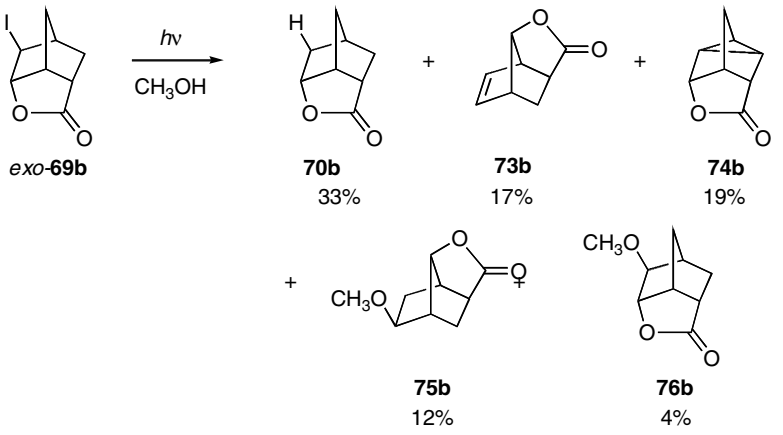
SCHEME 3

nortricyclene (**67**) and the ether **68** (R = CH_3), afford a ratio of in-cage radical to total ionic products of 1:3 for iodides **64a** but only 1:8 for bromides **64b**. Thus, of the material that is not lost by diffusion from the radical pair cage (**6**), a higher percentage is converted to products via ionic intermediates when X = Br, as expected based on the relative electronegativities of bromine and iodine.

Once out of the cage, the alkyl radical can abstract a hydrogen atom from the solvent or undergo combination/disproportionation with a second alkyl radical. Another available pathway in the case of iodides is transfer of an iodine atom from a molecule of unreacted starting material. Halogen atom transfer occurs readily for alkyl iodides ($k \approx 2 \times 10^5$ mol^{-1} sec^{-1})[25] and accounts for the observed interconversion of iodides **64a** (Scheme 3). In the more viscous solvent $(CH_3)_3COH$, in which escape from the radical cage (**6**) occurs more slowly, there is substantially less epimerization. In contrast with that for iodides, halogen atom transfer is much slower for alkyl bromides ($k \approx 6 \times 10^2$ mol^{-1} sec^{-1}),[25] permitting combination/disproportionation to compete. Hence bromides **64b** undergo no detectable epimerization.

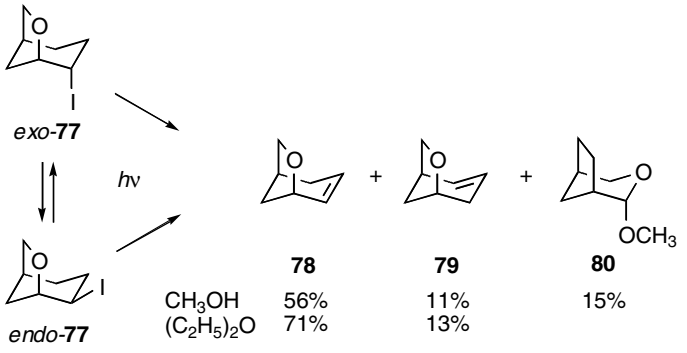
Analogously with the parent 2-norbornyl iodides **64a**, the iodo ethers **69a** underwent *exo,endo* equilibration, accompanied by formation of the reduction product **70a**, the rearranged elimination product **73a**, the 1,3-elimination product **74a**, and the ethers **75a** and **76a**.[17] Also formed was the acetal **72**, which deuterium labeling studies surprisingly showed arises via elimination to the bridgehead alkene **71** followed by addition of CH_3OH. In the presence of furan, the bridgehead alkene **71** was trapped by cycloaddition. Formation of the highly strained intermediate **71** underscores the strong driving force for elimination exhibited by alkyl halides on irradiation.



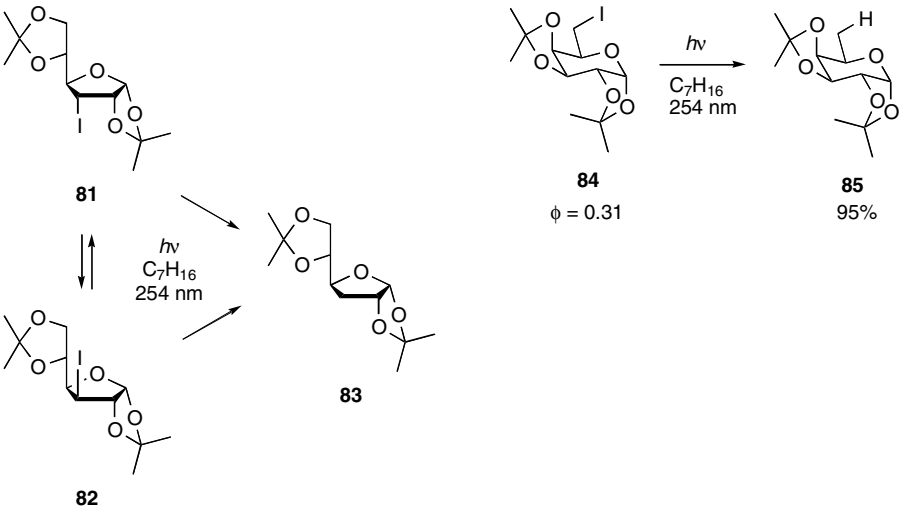


By contrast, the corresponding lactone **69b** underwent no detectable epimerization and afforded, principally, the reduction product **70b.**[17] The added inductive effect of the carbonyl oxygen atom apparently both retards electron transfer and renders the radical intermediate more reactive toward hydrogen abstraction from the medium, decreasing its lifetime and competing with the iodine exchange that leads to epimerization of iodo ether *exo*-**69a** (Scheme 3). The analogous elimination and trapping products **73b**–**76b** were formed, but there was no detectable formation of a product corresponding to acetal **72**, presumably because the increased strain introduced by the sp^2-hybridized carbonyl carbon atom precludes elimination to a bridgehead alkene.

The analogous iodo ethers **77** similarly underwent *exo,endo* equilibration, along with formation of the elimination product **78** and rearranged elimination product **79.**[26] In CH_3OH, the rearranged acetal **80** was also formed.

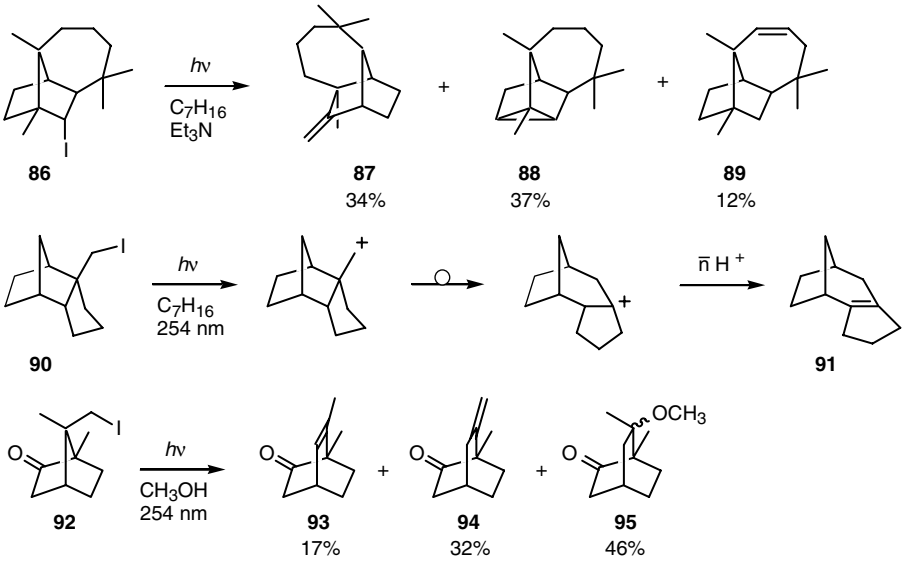


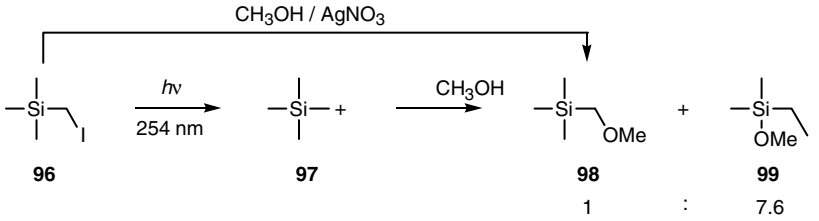
Epimerization was also observed in the interconversion of the deoxy iodo sugars **81** and **82.**[27] Interconversion occurred from either isomer with a quantum yield greater than unity, consistent with a mechanism analogous to that of Scheme 3. Also formed was the reduction product **83.** Similarly, the deoxy iodo sugar **84** afforded the reduction product **85.**[27] Irradiation of deoxy halo sugars is a useful synthetic application of the radical photobehavior of alkyl halides, affording the corresponding deoxy sugars in high yield under mild conditions.[28] Ionic products are not formed, even in nucleophilic solvents. Except at the anomeric position, carbohydrates form carbocations with difficulty because of the large number of electron-withdrawing oxygen atoms.



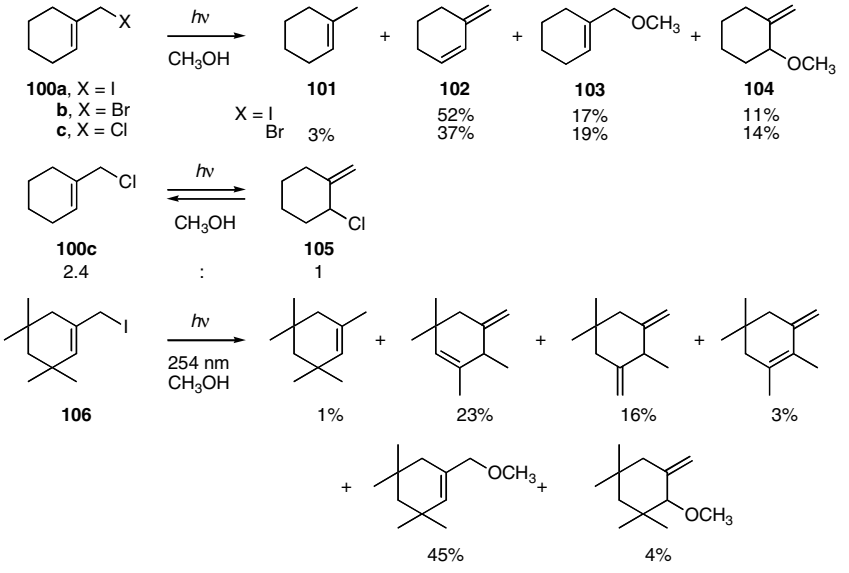
The *endo*-2-norbornyl analog longibornyl iodide (**86**) afforded principally the elimination products longifolene (**87**) and longicyclene (**88**), accompanied by a small amount of alkene **89** resulting from a transannular hydride shift.[29] Solvolysis of iodide **86** afforded only longifolene (**87**) and longicyclene (**88**), with none of the transannular elimination product **89**. Formation of this product on irradiation once again illustrates the high reactivity of "free" cationic intermediates generated photolytically from alkyl halides. Another example is the formation of the strained alkene **91** from the 2-(iodomethyl)norbornane **90**.[30]

Irradiation of 9-iodocamphor (**92**) in CH_3OH afforded the ring-expanded elimination products **93** and **94**, accompanied by a mixture of ethers **95**.[31] Thus, the CI chromophore can be selectively irradiated at 254 nm in the presence of a ketone carbonyl group. Under similar conditions (iodomethyl)trimethylsilane (**96**) afforded, principally, the silyl ether **99**, resulting from rearrangement of the α-silyl cation **97**.[32] By contrast, silver ion assisted methanolysis of iodide **96** afforded only the unrearranged ether **98** via S_N2 displacement, avoiding involvement of the α-silyl cation **97**.



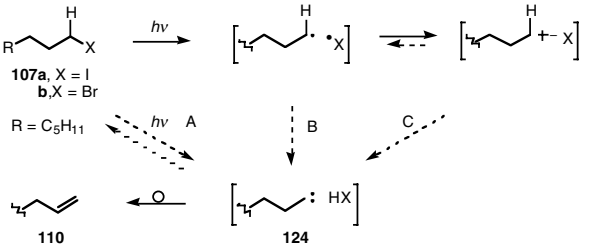


Even highly stabilized allylic cations undergo substantial elimination in a nucleophilic solvent when generated photochemically. Thus the allylic iodide **100a** and bromide **100b** afforded principally the elimination product **102**, along with the methyl ethers **103** and **104**, on irradiation in CH_3OH.[33] Similar behavior was exhibited by the tetramethyl derivative **106**. By contrast, the chloride **100c** simply underwent equilibration with the allylic isomer **105**, presumably via the radical pair.

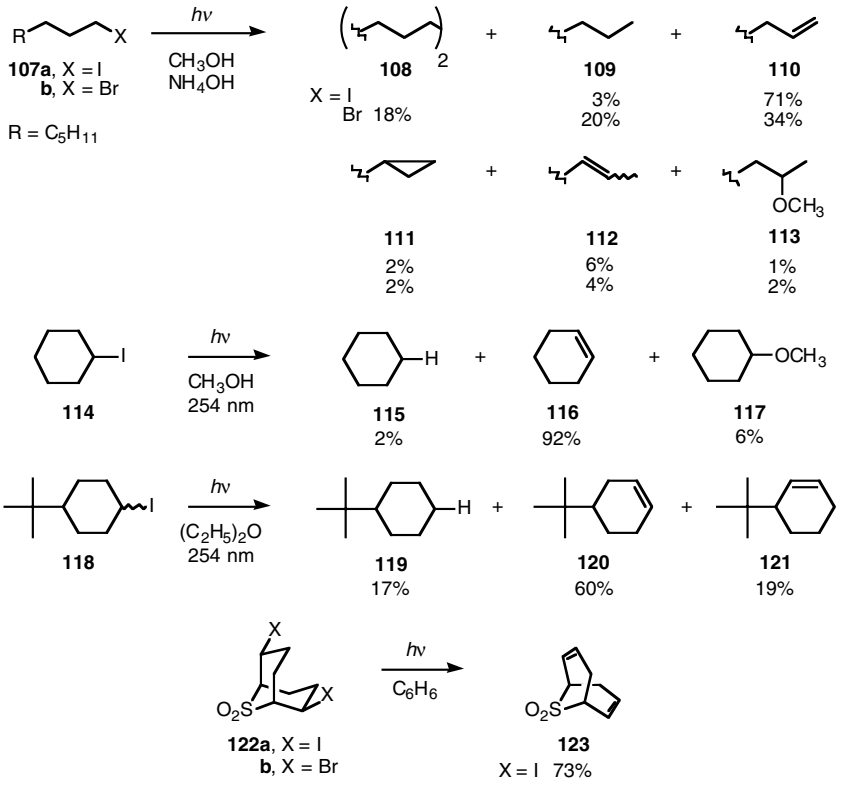


The 1-halooctanes **107** and iodocyclohexane (**114**) show once again the propensity of alkyl halides for photoelimination, giving primarily the elimination products 1-octene (**110**) and cyclohexene (**116**) in CH_3OH and only small amounts of the ethers **113** and **117**.[11,13,34] As is typical, bromide **107b** gave appreciable amounts of the out-of-cage radical products **108** and **109**. The *t*-butylcyclohexyl iodide **118** afforded substantial amounts of the rearranged elimination product **121**.[26]

In a dramatic application of the propensity of alkyl halides to undergo photoelimination, irradiation of the diiodosulfone **122a** proved to be the method of choice for effecting elimination to diene **123**, which was formed in good yield.[35] By contrast, the dihalosulfones **122** were either inert toward conventional elimination conditions or gave mainly methyl ethers on treatment with methanolic KOH. Irradiation of the dibromosulfone **122b** gave mainly reduction and no detectable formation of the elimination product **123**.



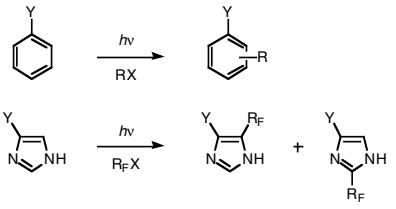
SCHEME 4



α-*Elimination: A Secondary Pathway to Unsaturated Products*

In the preceding discussion, it was assumed that elimination products such as 1-octene (**110**) are formed via transfer of a β-hydrogen atom or a β-proton from the corresponding radical or carbocation, respectively. However, deuterium labeling studies with 1-iodooctane (**107a**) showed that 17–29% of the 1-octene (**110**) is formed via α-elimination to the carbene intermediate **124**, depending on the solvent and irradiation conditions (Scheme 4).[34] Similarly, 27–30% of the cyclohexene (**116**) from 1-iodocyclohexane (**114**) arises via α-elimination. However, only 7% of the 1-octene (**110**) from bromide **107b** arises via α-elimination.[7]

As shown in Scheme 4 using the 1-halooctane system **107** as a model, the caged carbene-HX pair **124** may undergo undetected insertion to regenerate halide **107** in competition with rearrangement of the carbene to 1-octene (**110**). Thus, α-elimination may occur more extensively than reflected by the deuterium labeling results. Three possible routes to the carbene intermediate are outlined. The most obvious,



SCHEME 5

direct formation via concerted loss of HX (path A) is inconsistent with the observed lack of a deuterium isotope effect on the relative involvement of α-elimination in the formation of 1-octene (**110**). It is not clear which of the other two paths is involved in carbene formation. There is, however, precedent for the formation of carbene intermediates via transfer of α protons from carbocations.[36]

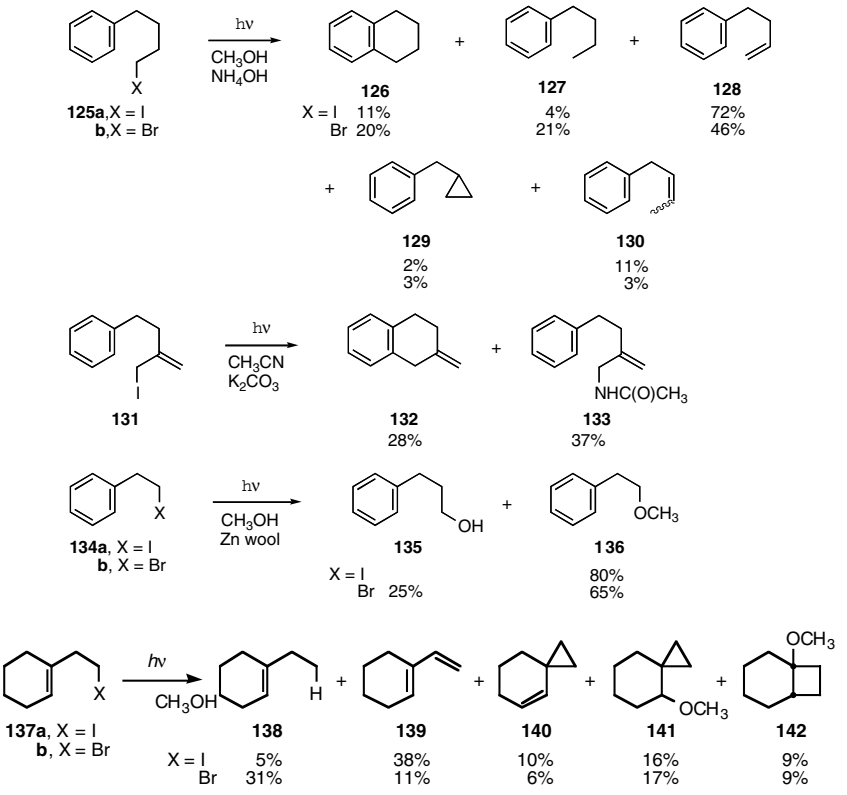
Trapping by Aromatic Solvents

Alkyl halides typically undergo slow elimination on irradiation in aromatic solvents, accompanied by the formation of alkylated aromatic products in low-to-moderate yields (Scheme 5).[37] These latter products were obtained in higher yields with methyl,[38] trifluoromethyl,[39] and allyl[40] iodides, which are incapable of undergoing competing elimination. Similarly, irradiation of 1-iodonorbornane (**8a**) in toluene afforded a mixture of 1-tolylnorbornanes (**8**, X = $C_6H_4CH_3$) in good yield.[13] Imidazole and its derivatives underwent facile trifluoromethylation or perfluoroalkylation on irradiation of perfluoroalkyl iodides in their presence in CH_3OH solution.[41] However, when the photolyses of simple alkyl halides were performed in CH_3OH or CH_3CN solutions containing aromatic substrates, nucleophilic trapping products (alkyl methyl ethers or *N*-alkylacetamides) were formed at the expense of aromatic substitution products.[37]

Since the absorption spectra of the CI and aryl chromophores have extensive overlap, it is not clear whether photoreaction involves direct absorption by the alkyl halide or whether the light is being absorbed by the aromatic substrate, followed by either energy or electron transfer with the alkyl halide. It is also not clear whether the aromatic substrates are capturing radical or cationic intermediates. Simple alkyl iodides afforded mixtures of toluene adducts having o:m:p ratios consistent with cationic attack.[37] This was reinforced by the formation of ethers or acetamides at the expense of aryl substitution products in the presence of CH_3OH or CH_3CN. On the other hand, the 1-tolylnorbornanes (**8**, X = $C_6H_4CH_3$) from 1-iodonorbornane (**8a**) were formed in a ratio typical of that for homolytic substitution.[13] It would be expected that methyl and trifluoromethyl iodides would afford only radical intermediates. However, they exhibited a lower reactivity at the ortho position than is generally typical of homolytic substitution reactions.[38,39] Similar results were afforded by allyl iodide.[40] Either competing trapping of radical and cationic intermediates is involved, or the mechanism is more complex than is apparent.

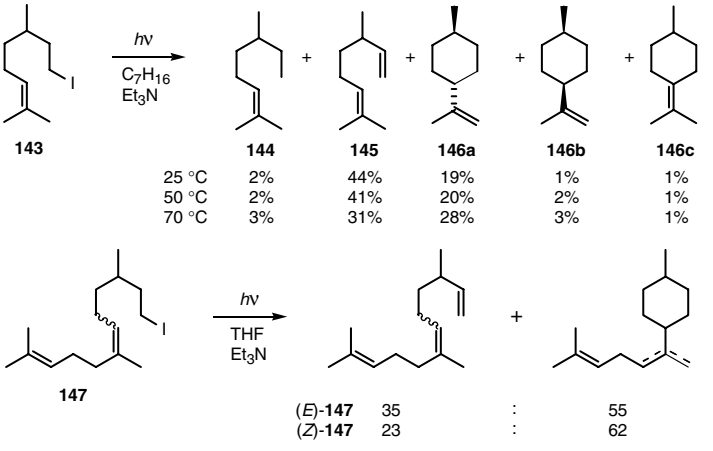
Cyclization

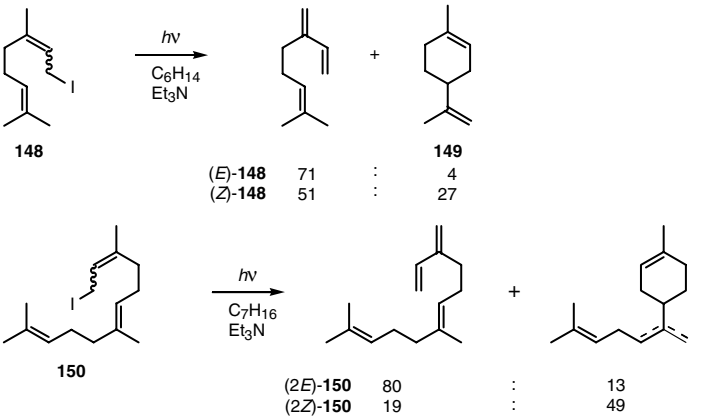
Trapping of the radical or cationic intermediates resulting from irradiation of alkyl halides can also occur intramolecularly. The 4-phenyl-1-butyl halides **125** afford the cyclized product **126** along with the additional products **127–130**.[7,42] As usual, elimination predominates over aryl substitution. The allylic analog **131**, which is structurally incapable of undergoing elimination, afforded the cyclization product **132**, along with the amide **133**, in CH_3CN.[42a] By contrast, the 2-phenyl-1-ethyl iodide **134a** gave only the ether **136**, whereas the bromide **134b** gave a mixture of ether **136** and the out-of-cage radical product **135**.[42b] Analogous behavior was exhibited in other alcoholic solvents. The olefinic analogs **137** afforded the cyclized products **140–142**, along with the reduction product **138** and elimination product **139**.[33]



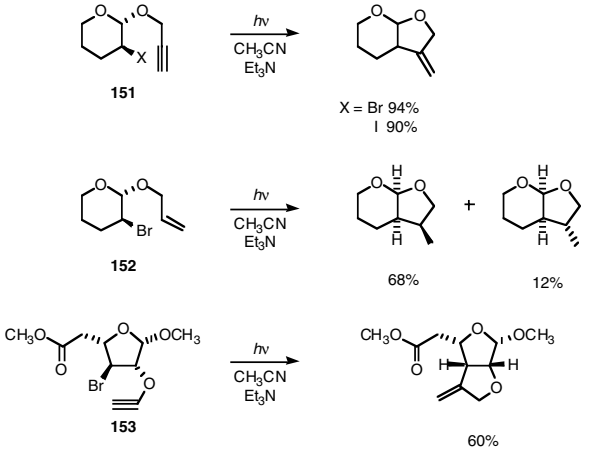
Charge-Transfer Irradiation: Radical Products

Irradiation of alkyl halides in the presence of amines proceeds via an amine–halide charge-transfer complex (**1**) to afford principally radical-derived products (Scheme 1). Thus citronellyl iodide (**143**) afforded a mixture of elimination (**145**) and cyclization products (**146**) accompanied by a small amount of reduction product **144**.[29,43] For reasons not clear, cyclization was somewhat more favored relative to elimination with increasing temperature and on going to the more polar solvent THF. Analogous behavior was exhibited by the 2,3-dihydrofarnesyl iodides **147**, which underwent competing elimination and cyclization.[43] Neryl iodide [(*Z*)-**148**] similarly afforded substantial amounts of both the elimination and cyclization products.[44] The isomeric geranyl iodide [(*E*)-**148**], which is structurally inhibited from undergoing cyclization, afforded a small amount of the cyclization product limonene (**149**), apparently via initial $E \rightarrow Z$ isomerization. Likewise, the farnesyl iodide (2*Z*)-**150** underwent principally cyclization, whereas the isomeric (2*E*)-**150** predominantly underwent elimination.[44]



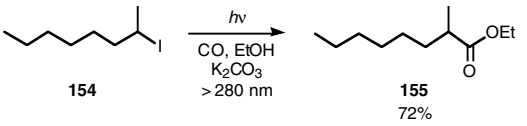


Irradiation of alkyl halides in the presence of amines is a synthetically useful method for generating radical-derived products that avoids the troublesome purification problems associated with the conventional method of using trialkyltin halides to generate radicals from alkyl halide precursors. This is illustrated by the bromides and iodides **151–153**, which afforded cyclization products in good to excellent yields.[45]



Irradiation of a number of alkyl iodides in the presence of CO and a variety of alcohols afforded the corresponding esters in good yield (59–87%) via trapping of the alkyl radical and alcoholysis of the resulting acyl iodide (Scheme 6).[46] Carboxylation occurred selectively at the carbon atom to which the iodine atom had been attached, and a wide range of aliphatic iodides, including tertiary, was effective. 2-Iodooctane (**154**) afforded the ester **155** in 72% yield, along with a mixture of 1- and 2-octenes (16%) as minor products. However, long irradiation times (12–50 h) and moderately high pressures (20–55 atm) were employed. Since irradiations were conducted through Pyrex (cutoff 280 nm) in polar solvents in the presence of a base, and no reaction occurred in the absence of base, the alkyl radicals were apparently formed via weak absorption of a charge-transfer complex (Scheme 1) rather than direct excitation of the C–I chromophore.

SCHEME 6



154 **155** 72%

An exception to the usual formation of radical-derived products in the presence of amines is a recent report that irradiation of 1-bromo- (**41b**) and 1-chloroadamantane (**41c**) and 1-chloronorbornane (**8c**) in the presence of primary amines afforded the substitution products **156** and **157**, along with the radical products adamantane (**42**) and an adamantyl dimer or norbornane (**9**) and a norbornyl dimer.[20b] However, the quantum yields were very small ($2–4 \times 10^{-7}$ for chloride **41b** and 6×10^{-9} for chloride **8c**), and neither the chemical yields of the products nor the relative yields of substitution and radical products were reported. Likewise, no comment was provided on the formation of monoalkyl amine intermediates. Since these amines are primary, electron transfer within the charge-transfer complex may occur less readily.

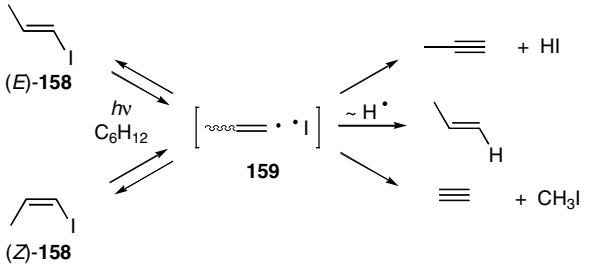
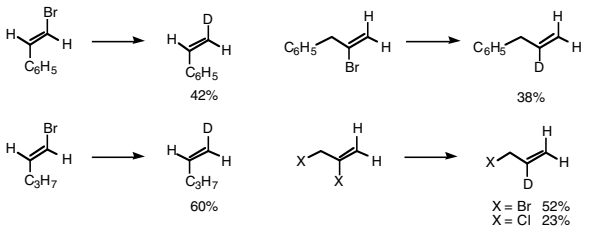
Vinyl Halides

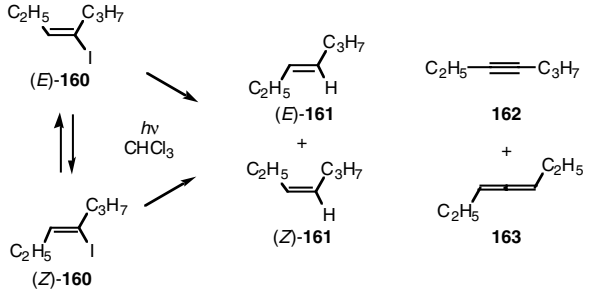
The photobehavior of vinyl iodides closely parallels that of their saturated alkyl analogs in solution, serving as a convenient and powerful method for the generation of vinyl cations that can be effected even at low temperature and in solvents of widely varying polarity. Once again, however, there is a strong propensity for elimination.

As with that of their saturated analogs, the photobehavior of vinyl iodides was initially interpreted exclusively in terms of radical intermediates. One of the first to be studied in solution, 1-iodopropene (**158**), was observed to undergo *E,Z*-isomerization accompanied by elimination to propyne, reduction to propene, and fragmentation to ethyne and CH_3I.[47,48] The radical pair **159** was proposed as the sole intermediate, even though elimination of HI could equally well involve the corresponding ion pair. The behavior of 4-iodo-3-heptene (**160**), which afforded the additional elimination product allene **163** besides the reduction products **161** and the alkyne **162**, was similarly interpreted as radical in character.[49]

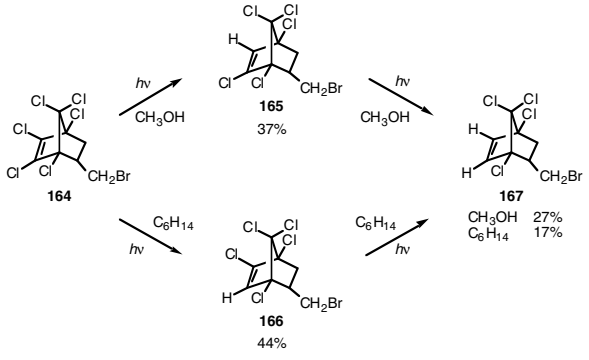




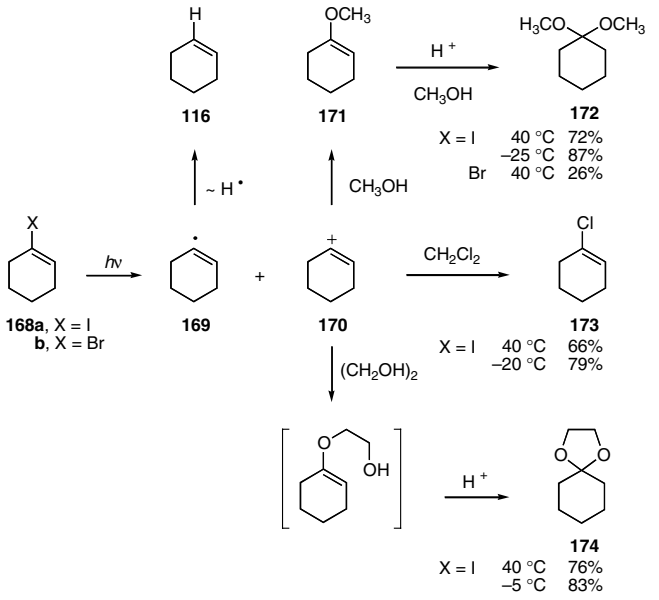
SCHEME 7



Advantage was taken of the formation of reduction products, which are undoubtedly of radical origin, to prepare specifically deuterated alkenes (Scheme 7).[50] It is interesting that substitution of a vinyl halogen atom by deuterium can be effected selectively in the presence of allylic bromides or chlorides, which normally are much more reactive, because they do not absorb strongly under the irradiation conditions. This was also seen in the irradiation of the insecticide bromodan (**164**), which afforded a mixture of the reduction products **165** and **167** in CH_3OH and **166** and **167** in C_6H_{14}.[51] It is not clear why the chlorine substituent at C2 or C3 is more reactive in CH_3OH or C_6H_{14}, respectively.

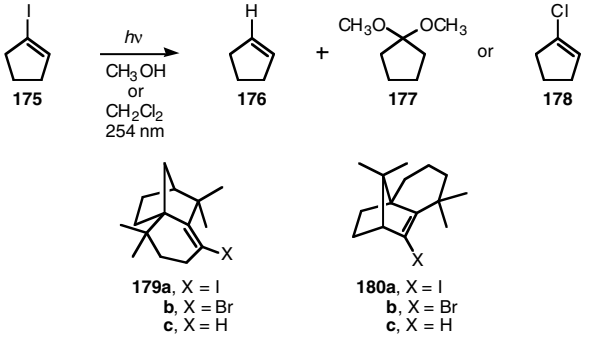


Evidence for the competing involvement of ionic intermediates in the photobehavior of vinyl halides was obtained by incorporating the chromophore in a cyclic environment, in which elimination is structurally inhibited. Thus, 1-iodocyclohexene (**168a**) afforded the nucleophilic trapping products **172–174** in high yields, clearly showing involvement of the vinyl cation **170**.[52] Irradiation in CH_3OH containing Zn as an acid scavenger afforded the vinyl ether **171** (65% yield) instead of the acetal **172**. As is typical, irradiation of bromide **168b** in CH_3OH afforded principally the reduction product cyclohexene (**116**) accompanied by smaller amounts of the acetal **172**.

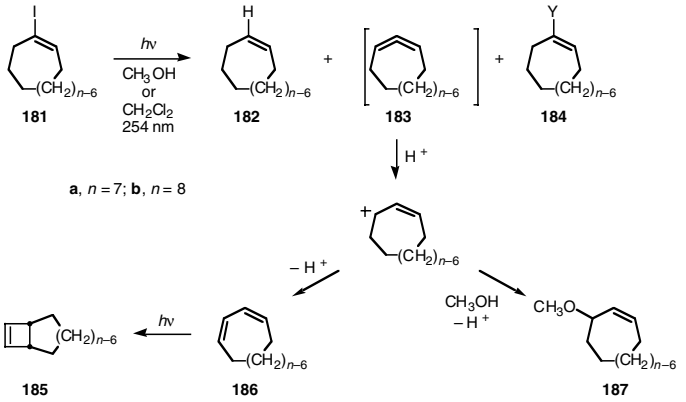


There was a moderate increase in the formation of the nucleophilic trapping products **172–174** relative to the reduction product cyclohexene (**116**) with decreasing temperature. The origin of this effect, which is general for vinyl iodides, is not clear. It does not appear to be due principally to the increased viscosity of the medium at lower temperatures, since vinyl halides show no significant increase in the yield of ionic products on going from CH_3OH to the highly viscous solvent $(CH_2OH)_2$. Saturated alkyl halides, which exhibit increased ionic behavior in more viscous solvents, do not exhibit a similar temperature effect.[33]

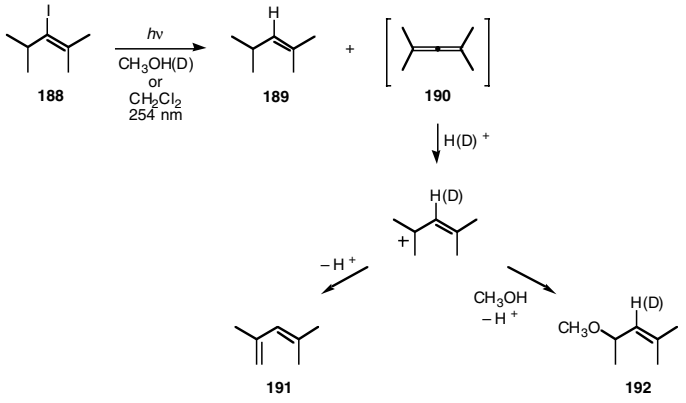
The cyclopentenyl analog **175** afforded principally the reduction product **176** accompanied by only a small amount of the trapping product **177** or **178** in CH_3OH or CH_2Cl_2, respectively, presumably because of the increased strain associated with incorporating an sp-hybridized center in a five-membered ring.[52] Nonetheless, these were the first unequivocal examples of the generation of a 1-cyclopentenyl cation from a cyclopentenyl precursor. The even more highly constrained cyclohexenyl halides **179** and **180** afforded exclusively the reduction product isolongifolene (**179c**) or neoisolongifolene (**180c**), respectively, on irradiation in CH_3OH.[53]



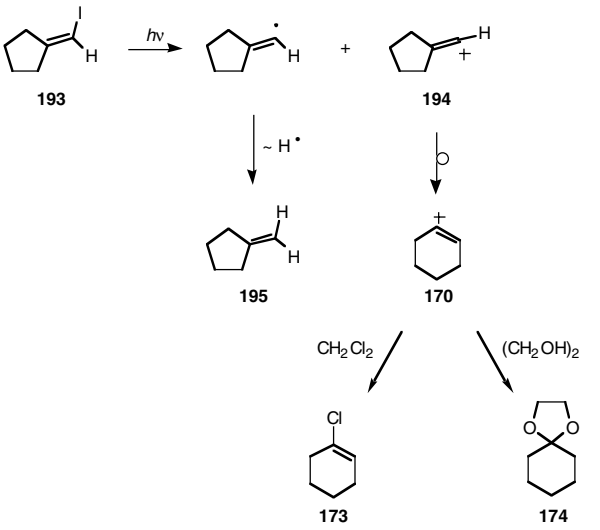
In the higher homolog, 1-iodocycloheptene (**181a**), the nucleophilic trapping product **184a** (Y = OCH_3 or Cl) predominated but was accompanied by the secondary products **185a** and **187a**, arising from competing elimination to the strained allene **183a**.[52] In 1-iodocyclooctene (**181b**), elimination to allene **183b**, leading to the secondary products **185b–187b**, predominated over nucleophilic trapping in CH_3OH and occurred exclusively in CH_2Cl_2. In each case, some of the reduction product **182** was also obtained.



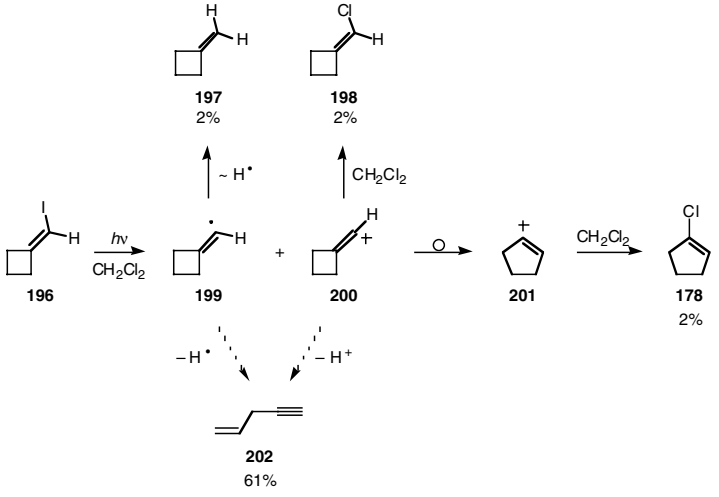
In the acyclic analog **188**, elimination occurred exclusively even in CH_3OH to give the secondary products **191** and **192** along with the reduction product **189**.[52] In CH_3OD, the allylic ether **192** was formed with deuterium incorporation as expected from protonation of the allene intermediate **190**. In marked contrast with its facile photoelimination, iodide **188** is totally inert toward methanolic $AgNO_3$.[52]



The exocyclic analog **193** similarly displays competing radical and ionic photobehavior. This is significant since vinyl cations generally require stabilization by an α substituent. Except for (halomethylene)cyclopropanes and β-aryl systems, which gain special stabilization from the β substituents, α-unsubstituted vinyl cations have not been generated solvolytically. Interestingly, the resulting vinyl cation **194**, which can assume the preferred linear geometry of an sp-hybridized center, undergoes rearrangement to the cyclohexenyl cation **170**, which is α-substituted but cannot be linear. Thus, irradiation of iodide **193** in CH_2Cl_2 or $(CH_2OH)_2$ afforded the reduction product **195** and either the vinyl chloride **173** or acetal **174**, respectively.[52]



Analogous behavior was exhibited by the higher homolog (iodomethylene)cyclohexane.[52] The smaller homolog **196**, however, proved to be a poor precursor to the highly strained cyclopentenyl cation **201**. Irradiation in CH_2Cl_2 afforded principally the enyne **202**, along with small amounts of the reduction product **197** and vinyl chlorides **198** and **178**.[52] It is not clear whether enyne **202** arises from fragmentation of the radical **199** or cation **200**.



The exocyclic vinyl halides **203** clearly show the strong effect of α substituents on vinyl cations. The α-unsubstituted derivatives **203** (R = H), which are inert toward methanolic $AgNO_3$, afforded only the reduction product camphene [**204** (R = H)] on irradiation in CH_3OH.[54] Ring expansion as exhibited by the exocyclic iodide **193** would afford a highly strained bicyclo[3.2.1]octenyl cation. By contrast, the methyl derivatives **203** (R = CH_3) afforded a mixture of the reduction products **204** (R = CH_3) and the allene **205**, and the phenyl derivatives **203** (R = C_6H_5) afforded principally the ethers **206** (R = CH_3) in CH_3OH.[54] The ratio of ethers **206** to reduction products **204** (R = C_6H_5) from bromide **203b** (R = C_6H_5) was 3.2:1.5:0.1:0.9 for the solvent series CH_3OH, CH_3CH_2OH, $(CH_3)_2CHOH$, and $(CH_3)_3COH$, respectively.[55] This follows the decreasing polarity of these solvents except for $(CH_3)_2CHOH$, which is an excellent hydrogen atom donor.

204 **205** **206**

The research groups of Taniguchi, Zupan, and Lodder have extensively studied the photobehavior of aryl-substituted vinyl halides.[56] Numerous examples of competing radical and ionic photobehavior have been observed; detailed review is beyond the scope of this report. Two of the earliest studies involved the 2,2-diarylvinyl halides **207**, which underwent predominant rearrangement–elimination to the tolans **208**, along with competing formation of several radical products.[57,58]

Alkynyl Halides

Early studies concentrated mostly on phenylethynyl halides and were interpreted in terms of radical intermediates.[59] Specific attempts to induce ionic photobehavior from the 1-halo-1-hexynes **209** in polar media, including the use of low temperature and viscous solvents, afforded almost exclusively radical-derived products.[15] This is consistent with the high ionization potentials of 1-alkynyl radicals.

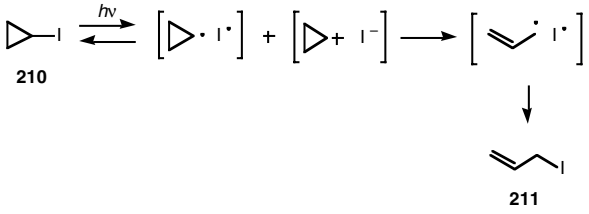
b, X = Br

Iodocyclopropane

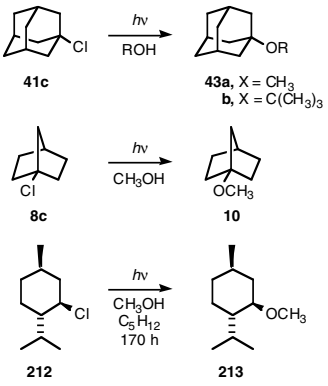
Irradiation of iodocyclopropane (**210**) in benzene solution afforded allyl iodide (**211**).[60] In the presence of TEMPO, products from trapping of both cyclopropyl radical and allyl radical were obtained. Since the ratio of the two products was not dependent on the concentration of TEMPO, the allyl radical is apparently a direct photoproduct rather than a secondary product from rearrangement of cyclopropyl radical. *Ab initio* calculations suggested that allyl radical arises via two crossings between open-shell and closed-shell surfaces; the $^1(n\sigma^*)$ state of iodocyclopropane (**210**) experiences a symmetry-allowed intersection with the closed-shell ion pair. The cyclopropyl cation thus generated undergoes a barrierless ring opening to generate allyl cation. In a second surface crossing, the resulting ion pair undergoes back electron transfer, by way of the same symmetry-allowed conical intersection, to generate allyl radical and an iodine atom. It is not clear how general such surface crossings may be in alkyl halides.



210 **211**

Alkyl Chlorides

Alkyl chlorides have been little studied because they absorb only at very short wavelengths. However, they form charge-transfer complexes with alcohols and amines that absorb at more accessible wavelengths. Irradiation of alkyl chlorides in the presence of amines is discussed above. Direct irradiation of 1-chloroadamantane (**41c**) and -norbornane (**8c**) in alcoholic solvents afforded ethers **43a–b** and **10** with quantum yields of 0.9–1.4 × 10^{-7} and 1.5 × 10^{-9}, respectively, in unstated chemical yields.[20b] Extended irradiation of (1*R*,2*S*,5*R*)-menthyl chloride (**212**) in CH_3OH afforded ether **213** in unstated yield.[20b] Interestingly, the 1*R*,2*S*,5*R* isomer was the only observed substitution product, although the C-5 epimer was apparently not specifically looked for.

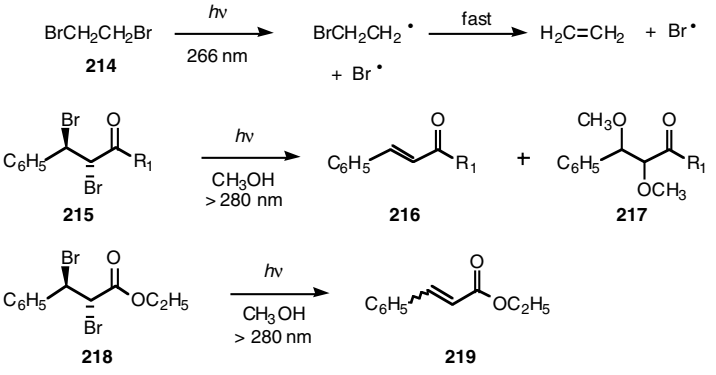


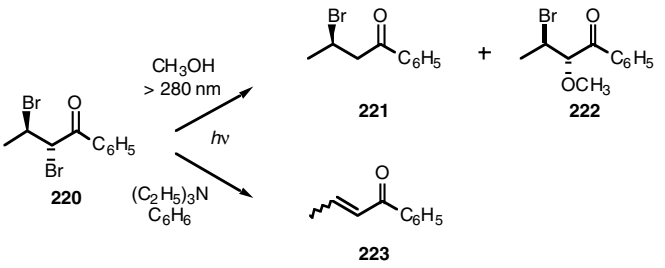
Dihalides

Dihalides undergo photocleavage of a single carbon–halogen bond and, like monohalides, exhibit competing radical and ionic behavior. In the case of geminal diiodides, the α-iodo substituent stabilizes the adjacent cation, facilitating ionic behavior.

Vicinal Dihalides

Laser flash photolysis of 1,2-dibromoethane (**214**) afforded two bromine atoms per photon absorbed.[61] Irradiation of dihaloketones **215** in CH_3OH afforded the (*E*)-enones **216**.[62] Competing ionic behavior resulted in accompanying formation of the dimethoxy derivatives **217**. The corresponding dibromoesters **218** gave a mixture of the *E*- and *Z*-unsaturated esters **219**.[62] Absorption by the phenyl group was apparently critical under the reaction conditions, since the aliphatic analog **220** afforded bromides **221** and **222** instead of the enones **223**.[62] This problem was avoided by irradiation in the presence of $(C_2H_5)_3N$, which presumably involves radical anion formation (Scheme 1). Under these conditions, a wide variety of vicinal dihalides undergo dehalogenation in moderate to excellent yields.[59,63]



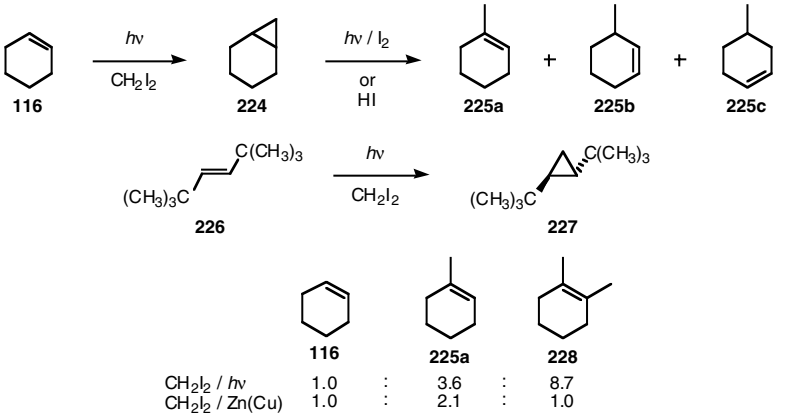


Geminal Dihalides

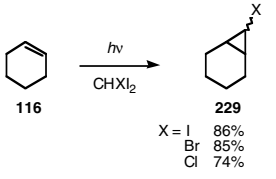
Appropriate dihalomethanes effect cyclopropanation of alkenes, whereas their higher homologs, which are capable of undergoing elimination, exhibit intramolecular behavior.

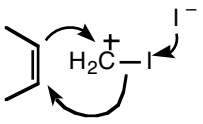
Dihalomethanes: Cyclopropanation of Alkenes

H.E. Simmons, co-discoverer of the cyclopropanation of alkenes with CH_2I_2 and Zn(Cu) couple, and co-workers observed early on that irradiation of CH_2I_2 in the presence of cyclohexene (**116**) afforded norcarane (**224**).[64] Because there was an accompanying formation of a mixture of the methylcyclohexenes **225**, which appeared to result from indiscriminate insertion into CH bonds as well as the π bond, it was concluded that the main product-forming intermediate is an excited state of CH_2I_2 accompanied by free CH_2**:**.[64] However, subsequent studies showed that the methylcyclohexenes **225** are secondary products that can be avoided by stirring the irradiation mixture with a scavenger solution to remove I_2 and HI.[10,65] Under these conditions, norcarane (**224**) is the exclusive product and can be isolated in excellent yield.[65] The procedure has proved effective for the cyclopropanation of a number of alkenes — especially sterically hindered ones such as **226**, which give little or no addition by the traditional Zn(Cu) couple procedures.[65,66] Addition occurs stereoselectively, with retention of stereochemistry. The relative rates of addition to the cyclohexenes **116**, **225a**, and **228** increase with increasing substitution — in contrast to the Zn(Cu) couple method, in which steric effects result in a decreased rate for the tetrasubstituted alkene **228**.[67]

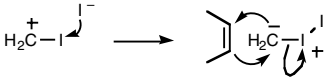


Cyclopropanation has also been observed on irradiation of CH_2Br_2 in the presence of alkenes, although in low yield.[68] However, irradiation of diiodo- or dibromohalomethanes in the presence of alkenes affords halocyclopropanes in good yield, as exemplified by formation of the 7-halonorcaranes **229**.[68,69]



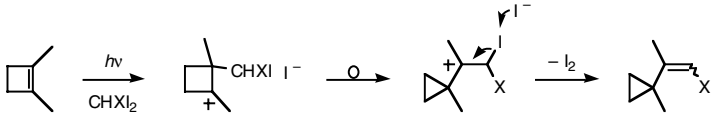


SCHEME 8



SCHEME 9

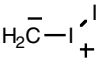
Based on the electrophilic nature of the reactive intermediate and on the photobehavior of higher homologs of CH_2I_2 described in the following section, it was proposed that photocyclopropanation involves attack of the ion pair $^+CH_2I\ I^-$ on the alkene (Scheme 8).[65] In support of this, irradiation of CH_2I_2 in the presence of LiBr afforded CH_2IBr and CH_2Br_2. Also, 1,2-dimethylcyclobutene (**230**) afforded the vinyl iodides **231**, as expected from initial addition of ^+CHXI followed by rearrangement.[69]



230 **231**

a, X = I; **b**, X = Cl

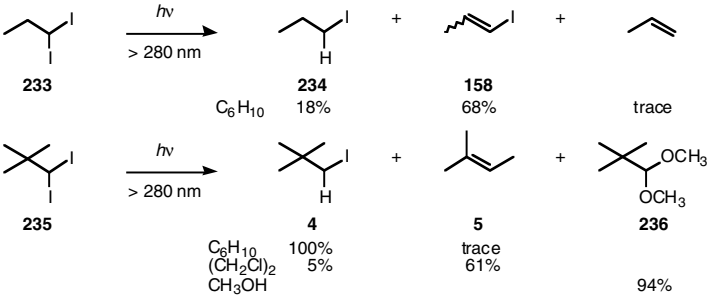
However, an isomeric intermediate, referred to as isodiiodomethane, has been observed on irradiation of CH_2I_2 in an argon or nitrogen matrix[70] or in solution,[71] for which the iodo-iodonium methylide structure (**232**) has been assigned.[72] Analogous intermediates have been observed for a number of other polyhalomethanes[73] except for CH_2FI, which showed no detectable isomerization.[73b] Isodiiodomethane (**232**) has been shown to react with cyclohexene (**116**) to afford I_2 and, presumably, norcarane (**224**), but no organic product was reported.[74] It has been proposed that isodiiodomethane (**232**) is the methylene transfer agent mainly responsible for cyclopropanation of alkenes on irradiation of CH_2I_2.[74,75] This is equivalent to involvement of the ion pair if the reaction occurs stepwise, since an initial attack of I^- on I would afford isodiiodomethane (**232**) (Scheme 8). Moreover, the ion pair may simply be regarded as a resonance form of isodiiodomethane (**232**).



232

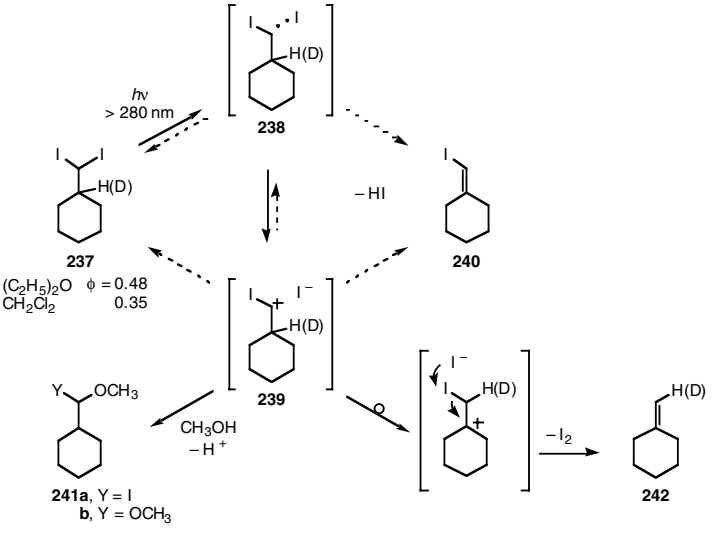
Higher Homologs

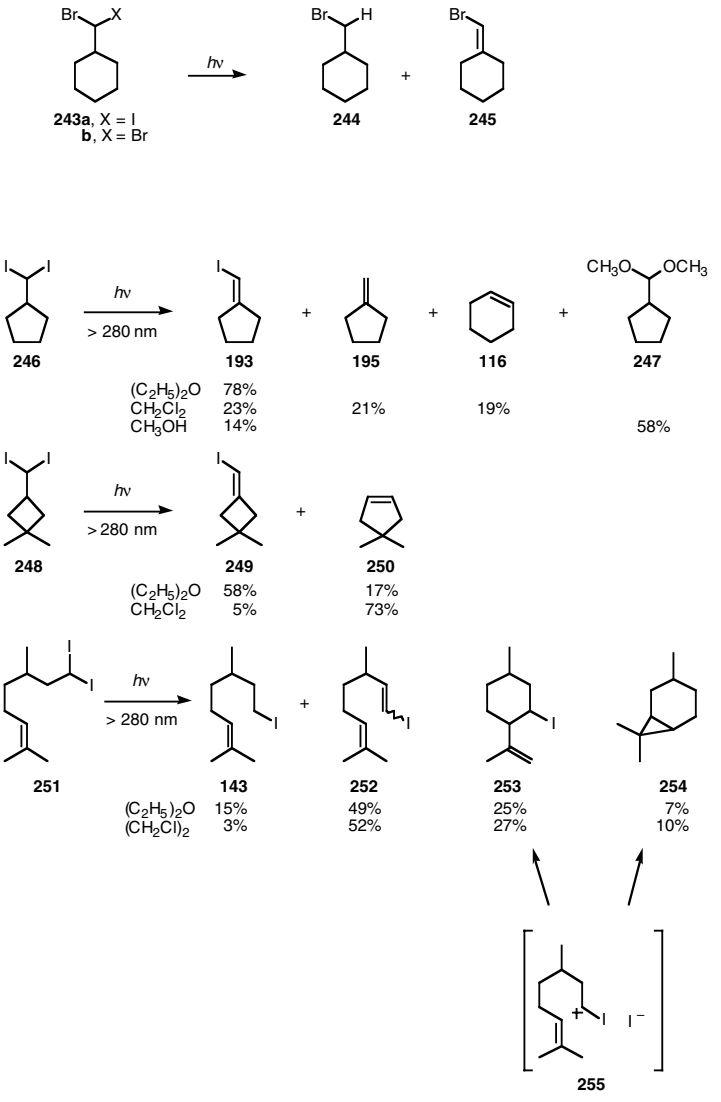
Elimination dominates the photobehavior of higher homologs. Early studies involved diiodide **233**, which on irradiation afforded the reduction and elimination products **234** and **158**.[10] The dimethyl derivative **235**, which is incapable of undergoing elimination, afforded the reduction product **4** almost exclusively.[10] However, it was more recently found that irradiation of diiodide **235** in the more polar solvent $(CH_2Cl)_2$ gives principally the alkene **5**, and irradiation in the polar but nucleophilic solvent CH_3OH affords the acetal **236**.[76,77]



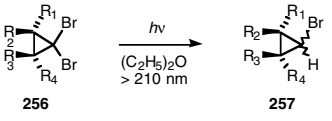
More detailed studies were conducted with the diiodide **237**.[76] Irradiation in a variety of solvents afforded predominantly the vinyl iodide **240**, which can arise from either the radical pair **238** or ion pair **239**. It was obtained from the labeled diiodide **237**-d_1 with complete loss of deuterium. In solvents having a dielectric constant ≥7.5, vinyl iodide **240** was accompanied by methylenecyclohexane (**242**). This is not a secondary product from photoreduction of vinyl iodide **240**, since the latter does not absorb under the irradiation conditions. The labeled diiodide **237**-d_1 afforded alkene **242**-$\boldsymbol{d_1}$, with almost complete retention of deuterium, which was located at the methylene position as expected from hydride rearrangement of the ion pair **239** followed by loss of I_2. Polar solvents apparently facilitate rearrangement of the ion pair **239**. Although shown here as stepwise, rearrangement and loss of I_2 may occur concertedly, in analogy with the mechanism for the cyclopropanation of alkenes (cf **227**). In the polar, but nucleophilic, solvent CH_3OH, trapping afforded the α-iodo ether **241a**, which underwent subsequent methanolysis to acetal **241b** as the principal product to the exclusion of methylenecyclohexane (**242**).

The bromo iodo derivative **243a** afforded mainly the elimination product **245**, whereas the dibromide **243b** gave mainly the reduction product **244** in the solvents $(C_2H_5)_2O$, CH_2Cl_2, and CH_3OH.[76] The cyclopentyl analog **246** displayed behavior analogous to that of diiodide **237** except for giving a mixture of methylenecyclopentane (**195**) and the ring-expanded cyclohexene (**116**), along with the vinyl iodide **193**, in CH_2Cl_2.[76] The cyclobutyl analog **248** afforded only the ring-expanded cyclopentene **250** and the vinyl iodide **249**.[76] Citronellal iodide (**251**) gave a mixture of products **143** and **252**–**254**.[76] Iodide **253** apparently arises from intramolecular trapping of the α-iodo cation **255** and carane (**254**) from competing intramolecular cyclopropanation analogous to that described above for CH_2I_2. It is interesting, however, that intermolecular addition of CH_2I_2 to alkenes gave no trapping analogous to the formation of iodide **253**.





Advantage has been taken of the predominant radical behavior of bromides to effect reduction of the dibromocyclopropanes **256** to the corresponding monobromides **257**.[78] Weak absorption by the monobromides **257** under the irradiation conditions permits the selective removal of a single halogen atom.



Vinylidene Dihalides

In accord with the trends observed in other systems, the dichloride **258c** gave only the reduction products **260** and **242**, while the dibromide **258b** gave a small amount of the nucleophilic trapping product **259b**, and the diiodide **258a** gave somewhat more of it.[52b] Similar behavior was exhibited by the norbornyl analogs **261**, with the dibromide **261b** affording only the reduction product **203b** and the diiodide **261a**

giving a mixture of iodide **203a** and the ether **262a**.[79] At –10°C, diiodide **261a** gave almost exclusively the ether **262a.** On further irradiation, the vinyl halides **203** underwent secondary conversion to camphene [**204** (R = H)], as described above.

Photochemical Generation of Glycosyl Radicals and Its Applications in Carbohydrate Synthesis

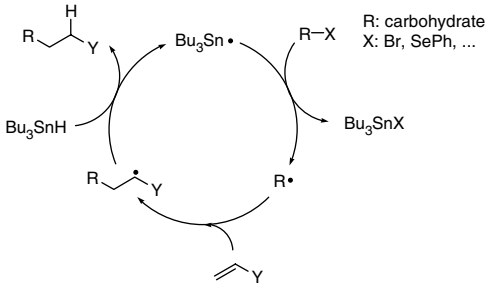
Kyoto University

2.1 Introduction

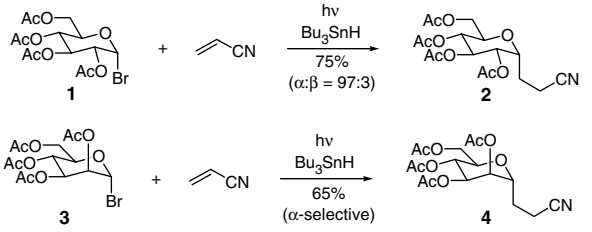
Addition of glycosyl radicals to alkenes is a key process in the synthesis of *C*-glycosides, which are well known to have potent antiviral, antibacterial, and antitumor activities. While various methods for the synthesis of *C*-glycosides under ionic conditions have been developed, the importance of radical-mediated synthesis should be stressed because of the mild reaction conditions employed. As radicals are neutral species, various polar functional groups in carbohydrate molecules are compatible under the reaction conditions, and the reaction is sometimes carried out without protecting the hydroxyl and amino groups.

Glycosyl radicals can be generated both thermally and photochemically. While the thermal generations using radical initiators are more popular than the photochemical methods to date, the photochemical path will become increasingly important from the viewpoint of selectivity and "green" chemistry. For example, the photochemical method allows radical generation at low temperature, and such mild conditions would be advantageous for chemo- and stereoselective reactions. In addition, radical generation by direct photolysis enables atom-economical reactions without using radical initiators or promoters. Furthermore, the absence of radical promoters can prevent undesirable competing side reactions of chain-carrying radicals, such as reduction of the glycosyl radical by tin hydride. Because of the importance of glycosyl radicals in organic synthesis, several reviews on this subject have been published recently.[1] However, no systematic reviews that focus on the photochemical reactions have been published. This

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1



SCHEME 2

review, therefore, will survey the photochemical generation of glycosyl radicals and applications to *C*-glycoside syntheses. This review also includes the photochemical generation of glycosyl carbenes, which are potentially important neutral and reactive species in *C*-glycoside synthesis.

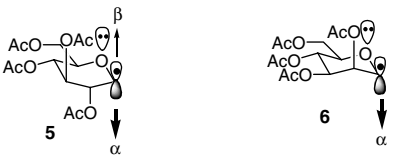
2.2 Intermolecular Carbon–Carbon Bond Formation

Tin Hydride–Mediated Reaction

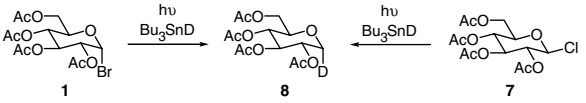
The tin hydride–mediated radical coupling reaction has been widely utilized in carbon–carbon bond formation under both thermal and photochemical conditions after the seminal reports from Giese's group. Among various haloglycosides and chalcogenoglycosides, bromo- and selenoglycosides have been widely utilized due to their stability under reaction conditions as well as the ease of preparation. The reaction is promoted by a tributyltin radical generated from tributyltin hydride through the radical chain mechanism shown in Scheme 1. Thus, the tributyltin radical reduces haloglycosides or chalcogenoglycosides to produce glycosyl radical R, which adds to alkenes. The subsequent hydride abstraction of the resulting radical species from tributyltin hydride gives the coupling product with the regeneration of the tributyltin radical.

Specific examples starting from bromoglycosides are shown in Scheme 2. Giese et al., reported that the glycosyl radical generated from the α-bromoglucopyranoside **1** by photolysis in the presence of tributyltin hydride and an excess of acrylonitrile gives the *C*-glycoside **2** in 75% yield.[2,3] The reaction predominantly gives the α-isomer, but a small amount of the β-isomer is also formed (α:β = 97:3). Bromomannoside **3** also reacts with acrylonitrile under similar conditions and exclusively gives the α-isomer of *C*-glycoside **4** in good yield.

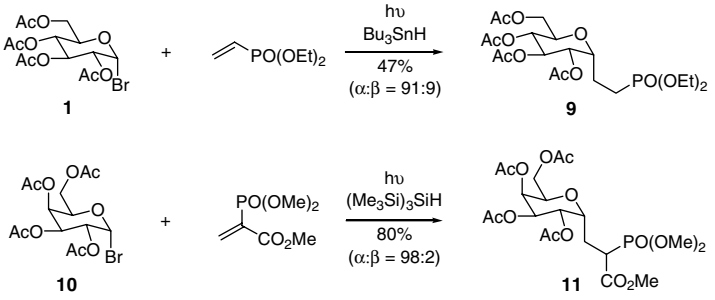
Giese rationalized the observed high α-stereoselectivity in terms of the stereoelectronic effects of radical species, namely the radical anomeric effects, by electron spin resonance (ESR) spectroscopy, as shown in Scheme 3.[4] The ESR of the glucopyranosyl radical **5** suggests that **5** adopts a boat rather than a chair conformation. This is attributed to the strong stabilizing interactions between the singly occupied molecular orbital (SOMO) of the radical and both the *n*-orbital of the adjacent pyranose oxygen and the



SCHEME 3



SCHEME 4



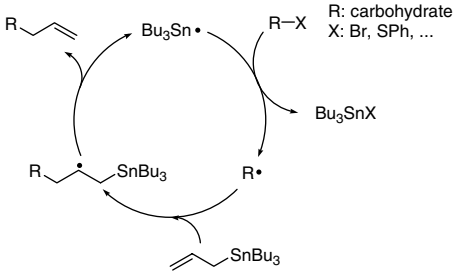
SCHEME 5

σ^*-orbital of the C2 carbon–oxygen bond. The reaction with alkene takes place preferentially from the more sterically accessible α-face (equatorial-like attack) in this conformation. This face selectivity is also electronically favored because the interaction of SOMO and the *n*-orbital is maintained during the bond-forming process. The mannosyl radical **6**, on the other hand, does not undergo conformational change and adopts a chair conformation due to the favorable stereoelectronic effects within this conformation. The reaction with alkene takes place exclusively from the sterically and electronically favored α-face.

The conformational change from the chair form in the radical precursors to the boat form in the anomeric glycosyl radicals is so rapid that stereochemical memory is lost upon the generation of the radical. Thus, the reduction of β- and α-haloglycosides **1** and **7** by tributyltin deuteride afforded α-deuterated product **8** regardless of the stereochemistry of the starting materials (Scheme 4).[5]

The reactivity of glycosyl radicals is unaffected by photo irradiation, but the photochemical method also suffers the following problems similar to those involved in the thermal method. First, since the anomeric glycosyl radicals are nucleophilic in character due to the interaction of the SOMO and the *n*-orbital of the pyranose oxygen, the alkene acceptors can only be electron deficient. Second, because the glycosyl radicals, e.g., R radical in Scheme 1, competitively react with tin hydride to form the reduced product, e.g., RH, a large excess of alkenes (usually 5- to 20-fold excess) is required to avoid undesirable side reactions. Third, because the tin radical must react much faster with the glycosyl radical precursors than with alkenes, the precursors must be sufficiently reactive towards tin radicals. Despite these disadvantages, this method has been widely used in *C*-glycoside synthesis.

Vinyl phosphates are electron-deficient alkenes sufficiently reactive to anomeric glycosyl radicals. Fessner et al. has applied this type of reaction to the synthesis of *C*-glycosyl phosphate derivatives (Scheme 5). Bromoglycoside **1** undergoes *C*-glycosylation with diethyl vinylphosphonate in the presence of tributyltin hydride to give **9** with high α-selectivity.[6] The use of tris(trimethylsilyl)silane, which is an



SCHEME 6

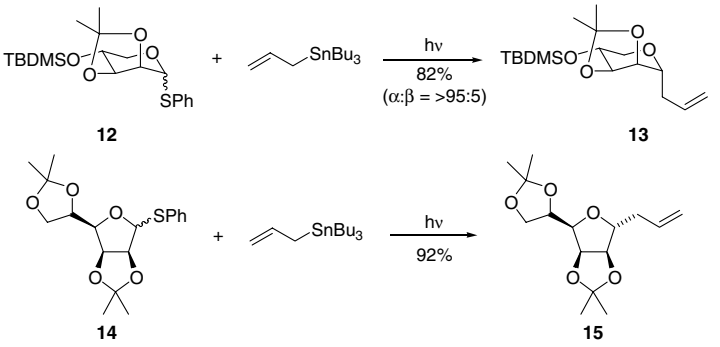
environmentally benign analogue of tributyltin hydride,[7] is also effective, and the *C*-glycosylation of bromoglycosides **10** with highly electron-deficient methyl 2-(dimethoxy-phosphoryl)-acrylate in the presence of tris(trimethylsilyl)silane gives **11** in good yield with excellent α-selectivity.[8] Anomeric sugar phosphates possess various important biological functions, and the *C*-glycosyl phosphate analogues can be used as hydrolytically stable mimics of naturally occurring sugar phosphates after hydrolysis of the protecting groups. In addition, the alkyl phosphonate esters are important building blocks as Horner–Wadsworth–Emmons reagents, and the phosphonate ester functional groups in the products can be used for further carbon–carbon bond formations.

Allyltin Method

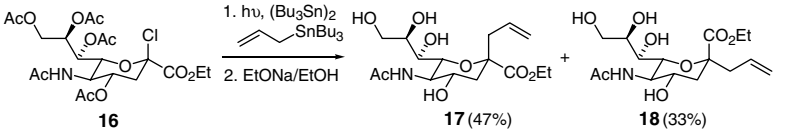
As a result of the seminal report from Keck's group, the addition of glycosyl radicals to allyltributyltin provides a general method for the preparation of *C*-allyl glycosides. The reaction is also promoted by tin radicals as in the tin hydride–mediated *C*-glycosylation, which reduces haloglycosides and chalcogenoglycosides to generate glycosyl radicals (Scheme 6). The radicals thus generated add to allyltributyltin, followed by the β-elimination of a tributyltin radical from the resulting radical intermediate to give the allylated products with the regeneration of tin radicals. This allylation has two advantages over the tin hydride method. Though the same R radical is generated by the tin hydride method, no competing reduction pathway of the R radical exists in the allylation method. Therefore, the use of a large excess of allyltributyltin is unnecessary. Second, while the alkene functionality is lost in the tin hydride method upon the addition of glycosyl radicals to alkenes, the double bond is retained in the products by the β-elimination of the tin radicals in the allylation reaction. The alkene functionality in the products can be used for further synthetic transformations.

Haloglycosides can be used as radical precursors in certain cases, but they are usually unstable under the reaction conditions. Instead, thioglycosides are more stable, and pyranoside- and furanoside-derived phenylthioglycosides are known to serve as excellent glycosyl radical precursors. The photochemical reaction is usually conducted at room temperature, while the thermal reaction requires elevated temperature, e.g., 80°C, in the presence of a radical initiator (AIBN). Hexabutylditin is sometimes used as a photo-labile radical initiator. The reaction exhibits similar stereoselectivity to that seen with electron-deficient alkenes and is controlled by the radical anomeric effects as discussed earlier in this chapter. Specific examples starting from thioglycosides are shown in Scheme 7.[9] Keck et al. has reported that the photochemical allylation of lyxose-derived thioglycosides **12** with allyltributyltin proceeds to give **13** as a single isomer. Furanose-derived thioglycoside **14** also undergoes stereoselective allylation to give **15** in excellent yield.

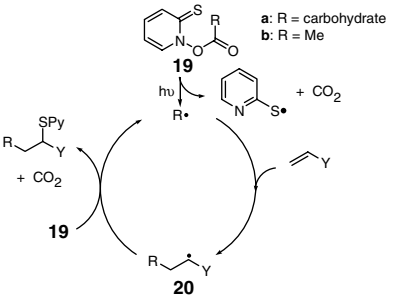
Bednarski has reported that this allylation reaction has been used for the key step in the synthesis of *C*-glycoside derivatives of sialic acids, which are the carbohydrate groups found at the terminal sites of cell-surface glycoproteins and glycolipids. Thus, the allylation of glycosyl chloride **16** with allyltributyltin under photo irradiation in the presence of hexabutylditin followed by hydrolysis gives an approximate 1:1 mixture of the α- and β-isomers. It is worth mentioning that while several synthetic approaches by



SCHEME 7



SCHEME 8

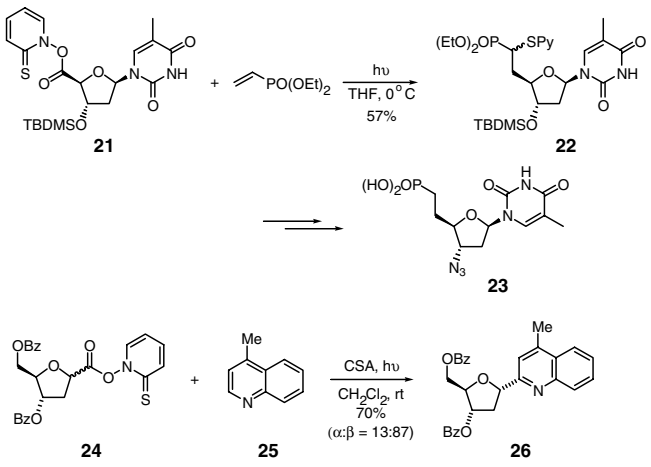


SCHEME 9

ionic reactions, e.g., Lewis acid-mediated allylation reactions, fail, only the radical method is successfully applicable for the synthesis of this highly functionalized allylated product.[10]

Photochemical Fragmentation of Barton Esters

Photochemical decarboxylation of carboxylic acids of 2-thioxo-2*H*-pyridin-1-yl ester **19** (Barton esters) can be applied successfully to *C*-glycosylation reactions according to a radical chain reaction (Scheme 9). The requisite Barton esters are easily prepared from the corresponding carboxylic acid through several synthetic routes by condensation with *N*-hydroxy-2-thiopyridone or its derivatives.[11] Photolysis of Barton ester **19a** generates 2-pyridylthiyl radical, carbon dioxide, and glycosyl radical R, which react with electron deficient alkenes to give **20**. Radical **20** then reacts with the sulfur moiety of **19a** to give the desired coupling product with the regeneration of radical R. The reaction proceeds by a 2-thiopyridyl group transfer, and the thiopyridyl group can be used for further synthetic transformations. For example, tin hydride–mediated radical reduction of the carbon–sulfur bond gives the corresponding reduced products, and oxidation of sulfur gives rise to β-elimination to give alkenes.



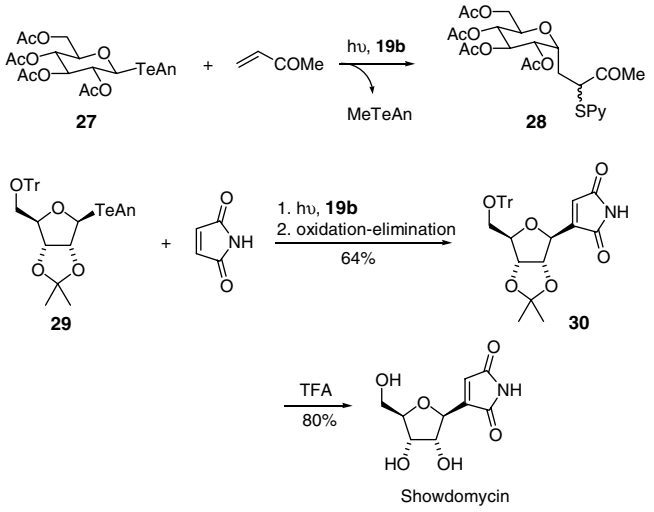
SCHEME 10

Specific examples are shown in Scheme 10. Barton et al. have reported that addition of a furanosyl radical generated from Barton ester **21** to diethyl vinylphosphonate takes place stereoselectively to give group-transfer product **22**. The high stereoselectivity is caused by introducing the bulky *t*-butyldimethylsilyl protecting group (TBDMS) for the C3′ hydroxyl. Radical-mediated reduction of the 2-pyridylthio group in **22** followed by synthetic transformation of the C3′ hydroxyl group to an azide enables the synthesis of the isostere of AZT-5′ monophosphate **23**.[12] Togo et al. have also used Barton esters for the direct synthesis of *C*-nucleosides based on the addition of anomeric glycosyl radicals to activated π-systems of electron-deficient heteroaromatic compounds. For example, the ribofuranosyl radicals generated from **24** add to 4-methylquinoline in the presence of acid to afford **26** in good yield.[13] The addition of an equal amount of acid is required to activate the heteroaromatic compounds.

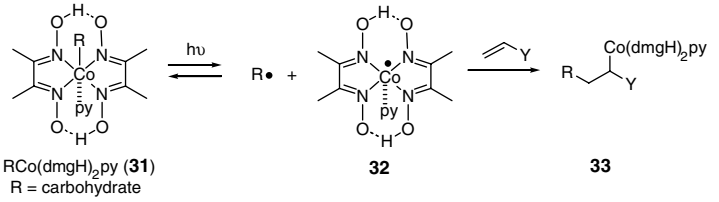
Barton et al. have reported that a combination of Barton ester **19b** (R = Me) and telluroglycosides under photochemical conditions also generates glycosyl radicals, which initiate *C*-glycosylation via radical chain reaction. Thus, methyl radicals generated by the photolysis of **19b** undergo homolytic substitution with aryltelluroglycosides to generate the resulting anomeric glycosyl radicals and methyl aryl telluride. The glycosyl radicals thus generated react with electron-deficient alkenes followed by 2-pyridylthio-group transfer with **19b** to give *C*-glycosides with the regeneration of a methyl radical. Specific examples starting from pyranose- or furanose-derived telluroglycosides are shown in Scheme 11.[14] Telluroglycoside **27** undergoes *C*-glycosylation with methyl vinyl ketone in the presence of **19b** under photo irradiation to give the group-transfer product **28**. The addition of ribofuranosyl radicals, generated from ribofuranosyl telluride **29**, to maleimide, followed by the oxidative elimination of the 2-pyridylthio group of the coupling product affords **30** as a single product. Deprotection of **30** under acidic conditions provides showdomycin, which belongs to the biologically active *C*-nucleosides. The stereoselective nature of the *C*-glycosylation provides a highly efficient synthetic route.

Direct Photolysis of Cobaloximes

Giese et al. have reported that the alkylcobaloxime complex **31** can act as a radical precursor because irradiation promotes the homolytic cleavage of the Co–C bond (Scheme 12). In the absence of radical traps, the radical R recombines with the Co(II) complex **32** to reform the starting material **31**. Dimerization and disproportionation reactions between the alkyl radicals occur only to a small extent. This feature may be explained by considering that the Co(II) complex **32** serves as a persistent radical.[15] The reversibility of the radical generation process in the current alkylcobaloxime system has advantages over radical chain reactions because competing side reactions involving radical promoters can be minimized.[16,17] In the presence of radical acceptors, such as alkenes, the glycosyl radical R generated from **31** undergoes group-transfer



SCHEME 11



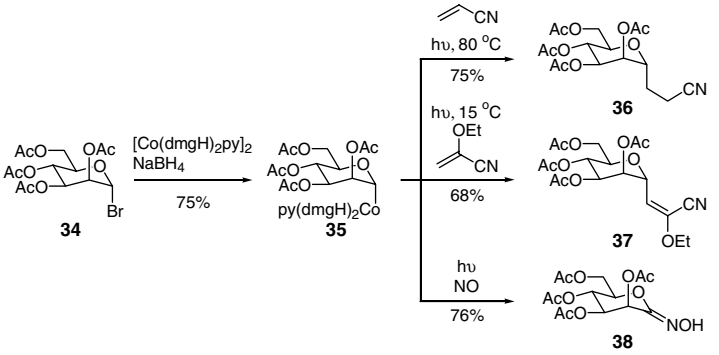
SCHEME 12

addition to alkenes, and the resulting alkylcobaloxime **33** either hydrolyzes or undergoes β-elimination to form alkenes.

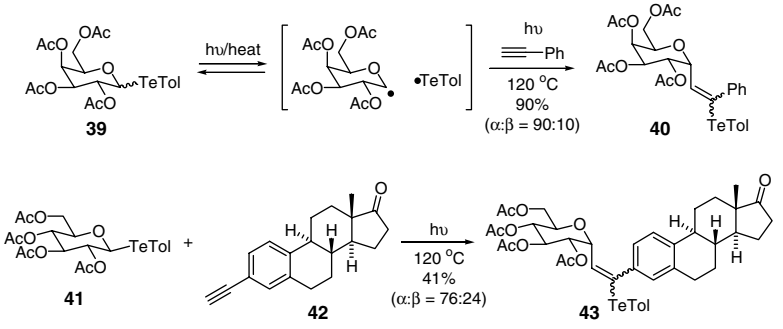
Specific examples are shown in Scheme 13. Giese et al. have reported that mannosyl cobalt complex **35**, which can be prepared from bromoglycosides **34** and Co(I) complexes generated from $[Co(dmgH)_2py]_2$ and sodium borohydride, reacts with alkenes under photo irradiation. The initially formed group-transfer product subsequently undergoes solvolysis in methanol or β-hydride elimination to give **36** or **37**, depending on the substituents on the alkenes. Nitrous oxide is a persistent radical and an excellent radical trapping agent, and the trapping of the mannosyl radical generated from cobalt complex **35** by nitrous oxide gives glycosyl oxime **38** with high efficiency.[18]

Direct Photolysis of Organotellurium Compounds

Yamago et al. have reported that direct photolysis of telluroglycosides also generates the corresponding anomeric glycosyl radicals and telluranyl radicals.[19] The radical generation is reversible as is the case with the cobaloximes. As the generated radicals recombine with the starting telluroglycosides in the absence of radical acceptors, isomerization of the anomeric carbon is observed. In the presence of radical acceptors, such as alkynes, the glycosyl radicals group transfer addition reactions.[20] This method offers several advantages. First, telluroglycosides are easily prepared from haloglycosides and are storable for a long period.[21] Second, the current method is free from the problems inherent in the tin hydride methods, such as the addition of tin radical to alkynes[22] or the simple reduction of glycosyl radicals. Finally, because the reaction proceeds via a group transfer, the carbon–tellurium bond in the products can be used for further synthetic transformations.



SCHEME 13

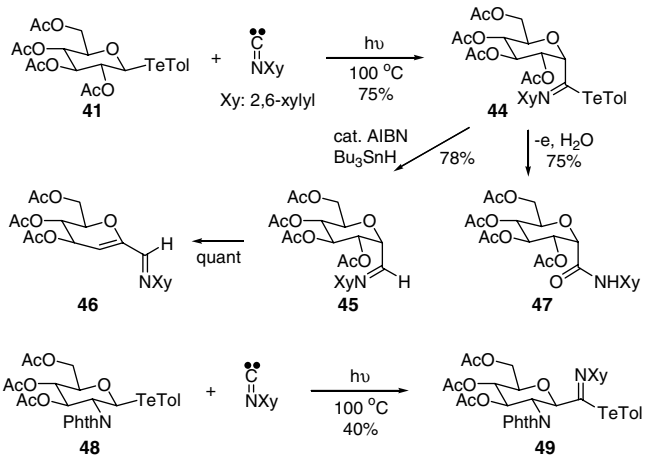


SCHEME 14

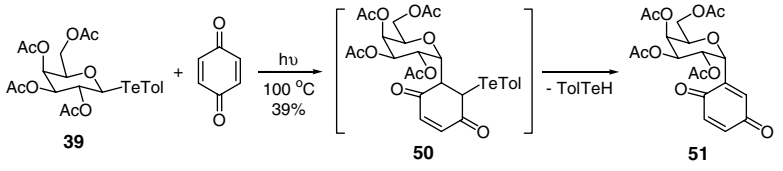
Specific examples for the synthesis of vinylic *C*-glycosides are shown in Scheme 14. Conjugated alkynes are excellent acceptors, and the photolysis of galactose-derived telluroglycoside **39** with phenylacetylene at 120°C affords the group transfer product **40** in excellent yield. While the same reaction proceeds in the dark, photo irradiation considerably increases the coupling efficiency. The reaction mainly gives the α-isomer (α:β = 90:10), and the anomeric stereoselectivity is somewhat lower than that in the conventional *C*-glycosylation with alkenes. This method can be applied to the synthesis of the sugar–steroid hybrid molecule **43** by the coupling of telluroglycoside **41** with the steroidal alkyne **42**.

Yamago et al. have also reported that isonitriles serve as excellent glycosyl radical trapping reagents in conjunction with the C1 homologation reaction. Therefore, the reaction of telluroglycoside **41** with xylylisonitrile under photo irradiation at 100°C affords group-transfer coupling product **44** in good yield (Scheme 15).[23] It is worth mentioning that carbon monoxide, which possesses an isoelectronic structure with isonitriles, is a totally inefficient reagent. The reaction proceeds with complete stereoselectivity and gives the α-isomer **44** as the sole product. The observed stereoselectivity is consistent with the anomeric radical effects as discussed earlier in this chapter. The complete α-selectivity is a general trend, and all pyranose-derived telluroglycosides afford the α-anomer with a single exception; the reaction of 2-phthaloyl protected aminoglycoside **48** gives the β-isomer **49** exclusively. The origin of the observed β-selectivity is suggested by the intramolecular participation of the polar C2 phthaloyl (Phth) group to the glycosyl radical to shield the α-face. The imidoylations also take place with complete *syn* selectivity with respect to the stereochemistry of the imine moiety. This is due to the predominant participation of thermodynamically stable *anti* imidoyl radicals in the tellurium-group transfer step.

The imidoylated products serve as important building blocks for the synthesis of a variety of *C*-glycosides through carbon–tellurium bond modifications (Scheme 15). For example, radical-mediated



SCHEME 15



SCHEME 16

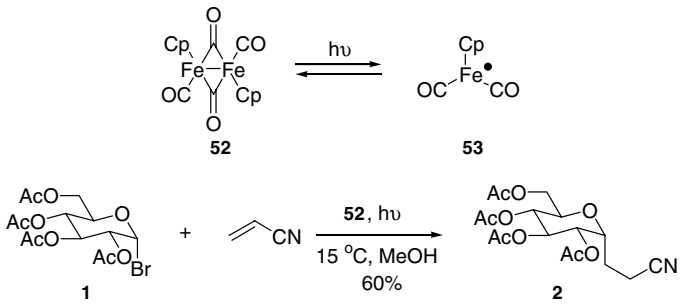
reduction of the carbon–tellurium bond in **44** with tributyltin hydride affords glycosyl imine **45**, which is further converted quantitatively to glycal **46**. Oxidative hydrolysis of **44** gives 1-acylglycosides **47**.

Yamago et al. have also reported that quinones serve as excellent acceptors for glycosyl radicals.[24] Therefore, heating a solution of telluroglycoside **39** and 1,4-benzoquinone under photo irradiation affords galactose-substituted 1,4-benzoquinone **51** (Scheme 16). While the reaction also takes place in the dark, photo irradiation considerably accelerates the rate of conversion. The reactions can be carried out both in polar protic and nonpolar aprotic solvents, and the lack of solvent effects is consistent with the involvement of neutral radical species. The reaction initially gives group-transfer product **50**, which subsequently eliminates tellurol to give **51**.

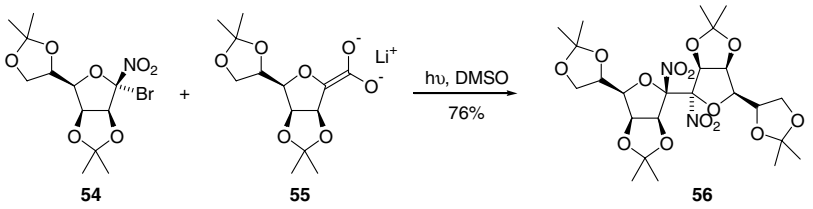
Miscellaneous

Giese et al. have reported that irradiation of the dimeric iron complex **52** generates the monomeric iron radical **53**, which abstracts halogen atoms from bromoglycosides to give the corresponding glycosyl radicals and $Cp(CO)_2FeBr$ (Scheme 17). Therefore, irradiation of bromoglycoside **1** with **52** in the presence of acrylonitrile in methanol gives *C*-glycoside **2** in 60% yield. The reaction is believed to proceed through an organoiron-transfer reaction, followed by solvolysis of the organoiron intermediate in methanol in an ionic manner.[25]

Vasella et al. have reported that glycosyl radicals generated by direct photolysis from 1-*C*-nitroglycosyl halides undergo additions to an anion of nitroalkanes. For example, irradiation of the 1-*C*-nitromannosyl bromide **54** with the lithium salt of 1-deoxy-nitromannose **55** gives dimeric glycoside **56** in good yield (Scheme 18).[26]



SCHEME 17



SCHEME 18

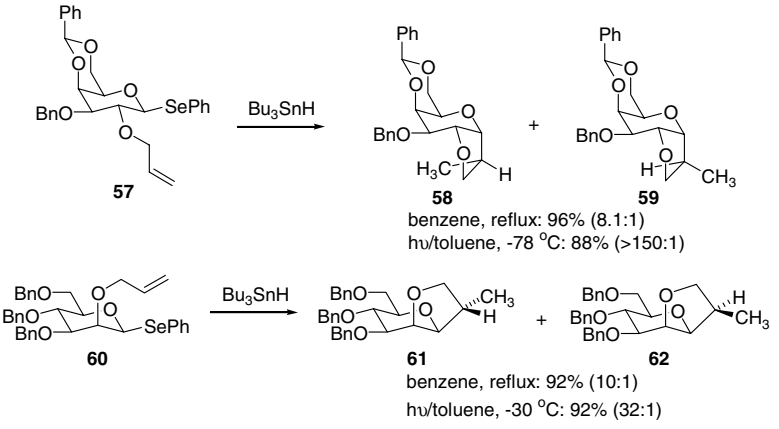
2.3 Intramolecular Carbon–Carbon Bond Formation

C-Glycosides can also be prepared by intramolecular addition of an anomeric glycosyl radical to an acceptor, which is tethered to a suitable hydroxyl group of the glycoside. Because intramolecular cyclizations such as the 5-*exo*-trig process take place very rapidly compared to intermolecular additions, the intramolecular reactions do not require activation of the alkenes by electron-withdrawing substituents. In addition, while the intermolecular addition predominantly gives α-glycoside, the stereochemistry of the intramolecular reaction is controlled by the conformational constraint of the tether to give either α- or β-glycosides selectively. De Mesmaeker et al. reported that the configuration of C2 is transformed to the stereochemistry of the products in the case of C2 hydroxyl-linked allylic acceptors (Scheme 19).[27] Thus, the 2-*O*-allyl-1-selenogalactopyranoside **57**, possessing a C2-equatorial substituent, affords the α-*C*-isomers **58** and **59**, whereas the 2-*O*-allyl-1-selenomannoside **60,** possessing a C2-axial substituent, affords the β-*C*-glycosides **61** and **62**. It is also worth noting that the decrease of reaction temperature caused by using photochemical radical generations increases stereoselectivity, and virtually a single stereoisomer is formed at temperatures below –30°C.

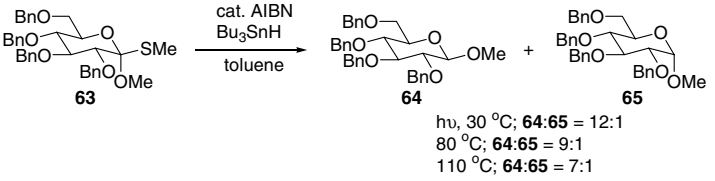
2.4 Stereoselective Reduction

Because of the inherent stereoselectivity in the reaction of anomeric glycosyl radicals with radical acceptors, the β-*O*-glycosides can be successfully synthesized by stereoselective reduction of 1-substituted anomeric glycosyl radicals. Kahn et al. reported that the reduction of 1-methoxy substituted methylthioglycoside **63** with tributyltin hydride in the presence of AIBN preferentially occurs from the axial direction to give the β-glycoside **64** as the major isomer (Scheme 20). The formation of the β-isomer **64** increases on decreasing the temperature, and photochemical radical generation at 30°C shows the highest selectivity (**64**:**65** = 12:1) compared to thermal generation at 80°C and 110°C.[28]

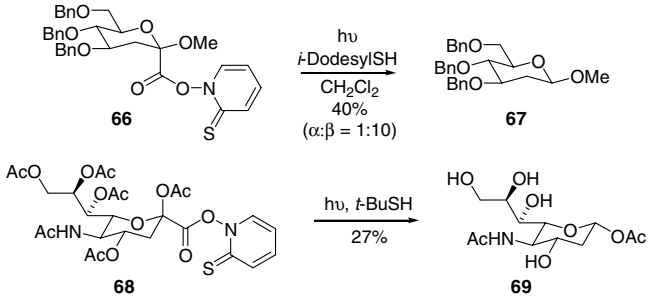
The drawback of this strategy lies in the tedious synthetic procedures for the formation of the requisite 1-substituted thioglycosides. Crich et al. have developed a more general protocol mediated by Barton esters and has applied this to the synthesis of the β-isomer of 2-deoxy glycosides and mannosides.[29,30]



SCHEME 19



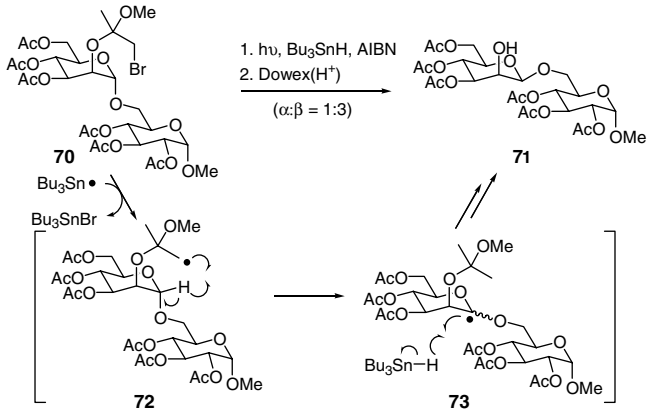
SCHEME 20



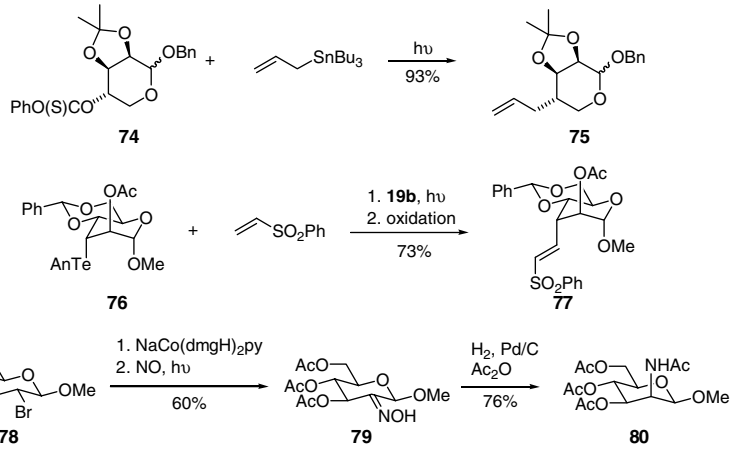
SCHEME 21

Although many biologically active natural products possess the β-linkage of 2-deoxy glycosides and mannosides, stereoselective synthesis is problematic under conventional ionic reactions. Specific examples for the synthesis of the β-isomer of 2-deoxyglycosides are shown in Scheme 21. Photolysis of the Barton ester **66** in the presence of *t*-dodecyl mercaptan gave the 2-deoxy-β-D-glycoside **67** with high stereoselectivity. Wong et al. have also utilized the same protocol for the synthesis of the decarboxylated analogue of 3-deoxy-D-*manno*-2-octulosonic acid, which is a vital component of the outer membrane lipopolysaccharide of Gram-negative bacteria.[31]

Crich et al. have used the radical translocation method for the generation of anomeric glycosyl radicals and has also applied this to the stereoselective synthesis of β-mannoside (Scheme 22).[32] Photolysis of the readily available α-mannoside **70**, which possesses a C2-bromoethoxy group, with tributyltin hydride in the presence of a catalytic amount of AIBN affords β-mannoside **71** as a major product after acid hydrolysis of the resulting C2-acetal group. The reaction proceeds through the formation of radical **72**



SCHEME 22



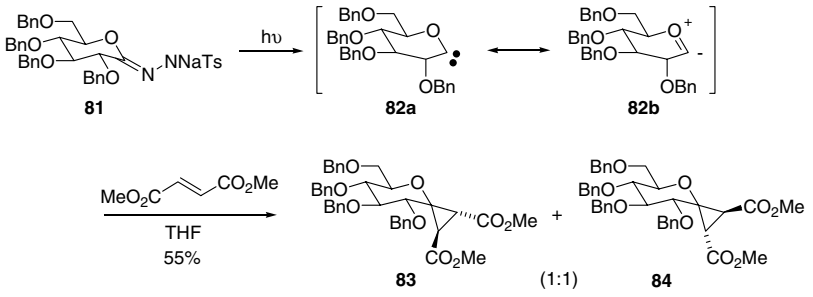
SCHEME 23

from **70** by bromine atom abstraction by the tributyltin radical. Subsequent intramolecular 1,5-hydrogen atom transfer generates the anomeric glycosyl radical **73**, which undergoes α-face selective hydrogen atom abstraction from tributyltin hydride to give the β-mannoside **71**.

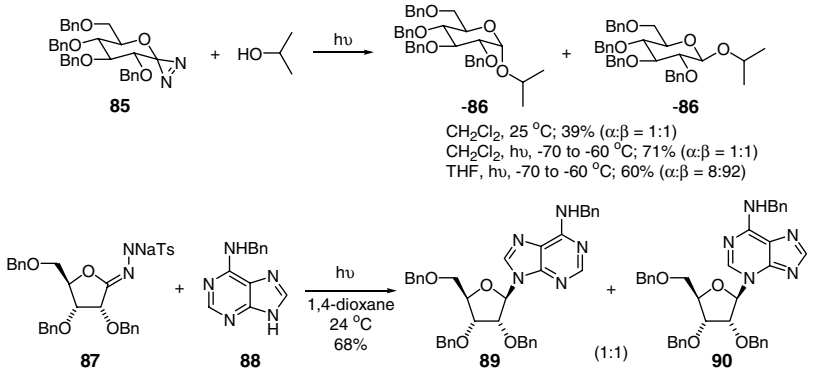
2.5 Nonanomeric Glycosyl Radicals

A major strategy for the preparation of branched-chain sugars is the intermolecular addition of nonanomeric carbohydrate-based radicals to a π-system. Since no special electronic factors, such as radical anomeric effects, are present, the stereoselectivity is controlled sterically, and the stereochemistry of the substituents adjacent to the radical center mainly governs the stereochemical control. Representative results are summarized in Scheme 23.

The allyltin method developed by Keck et al. also provides a general method for the preparation of allyl branched carbohydrates through nonanomeric radicals. For example, irradiation of L-lyxose derivative **74** in the presence of allyltributyltin gives the corresponding allylated product **75**, which was transformed into pseudomonic acid C.[33] Barton esters have also been applied to the synthesis of branched carbohydrates. Barton et al. have reported that telluroglycoside **76** generates the corresponding glycosyl radical by the treatment of Barton ester **19b** under photo irradiation, and the trapping of the resulting



SCHEME 24



SCHEME 25

radical with vinyl sulfone followed by oxidation of the group-transfer product affords **77** in good yield.[14] Giese et al. have applied the cobaloxime method for the synthesis of 2-deoxy-2-amino-mannoside synthesis. Therefore, trapping of glycosyl radicals generated from cobaloximes derived from **78** and Co(I) species with nitrous oxide gives oxime **79** efficiently. Stereoselective hydrogenation of the oxime moiety in **79** affords 2-deoxy-2-amino-mannoside **80**.[18]

2.6 Glycosylidene Carbenes

Anomeric glycosylidene carbenes are neutral and nucleophilic species, and their additions to electron-deficient π-acceptors provide a valuable method for the synthesis of functionalized carbohydrate molecules. Vasella has reported that the sodium salts of glycosyl tosylhydrazones, e.g., **81**, and glycosyl diazenes, e.g., **85**, are excellent precursors for glycosylidene carbenes under photochemical conditions, whereas glycosyl diazenes also generate glycosyl carbenes under thermal conditions. Photolysis of **81** generates glycosylidene carbene **82a**, which can also be considered as the zwitterionic resonance structure **82b** due to the interaction of one of the *p*-orbitals of the carbene and the *n*-orbital of the adjacent pyranose oxygen (Scheme 24). In the presence of electron-deficient alkenes, such as dimethyl fumarate, **82** adds to alkenes to give a mixture of the cyclopropane products **83** and **84**.[34]

Vasella has also reported that, because of the zwitterionic character of **82**, the glycosylidene carbenes insert into the polar oxygen–hydrogen bond in hydroxyl groups or the nitrogen–hydrogen bond in pyrrole derivatives. Specific examples are shown in Scheme 25. While the diazene **85** generates the glycosylidene carbene under thermal conditions, photochemical reaction under low temperature remarkably increases the efficiency of the insertion reaction and affords the desired *O*-glycoside **86** in good yield.[35] The solvent considerably affects the stereoselectivity, and the reaction in tetrahydrofuran (THF) predominantly gives

the β-isomer of **86**, whereas the reaction in dichloromethane gives a 1:1 mixture of the α- and β-isomers of **86**. The glycosylidene carbene derived from furanosyl tosylhydrazone **87** reacts with *N*-benzyladenine (**88**) under photochemical conditions to generate a 1:1 mixture of two nucleotides, **89** and **90**.[36] The formation of **89** is due to the insertion of the glycosylidene carbene into the nitrogen–hydrogen bond, and that of **90** is due to the addition of the carbene to the nucleophilic N(3) position of **88**.

Comparison between Reactions Induced by UV/Vis Photons and Ionizing Radiation in Hydrocarbon-like Media

Gerald O. Brown
Georgetown University

Richard G. Weiss
Georgetown University

3.1 Introduction

A review of selected chemical and physical transformations of systems in hydrocarbon mixtures and solid polymer media induced by high-energy (keV–MeV range) radiation (i.e., "ionizing" radiation[1]) is presented. Where literature data are available, these results are compared with processes induced by eV range photons in the near UV and visible range of the electromagnetic spectrum. Radiation chemistry has been investigated primarily in aqueous media.[2] For instance, about 200 publications in the 1970s alone dealt with aqueous systems.[5] However, a considerable amount of work has been performed in organic liquids[3] and solid organic media, also.[4]

The most common ionizing radiation sources are γ-rays, x-rays, neutrons, and charged particles such as fast electrons, protons, and alpha particles. Unlike photochemistry, which relies on absorption of individual UV/Vis photons by single chromophores (i.e., distinct functional groups within molecules),

0-8493-1348-1/04/$0.00+$1.50

initial interactions of ionizing radiation with matter are much less discriminating; each quantum of ionizing radiation can cause formation of many ionized and/or electronically excited species.[5] Only secondary or tertiary interactions of ionizing radiation with matter lead to *distinct* electronic excitation or ionization of chromophores with the lowest energetic thresholds.

Comparative Terms and Units in UV/Vis Photon and High-Energy Radiation Chemistry

Quantum yield (Φ_x) (Equation 3.1) is the accepted expression of efficiency for formation of a species **X** or the occurrence of a process **X** in photochemistry.[6]

The G-value ($\mathbf{G_x}$) (Equation 3.2) is used to express the efficiency of reactions or processes induced by ionizing radiation.[6] Although Φ_x and $\mathbf{G_x}$ are quantitative measures of efficiency, the former is based on the number of quanta absorbed (but not their energy), and the latter relies on the total energy absorbed (but not the number of quanta). Neither considers the radiation flux or depends on the mechanism for formation of **X**.

$$\Phi_X = \frac{\text{number of species X formed or processes X followed}}{\text{number of photons absorbed by the system}} \tag{3.1}$$

$$G_X = \frac{\text{number of } \mu\text{moles of species X formed}}{\text{Joules per kg material}} \tag{3.2}$$

The denominator of Equation 3.2, the dose in Grays (Gy),[7] can be obtained from Equation 3.3 for charged particles, where **F** is the fluence in cm^{-2}, **E** is the energy of an Avogadro's number of particles in MeV, ρ is the density of the material in g/cm^3, and **R** is the maximum depth of particle penetration in cm (i.e., particle range) calculated by the Transport of Ions in Materials (TRIM) code.[8] Fast neutrons deposit their energy in organic matrices through nuclear collisions. As a result, the dose they impart is calculated on the basis of fluence and a probability function for collisions.[9]

$$\text{Dose}(\text{Gy}) = \left(1.60 \times 10^{-10}\right) \text{FE}/\text{R}\rho \tag{3.3}$$

Energy Deposition by Ionizing Radiation

The rate of energy transfer from quanta of ionizing radiation (as charged particles) to a material can be calculated from linear energy transfer (LET) equations.[10] The LET depends on the depth of penetration and the degree of deceleration of the ionizing radiation. The dominant initial interaction between high-energy radiation and a material is inelastic collisions with electrons in atoms.[5] The ejected electrons emit photons as they decelerate (i.e., Bremsstrahlung),[5] and the energies of the emitted photons are reduced further via Compton scattering (in which inelastic collisions between the Bremsstrahlung photons and loosely bound or free electrons lead to other photon emissions). These primary events create energy "tracks" within the material. Electronically excited states and ions of specific chromophores are created via interactions with ejected electrons along "spurs" of tracks. At penetrations near the stopping distances, the Bragg maximum where LET is highest, the spatial density of spurs is greater, and they have a larger probability of overlapping.[11] Consequently, the concentrations of ions and electronically excited chromophores are highest in these regions. An energy deposition profile for protons of three different kinetic energies is shown in Figure 3.1.

Sources of High-Energy Radiation

Decay of ^{60}Co from thermal neutron bombardment of ^{59}Co is accompanied by emission of 1.2 MeV γ-rays, and decay of ^{137}Cs provides 0.66 MeV γ-rays.[12] Broad-band x-ray sources, as Bremsstrahlung, can

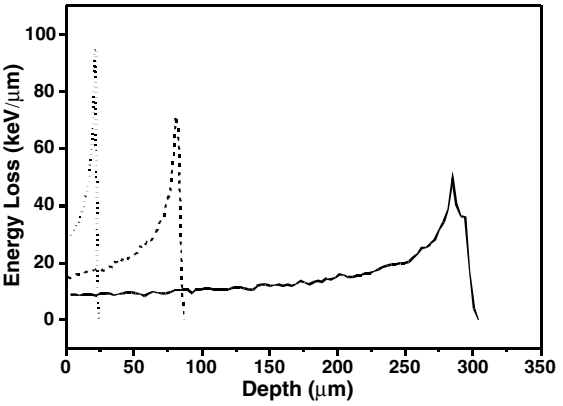

FIGURE 3.1 Profile for loss of energy by 1.0 (L), 2.2 (---), and 4.5 MeV (—) protons to a polyethylene matrix calculated by the TRIM code.[8]

be generated when electrons in a beam (from particle accelerators, for instance) are slowed as they pass through a target material composed of high atomic number nuclei such as tungsten, gold, or lead.[13] Intense beams of a wide range of x-rays are also emitted in synchrotrons as high-energy particles are accelerated along a circular path in the storage ring.[14] Monochromators can select narrow energy ranges of x-rays for sample bombardment.

Van de Graaf accelerators are good sources of electron beams.[24] A positive or negative electrostatic charge is carried to a high-voltage electrode by a rapidly moving belt, and the difference in potential between the electrode and the ground accelerates electrons or positive ions to high velocities. Emitted electrons from a cathode source that is placed at the high potential end of the tube are accelerated at 2–5 MeV energies and then directed towards the target sample. Febetrons, consisting of a bank of capacitors charged in parallel, are another source of fast electrons.[12] A high potential is created when a spark gap switches the capacitors from parallel to series. A very large pulse of electrons with a wide distribution of energies is then discharged through a cathode tube. Electron beams can also be produced using a linear accelerator (LINAC) or a radio-frequency photocathode electron gun (RFPE).[12] Both use traveling waves of electromagnetic radiation (in the radio or microwave frequency range) to accelerate charged particles, and both are capable of producing short pulses of electrons that are particularly useful in time-dependent radiolysis studies.

A variety of positively charged ion beams can be accelerated by tandem Van de Graaf accelerators.[15] Negative-ion sources permit production of ions from most elements in the periodic table. Gaseous and solid elements are normally ionized using radio frequency sources and sputtered cesium, respectively. Negative ions from the source are injected into the low-energy side of the tandem accelerator by an injector magnet and accelerated towards the positive terminal, where (some) electrons are removed by a nitrogen stripper gas or thin carbon foils. The positive ions are accelerated from the terminal and exit from the high-energy end of the tandem accelerator. A 90° analyzing magnet selects ions within narrow mass-energy ranges.

Radiolyses in Liquid Organic Media

Lipsky has investigated ionization processes by high-energy photons and electrons in the liquid phases of alkanes and the subsequent geminate ion-pair states induced.[16] In particular, he and others examined the influence of applied magnetic and electric fields on the fluorescence that accompanies recombination of the ion pairs and found that it depends on initial geminate ion-pair separation distances.[17,18]

Early studies by Thomas et al. demonstrated that large yields of excited singlet and triplet states are formed upon pulsed radiolyses of aromatic molecules in liquid and solid solutions of cyclohexane or benzene.[19] Ion recombination and direct excitation by secondary, low-energy electrons were suggested

as the major sources of solute excited states in cyclohexane, while energy transfer from excited solvent molecules was cited as the probable mechanism for formation of solute excited states in benzene and toluene.[20] In the latter, very rapid ion-recombination reactions lead to both excited singlet and triplet states of the solvent molecules.

Seminal studies by Hammond and co-workers compared γ–radiolyses and photolyses of several types of molecules in liquid organic media. For instance, γ-radiolyses and triplet-sensitized photolyses resulted in very similar steady-state *cis–trans* compositions of a series of alkenes, including stilbenes, 1,2-diphenylpropenes, and piperylenes in benzene solutions (Table 3.1).[21,22] The high **G** values for triplet state formation during γ-radiolyses were attributed to rapid energy transfer to the alkenes, which competes with triplet-triplet annihilation reactions within spurs (where the local density of excited state solvent molecules is high) (Scheme 1).[23]

Radiolyses of "Simple" Alkanes

γ–Radiolyses of *n*-alkanes cause random cleavage of both CC and CH bonds, leading to the evolution of molecular hydrogen and lower molecular weight hydrocarbons. Chain shortening becomes less important as the length of the *n*-alkane increases, and the major products from long *n*-alkanes have more carbon atoms than their parents do.[24] The long *n*-alkanes are gelled at higher doses and their melting points are increased. As indicated by electron paramagnetic resonance (EPR) analyses of frozen alkane samples, CC bond cleavage by high-energy radiation occurs preferentially at tertiary centers and is least probable at primary ones.[24]

Hydrogen, cyclohexene, and bicyclohexyl are the major products from radiolyses of cyclohexane.[25] Scission of a CH bond is a major reaction mode. At high doses, polymeric species are formed upon secondary reaction of cyclohexyl radicals with cyclohexene molecules.

The specific nature of γ-radiation–induced reactions of solid *n*-alkanes depends on details of the layered molecular packing[26,27] of the matrix. Toriyama et al. found that the centers of the initially formed radicals of long *n*-alkanes are at terminal carbon atoms (R_I•; i.e., $-CH_2$· a primary radical).[28,29] *n*-Alkanes with an even number of carbon atoms and shorter than tetracosane (≤24 carbon atoms) form triclinic crystals, where the hydrogen atom of a neighboring molecule closest to a terminal radical center of R_I• is at C2 or C3. As a result, there is a higher probability of *nondegenerate* intermolecular hydrogen abstraction to

form either $R_{II}\bullet(-\dot{C}HCH_3)$ or $R_{III}\bullet(-\dot{C}HCH_2CH_3)$, secondary radicals, than in long *n*-alkanes with an odd number of carbon atoms. Their layers are orthorhombically ordered so that the closest *intermolecular* hydrogen atom to an $R_I\bullet$ center is at C1; intermolecular hydrogen abstraction, if it occurs, should be degenerate because the probability of hydrogen abstraction (and radical center migration) decreases as the distance from the initial radical center to the nearest intermolecular hydrogen atom increases. In addition, the distances between $R_I\bullet$ centers and the nearest H-atom on a neighboring chain are intrinsically longer in orthorhombic than in triclinic crystals.

Pyrene and Perylene Doped Alkane Matrices

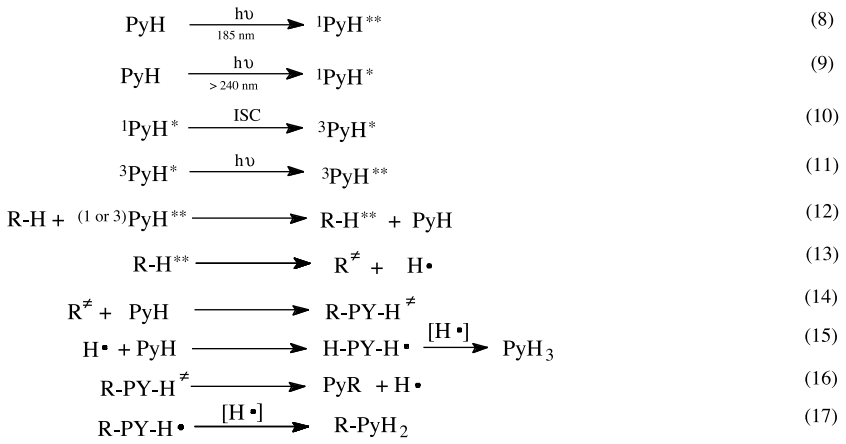
Lamotte et al. have examined the reactivity of upper electronically excited states of pyrene and perylene in liquid and solid alkane solutions.[30]At low temperatures, irradiation of pyrene at 185 or 248 nm in both methane and cyclohexane matrices leads to four detected photoproducts, including high yields of 1-substituted pyrenyl derivatives. Several substituted perylenes were obtained upon 185 or 248 nm irradiation in liquid and solid alkane solutions. A mechanism for alkylation of the aromatic solutes involving sequential absorption of two photons at 248 nm or one photon at 185 nm has been proposed.

Recently, the photochemical attachment of *n*-alkanes with 8,19, 20, 21, 24, and 28 carbon atoms and 1-eicosene to pyrene has been investigated.[31] The dependence of attachment selectivity (based on the degree of retention of the pyrenyl aromatic system in the products and the fraction of them in which attachment is at the 1-position of the *n*-alkane and the 1-position of pyrene) and efficiency (based on the relative yields of attached products when irradiations were performed under conditions of constant flux) on solvent phase, pyrene concentration, radiation wavelength (above and below 300 nm), and alkane chain length was explored. Without exception, attachment was more efficient and selection was greater in the solid than in the liquid phases of the alkanes. Also, the efficiency decreased significantly when initial pyrene concentrations were $> 10^{-5}$ *M*. Reactions in the solid state of solid *n*-alkanes with ≥21 carbon atoms yielded 1-(*n*-alkyl)pyrenes almost exclusively when the radiation wavelength was >300 nm. This behavior was attributed, in part, to the location of the pyrene molecules at the interfaces between alkane lamellae.

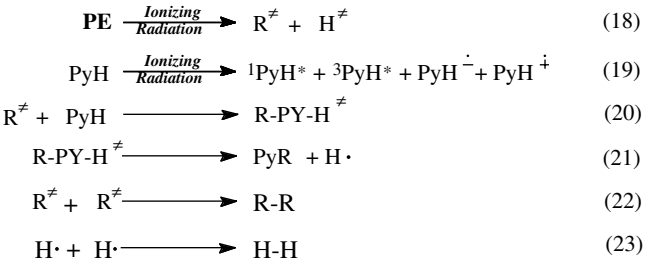
Degassed cyclohexane and *n*-alkane solutions of pyrene have also been exposed to <1.3> MeV x-rays.[32] Although the major products, 1-alkypyrenes, suggest a mechanism of attachment similar to that initiated by eV range photons, this does not appear to be the case (Scheme 2). Whereas eV range photons excite pyrene chromophores selectively in a sea of nonabsorbing C-H and C-C bonds from the alkane solvent, the initial interaction of MeV range x-rays is predominantly with the solvent matrix.[24]

The vertical (gas phase) ionization potential of pyrene is *ca.* 6.2 eV.[33] If the same ionization potential applies in alkane solutions, absorption of 185 nm photons (6.7 eV) can produce highly excited (i.e., "high-Rydberg") singlet states ($^1PyH^{**}$),[30,34] and cation radicals. However, excitations with >240 nm (<5.1 eV) yield lower-lying excited singlet states which undergo efficient intersystem crossing to the longer-lived lowest triplet state ($\Phi_{ST} = 0.37$ and $\tau_T = 180$ μsec at 25°C in cyclohexane[35]) that subsequently can absorb another photon under the high-flux conditions employed.[30,36,37] The highly energetic $^3PyH^{**}$ and $^1PyH^{**}$ states initiate the photochemistry of attachment by transferring their excitation energy to neighboring solvent molecules (RH), which dissociate to radicals (or ions) via CH or CC cleavage reactions.[30] The so-formed alkyl radicals then can add preferentially to their ground-state pyrene donors provided diffusion is slower than reaction. Finally, the 1-alkylpyrenes are produced after formal loss of H• (step 16 in Scheme 2).

Due to the rather indiscriminate mode of initial interaction of ionizing radiation with matter and the much higher population of CH or CC bonds of the alkane chains of the solvent matrix (than pyrene molecules), the primary loci of energy deposition for secondary radiation evolved from x-rays or MeV range protons reside in the solvent. In principle, therefore, attachment can occur *without* formation of $^1PyH^{**}$, $^3PyH^{**}$ (steps 8 through 11 in Scheme 2), or any other pyrene-based excited states; step 18 of Scheme 3 is a mechanistic departure point when films are bombarded by ionizing radiation. However, there is strong experimental evidence to support step 18, also.[38–40]



SCHEME 2 Proposed mechanism for attachment of pyrene (PyH) to polyethylene/alkanes using eV range photons. For 185 nm excitations, steps 9 through 11 are omitted (one photon process). Steps 9–17 are presumed to occur using >240 nm radiation (two photon process). When an intermediate has a ≠ sign (symbolizing · or +) on one side of an equation only, an electron (from pyrene, the polyethylene/alkane matrix, or a species derived from them) must be added to balance charges/electrons.



SCHEME 3 Proposed mechanism for attachment of pyrene to polyethylene using high-energy radiation. When an intermediate has a ≠ sign (symbolizing · or +) on one side of an equation only, an electron (from pyrene, the polyethylene/alkane matrix, or a species derived from them) must be added to balance charges/electrons.

3.2 Radiolyses in Block Polymers

Polyethylene (PE)

The degree of crystallinity in a PE sample is strongly dependent on the degree of chain branching that is incorporated at the time of polymerization. Highly branched polyethylenes have very small, distorted crystallites and low overall crystallinities. Their melting points and densities are lower than those of polyethylenes with higher degrees of crystallinity. Less branched polyethylenes have much larger crystallites and higher melting points and are much stiffer, more brittle, higher density materials.

High-energy radiation induces similar effects in polyethylene and low molecular weight paraffins.[41] Molecular hydrogen and low molecular weight hydrocarbons are formed, as well as insoluble polymer networks from chain cross-linking. Loss of crystallinity, associated with PE radiation damage, increases with increasing dose, and yellowing from oxidation is frequently observed during irradiations of PE in the presence of oxygen.

$$\mathbf{PE} \xrightarrow[radiolysis]{pulsed} \mathbf{PE}^{+} + e^{-} \quad (24)$$

$$e^{-} + PyH \longrightarrow PyH^{-} \quad (25)$$

$$\mathbf{PE}^{+} + PyH \longrightarrow PyH^{+} + \mathbf{PE} \quad (26)$$

$$PyH^{-} + PyH^{+} \longrightarrow {}^{3}PyH^{*} \quad (27)$$

SCHEME 4 Proposed mechanism for pulsed γ-radiolysis of pyrene-doped PE.[52]

Molecular Hydrogen Formation during Heavy-Ion Bombardment of Polyethylene and Other Polymer Films

LET dependence has been related to hydrogen yields in PE, polypropylene (PP), poly(methyl methacrylate) (PMMA), and polystyrene (PS) when their films were exposed to γ-rays, MeV range protons, and MeV range carbon ions.[42–44] The number of hydrogen molecules formed per incident particle, when each is stopped within a film, increases with particle energy and charge, but the G values decrease.

The yields of molecular hydrogen generally increased with particle LET in a dose range from 0.2 eV/nm of film thickness for γ-rays to 800 eV/nm for 30 MeV $^{12}C^{+4}$ ions.[42] PMMA and PS samples exhibited lower yields of molecular hydrogen than PE and PP when exposed to γ–rays. Although the four polymers approach a common value in the high LET region, the rate of increase in yields of molecular hydrogen with increasing LET was larger for PMMA and PS than for PE and PP in the lower LET region.

The relatively high yields of molecular hydrogen suggest that homolytic CH scissions and hydrogen atom abstraction reactions are a major reaction pathway during γ–radiolyses of PE and PP. Consistent with this hypothesis, the yields of molecular hydrogen are usually large when aliphatic hydrocarbons are exposed to ionizing radiation and the mechanisms involve homolytic cleavage of CH bonds.[45–47]

Degradation and Cross-Linking of Polyethylene Films by Ionizing Radiation

The effects of electron beams, fast neutron beams, and γ-rays on the crystallinity of low- and high-density PE films have been analyzed by x-ray diffraction (XRD) and differential scanning calorimetry (DSC).[48] The melting point of PE is known to decrease as the sizes of its crystallites and the organization of chains within them decrease.[3] Thus, lowered melting temperatures of low-density PE with higher γ-ray doses[48] are consistent with increased chain disorganization (from shortened chains) and frequency of chain branches that accompany CC and CH bond scissions. Their effect on polymer morphology outweighs that of increased cross-linking, another consequence of polymer chain scissions. In addition, increased intensities and shifts in position of x-ray peaks of low-density PE samples were observed as doses of γ-radiation were increased. They were interpreted as another indication of the greater importance of degradation at lower doses and more cross-linking at higher doses.[48]

Pulsed Radiolyses of Pyrene-Doped PE

Pulsed radiolyses with electrons of pyrene doped polyethylene samples have been examined over a wide temperature range.[49,50] Time-dependent changes in concentration of pyrenyl excited states and ions were used to study mechanisms of energy- and charge-transfer within the polymer matrix. Fast exciton migration is followed by molecular ion rearrangement and recombination to form pyrene excited states (step 28 in Scheme 4).[51–53]

These mechanistic pathways were inferred previously by Thomas et al. based on results from pulsed radiolyses (using 0.4 MeV electrons) of pyrene-doped aromatic polymers such as PS.[54] Especially in the absence of strong electron acceptors, ionizing radiation induces efficient charge separation via electronic hopping and molecular diffusion. In addition, the formation of excited singlet and triplet states of

$$\mathbf{PS} \xrightarrow[\textit{Electrons}]{\textit{0.4 MeV}} \mathbf{PS^+} + e^- \quad (28)$$

$$\mathbf{PS^+} + e^- \longrightarrow {}^{1,3}\mathbf{PS^*} \quad (29)$$

$$PyH + e^- \longrightarrow PyH^- \quad (30)$$

$$\mathbf{PS^+} + PyH \longrightarrow PyH^+ \quad (31)$$

$$\mathbf{PS^+} + PyH^- \longrightarrow {}^{1,3}PyH^* \quad (32)$$

$$PyH^+ + PyH \longrightarrow {}^{1,3}PyH^* \quad (33)$$

SCHEME 5 Proposed mechanism for formation of intermediates upon bombardment of pyrene (PyH) in PS with 0.4 MeV electrons.

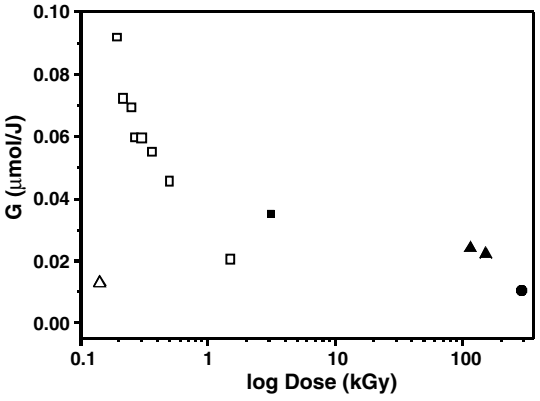


FIGURE 3.2 Plot of G versus log (dose) for 10^{-2} mol/kg pyrene in PE42 films bombarded with 4.5 MeV protons (□),1.0 MeV protons (●), 32 MeV electrons (■), 7.0 MeV alpha particles (▲), <2.0> MeV neutrons (△).

aromatic groups was observed in the polymers, primarily by geminate recombinations of polymer-based radical-cations and displaced electrons (Scheme 5).[54,55]

Bombardment of Pyrene-Doped Polyethylene Films with Neutrons, Electrons, Protons, and Alpha Particles

As an extension of studies in *n*-alkanes (Scheme 1), pyrene-doped polyethylene films have also been exposed to ionizing radiation.[56,57] Polyolefins with fluorescent probes such as pyrenyl groups,[58] selectively labeled at interior positions, have permitted the micromorphological consequences of several macro perturbations (e.g., film stretching) to be investigated.[59]

The influences of variables such as the type of ionizing radiation, the amount of kinetic energy of the bombarding particle, dose, polymer crystallinity, and initial pyrene concentration on the efficiency and selectivity of attachment of pyrene molecules to chains of PE films have been examined.[56,57] Irrespective of the type of ionizing radiation, selectivity and attachment efficiency (G) increased with decreasing particle dose (Figure 3.2). At higher doses, the dependence of G on initial pyrene concentrations was smaller because the number of polyethylene-based radicals and ions probably exceeded the (depleted) concentration of pyrene molecules. As expected, the damage to the polymer matrices, as determined from differential scanning calorimetry thermograms, also increased with increasing dose. Attachment efficiency (G) decreases as PE crystallinity increases under otherwise identical experimental conditions.

Interestingly, the efficiency of attachment is more or less independent of the kinetic energy of the particles (Table 3.2).[60] Due to the manner by which fast neutrons interact with polyethylene films, no penetration range can be calculated.[9]

TABLE 3.2 Comparison of 1-Pyrenyl Attachment Efficiencies (G) upon Bombardment of 10^{-2} mol/kg Pyrene in PE42 Films by Different High Energy Particles

Particle Type	Kinetic Energy (MeV)	Penetration Range (cm)	Dose (kGy)	G (μmol/J)
Electrons	32	12.8	3180	0.035
Protons	2.2	81×10^{-4}	0.344	0.3
Alphas	7.0	54×10^{-4}	0.247	0.9
Neutrons	<2.0>[a]	[b]	0.141	<0.05[c]

[a] Average value.

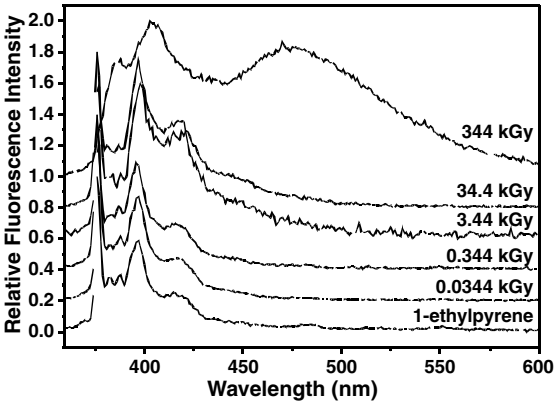

FIGURE 3.3 Emission spectra (λ_{ex} 343 nm) of 42% crystallinity PE films doped with 10^{-2} mol/kg pyrene after bombardment with 2.2 MeV protons (and removal of unreacted pyrene) as a function of dose at constant fluence and the emission spectrum of 10^{-6} mol/kg 1-ethylpyrene in 42% crystallinity PE. Spectra are normalized for intensity at 377 nm except that from 344 kGy dose. Spectra are offset for clarity.[56]

Attachment selectivity was independent of proton and alpha particle kinetic energies within the ranges (1–4.5 MeV for protons; 3–7 MeV for alpha particles) explored. However, the selectivity decreased with increasing doses of electrons, protons, or alpha particles (Figure 3.3). Higher doses generate more radicals and ions in a unit volume within a film and increase the probability of secondary events through track overlaps.[61]

A mechanism to describe the high-energy, radiolysis-initiated attachment of pyrene molecules to PE chains has been proposed by Biscoglio and Thomas.[62] Its principal claim, that preformed carbon-centered PE radicals or cations add to ground-state pyrene molecules, is supported by transient absorption spectra. Signals ascribed to electronically excited singlet and triplet states ($^1Py^*$, $^3Py^*$), and radical ions ($Py^{+\bullet}$, $Py^{-\bullet}$) of pyrene were detected initially after initiation of reactions by a pulse of 0.4 MeV electrons, but decayed to undetectable levels within 4 msec. However, polymer-centered radicals remained 4 msec after pulsed excitation and are presumed to decay according to step 19 of Scheme 3. Another transient absorption, consistent with a PE-bound 1-pyrenyl radical (RPyH•), persisted up to 3 sec after the excitation pulse.

Excitation and emission spectra from pyrenyl groups attached to polyethylene films upon exposure to low doses of eV-range photons and MeV-range particles cannot be distinguished, and both are very selective. As mentioned, the attachment selectivity does decrease with increasing photon or MeV-range

TABLE 3.3 Comparison of G Values for UV Photolysis (313 nm) and γ-Radiolysis of Symmetrical Aliphatic Ketones at 35°C

	G (Photolysis)[a]			G (Radiolysis)		
Ketone	$CO_{(I)}$	Methyl $Ketone_{(II)}$	Ratio (G_I/G_{II})	$(Alkane/2)_{(I)}$[b]	Methyl $Ketone_{(II)}$	Ratio (G_I/G_{II})
4-Heptanone	0.44	3.8	0.12	0.71	0.49	1.45
5-Nonanone	0.025	2.8	0.0090	0.43	0.51	0.88
6-Undecanone	0.020	2.4	0.0083	0.28	0.45	0.62
7-Tridecanone	0.017	2.0	0.0085	0.18	0.26	0.69
8-Pentadecanone	0.015	1.7	0.0088	0.065	0.092	0.71
12-Tricosanone	0.012	1.5	0.0080	0.040	0.081	0.69

Note: The subscripts I and II refer to products from Norrish Type I and Type II reactions, respectively.

[a] In the photolyses, $\mathbf{G} = \phi(100/\varepsilon_p)$, where ϕ is the quantum efficiency for a process and ε_p is the energy of the photons in eV.

[b] In the radiolyses, the **G** value of $CO_{(I)}$ = the **G** value of $(alkane/2)_{(I)}$.[64b]

particle dose. The lowest and highest photon doses employed for pyrene attachment were ~$(2–7) \times 10^3$ kGy and $(2–9) \times 10^4$ kGy, respectively, as estimated by fulgide actinometry.[56] The magnitude of the corresponding G value is significantly lower than most of those found upon particle bombardments despite the fact that all of the energy is deposited initially only into the pyrene molecules. Clearly, the vast majority of pyrene molecules in their singlet and triplet excited states (steps 10 and 11 in Scheme 2) must return radiatively or radiationlessly to their ground state without reacting.

Comparative Effects of UV photons and γ-Rays on the Degradation and Cross-Linking of Model Ketone-Containing Polymers

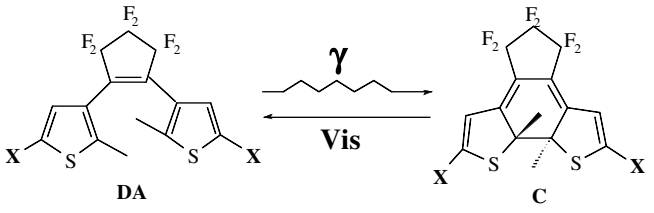
Guillet et al. have compared the effects of ^{60}Co γ-radiolysis and UV photons on the reactions of a series of model polymers containing ketone functional groups under vacuum.[63–65] A quantum yield for chain scission in a styrene-methyl vinyl ketone copolymer (containing 0.5% methyl vinyl ketone) was calculated to be 0.002 from the G values for γ-radiolysis;[63] the quantum yield for UV photolysis was 0.2, two orders of magnitude greater. The much lower efficiency of the γ-radiolysis can be attributed to the phenyl rings of the polymer, which are high energy sinks. No such protective effect occurs when the carbonyl groups are excited directly by UV photons.

The excited states of symmetrical aliphatic ketones produced upon γ-radiolyses are largely localized in the same n,π^* excited states that are produced upon excitation by UV photons.[64] In addition, the molecular weights of PE and copolymers of ethylene and carbon monoxide were increased by γ-radiolyses because cross-linking was more favorable than main chain scissions.[65] UV irradiation of the copolymer resulted in significant decreases in molecular weight as a result of the dominance of main chain scissions via a Norrish Type II processes.

Pitts and Osborne have compared the γ-radiolyses and UV photolyses of low molecular weight methyl ketones, which undergo both Norrish Type I and II processes.[66] They were unable to formulate a detailed mechanism for the γ-radiolyses due to the multiplicity of excitation processes and the large number of possible excited species present. However, the gross pathway of reaction appears to be similar to that initiated by UV photons (i.e., predominantly Norrish Type I and II processes). From the product ratios, the authors estimated that carbonyl groups are ~4 times more reactive than methylene groups when exposed to γ-rays (Table 3.3).

Diarylethene (DA) Doped Polymers as Dosimeters

Recently, thermally irreversible photochromic heterocyclic diarylethenes,[67] such as DA, have been examined as radiation dosimeters.[68,69]



X = CH_3 or C_6H_5 (34)

DA, both neat and in colorless single crystals[68] and doped at 0.1–30 wt% into PMMA or PS films, changes from colorless (DA form) to red (closed form C), when DA (X = CH_3) is exposed to γ-radiation.[69] A visible absorbance from PS films containing 2.0 wt% DA was detected after doses as low as 100 Gy, and the absorbance increased linearly with dose to 3000 Gy. Greater sensitivity was achieved by increasing film thickness: at 2 wt% DA**,** the color change induced in a 7.5 mm-thick film by 100 Gy was equivalent to that observed in a 0.75-mm thick film after exposure to 1000 Gy.

Coloration efficiency, defined as the magnitude of the absorbance from C at 600 nm, was also found to depend on DA (X = C_6H_5) concentration, and saturation (i.e., nonlinear response) was noted at 25 wt% at a total dose of 1000 Gy. From a plot of coloration intensity versus DA concentration in PS films of constant thickness, an energy transfer distance, $R_0 \cong 14$ Å, from an aromatic group of PS to a molecule of DA could be calculated using a modified Perrin expression (Equation 3.36).[70] $\mathbf{A_\infty}$ and $\mathbf{A_D}$ are absorbances extrapolated to infinite concentration and at known concentrations of DA, respectively. N is Avogadro's number and V is the reaction volume, assumed to be $4/3\ \pi\ \mathbf{R_o}^3$, where $\mathbf{R_o}$ is the distance at which 50% of the PS* transfer their excitation energy to molecules of DA.

$$\ln\left(\frac{A_\infty}{A_\infty - A_D}\right) = VN[DA] \tag{3.35}$$

In the initial step of the proposed mechanism for energy transfer (Scheme 6),[69] the PS matrix transfers some of the energy from a γ-ray to form highly excited states localized on the phenyl groups, PS**, that rapidly undergo internal conversion to low-lying excited states, PS*. The excitation energy of the PS* groups is transferred to nearby DA molecules, allowing formation of C and film coloration.

$$\mathbf{PS} \xrightarrow{\gamma\text{-}rays} \mathbf{PS^{**}} \tag{36}$$

$$\mathbf{PS^{**} + PS} \longrightarrow \mathbf{PS + PS^{*}} \tag{37}$$

$$\mathbf{PS^{*} + DA} \longrightarrow \mathbf{PS + DA^{*}} \tag{38}$$

$$\mathbf{DA^{*}} \longrightarrow \mathbf{C} \tag{39}$$

SCHEME 6 Proposed mechanism of γ-ray induced coloration of DA in PS films.[69]

3.3 Conclusions

This review has compared how energy from high-energy particles (i.e., ion beams, neutrons, γ-rays, x-rays, and fast electrons in the MeV range) and low-energy radiation (i.e., photons in the eV range) is deposited in liquid and solid hydrocarbon-like media and the experimental consequences of the differences. Exposure of a sample to high-energy radiation results in rather indiscriminate energy deposition initially, leading subsequently to the creation of highly excited species that are normally unattainable via

irradiation with eV range photons. Deciphering how energy flows within the sample matrices and to added photo-reactive species provides insights into how various high-energy quanta deposit energy in materials. Where possible, the photoprocesses suffered by solute molecules under conditions of UV/Vis and high-energy particle bombardment has been compared. The examples included here demonstrate that very selective photochemical processes with relatively high efficiencies are possible when the particle type, dose, medium ,and solute molecule are carefully controlled.

Oxidative Single Electron Transfer (SET) Induced Fragmentation Reactions

Angelo Albini
University of Pavia

Maurizio Fagnoni
University of Pavia

4.1 Introduction

The excited states of organic molecules present, as demonstrated throughout this book, a rich and diverse chemistry. However, a property that is common to all excited states is that of being both much better oxidants and much better reductants than the corresponding ground states. This makes redox processes involving organic molecules, a rare occurrence in ground state chemistry, a frequent path in excited state chemistry.[1–5] When the light-absorbing molecule is relatively stable as a radical ion, it functions as an electron transfer sensitizer, and the chemical reaction of the oppositely charged radical ion can be exploited. In this chapter, the use of electron accepting sensitizers is considered. Aromatic nitriles or esters, quinones, and aromatic ketones are used. These satisfy the requirement of chemical stability in the reduced state and are strong oxidants indeed [e.g., 1,4-dicyanonaphthalene, DCN (S_1), E_{red} 2.17 V vs. SCE; 1,2,4,5-tetracyanobenzene, TCB (S_1), 3.44 V; tetrachloro-*p*-benzoquinone (T_1), 3.33 V; α,α,α,–trifluoroacetophenone (T_1), 1.65 V]. The radical cation formed in the photoinduced Single Electron Transfer (SET) process may undergo addition or rearrangement processes. In the following, however, attention will be concentrated on reactions involving the fragmentation of the substrate RX.

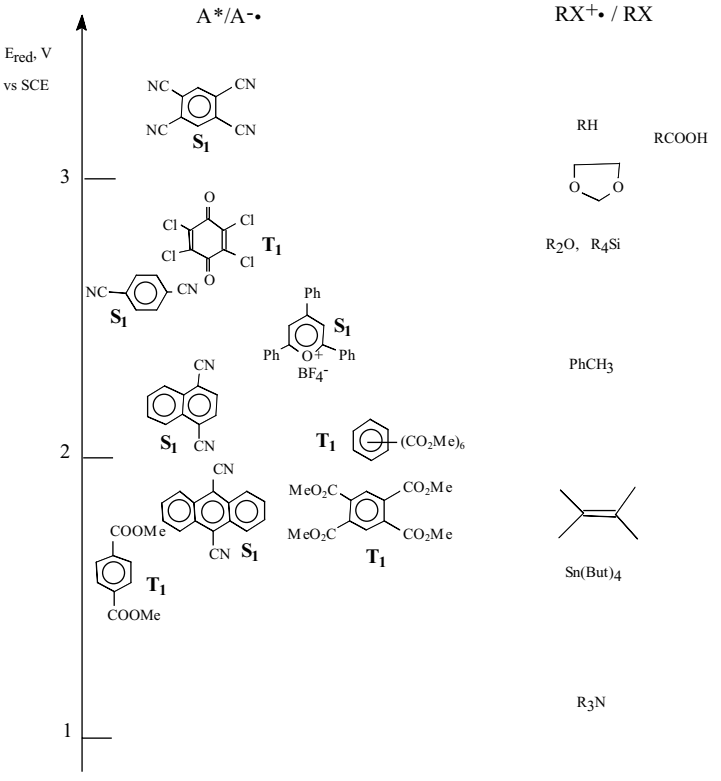
$$\text{Sens} + h\nu \rightarrow \text{Sens}^{\star} \tag{4.1}$$

$$\text{Sens}^{\star} + \text{R-X} \rightarrow \text{Sens}^{-\bullet} + \text{R-X}^{+\bullet} \tag{4.2}$$

$$\text{R-X}^{+\bullet} \rightarrow \text{R}^{\bullet} + \text{X}^{+} \rightarrow \text{Products} \tag{4.3}$$

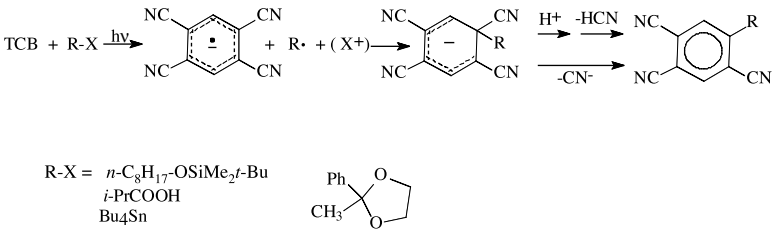
0-8493-1348-1/04/$0.00+$1.50

In the key step, a mesolytic process, as it has been dubbed, cleavage of a σ bond yields a radical and a cation.[6–13] The same result may be obtained through nonphotochemical means, such as anodic oxidation or ground state oxidation by an inorganic reagent. Excitation through light absorption generates the actual oxidant (the excited state) in a very low steady state concentration and in solution, thus differing from electrochemistry, where holes are concentrated on the electrode, and from oxidation with inorganic species, where a relatively high concentration of the oxidant must be added. Therefore, photosensitization is a much milder method, where e.g., over-oxidation of the radical formed initially to a cation, a common occurrence with the other two methods, is easily avoided. On the other hand, the strongly positive reduction potential of many organic molecules in the excited state (compare the examples above) makes redox sensitization an effective process also for quite modest donors, for which no thermal counterpart exists, and photosensitization is a much more flexible method than γ radiation. The range of application of photosensitized (by A*, in the singlet or triplet state) oxidation of organic molecules (RX) is pictorially represented in Equation 4.4.



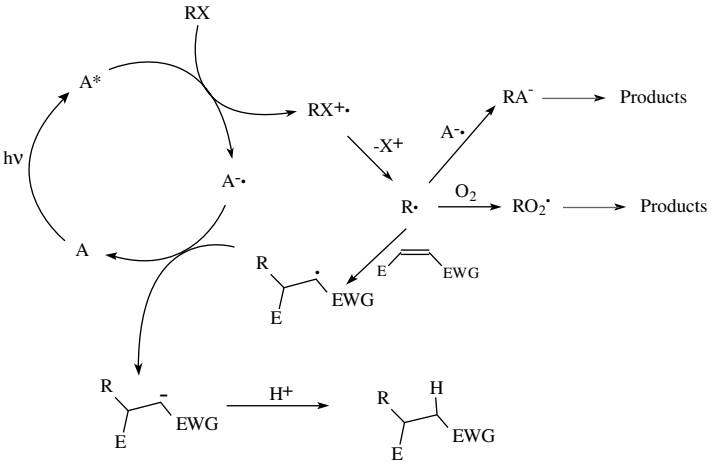
(4.4)

The efficiency and mildness characteristic of this method have led to the widespread use of electron transfer photosensitized oxidation followed by fragmentation as a novel method for the generation of radicals (and, generally less importantly from the synthetic point of view, of cations) from unusual precursors. The sensitizers initiate the process and at some stage of the following chemistry give back to some intermediate the electron initially accepted, so that it is not consumed during the process, and the sensitizing cycle continues. Alternatively, they function as the radical trap (see an example for the case of TCB in Equation 4.5).



(4.5)

Typical reactions of the thus formed (usually alkyl) radicals (R·) are trapping by electrophilic alkenes (EWG = electron-withdrawing substituent), resulting in conjugate alkylation, or by oxygen, leading to oxidation, besides the above mentioned coupling with the radical anion of the sensitizer, giving addition or substitution products (see Equation 4.6).

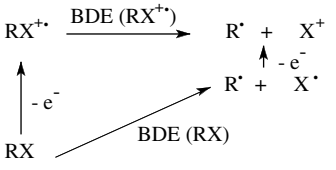


(4.6)

In this chapter, attention is given to the fragmentation step, and thus, after an introductory section on the scope of the method, the material is organized according to the structure of the donor and, within each category, according to the structure of the electrofugal group cleaved in the key chemical step.

4.2 Scope of Radical Cation Fragmentation

The feasibility of the fragmentation can be assessed through thermochemical cycles (see Equation 4.7).[9,14–17]



(4.7)

Some examples are presented in Table 4.1, where it is apparent both that many organic substrates can undergo photoinduced oxidation with the sensitizers mentioned above and that one electron oxidation dramatically weakens σ bonds. In fact, it has been shown above that the reduction potential of excited

COOMe	C-H		8.8

[a] The radical cation fragmentation occurs unimolecularly.

[b] The radical cation fragmentation involves assistance by cerium ammonium nitrate (0.15 *mM*), the photochemical precursor of the oxidant used in this case, the nitrato radical.

[c] The process is assumed to involve deprotonation from the radical cation of the acid, followed by C-C bond fragmentation at the neutral radical level.

sensitizers is usually larger than 1.5 V vs. SCE and can be in excess of 3 V. Thus both π donors such as aromatics and alkenes and n donors can be oxidized. Indeed, very strong oxidants such as TCB in the singlet-excited state oxidize alkanes, also. Furthermore, the energy involved in single electron transfer is often in the same order as bond energy, and fragmentation becomes in many cases close to thermo neutral or even conspicuously exothermal. On the other hand, the thermochemical data are not per se an indication of which cleavage path(s) are sufficiently fast to compete with back electron transfer (BET, see Equation 4.8)

$$Sens^{-\cdot} + R\text{-}X^{+\cdot} \rightarrow Sens + R\text{-}X \tag{4.8}$$

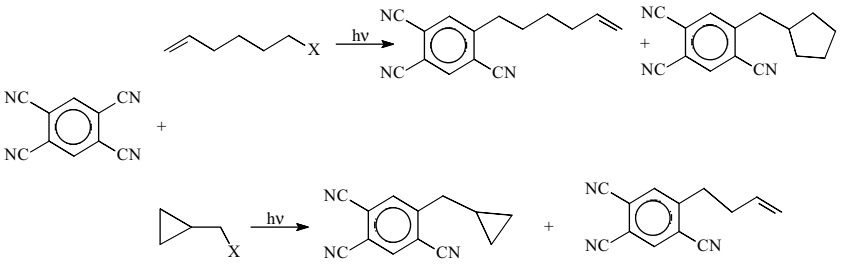
or with other reactions of the radical cation, the competition being at any rate strongly dependent on the choices of the sensitizer and the medium (see below some hints about the dynamics of the process). A number of direct measurements of the cleavage rate are now available. As an example, one may refer to a recent determination of the fragmentation rates of some 4-methoxybenzyl derivatives in order to appreciate the variety of electrofugal groups and also to highlight the kinetic difference between them (see Table 4.2).[18]

As it appears from Table 4.2, CC bond fragmentation is a very fast process with electrofugal groups such as disubstituted α-alkoxy cation or (substituted) α,α-dialkoxy cations, and the CSi bond cleaves very quickly. CH bond cleavage is a much slower process, in the cases discussed occurring only as a nucleophile-assisted (in this case by cerium ammonium nitrate) process. Notice that the data refer to

the highly stabilized radical cation of anisole derivatives. With poorer donors, and thus higher energy radical cations, the same processes may be orders of magnitude faster, but the scale of reactivity remains as illustrated, e.g., for benzylic donors the relative rate of cleavage remains in the order k_{cl} ($-SiMe_3^+$) > 10 k_{cl} ($-CO_2 - H^+$) > 10 k_{cl} ($-H^+$).[19] It may be noted that deprotonation is in most cases predicted to be the most exothermic process by thermochemical considerations (see Table 4.1). Nevertheless, less exothermic or even slightly endothermic processes involving different fragmentations, e.g., CC bond breaking, often compete successfully, possibly due to the more important change in the solvation sphere imposed by deprotonation. Some kind of assistance by a purposely added nucleophile, the sensitizer, or the solvent can in fact strongly affect competition between alternative fragmentation processes and between these and BET. Several studies have been devoted to the determination of the detailed mechanism for the (nucleophile-assisted) fragmentation of radical cations, always among benzylic derivatives. These are by far the best-studied class.[20–23]

From the point of view of synthetic application, the most important point is the type of radical generated. In most instances the electron-donating moiety, whether a π donor (aromatic or olefin) or an n donor (a heteroatom), is located in the part of the molecule that forms the radical R·, usually in the α–position with respect to the cleaving σ bond (see Equation 4.3). Splitting of cation X thus gives an α-substituted (and stabilized) radical, such as benzyl, allyl, or α-heteroatom substituted. In other cases, however, the donating moiety is part of the electrofugal cation X^+, as is the case with tetraalkylsilanes or with ketals (vide infra). In this case a nonstabilized alkyl radical is generated, just as when an alkane is directly oxidized and deprotonates from the radical cation. The chemistry of the radicals formed follows the patterns indicated in Equation 4.6. An exception is strongly stabilized radicals (e.g., benzhydryl) that usually dimerise or undergo electron transfer steps (see the following section and Equation 4.12).

Furthermore, the above presentation has been grossly oversimplified. Actually, association between the radical ions and solvation has an important influence on the various steps of the reaction. Thus, fragmentation of the radical cation may take place either when it is still more or less strongly associated with the oppositely charged radical ion (from the sensitizer) or when it is a free solvated ion. This has a role not only in the fragmentation efficiency but also in the probability that the resulting radical can be trapped by an addend that is different from the sensitizer radical ion. This point has been the subject of in-depth investigations, as it appears in several of the references that will be mentioned where appropriate. A general idea of the kinetics involved has been obtained, for aliphatic donors, by using rearranging radicals (radical clocks, see Equation 4.9).[24]



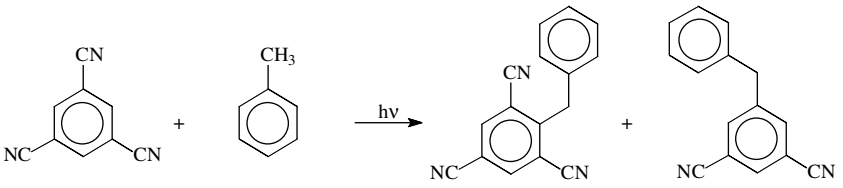
X = Electrofugal group (4.9)

4.3 Aromatic Donors — Benzylic Cleavage

Deprotonation

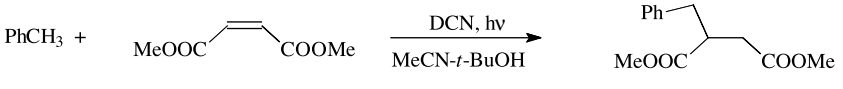
Aromatic donors form the largest class of substrates fragmentable by electron transfer in view of their accessible oxidation potential and the easy cleavage at the benzylic position. Pioneering work by Nicholas and Arnold[14] demonstrated the high acidity of the toluene radical cation. The process has been extended

over the years to the cleavage of bonds different from CH, in particular CC, CSi, CSn, and others, and these will be dealt with in this order in the following discussion. However, from the preparative point of view, deprotonation is often fast enough to generate benzyl radicals with reasonable efficiency by loss of a proton from the α–site and obtain benzylation reactions. Typical examples are substitution or addition reactions to the sensitizer, e.g., a cyanoaromatic (see Equation 4.10),[25–30] phthalimides,[31] quinones,[32] and immonium salts.[33,34]



(4.10)

Evidence that stereoelectronic effects are important has been obtained by studying the intramolecular deprotonation selectivity in asymmetric polymethylbenzenes, which is the same in photoinduced SET and in activation by inorganic oxidants,[26,35] or the methyl vs. *iso*-propyl selectivity in cymenes.[36] When the benzyl radicals are highly stabilized, they undergo dimerization.[37] More interestingly from the synthetic point of view, these may be used for the photoinduced benzylation of electrophilic alkenes both by using molecular sensitizers such as DCN (1,4-dicyanonaphthalene, see Equation 4.11)[38] and by using titanium dioxide powder photocatalysis,[39] as well as for selective oxidation at the benzylic position[40–45] and photoinduced nitration with tetranitromethane.[46]

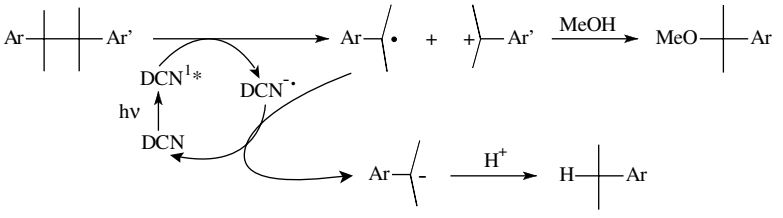


(4.11)

Other Fragmentations

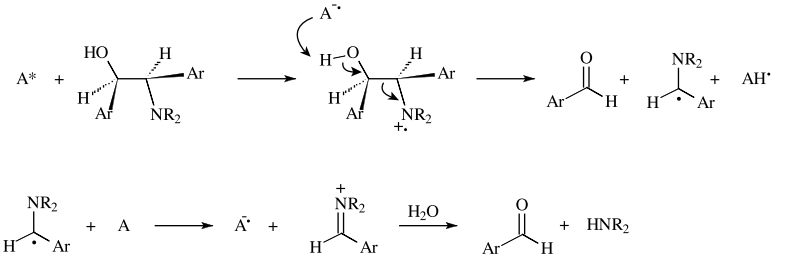
Benzyl radicals are likewise obtained from radical cations by fragmentation of other electrofugal cations, in particular carbon–carbon bond fragmentation with various C-centered cations as leaving groups, such as a benzyl cation in bibenzyl derivatives,[47–49] stabilized alkyl groups,[50,51] e.g., the *t*-butyl cation in neopentylbenzene, proton and carbon dioxide in phenylacetic acids,[19,52] as well as heteroatom stabilized cations such as α-alkoxy[53–57] or α,α-dialkoxy cations and α-amino cations.[58,59] The radical cation of triarylmethylarylketones gives the triarylmethyl cation and the benzoyl radical upon triphenylpyrylium-sensitized oxygenation, but that of less heavily substituted benzylarylketones appears to cleave both ways.[60] Also in this case, benzyl radicals are trapped by the sensitizer or other additives, or otherwise couple. The recombination of the radical and cation sites leads to isomerization in some phenylcycloalkanes.

Several classes of such fragmentation reactions have been studied in detail in order to understand the effect of substituents, the stereoelectronic requirements, and the effects of the medium and of nucleophiles. The mesolytic fragmentation of bibenzyls with the reduction of the radical and nucleophilic trapping of the cation is the main process for stabilized fragments, typical examples being cumyl or benzhydryl (see Equation 4.12). The relative stability of radical and cation makes the cleavage selective for Ar ≠ Ar′.[17,61–63]



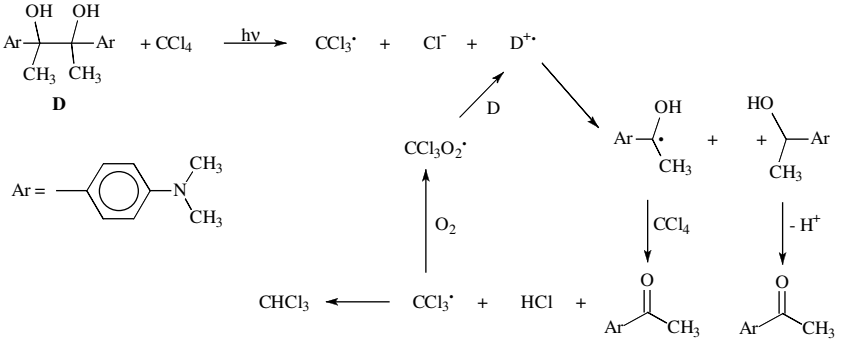
(4.12)

Another extensively investigated class, besides that of 2-phenylethyl ethers mentioned above, is that of 1,2-diarylpinacols, aminoalcohols, and diamines.[64] A variety of electron transfer sensitizers have been used with these substrates: besides aromatic acceptors, chloranil and related benzoquinones (in some cases by specific irradiation in the absorption band of the charge transfer complex formed with these donors)[65] have been used. Also, singlet oxygen is an effective SET agent with good donors.[66] With diphenylpinacol and 1,2-diphenyl-2-aminoethanols the chemical reaction, viz. oxidative (retropinacol) cleavage, is clean but the quantum yield is low, though it increases under co-sensitized (by biphenyl) conditions[67–70] because the unimolecular fragmentation of the radical cation competes unfavorably with back electron transfer. The process occurring actually involves proton transfer to the sensitizer radical anion as the rate-determining step followed by CC bond cleavage at the alkoxy radical level (see Equation 4.13).



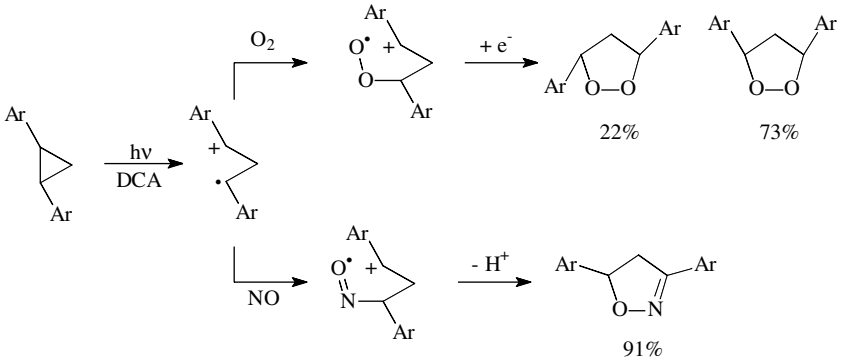
(4.13)

However, in the case of benzopinacol and with methylviologen as the sensitizer, unimolecular fragmentation of the radical cation has been detected ($\tau \approx 10$ psec).[71] With ring electron donating substituted pinacols[72] and with 1,2-diphenyldiamines,[73] unassisted fragmentations are much faster (up to 10^6–10^8 sec^{-1}). An important application is the co-fragmentation of such radical cations and of fragmentable radical anions, such as those of alkyl halides (see Equation 4.14)[74,75] or those of electron-deficient pinacols.[76]



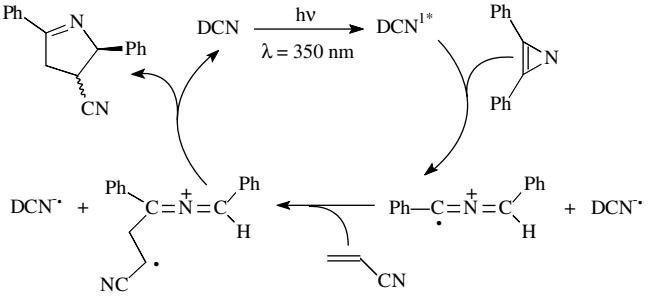
(4.14)

A particular class of benzylic CC bond cleaving radical cations is that of arylated cyclopropanes and their heterocyclic analogues. Thus, 1,2-diarylcyclopropanes[77–81] as well as 2,3-diaryloxiranes[77,82–84] and 2,3-diarylaziridines (2-monophenyl aziridine derivatives have also been studied)[77,85,86] undergo CC fragmentation upon photoinduced electron transfer sensitization. This results, after back electron transfer, in *cis-trans*-isomerization or trapping, unless a further fragmentation intervenes.[85] Trapping, whether it occurs at the radical cation level or at the ylide level after back electron transfer, has some synthetic interest. Additions to electrophilic alkenes,[82] to oxygen[77,79,80,83,84] or to nitrogen oxide (see Equation 4.15),[81] as well as to the sensitizer,[78] have been observed.



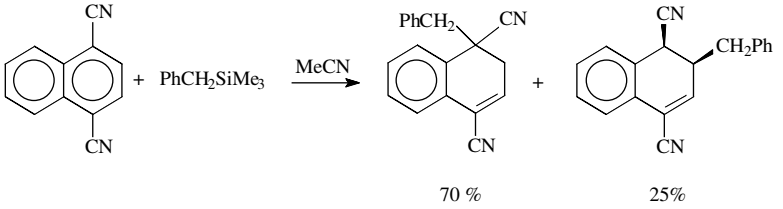
(4.15)

Diphenylazirines also cleave and the open form can be trapped to yield imidazoles and heterophanes (see Equation 4.16).[12]

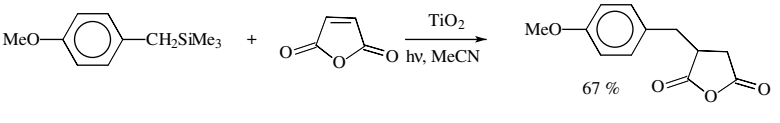


(4.16)

Among heteroatom centered leaving groups, an efficient reaction is the fragmentation in benzylsilanes, germanes, and stannanes, which has been largely exploited for benzylation reactions both with organic sensitizers (see Equation 4.17) [87–92] and through photocatalysis (see Equation 4.18).[39]



(4.17)

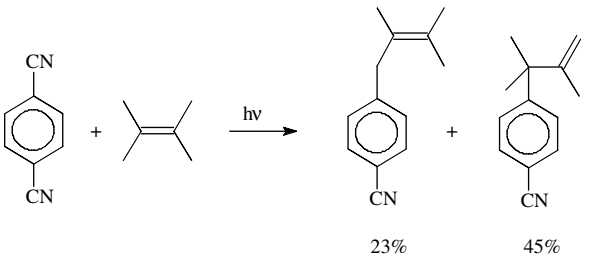


(4.18)

Di- and triphenylmethylphenyl sulfides cleave in the opposite direction giving benzyl cations and phenylthiyl radical,[93] and the same applies to benzylphenyl selenides.[94]

4.4 Olefinic Donors — Allylic Cleavage

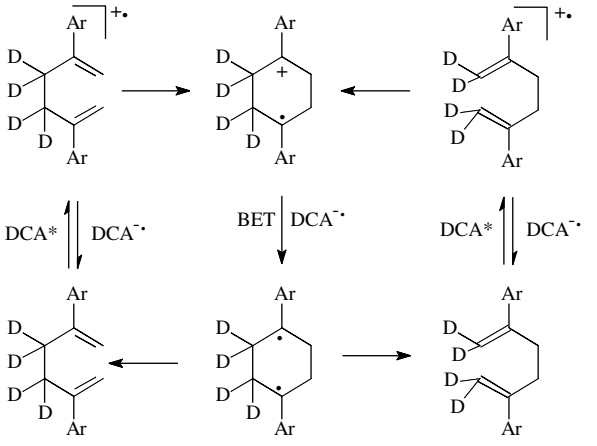
Alkenes are reasonably good donors. Allylic deprotonation from the radical cation is usually a slow process, but it does occur to some extent as indicated by the allylation of aromatic nitriles used as electron transfer sensitizers, which takes place to a variable extent (see Equation 4.19).[95–98]



(4.19)

Solvent addition to the alkene radical cation is often preferred to fragmentation in nucleophilic media such as alcohols (this gives rise to another useful photosubstitution process on aromatics, the photo-NOCAS reaction discussed elsewhere in this Handbook).[99]

Allylic carbon–carbon bond cleavage occurs more effectively: examples are the stereospecific Cope rearrangement observed with 2,5-diary-1,5-hexadienes upon electron transfer sensitization (see Equation 4.20)[100,101] and the cleavage of the four-membered ring in pinenes at the radical cation stage.[102]



(4.20)

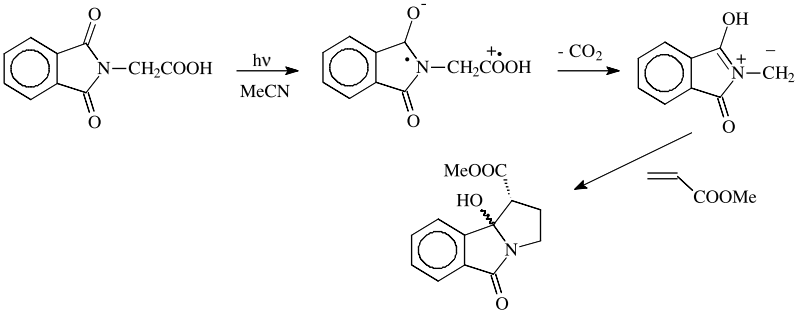
Allylic silanes, germanes, and stannanes have been found to fragment smoothly in the presence of various acceptors, leading to the allylation of ketones,[103–106] imminum salts,[107] and aromatics.[108,109]

4.5 Aliphatic Donors

Nitrogen-Containing Donors

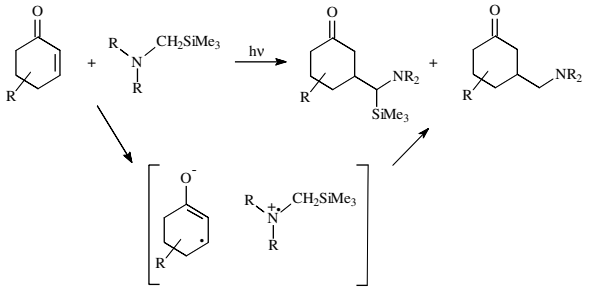
Amines form relatively stable radical cations, and back electron transfer often overrides chemical reactions, except in the presence of good electrofugal groups in the α–position. Nevertheless, α-deprotonation (or alternatively a proton or hydrogen transfer process within an exciplex) may be fast enough to cause addition to unsaturated esters and ketones,[110–113] aromatics,[114] and arylalkenes.[115,116] Deprotonation and further oxidation of some tertiary amines appear to produce aminium salts that are then allylated by allyl radicals simultaneously produced by fragmentation of allylsilane. Both processes are brought about by photosensitized electron transfer.[117]

Carbon–carbon bond cleavage is important in the retro-aldol fragmentation of 2-aminoethanol and in the decarboxylation of α-aminoacids. As an example, decarboxylation in α-anilinocarboxylic acid has been shown to be an unusually fast process (10^6 to 10^7 sec^{-1}) and to occur unimolecularly, differently from deprotonation and desilylation from structurally related anilines.[20] The decarboxylation of the *N*-phthaloyl derivatives of α-amino acids has been extensively investigated (see e.g., Equation 4.21).[118–122]



(4.21)

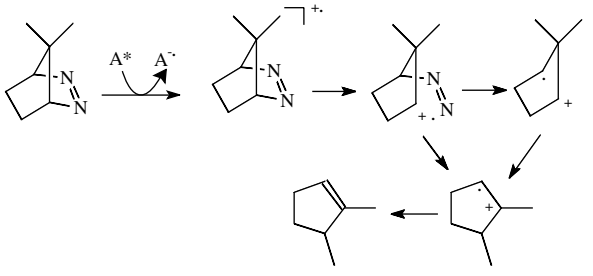
With aliphatic amines, the silyl cation has been shown once again to be an excellent electrofugal group, and α–silylamines have proved to be convenient precursors for the generation of alkyl radicals and the alkylation of cyanoaromatics[123,124] and of unsaturated ketones (see Equation 4.22).[125–131] The latter reaction has a wide synthetic potential.



(4.22)

Electron transfer photosensitization of spiro-diaziridines with aromatic ketones is a method for the generation of carbenes initiated by CN bond fragmentation at the cation radical stage.[132]

Aliphatic azo derivatives extrude nitrogen upon photosensitized electron transfer, and this is a smooth entry to distonic radical cations, the chemistry of which has been studied in a number of cases. As an example, the cationic character of the intermediate in the photolysis of 7,7-dimethyl-2,3-diazabicyclo[2,2,1]hept-2-ene is clearly demonstrated by the Wagner–Meerwein rearrangement leading to 2,3-dimethylcyclopentene (see Equation 4.23).[133–135]



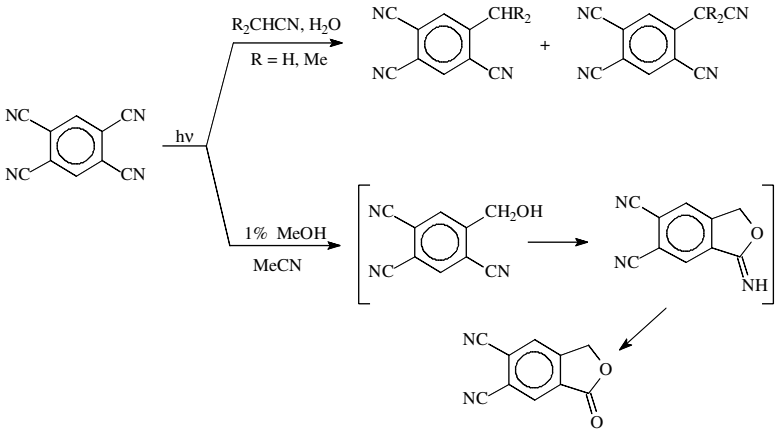
(4.23)

Oximes are deprotected to ketones by photosensitization with chloranil, apparently via proton transfer from the radical cation to the radical anion of the acceptor.[136]

With particularly strong acceptors, such as singlet excited tri- and tetracyanobenzenes, weak donors such as aliphatic nitriles can deprotonate from the α-position (see Equation 4.24)[137,138] and alkylate the sensitizer.

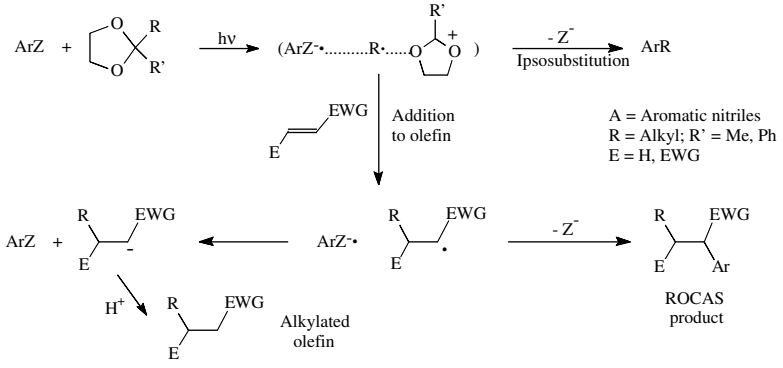
Oxygen- and Sulfur-Containing Donors

Photosensitized oxidation of ethers causes α-deprotonation; in the case of methyl neopentyl ether, CC and CH fragmentation compete.[139] The resulting radicals react with the sensitizer, viz. an aromatic nitrile[139–143] or an iminium salt.[144] As in the case of amines, α-trimethylsilyl ethers and thioethers are excellent precursors for the corresponding α-heteroatom-substituted alkyl radicals.[123,124] The potassium salts of α–oxoalkyl and α-thioalkyl carboxylic acid decarboxylate upon photosensitization by phthalimides.[145] Alcohols undergo, as expected, α-CH and no OH deprotonation, via the radical cation formed with sensitizers such as tetracyanobenzene (see Equation 4.24)[124] and pyrrolinium salts.[144]



(4.24)

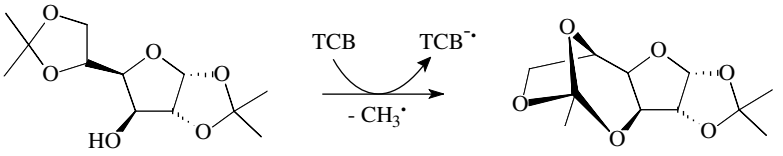
Acetals and ketals cleave to yield alkyl radicals and α,α-dioxo substituted cations. This is one of the cases where the electron-donating moiety is incorporated in the electrofugal group, and a nonstabilized alkyl radical is formed. This is an efficient process, and such substrates, in particular 2-alkyl and 2,2-dialkyl-1,3-dioxolanes, serve as useful precursors for the mild generation of alkyl radicals that can be trapped by the sensitizer (see Equation 4.5)[146] or, more usefully from the synthetic point of view, by electrophilic alkenes. In the latter case, the resulting adduct radical may in turn enter into a substitution process on the aromatic nitrile (the ROCAS process, Radical Olefin Combination Aromatic Substitution)[147] or be reduced by the radical anion of the sensitizer and be protonated. In the last case, the sensitizer is regenerated and conjugate radical alkylation results (see Equation 4.25).



(4.25)

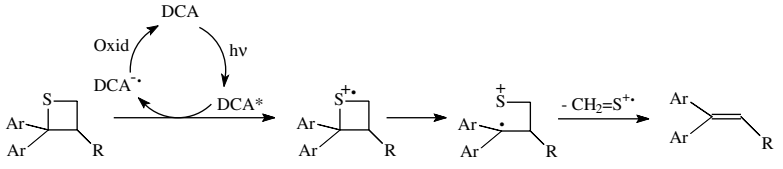
The thermodynamic conditions governing this partitioning have been defined,[148,149] and acetals and further radical precursors have been extensively applied for conjugate alkylation.[150–153] Photosensitized conjugate addition is particularly effective when using aromatic esters in the place of nitriles as the

sensitizers, since the former compounds are consumed at a lower rate and their turnover number is particularly favorable.[154] Fragmentation of acetals and thioacetals serves also as a mild procedure for deprotection of carbonyls[155–157] (including fragmentation of the glucoside bond in aryl glycosides),[158,159] and some useful chemistry can be carried out also via transformations of the electrofugal cation, as shown for the case of some carbohydrate ketals (see Equation 4.26).[160]



(4.26)

Among other sulfur containing donors, thiocarbonates also cleave,[161] and electron transfer from cysteine leading to decarboxylation involves the sulfur atom at all pHs.[162] Electron transfer photosensitization of some 2,2-diarylthietanes causes retrocycloaddition and yields 1,1-diarylethylenes (see Equation 4.27, DCA = 9,10-dicyanoanthracene).[163]

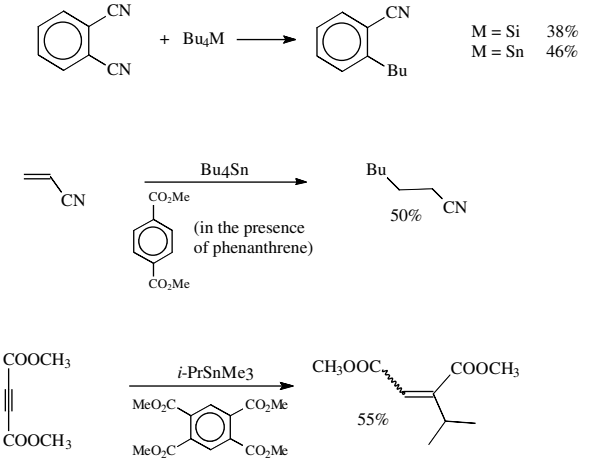


(4.27)

Silylethers also give alkyl radicals (see Equation 4.5),[124] and siloxycyclopropanes yield β-keto radicals.[164] Arylpinacol silyl ethers can be used to silylate tetrachloro-*p*-benzoquinone.[165]

Organometallic Donors

Tetralkyl-silanes, -germanes, and –stannanes,[24,166,167] as well as disilanes[168] and distannanes,[166] have been successfully used as alkyl radical precursors. The use of alkyl radicals is closely parallel to that presented above starting from ketals for the substitutive alkylation of aromatics and the conjugate addition to alkenes and alkynes (see Equations 4.5 and 4.28). Notice, however, that the final result depends on the sensitizer-trap used. Thus, *N*-methylacridinium perchlorate is reductively alkylated by hexamethyldisilane[168] but undergoes reductive dimerization with the corresponding digermanes and distannanes.[169]

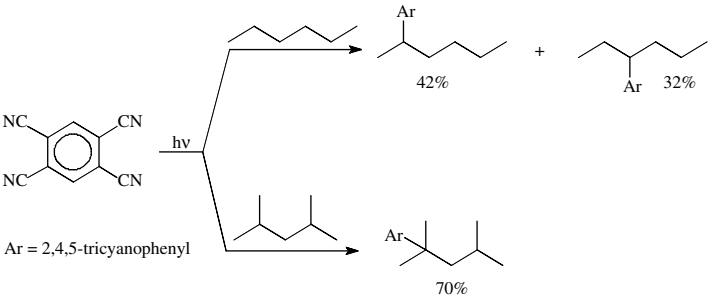


(4.28)

Alkylborates likewise generate alkyl radicals efficiently that alkylate the sensitizer (an aromatic nitrile).[170,171] On the other hand, disilanes may undergo cleavage of the SiSi bond and act as silylating agents, as is the case for the silylation of tetrachloro-*p*-benzoquinone[172] and (in low yield) of polycyanobenzenes[173] by hexamethyldisilane. Polysilanes containing a terminal hydroxyl group have been found to undergo SiSi bond fragmentation followed by intramolecular trapping to yield cyclic siloxanes upon photosensitization by DCA.[174]

No Donating Moiety

Strong acceptors such as tetracyanobenzene can oxidize and decarboxylate aliphatic acids (see Equation 4.5)[175] as well as *t*-butyl esters.[176] Indeed, simple alkanes also undergo photosensitized oxidation and are deprotonated via the radical cation under these conditions. The radicals are identified from the alkylation of the sensitizer (in this case, TCB, see Equation 4.29).[177–180]



(4.29)

Ring opening and rearrangement have been observed with strained hydrocarbons such as bicyclo[2.2.0]hexane,[181] cubane (see Equation 4.30),[182] and other cage hydrocarbons.[183]

Photochemistry in Ionic Liquids

Richard M. Pagni
University of Tennessee

Charles M. Gordon
University of Strathclyde

5.1 Introduction

A molten salt is a liquid consisting of a compound or mixture of compounds in which all, or virtually all, of the components are ionic. Liquid NaCl (m.p. 801°C), KSCN (m.p. 173.2°C), and pyridinium chloride (m.p. 146.0°C) are thus one-component molten salts. On the other hand, an ionic liquid, a term also used to refer to a salt solution, is a molten salt that is a liquid at or near room temperature. Although organic chemistry in molten salts has been known for decades,[1] molten salts were and continue to be used primarily in the study of inorganic chemistry and electrochemistry. With the fairly recent development of ionic liquids, however, the study of organic and organometallic chemistry in ionic media has come to the fore.[2] Surprisingly, many ionic compounds and their mixtures are liquids at room temperature. Consider the following three examples:

Ethylammonium nitrate, with a melting point of 4°C, has been used successfully as a medium for the Diels–Alder reaction.[3]

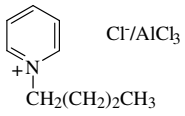
Lithium perchlorate in diethyl ether (LPDE), which is used widely in organic synthesis,[4] is an ionic liquid when the lithium perchlorate concentration is greater than 4.25 *M* because all of the ether is complexed to Li^+.[5] The primary means by which LPDE operates is via Li^+ catalysis.[6,7]

"Almost anhydrous" tetrabutylammonium fluoride, prepared by heating the corresponding hydrate at 40–45°C, is an excellent source of naked fluoride in organic synthesis.[8]

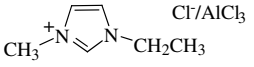
Even though the above three ionic liquids have considerable utility and interest, they do not represent the mainstream. The ionic liquids that are the most widely used, and the ones used in photochemical studies to date, contain 1-alkylpyridinium or 1,3-dialkylimidazolium ions. The first of these to be prepared was the two-component ionic liquid consisting of mixtures of crystalline 1-butylpyridinium chloride ([bp][Cl]) and aluminum chloride that are liquids at 40°C over a wide range of BPC to $AlCl_3$ ratios.[9] The second consists of mixtures of 1-ethyl-3-methyl-imidazolium chloride ([emim][Cl]) and $AlCl_3$ that are liquids at room temperature and below over a wide range of [emim][Cl] to $AlCl_3$ ratios.[10] These conducting media, which have been used extensively in electrochemical studies, have interesting acid–base properties. When the heterocyclic chloride is in excess, the medium is basic because of the presence of Cl^- (and $AlCl_4^-$). When aluminum chloride is in excess, the ionic liquid is acidic because of the presence of $Al_2Cl_7^-$, a powerful Lewis acid. HCl in acidic [emim][$Cl/AlCl_3$] has superacidic properties and is the strongest chlorine-containing Brønsted acid known.[11,12] These ionic liquids are not particularly

0-8493-1348-1/04/$0.00+$1.50

viscous, have very little vapor pressure at room temperature, and readily dissolve an array of organic and inorganic compounds. Because the ionic liquids contain $AlCl_3$, however, they must be prepared and handled on vacuum lines and in glove boxes. Furthermore, products are generally removed from them by extraction only after they are quenched with water which, of course, destroys the ionic liquid.

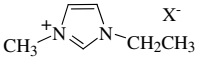


BPC/$AlCl_3$

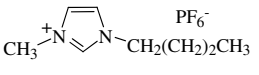


emimCl/$AlCl_3$

Many imidazolium and pyridinium salts are liquids at room temperature, even in the absence of $AlCl_3$. 1-Ethyl-3-methylimidazolium tetrafluoroborate ([emim][BF_4]) and acetate ([emim][OAc]) are both liquids at room temperature.[13] By systematically varying the size of the alkyl chains of the heterocyclic cations and the nature of the anion, it is possible to synthesize a large number of salts that are liquids at room temperature. 1-Butyl-3-methylimidazolium hexafluorophosphate ([bmim][PF_6]), which is insoluble in both water and alkanes, is perhaps the most widely used of the neutral, air stable ionic liquids. Because these ionic liquids have virtually no vapor pressure and have large liquidus ranges, they have found wide application in the field of green chemistry.[2,14,15] Procedures to remove products from the ionic liquids and to clean up ionic liquids for reuse (they are often expensive and cannot be distilled) are still being developed.



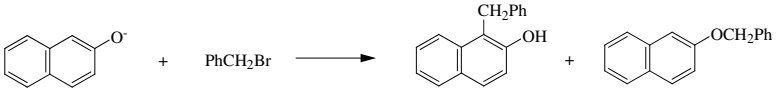
X = BF_4 ($emimBF_4$)
X = OAc (emimOAc)



bmimPF_6

Because they are ionic in nature, ionic liquids (IL) should have large cohesive energy densities and solubility parameters; this is the case for the few ILs examined to date.[16] Generally, nonelectrolyte solutes are soluble in solvents in which the solute and solvent have similar solubility parameters.[17] One would thus expect solutes with low solubility parameters, the majority of solutes, to be poorly soluble in ionic liquids that have high values. As attested by the large number of reactions taking place in these media, this is not the case.[2] Perhaps the correlation breaks down because ionic liquids themselves are ionic.

Because they have no hydroxyl groups and are polar, ionic liquids should be categorized as aprotic dipolar solvents. Anions in typical aprotic solvents such as dimethyl sulfoxide are poorly solvated and, as a result, function as good bases and nucleophiles. In the S_N2 reaction of benzyl bromide with the nucleophile 2-naphtholate, products arise with the phenolate oxygen and C1 of the naphthalene ring functioning as nucleophiles. In protic solvents such as ethanol, where hydrogen bonding with the phenolate oxygen occurs, large amounts of C-alkylation occur.[18] In aprotic solvents such as dimethyl sulfoxide, however, mostly O-alkylation occurs.[18] In the ionic liquids (n-Bu)$_4$NBr[19], (n-Bu)$_4$PBr[19], and bmimPF_6,[20] the reaction gives mostly O-alkylation. These results are consistent with the ionic liquids acting as aprotic dipolar solvents.



Although the above results are qualitatively consistent with ionic liquids being aprotic dipolar media, they are not definitive. The best currently available methods for characterization of solvents, including ionic liquids, involve the use of photophysical data and are the topic of the next section.

5.2 Photophysical Investigations in Ionic Liquids

Photophysical investigations of the behavior of solvatochromic probes have been widely used to give information about the properties of reaction media. The use of ionic liquids as reaction solvents dates back several years, as has been outlined in the preceding section. Despite this, only recently have photophysical measurements been extensively employed to determine their properties as solvents. Probably the most important feature to bear in mind, when considering the use of solvatochromic probe molecules in ionic liquids, is the purity of the solvent. While conventional organic solvents may be purified by distillation, the lack of vapor pressure means that ionic liquids cannot be purified in this manner. It has been shown that the presence of even small quantities of impurities such as halide ions and water can have a large effect on physical properties such as viscosity of ionic liquids.[21] Similarly, the presence of even small amounts of impurity can have drastic effects on the interactions with solvatochromic probe molecules. Bearing this in mind, some investigations into the polarity of ionic liquids have used mixtures with known quantities of other co-solvents, most commonly water.

The vast majority of photophysical investigations have focused on the widely used 1,3-dialkylimidazolium cation–based ionic liquids. Therefore, the major part of this section will consider these salts. Previously, a few workers looked at the behavior of solvatochromic probe molecules in other ionic liquids. In 1991, Herfort and Schneider reported the behavior of Reichardt's dye in ethylammonium nitrate (EAN) and its mixtures with water, methanol, *t*-butanol, dimethyl sulfoxide (DMSO) and dimethoxyethane (DME).[22] Reichardt's dye has been widely used as a probe of solvent polarity, and the molar transition energy $E_T(30)$ is a widely used polarity scale [molar transition energy $E_T(30) = 28592/\lambda_{max}$ (kcal mol^{-1})].[23] The value of $E_T(30)$ for pure EAN was reported to be in the range 59.8–60.3 kcal mol^{-1}, not much lower than the value obtained for water (62.0 kcal mol^{-1}). Even small quantities (ca. 5×10^{-3} mole fraction) of EAN added to organic co-solvents resulted in large increases in the value of $E_T(30)$, suggesting strong specific hydrogen bonding interactions between Reichardt's dye and EAN. This hypothesis was tested by comparison with the effect of added tetraethylammonium salts to DMSO, which resulted in little change in $E_T(30)$ at salt concentrations up to 0.14 *M*.

Prior to this, Poole et al. reported a Kamlet–Taft analysis of a range of alkylammonium salts using the Reichardt's dye and a series of nitroaromatic compounds to calculate the parameters π^*, α, and β.[24] The $E_T(30)$ values reported for tetraalkylammonium salts were generally in the range 45–51 kcal mol^{-1}, significantly lower than those for salts containing at least one proton directly attached to the quaternary nitrogen atom on the cation, such as EAN. As a result, the α parameters (a measure of solvent hydrogen bond donor acidity) for the latter salts were significantly higher. There also appeared to be little dependence of $E_T(30)$ or α on the anion present. Parameter π^* (a measure of dipolarity/polarizability) was similar in all cases, being close to unity (the standard reference value for DMSO). Fewer examples of parameter β (solvent hydrogen bond basicity) were quoted, but these appeared more dependent on the anion than the cation present.

In 1994, Bart et al. reported the solvation dynamics of coumarin 153 in a range of molten tetraalkylammonium salts.[25] Since these salts have melting points in the range 105–170°C, they do not qualify as ionic liquids by the current definition (usually melting point <100°C), but the results gained are of relevance to those discussed below. It was found that the emission maxima of the salts decreased steadily with increasing alkyl chain length, indicating decreasing polarity. A correlation of the emission maxima with the $E_T(30)$ gave estimated values for the latter parameter ranging from 60 kcal mol^{-1} for tetrapropylammonium hydrogen sulfate (TPAHS), close to the value for water, to 38 kcal mol^{-1} for tetradodecylammonium perchlorate (TDDAPCl), close to the value for THF. The time-resolved emission showed biphasic solvent dynamics. The short-lived component lifetime ranged from 35 psec for TPAHS to 200 psec for TDDAPCl, while the longer-lived component lifetime ranged from 125 to 2000 psec for the same salts. The dynamic behavior was tentatively explained in terms of separate contributions from the cation and anion.

The first paper to describe measurements on the 1,3-dialkylimidazolium salts was that of Bonhôte et al. in 1996, in which the emission spectra of 1-pyrenecarboxaldehyde (PyCHO), pyrene, and 1-bromonaphthalene in [emim][Tf_2N] were reported.[26] Perhaps surprisingly, the measurements using PyCHO

were similar to those obtained for solvents of low dielectric constant ($\varepsilon < 10$). The same study noted that the position of λ_{em} was very sensitive to the addition of methanol. Thus, the addition of 10% w/w methanol resulted in a shift in λ_{em} from 431 nm in pure [emim][Tf_2N] to 440 nm. The measurements using pyrene indicated a ratio of $I_1/I_3 = 1.54$ (not 1.18 as reported in the paper), approximately halfway between the values for CH_3OH (1.33) and CH_3CN (1.85). The emission lifetime of pyrene was 300 nsec in degassed [emim][Tf_2N], as against 145 nsec in aerated solutions. These data were used to estimate the saturation O_2 solubility to be ca. 6×10^{-3} *M*. Finally, the observation of room temperature phosphorescence in Ar-purged [emim][Tf_2N] suggested that the high viscosity of the reaction medium allowed considerable stabilization of triplet states. Probably the most significant conclusion to be drawn from these results was that one must be careful when considering the nature of ionic liquids as solvents. In the first instance, they appear to be low dielectric liquids (based on the measurements with PyCHO) but also solvents of relatively high polarity (as determined using pyrene).

Since that time, the number of papers reporting the solvent properties of ionic liquids as measured by solvatochromic probes has increased greatly, and these will be summarized below. The first papers specifically reporting the polarity of 1-alkyl-3-methylimidazolium based ionic liquids used the solvatochromic dyes Nile Red[27] and Reichardt's dye,[28] the solvatochromic salt [Cu(acac)(tmen)][BPh_4] (acac = acetoacetonate, tmen = *N,N,N′,N′*-tetramethyleneethylenediamine),[28] and the fluorescent probe molecules 4-aminophthalimide (AP) and 4-(*N,N*-dimethylamino)phthalimide (DAP).[29] The study using Nile Red was carried out on ionic liquids containing a range of $[Rmim]^+$ cations (R = butyl, hexyl, octyl, and decyl) and anions ($[NO_2]^-$, $[NO_3]^-$, $[BF_4]^-$, $[PF_6]^-$, and $[Tf_2N]^-$), with results as indicated in Table 5.1. Little difference in λ_{max} was observed between the different salts, the range being 556.0 nm (for [bmim][NO_2]) to 545.7 nm (for [C_{10}mim][BF_4]). These values equate to molar transition energies (E_{NR}) in the range 51.4–52.4 kcal mol^{-1}, close to that obtained for ethanol (52.1 kcal mol^{-1}) or other short-chain alcohols. Salts based on the [bmim] cation gave similar $E_T(30)$ values regardless of anion, generally close to those obtained for short chain primary alcohols (see Table 5.1).[28] A slight decrease in $E_T(30)$ was obtained on increasing the length of the alkyl chain at the 1-position to octyl. A more significant decrease in $E_T(30)$ was observed when an extra methyl group was present at the 2-position of the imidazolium ring. Aki et al. reported $E_T(30)$ values for four ionic liquids determined indirectly from the emission maximum, quantum yield, and fluorescence lifetime of DAP.[29] The values gained for [bmim][PF_6] appeared initially to be very similar to that obtained directly using Reichardt's dye (52.4 kcal mol^{-1} as compared to 52.2 kcal mol^{-1}), although rigorous drying of the liquid by heating at 75°C *in vacuo* for 24 h resulted in a decrease in the estimated value of $E_T(30)$ to 49.0 kcal mol^{-1}. A similar value was obtained for [bmim][NO_3], but for [C_8mim][PF_6], it was 46.8 kcal mol^{-1}. The other ionic liquid studied was 1-butylimidazolium tetrafluoroborate, which gave a value of $E_T(30)$ that was lower still (44.9 kcal mol^{-1}). These data seem to show that, although care must be taken in the interpretation of small data sets, families of ionic liquids show distinct trends in their interactions with different probe molecules.

One important observation from these data is that, using the probe molecules mentioned above, the apparent polarity of the ionic liquids studied was almost entirely dependent on the cation. The role of the anion in the properties of ionic liquids was probed using [Cu(acac)(tmen)][BPh_4] (acac = acetylacetone, tmen = *N,N,N′,N′*-tetramethyleneethylenediamine).[28] This square planar salt exhibits large shifts in the position of its lowest energy d-d band depending on the donor properties of its environment. The position of λ_{max} was found to vary considerably depending on the anion present, from 516.5 nm in [bmim][PF_6] to 601.5 nm in [bmim][TfO]. No significant shift in λ_{max} was observed for salts with the same anion but different cations, however.

Soon after these studies, Fletcher et al. reported the behavior of a number of solvatochromic probes (Reichardt's dye, pyrene, dansylamide, Nile Red, and 1-pyrenecarbaldehyde) in [bmim][PF_6].[30] The results gained using pyrene indicated a value of $I_1/I_3 = 1.84$, close to that of acetonitrile (1.88) and considerably higher than that of ethanol (1.37). The dansylamide results compared both the value of λ_{max}^{flu} and also the Stokes shift ($\nu_{max}^{abs} - \nu_{max}^{flu}$). The position of λ_{max}^{flu} was close to that obtained in ethylene glycol, while the Stokes shift result was closer to that for acetonitrile. For Nile Red, instead of the absorbance spectrum as in reference 27, the emission and excitation maxima were reported. The

TABLE 5.1 Values of E_{NR} and $E_T(30)$ Recorded in a Range of Ionic Liquids

position of both was very close to those observed for water, indicating a significant deviation from the absorbance spectrum results. Finally, the emission maximum of pyrenecarbaldehyde in [bmim][PF_6] was observed at 428 nm, close to the value of 431 nm reported for the same probe molecule in [emim][Tf_2N].[26] The authors concluded that, overall, [bmim][PF_6] showed a polarity most closely related to acetonitrile or DMSO. They did stress, however, that the wide range of interactions that contribute to "polarity" meant that such a comparison must be treated with care.

A recent paper by Baker et al. reports the results of a study on [bmim][PF_6] to determine the Kamlet–Taft parameters π, α, and β.[31] The authors also discuss the temperature dependence of $E_T(30)$ and the influence of water. The value of $E_T(30)$ in dry [bmim][PF_6] shows a linear correlation with temperature over the range 10–70°C. As noted by previous workers, the presence of water not only results in a small increase in the value of $E_T(30)$ but also in a near doubling of the temperature dependence of this parameter. It should be noted that for the study using "wet" [bmim][PF_6], a dichloro-analogue of Reichardt's dye was used because of problems with protonation of the standard molecule. The Kamlet–Taft parameters were assembled by combining the Reichardt's dye data with those obtained using 4-nitroaniline and *N,N*-diethyl-4-nitroaniline. Based on these, at 20°C the parameters for dry [bmim][PF_6] were $\pi^* = 0.92$, $\beta = 0.21$, and $\alpha = 0.76$. The values of π^* and β were little affected by the addition of water, whereas α increased to 0.88 in the presence of 2% v/v water. This is to be expected as α is the solvent hydrogen bond donating acidity. Furthermore, the temperature dependence of α was much greater in the wet liquid.

Dzyuba and Bartsch have recently reported a study of the polarity of ionic liquids containing nonalkyl substituents.[32] They found that the presence of an ether linkage in one of the side-chains and especially a hydroxide group gives a significant increase in polarity as determined by $E_T(30)$ values (Table 5.1). Nile Red gave a similar behavior trend, although the variation in E_{NR} values was rather smaller. In the same study, it was reported that the water content of the ionic liquids made little difference to the values of $E_T(30)$ or E_{NR}. For example, [pmim][Tf_2N] gave an $E_T(30)$ value of 52.0 kcal mol^{-1} with a water content of 3810 ppm, which decreased only slightly to 51.9 when the water content was reduced to 160 ppm. A more significant effect of water content was noted by Wasserscheid et al. for [bmim][PF_6].[33] In this case, the presence of 0.15 *M* water in [bmim][PF_6] increased the value of $E_T(30)$ to 52.9 kcal mol^{-1} from 52.3 kcal mol^{-1} for the dried (water content ca. 6.0×10^{-3} *M*) liquid.

Fletcher et al. have reported a study on the fluorescence quenching of several polyaromatic hydrocarbons (PAHs) in [bmim][PF_6].[34] The emission spectra of all probe molecules indicated more favorable interactions between the excited state PAH and [bmim][PF_6] than with acetonitrile, although the exact cause of this observation was not determined. Fluorescence quenching by nitromethane indicated the interesting observation that alternant PAHs (i.e., those with fully conjugated aromatic systems such as pyrene) were selectively quenched in [bmim][PF_6] compared with nonalternant PAHs (disrupted aromaticity). For example, effectively no quenching of the fluorescence of fluoranthene was observed in [bmim][PF_6] containing up to 0.123 *M* nitromethane, whereas a Stern–Volmer quenching constant (K_{SV}) of 2.4 M^{-1} was obtained for anthracene in the same solvent/quencher mixture. This result can be compared with K_{SV} = 21.1 M^{-1} in acetonitrile/nitromethane mixtures. The much lower value of K_{SV} in the ionic liquid was attributed to the much higher viscosity of [bmim][PF_6].

Three recent papers report the results of solvation dynamics in ionic liquids as probed by fluorescence lifetimes of a range of probe molecules. Baker et al. have reported a study of the local microenvironment (cybotactic region) surrounding pyrene, PRODAN (6-propionyl-2-dimethylaminonaphthalene), and BTBP [*N,N′*-bis(2,5-di-*tert*-butylphenyl)-3,4,9,10-perylenedicarboximide] in [bmim][PF_6].[35] One notable observation was the fact that the Ham effect for pyrene in [bmim][PF_6], I_1/I_3, was 2.079 in dry [bmim][PF_6] and 2.080 in the same solvent after exposure to the atmosphere for 5 h. Note that this is a higher value than that reported in reference 30. Since such treatment is known to result in the uptake of ca. 1% w/w water, it appears that the solvation of pyrene in [bmim][PF_6] is not affected by the presence of water. Similarly, the fluorescence lifetimes (251 nsec "dry" and 247 nsec "wet" [bmim][PF_6]) were not affected by the presence of water and were significantly longer than that previously reported for pyrene dissolved in water. The addition of CO_2 up to a pressure of 130 bar to a solution of pyrene in [bmim][PF_6] was found to result in only a decrease of approximately 10% in the value of I_1/I_3 up to the critical pressure (ca. 70 bar), and thereafter no further change was observed. This suggests that the intermolecular interactions between pyrene and [bmim][PF_6] are disrupted relatively little by the presence of CO_2. The multifrequency phase modulated behavior of the emission spectrum of PRODAN was used to probe the dipolar relaxation of [bmim][PF_6] surrounding the probe molecule. The results gained indicated that two separate nanosecond relaxation processes were occurring. A combination of the pyrene and PRODAN results was used to estimate values of 11.4 ± 1.0 for the dielectric constant ε and 1.523 ± 0.025 for the refractive index *n* of [bmim][PF_6]. Finally, the rotational reorientation dynamics (ϕ) of BTBP in [bmim][PF_6] were reported to show an activation energy of 9.3 ± 0.45 kcal mol^{-1}, very close to the activation energy for viscous flow (9.28 ± 0.2 kcal mol^{-1} in this study). In this case a fivefold decrease in the value of ϕ was observed between 0 and 150 bar CO_2.

A recent study reports the solvation dynamics of coumarin 153 and 6-propionyl-2-dimethylaminonaphthalene (PRODAN) in [emim][BF_4] and [bmim][BF_4].[36,37] The fluorescence decay profiles showed biphasic solvation dynamics as was observed for molten tetraalkylammonium salts.[25] The results were interpreted as indicating a short-lived component resulting from the motion of the anion, followed by a longer-lived component resulting from the motion of both the anion and the cation. In the same papers, estimates of the value of $E_T(30)$ were made for these solvents based on comparisons of the λ_{em} values for each probe molecule in conventional solvents. The values obtained (48.9 from coumarin 153 and 47.1 kcal mol^{-1} from PRODAN for [bmim][BF_4]) were somewhat lower than those measured directly using Reichardt's dye.[28]

The studies reported above can probably be summarized by two general comments. First, although a wide range of photophysical measurements has been carried out in the most widely used ionic liquids, many gaps remain in our understanding of these materials. Such studies are still required to be carried out on salts with a wider range of structural variations in order to give a better understanding of how these affect solvent properties. Second, it is clear from the contrasting results gained using different probe molecules that ionic liquids cannot generally be portrayed as being "like a short chain alcohol" or "like a dipolar aprotic solvent." That they are generally polar materials is clear, but their basicity is very dependent on the anion present, and it also appears that they have low dielectric constants. The considerable variation in properties among different ionic liquids suggests that they do indeed live up to the

TABLE 5.2 Arrhenius Parameters for the Reaction between ^{3}Bp* and N in a Range of Ionic Liquids and Conventional Solvents, along with Andrade Parameters for the Same Solvents

Solvent	η/cP[a]	ln η	E_η	k_q/mol^{-1}dm^{3}sec^{-1}[a]	ln A	E_a/kcal mol^{-1}

[a] At 298 K.

title of "designer solvents." It is probably best to avoid using the traditional definitions of polarity such as "dipolar aprotic" and better to consider the specific interactions any particular ionic liquid is likely to engage in with particular solute molecules.

5.3 Reactive Intermediates in Ionic Liquids

The study of mechanistic processes and more specifically reactive intermediates in room temperature ionic liquids has lagged considerably behind their use as reaction solvents. Recently, however, a number of reports have appeared on the study of intermediate species formed using laser flash photolysis and pulse radiolysis. The first report of laser flash photolysis in room temperature ionic liquids (RTILs) was by Gordon and McLean, who studied the electron transfer reaction between photoexcited $[Ru(bpy)_3]^{2+}$ and methylviologen dication (MV^{2+}) in [bmim][PF_6].[38] The Arrhenius activation energy was calculated as 9.9 kcal mol^{-1}, slightly higher than the activation energy for viscous flow in the same liquid of 9.0 kcal mol^{-1}. Thus, the electron transfer process is effectively diffusion controlled, although the additional 1 kcal mol^{-1} might indicate a small extra contribution from electrostatic repulsion. Another interesting observation was that the cage escape yield (η_{ce}) for the formation of $MV^{\cdot+}$ was much higher than expected based on the high viscosity of the ionic liquids. More recently, the same authors have reported the behavior of triplet excited state benzophenone (^{3}BP*) in a range of ionic liquids. The quenching reaction with naphthalene (N) was studied for five ionic liquids based around the 1-alkyl-3-methylimidazolium cation and the $[PF_6]^-$ and $[Tf_2N]^-$ anions.[39] In all cases, it was found that the rate of quenching was diffusion controlled; the values of E_a were almost identical to the activation energy for viscous flow. Thus, the bimolecular rate constants reported in this paper represent the limiting values for diffusion-controlled processes between neutral reactants of this type in the ionic liquids. Examples of the bimolecular rate constants obtained are illustrated in Table 5.2.

An isokinetic relationship between pre-exponential factors and E_a was also reported. In the absence of quenchers, it was found that the degree of hydrogen abstraction from 1-alkyl-3-methylimidazolium–based ionic liquids was considerably lower than that observed for conventional solvents such as toluene or butan-1-ol.[40] Furthermore, the activation energy for this process was similar in all ionic liquids studied (ca. 6 kcal mol^{-1}) and roughly 2.4 kcal mol^{-1} higher than the values obtained in the conventional solvents.

Pulse radiolysis has also been used to generate reactive intermediates in ionic liquids. The products formed have been studied at low temperatures in frozen ionic liquid glasses, and their kinetics have also been investigated at higher temperatures. Two similar studies were reported almost simultaneously in 2001.[41,42] In both of these, the reaction of $[bmim]^+$ with e_{aq} to form the equivalent radical species was reported in aqueous solution (Equation 5.1).

$$\left[\text{bmim}\right]^+ + e_{aq} \rightarrow \left[\text{bmim}\right]\cdot \tag{5.1}$$

Identification of the main product as [bmim]· was confirmed by its λ_{max} value of 320 nm. Similar values for the bimolecular rate constant of this reaction were reported in the two studies (1.9×10^{10} l mol^{-1} sec^{-1} in reference 41 and 1.5×10^{10} l mol^{-1} sec^{-1} in reference 42). In reference 41, the reaction of [bmim]$^+$ with ·OH and $SO_4^{\cdot-}$ was also reported, the latter resulting in the formation of [bmim]$^{\cdot 2+}$ (Equation 5.2).

$$\left[\text{bmim}\right]^+ + SO_4^{\cdot-} \rightarrow \left[\text{bmim}\right]^{\cdot 2+} + SO_4^{2-} \tag{5.2}$$

Pulse radiolysis of neat ionic liquids was also reported to give [bmim]· and [bmim]$^{\cdot 2+}$, although Behar et al. suggested that other radical adducts might also be formed. One notable feature was that the transient spectra measured on radiolysis of [bmim][PF_6] and [bmim][Tf_2N] were effectively identical, while the spectra recorded on radiolysis of [bmim]Br showed clear evidence for the formation of $Br_2^{\cdot-}$.[43]

Both investigations also reported the pulse radiolysis of solutes dissolved in ionic liquids. Behar et al. studied the effect of the presence of O_2 and CCl_4 in [bmim][PF_6]; their results suggested that the latter was a more effective radical scavenger. They also looked at the formation of the radical cations of chlorpromazine (ClPz·$^+$) and *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine (TPMD·$^+$) in the same solvent. Finally, the kinetics of oxidation of ClPz in [bmim][PF_6] were studied. The experimentally determined bimolecular rate constant values were corrected for the high viscosity of the ionic liquid by estimation of the values of k_{diff}, the diffusion-controlled rate constant, using Equation (5.3),

$$k_{diff} = 8000\,RT/3\eta \tag{5.3}$$

where R is the gas constant, T is the absolute temperature, and η the viscosity in Pa sec.* The activation-controlled rate constants thus gained were reported to be in the range 2.6×10^7 to 1.12×10^8 l mol^{-1} sec^{-1} over the temperature range 22 to 75°C. The value at 22°C is comparable to that obtained for secondary alcohols such as 2-propanol. The study by Marcinek et al.[42] also reported the formation of naphthalene radical cation and the radical anion of tetracyanoquinodimethane (TCQM$^{\cdot-}$) in glassy [bmim][Tf_2N]. In the case of TCQM$^{\cdot-}$, it appeared that the solute trapped the majority of electrons generated, probably because of the low reducibility of [bmim]$^+$. Under cryogenic conditions these radical ions were completely stable, only decaying when the solid glasses melted. One interesting feature was the demonstration that both radical cations and anions may be formed simultaneously in ionic liquids. Finally, the ionic liquids were used as media for the characterization of previously unobserved radical cations formed in the radiolysis of 1-methyl-1,4-dihydronicotinamide (MNAH), a structural analogue of nicotinamide adenine dinucleotide reduced form (NADH). The low solubility of this molecule in organic solvents conventionally used for pulse radiolysis experiments had previously hindered this investigation. Using a glassy [bmim][PF_6] matrix, the intermediates *keto*- and *enol*-MNAH$^{\cdot+}$ shown in Scheme 1 were identified for the first time.

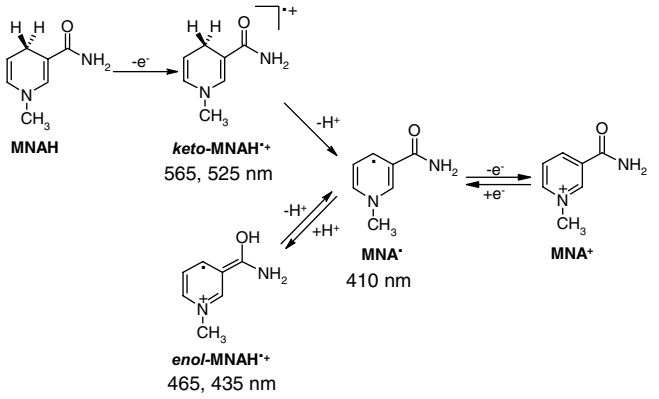
Since this time, further pulse radiolysis results have been reported in the ionic liquids methyltributylammonium *bis*(trifluoromethylsulfonyl)imide ([mtba][Tf_2N]), *N*-butylpyridinium tetrafluoroborate ([bupy][BF_4]), and *N*-butyl-4-methylpyridinium hexafluorophosphate ([bupic][PF_6]).[43] The former liquid was chosen because radiolysis produces solvated electrons that do not react with the parent ions and can thus be scavenged by reactive solutes (Equation 5.4).

$$[R_4N][Tf_2N] \quad \sim\sim\rightarrow \quad e_{solv}, H^+, [R_4N]^{\bullet 2+}, [NTf_2]^{\bullet}, R^{\bullet} \tag{5.4}$$

The *N*-alkylpyridinium-based cations do react with solvated electrons, producing a pyridinyl radical that can transfer an electron to many solutes (Equations 5.5 and 5.6).

$$[bupy][BF_4] \quad \sim\sim\rightarrow \quad e_{solv}, H^+, [bupy]^{\bullet 2+}, [BF_4]^{\bullet} \tag{5.5}$$

*It should be noted that the work reported in reference 37 suggests that this approximation may not be valid for solvents of such high viscosity.



SCHEME 1 (Taken from reference 42 © American Chemical Society)

$$\left[\text{bupy}\right]^{+} e_{\text{solv}} \rightarrow \left[\text{bupy}\right]^{\cdot} \tag{5.6}$$

Radiolytic reduction reactions have been carried out on substrates such as quinones, benzophenone, methyl viologen, and nitroaromatic compounds. In [mtba][Tf_2N], the principal reactions were reduction of the substrates by solvated electrons and organic radicals derived from the solvent. For example, irradiation of benzoquinone (BQ) or duroquinone (DQ) resulted in the formation of the protonated semiquinone radical, with the proton formed by radiolysis of [mtba][Tf_2N] (Equation 5.7). The addition of triethylamine to capture the protons resulted instead in the formation of the semiquinone radical anions (Equation 5.8).

$$\text{BQ} + e^{-}_{\text{solv}} + \text{H}^{+} \rightarrow \text{BQH}\cdot \tag{5.7}$$

$$\text{BQ} + e^{-}_{\text{solv}} \rightarrow \text{BQ}^{\cdot -} \tag{5.8}$$

When the same reaction was carried out with benzophenone (BP), the first product formed was the radical anion $BP^{\cdot -}$ (λ_{max} = 700 nm), which was converted within 10 μsec into BPH· (λ_{max} = 545 nm). The measured absorbance of BPH· was used to estimate the radiolytic yield of solvated electrons (0.9×10^{-7} mol J^{-1} in the absence of amine and approximately twice as much when amine was present).

Solutes in [bupy][BF_4] and [bupic][PF_6] were reduced by butylpyridinyl radicals ([bupy]·) formed on radiolysis of these salts instead of solvated electrons. Bimolecular rate constants were reported for the reaction of [bupy]· with a number of solutes. Comparison of these values with calculated values of k_{diff} for the ionic liquids (calculated using Equation 5.3) gave the surprising result that the rate of reaction was an order of magnitude higher than k_{diff}. This was explained by an electron transfer mechanism involving hopping of the electron between solvent cations, thus preventing the need for direct diffusion of [bupy]· to the substrate. It should be noted, however, that k_{diff} values calculated using Equation 5.3 are significantly lower than those measured by McLean et al.,[39] perhaps suggesting that this approximation may not be particularly accurate for these relatively viscous RTILs.

The secondary electron transfer between $MV^{\cdot +}$ and DQ (Equation 5.9) was also studied in [bupy][BF_4] containing varying amounts of water.

$$\text{MV}^{+} + \text{DQ} \rightleftharpoons \text{MV}^{2+} + \text{DQ}^{\cdot -} \tag{5.9}$$

In this case, the bimolecular rate constant in the absence of water was k_q 1.4 (± 0.2) × 10^5 l $mol^{-1}sec^{-1}$, approximately two orders of magnitude lower than the estimated value of k_{diff}. The addition of even small

quantities of water resulted in a large increase in k_q. It was also found that the driving force of this reaction is in fact to the left, as is also found with 2-propanol. The reaction could be driven to the right, however, by protonation of $DQ^{-\bullet}$.

The same study reported radiolytic oxidation of both TPMD and ClPz in neat ionic liquids and also the oxidation of ClPz and Trolox by $CCl_3O_2\cdot$ radicals formed in the presence of CCl_4. Unlike the similar study in [bmim][PF_6] reported above, in [mtba][Tf_2N], oxidation of both TPMD and ClPz to their corresponding radical cations occurred even in the absence of CCl_4. The yield of $ClPz^{\cdot+}$ was small, but its formation even in the absence of oxygen indicates that oxidizing species are formed in this IL. Experimental rate constants for the oxidation of ClPz by $CCl_3O_2\cdot$ in all ionic liquids were found to be within an order of magnitude of 1×10^7 l mol^{-1}sec^{-1}, but always lower than the calculated values of k_{diff} by a factor of 1.5 to 2. Rate constants for the oxidation of Trolox were slightly lower than those for the oxidation of ClPz.

Most recently, Grodkowski and Neta have reported a pulse radiolysis study of the reaction kinetics of $\cdot CF_3$ in the ionic liquid [mtba][Tf_2N].[44] Radiolysis of CF_3Br resulted in the formation of $\cdot CF_3$ (identified by a peak at $\lambda = 405$ nm), although there was also evidence for the formation of this radical as a breakdown product of the $[Tf_2N]^-$ anion. Radiolysis of pyrene in the same solvent gave the pyrene radical anion and cation (identified by peaks at λ = 495 and 450 nm), which decayed rapidly, as well as the protonated pyrene radical anion, which had a longer lifetime. Pulse radiolysis of a pyrene solution that was saturated with CF_3Br gave an intense peak at $\lambda = 405$ nm. This product was assigned as $\cdot PyrCF_3$, formed by reaction of the preferentially formed $\cdot CF_3$ with pyrene. The rate constants for the reaction of $\cdot CF_3$ with pyrene and phenanthrene were reported in [mtba][Tf_2N] containing either CF_3Br or 0.2 mol l^{-1} $HClO_4$. Effectively identical bimolecular rate constants were observed for each substrate in both media. In some cases, the absolute rate constants determined for the reaction of $\cdot CF_3$ with pyrene or phenanthrene were used to determine rate constants for reactants that did not form readily observable species (crotonic acid, valeric acid and 2-propanol) using competition kinetics. The overall conclusion of these studies was that experimental rate constants for hydrogen abstraction and addition reactions of $\cdot CF_3$ in [mtba][Tf_2N] were slightly lower than in water or acetonitrile, while those for electron transfer reactions were generally an order of magnitude or more lower in the RTIL than in water or alcohols.

5.4 Product and Mechanistic Studies

Although photochemistry in ionic liquids is a relatively new subject, photochemistry in salt solutions is well known.[45,46] Added salts will, of course, alter the polarity of a solvent and thus may affect the energetics of electronic transitions. Adding a salt such as $LiClO_4$, $NaClO_4$, $Mg(ClO_4)_2$, or Bu_4NClO_4 to a solvent often enhances the quantum yield of a photoinduced electron transfer reaction. This occurs by exchanging ions in the initially formed ion pair with ions in the salt, thus inhibiting back electron transfer that regenerates the donor (D) and acceptor (A). Similar effects could take place in ionic liquids.

$$D \xrightarrow{h\nu} D^*$$

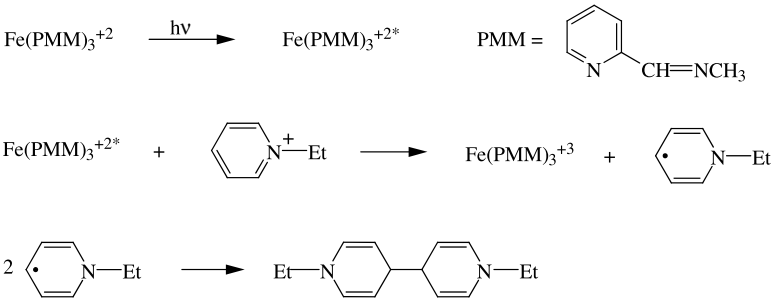
$$D^* + A \longrightarrow [D^{+\bullet} A^{-\bullet}]$$

$$[D^{+\bullet} A^{-\bullet}] + LiClO_4 \rightleftharpoons [D^{+\bullet} ClO_4^-] + Li^+, A^{-\bullet}$$

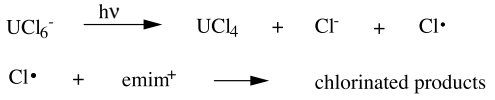
$$[D^{+\bullet} ClO_4^-] \longrightarrow \text{Products}$$

Photochemistry in ionic liquids to date has been carried out exclusively with pyridinium and imidazolium salts. Pyridinium[47,48] and imidazolium[49,50] salts dissolved in conventional solvents are known to be photoactive. The ionic liquid [bmim][PF_6] yields as yet uncharacterized photoproducts when photolyzed below 300 nm.[51] Because the pyridinium- and imidazolium-based ionic liquids have little absorption above 300 nm, photodegradation of the solvent will be minimized when a photoreaction is initiated with light of wavelength >300 nm. The substrate must have, of course, an absorption band above 300 nm.

Even here, the heterocyclic cation may participate in the subsequent chemistry. Most of the reactions described below are initiated by photoinduced electron transfer, whose energetics are determined using the Rehm–Weller equation.[52] In most instances, the equation contains a Coulombic term due to the attraction of the radical cation ($D^{+\cdot}$) and radical anion ($A^{-\cdot}$) in the initially formed ion pair. If the acceptor is a pyridinium or imidazolium ion of the ionic liquid, however, the Coulombic term is zero because the reduced acceptor has no charge.

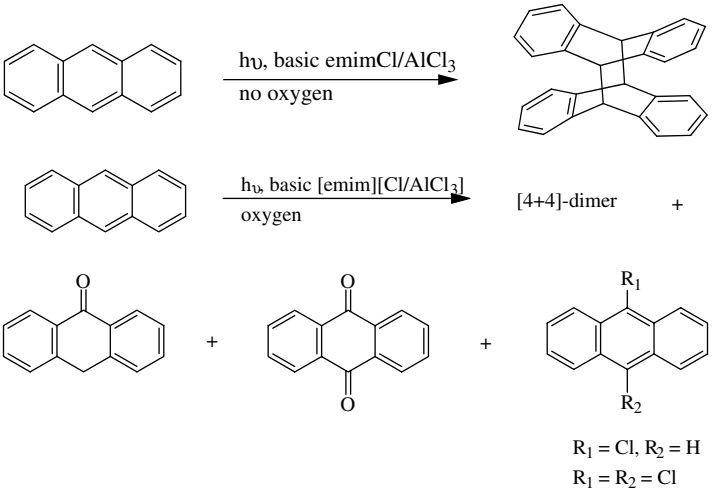


The first photochemical experiments in an ionic liquid were those of Osteryoung and co-workers,[53] who investigated the behavior of 10 Fe(II) tris complexes including $Fe(PMM)_3^{+2}$, where PMM = 2-pyridinecarboxaldehyde *N*-methylimine, in Lewis acidic *N*-ethylpyridinium bromide/$AlCl_3$ (1:2) using visible light. UV/vis spectroscopy showed that the Fe(II) complexes were converted cleanly into the corresponding Fe(III) complexes, which were also made independently. The appearance of a band at 680 nm, independent of the complex used, was attributed to the reduction product, a dimer of the *N*-ethylpyridinyl radical. That these reactions occurred by photoinduced electron transfer from the iron complex to the pyridinium cation was verified by comparing the relative rate of disappearance of the 10 complexes to their oxidation potentials. Complexes that were calculated to undergo the electron transfer exothermically according to the Rehm–Weller equation had quantum yields of disappearance close to one. When the electron transfer became endothermic, the quantum yield fell off linearly with increasing $E_{1/2}$ values of the complexes. In a second inorganic example, the substrate is reduced and the ionic liquid cation oxidized.[54] UCl_6^-, which is stable in acidic [emim][Cl]/$AlCl_3$ (43:57), has a ligand-to-metal charge transfer band at 457 nm. Photolysis into this band afforded uranium(IV) chloride and a transient chlorine atom that reacted in turn with the imidazolium cation to afford unknown products. Interestingly, UCl_6^- is photo inert in acidic NaCl/$AlCl_3$ (45:55) at 320°C. Here there is no chemical outlet for the chlorine atom.

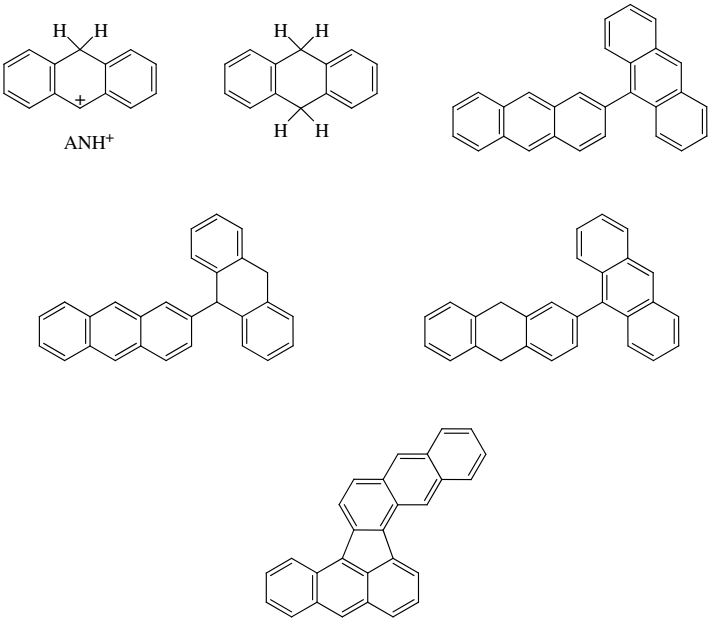


The photochemistry of anthracene (AN) has been studied for close to 150 years. In fact, it was the first substrate whose photochemistry was studied in a laboratory. It is now well established that in virtually every solvent in which it has been studied, AN reacts in the same way.[55] In degassed or deoxygenated solution, the reaction proceeds through the singlet excited state of AN, AN^{*1}, which reacts with ground state AN to form an excimer, which in turn collapses to a [4 + 4]-dimer. In water, on the other hand, the complex chemistry is initiated by electron transfer from AN^{*1} to water.[56] In oxygenated solvent the reaction proceeds differently. AN^{*3}, formed by intersystem crossing of AN^{*1}, on collision with O_2 yields AN and singlet O_2, $^1O_2$. Reaction of $^1O_2$ with AN affords the [4 + 2]-*endo* peroxide. In degassed basic [emim][Cl]/$AlCl_3$ (55:45), the photochemistry of AN occurs in the normal manner, yielding the [4 + 4]-dimer quantitatively, in spite of the fact that the electron transfer from AN^{*1} to $emim^+$ is exothermic by more than 5 kcal mol^{-1}.[57] In oxygenated basic [emim][Cl]/$AlCl_3$ of the same composition, the photoreaction affords anthrone, anthraquinone, 9-chloroanthracene, 9,10-dichloroanthracene, and the [4 + 4]-dimer.[58] One may

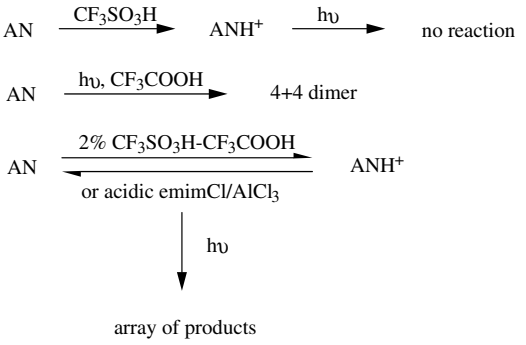
assume that the [4 + 4]-dimer is formed by the mechanism previously described. The formation of the chlorinated products may be rationalized as follows: AN^{*1} undergoes electron transfer with O_2 to form a radical cation, $AN^{+\cdot}$ and superoxide, $O_2^{-\cdot}$. $AN^{+\cdot}$ then reacts with Cl^-, a component of the IL, to form a radical that eventually yields 9-chloroanthracene (9-ClAN). 9-Chloroanthracene then affords 9,10-dichloroanthracene by an identical mechanism. The mode by which the oxygenated products are formed is not known but may involve the reaction of $AN^{+\cdot}$ with $O_2^{-\cdot}$.



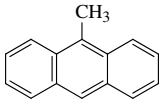
Unlike the basic solution of AN, which is colorless, the acidic [emim][Cl]/$AlCl_3$ (45:55), which contains the powerful Lewis acid, $Al_2Cl_7^-$, is green due to the presence of about 3% of protonated anthracene, ANH^+. Even the most rigorously purified IL contains traces of HCl, a very strong acid, in the acidic IL.[11,12] Photolysis of the degassed green solution afforded an array of reduced, neutral, and oxidized monomeric and dimeric products. At 13% conversion, the products were 9,10-dihydroanthracene, 2,9′-bianthracene, 9′,10′-dihydro-2,9′-bianthracene, 9,10-dihydro-2,9′-bianthracene, anthra[2,1-a]aceanthrylene, and an unidentified hydrocarbon with a structure similar to the aceanthrylene.



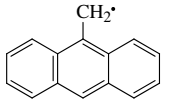
By seeing how the product distribution is affected by deliberately adding HCl to the AN solution or removing it by adding methylaluminum sesquichloride, a mechanism for the photoreaction could be formulated involving $AN^{+\cdot}$. The photoreaction is initiated by photoinduced electron transfer, AN^{*1} to ANH^+ and/or AN to ANH^{+*}, as both AN and ANH^+ absorb the light to form $AN^{+\cdot}$ and ANH·. When $AN^{+\cdot}$ is generated photochemically in water, it reacts with the water.[56] No bases with which $AN^{+\cdot}$ can react are present in the acidic IL. The species $AN^{+\cdot}$ and ANH· thus undergo a series of electron transfer, hydrogen transfer, and coupling reactions to yield the observed products. It was possible to mimic the behavior of AN in acidic [emim]Cl/$AlCl_3$ by using CF_3SO_3H and CF_3COOH instead.[59] In the very strong acid, CF_3SO_3H (H_o = –14.0), AN is completely protonated, and it did not react photochemically. In the much weaker acid, CF_3COOH (H_o = –2.7), AN is unprotonated, and it reacted to yield the 4 + 4 dimer quantitatively. In a mixture of 2% CF_3SO_3H in CF_3COOH (w/w) with H_o = –8.1, where AN and ANH^+ are both present, the photochemistry yielded the same products and in approximately the same amounts as seen in the acidic IL.



It is clear that the photochemistry of polyaromatic hydrocarbons (PAHs) in strong acid solutions, especially when the hydrocarbon and its conjugate acid are present, has synthetic potential. It may be possible to prepare previously unknown PAHs or ones difficult to prepare by known methodology by the photochemical method. Unlike AN, 9-methylanthracene (9-CH_3AN) does undergo photoinduced electron transfer in degassed basic [emim][Cl]/$AlCl_3$ and also *N*-butylpyridinium chloride [bp][Cl]/$AlCl_3$.[60] The electron transfer from 9-CH_3AN^{*1} to the heterocyclic cation in each IL is exothermic in each case, and the resulting radical cation, 9-$CH_3AN^{+\cdot}$, has a chemical outlet by its reaction with Cl^-, an IL component, to form the 9-anthrylmethyl radical, 9-$ANCH_2$·, and HCl. Radical cations of methylarenes are known to be very acidic.[61] Not only HCl but also $emim^+$ serve as a proton donor in [emim][Cl]/$AlCl_3$. Alder and co-workers had previously shown that imidazolium cations have appreciable acidity.[62] Interestingly, deprotonation of $emim^+$ yields a heterocyclic carbene, a species of current interest.[63] 9-$ANCH_2$· has many potential outlets including dimerization, hydrogen atom abstraction, addition to 9-CH_3AN, and reduction. Reduction is possible because of the presence of emim· (or bp·), a potential electron donor formed in the initial electron transfer step.

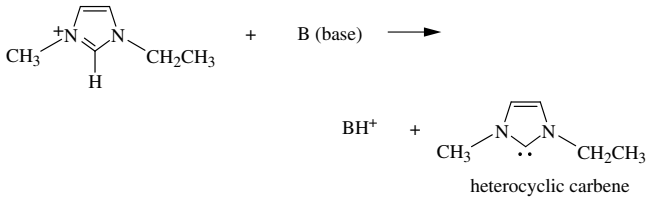


9-CH_3AN

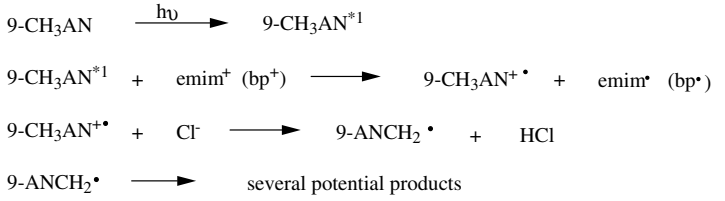


9-$ANCH_2$•

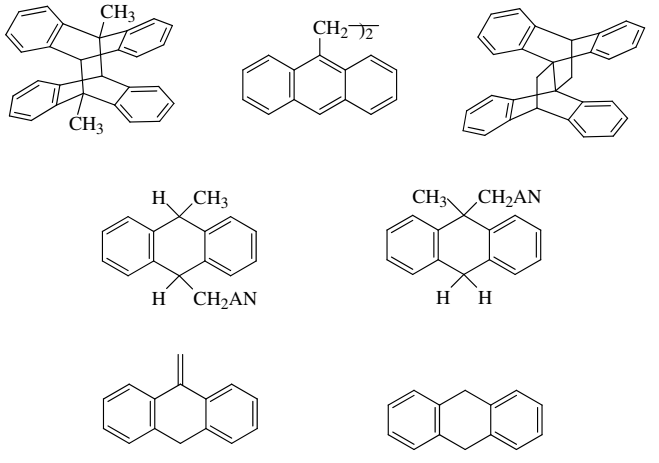
HCl and emim$^+$ - potential proton donors



emim$^\bullet$ and bp $^\bullet$- potential reductants

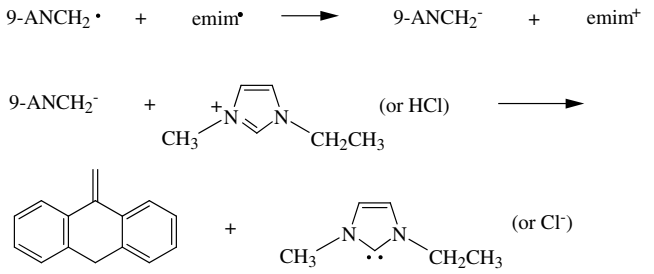


The photochemistry of 9-CH_3AN in degassed basic [emim][Cl]/$AlCl_3$ (55:45) afforded seven products, none of which was chlorinated. The major product was the *anti* [4 + 4]-dimer, presumably formed by the mechanism described early for the photodimerization of AN, which does not involve electron transfer. In addition, two dimers of 9-$ANCH_2$·, the head-to-head 1,2-bis(9-anthrylmethyl)ethane formed in trace amounts and the head-to-tail lepidopterene, were formed. The unusual lepidopterene having C_{2h} symmetry has two adjacent quaternary carbon atoms. There were also two isomeric products, both in small amounts, resulting from the addition of 9-$ANCH_2$· to the 9 and 10 positions of 9-CH_3AN followed by hydrogen abstraction. The last two products were identified as 9-methylene-9,10-dihydroanthracene in trace amounts and 9,10-dihydroanthracene.

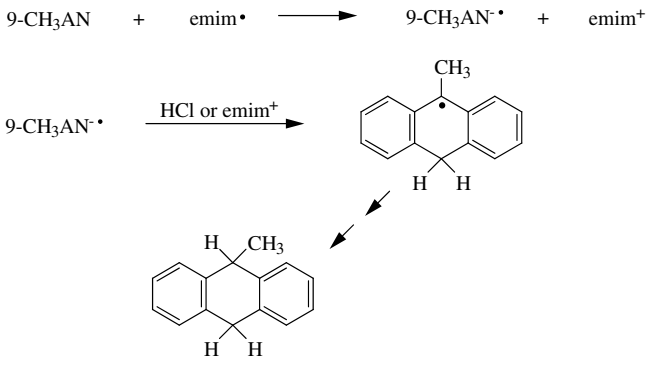


The formation of 9-methylene-9,10-dihydroanthracene is unexpected. Although one would assume that it arises by carbon 10 of 9-$ANCH_2$· abstracting a hydrogen atom from another species, this is not the case. Photolysis of 9-chloromethylanthracene in the IL, for example, yielded 9-CH_3AN and the two dimers of 9-$ANCH_2$·, but none of the methylene compound. Likewise, reduction of 9-chloromethylanthracene with AIBN/Bu_3SnH yielded 9-CH_3AN exclusively. The isomer of 9-CH_3AN is formed in two

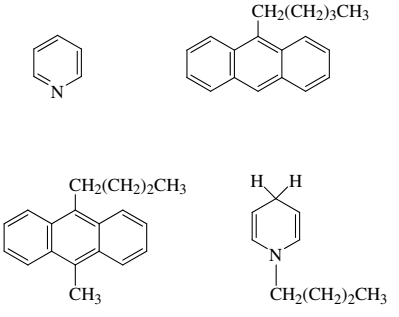
steps from 9-$ANCH_2$·. In the first, 9-$ANCH_2$· is reduced by emim· to yield the carbanion 9-$ANCH_2^-$, and in the second, carbon 10 of the anion abstracts a proton. 9-$ANCH_2^-$ is known to be protonated at carbon 10.[64] Deuterium labeling experiments clearly showed that both HCl and $emim^+$ served as proton sources in this last reaction.



9,10-Dihydroanthracene is also formed in an interesting fashion. The initial step is the reduction of 9-CH_3AN by emim·, a reaction exothermic by 9 kcal mol^{-1} in the IL, to form the radical anion 9-$CH_3AN^{-\bullet}$ and $emim^+$. Proton transfer from HCl and $emim^+$ (deuterium labeling experiments) followed by further reduction yields the observed product.



That the reaction, surprisingly, proceeds through 9-$CH_3AN^{-\cdot}$ was demonstrated by repeating the photochemistry in [bp][Cl]/$AlCl_3$. The cation bp^+ is more easily reduced than $emim^+$, but its reduction product bp· is a much poorer reducing agent than emim·. In fact, the reaction bp· + 9$CH_3AN \rightarrow bp^+$ + 9-$CH_3AN^{-\cdot}$ is endothermic by 10 kcal mol^{-1}. The photochemistry here yielded the [4 + 4]-dimer and the head-to-head and the head-to-tail dimers of 9-$ANCH_2$·, which was the major product; no 9,10-dihydroanthracene was formed. In addition, the photoreaction yielded several products not seen in [emim][Cl]/$AlCl_3$ including pyridine, 9-pentylanthracene, 9-butyl-10-methylanthracene, and *N*-butyl-1,4-dihydropyridine. Clearly, the first three of these new products arise by reaction of 9-$ANCH_2$· with bp·.

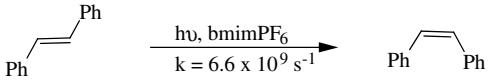


The most unusual feature in the rather complicated photochemistry of 9-CH_3AN in [emim][Cl]/$AlCl_3$ is the formation of both 9-$CH_3AN^{+\cdot}$ and 9-$CH_3AN^{-\cdot}$ at different stages of the reaction. Although this is rare, there are undoubtedly other methylarenes for which this is possible. ILs are well placed to probe for this chemistry.

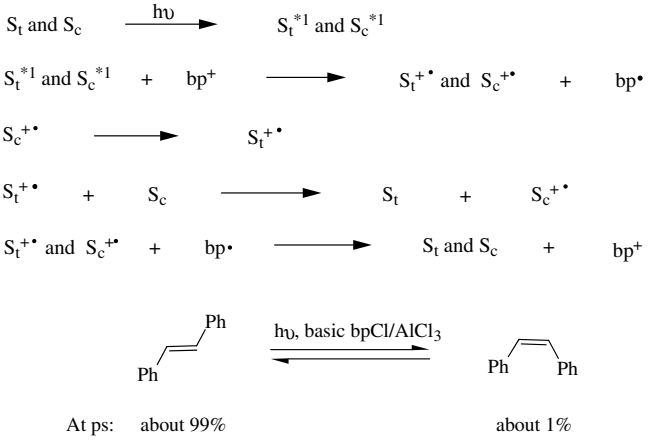
The photoisomerization of *cis*- and *trans*-stilbene (S_c and S_t) has been studied quite extensively and occurs by several different mechanisms depending on reaction environment and conditions.[65] Two of these relevant to ionic liquids will now be described. In most solvents, direct irradiation of S_c and S_t results in isomerization by the singlet mechanism in which the singlet excited states of the substrates, S_c^{*1} and S_t^{*},[1] twist about their ethylene double bonds to form a common perpendicular excited state, p^{*1}. The excited state p^{*1} in turn undergoes radiationless transition to yield p on the ground state surface, which decays to S_c and S_t. The photostationary state (PS) that results depends on the extinction coefficients of S_c and S_t and their respective quantum yields of interconversion. If light of $\lambda > 300$ nm is used, the PS should be rich in S_c unless something about the quantum yields is unusual.

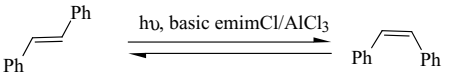
In the Electron Transfer Mechanism, the radical cations of the substrates, $S_c^{+\cdot}$ and $S_t^{+\cdot}$, are involved in the isomerization.[66] S_c^{*1} and S_t^{*1} formed on direct irradiation transfer an electron to a suitable acceptor to form $S_c^{+\cdot}$ and $S_t^{+\cdot}$. Here the isomerization is essentially one way, $S_c^{+\cdot} \rightarrow S_t^{+\cdot}$, while $S_t^{+1\cdot}$ serves as a conduit for the formation of more S_c^{+} in the reaction $S_t^{+\cdot} + S_c \rightarrow S_t + S_c^{+\cdot}$. At some later stage, back electron transfer regenerates S_c and S_t. The electron transfer mechanism will yield a PS very rich in S_t. In CH_3CN, the PS contains 98.8% S_t, for example.[66]

The *cis,trans*-photoisomerization of S_t and S_c does indeed take place in ILs.[51,67] Ozawa and Hamajuchi showed, for example, that S_t photoisomerizes to S_c in bmimPF_6,[51] almost certainly by the singlet mechanism. Transient fluorescent measurements showed that S_t isomerizes to S_c with a rate constant of 6.6×10^9 sec^{-1}. This is almost seven times faster than what is expected based on the polarity and viscosity of [bmim][PF_6].



S_t and S_c interconvert photochemically in basic emimCl/$AlCl_3$ and bpCl/$AlCl_3$, but by different mechanisms.[67] The photoisomerization could not be studied in the Lewis acidic ionic liquids because this results in the very large Brønsted acidity of traces of HCl in the media; S_t, for instance, underwent an acid-catalyzed dimerization in acidic [emim][Cl]/$AlCl_3$. In basic [bp][Cl]/$AlCl_3$, both S_c and S_t photoisomerize cleanly to give a PS containing ~99% S_t. In addition, the electron transfers from S_t^{*1} and S_c^{+1} to bp^+ are quite exothermic (electron transfers from the triplet states are endothermic). Thus, the isomerizations in [bp][Cl]/$AlCl_3$ occur by the Electron Transfer mechanism.

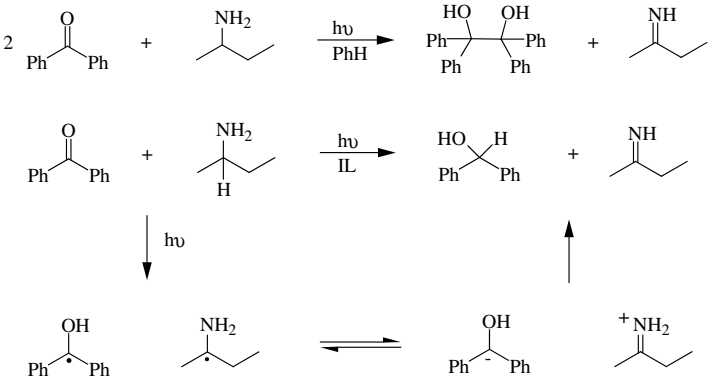




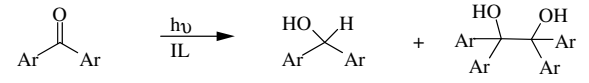
At ps: about 55% about 45%

The stilbenes S_t and S_c isomerize photochemically in basic emimCl/$AlCl_3$, but not by the electron transfer mechanism. S_t and S_c do interconvert but, in addition, yield small amounts of unidentified products. As a result, it is not possible to calculate the PS exactly. An estimate of 55% S_t and 45% S_c at the PS seems reasonable. The low value of S_t at the PS clearly rules out the electron transfer mechanism even though electron transfer from both S_t^{*1} and S_c^{*1} to $emim^+$ is calculated by the Rehm–Weller equation to be exothermic. The PS is unusual for the isomerization occurring by the singlet mechanism, however. With >300 mm, which was used here, the PS should have been rich in S_c unless there is something unusual about the quantum yields of interconversion, $\Phi_{t\rightarrow c}$ and $\Phi_{c\rightarrow t}$.

A different type of photoreaction in ILs has been studied by Jones and co-workers: the photoreduction of benzophenones by primary amines.[68] Prior work by Cohen demonstrated that photolysis of benzophenone in benzene in the presence of *sec*-butylamine afforded benzopinacol (and an imine).[69] This reaction proceeds through a radical pair formed by hydrogen-atom abstraction by the triplet excited state benzophenone from the amine. In the much more polar environment of an IL, the radical pair may instead undergo single electron transfer to form an iminium cation and a hydroxyl-substituted carbanion. Proton transfer from the cation to the anion will yield benzhydrol and an imine.



Which reduction product, benzopinacol or benzhydrol, is formed depends on the IL used and the substituents on the benzophenone. In the ILs, *sec*-butylammonium trifluoroacetate with added *sec*-butylamine and isopropylammonium nitrate with added isopropylamine, benzophenone afforded benzopinacol exclusively. On the other hand, benzophenone yielded benzhydrol exclusively in several emim and bmim ILs. The origin of this difference in behavior is unclear. Benzophenones with electron-withdrawing substituents (2-CO_2CH_3, 3-CO_2CH_3, 4,4-diCl) afforded the corresponding benzhydrol quantitatively in $bmimBF_4$. These substituents, of course, stabilize the hydroxyl-substituted carbanions. 4-Methoxy- and 4,4-dimethoxybenzophenone gave mixtures of benzopinacol and benzhydrol in $[emim]^+$ and $[bmim]^+$ ILs, with the dimethyoxy compound giving more benzopinacol than the monomethoxy compound. There appears to be a correlation between the product distribution and the electron-donating ability of the aryl rings. Interestingly, when 4,4-dimethoxybenzophenone is reduced in eight$[emim]^+$ and $[bmim]^+$ ILs, the benzhydrol to benzopinacol ratio varies from 30:70 ([bmim][OTf]) to 75:25 ([bmim][NO_3]). There is no obvious property of the ILs that accounts for these differences.



Ar = 4-MeOPh bmimOTf: 30 70

bmimNO3: 75 25

Photochemically Induced Alkylation Reactions

Nathalie Huther
University of York

Andrew F. Parsons
University of York

6.1 Introduction

A considerable number of photochemical reactions are widely utilized in modern organic synthesis. Light-induced reactions have been shown to afford a mild and efficient approach to a variety of complex target molecules.[1] These reactions can offer a chemo-, regio-, and stereoselective approach to molecules, which can be difficult or impossible to achieve using other synthetic methods. Reactants can be irradiated with light of a particular energy so that only certain bonds are broken. This means that photolysis can be a cleaner method of synthesis than thermolysis, where heating to high temperatures can lead to the cleavage of a variety of bonds. The use of high-energy ultraviolet light also allows the cleavage of even strong bonds at low temperatures, and this has found application in classical hydrocarbon chlorination and nitrosation reactions, which have been carried out on a large scale in industry.[2,3]

Of particular importance in organic synthesis is the construction of carbon–carbon bonds, and this can be achieved using a variety of intra- and inter-molecular photochemical processes. Whereas acidic or basic conditions are required for ionic carbon–carbon bond-forming reactions, the corresponding photochemical reactions can be conducted under neutral conditions, and thus a variety of sensitive functional groups can be tolerated in both the reactants and products. This review will aim to briefly survey some of the different photochemical methods that are now available for the formation of carbon–carbon bonds by alkylation reactions involving free radical intermediates. A number of strategies have been developed ranging from initiation of radical chain reactions by photolysis of azo compounds or peroxides to the excitation of carbonyl compounds in Norrish type II reactions. Of particular recent interest has been the development of photoinduced electron-transfer reactions (often in the presence of photosensitizers), and the use of this method to prepare carbon–carbon bonds is also highlighted. A number of different functional groups can be employed to generate radicals in alkylation reactions, and these groups are discussed individually.

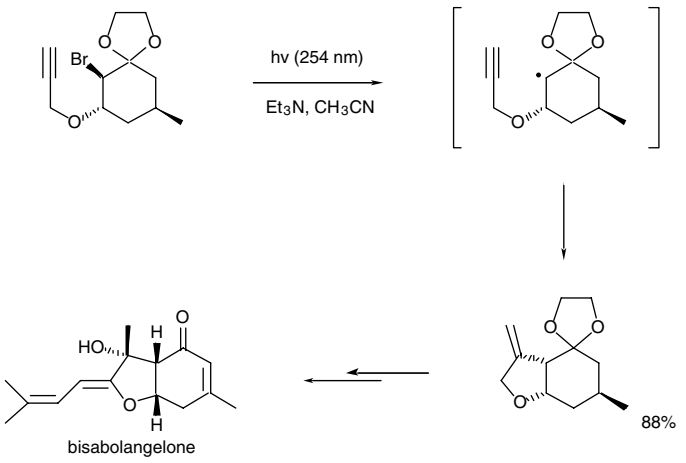


SCHEME 1

6.2 Photochemical Alkylations

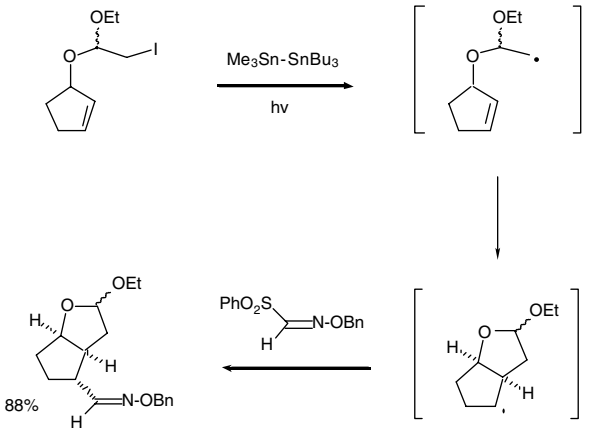
Organohalides

The direct photolysis of alkyl or aryl halides in solution to form carbon-centered radicals is rarely used in organic synthesis.[4] Alkyl iodides usually afford mixtures of radical and ionic products, while alkyl bromides can produce radical-derived products but in low yield. A notable exception is the photocyclization of haloarenes, which has been shown to produce carbon-centered radicals that can add to aromatic rings. A similar reaction has recently been observed on irradiation of iodoheterocycles, with substituted benzenes or electron-poor alkenes, to form arylated or alkylated heterocycles in good yield.[5] Related reactions have also been reported on irradiation of 4-chloroanilines in the presence of (electron-rich) alkenes, although in this case, the alkylations appear to involve the formation of a phenyl cation.[6] An alternative approach to form carbon-centered radicals is to irradiate the alkyl iodide or bromide in the presence of triethylamine; this is proposed to form an amine–halide exciplex, which cleanly breaks down to give a carbon-centered radical and a halide anion. Cossy and co-workers have shown this to be a fast, convenient, and chemoselective method of radical generation, which has recently been used to prepare the bicyclic core of (±)-bisabolangelone (Scheme 1).[7]

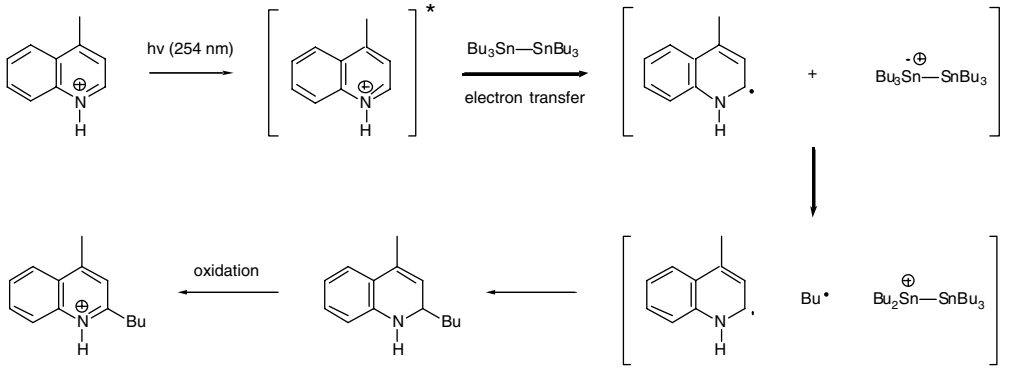
Organoditin Compounds and Dimanganese Decacarbonyl

Irradiation of hexaalkylditin or hexaarylditin compounds ($R_3Sn–SnR_3$) can lead to homolysis of the weak tin–tin bond to form tin-centered radicals ($R_3Sn^{\cdot}$).[8] Absorption of UV light (for Bu_6Sn_2, λ_{max} = 236 nm) can produce a $\sigma \rightarrow \sigma^*$ transition to give an excited state with a weaker Sn–Sn bond. Photolysis of ditin compounds in the presence of triplet sensitizers (including acetone) has also been reported to afford a particularly mild approach to tin-centered radicals.[9] It should be noted that dimers of other group 14 elements can also undergo homolysis, and for hexamethyl compounds (Me_6M_2; where M = group 14 element), the strength of the M–M bond decreases as the size of the element increases; lead-centered radicals are therefore more easily formed than tin-centered radicals.

The resulting tin-centered radicals can react with a variety of organohalides (or related compounds) to efficiently form carbon-centered radicals; this type of reaction has played a central role in the development of synthetic and mechanistic organic radical chemistry.[10,11] Halogen-atom abstraction from alkyl or aryl halides allows the controlled formation of a variety of carbon-centered radicals, which can undergo a number of intra- or intermolecular carbon–carbon bond forming reactions. This includes cascade (or



SCHEME 2



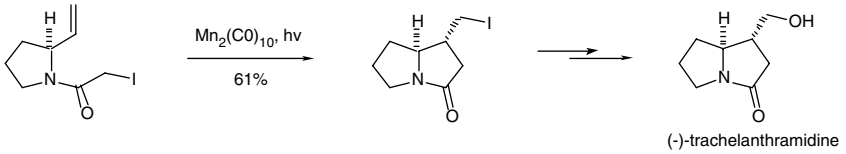
SCHEME 3

domino) reactions, as illustrated by the intra- followed by intermolecular radical reaction sequence shown in Scheme 2.[12]

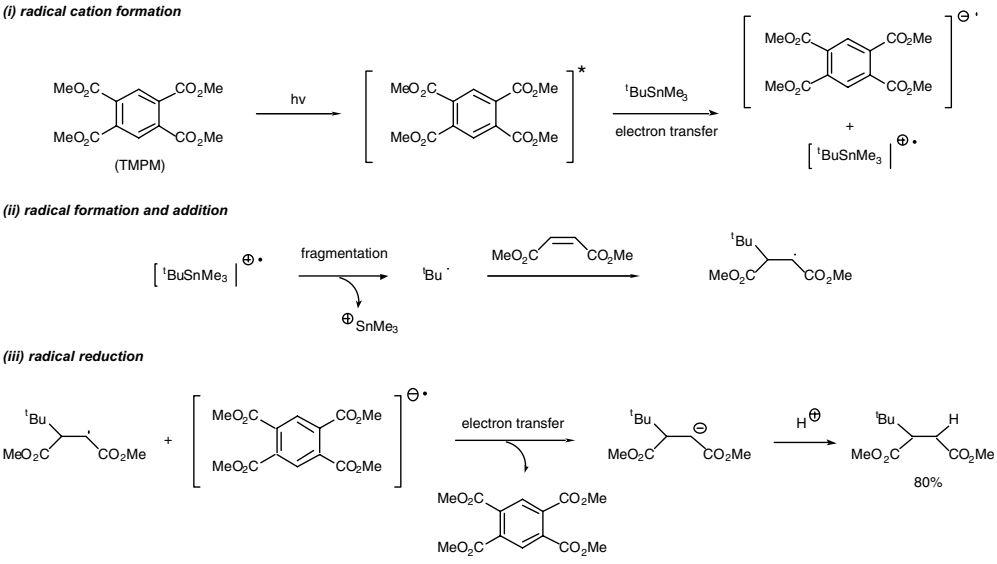
Electron transfer reactions[13] involving hexabutylditin have also been reported, and these types of reactions have been shown to lead to the alkylation of protonated pyridine derivatives including lepidine (Scheme 3).[14] Similar reactions using tetraalkyltin compounds are also possible, as outlined in the next section of this chapter.

It should be noted that the majority of radical reactions involving tin-centered radicals involve the use of tin hydrides, especially ^{n}tributyltin hydride, Bu_3SnH. This reagent can be used to reduce a variety of organohalides via radical intermediates, and the reactions can be initiated by photolysis of peroxides or azo compounds (chiefly azobisisobutyronitrile, AIBN).[15]

Other organometallic dimers can produce metal-centered radicals, and dimanganese decacarbonyl $[Mn_2(CO)_{10}]$ can undergo efficient homolytic cleavage of the relatively weak Mn–Mn bond on photolysis using visible light.[8] The resulting manganese pentacarbonyl radical $[^{\cdot}Mn(CO)_5]$, like tin-centered radicals, can abstract halogen atoms from organohalides to form carbon-centered radicals under mild reaction conditions. This has been successfully exploited in a number of dimerization, cyclization, and intermolecular addition reactions, including an enantioselective approach to the pyrrolizidine alkaloid (–)-trachelanthramidine (Scheme 4).[16,17]



SCHEME 4



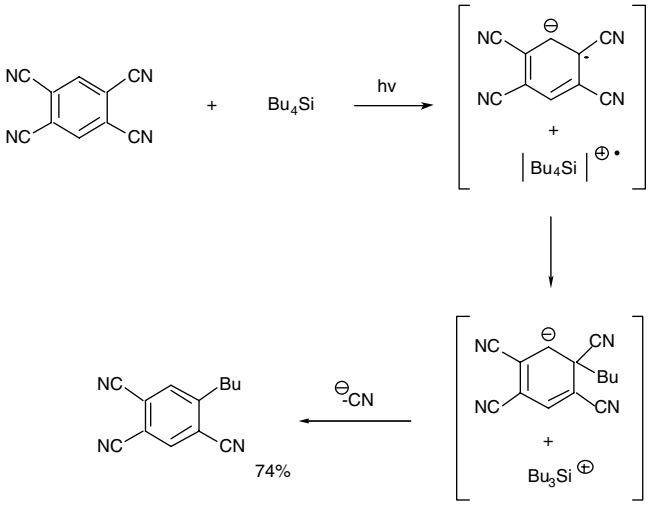
SCHEME 5

Tetraalkylstannanes and -silanes

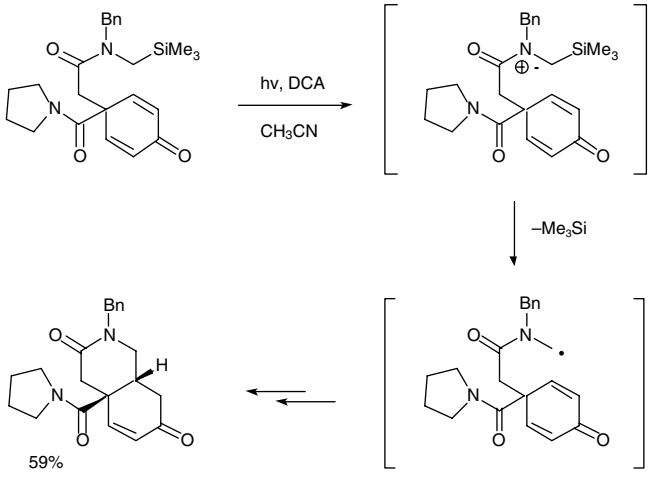
The facile photosensitized oxidation of tetraalkylstannanes (R_4Sn) and related group-14 compounds has been widely exploited by Mella and co-workers to form carbon-centered radicals.[18] Photoinduced electron transfer from tetraalkylstannanes to a sensitizer, such as aromatic nitriles and esters (including tetramethyl pyromellitate, TMPM), affords a radical cation $[R_4Sn]^{+\cdot}$ that can fragment to form an alkyl radical ($R^{\cdot}$) together with the R_3Sn^+ cation. The alkyl radicals can then react with electron-poor alkenes, alkynes, aromatics, or the radical anion formed from the photosensitizer to form new carbon–carbon bonds. Careful choice of the photosensitizer can ensure that the radical anion selectively reduces the radical adduct (derived from addition to a double bond) rather than the first-formed alkyl radical (Scheme 5).

Similar reactions can occur using tetraalkylsilanes including benzyl- and allyl-silanes and, for example, photo-induced electron transfer in the presence of aromatic nitriles can afford alkylated products.[13a] These reactions can lead to the regioselective replacement of a cyano substituent with an alkyl group as shown in Scheme 6.[19] Mechanistic studies support the unimolecular fragmentation of the intermediate radical cation $[Bu_4Si]^{+\cdot}$ followed by radical–radical combination.[18c]

Related alkylation reactions involving electron-transfer have also been observed using silyl amines (including $Et_2NCH_2SiMe_3$) and silyl amides. Photolysis of these types of compound in the presence of conjugated cyclohexenones and the sensitizer 9,10-dicyanoanthracene (DCA) can lead to carbon–carbon bond formation in modest to very good yields. Electron-transfer forms α-amino radical cations, which fragment to form nucleophilic carbon-centered radicals, and examples of intermolecular[20] and intramolecular (Scheme 7)[21] addition reactions have been documented (see also the section "Amines and Alcohols" in this chapter).



SCHEME 6

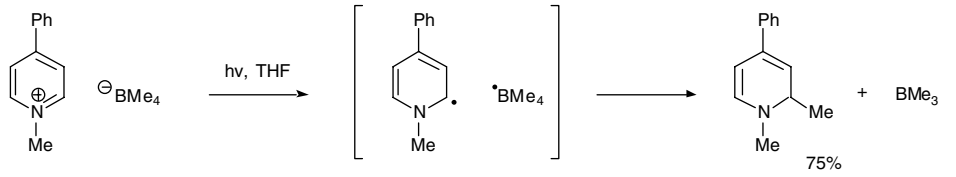


SCHEME 7

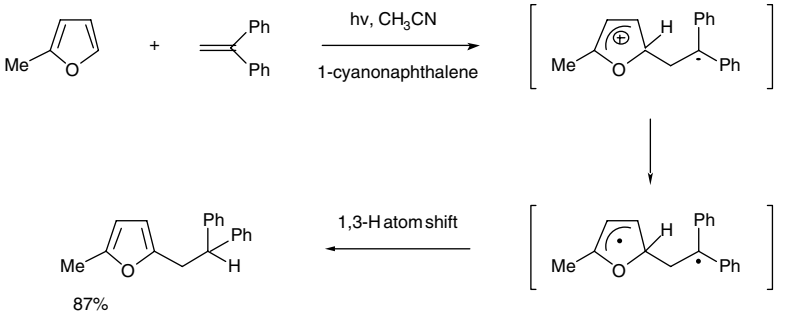
Organoborates

Photoinduced alkylation of aromatic compounds has been reported using alkyltriphenylborates.[22] Irradiation of acetonitrile solutions of dicyanoarenes with methyl- or benzyl-triphenylborate ($MeBPh_3^-$ or $BnBPh_3^-$) gave good yields of alkylcyanoarenes (cf. Scheme 6). The reaction is believed to be initiated by a photoinduced electron-transfer from the alkyltriphenylborate to the excited dicyanoarene followed by a fast cleavage of the alkyltriphenylborane radical ($RBPh_3^{\cdot}$) to form an alkyl radical. Coupling between the radical anion (derived from the dicyanoarene) and the alkyl radical produces a new carbon–carbon bond. Similar reactions have been reported using butyltriphenylborate and anthracene,[23] and more recently, using pyridinium tetraalkylborates (Py^+, BR_4^-).[24] For example, the efficient transfer of a methyl group (involving radical–radical coupling within a solvent cage) from tetramethylborate to pyridinium cations affords adducts in good yield (Scheme 8).

It should also be noted that 1,3-diketonatoborinates derived from 9-borabicyclo[3.3.1]nonane and 1,3-diketones have been shown to undergo a photo-rearrangement leading to an intramolecular alkylation and the formation of aldol products.[25]



SCHEME 8



SCHEME 9

Heteroaromatics

A variety of photoinduced electron transfer reactions leading to the alkylation of heteroaromatic compounds are known. A typical example involves the reaction of five-membered heterocycles with electron-rich alkenes as illustrated in Scheme 9.[26] Thus, photolysis of furans in the presence of 1,1-diarylethenes and a sensitizer (such as 1-cyanonaphthalene) gives alkylated products in good yield following an unusual 1,3-hydrogen atom shift.

Related intramolecular alkylation reactions are possible, and the use of chloroacetamides as substrates for photocyclization has been shown to be an important method for making heterocyclic compounds, particularly medium-ring lactams (Scheme 10).[27]

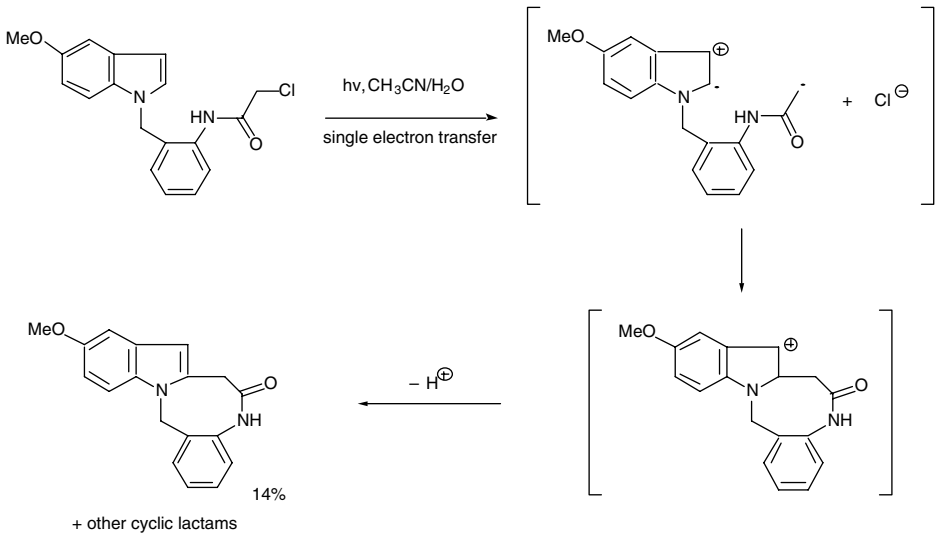
Toluene

The formation of benzyl radicals from toluene can be achieved by photosensitization in the presence of 1,4-naphthalenedicarbonitrile (DCN). Photoinduced electron-transfer from toluene to DCN is followed by proton transfer and radical coupling or addition to electrophilic alkenes (including dimethyl maleate) to form new carbon–carbon bonds (Scheme 11).[28]

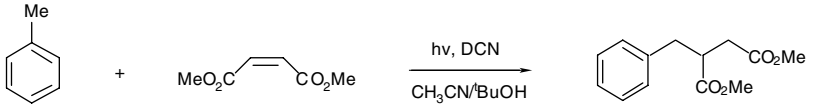
It should also be emphasized that benzyl radicals can be formed from toluene by hydrogen atom abstraction reactions. This may involve, for example, reaction with reactive oxygen-centered radicals derived from the photolysis of peroxides (see "Amino Acids and Peptides" later in this chapter).

Phthalimides and Ketones

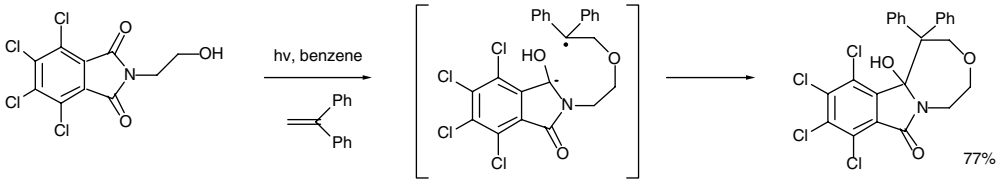
The photoinduced cyclization of *N*-substituted phthalimides has proved an effective method for the synthesis of medium- to large-membered rings. These alkylation reactions can involve either electron-transfer or hydrogen-atom abstraction reactions.[29] For example, irradiation of *N*-(2-hydroxyethyl)-4,5,6,7-tetrachlorophthalimide in the presence of 1,1-diphenylethene leads to electron transfer and the formation of a tricyclic derivative in good yield (Scheme 12).[30] The regioselectivity of this reaction can be explained by the positive charge in the intermediate radical cation being largely concentrated at the terminal carbon atom; this cation is susceptible to nucleophilic attack by the primary alcohol to form a



SCHEME 10



SCHEME 11

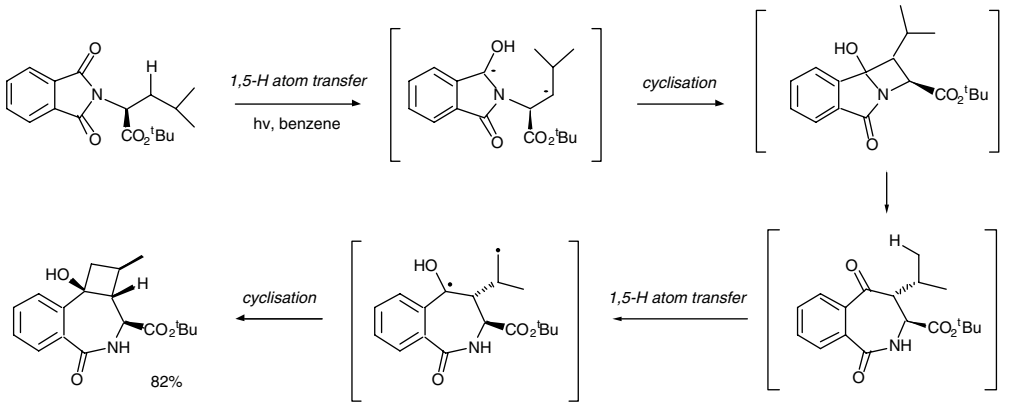


SCHEME 12

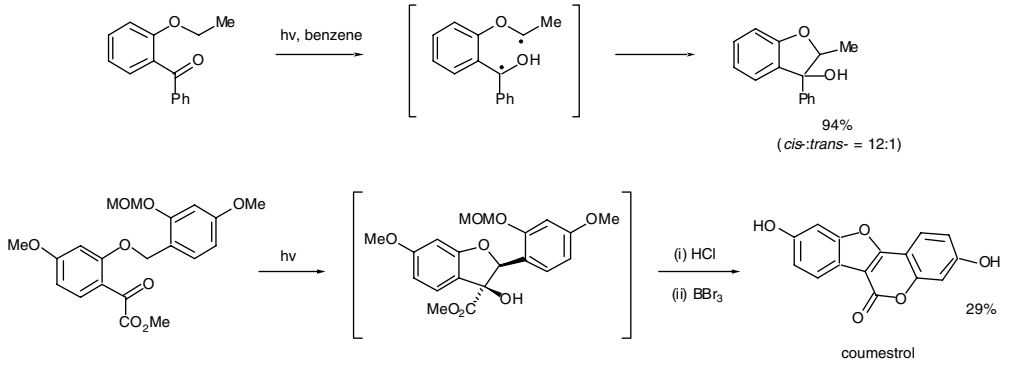
new C–O bond. Related intermolecular single electron-transfer reactions involving the alkylation of *N*-methyl phthalimide by α-keto carboxylates have also been reported.[31]

A variety of photochemical reactions involving phthalimides can be attributed to reaction of the excited state of the phthalimide group by 1,5-hydrogen atom transfer in a Norrish Type II reaction. Following abstraction of a hydrogen atom from the γ-CH position, the resulting 1,4-biradical can undergo Norrish type I fragmentation or alternatively, Yang cyclization. Steric factors play a large part in determining the ratio of fragmentation to ring closure. As shown in Scheme 13, a tricyclic product can be isolated from a remarkable phthalimide reaction involving two Yang-type cyclizations (Scheme 13).[32]

As with phthalimides, photolysis of alkyl aryl ketones can give rise to hydrogen atom abstraction reactions leading to the formation of cyclic products. Although 1,5-hydrogen atom abstraction is generally preferred (because of stereoelectronic/geometric requirements),[1,33] reactions involving 1,6-hydrogen atom abstraction have also been reported.[34] Examples of these types of reaction include the photocyclization of γ-ketoamides to form 6-membered lactams, the photocyclization of 2-alkoxybenzophenones to form dihydrobenzofuranols (Scheme 14), the photochemical cyclization of a glyoxylate ester to form coumestrol (Scheme 14), and the diastereoselective cyclization of *o*-benzylaminophenylketones to form



SCHEME 13



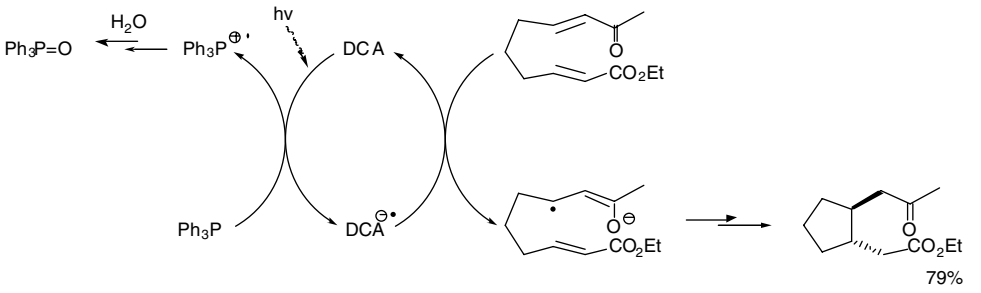
SCHEME 14

dihydroindolinols.[35] Intermolecular hydrogen atom abstraction reactions are very common; indeed, aromatic ketones (and also quinones) are often employed as sensitizers in photochemical alkylations (as illustrated in the sections "Amines and Alcohols" and "Amino Acids and Peptides" later in this chapter). This includes, for example, mediating the cyclization of aldehydes onto acceptor double bonds by generation of intermediate acyl radicals (RCO·).[36]

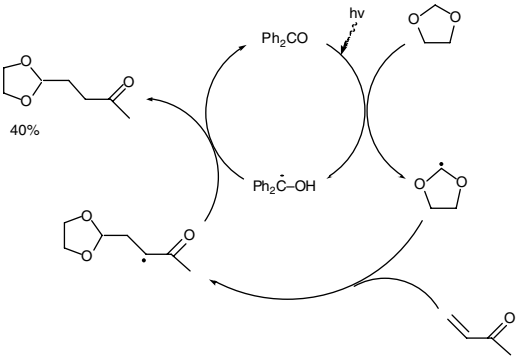
Novel photo-induced electron-transfer reactions have recently been reported using α,β-unsaturated ketones. Photolysis in the presence of an electron acceptor (such as 9,10-dicyanoanthracene, DCA) and a sacrificial electron donor (triphenylphosphine) leads to the formation of carbon-centered radicals, which can cyclize to form carbocycles as shown in Scheme 15.[37]

1,3-Dioxolanes

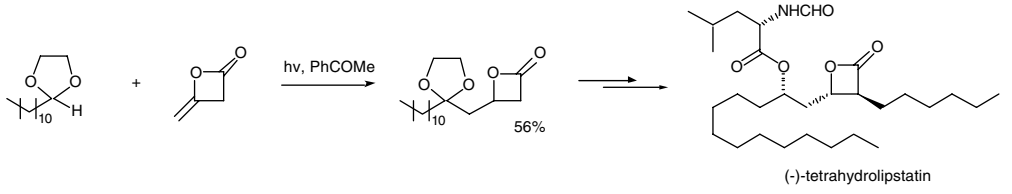
Irradiation of 1,3-dioxolanes in the presence of a sensitizer such as benzophenone (Ph_2CO), leads to the abstraction of an acetal hydrogen atom (by the triplet state ketone) to generate 1,3-dioxolanyl radicals, together with the resonance-stabilized diphenyl ketyl radical (Scheme 16). These nucleophilic 1,3-dioxolanyl radicals have been shown to add to a variety of alkenes to form adduct radicals, which can then accept a hydrogen atom from the diphenyl ketyl radical to give the desired alkylated product.[38] The diastereoselective addition of 1,3-dioxolanyl radicals to alkenes bearing chiral auxiliaries has also recently been reported,[38b] while the photochemical alkylation of diketene with 2-undecyl-1,3-dioxolane has been utilized as a key step in the synthesis of (–)-tetrahydrolipstatin (Scheme 17).[39]



SCHEME 15



SCHEME 16

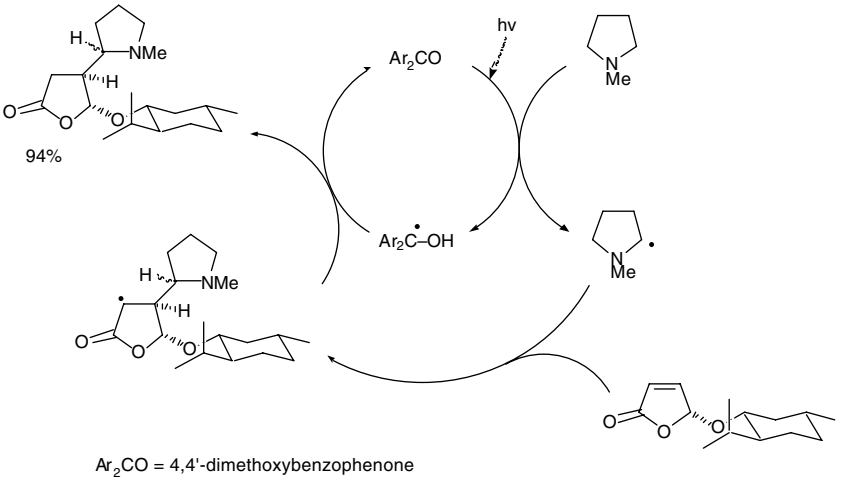


SCHEME 17

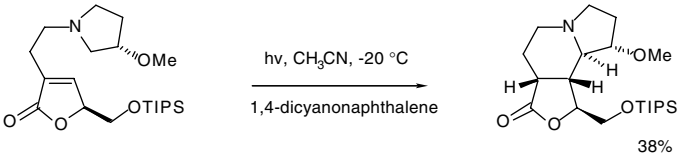
Amines and Alcohols

α-Aminoalkyl radicals [$R_2(R_2N)C^{\cdot}$] can be generated from amines [$R_2(R_2N)CH$] via photoinduced electron transfer reactions in the presence of sensitizers (including aromatic ketones). These nucleophilic radicals have been shown to add to electron-poor alkenes, leading to the efficient construction of carbon–carbon bonds adjacent to nitrogen. This has proved to be an effective method for the formation of lactams from, for example, reaction of *N*-allylamines with α,β-unsaturated esters.[40] The diastereoselective addition of tertiary amines to a chiral furanone derivative has also been reported (Scheme 18), as has a related intramolecular cyclization reaction to form the indolizidine alkaloid skeleton (Scheme 19).[41]

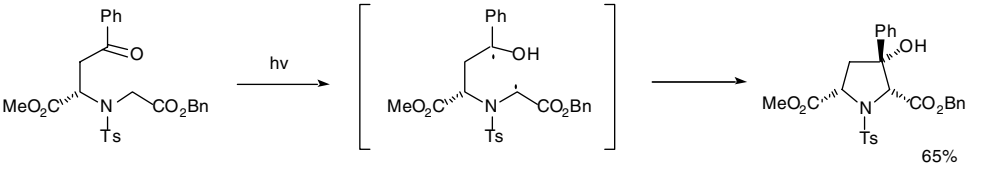
Similar intermolecular alkylation reactions can occur by irradiation of primary or secondary alcohols in the presence of sensitizers. The resulting α-hydroxyalkyl radicals [$R_2(HO)C^{\cdot}$] have been shown to add to a range of double bond acceptors. Recent examples, which lead to the formation of new carbon–carbon bonds, include addition to maleimides,[42] a dihydropyrrole,[43] and a 2,2-difluorovinyl carbamate.[44]



SCHEME 18



SCHEME 19



SCHEME 20

Amino Acids and Peptides

A variety of photochemical methods have been reported for α-alkylation of amino acids and in particular glycine derivatives.[45] Norrish-Yang photocyclization reactions have been used extensively to prepare nitrogen heterocycles, particularly proline derivatives (Scheme 20), from acyclic glycine derivatives bearing an aromatic ketone.[34,35] Related photocyclizations of oligopeptide-linked anthraquinones have also been reported, and interestingly, these radical coupling reactions resulted in the formation of a C–O rather than a C–C bond.[46]

Intermolecular radical reactions have also been reported, including selective radical–radical coupling reactions. These reactions involve the formation of α-amino acid radicals (stabilized by the captodative effect), which can couple to, for example, benzyl radicals to form phenylalanine derivatives (Scheme 21).[47] The benzyl radicals are generated by hydrogen-atom abstraction from toluenes using alkoxyl radicals derived from peroxides and/or aromatic ketone sensitizers.

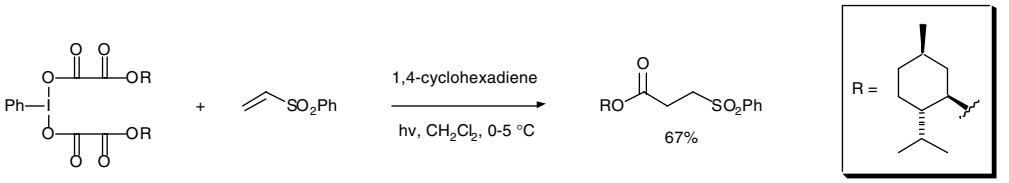
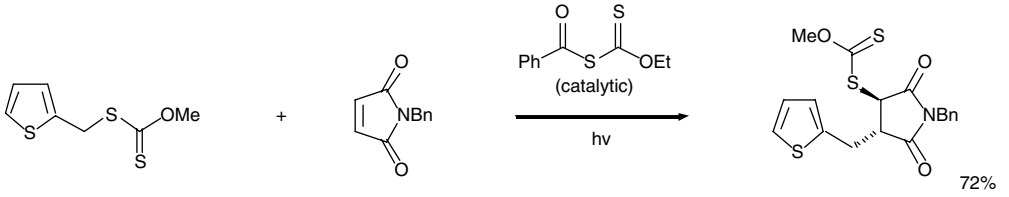


SCHEME 22



SCHEME 23

6.3 Summary and Outlook

This short review has highlighted a diverse range of mild and efficient photochemical methods for the formation of carbon–carbon bonds. These intra- or intermolecular free radical reactions have been shown to afford a versatile and controlled synthetic approach to a wide variety of organic products. Many of the photochemical methods can be thought of as offering "clean" (or "green") synthetic approaches to compounds — an active area of current research. Bearing in mind the versatility of radical reactions and the relatively small number of radical-generating systems currently available, it is expected that future research will lead to the development of new environmentally friendly photochemical alkylation reactions. Recent examples of particularly interesting alkylation methods include the use of organohypervalent iodine compounds[48] as a route to carbon-, oxygen-, or nitrogen-centered radicals (Scheme 22), and chain reactions involving xanthates, which can be initiated by using catalytic amounts of *S*-benzoyl xanthates (Scheme 23).[49] The development of these and related free-radical methods should help to promote the more widespread use of photochemical alkylations in both academia and industry in the future.

SET Addition of Amines to Alkenes

Frederick D. Lewis
Northwestern University

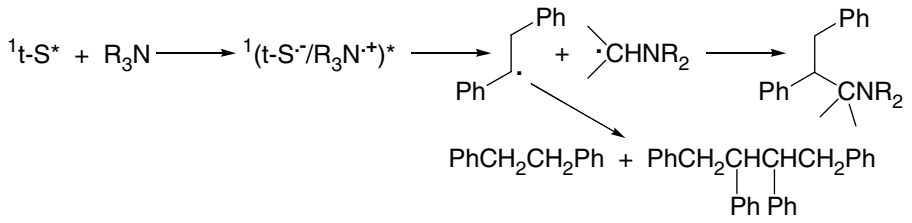
Elizabeth M. Crompton
Northwestern University

7.1 Introduction

Amines are good electron donors that participate in a wide variety of electron transfer reactions.[1–3] The free energy for a photochemical electron transfer quenching process can be estimated from the singlet energy and reduction potential of the excited state, the oxidation potential of the amine, and the solvent polarity using Weller's equation [$\Delta G_{et} = E^* - (E^{ox} - E^{red}) - (e^2_o/\varepsilon R)$].[4] Amine oxidation potentials decrease in the order tertiary > secondary > primary amines and aromatic > aliphatic amines. However, the irreversible nature of the oxidation of aliphatic amines results in considerable uncertainty in their oxidation potentials and hence in the calculated free energy for a photochemical single electron transfer (SET) process.[5]

Quenching of singlet state reactants by tertiary amines can result in the formation of fluorescent exciplex or radical ion pair intermediates, which can be detected by transient absorption spectroscopy or other spectroscopic techniques such as chemically induced dynamic nuclear polarization (CIDNP).[6] These intermediates can either undergo charge recombination, resulting in regeneration of the ground state reactants, or chemical reactions leading to product formation. Amine oxidation results in a dramatic increase in the acidity of the α-CH bonds, and thus proton transfer is the expected chemical reaction for tertiary amine cation radicals, except in the case of α-trimethylsilylamines, which can undergo nucleophilic displacement of the silyl group in competition with deprotonation. Secondary and primary amines undergo either α-CH or NH deprotonation reactions, depending upon the proton acceptor. Deprotonation and desilylation of the amine cation radicals yield free radical intermediates and hence,

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1

the ultimate products of photoinduced SET reactions of amines typically result from radical pair combination or radical–neutral addition reactions.

Several comprehensive reviews of photochemical SET reactions of amines are available,[1–3] as are more specialized reviews of the reactions of amines with specific classes of excited states.[6–8] These include reviews of the photochemical reactions of amines with arenes and iminium ions, which appeared in the first edition of this Handbook. The present article provides an overview of the photochemical addition reactions of amines with alkenes. Detailed information about the mechanisms and dynamics of these reactions is provided in the original literature and the comprehensive reviews.

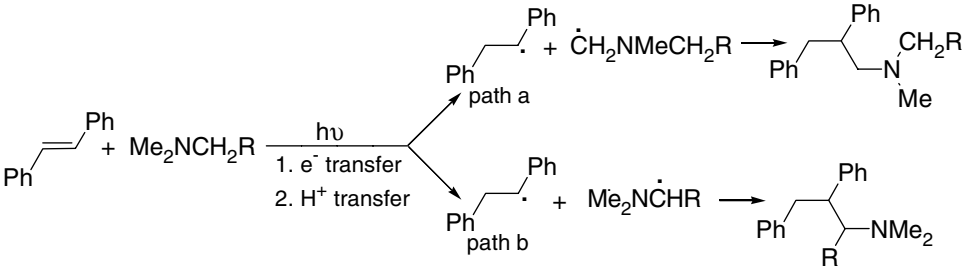
7.2 Additions of Stilbenes with Amines

Irradiation with Tertiary Amines

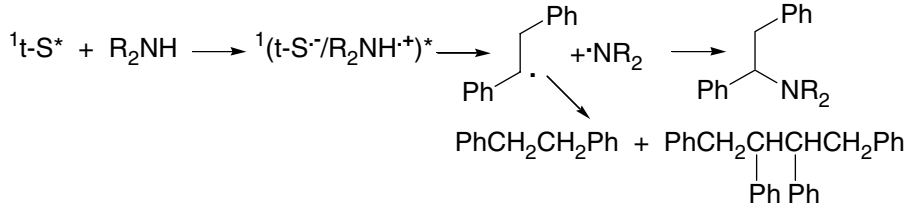
From a historical perspective, investigations in the 1970s and 1980s of the addition reactions of the excited singlet state of *trans*-stilbene with alkylamines provided the basis for our current mechanistic understanding of SET addition reactions involving amines. These reactions have been the topic of several reviews, and thus a brief review will suffice.[1–3,6,9–11] The direct irradiation of stilbene with symmetric trialkylamines such as Et_3N in acetonitrile solution affords a single adduct and other products characteristic of radical pair intermediates (Scheme 1).[12] The preparative yields of stilbene–amine adducts are modest (<50%), as expected for a radical pair process. Radical pair formation was proposed to occur via electron transfer followed by proton transfer from the α-carbon of the amine cation radical to the stilbene anion radical. The formation of a radical ion pair as a putative intermediate in these reactions is supported by the observation in nonpolar solvents of stilbene–amine exciplex fluorescence without adduct formation,[12] by the presence of the stilbene anion radical observed by time-resolved Raman spectroscopy,[13] and by a CIDNP study of the reaction products.[14]

The addition reactions of singlet stilbene with nonsymmetrical tertiary amines yield addition products resulting from proton transfer from each of the nonequivalent α-carbons (Scheme 2).[15] The adduct resulting from proton transfer from the *less substituted* carbon of simple trialkylamines, such as *N,N*-dimethylisopropylamine, is formed selectively. In contrast, the adduct resulting from proton transfer from the *more substituted* carbon is formed selectively in the case of *N,N*-dimethylallylamine and other amines possessing a radical-stabilizing α-substituent.[16] The former result was attributed to a stereoelectronic effect on the proton transfer process and the latter result to the effects of substituents upon the kinetic acidity of the α-protons.[3] Similar trends have been reported for other amine photooxidation reactions. The selectivity pattern is dependent upon the identity of the proton acceptor.

The addition reactions of ring-substituted stilbenes with Et_3N are nonregioselective.[17] (Aminoalkyl)stilbenes in which a trialkylamine is appended to the stilbene ortho position with a mono-, di-, or trimethylene linker form fluorescent intramolecular exciplexes but fail to undergo intramolecular addition, even in polar solvents.[18] It is possible that the exciplex or radical ion pair geometry is not suitable for a least-motion proton transfer process.



SCHEME 2



SCHEME 3

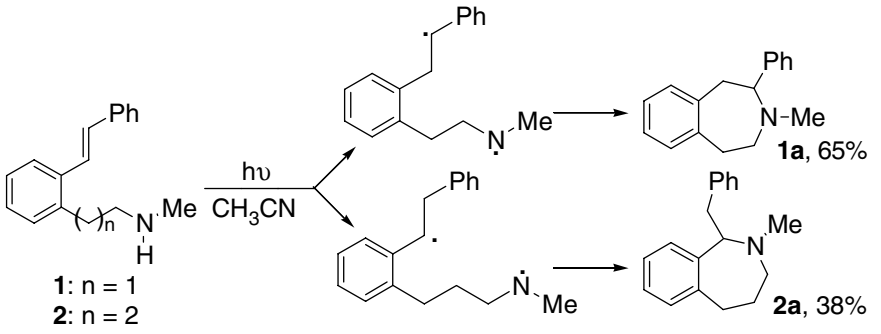
Irradiation with Secondary Amines

The reactions of singlet stilbene with secondary amines such as Et_2NH yield a single adduct and other products characteristic of radical pair intermediates in both polar and nonpolar solvents (Scheme 3).[12] Selective NH proton transfer has been attributed to either greater NH vs. α-CH cation radical acidity or to NH-stilbene hydrogen bonding in an exciplex or radical ion pair intermediate.[19] The addition of singlet ring-substituted stilbenes with Et_2NH is also nonregioselective.[18]

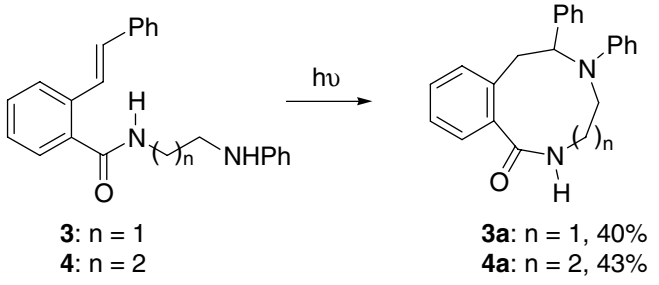
(Aminoalkyl)stilbenes **1** and **2**, in which a *N*-methylamine is appended to the stilbene ortho position with a di- or trimethylene linker, undergo intramolecular addition reactions, yielding 3-benzazepine and 2-benzazepine products **1a** and **2a**, respectively (Scheme 4).[18] Note that the NH proton transfer occurs regioselectively to the end of the stilbene double bond proximal to the point of attachment of the ethylene linker, but distal to the point of attachment of the propylene linker. This selectivity was attributed to a least-motion pathway for intramolecular exciplex proton transfer. The (aminoalkyl)stilbenecarboxamides **3** and **4** also undergo regioselective intramolecular addition (Scheme 5) to form the medium-ring azalactams **3a** and **4a**, respectively, in moderate yield (ca. 40%).[20] Singlet stilbenes fail to undergo either inter- or intramolecular reactions with primary amines, reflecting the inability of primary amines to quench stilbene fluorescence.

Irradiation with Heterocyclic Amines

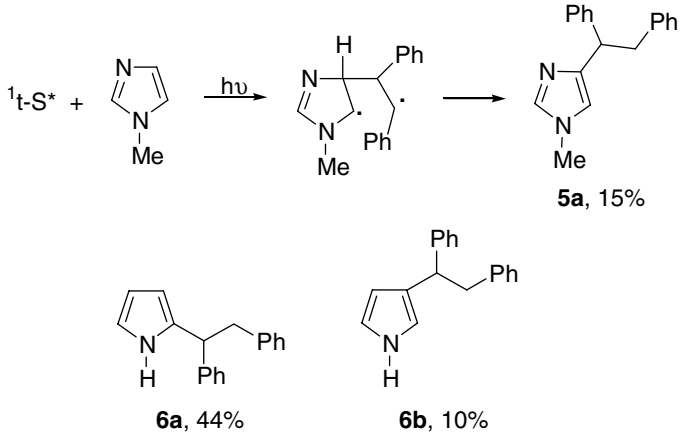
Irradiation of stilbene in *N*-methylimidazole results in the formation of the α-CH adduct **5a**.[21] Adduct formation is proposed to occur via a 1,4-biradical intermediate (Scheme 6). Similarly, irradiation of stilbene in pyrrole yields two CH adducts, **6a** and **6b**.[22] Irradiation of stilbene with indole or carbazole in acetonitrile solution results in the formation of both NH and CH adducts in low yield. However, irradiation of polycrystalline mixtures of stilbene and these heterocycles yields predominantly the NH adducts in moderate yield (ca. 50%). The role of electron transfer in these reactions has not been established; however, exciplex fluorescence is observed upon quenching of stilbene by *N*-methylpyrrole in cyclohexane solution.



SCHEME 4



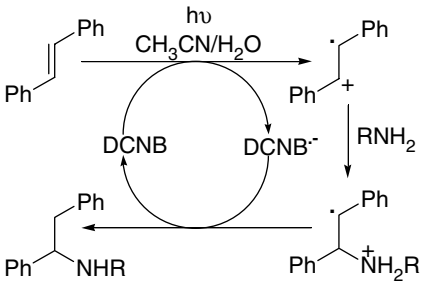
SCHEME 5



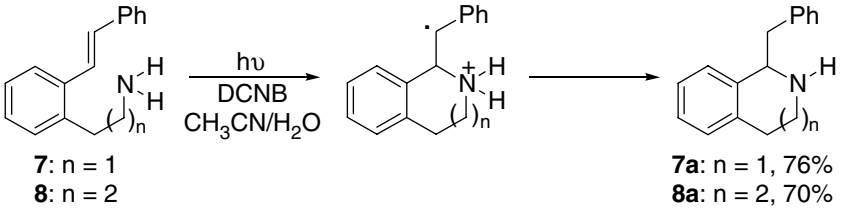
SCHEME 6

ET-Sensitized Irradiation with Ammonia and Primary Amines

Whereas singlet stilbene fails to react with primary amines or ammonia, irradiation in the presence of the electron acceptor *p*-dicyanobenzene (DCNB) in acetonitrile–water solution results in efficient addition via an ET-sensitized mechanism.[23] The mechanism of this reaction involves nucleophilic addition of the amine to the stilbene cation radical, which is generated via stilbene photooxidation by singlet DCNB (Scheme 7). The yields, in some cases, are excellent — exceeding 90%. DCNB-sensitized addition of stilbenes and secondary amines is not successful, a consequence of more facile oxidation of the



SCHEME 7



SCHEME 8

secondary amines vs. stilbene. The DCNB-sensitized addition reactions of ring-substituted methyl- and chlorostilbenes display modest regioselectivity. However, addition of ammonia to *p*-methoxystilbene is highly regioselective, reflecting localization of the positive charge on the benzylic carbon stabilized by the methoxyphenyl group. This selectivity has been exploited in the photochemical synthesis of intermediates, which were converted nonphotochemically to isoquinolines and other alkaloids.[24]

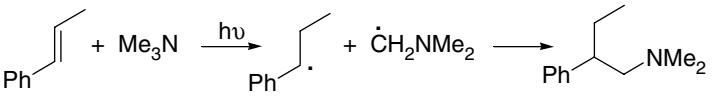
(Aminoalkyl)stilbenes **7** and **8**, in which a primary amine is appended to the stilbene ortho position with a di- or trimethylene linker, undergo DCNB-sensitized intramolecular addition reactions, yielding isoquinoline and benzazepine products **7a** and **8a**, respectively (Scheme 8).[18] In both cases, ring formation occurs via intramolecular nucleophilic addition to the end of the stilbene double bond proximal to the point of attachment of the aminoalkyl group. Addition to the distal end of the double bond presumably would form a less stable distonic cation radical intermediate.

7.3 Additions of Styrenes with Amines

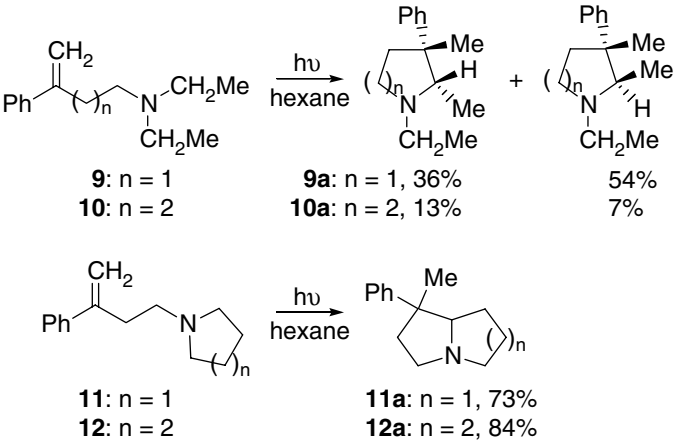
Irradiation with Tertiary Amines

The photochemical behavior of singlet styrenes in the presence of tertiary alkylamines has received far less attention than the behavior of singlet stilbene. However, the behavior of styrene and 1- and 2-phenylpropene is qualitatively similar to that of singlet stilbene.[25–28] As is the case for stilbene, the formation of fluorescent exciplexes are observed upon quenching of singlet styrenes by tertiary but not by secondary amines. One operational difference is the formation of styrene–amine adducts in both polar and nonpolar solvents. The addition reaction of 1-phenylpropene with Me_3N is regioselective, yielding only the α-substituted adducts (Scheme 9).[25] This is indicative of α-CH proton transfer to form a benzyl radical, which then undergoes radical pair combination.

The intramolecular addition reactions of aminoalkylstyrenes have proven to be a particularly fruitful subject of investigation. Photocyclization reactions of the *N,N*-diethyl α-aminoalkylstyrenes **9** and **10** yield the pyrrolidine **9a** and piperidine **10a**, respectively (Scheme 10), as mixtures of diastereoisomers.[29,30] Similarly, the cyclic amines **11** and **12** yield the bicyclic adducts **11a** and **12a**, respectively (presumably as mixtures of diastereoisomers), in good preparative yield. These reactions are assumed to occur via



SCHEME 9



SCHEME 10

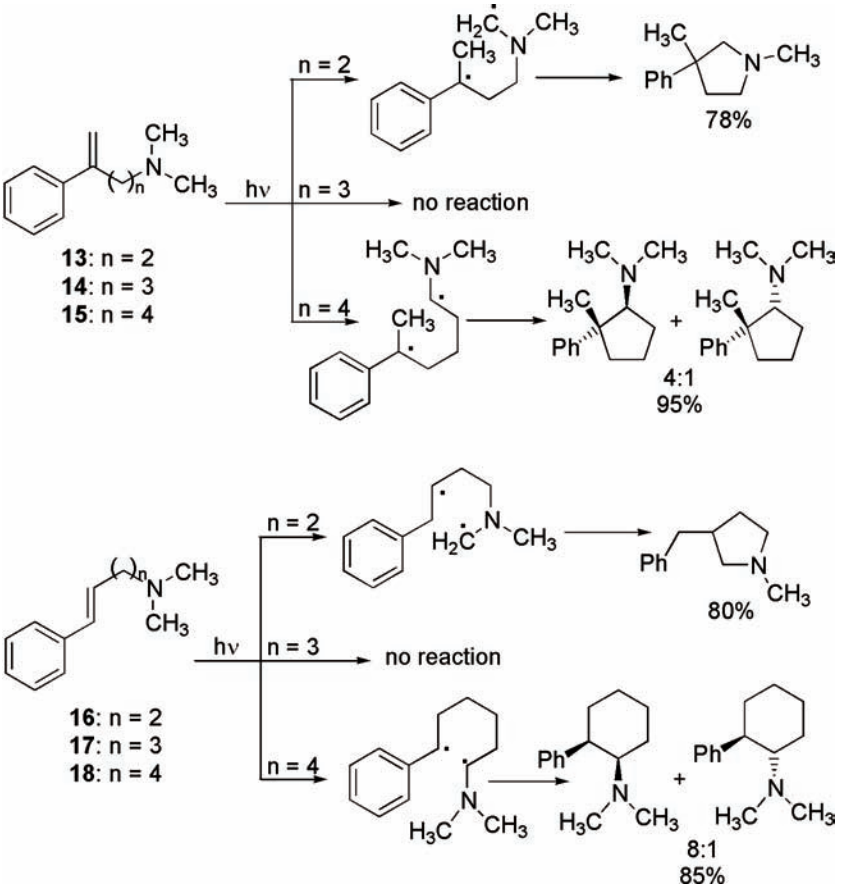
biradical intermediates formed by the regioselective transfer of an amine α-CH to the unsubstituted end of the styrene double bond.

The effect of alkyl chain length on the photochemical behavior of the *N,N*-dimethyl α-aminoalkylstyrenes **13–15** and the β-aminoalkylstyrenes **16–18** is summarized in Scheme 11, which includes the putative biradical intermediates in these reactions.[31] Mechanistic studies indicate that the biradical intermediates are formed via proton transfer in a fluorescent exciplex intermediate. There are several noteworthy features of the chain-length dependence of these reactions. First, the aminopropyl systems **14** and **17** form stable exciplex intermediates, which are chemically unreactive. Second, the aminoethyl system **13** forms the more stable benzylic radical, whereas **16** forms the less stable 2-phenylalkyl radical. Finally, both aminobutyl systems **15** and **18** form α-aminoalkyl radicals rather than α-aminomethyl radicals. The latter would have been expected on the basis of the selective formation of the less substituted α-aminoalkyl radicals in the reactions of singlet stilbene with *N,N*-dimethylalkylamines.[15] The chain-length-dependent behavior of **13–18** has been ascribed to the geometry of their intramolecular exciplexes, which are assumed to optimize overlap of the amine lone pair and styrene double bond while minimizing nonbonded repulsion. The resulting exciplex geometries permit least motion α-CH transfer leading to formation of the biradical intermediates shown in Scheme 11. Evidently, no least motion pathway is available for the aminopropyl systems **14** and **17**.

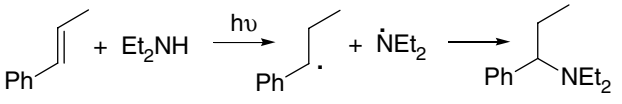
Irradiation with Secondary and Primary Amines

The intermolecular reactions of singlet styrenes with secondary amines have also received relatively little attention. Reaction of either 1-phenylpropene or 2-phenylpropene with Et_2NH yields a single adduct and other products characteristic of a radical pair intermediate (Scheme 12).[25,27,28] Presumably, regioselective NH proton transfer in a nonfluorescent exciplex intermediate yields the radical pair. Adduct formation between singlet styrenes and primary amines has not been reported.

The intramolecular reactions of the secondary α-(aminoalkyl)styrenes and β-(aminoalkyl)styrenes are dependent upon both the alkyl chain length and its point of attachment. The products of direct irradiation of the α-(aminoalkyl)styrenes **19–21** are shown in Scheme 13 along with their putative



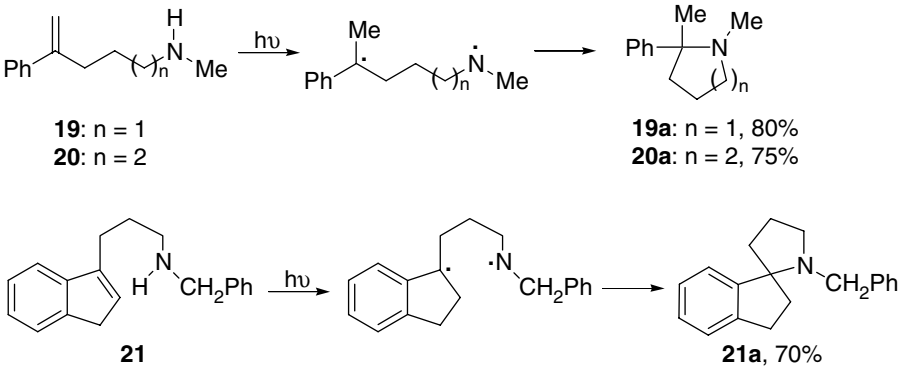
SCHEME 11



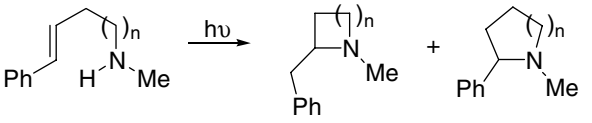
SCHEME 12

biradical intermediates.[28] The 1,n-biradical intermediates (n = 5 or 6) undergo combination to afford **19a–21a** in 70–80% yield. In all of these reactions, the NH proton transfer process selectively yields the more stable benzyl radical, as is the case in the intermolecular reactions of styrenes with secondary amines (Scheme 12).

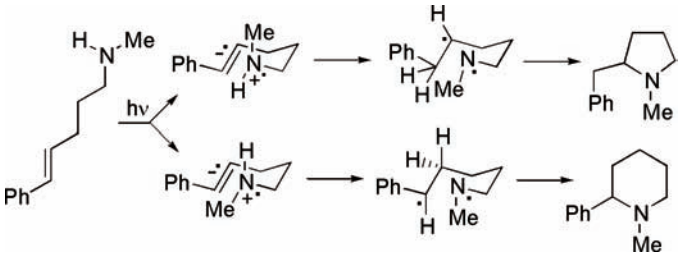
The intramolecular reactions of β-(aminoalkyl)styrenes **22–24** yield more complex product mixtures, resulting from NH transfer to either end of the styrene double bond (Scheme 14).[27] The aminoethylstyrene **22** selectively forms adduct **22b** via the 2-phenylalkyl radical intermediate, whereas the aminobutylstyrene **24** selectively forms adduct **24a** via the benzyl radical intermediate. The aminopropylstyrene **23** affords the two regioisomeric adducts **23a** and **23b** in a 1:2.4 ratio. Formation of the less stable biradical intermediate is attributed to the similar energies of the folded conformations required for 1,5- vs. 1,6-proton transfer (Scheme 15). Intramolecular addition is also observed for the primary (aminoalkyl)styrene analog of **23**, affording the analogous adducts in a 1:1.4 ratio. This is the only example of which we are aware of addition of a primary amine to a singlet styrene.



SCHEME 13



SCHEME 14



SCHEME 15

In most studies of styrene–amine photochemical addition reactions, the singlet styrene interacts with a ground state amine. The roles of styrene and amine are reversed in a study of the photochemical behavior of the (styrylalkyl)anilines **25–27**, in which the aniline singlet state lies slightly below the styrene singlet state.[32] Irradiation of **25** and **26** affords the intramolecular adducts **25a** and **26a**, respectively, as the major products, whereas **27** affords mainly adduct **27b** (Scheme 16). Presumably, electron transfer quenching of singlet aniline by ground state amine yields the same exciplex intermediate that would be formed by the reverse process.

An interesting mechanistic variant of styrene–amine addition upon direct irradiation is presented by the reaction of the *o*-hydroxystyrene **28** with $MeNH_2$ to yield the adduct **28a** in 62% yield (Scheme 17).[33] The initial step in the reaction mechanism is deprotonation of the acidic singlet state of **28** by the amine to yield a phenolate–ammonium ion pair. Reprotonation of the phenolate ion yields a zwitterion, which is trapped by the nucleophilic amine. Thus, the amine serves both as a base and as a nucleophile in this reaction.

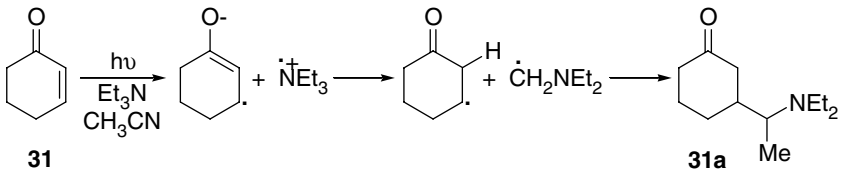
SCHEME 18

ET-Sensitized Irradiation with Ammonia and Primary Amines

The DCNB-sensitized addition reactions of 1,1-diarylethylenes with ammonia or primary amines yield the *anti*-Markovnikov adducts.[34] The mechanism is analogous to that shown in Scheme 7 for addition to stilbene. The regioselectivity is determined by nucleophilic attack of the amine on the alkene cation radical to yield the more stable benzyl radical intermediate. The mechanism and dynamics of the reactions of *p*-methoxystyryl radical cations with amines have been investigated.[35] Aniline and Et_3N are found to react as electron donors with rate constants near the diffusional limit. Primary amines react as nucleophiles, with somewhat slower rate constants.

The DCNB-sensitized addition of ammonia to the 1-arylbutadiene **29** occurs selectively to afford the allylamine **29a** (Scheme 18).[36] The locus of amine addition is determined, as expected, by formation of the most stable radical intermediate, in this case the 1-phenylallyl radical. Reduction of this radical by $DCNB^{-}\cdot$ yields the 1-phenylallyl anion, which is selectively protonated at the locus of highest charge density, adjacent to the phenyl ring. The nonsymmetric 1,4-diphenylbutadiene **30** affords a 5:1 mixture of the adducts **30a** and **30b**.



SCHEME 19

7.4 Additions of α,β-Unsaturated Carbonyl Compounds with Amines

Irradiation with Tertiary Amines

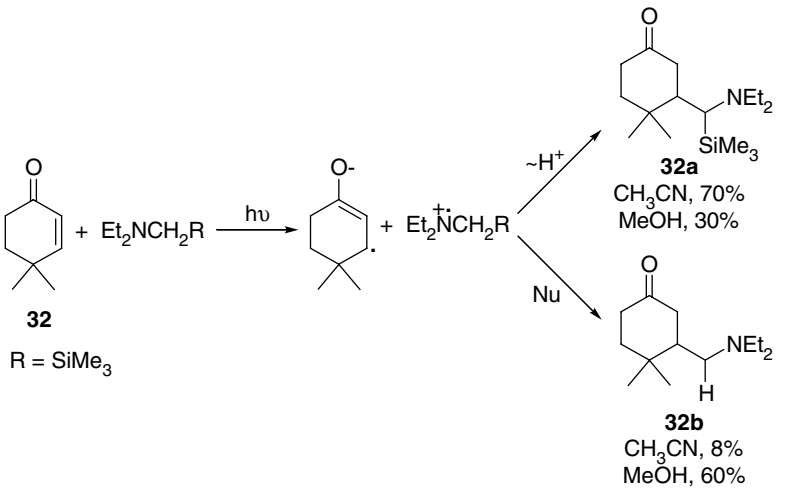
The direct and sensitized irradiations of several α,β-unsaturated carbonyl compounds with tertiary amines have been the subject of several recent reviews.[1–3,37] Direct irradiation with Et_3N is reported to yield the products of amine α-CH addition across the conjugated carbon–carbon double bond. For example, the reaction of cyclohexenone **31** with Et_3N in acetonitrile solution affords the adduct **31a** (Scheme 19), as well as the products of reduction and dimerization of **31**.[38] Investigation of the mechanism led to the proposal that electron transfer quenching of the triplet enone by a ground-state amine yields the radical ion pair, which undergoes regioselective proton transfer to form the radical pair precursor of the addition and reduction products. The yields of adducts between enones and tertiary amines are generally poor.[38,39] No reports exist of photochemical reactions of triplet enones with secondary or primary amines. The intramolecular addition of a secondary aniline to an unsaturated ester, ethyl 5-(phenylamino)-2-pentenoate, has been reported.[32] This reaction presumably involves reduction of the acrylate by the singlet aniline.

Irradiation of the cyclohexenone **32** with the tertiary α-silylamine $Et_2NCH_2SiMe_3$ affords two adducts **32a** and **32b** in a product ratio that is solvent dependent (Scheme 20).[40,41] In acetonitrile solution, the formation of **32a** as major product can be attributed to selective α-CH deprotonation adjacent to the silyl substituent, whereas the formation of **32b** as the major product in methanol solution can be attributed to nucleophilic displacement of the silyl group followed by addition of the radical $EtNCH_2$· to either the neutral enone or its anion radical. Intramolecular analogs of this reaction have also been studied for substrates **33** and **34** and display highly selective α-CH deprotonation adjacent to the silyl substituent in acetonitrile solution to yield **33a** and **34a** and desilylation in methanol solution to yield **33b** and **34b** (Scheme 21).[42,43] Intramolecular addition can also compete with *trans,cis* isomerization of acyclic enones, whereas intermolecular addition is too slow to do so.[41,42]

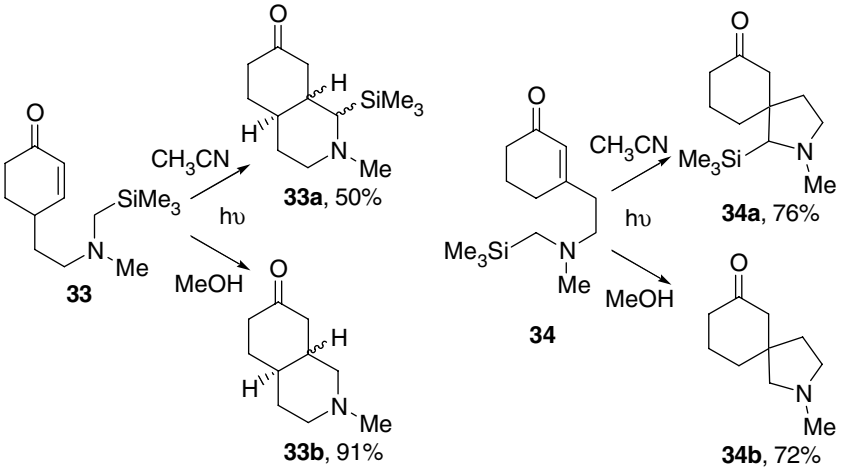
The effects of α-substituents on the amine cation radical kinetic acidities were probed by determining the product ratios for intramolecular enone–amine cyclization of several nonsymmetically substituted β-(aminoethyl)cyclohexenones (Scheme 22).[43,44] The observed trend, C≡CH > $CH{=}CH_2$ > Ph > CO_2Et > $SiMe_3$ > Me ~ H, is similar to that observed for the addition of substituted tertiary amines to singlet stilbene.[16] The dynamics of deprotonation of the corresponding tertiary anilines have been investigated by means of time-resolved spectroscopy.[45]

ET-Sensitized Irradiation with Tertiary Amines

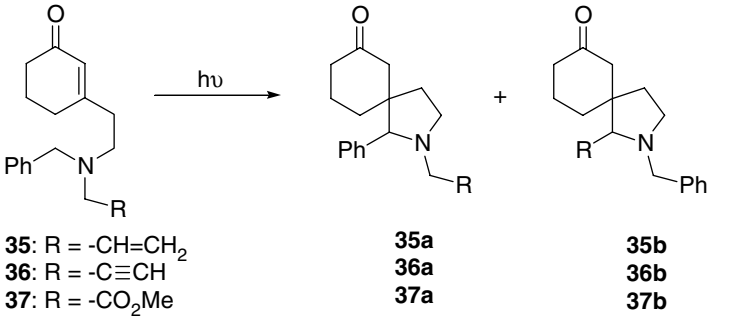
Irradiation of methyl methacrylate or acrylonitile with Et_3N in the presence of either anthraquinone or 9,10,-dicyanoanthracene (DCA) sensitizers results in the formation of complex mixtures of adducts containing one or more conjugated alkenes.[46] ET-sensitized addition reactions of *N*-alkylpyrrolidines to a variety of electron deficient alkenes have recently been reported to occur with high yields.[47] For example, addition of *N*-methylpyrrolidine to methyl acrylate **38** affords adduct **38a**. The proposed mechanism of this reaction is outlined in Scheme 23. Addition to the furanone **39**, which possesses a chiral auxiliary,



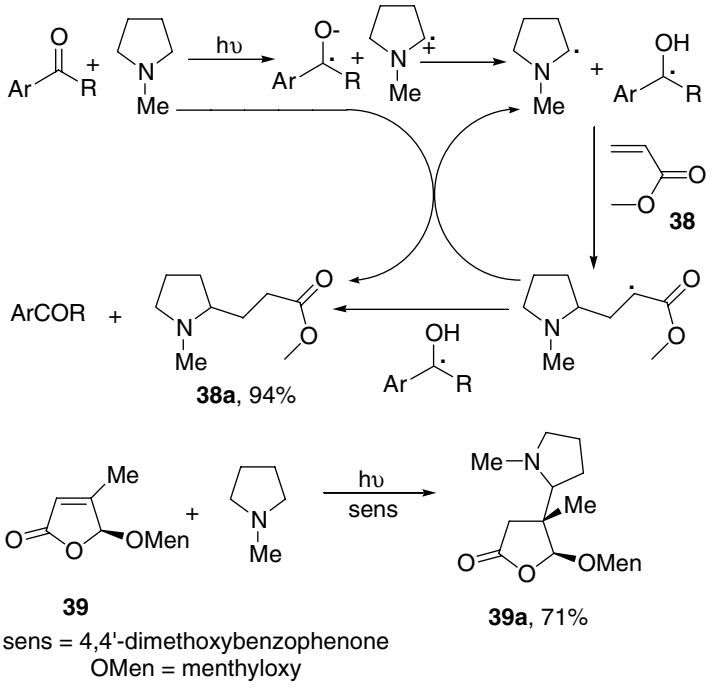
SCHEME 20



SCHEME 21



SCHEME 22



SCHEME 23

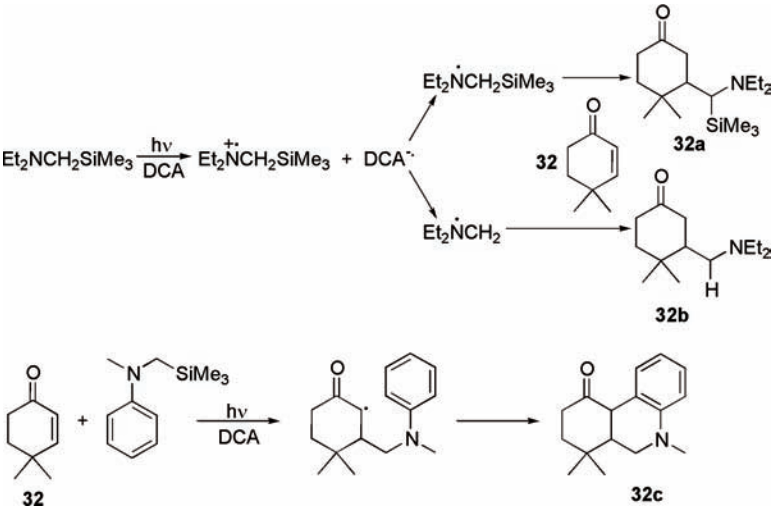
displays high facial selectivity in the formation of **39a**. High yields require the use of an unusual ET sensitizer, 4,4′dimethoxybenzophenone, which selectively deprotonates the more substituted α-CH bond of the amine cation radical. Furthermore, the resulting ketyl radical reduces the intermediate radical adduct rather than undergoing pinacol formation (Scheme 23). This methodology has been extended to the tandem addition reactions of **39** with *N,N*-dialkylanilines and with *N*-allyl- and *N*-propargylpyrrolidines.[48] These addition reactions can also be sensitized by TiO_2.[49]

Irradiation of cyclohexenone **32** with the tertiary α-silylamine $Et_2NCH_2SiMe_3$ in methanol solution in the presence of the electron acceptor 9,10-dicyanoanthracene (DCA) yields predominantly the desilylated adduct **32b**. The product ratios depend on amine concentration.[41] The mechanism proposed for adduct formation is outlined in Scheme 24. Oxidation of the tertiary amine by singlet DCA yields the amine cation radical, which undergoes desilylation upon nucleophilic reaction with the solvent. Addition of the α-aminoalkyl radical to the neutral enone affords the radical adduct, which is reduced by $DCA^{-}\cdot$ and protonated by solvent.[50] Intramolecular trapping of the radical adduct can compete with reduction by $DCA^{-}\cdot$, as seen in the reaction of **32** with an α-silylaniline, which yields the tandem addition product **32c** (Scheme 24).[51]

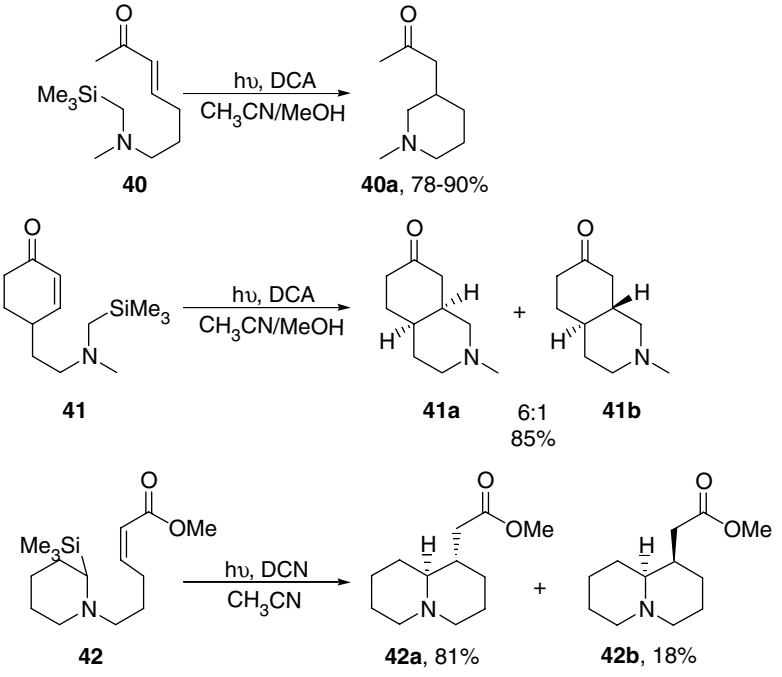
The DCA- and 1,4-dicyanonaphthalene (DCN)-sensitized intramolecular reactions of both acyclic and cyclic enones with acyclic and cyclic α-silylamines have been studied extensively, from both mechanistic and synthetic perspectives.[42,43] As examples (Scheme 25), DCA-sensitized irradiation of the acyclic enone **40** affords the piperidine **40a**,[50] irradiation of the γ-silylaminoethylcyclohexanone **41** affords the hydroisoquinolones **41a** and **41b** in a 6:1 ratio,[43] and irradiation of the unsaturated ester **42** affords a mixture of the hydroquinolizines **42a** and **42b** in a 5:1 ratio.[52] DCA-sensitized reactions of α-silylamines have been used to synthesize key intermediates in the total synthesis of several natural products.[1,3]

ET-Sensitized Irradiation with Secondary and Primary Amines

Anthraquinone (AQ)-sensitized irradiation of methyl acrylate **43** with the secondary amines diisopropylamine or pyrrolidine affords the lactams **43a–c** (Scheme 26).[46,53] The use of reduced reaction temperatures

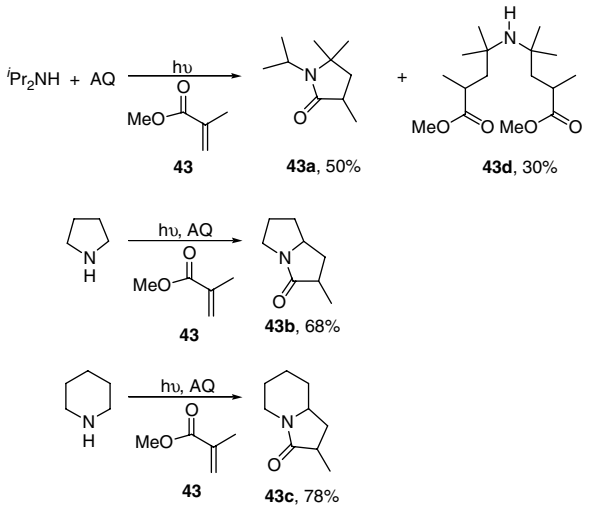


SCHEME 24

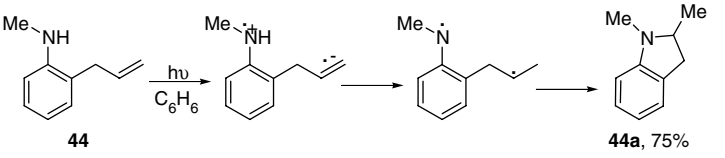


SCHEME 25

(0°C) is necessary for the photochemical reaction to compete with thermal Michael addition. The mechanism of the reaction is presumed to involve ET-sensitized addition to yield β-aminoesters, followed by thermal cyclization to yield the lactams. The use of acrylonitrile in place of methyl acrylate affords more complex product mixtures, resulting from trapping of the intermediate radical adducts by acrylonitrile.



SCHEME 26



SCHEME 27

7.5 Additions of Unactivated Alkenes and Fullerenes with Amines

There have been relatively few reports of photochemical addition reactions of unactivated alkenes with amines, under either conditions of direct irradiation or ET sensitization. Direct irradiation of the *o*-allylaniline **44** is reported to yield the indoline **44a** (Scheme 27).[54] Electron transfer from singlet aniline to the ground state alkene followed by NH proton transfer would yield the biradical precursor of **44a**. Similar intramolecular addition reactions occur for the *N*-phenyl and primary anilines. Intramolecular aniline–alkene addition is not observed for *N*-phenyl-5-hexene-1-amine.[32]

Intramolecular addition of unactivated alkenes and α-silylamines can be sensitized by DCN.[55] For example, irradiation of **45** or **46** results in regioselective formation of the adduct **45a** or **46a** (Scheme 28). The addition reaction is proposed to occur via cyclization of the α-silylmethyl radical cation prior to desilaytion, on the basis of the absence of products expected from the aminoalkyl radical intermediate.

Direct irradiation of [60]fullerene **47** in the presence of trimethylamine is reported to yield the adducts **47a** and **47b** as primary and secondary products (Scheme 29).[56,57] Only small amounts of these adducts are isolated from complex product mixtures. Formation of **47a** is proposed to occur via an electron transfer, proton transfer, radical coupling mechanism similar to that for addition of stilbene and trialkylamines.[56] Formation of **47b** is found to require oxidation of **47a** by singlet fullerene. Direct irradiation of **47** with dimethylamine in the presence of air is reported to result in the formation of the tetra(amino)fullerene epoxide **47c** (Scheme 29).[58] Isolated yields as high as 98% are reported for the reaction of *N*-methylpiperazine. More hindered secondary amines such as Et_2NH and primary amines fail to undergo this extraordinary reaction.

7.6 Concluding Remarks

The photochemical addition reactions of amines to alkenes have provided a remarkably fertile area for synthetic and mechanistic investigations for over three decades. Each decade has brought the discovery of significant new reactions. Much of the body of work described in this review now appears to be complete, including the authors' own work on stilbene–amine and styrene–amine reactions. Thus, as we pause to take stock of what has been accomplished, we look forward to discoveries of new reactions and mechanistic insights.

8.1 Introduction and Definition of the Reaction

The active species in Type II photooxygenation reactions is molecular oxygen in its first excited singlet state, as already postulated by Kautsky et al.[1] This has been unambiguously proven by the elegant experiments performed by Foote et al., in which reactions of photochemically generated singlet molecular oxygen were compared with the corresponding reactions of the active oxygen formed in the hypochlorite/hydrogen peroxide system.[2] The results from these allylic oxidations with singlet molecular oxygen ($^1O_2$) are clearly different from those of autoxidative (triplet oxygen) pathways.[3] Several reaction modes of $^1O_2$ with unsaturated organic molecules are known ([4 + 2]- and [2 + 2]-cycloaddition, ene and silyl-ene-reaction, physical quenching) and have been summarized in excellent reviews.[4] For the allylic activation of CC double bonds in the presence of allylic hydrogen atoms, the ene-reaction is the most prominent path. G.O. Schenck first described the reaction in a patient in 1943, and hence it is known as the Schenck reaction.[5] In the course of this reaction, $^1O_2$ attacks one center of a CC double bond with abstraction of an allylic hydrogen atom or an allylic silyl group (bound to oxygen) and simultaneous allylic shift of the double bond. As the result of this reaction, allylic hydroperoxides or O-silylated α-hydroperoxy carbonyl compounds are formed.

8.2 Mechanism of the Singlet Oxygen Ene-Reaction

Theoretical Models

In the last 20 years, several mechanisms have been postulated for this reaction with concerted or "concerted two-stage" mechanisms,[6] as well as 1,4-biradicals,[7] 1,4-zwitterions,[8] or perepoxides[9] as intermediates. A series of semiempirical and *ab initio* calculations has been published, but the exact mechanism of this reaction type is still doubtful.[10] The suprafacial reaction course (see Section 8.4), the lack of

0-8493-1348-1/04/$0.00+$1.50

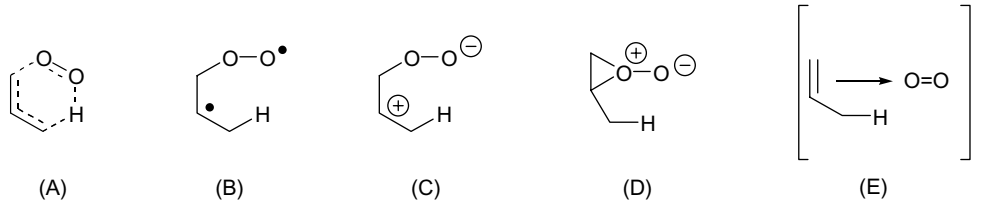

FIGURE 8.1

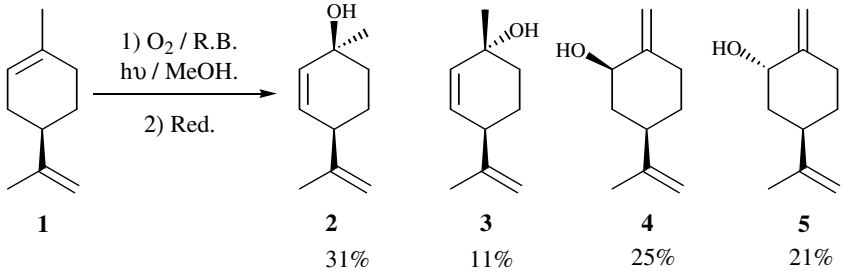
Markovnikov effects, and the results of Stephenson's intramolecular and intermolecular isotope effect test[11] provide evidence for the formation of the perepoxide D (first proposed by Sharp in 1960)[12] or a similar enophile–substrate encounter complex (exciplex E) as intermediate (Figure 8.1). In a recent report by Leach and Houk, the ene-reaction of singlet oxygen with alkenes is described to proceed "through a highly asynchronous concerted mechanism, involving regions of the potential surface with both perepoxide and polarized biradical character. Although both biradical and perepoxide intermediates can be located on the potential energy surface, both are bypassed by way of a valley ridge inflection, and the reaction is concerted."[13]

Experimental Conditions

Singlet molecular oxygen ($^1O_2$) may be generated by several methods.[14] From an experimental point of view, however, the most convenient process is the photochemical route. Photosensitization is advantageous because of its flexibility in regard to reaction temperature, solvent, sensitizer, and light source. In solution, $^1O_2$ is efficiently deactivated not only by chemical reactions with appropriate acceptor molecules but also physically by the solvent and the sensitizer and in many cases even by the acceptor itself. Therefore, $^1O_2$ has to be generated repeatedly, and only photosensitization can do this. Nevertheless, selectivity problems arise from incorrectly chosen parameters such as solvent and sensitizer, because competing reaction modes ("physical" quenching, electron-transfer reactions, cycloadditions) are influenced differently by the solvent polarity and the nature of the sensitizer.[15] The lifetime of $^1O_2$ is also very sensitive to changes of the solvent structure.[16] An additional problem comes from changing the type of the oxygen activation, i.e., "type II" and "type III." When powerful electron acceptors such as 9,10-dicyanoanthracene (DCA) or methylene blue (MB) are used as sensitizers, a photoinitiated electron-transfer processes may be initiated, which may lead to a different reactivity and product pattern.[17] In many cases, the superoxide anion radical, which is also produced from singlet oxygen, is important in these reactions. The solvent polarity again plays an extremely important role in these "polar reactions."[18] For $^1O_2$-selective reactions, some experimental rules should be considered (these considerations are also valid for [4 + 2]- and [2 + 2]-cycloadditions of singlet oxygen):

- Nonpolar solvents (halogenated, at best fluorinated hydrocarbons) suppress electron transfer and increase the lifetime of singlet oxygen. In polar solvents, [2 + 2]-cycloadditions are considerably faster than in nonpolar solvents.
- Weak electron acceptors [tetraphenylporphyrin (TPP), metalloporphyrins, haematoporphyrin (HP)] with low triplet energies [MB: 33.5; TPP: 34.0; HP: 37.2; RB: 39.2–42.2 kcal/mol][19] should be used as sensitizers. Octachlorinated TPP has been reported as a superior sensitizer and shows largely improved turnover numbers.[20] The use of Rose Bengal (RB) is advantageous in polar solvents, but in some cases even RB may undergo electron-transfer photooxygenations.[21] Methylene Blue (MB) should be avoided due to competing electron transfer. Recently, fullerenes have been described as excellent sensitizers for singlet oxygen formation,[22] and so has lumiflavin (LF).[23]
- Long-wavelength light should be used ($\lambda > 400$ nm). If high-pressure mercury lamps are utilized, filters should be employed to exclude high-energy UV light.[24] Medium-pressure mercury lamps and tungsten lamps[25] have also been applied without the need of filters. Sodium (street) lamps are most convenient and inexpensive.



SCHEME 1

- In most cases, only a little activation energy is necessary for the described transformations (1–5 kcal/mol),[26] which accounts for the insensitivity of the rates of singlet-oxygen photooxygenations to reaction temperature, i.e., the reactions may be also carried out at low temperatures (in order to circumvent secondary reactions of the peroxidic products).
- (+)-Limonene (**1**) is a singlet-oxygen acceptor with a very characteristic pattern of regioisomeric and stereoisomeric allylic hydroperoxides **2–5** as products (Scheme 1). Under autoxidative conditions, this pattern is changed completely, and additional products without allylic shift of the CC double bond are formed.[27]
- The regio- and stereoselectivity of a particular transformation should be determined directly at the stage of the peroxidic product. A number of examples are known in which further transformations (reduction, rearrangement, cleavage) change the regioisomeric as well as the stereoisomeric composition of the products.
- Addition of radical-scavenging reagents, e.g., 2,6-di-*t*-butylphenol, inhibits radical autoxidation reactions[28] but does not alter the singlet oxygen reaction. As a test for the involvement of singlet oxygen, an efficient quencher such as DABCO (1,4-diazabicyclo[2.2.2]octane) may be added.[29]

8.3 Selectivity

Chemoselectivity

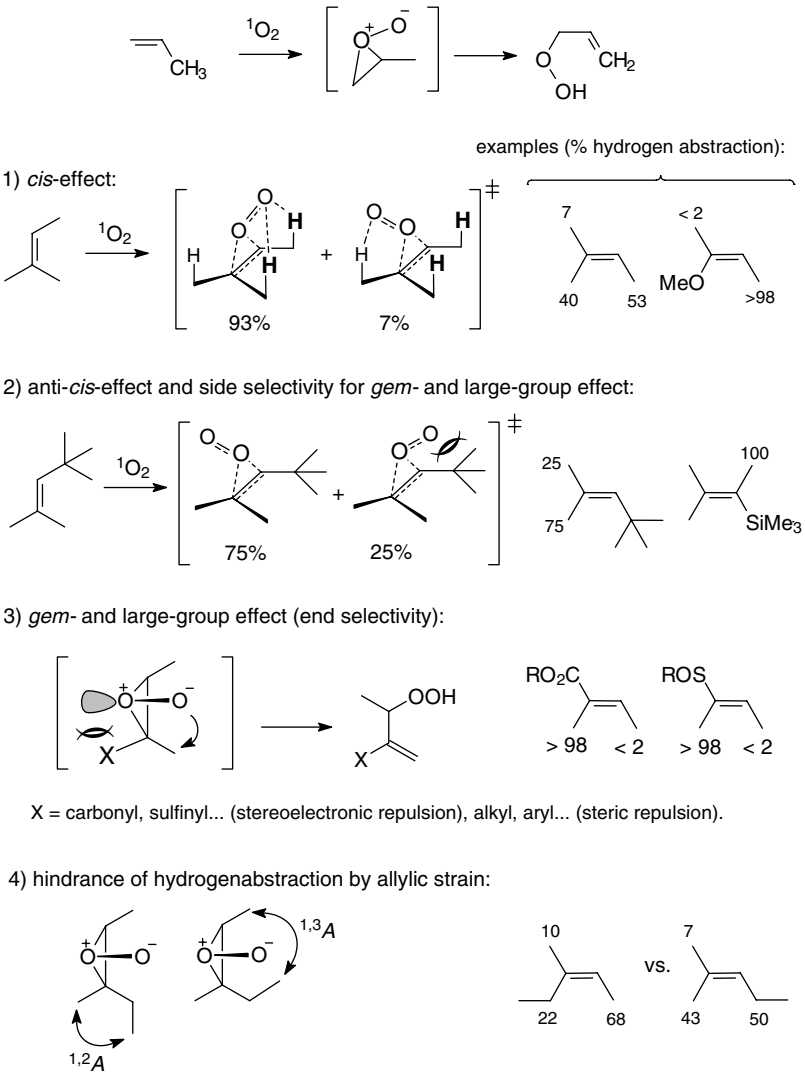
Electron-rich monoalkenes interact with singlet oxygen in three ways: physical quenching, [2 + 2]-cycloaddition, and ene-reaction. Which reaction mode dominates depends on the ionization potential of the double bond, the appropriate alignment of allylic hydrogens, and the polarity of the solvent.[30] Methyl-substituted acyclic enol ethers, for example, give ene products in a multitude of solvents,[31] whereas the corresponding cyclic enol ethers (2,3-dihydrofurans) give mixtures of allylic hydroperoxides (ene products) and 1,2-dioxetanes ([2 + 2]-cycloaddition) with notable solvent dependency.[32] While the photooxygenation of alkenyl arenes within thionin-supported zeolite Na-Y surprisingly afforded the ene products in a highly chemoselective manner, these ene products were less favored compared to [4 + 2]- and [2 + 2]-cycloadducts when the reaction was carried out in solution.[33]

Locoselectivity

In polyolefins, the locoselectivity of singlet-oxygen ene-reactions may be predicted by considering the ionization potentials of the corresponding model monoolefins.[34] Steric and electronic effects operate, moderating the reactivity of the double bond or influencing the trajectory of the incoming enophile. As a rule of thumb, each additional alkyl group increases the ene-reactivity by a factor of about 10 to 20.[35]

Regioselectivity

Alkenes with different allylic hydrogens may yield various regioisomeric products on reaction with singlet oxygen. For controlling the regioselectivity of such allylic oxidations by $^1O_2$, several general effects are



SCHEME 2

known that help in designing appropriate compounds for the regioselective introduction of hydroperoxy groups: the *cis* (or *syn*) effect, the *gem* effect, and the large-group effect (Scheme 2)**.**

The *cis* (or *syn*) effect promotes highly selective hydrogen abstraction from the higher substituted *side* of a trisubstituted CC double bond, when both substituents bear allylic hydrogens (*twix* and *lone*)[36] or one substituent is alkoxy (*lone*).[37] The *gem* effect leads to highly selective abstraction of an allylic hydrogen from a substituent at the α position of an α,β-unsaturated carbonyl compound (*twix*).[38] The large-group effect leads to selective (moderate) abstraction of an allylic hydrogen from the substituent with a large group at the same carbon atom of the CC double bond.[39] For example, a R_3Si substituent at the *twin* site of the CC double bond directs singlet oxygen towards the geminal position (*twix*).[40] The termini *twix*, *twin,* and *lone* are defined as follows: attention is focused on the central alkyl substituent, which is defined as the *twixt* group (R_{twix}, for simplification the last "t" has been dropped); "*twixt*" comes from old English and means "between," i.e., R_{twix} is between a geminal and a vicinal alkyl group. The other geminal substituent is then designated as the *twin* group (R_{twin}) and the remaining vicinal substituent as the *lone* group (R_{lone}).

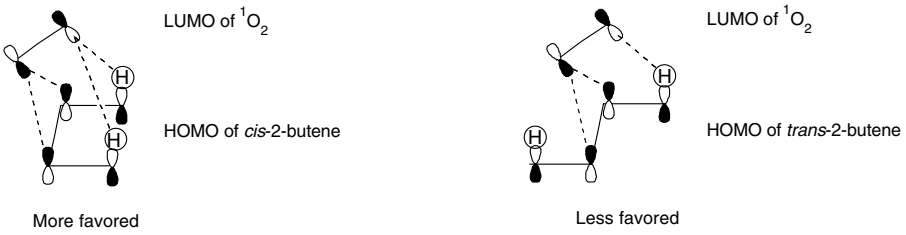


FIGURE 8.2

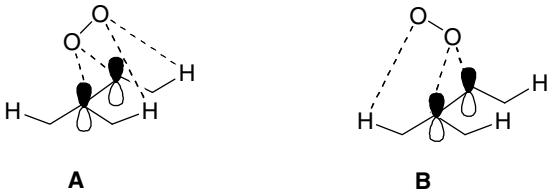

FIGURE 8.3

Two detailed reviews have covered the regioselectivity in the singlet-oxygen ene-reaction.[41]

Analogies to the ene reaction of triazolinedione and nitrosoarene are helpful to understand the steric and electronic effects, which control the regioselectivity.[42] The mechanistic rationalization is not simple, since the regioselection occurs at different stages of the reaction. In the first step, namely the formation of the three-membered ring structure, the side of the double bond for hydrogen abstraction is determined. Here, the *cis* as well as anti-*cis* effects[43] and the side selectivity for the *gem* or the large-group effect operate. Once the enophile is fixed in the perepoxide-type geometry and points to one side of the double bond, there is a second choice between the *cis*-positioned allylic hydrogens for abstraction. The steric or stereoelectronic response of a substituent X weakens the C(1)-O^+ bond and pushes the free electron pair of O^+ towards the unsubstituted corner of the double bond, which results in a *skew* line arrangement of the enophile toward the double bond · to afford the major product by hydrogen abstraction at the geminal substituent (*vide infra*). Another steering effect is the hindrance of hydrogen abstraction. When the CH bond assumes a conformation perpendicular to the double bond for abstraction, unfavorable allylic strain may build up, which favors abstraction at the other *cis*-positioned substituent.

The different effects are now discussed separately in detail.

Several models have been proposed to explain the *cis* effect: in one of these Houk and co-workers[44] postulated that the lower the rotational barrier of a specific alkyl group at the double bond, the higher the reactivity of this group toward hydrogen abstraction by singlet oxygen. The respective hydrogen atoms adopt more readily the favored perpendicular conformation with respect to the double bond; however, several recent results contradict this computational analysis.[45] Stephenson suggested that orbital interaction between the HOMO of the olefin and the LUMO of singlet oxygen stabilizes the transition state for the perepoxide-like exciplex formation.[46] This interaction is favored in the case of *cis*-2-butene, in which the allylic σ orbitals and the HOMO of the olefin generate a system similar to π_3 of butadiene; hence, the ene-reaction of singlet oxygen with *trans*-2-butene is less favorable (Figure 8.2).

Frimer and Barlett et al.[47,48] assumed that the formation of the CO bond requires a closer approach to the alkene carbons compared to the CH bond cleavage; consequently, transition state **A** is less hindered and energetically preferred relative to transition state **B** (Figure 8.3).

The fact that singlet oxygen ene-reactions with *cis*-olefins have less negative activation entropies and about 2–8 times larger reaction rates (e.g., for *cis*-2-butene: $\Delta S^{\#} = -32$ e.u., $\Delta H^{\#} = 1.6$ kcal/mol; for *trans*-2-butene: $\Delta S^{\#} = -42$ e.u., $\Delta H^{\#} = 0.3$ kcal/mol) than with *trans*-olefins implies that the transition states

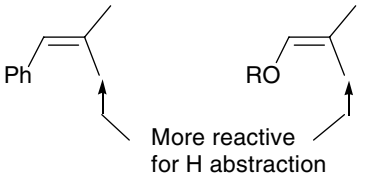

FIGURE 8.4

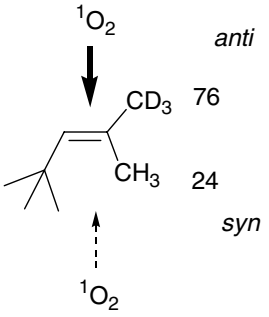

FIGURE 8.5

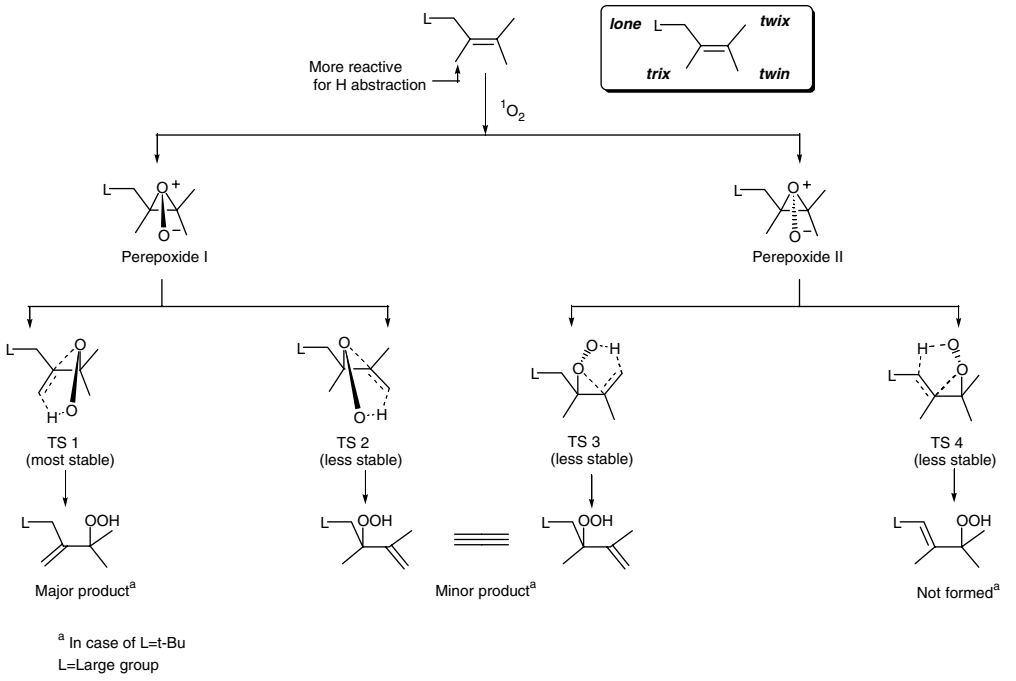
for the ene-reaction are "more organized" or further along the reaction coordinate for *trans*-olefins than it is for *cis*-olefins. The possibility for simultaneous interaction of $^1O_2$ with two allylic hydrogens in *cis*-olefins reduces the activation entropy.[49,50] In conclusion, the simultaneous interaction between singlet oxygen and two allylic hydrogen atoms on the more substituted side of the double bond stabilizes the transition state that leads to the perepoxide-like exciplex, and abstraction of these hydrogens is favored.

In analogy, trisubstituted styrenes and enol ethers exhibit similar *cis* effects (*syn* effect or *syn* selectivity), resulting from the simultaneous interaction of the incoming singlet oxygen with one allylic hydrogen and either a phenyl or an alkoxy group, which stabilizes the transition state for the perepoxide-like structure (Figure 8.4).

The regioselectivity that results from the large-group nonbonded interaction may be rationalized in the case of trisubstituted alkenes with bulky *cis*-alkyl groups;[51] the steric repulsion between singlet oxygen and the bulky group directs the enophilic attack. The absence of the stabilizing interaction of singlet oxygen with the allylic hydrogen atoms on the same side of the double bond in the transition state additionally accounts for the observed anti-*cis* effect with abstraction of the hydrogen atom at the *lone* site (Figure 8.5).

Hydrogen abstraction from the alkyl group geminal to the bulky vinylic or allylic substituent in alkenes may be rationalized by repulsive large-group nonbonded steric interactions between the O^+ atom in the perepoxide-like structure and the large-group at the *lone* site (Scheme 3). Consequently, the CO bond next to the bulky substituent (*lone* site) is lengthened and thereby weakened in comparison to the CO bond at the less substituted end of the alkene. Since hydrogen abstraction at the "large group" is hindered by allylic strain, hydrogen abstraction is preferred from the alkyl group geminal to the bulky substituent (*trix*).[52–54]

The geminal regioselectivity is also observed for alkenes with carbonyl groups (carboxylic acids,[55] aldehydes,[56] ketones,[57] amides,[58] or esters[59]) and other functionalities at the α position (Figure 8.6) (cyano, sulfinyl,[60] iminyl,[61] silyl,[62] or stannyl[63] groups). This is rationalized in terms of the 1,3-nonbonding interaction already used to explain the large-group effect; additionally, a resonance effect is proposed that stabilizes the transition state that leads to the conjugated products. Stereoelectronic effects were used to explain the geminal selectivity observed for vinylsilanes and vinylstannanes.[64]



SCHEME 3

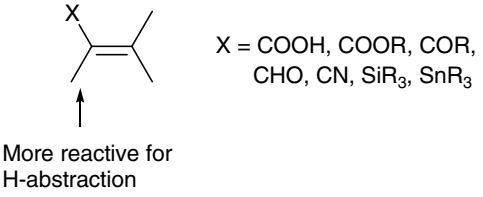


FIGURE 8.6

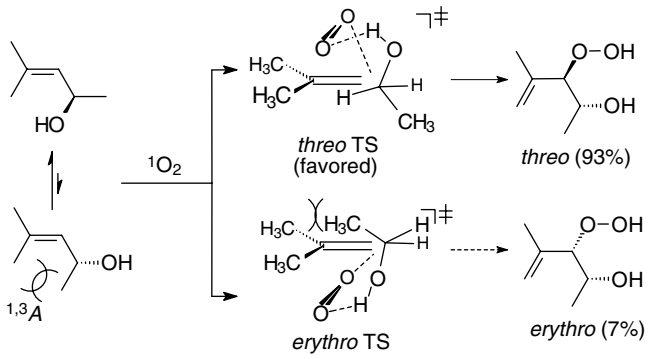
Stereoselectivity

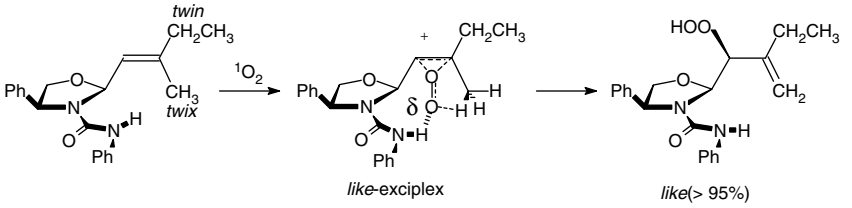
The stereoselectivity of the singlet oxygen ene-reaction has been investigated in detail in the last decade.[41b,65] The singlet oxygen attacks in a suprafacial process, and hydrogen abstraction occurs from the same π face of the olefinic double bond.[66] In principle, there are two means for stereoselectivity control, namely steric as well as stereoelectronic and electronic (hydrogen bonding) interactions, both of which direct the incoming enophile to one π-face of the double bond. In view of the small size of the singlet-oxygen enophile, the electronic influence is more effective. Remarkable steering effects of the diastereoselectivity for the ene-reaction were discovered with chiral allylic alcohols (Scheme 4).[67]

The hydroxy group is conformationally aligned by 1,3-allylic strain, and hydrogen bonding coordinates the incoming enophile with preferential formation of the *threo*-configured ene product. By the use of chiral auxiliaries, which also coordinate the singlet oxygen through hydrogen bonding, diastereomerically pure, optically active hydroperoxides or alcohols may be synthesized.[68] As shown in Scheme 5, the coordination through hydrogen bonding may also control the regioselectivity.

For the ene-reaction of tiglic acid derivative **6** (Figure 8.7), a low diastereoselectivity was achieved even at –60°C (*de* 64%). The naphthyl group aligns parallel and next to the tiglate ester group and hence, one of the alkene diastereotopic faces is shielded.[69] From the tiglic amides **7**, no diastereoselectivity control



SCHEME 4



SCHEME 5

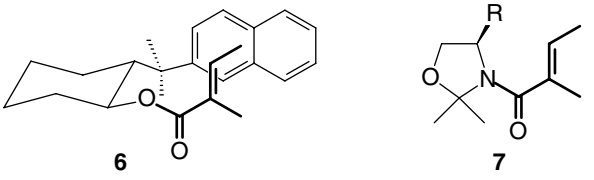


FIGURE 8.7

was achieved with $^1O_2$, although these substrates react with triazolinedione to afford one diastereoisomer.[70]

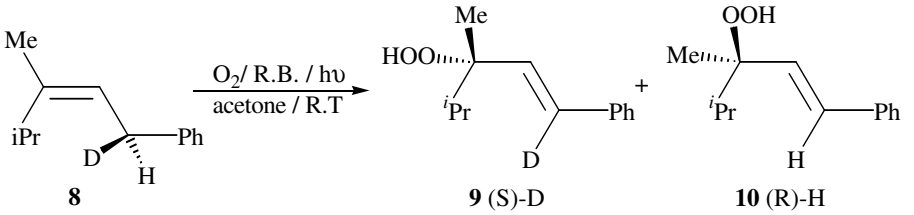
8.4 Substrates for Ene-Reactions

Acyclic Substrates

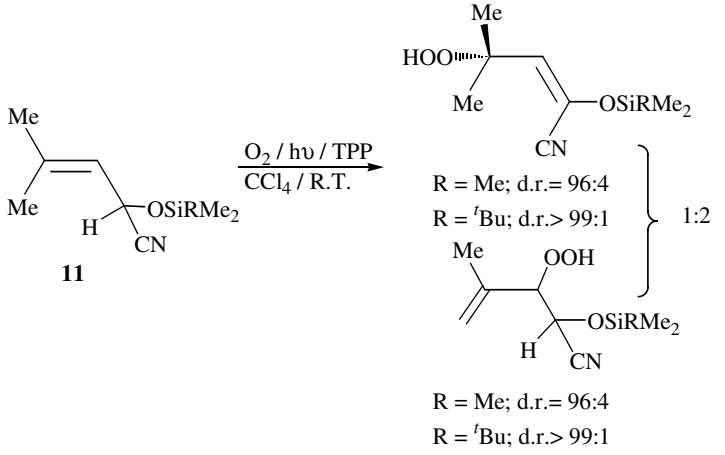
Alkenes and Alkadienes

Stephenson et al. have shown, with optically active monodeuterated olefin **8**, that the ene-reaction is a highly stereoselective suprafacial process in which the proper arrangement of the allylic hydrogens controls the stereochemical course.[71] In the model reaction with the stereolabeled substrate **8**, no isotope discrimination was found: the allylic hydroperoxide **7** with (R)-configuration and deuterium migration was formed in equal amounts as the corresponding (S)-hydroperoxide **10** with hydrogen migration (Scheme 6).

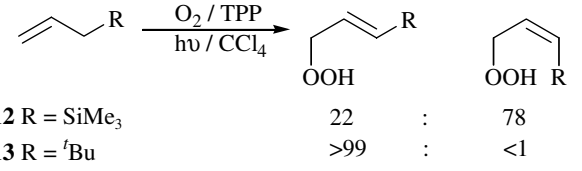
Similar results were obtained in the photooxygenation of silyl cyanohydrins of α,β-unsaturated aldehydes.[56] The trimethylsilyl and *t*-butyldimethylsilyl cyanohydrins of senecioaldehyde **11** react with low regioselectivity (because of the *cis*-effect) but high diastereoselectivity (Scheme 7). In both cases, the two



SCHEME 6



SCHEME 7

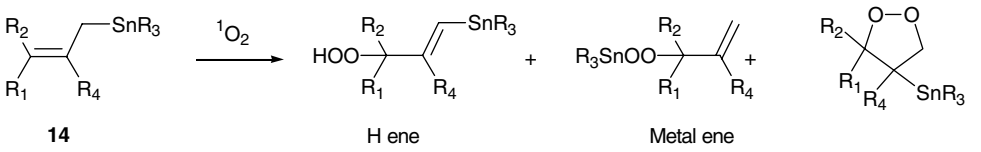


SCHEME 8

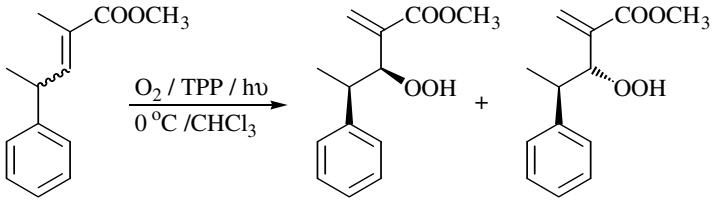
regioisomeric allylic hydroperoxides were formed with identical diastereomeric ratios, which clearly demonstrates the necessity for a common symmetrical intermediate, presumably with perepoxide-type geometry. The relative configuration of the photooxygenation products, to assess the π-facial preference, was not determined.

Shimizu et al. have shown that certain allylsilanes react with singlet oxygen *Z*-selectively.[72] They compared the reaction of allyltrimethylsilane **12** (d.r. = 22.78) with that of the corresponding hydrocarbon, 3-*tert*-butyl-1-propene **13**, for which a diastereomeric ratio of >99:1 in favor of the *trans*-diastereomer was found (Scheme 8).

Kropf and Reichwaldt have investigated chiral trisubstituted monoalkenes.[73] Diastereomeric ratios from 1:4.4 to 1:5.3 (*threo:erythro*) were obtained. In one case, two regioisomeric products were formed with identical d.r. values, which again validates that a stereoselective, suprafacial mechanism applies. Dang and Davies[74–77] have reported that the reaction of singlet oxygen with allylic stannanes **14** affords metal-ene, hydrogen-ene, and cycloaddition products (Scheme 9). The amount of the metal-ene product may be enhanced by using substrates with electropositive tin centers (attached to electron withdrawing groups).



SCHEME 9



SCHEME 10

α,β-Unsaturated Carbonyl Compounds and Derivatives

The photooxygenation of α,β-unsaturated esters **15** with a stereogenic center at the γ–position leads to allylic hydroperoxides with > 99% regiocontrol ("*gem* effect" operates) and the preferred formation of the R*S* (unlike, *ul*)-products (Scheme 10).[78]

The diastereoselectivity was modest (d.r. = 65:35) when the *Z*-**15** substrate was used and substantial (d.r. = 80:20) for the *E*-**15** diastereomer, which again demonstrates the importance of secondary orbital effects as postulated in the perepoxide mechanism. For chiral allylic alcohols, a remarkably high diastereoselectivity for acyclic substrates was obtained,[79] called the "hydroxy-directing" effect, in which the incoming singlet oxygen is associated with the allylic hydroxy group through hydrogen bonding. A large number of substrates with a variety of allylic substituents have been investigated and classified as either having attractive (as OH, NH_2, $^+NH_3$) or repulsive (HNAc, HNBoc, *t*-Bu, Cl^-) interactions with the pendant oxygen atom in the perepoxide-like structure.[80] Substituents with attractive interactions (H-bonding) direct *threo*-selectively whereas those with repulsive interactions (steric or electrostatic) direct *erythro*-selectively.[81]

Cycloalkenes

Exocyclic CC Double Bonds

The diastereofacial differentiation in *exo*-alkylidenenorbornenes was investigated for 2-ethylidenebicyclo[2.2.1]hept-5-ene (**16**).[82] The *exo*- and *endo*-2-hydroxy-2-vinylnorborn-5-enes **17** and **18** were formed as main products in a 35:12 ratio with the regioisomeric 2-(1-hydroxyethyl)-norbornadiene **19** (23%) as a third component; traces of two ketones could be detected as secondary products (Scheme 11).

Schmid and Hofheinz described an important application of this reaction to the total synthesis of the antimalarial drug artemisinin.[83] The key step in the (–)-isopulegol-based synthesis is the ene-reaction of singlet oxygen with an enol ether (Scheme 12). This reaction leads to an allylic hydroperoxide **20** when the reaction is performed in the nonpolar solvent, CH_2Cl_2. The use of the more polar, protic methanol inverts the regioselectivity, and the α-hydroperoxy acetal **21** is formed (presumably by trapping of an intermediary 1,4-zwitterion), which is cyclized to the target molecule **22** by acid catalysis.

The photooxygenation of 7-isopropylidinenorbornene discloses a preference for the attack of singlet oxygen on the *anti* face of the isopropylidine double bond (Scheme 13).[84] The stereoselectivity for a series of 7-isopropylidinebenzonorbornenes[85,86] was found to be sensitive to the electronic properties of the

22

SCHEME 12

annulated arene ring, which suggests an anchimeric assistance through π–electron donation from the aryl ring to the perepoxide-like structure.

Endocyclic CC Double Bonds

When 2-substituted (methyl or trimethylsiloxy) norborn-2-enes and 1,7,7-trimethylnorborn-2-enes are treated with $^1O_2$, ene products are formed efficiently.[87] In case of the trimethylsiloxy-substituted derivative **23**, migration of the trimethylsilyl group occurs, and O-silylated α-hydroperoxy ketones **24**, which are readily reduced to O-silylated α-hydroxy ketones **25** (Scheme 14) are isolated. High *exo* selectivity is observed for the 7,7-unsubstituted substrates and *endo* selectivity for the 7,7-dimethyl ones. The steric demand seems to be higher for the silyl-ene reaction, for which *endo/exo* ratios from 0:100 to 94:6 were observed, whereas 2-methylnorborn-2-ene shows a 98.5:1.5 *exo* diastereoselectivity.[88]

Anellation of cyclopropane rings to cycloalkenes alters the ground-state geometry of the ring system, which may lead to considerable diastereotopic differentiation in the ene-reaction when singlet oxygen attacks the CC double bond. Several model systems were tested by Paquette and co-workers.[89] The photooxygenation of cholesterol (**26**) and cholest-5-en-3-one (**27**) has been investigated in detail by

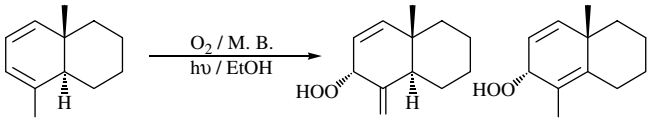
Schenck and Davies[90] (Scheme 15). While the reaction of $^1O_2$ with **26** results exclusively in the 5α-hydroperoxy product **28**, **26** gives a complex mixture with the hemiperketal **29** as major product from 5α-attack.

exo-Methylene functionalities may readily be generated from the corresponding substrates with endocyclic double bonds when allowed to react with singlet oxygen.[91] This is an important application because the stereochemistry of the newly formed chirality center is perfectly controlled, and the resulting products are synthetically valuable. Since bridgehead hydrogens cannot be abstracted, these ene-reactions are also highly regioselective. Ene-reactions with bicyclic systems are not limited to monoolefins; 1,3 dienes with suitable stereogenic centers react in this fashion, as shown for the photooxygenation of hexahydronaphthalene **30**. No [4 + 2]-cycloadducts were found in the reaction of the diene **30** with $^1O_2$



30 10-15% 85-90%

SCHEME 16

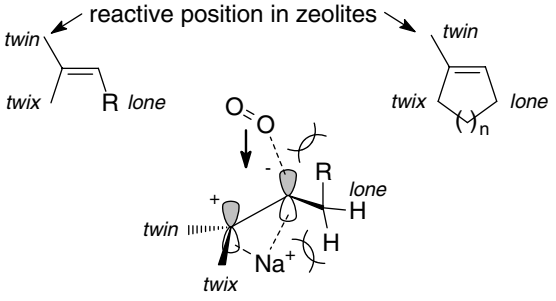


FIGURE 8.8

(Scheme 16). As major product, the allylic hydroperoxide from bridgehead-hydrogen abstraction was isolated.[92]

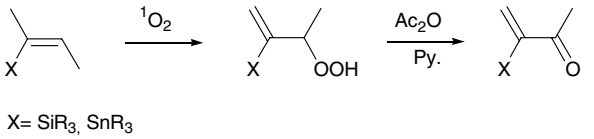
8.5 Photooxygenation in Zeolites

In 1996, Li and Ramamurthy reported the use of zeolites to enhance the regioselectivity in the $^1O_2$ ene-reaction.[93] In contrast to the reaction in solution, in which the *cis* effect applies,[26] a remarkable *twin* selectivity is observed in zeolites.[94] This was mechanistically rationalized in terms of coordination of the double bond to the Na^+ ion in the zeolite (cation-π interaction), which polarizes the double bond for Markovnikov selectivity and induces conformational constraint in the allylic *cis* substituents (Figure 8.8). The latter effect disfavors sterically the formation of the *cis* perepoxide-like structure or prevents a perpendicular orientation of the *cis*-hydrogens for coordination and abstraction.[93,95] Complications may arise from the formation of tertiary hydroperoxides from *lone*-hydrogen abstraction, which may selectively decompose on prolonged irradiation; this falsifies the regioselectivity.[96]

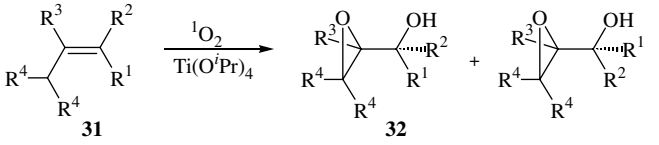
Furthermore, an increase in asymmetric induction, in cases where the stereogenic center in the substrate resides at remote positions with respect to the double bond, can also be observed within the zeolite cavity.[97] A thorough experimental reexamination and mechanistic interpretation have recently been published.[41b]

8.6 Further Transformations of Ene Products

Allylic hydroperoxides are easily reduced with a variety of reducing agents, of which sodium sulfite or sodium iodide are convenient for substrates that are not sensitive to water and further oxidation. For more sensitive hydroperoxides, dialkyl or aryl alkyl sulfides in organic solvents may be used. Triphenylphosphine and triethyl- or triphenylphosphite also have been employed successfully. These reductions all preserve the configuration at the hydroperoxy-substituted carbon atom. The resulting allylic alcohols are valuable building blocks for organic synthesis. The compounds obtained may be transformed to a multitude of highly useful target molecules. An efficient synthetic access to epoxy alcohols is the "one-pot" synthesis of epoxy alcohols in the photooxygenation of alkenes **31** in the presence of transition-metal complexes derived from Ti, V, and Mo (Scheme 17).[98]



SCHEME 18



SCHEME 17

The products are formed in good chemical yields and high diastereoselectivity, analogous to the Sharpless-method; from acyclic substrates, R*S* (unlike, *ul*)-products **32** were formed preferentially. The allylic hydroperoxides obtained from the photooxygenation of vinylic silanes or stannanes are readily dehydrated to α,β-unsaturated carbonyl products with a silyl or stannyl group at the α carbon (Scheme 18).

Two carbonyl fragments could also be formed on acid-catalyzed hydrolysis of the allylic hydroperoxides that mostly proceeds through Hock-type fragmentation. Allylic alcohols obtained by reduction of the corresponding allylic hydroperoxides are versatile building blocks with diverse synthetic utility;[99] they could also be either regioselectively dehydrated to 1,3-dienes[100] or oxidized to α,β-unsaturated ketones.[101] The ene-reaction was also utilized in the synthesis of some natural products[102] and diastereoselective allene derivatives.[103]

Photoreactions of Alkenes in Protic Media

Paul J. Kropp
University of North Carolina

9.1 Photochemical Behavior

Principal Pathways

On sensitized irradiation, alkenes undergo principally *E,Z*-isomerization, unless it is structurally inhibited. In weakly protic media, the highly strained *E*-isomers arising from cyclohexenes, cycloheptenes, and cyclooctenes undergo protonation. Similar behavior is exhibited on direct irradiation. In addition, on direct irradiation styrenes undergo protonation whether they are cyclic or acyclic, and alkenes undergo nucleophilic trapping in hydroxylic solvents to afford alcohols or ethers. This chapter is concerned principally with this latter process, as well as photoprotonation of cycloalkenes. Emphasis is given to developments since the topic was reviewed extensively in 1979.[1] The photobehavior of alkenes on direct irradiation in nonhydroxylic media is discussed in Chapter 13.

Spectroscopic Properties

The ultraviolet absorption spectra of simple alkenes in solution typically consist of single, featureless bands with maxima at 185–195 nm ($\varepsilon = 5\text{–}10 \times 10^3$) and tails extending to 210–255 nm.[2] Absorption extends to longer wavelengths with increasing degrees of substitution. Hydroxylic solvents, which are frequently used as proton sources, have cutoffs at 205–210 nm. Highly substituted alkenes can be irradiated in such media with medium-pressure mercury lamps and quartz optics, but less highly substituted alkenes do not absorb light under these conditions. Since alkenes do not undergo intersystem crossing, sensitized irradiation is required to induce triplet photobehavior. Best results are obtained using aromatic sensitizers such as *p*-xylene or phenol, which have maximum absorption in the region 250–270 nm. For this either a low- or medium-pressure arc and quartz or Vycor optics can be used. A preparative procedure has been described.[3] Phenol can serve as both the sensitizer and a proton source.[4] It has the added advantage of being easily removed from the irradiation mixture by extraction with base.

In the triplet manifold of alkenes one excited state, $\pi\pi^*$, is clearly low lying, separated from the πR(3s) Rydberg triplet by approximately 2 eV.[5] By contrast, as is detailed in Chapter 13, two or more excited states are low lying and close in energy in the singlet manifold — including the $\pi\pi^*$ and πR(3s) Rydberg states, which do not communicate effectively. Hence, the sensitized photobehavior of alkenes is usually much simpler than that resulting from direct irradiation.

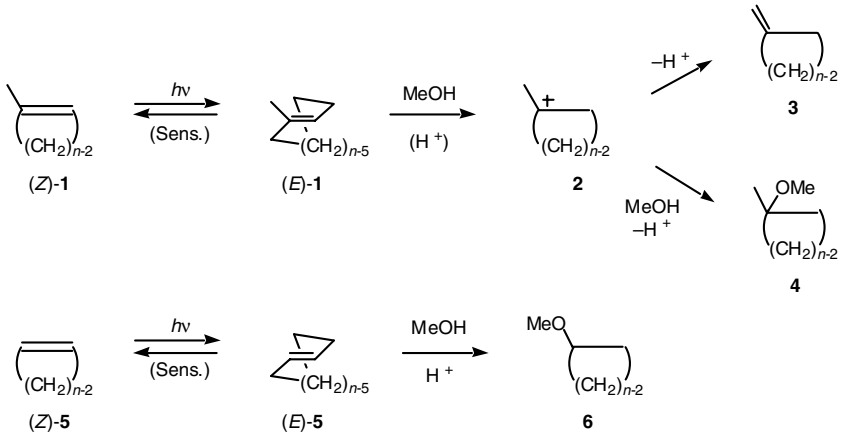
9.2 Examples and Mechanisms

Sensitized Irradiation

On sensitized irradiation, acyclic and large-ring cyclic alkenes having a nine-membered ring or larger undergo only *E,Z*-isomerization, whether in protic or aprotic media.[6] By contrast, sensitized irradiation of cyclohexenes, cycloheptenes, and cyclooctenes in protic media results in photoprotonation.[7] Thus, for example, *p*-xylene-sensitized irradiation of 1-methylcyclohexene [(*Z*)-**1b**] in methanol affords a mixture of the exocyclic isomer **3b** and the ether **4b**.[8] The cycloheptyl and cyclooctyl analogs (*Z*)-**1c** and **-1d** afford principally the corresponding ethers **4c–d**, accompanied by small amounts of the exocyclic isomers **3c–d**. Similar behavior is exhibited by the unsubstituted analogs (*Z*)-**5b–d**, which afford the ethers **6b–d**.



a, *n* = 5; **b**, *n* = 6; **c**, *n* = 7; **d**, *n* = 8

It was proposed that photoprotonation of cyclohexenes, cycloheptenes, and cyclooctenes involves initial formation of the corresponding *E*-isomers, which are much more easily protonated than the starting *Z*-isomers because of the attendant reduction in strain.[6a] A fine balance exists between the reactivity of the *E*-isomers and the acidity of the alcoholic medium. The highly strained and alkyl-substituted *(E)*-1-methylcyclohexene [*(E)*-**1b**] is readily protonated in neutral methanol. However, the higher homologs *(E)*-**1c–d**, as well as the unsubstituted analogs *(E)*-**5b–d**, require the presence of small amounts of mineral acid (e.g., 0.3–0.6% H_2SO_4), conditions under which the *E*-isomers are protonated but the *Z*-isomers are stable.

Cyclooctenes

Substantial support for the proposed formation of (*E*)-cycloalkene intermediates on sensitized irradiation and their involvement in photoprotonation has been obtained. Irradiation of (*Z*)-cyclooctene [(*Z*)-**5d**] with the triplet sensitizers benzene, toluene, or xylene afforded a mixture of the *E*- and *Z*-isomers with a photostationary *E:Z* ratio of 0.05.[9] The use of methyl benzoate as the sensitizer, which involves the formation of a singlet exciplex followed by decay to the twisted $\pi\pi^*$ singlet excited state, gave a higher *E:Z* ratio of 0.36:1.[10] The decay ratio to the *E* vs. *Z* isomer is higher for the singlet than for the triplet-excited state, providing a simple method for the preparation of moderate amounts of the *E*-isomer. The highly strained (*E*)-**5d** was found to undergo acid-catalyzed addition of methanol 3000 times more rapidly than the *Z* isomer.[11]

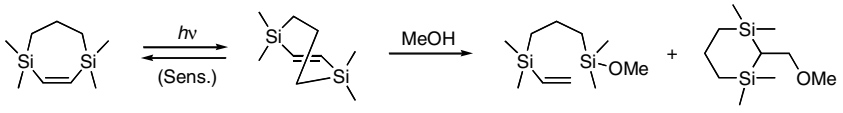
Cycloheptenes

Methyl benzoate sensitized irradiation of (*Z*)-cycloheptene [(*Z*)-**5c**] in neutral methanol at –78°C similarly afforded a mixture of the *E*- and *Z*-isomers with an estimated *E*:*Z* photostationary ratio of 0.25:1.[12] The *E*-isomer is stable in methanol at –78°C but, on being warmed to room temperature in the absence of dioxygen, underwent unimolecular decay to the *Z*-isomer quantitatively with E_a = 17.4 ± 0.7 kcal/mol, $\Delta G^{\ddagger}_{266}$ = 19.4 ± 1.4 kcal/mol, $\Delta H^{\ddagger}_{266}$ = 17.0 ± 0.7 kcal/mol, and $\Delta S^{\ddagger}_{266}$ = –9 ± 8 kcal/K mol. The lifetime in methanol at –10°C was 38.3 min. In the presence of air, isomerization occurs by an alternative mechanism involving a termolecular complex between triplet dioxygen and two molecules of (*E*)-**5c**.[13]

Irradiation of (*Z*)-cycloheptene [(*Z*)-**5c**] in acidic methanol at –78°C afforded ether **6c**. When an irradiation was conducted in neutral methanol and the resulting irradiation mixture allowed to stand in the dark at –78°C for 24 h before the addition of acid, ether **6c** was obtained in a similar yield. This clearly rules out the protonation of an excited state in the formation of ether **6c**. A kinetic study showed that (*E*)-cycloheptene [(*E*)-**5c**] undergoes protonation 7.7 × 10^8 times faster than its *Z*-isomer and 3.3 × 10^5 times faster than its higher homolog, (*E*)-cyclooctene [(*E*)-**5d**].

Generation of (*E*)-cycloheptene [(*E*)-**5c**] by methyl benzoate irradiation has also permitted its ^{1}H NMR and UV spectra to be obtained.[14] The UV maximum is shifted 40–50 nm to the red compared with the *Z*-isomer, suggesting substantial twist about the double bond, but the vinyl proton coupling shows that these atoms have a dihedral angle very close to 180°. Apparently, the vinyl carbon atoms mainly pyramidalize, rather than twist, to accommodate the strained ring.

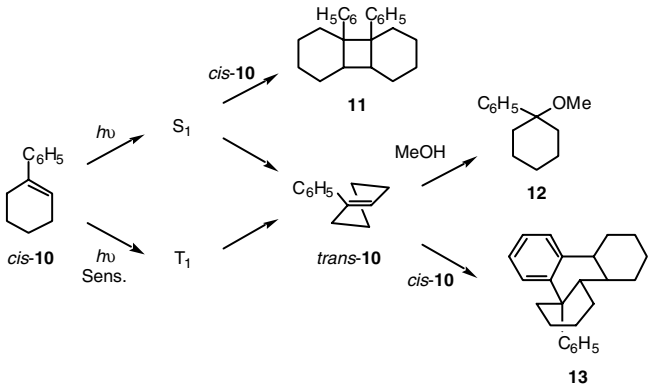
Evidence has also been obtained for the intermediacy of the (*E*)-cycloheptene (*E*)-**7** in the formation of methyl ethers **8** and **9** on direct, *p*-xylene-sensitized and methyl benzoate–sensitized irradiation of the 3,7-disilacycloheptene (*Z*)-**7** in acidified methanol.[15] Sensitized irradiation of (*Z*)-**7** in methylcyclohexane solution at –75°C followed by siphoning of the irradiation mixture into acidified methanol similarly afforded ethers **8** and **9**, showing that a long-lived intermediate is involved. Addition of cyclopentadiene to the cold irradiation mixture in the dark afforded a Diels–Alder adduct shown to have a trans ring juncture.



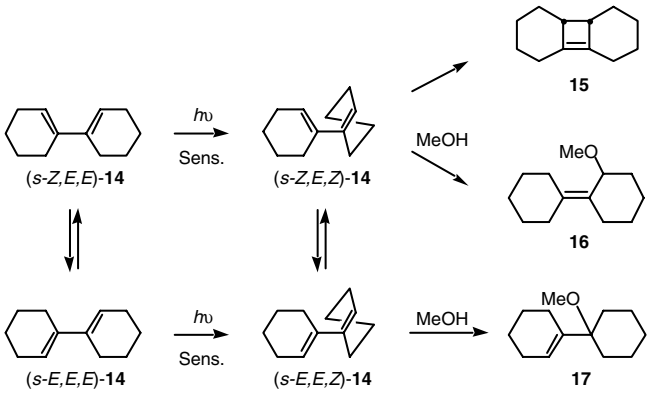
(*Z*)-**7** **8** (*E*)-**7** **9**

Cyclohexenes

Although they have much shorter lifetimes because of their higher strain, a number of (*E*)-cyclohexene derivatives have been observed on direct or photosensitized irradiation of the *Z*-isomers using flash spectroscopic techniques. The first observation of an (*E*)-cyclohexene derivative involved 1-phenylcyclohexene (*cis*-**10**), which afforded a transient having a lifetime of 9 μsec in methanol at 25°C.[16] Either direct or sensitized irradiation in methanol of *cis*-**10** affords the ether **12**.[17] On direct irradiation, a diastereomeric mixture of the cyclobutane dimers **11** is also formed.[18] Kinetic studies showed that ether **12** is formed on direct and sensitized irradiation via a common intermediate having the same lifetime as the spectroscopic transient.[19] The proposed trans stereochemistry for the transient was supported by the finding that direct or sensitized irradiation of *cis*-**10** in neutral methanol at –75°C afforded dimer **13**, which was shown to have a trans juncture by x-ray crystallographic analysis.[20] Time-resolved photoacoustic calorimetry has shown that the enthalpy of isomerization to the highly strained *trans*-isomer is 45 kcal/mol.[21]

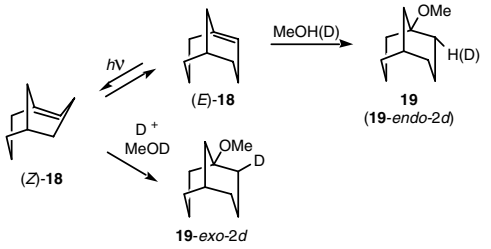


Either direct or triplet-sensitized irradiation of diene (*E,E*)-**14** in methanol affords the *cis*-cyclobutene **15** and the methyl ethers **16** and **17**.[8b,22] Laser flash spectroscopy revealed the formation of a ground-state intermediate having λ_{max} = 360 nm and a lifetime of 0.8 μsec at 23°C in methanol.[22] Based on the change of the quantum yields for the formation of ethers **16** and **17** with E_T for a variety of sensitizers, it was concluded that cyclobutene **15** and ether **16** arise from the *s-Z*-conformation of isomer (*E,Z*)-**14** and ether **17** from the *s-E*-conformation.[23] In view of large deuterium isotope effects, k_H/k_D, of 8 ± 1 and 10 ± 2, that were observed for the formation of ethers **16** and **17**, respectively, in CH_3OD, concerted formation of the CH and CO bonds in the transition states for ether formation was proposed.



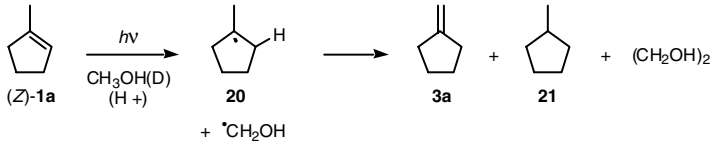
The spectroscopic and kinetic properties of five additional (*E*)-cyclohexene derivatives have recently been determined.[24] The properties of all of the (*E*)-cyclohexene derivatives that have been reported are remarkably constant: the ππ* maxima of the *E*-isomers are generally shifted to the red by about 15,000 cm^{-1} relative to the *Z*-forms; the activation energy for the thermal *E*→*Z* isomerization is about 10 kcal/mol, the corresponding pre-exponential factor is in the range 10^{12}–10^{13} sec^{-1}, and they undergo extremely efficient protonation by acid. *Ab initio* calculations have confirmed that the parent (*E*)-cyclohexene [(*E*)-**5b**] corresponds to a local minimum, although the activation energy for its isomerization to the *Z*-isomer is small.[25]

Support for the involvement of (*E*)-cyclohexenes in photoprotonation has also come from the stereochemistry of protonation.[26] Direct or sensitized irradiation of (*Z*)-bicyclo[3.3.1]non-1-ene [(*Z*)-**18**] in neutral methanol afforded ether **19**.[2a] On irradiation in CH_3OD the labeled ether **19**-*endo*-2*d* was obtained, whereas reaction of (*Z*)-**18** with CH_3OD catalyzed by DCl gave ether **19**-*exo*-2*d*. These results are consistent with preferential protonation of alkenes (*Z*)- and (*E*)-**18** from their less hindered faces. Protonation of (*E*)-**18** was found to have a large kinetic isotope effect, k_H/k_D, of eight, indicating that proton transfer is about half completed in the transition state.



Cyclopentenes

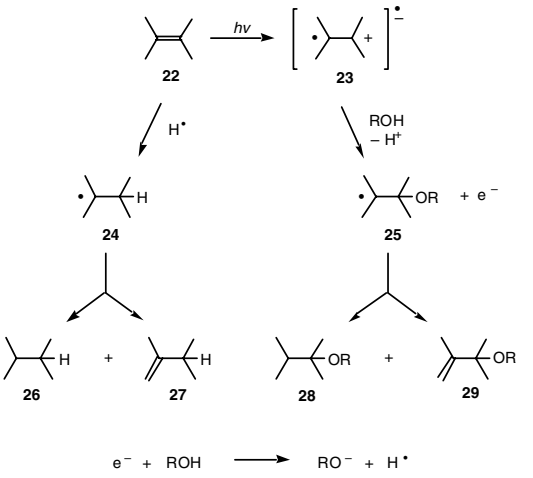
In contrast with their higher homologs, cyclopentenes display no ionic behavior on sensitized irradiation in protic media. For example, sensitized irradiation of 1-methylcyclopentene [(*Z*)-**1a**] in either neutral or acidified methanol affords a mixture of the exocyclic isomer **3a**, the saturated product **21**, and ethane-1,2-diol — as expected from initial abstraction of a hydrogen atom from the solvent by the $\pi\pi^*$ excited state followed by disproportion of the resulting radical **20**.[8] In CH_3OD, the photoproducts **3a** and **21** are formed with no detectable incorporation of deuterium. Thus, cyclohexene is apparently the smallest-sized cycloalkene that can accommodate an *E* double bond. Being unable to relax to an orthogonal conformation, the $\pi\pi^*$ triplet intersystem crosses to the ground state more slowly and has a sufficiently long lifetime to undergo intermolecular reaction, in which it displays radical behavior.



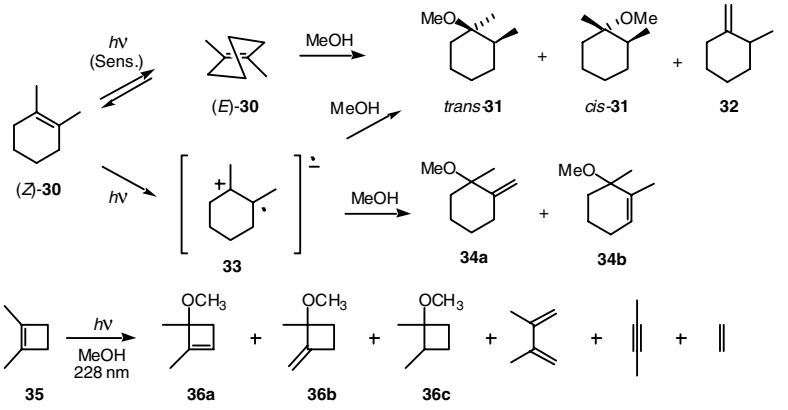
Direct Irradiation

Alkenes

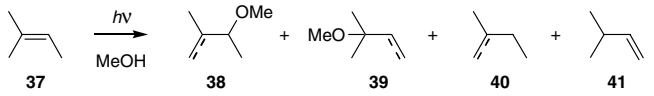
Alkenes undergo *E,Z*-isomerization on direct, as well as sensitized, irradiation. However, since there are two or more low-lying excited states in the singlet manifold, the singlet photobehavior of alkenes is complex. On direct irradiation in hydroxylic solvents, tetrasubstituted alkenes afford, in addition to *E,Z*-isomerization, mixtures of saturated and unsaturated alcohols or ethers.[8b,27] Thus, for example, 2,3-dimethyl-2-butene (**22**) affords a mixture of the alcohols or ethers **28** and **29**, which apparently arise via nucleophilic trapping of the πR(3s) Rydberg excited state (**23**) followed by disproportionation of the resulting radical **25**.[8b] Small amounts of the hydrocarbons **26** and **27** are also formed, apparently via trapping of hydrogen atoms formed by attack of free electrons on the solvent. Since formation of the πR(3s) state involves promotion of one of the π electrons to an orbital having approximately the size and shape of a 3s helium orbital, it has an electron-deficient core with radical cation character. Undergoing nucleophilic trapping in hydroxylic media was the first chemical property of this state to be established. In nonnucleophilic media, it rearranges to carbene intermediates, as detailed in Chapter 13.



The cyclic analog (*Z*)-**30**, which on *p*-xylene-sensitized irradiation in methanol gives the epimeric ethers **31** and the exocyclic isomer **32**, affords in addition the unsaturated ethers **34** on direct irradiation.[8b] There is apparently competing protonation of the *E* isomer [(*E*)-**30**] and nucleophilic trapping of the πR(3s) excited state (**33**). This is consistent with the ππ* and πR(3s) states being close lying and both readily populated in tetrasubstituted alkenes. The cyclobutene analog **35**, which is incapable of *E,Z*-isomerization, afforded principally a mixture of the saturated and unsaturated ethers **36** on irradiation in methanol at 228 nm, along with small amounts of the ring opening and fragmentation products that are formed in the gas phase and hydrocarbon media.[28] The latter products increased relative to the ethers **36** at 214 nm, which is overlapped more effectively by the ππ* rather than the πR(3s) absorption band. This wavelength dependence supports the proposed involvement of the πR(3s) excited state in nucleophilic trapping.

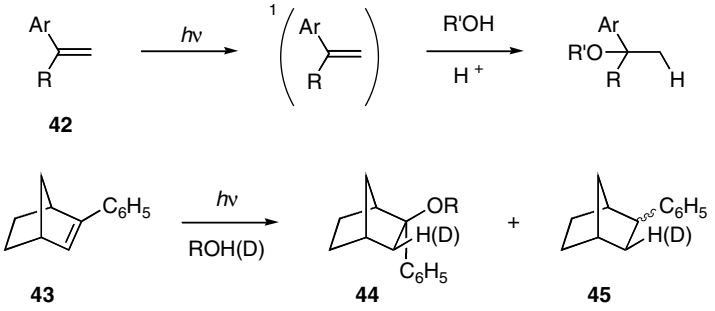


The trisubstituted alkene **37** similarly affords a mixture of the saturated and unsaturated ethers **38** and **39** and hydrocarbons **40–41** in methanol, but only on extended irradiation.[8b] By contrast, the cyclic analog 1-methylcyclohexene [(*Z*)-**1b**] affords only the exocyclic isomer **3b** and the saturated ether **4b** on direct irradiation in methanol.[8b] Similarly, the higher homologs (*Z*)-**1c–d** afford ethers **4c–d**, accompanied by small amounts of the exocyclic isomers **3c–d**, in acidified methanol. Apparently the πR(3s) excited state, which is significantly more sensitive to alkyl substitution, is higher lying than the ππ* state in trisubstituted alkenes. Disubstituted alkenes do not have sufficient absorption above the cutoffs of hydroxylic solvents to give photoproducts in these media.



Styrenes

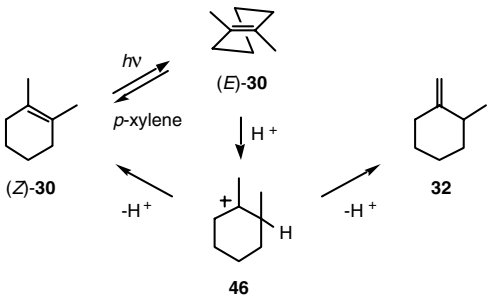
Acyclic styrenes (**42**) undergo Markovnikov addition on direct, but not sensitized, irradiation in water or methanol.[29] The reaction is acid catalyzed but employs considerably lower acid concentrations or weaker acids than required for ground-state addition. The proposed mechanism is protonation of the first excited singlet state, which is estimated to occur 10^{11}–10^{14} times more rapidly than protonation of the ground sate. Similar behavior is exhibited by the cyclic analog **43**, which on direct irradiation in aqueous or alcoholic media affords principally the alcohol or ether **44**, accompanied by smaller amounts of an epimeric mixture of the reduction products **45**.[30] Labeling studies showed that both types of products are formed via initial 3-*exo* protonation. Again, no reaction occurs on photosensitized irradiation. However, as noted above, the larger-ring analog *cis*-1-phenylcyclohexene (*cis*-**10**) undergoes addition of methanol on either direct or sensitized irradiation, with protonation in both cases involving the *trans*-isomer.[19] Thus, in contrast with acyclic and small-ring cyclic styrenes, in which the first singlet excited state undergoes protonation, the highly strained isomers of medium-ring cyclic styrenes are apparently more rapidly protonated.



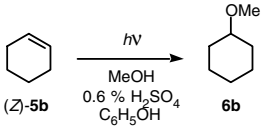
Synthetic Applications of Photoprotonation

There are several synthetically useful applications of the photoprotonation of cycloalkenes:

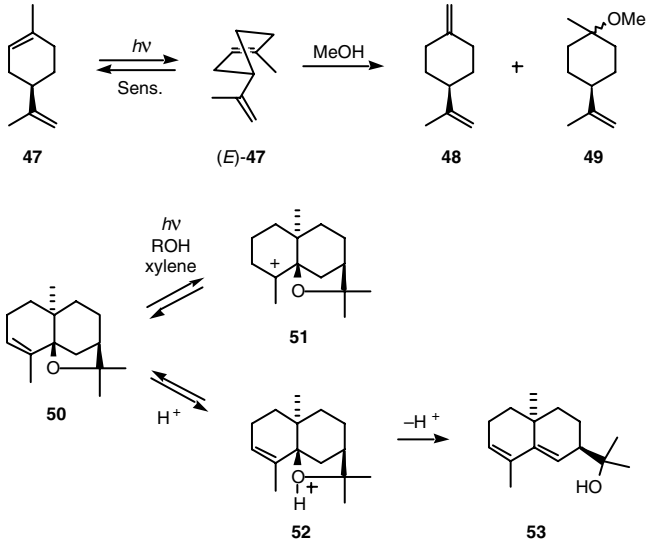
1. *Irradiation of 1-alkylcyclohexenes, cycloheptenes, and cyclooctenes in non-nucleophilic, protic media is a useful method for effecting contra thermodynamic isomerization to the exocyclic isomer.* For example, sensitized irradiation of 1,2-dimethylcyclohexene [(*Z*)-**30**] in ether containing a trace of sulfuric acid afforded the exocyclic isomer **32** in excellent yield.[31] In the absence of competing nucleophilic trapping, the cycloalkyl cation **46** resulting from photoprotonation simply undergoes deprotonation to afford a mixture of exocyclic and endocyclic alkenes. Any endocyclic alkene formed undergoes photoprotonation again and is recycled. The exocyclic isomer, on the other hand, is photo inert under these conditions except for *E,Z*-isomerization, which simply involves interchanging the positions of the vinyl hydrogen atoms and does not produce a strained *E* intermediate. Hence, there is a net isomerization of the double bond to the thermodynamically less stable exocyclic position.



2. *Photoprotonation is a convenient method for effecting complete addition of water or an alcohol to a cyclohexene, cycloheptene, or cyclooctene.* Acid-catalyzed addition is reversible and does not go to completion, whereas the photochemical method proceeds until all of the alkene has been consumed. Moreover, since photoprotonation can be effected at low acid concentrations, even less highly substituted cycloalkenes, which are not readily protonated in the ground state, undergo photoprotonation readily. In many cases, photoprotonation affords addition when acid-catalyzed addition fails. For example, sensitized irradiation of cyclohexene [(*Z*)-**5b**] in methanol containing 0.6% sulfuric acid affords ether **6b** in excellent yield; in a preparative procedure it was isolated in 70% yield.[32] By contrast, treatment of cyclohexene in the dark with methanol containing 10 times the concentration of acid afforded no detectable ether formation.



3. *The photochemical method permits the selective protonation of a cyclohexene, cycloheptene, or cyclooctene in the presence of a second double bond located in an acyclic, exocyclic, or larger ring cyclic environment.* For example, light-induced addition of methanol to *(R)*-(+)-limonene (**b**) afforded specifically a mixture of the epimeric ethers **49**, along with the exocyclic isomer **48**.[3,33] Acid-catalyzed, nonphotochemical additions to limonene (**47**) generally afford a mixture of products resulting from competing protonation of both double bonds. The selective photoreactivity stems from the fact that *E,Z*-isomerization of the cyclohexene moiety affords a strained alkene whereas isomerization of the second double bond does not.



A similar type of selectivity is seen in the xylene-sensitized irradiation of the sesquiterpene α-agarofuran (**50**) in alcoholic media, which affords products resulting from selective protonation of the double bond to afford the cationic intermediate **51**.[34] By contrast, treatment with standard methods of protonation in the dark resulted in attack at oxygen (**52**) and opening of the oxide ring to afford alcohol **53** without rearrangement.[35]

These are just a few of the ways that a creative chemist can make use of the photoprotonation of cycloalkenes to induce selective reactivity in synthesis.

Silyl Enol Ether Radical Cations: Generation and Recent Synthetic Applications

Jens Otto Bunte
Universität Bielefeld

Jochen Mattay
Universität Bielefeld

10.1 Introduction

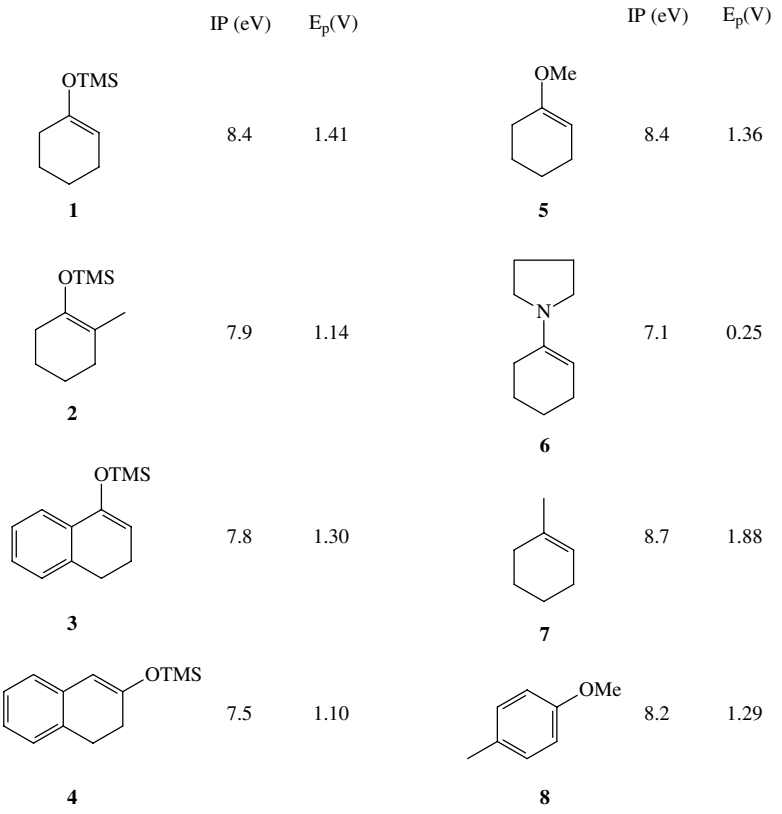
Silyl enol ethers are a class of electron-rich, nonaromatic compounds that easily form reactive radical cations on one electron oxidation. The silyl enol ether functional group is closely related to the carbonyl function and consequently, syntheses of silyl enol ethers generally make use of enolates. In addition, silyl enol ethers can be described as masked enols or enolates since their reactions often yield ketones.[1] A number of oxidation reactions of silyl enol ethers making use of oxygen[2] or oxygen-containing reagents such as peroxides,[3] peracids (known as Rubottom oxidation),[4] dioxirane,[5] osmium tetraoxide,[6] or triphenyl phosphite ozonide[7] have been described in the literature. In all cases either α-hydroxy-ketones or the silyl enol ether epoxides are formed.

This chapter reviews recent advances in the chemistry of radical cations of silyl enol ethers, focusing on their photochemical generation and usage in intramolecular reactions. Only oxidants that do not react via inner-sphere electron transfer are discussed as oxidants for the silyl enol ethers. In general, one electron oxidation leads to the formation of radical cations, and therefore this process can be regarded as an umpolung reaction.[8] The former nucleophilic silyl enol ether now acts as an electrophile. The synthetic possibilities resulting from this change in reactivity and the underlying mechanistic features of the oxidation process will be discussed in the following sections.

10.2 One Electron Oxidation of Silyl Enol Ethers

An assessment of the electron donor properties of silyl enol ethers can be made by comparison of their ionization potentials and anodic oxidation potentials with those of related compounds. Scheme 1 summarizes selected examples.

0-8493-1348-1/04/$0.00+$1.50



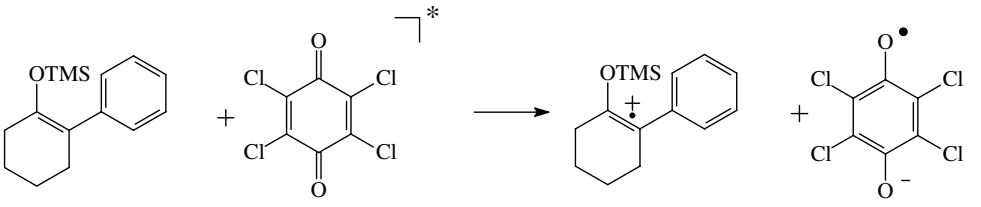
SCHEME 1 Ionization potentials (IP) and anodic potentials (E_p vs. SCE) of silyl enol ethers and related compounds.[9] (References for **6** (E_p),[10] **7**, **8** (IP),[11] **7** (E_p)[12] and **8** (E_p)[13]).

Silyl enol ethers such as **1** can be more easily oxidized than the corresponding alkenes, as seen in comparison with methyl-cyclohexene (**7**). In general, their electron donor properties are comparable to those of electron-rich arenes such as anisoles **8**, but are clearly lower than, for example, the heteroanalogue enamines, such as **6**. A significant change in the redox properties of silyl enol ethers can be achieved by increasing the degree of substitution at the double bond (as in **2**) or by incorporation of the double bond into a mesomeric system (as in **3** or **4**). In contrast, variation of the silyl group or changing to an alkyl enol ether does not significantly influence the oxidation potential (as seen with **5**).

Removal of an electron in solution can be accomplished in different ways, for example by use of chemical oxidants, electrochemical (anodic) oxidation, or photoinduced electron transfer (PET). However, oxidations involving chemical oxidants should be assessed carefully with respect to inner sphere oxidation mechanisms, which are known for several common metal ion oxidants.[14]

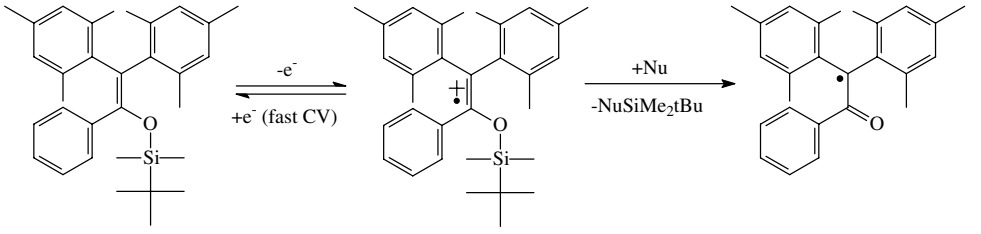
Although relatively short-lived, radical cations are the primary products of the electron transfer (ET) step. Evidence for the formation of radical cations has been presented for silyl enol ether systems that form stabilized radical cations. Kochi and coworkers investigated the photoinduced electron transfer between different silyl enol ethers and chloranil in detail.[15,16] In a system suitable for the spectroscopic study of the radical cation intermediate, chloranil (CA) is electronically excited to its triplet state ^{3}CA* (**10**). Subsequent electron transfer generates the corresponding radical ion pair (**11/12**). All these transient species have been observed by time-resolved spectroscopy.

Schmittel et al. investigated highly stabilized silyl enol ethers such as **13** by cyclic voltammetry (CV).[17] They found irreversible first oxidation potentials for their substances at low scan rates, which is consistent with findings for other silyl enol ethers and consistent with a mechanism including a fast follow-up



9 **10** **11** **12**

SCHEME 2 Formation of silyl enol ether radical cation **11** via electron transfer.



13 **14** **15**

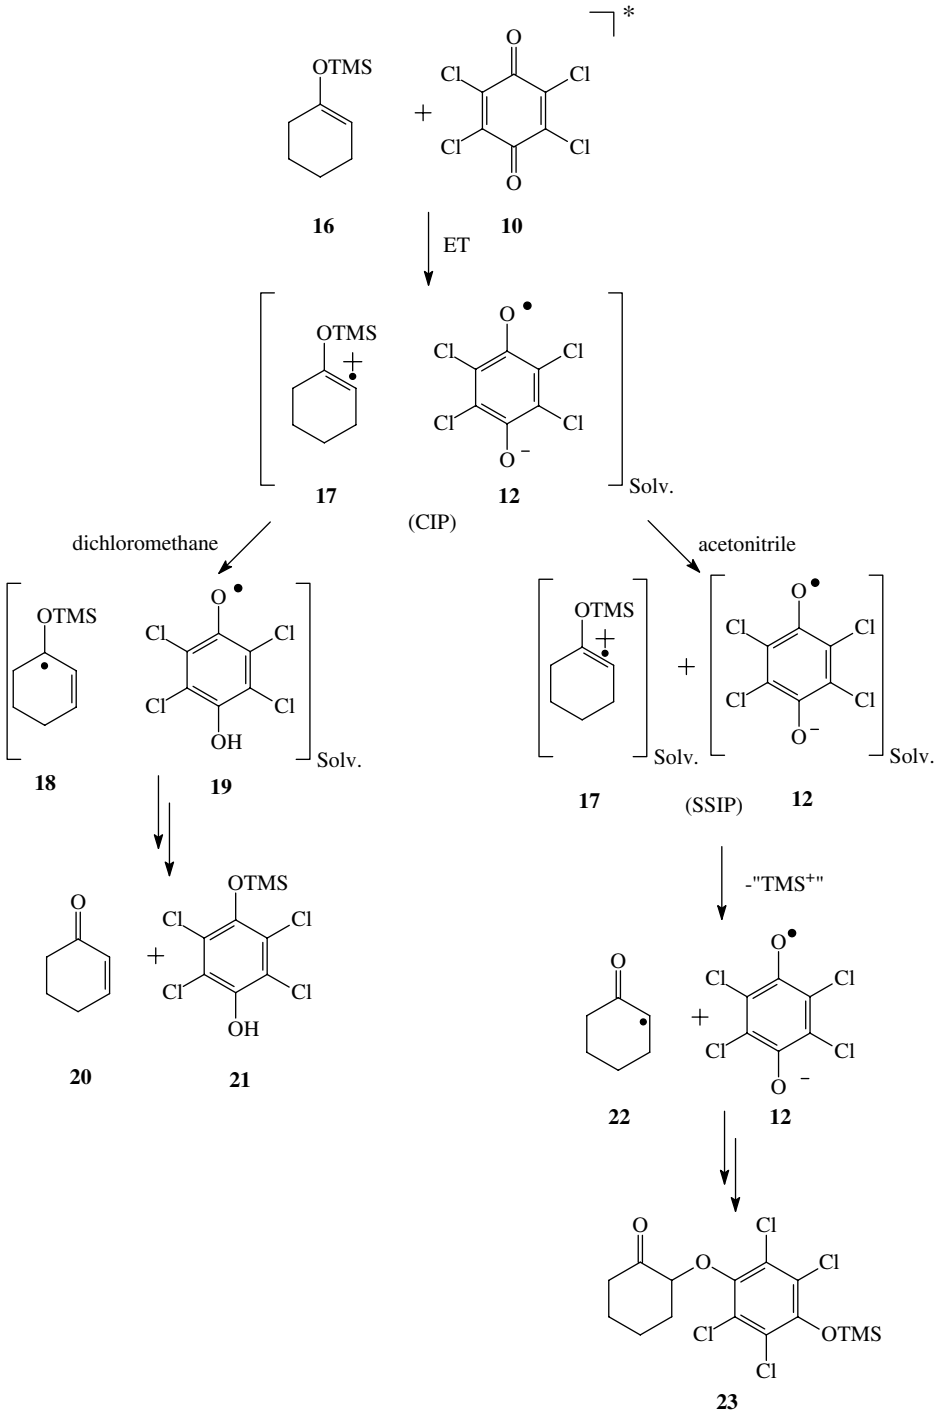
SCHEME 3 Reversible oxidation of **13** vs. loss of the silyl cation.

reaction after electrochemical oxidation. In fast scan CV experiments (scan rates up to 2000 V sec^{-1}), they were able to reduce reversibly the generated radical cation **14**. The authors reported a strong solvent dependence on the conditions for reaching a reversible CV, indicating differences in the rate constants for the follow-up reactions. For example, in acetonitrile this reaction proceeded significantly faster than in dichloromethane, whereas addition of nucleophiles increased the rate constant for the process as well. These facts are interpreted as a nucleophile-assisted cleavage of the silicon–oxygen bond leading to the α-carbonyl radical **15**.

In PET reactions, the choice of solvent is crucial, but not only due to the possibility of SiO bond cleavage. Even the fate of the contact radical ion pair (CIP) formed by electron transfer is determined by the solvent applied (Scheme 4). Kochi and coworkers assigned different reaction pathways for the radical ion pair generated from excited chloranil (**10**) and the silyl enol ether **16** in dichloromethane and acetonitrile.[15,16] In the less polar solvent dichloromethane, the contact ion pair (**17,12**) decays to the radical pair (**18,19**) by interionic proton transfer. Oxidative elimination yields the enone **20** and tetrachlorohydroquinone-mono-trimethylsilyl ether (**21**).

A different reaction takes place with acetonitrile as solvent. The initially formed contact ion pair (**17,12**) undergoes diffusive separation to the corresponding solvent-separated ion pair (SSIP). The Si-O bond is cleaved by assistance of the nucleophilic solvent, and the resulting α-carbonyl radical **22** combines with the chloranil radical anion **12** to yield the final product **23**.

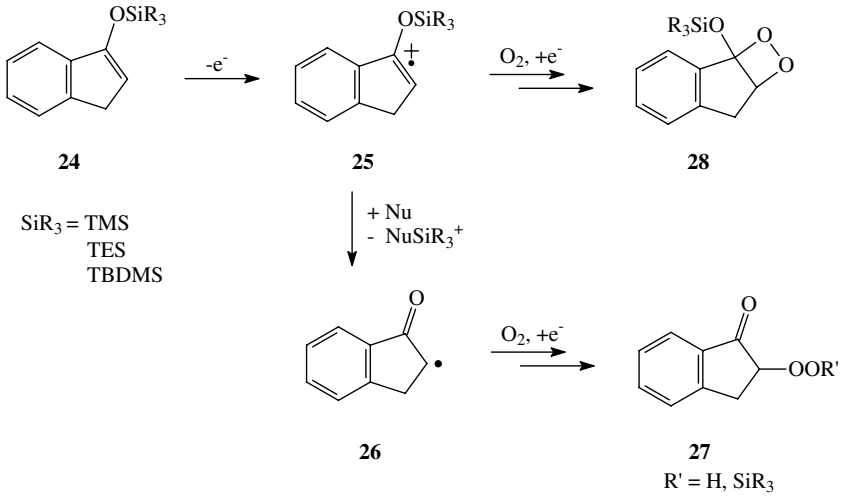
The two reaction channels described represent the most important steps following the generation of the initial radical cation and can be directly incorporated into synthetic applications involving silyl enol ether radical cations. Deprotonation of the radical cation is a way to conduct a ketone–enone transformation via the silyl enol ether. Other synthetic applications utilizing the radical cation or the α-carbonyl radical are coupling reactions of silyl enol ethers, intramolecular addition to double bonds, or introduction of substituents other than carbon at the α-carbonyl position, respectively. Examples for these synthetic transformations will be presented in the following sections.



SCHEME 4 Different reaction pathways in dichloromethane and acetonitrile.

10.3 Transformation of Silyl Enol Ethers into Enones

The conversion of ketones to the corresponding α,β-unsaturated carbonyl compounds is an important transformation in organic synthesis. Methods utilizing the silyl enol ether became important because of



SCHEME 5 Photooxygenation of silyl enol ethers via radical cations.

the possibility of regioselective formation of the silyl enol ether and consequently the enone double bond. Several methods to conduct this transformation are available; procedures using singlet oxygen,[18] palladium catalysis,[19,20] or dichlorodicyanoquinone (DDQ)[21,22] have been described. The reaction mechanism involving quinones as oxidizing agent has been investigated by Kochi et al. (Scheme 4).[23] Recently, Nicolaou et al. presented an oxidation of silyl enol ethers by *o*-iodoxybenzoic acid (IBX), for which they also postulated an electron transfer as the key step.[24]

10.4 Introduction of Noncarbon Substituents at the α-Carbonyl Position

Before describing one of the most important synthetic aspects, i.e., the addition to carbon–carbon double bonds (see Sections 10.5 and 10.6), we will briefly discuss functionalization reactions leading to α-heterosubstituted carbonyl compounds. However, although several of the oxidation reactions of silyl enol ethers with oxygen-containing compounds lead to α-hydroxy-carbonyl compounds as α-carbonyl functionalization, radical cations are not involved in these reactions.[2–7]

Photooxygenations of silyl enol ethers via electron transfer oxidation have been investigated by Abe and coworkers.[25] They obtained two different oxidation products depending on the nucleophilicity of the solvent and the bulkiness of the silyl group. Using 9,10-dicyanoanthracene (DCA) as sensitizer and the silyl enol ethers **24** (TMS = trimethylsilyl, TES = triethylsilyl, TBDMS = *t*-butyldimethylsilyl) as starting material, they generated the corresponding radical cations **25**. Nucleophilic solvents and less sterically hindered silyl groups lead to products derived from the α-carbonyl radicals **26**, whereas less nucleophilic solvents underwent dioxetane (**28**) formation resulting from a postulated addition of oxygen to the radical cation. as shown in Scheme 5.

The simplest way of introducing a "functional group" at the α-carbonyl position is the addition of a hydrogen atom. Although there is no increase in molecular complexity, this is one of the most fundamental applications of PET-reactions involving silyl enol ethers. Gassman et al. showed that trimethylsilyl enol ethers **30** can be selectively deprotected in the presence of trimethylsilyl ethers by PET-induced cleavage of the SiO bond in a methanol/acetonitrile mixture (Scheme 6). Saturation of the resulting α-carbonyl radical leads to the formation of the final ketone **31**.[26]

Kochi and co-workers presented a synthesis of α–nitroketones involving silyl enol ether radical cations as key intermediates.[27] Remarkably, the reaction of silyl enol ethers with tetranitromethane yielded α-nitroketones under both thermal and photochemical conditions.

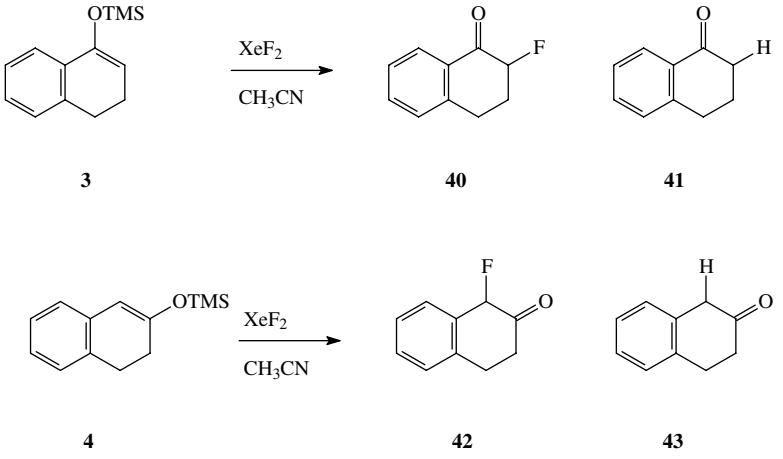
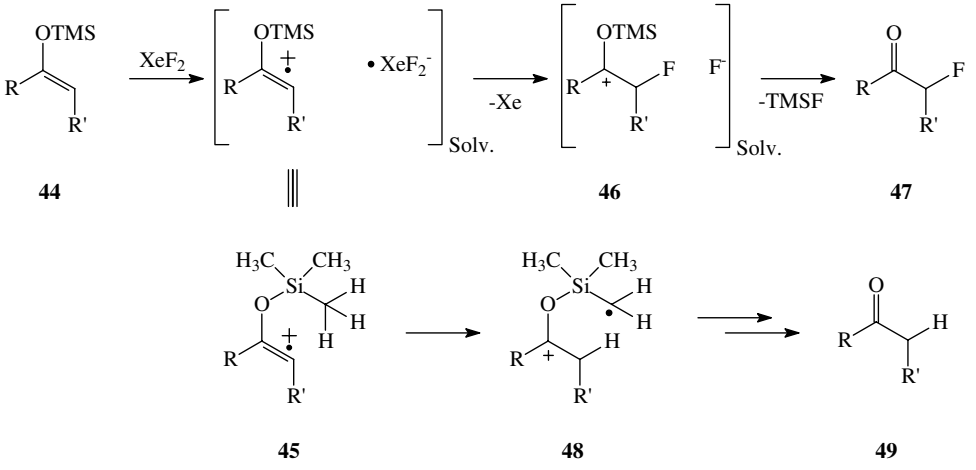
SCHEME 8 Stabilizing effects in tetralone based silyl enol ether radical cations.

The same authors also observed an interesting difference in the behavior of the α- and β-tetralone silyl enol ethers **3** and **4**, providing a further indication for the presence of radical ions as reactive intermediates in this reaction.[27] The α-tetralone silyl enol ether radical cation **36** reacted with nitrogen dioxide to form cation **37**, whereas the β-tetralone based radical cation **38** reacted much more slowly and gave a mixture of products (Scheme 8). Due to the mesomeric stabilization of the radical cation **38,** its lifetime increased dramatically as observed by time resolved spectroscopy. This favors a cage escape of the radical cation and opens the possibility for further reactions.



SCHEME 9 Fluorination of tetralone silyl enol ethers **3** and **4**.



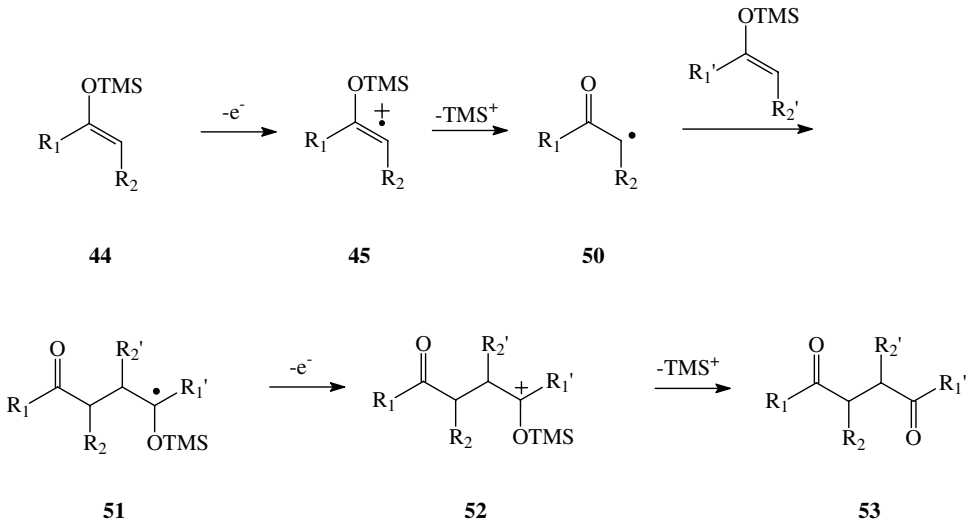
SCHEME 10 Mechanism of the reaction between silyl enol ethers and xenon difluoride.

Ramsden et al. have obtained similar results for tetralone silyl enol ether radical cations.[28] They investigated the reaction of various silyl enol ethers with xenon difluoride in acetonitrile and found a new method for the selective preparation of α-fluoroketones (Scheme 9).

The reaction of the α-tetralone silyl enol ether **3** with xenon difluoride gave fluoroketone **40** in a high yield of 90%. Ketone **41** was obtained as a byproduct in 4% yield. In contrast, the β-tetralone based silyl enol ether **4** formed fluoroketone **42** in 14% yield and ketone **43** as main product in 52% yield. The reaction mechanism proposed is shown in Scheme 10.

One electron oxidation of silyl enol ether **44** leads to the formation of a radical ion pair of **45** and the xenon difluoride radical anion. Subsequent transfer of a fluoride radical yields cation **46**, which reacts by loss of the trimethylsilyl cation to yield the fluoroketone **47**. The formation of ketone **49** is explained by a [1,5]-hydrogen migration from the trimethylsilyl group to the radical cationic moiety of **45**, leading to the formation of **48**.

The high yield of ketone **43** was based on a longer lifetime of the corresponding radical cation due to the stabilizing effect of the conjugated aromatic system. The increased lifetime allows a separation of the radical ions, and an intramolecular hydrogen abstraction becomes favored. This out-of-cage scenario



SCHEME 11 Coupling of silyl enol ether via radical cations.

also becomes obvious from the product composition. The combined yield of **42** and **43** is 66%, whereas the remaining 34% comprises products incorporating the solvent molecules.

10.5 Coupling Reactions of Silyl Enol Ethers

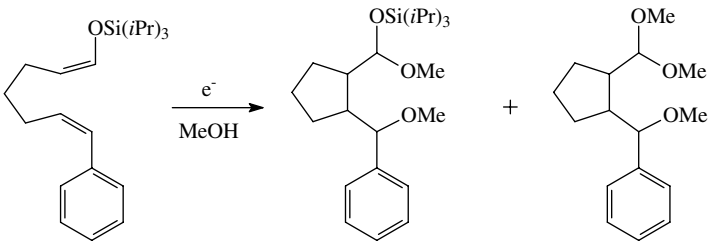
The general mechanistic scenario of the silyl enol ether coupling (**44**→**53**) can be described as formation of a silyl enol ether radical cation **45** and its corresponding α-carbonyl radical **50**, addition of this electrophile to a second silyl enol ether double bond, a second one electron oxidation of the intermediate radical **51,** and a final desilylation to **53** (Scheme 11). Ceric (IV) ammonium nitrate (CAN),[29,30] dichloro-ethoxy-oxyvanadium(V),[31] and dichloro(2,2,2-trifluoroethoxy)-oxovanadium(V)[32] have been applied as suitable one electron oxidants for the described transformation.

When identical silyl enol ethers are used in the coupling reaction ($R_1 = R_1'$, $R_2 = R_2'$), homocoupling to symmetrical 1,4-diketones can be achieved (Scheme 11).[31] For the synthesis of unsymmetrical 1,4-diketones, the two silyl enol ethers must differ significantly in terms of their oxidation potentials. This can be realized by selecting monosubstituted silyl enol ethers (R_2' = H) and 1,2-disubstituted silyl enol ethers for the coupling reaction.[29,31,32] Another possible way to reduce the oxidation potential is by the use of mesomeric stabilization (*vide supra*).[30] In the coupling reactions presented so far, the reactivity of silyl enol ethers is twofold. The component that is more easily oxidized forms the radical cation and consequently the α-carbonyl radical. In contrast, the second component acts as an electron-rich double bond in the radical addition reaction.

Electron-rich compounds with an oxidation potential lower than that of silyl enol ethers can be oxidized in the presence of silyl enol ethers, and in this case the silyl enol ether behaves as an electron-rich double bond. This strategy has been realized with enamines,[33] benzylsilanes,[34] organoselenium compounds,[35] and alkoxy-substituted arenes.[36]

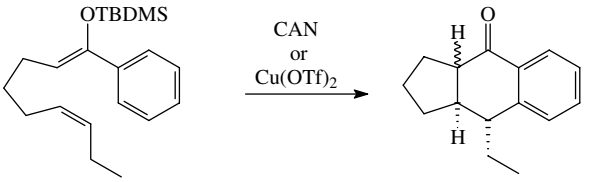
Coupling reactions of silyl enol ether radical cations with double bonds other than silyl enol ethers have been investigated as well. Reactions with butadiene,[37] ethyl vinyl ether,[38] and allylic silanes[39] have been reported.

For the more important coupling reaction of silyl enol ethers, the Mukaiyama Aldol reaction, electron transfer reactions of silyl enol ethers have to be taken into account. As commonly used catalysts, transition metal complexes can be deactivated by electron transfer reduction, leading to a significant change in Lewis acidity as has been shown by Bosnich and co-workers.[40] Setsune et al. reported another connection



54 **55** **56**

SCHEME 12 Oxidative cyclization by anodic oxidation.



57 **58**

SCHEME 13 Oxidative cyclization by oxidation with metal salts.

between the Mukaiyama Aldol reaction and the electron transfer processes. They investigated PET catalysis of the Mukaiyama Aldol reaction using modified porphyrins.[41]

10.6 Intramolecular Addition of Silyl Enol Ether Radical Cations to Double Bonds

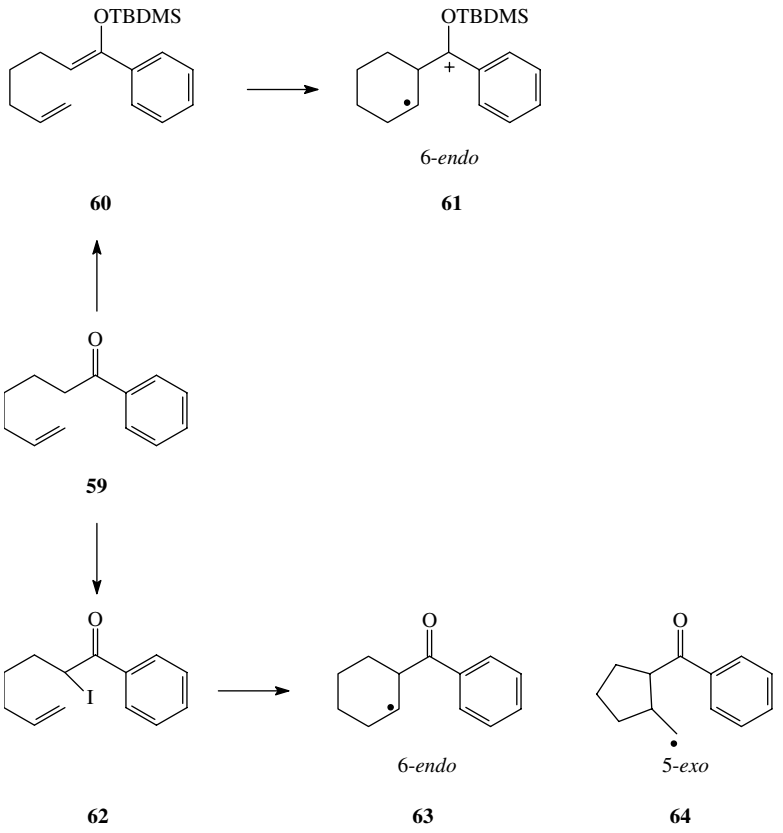
In this important area of silyl enol ether chemistry, similar transformations have been realized by transition metal catalysis; for example, silyl enol ethers carrying suitable olefinic side chains have been cyclized in the presence of palladium(II) complexes.[42,43]

Moeller and co-workers published the electron transfer cyclization of silyl enol ethers initiated by anodic oxidation.[44] The *in situ* generated radical cation of **54** intramolecularly attacks the double bond. The resulting benzylic radical position is further oxidized and attacked by a solvent molecule as well as the remaining cationic center to yield **55**. Cleavage of the SiO bond leads to the formation of **56** (Scheme 12).

Snider et al. investigated the oxidative cyclization of silyl enol ethers by use of CAN or cupric triflate.[45]

The transformation **57**→**58** includes two consecutive ring closure steps, two single electron oxidations, the desilylation step, and a deprotonation and can be regarded as a domino cyclization (Scheme 13).[46]

As can be seen from the reactions described so far, desilylation of the primary radical cation is a major pathway in silyl enol ether chemistry. Thus, it becomes important to know whether the reactive intermediate of the cyclization reaction is indeed the primary radical cation or its corresponding α-carbonyl radical. Curran et al. investigated the free radical atom transfer reaction of several α-iodo carbonyl compounds with hexabutylditin.[47] The reaction with **62** led to the formation of products resulting from both the 6-*endo* closed radical **63** and the 5-*exo* closed radical **64**. In contrast, the CAN-induced cyclization of **60** solely gave products resulting from a 6-*endo* ring closure reaction. In this context, Snider et al. proposed a reaction mechanism with the radical cation as the reactive key-intermediate in the cyclization step leading to exclusive 6-*endo* ring closure.[45]



SCHEME 14 Comparison between radical and radical cationic ring closure selectivity.

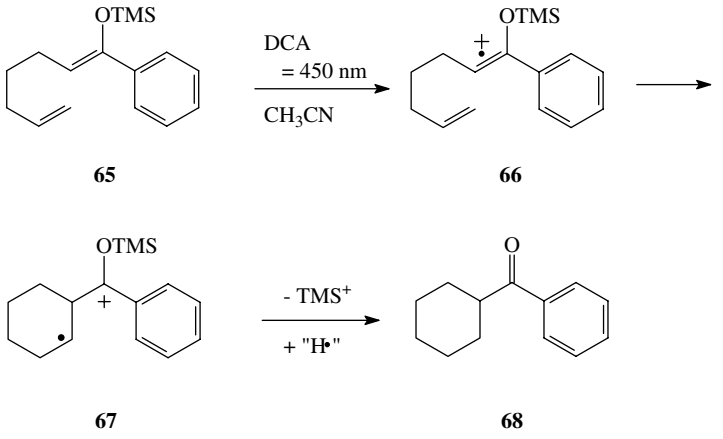
The corresponding trimethylsilyl enol ether **65**, which is unstable under CAN oxidation conditions, has been successfully cyclized by Mattay and co-workers via PET with 9,10-dicyanoanthracene (DCA) as sensitizer (Scheme 15).[48] The selective formation of the 6-*endo* cyclization products was explained through the radical cation **66** as the reactive intermediate in the ring closure step. Loss of the trimethylsilyl cation is assumed to occur from radical cation **67** after cyclization. However, the source of the required hydrogen transfer step has not been clarified in detail.

The introduction of substituents at the olefinic double bond (as in **69**, **71**) leads to the stereoselective formation of the corresponding cyclization products **70** and **72**, respectively. The cyclization of the radical cation of **69** directly leads to the *trans* orientation of the substituents in **70**, whereas the high stereoselectivity in the formation of **72** results from a selective saturation of the intermediate radical moiety (Scheme 16).[48]

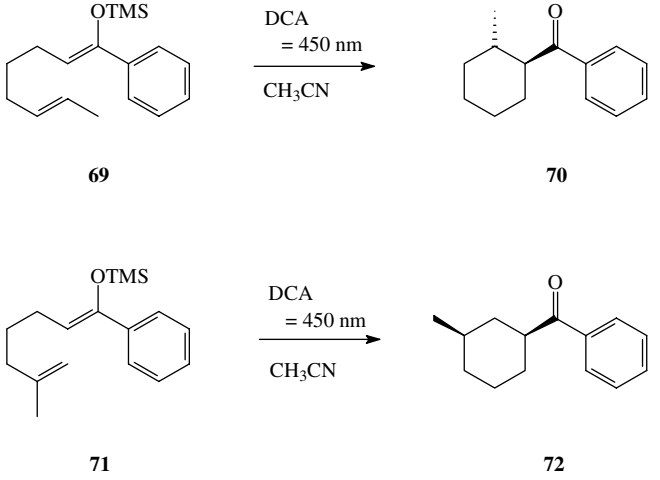
Analogous to the double cyclizations found by Snider and co-workers, a change to the bulkier triisopropylsilyl group as realized in **73** resulted in the additional formation of the tricyclic ketone **74** (Scheme 17).[45]

Introduction of an alkyne side chain (as in **75**), exclusively led to the formation of **76** via a double cyclization sequence (Scheme 18).[49]

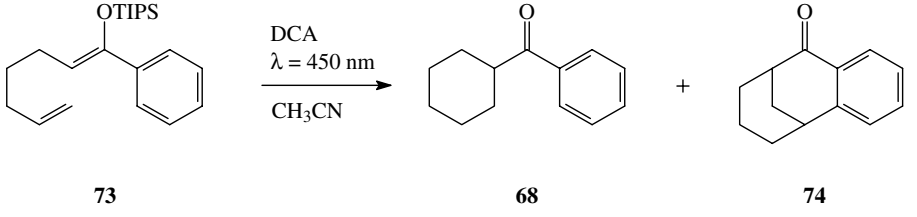
A further extension of this work to silyl enol ethers derived from cyclic ketones not only confirmed the strong preference for the 6-*endo* ring closure, but additionally revealed a high diastereoselectivity shown in the exclusive formation of *cis*-junctions between the ring constructed in the cyclization and the ketone ring. Thus, this procedure can be seen as a useful tool for the construction of fused carbocycles (Scheme 19).[50]



SCHEME 15 PET-induced cyclization of **65**.

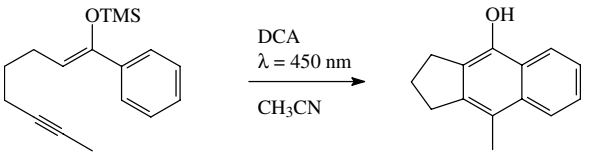


SCHEME 16 Introduction of substituents at the olefinic double bond.



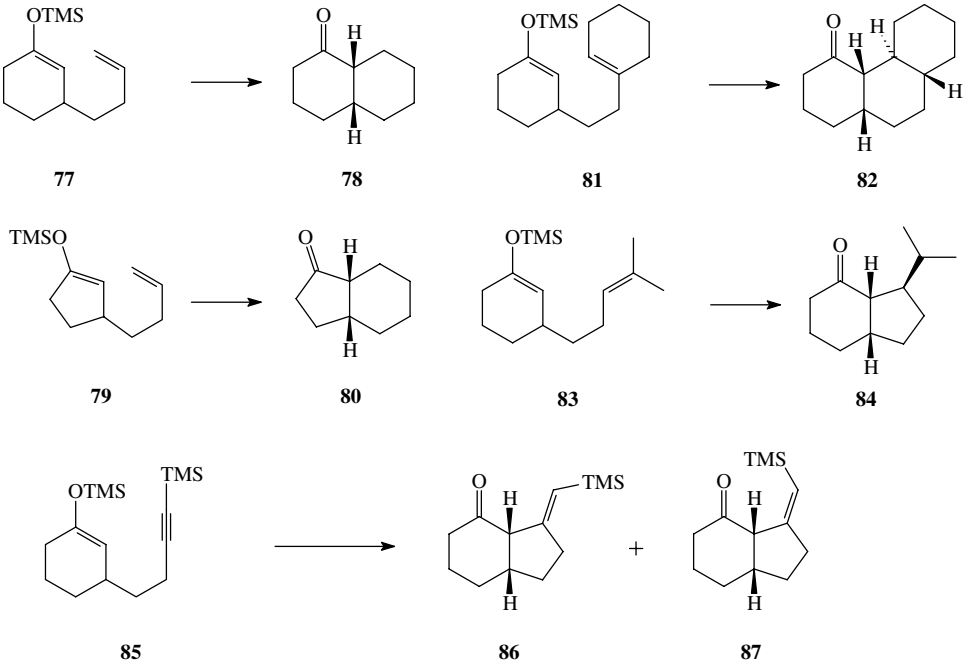
SCHEME 17 Double cyclization of **73**.

The silyl enol ether **83** represents an exception from the 6-*endo* cyclization rule. The reason for this differing behavior can be seen in the stability of the tertiary radical intermediate and the bulkiness of the trisubstituted double bond. The alkyne substituted silyl enol ether **85** resulted in the formation of the isomeric olefins **86** and **87** in a 1:1 ratio.

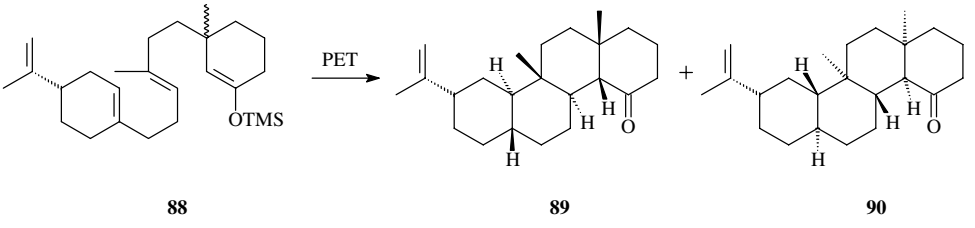


75 **76**

SCHEME 18 Double cyclization with alkyne side chain.

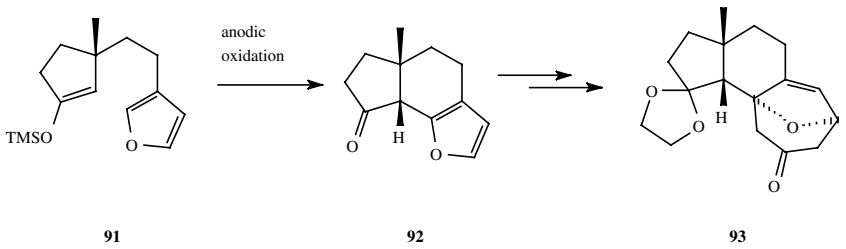


SCHEME 19 PET cyclizations in acetonitrile with DCA as sensitizer.



SCHEME 20 Cascade cyclization of silyl enol ether **88**.

In order to explore the scope and limitations of this reaction for the synthesis of complex carbocycles, the silyl enol ether **88** has been synthesized and efficiently cyclized in the anticipated way.[51] The cyclization reaction of **88** further revealed a remarkable stereoselectivity (Scheme 20). Besides a complete 6-*endo* selectivity, the five new stereogenic centers are built-up in an *anti:trans*-fashion, yielding solely one configuration of the bridgehead carbon atoms from the diastereomeric mixture of **88**.



SCHEME 21 Synthesis of the cyathin skeleton **93**.

An elegant access to natural product synthesis was realized by Wright and co-workers, who obtained a *cis*-junction through the cyclization reaction of **91**.[52] The silyl enol ether **91** is electrochemically oxidized and subsequently cyclizes to yield compound **92**. In three further steps, the cyathin core **93** can be prepared.

Acknowledgments

Financial support of our own research was provided by the Ministerium für Schule, Wissenschaft und Forschung des Landes Nordrhein-Westfalen (MSWF-NRW), the Deutsche Forschungsgemeinschaft (DFG), the Fonds der Chemischen Industrie, the Volkswagen-Stiftung, the AG-Solar project of NRW, and the Innovationsfonds der Universität Bielefeld and is gratefully acknowledged. We also thank the state of Nordrhein-Westfalen for granting a predoctoral scholarship for J.O.B. and Michael Oelgemöller (Bayer CropScience K.K.) for his help in the preparation of the manuscript.

C–X Bond Fission in Alkene Systems

Tsugio Kitamura
Saga University

11.1 Introduction

This chapter describes the photochemical C-X bond fission in alkene systems that have halogen atoms bonded to the carbon–carbon double bond. The substitution of halogen atoms in alkenes results in a red shift of the π,π^* absorption band because of the interaction between the lone pair on the halogen atom and the π-orbitals.[1,2] However, the UV absorption of aliphatic alkenyl halides, except for the iodides, lies in a region of short wavelength less than 254 nm (Table 11.1). Therefore, the majority of the alkenyl halides studied in these photolyses are the iodides.

Introduction of aromatic substituents to the carbon–carbon double bond leads to considerable π-conjugation causing the absorption to move to longer wavelength (>254 nm) with a concomitant increase in the extinction coefficient. 1,2-Diaryl- and triarylvinylhalides, including the bromides and chlorides, have absorptions at wavelengths around 300 nm. Therefore, these systems have been used mostly for synthetic applications because the secondary photochemical reactions can be eliminated by the use of a suitable filter.

The excitation energy obtained by absorption of light is consumed chemically by isomerization, extrusion of small molecules, and bond fission. In this chapter, the bond fission aimed at synthetic application is discussed. The ease of bond fission is proportional to the bond strength of the C-X bond. As shown in Table 11.2, the bond strength of the C-X bond in alkenyl halides is much higher than that of alkyl halides and is intermediate between those of the corresponding ethyl and phenyl halides. The C-X bond increases in strength in the order: I < Br < Cl < F. The bond dissociation energy of vinyl fluoride (479 kJ mol^{-1}) is higher than the energy of the light from low-pressure Hg lamps (254.7 nm = 472 kJ per Einstein) and accordingly, the direct photochemical cleavage of a carbon–fluorine bond is extremely rare.

11.2 Mechanism for C-X Bond Fission in Alkene Systems

Previously, Sammes[2] and Lodder[18] have reviewed the photochemistry of the carbon–halogen bond. Photolysis of alkenyl halides is well known, but little attention has been paid to the synthetic applications.

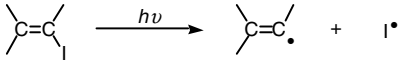
1-Bromo-2,2-bis(*o*-methoxyphenyl)-1-phenylethene	284 (4.02)	Cyclohexane	15

TABLE 11.2 Comparison of Bond Dissociation Energies of the C–X Bond among Ethyl, Vinyl, and Phenyl Halides

Ethyl halide[16]	D (C–X) (kJ mol^{-1})	Vinyl halide[17]	D (C–X) (kJ mol^{-1})	Phenyl Halide[16]	D (C–X) (kJ mol^{-1})
CH_3CH_2–F	452	CH_2=CH–F	497	Ph–F	527
CH_3CH_2–Cl	335	CH_2=CH–Cl	372	Ph–Cl	402
CH_3CH_2–Br	285	CH_2=CH–Br	320	Ph–Br	339
CH_3CH_2–I	222	CH_2=CH–I	260	Ph–I	272

One advantage for synthetic application of alkenyl halide photochemistry is that the reactions that alkenyl halides undergo allow for the introduction of a C-C double bond into the product molecule.

The well-known principal example in solution is the homolysis of the C-X bond, affording a radical pair composed of a vinyl radical and a halogen atom, as represented by the photolysis of alkenyl iodides (Equation 11.1).[2]

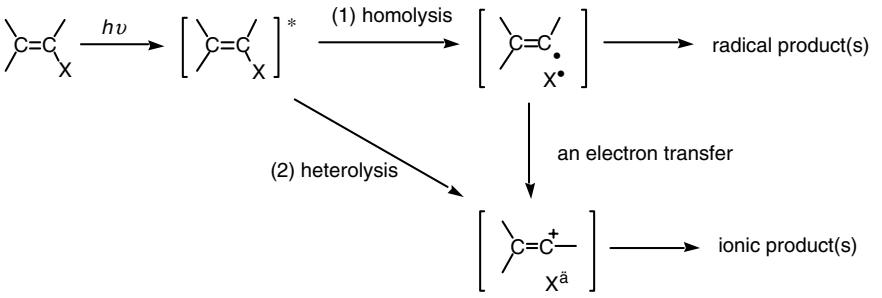


(11.1)

The main reaction of the vinyl radical is abstraction of a hydrogen or halogen atom. The dimerization of the vinyl radical is extremely rare because of its high reactivity.

A novel aspect of the photochemical behavior of alkenyl halides is the generation of vinyl cations.[18,19] The detailed mechanism of the formation of the vinyl cations has not yet been fully established. Two possible paths for cation formation have been postulated:

1. Homolytic cleavage of the C-X bond and subsequent electron transfer within the radical pair[20–23]
2. Direct heterolysis of the C-X bond[24] (Equation 11.2)

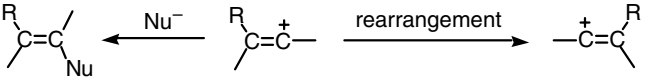


(11.2)

Recent studies by laser-flash photolysis showed that vinyl cations are formed quite rapidly after excitation of alkenyl halides, suggesting that photolysis of aromatic alkenyl halides induces both heterolysis and homolysis of the C-X bond. The synthetically interesting and useful characteristics of these processes are:

1. The generation of unstable vinyl cations, e.g., α-unsubstituted or cyclic vinyl cations
2. The mild reaction conditions
3. The use of aprotic solvents or less polar solvents

The reactions that the vinyl cations can undergo are nucleophilic substitution and rearrangement, similar to those of solvolytically generated vinyl cations[25] (Equation 11.3). The photolysis procedures have the advantage that they can be applied to a wide variety of substrates.



(11.3)

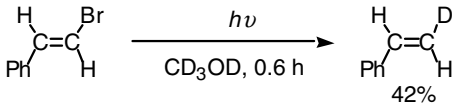
Some general rules can be used to predict the outcome of irradiation of alkenyl halides. Thus, the photolysis of α-arylvinylhalides leads to stable α-arylvinyl cations, and the vinyl cation route is followed predominantly. A nucleophilic reagent can capture such intermediates. Conversely, in the cases that produce unstable vinyl cations, vinyl radicals are formed preferentially, or else the formation of radical and cation intermediates competes. Clearly, the nature of the substituent is important in predicting the reactions of the vinyl cations. Results indicate that the nucleophilic trapping of the vinyl cations follows the order:[26] H << alkyl << Ph < *p*-MeC_6H_4 < *p*-$MeOC_6H_4$. The halogen employed is also important, with chlorides and bromides better than iodides at undergoing fission. Fluorides, as mentioned previously, are inactive in photolysis.[27a] In aliphatic alkenyl halides,[3] conversely, iodides afford ionic intermediates more preferentially than do bromides or chlorides. However, capture by nucleophiles is restricted to the nucleophilic solvent employed.

11.3 Synthetic Applications

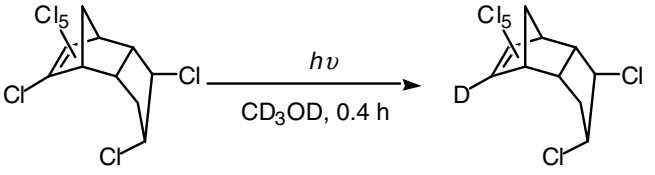
Reduction: Abstraction of a Hydrogen Atom

As described above, synthetic applications using alkenyl halides are divided into two classes: radical and ionic reactions. The most common reaction of the alkenyl radical is abstraction of a hydrogen atom.[5] Although this reaction is useful for reduction of organic halides, its synthetic usefulness is low since most alkenyl halides are prepared from the corresponding alkenes, and replacement of the halogen by hydrogen simply reforms the starting material. However, deuteration can be carried out successfully by the photochemical reaction. Several alkenyl bromides and chlorides are transformed to the deuterated alkenes in good to high yields (Equation 11.4 and Equation 11.5).[27] An interesting feature of this deuteration is

that only the site to which the halogen is attached is deuterated. This procedure can also be applied effectively to aryl halides.[27]

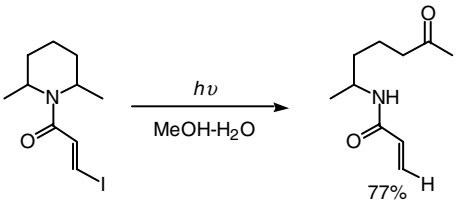


(11.4)



(11.5)

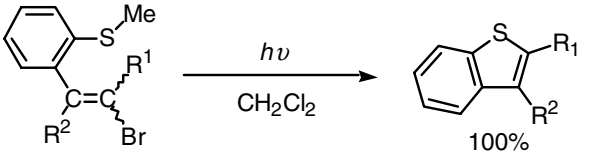
Other interesting reactions involve the photolysis of β-iodoacrylamides (Equation 11.6), which brings about an intramolecular hydrogen abstraction and subsequent dealkylation, i.e., ring opening of the amine moiety.[6]



(11.6)

Intramolecular Cyclization

Intramolecular cyclization by radicals is one of the strategies used to synthesize cyclic compounds or heterocycles. One such example is the intramolecular attack of vinyl radicals at sulfur, which is reported to be an efficient synthesis of benzo[b]thiophenes[21g,28] (Equation 11.7).



R^1, R^2 = H, Me, Ph

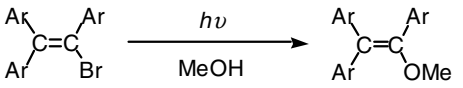
(11.7)

Dimerization

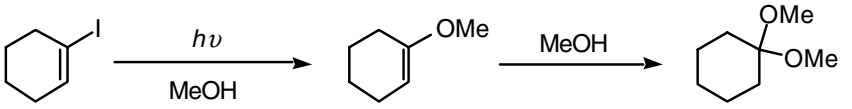
Tadros et al.[29] reported the dimerization of 1-bromo-2,2-bis(*p*-methoxyphenyl)ethene in acetic acid under sunlight irradiation. However, recent reports concerning this type of compound, 1,1-diaryl-2-haloethenes,[21a,b,g,22a,b] present a more complex reaction system with several processes taking place such as hydrogen abstraction, rearrangement, dimerization, and capture of the solvent.

Substitution by Solvents

Ionic reactions occur preferentially when aliphatic alkenyl iodides and aromatic alkenyl chlorides and bromides are irradiated. The trapping of the vinyl cations generated by irradiation readily takes place in nucleophilic solvents such as alcohols. In these cases, enol ethers or acetals are the main products (Equation 11.8 and Equation 11.9).[3,20,24,30]

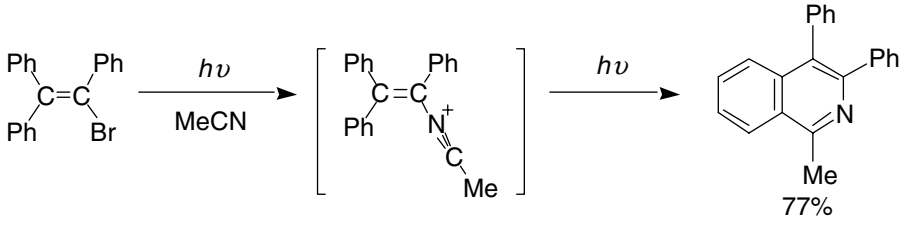


(11.8)



(11.9)

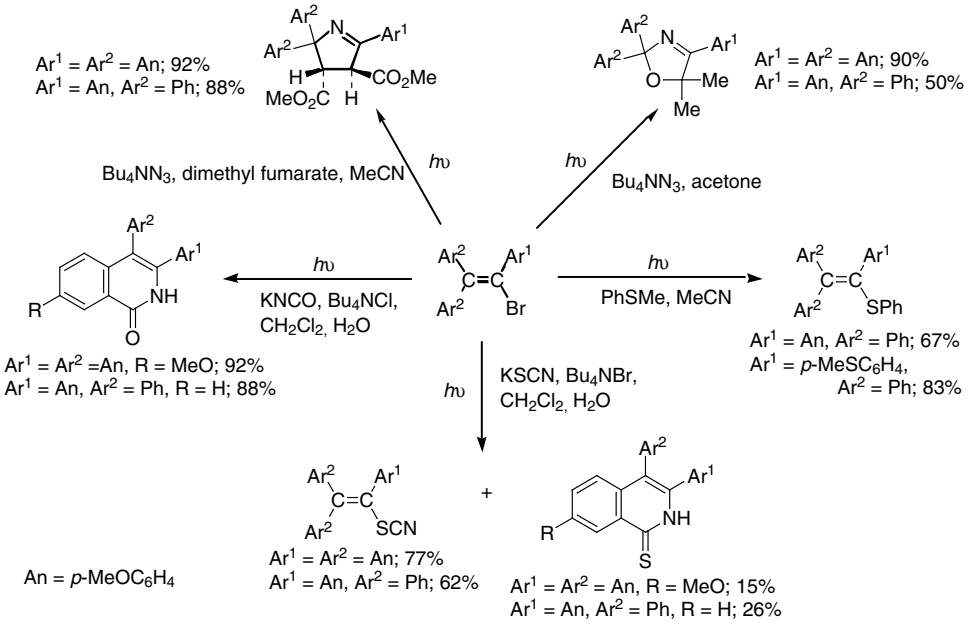
When nitriles such as acetonitrile are used as the solvent, a Ritter-type reaction is observed, in which the photogenerated vinyl cation is trapped to yield an intermediate nitrilium ion. This ion cyclizes, when there is an aryl group at the β-position of the vinylnitrilium ion, to give isoquinolines in good yield (Equation 11.10).



(11.10)

Substitution by Nucleophiles

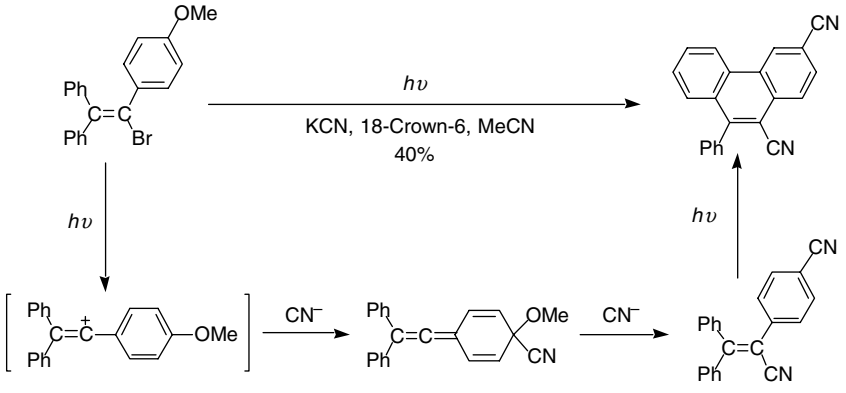
Other reactions of synthetic utility can be observed when suitable nucleophiles are added to the reaction system. Typical examples of these nucleophiles are azide,[26,32] cyanate,[33] thiocyanate,[33] and cyanide anions and thioanisole.[34,39] Reactions using these nucleophiles provide a reaction path to functionalized vinyl derivatives. The transformations are successfully achieved by using triaryl-substituted alkenyl halides. The reactions with such nucleophiles provide an efficient path to heterocyclic compounds, among others. Some examples, such as the pyrrolines, isoxazolines, isoquinolones, and thio derivatives, are prepared by this method and are shown in Equation 11.11.



(11.11)

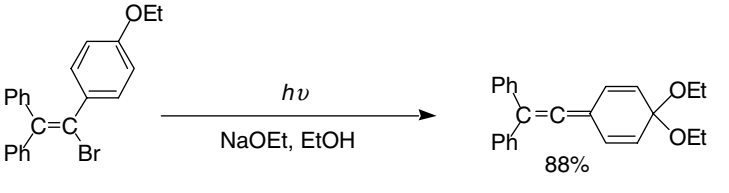
ipso-Substitution

Substitution at the aromatic ring (*ipso*-substitution) is also observed, but only in the cases of *p*-alkoxyphenylvinylhalides.[34,35] The *ipso*-substitution process was first observed in the reaction with cyanide anion as the nucleophile. The irradiation illustrated in Equation 11.12 brings about double substitution followed by a *cis*-stilbene type photocyclization to afford the dicyanophenanthrene shown.[34]

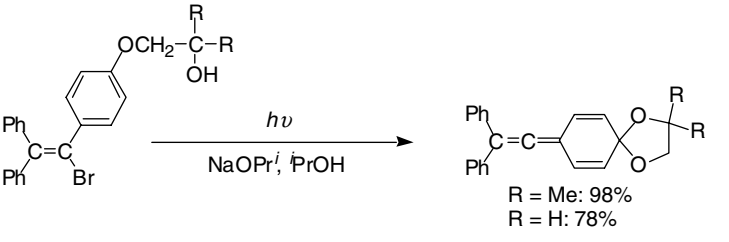


(11.12)

The intermediate *ipso*-adduct can be isolated in high yield when alkoxide anions are used as the nucleophile and the reaction temperature is controlled between 0 and 5°C (Equation 11.13).[35b] The *ipso*-adduct is obtained by intramolecular trapping by a pendant alkoxy chain at the *para*-position (Equation 11.14). The resulting spiro *ipso*-adducts are stable at room temperature.[36]



(11.13)



(11.14)

Intramolecular Cyclization

Intramolecular trapping of the vinyl cations provides a useful synthetic approach to several classes of molecule. The presence of an *ortho*-substituted aryl group at the β-position facilitates the cyclization. Benzofurans[21c] and dibenz[b,f]oxepines[37] can be prepared by this method (Equation 11.15 and Equation 11.16). The β-*p*-oxidophenyl group participates to give spiro cyclopropenes[38] (Equation 11.17).

Low Temperature Matrix Photochemistry of Alkenes

Ian R. Dunkin
University of Strathclyde

12.1 Introduction

This chapter covers photochemical studies of alkenes and cycloalkenes isolated in very low temperature matrices, typically solidified noble gases or nitrogen at temperatures of 10–20 K. Under the conditions of such *matrix isolation,* trapped species are prevented from diffusing and are therefore prevented from undergoing bimolecular reactions. As a result, extremely reactive species can be stabilized and investigated by a variety of normal spectroscopic methods, of which IR spectroscopy usually provides the most useful structural information. A brief description of the matrix-isolation technique and an account of its applications in several areas of organic photochemistry are given in a later chapter.

The matrix stabilization of reactive species has been exploited in a number of ways in the investigation of alkene photochemistry. Examples include the identification of reactive products, such as radicals, resulting from alkene photolysis, the direct observation of the dimerizations and rearrangements of carbenes to alkenes, the generation of strained alkenes, and studies of alkene oxidation resulting from irradiation of contact charge-transfer complexes between alkenes and NO_2. Sometimes, the principal advantage of matrix isolation derives not from the ability to stabilize reactive species but simply from the fact that the IR bands of matrix-isolated species tend to be very narrow. As a consequence, overlap between the IR bands of different compounds in product mixtures is minimized. This facilitates identification of the individual species present. Moreover, matrix IR frequencies are generally not greatly shifted from gas-phase frequencies, so calculated and experimental spectra can be expected to be in good agreement. In recent years, density functional theory (DFT) has been conspicuously successful in predicting the IR spectra of matrix-isolated species.[1]

Related topics that lie outside the scope of this chapter include thermal reactions in matrices between alkenes and reactive species such as F atoms and NH, even when these have been generated photochemically, the photochemistry of alkene radical cations, and matrix studies of azaalkenes, silaalkenes, and other alkene analogues.

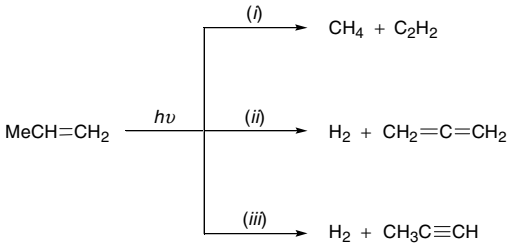


SCHEME 1

12.2 Photolysis of Alkenes in Matrices

Monoenes

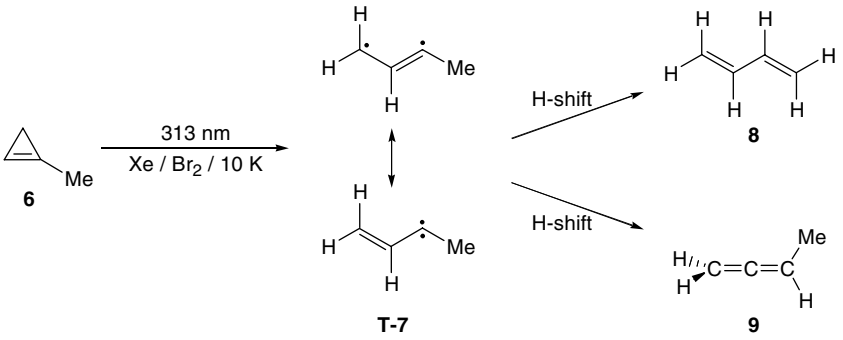
The lowest energy absorptions of simple monoenes lie well into the vacuum-ultraviolet region of the spectrum, and the high-energy reactions, which result from absorption at these wavelengths, tend to be nonspecific. In fact, very few matrix-isolation studies of the photolysis of simple alkenes have been conducted.

Propene has been photolyzed in Ar and N_2 matrices with microwave powered hydrogen, bromine, and nitrogen discharge lamps as the light sources.[2] It was found that propene decomposition occurred most efficiently by absorption of the 121.5 nm hydrogen emission. Although the energy at this wavelength lies above the ionization threshold, no evidence of propene ionization was obtained. The major products, identified by IR spectroscopy, were methylacetylene, allene, methane, and acetylene. These were presumed to arise in the three primary processes shown in Scheme 1, with process (*i*) predominating. It is noteworthy that neither ethene nor the methyl radical was formed in sufficient amounts to be detected. Moreover, in additional experiments, propene was photolyzed in CO and CO-doped Ar matrices in order to probe for the generation of H atoms or methylene (CH_2). These species would have reacted with CO to give the formyl radical (HCO) or ketene, respectively, both with easily recognized IR spectra. Neither of these CO-trapping products was detected, however. Thus, the matrix-isolation experiments provided good evidence that the primary photoprocesses occurred by extrusion of methane [process (*i*)] or molecular hydrogen [processes (*ii*) and (*iii*)] and not via radical or ionic fragmentations.

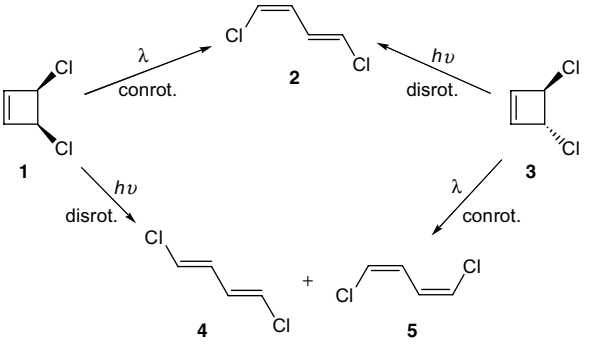
Similar studies were made of the vacuum ultraviolet (VUV) photolysis of fluoroethene[3] and all three difluoroethenes.[4] A major pathway in these reactions was the extrusion of molecular HF, yielding acetylene and fluoroacetylene, respectively. In contrast to the behavior of propene, however, a significant radical-fragmentation pathway was also observed, which gave $C_2H_2F\cdot$ from fluoroethene and $C_2HF_2\cdot$ from the difluoro compounds. Interconversion of the difluoroethenes was observed to a minor extent.

The absorptions of chloro-, bromo-, or iodo-substituted monenes are accessible to longer wavelength light sources than those of unsubstituted or fluoro-substituted analogues. Photolysis of 3-chloro-, 3-bromo-, and 3-iodopropene was carried out in Ar matrices with a medium pressure mercury arc.[5] In each case, the matrix IR spectra indicated that the major product was a complex between allene and the photoextruded hydrogen halide. Propyne and cyclopropyl halides were produced by secondary photolysis of the allene complexes. More recently, it was found that similar matrix photolyses of vinyl bromide and vinyl iodide gave hydrogen halide–acetylene complexes as the primary products and the corresponding haloacetylenes as secondary products.[6]

An interesting matrix effect was discovered for the photolysis of 1,2-dichloroethenes, the products of which differed in xenon and krypton matrices.[7] In Xe, photolysis of *E*- and *Z*-1,2-dichloroethene at 237 nm resulted in elimination of both Cl_2 and HCl, whereas in Kr, only HCl elimination and isomerization were observed. The results indicated that a triplet pathway operated in Xe but not in Kr, and this difference was attributed to intersystem crossing aided by the heavy-atom effect of the Xe matrix.



SCHEME 3



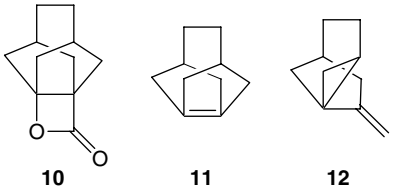
SCHEME 2

A second type of matrix effect has been observed for the photochemical ring opening of *cis*-3,4-dichlorocyclobutene (**1**) and *trans*-3,4-dichlorocyclobutene (**3**) (Scheme 2).[8] The thermally induced ring opening of **1** and **3** occurred with high stereospecificity via a conrotatory pathway, in accordance with the Woodward–Hoffman rules. On the other hand, direct excitation (193 nm) of **1**, matrix isolated in Ar or Xe, gave rise to products from the allowed disrotatory pathway (**4** and **5**) and also from the forbidden conrotatory route (**2**). IR bands of all the products increased at about the same rates, thus excluding the likelihood that **2** was formed in a secondary isomerization process. The stereoisomers **1** and **3** have no significant absorption at $\lambda > 230$ nm and were found to be photostable to light of $\lambda > 254$ nm in Ar matrices. Remarkably, however, both compounds were rapidly photolyzed by light of $\lambda > 270$ nm in Xe matrices, and both underwent *conrotatory* ring opening, the expected pathway for the thermal reaction. Under these conditions, the light was apparently absorbed by the solid xenon in a cooperative process with the dichlorocyclobutene molecules, and the reaction probably occurred via vibrationally excited molecules in the electronic ground state. Although no reactive species were observed in these experiments, matrix isolation brought the advantage of very narrow bandwidths in the product IR spectra. Thus, with minimal overlap of bands and also in conjunction with DFT computations, the products and their various conformations could be readily identified.

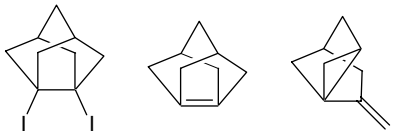
The addition of halogens, e.g., bromine, to Xe matrices is a refinement of the technique for photochemically inducing reactions of vibrationally excited electronic ground-state molecules, which has been developed in the last few years. Thus, 1-methylcyclopropene (**6**) was found to be stable towards light of 248, 254, or 313 nm in Ar matrices but was photolyzed by 313 nm light in Br_2-doped Xe matrices (Scheme 3).[9] The stable products were identified by their IR absorptions as buta-1,3-diene (**8**) and methylallene (**9**), but an additional set of IR bands was also observed in the product spectra. These absorptions decreased in intensity rapidly on subsequent irradiation at 313 or 366 nm, while the absorptions of **6**, **8**, and **9**

increased. A thorough DFT study showed that the additional IR bands belonged to triplet but-2-ene-1,3-diyl (**T-7**), which could therefore be identified as the primary photoproduct. The formation of this biradical from **6** corresponds to the theoretically calculated lowest energy ground-state pathway. In parallel experiments, propene-1,3-diyl was seemingly formed from cyclopropene under similar conditions, although the identification of the biradical was less certain in this case.

An alternative use of matrix isolation is to stabilize highly reactive species generated thermally, which can then serve as the starting materials for photochemical studies. A good example of this approach is provided by the highly strained, doubly pyramidalized alkene **11**, which has been generated by flash vacuum pyrolysis of the β-lactone **10** and isolated in Ar matrices by co-condensation of the pyrolysate with argon.[10,11] The strained alkene was found to have a broad UV absorption with λ_{max} = 245 nm, and irradiation with the 248 nm line of a KrF laser or with a low pressure Hg arc caused a gradual conversion of **11** into **12** in a reverse of the usual vinylcyclopropane rearrangement. Analogous attempts were made to generate alkene **14**, which is even more strained than **11**, by pyrolysis of the corresponding β-lactone.[12] These failed because the lactone was much more resistant than **10** to pyrolysis. Nevertheless, **14** was successfully matrix isolated by reaction of the diiodo precursor **13** with potassium or cesium vapor, followed by condensation with excess argon. Computations suggested that alkene **14** has a nearly tetrahedral geometry at the olefinic carbon atoms. On photolysis at 248 nm, **14** was converted into a new product, which was tentatively identified as **15** on the basis of the similarity of its matrix IR spectrum to that of **12**.



10 **11** **12**

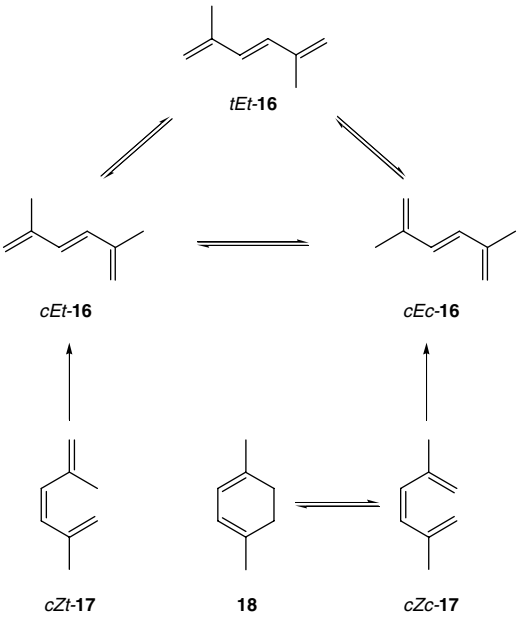


13 **14** **15**

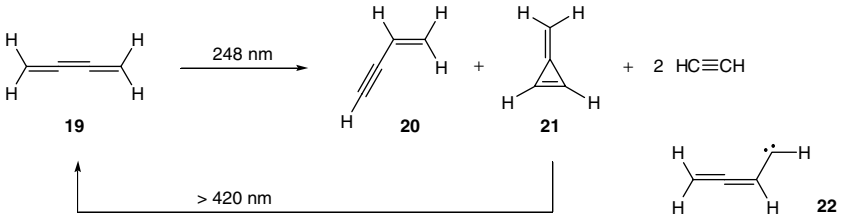
Dienes, Trienes, and Higher Polyenes

The photolyses of cyclohexa-1,3-diene,[13] cycloocta-1,3,5-triene,[14] and bicyclo[4.2.0]octa-2,4-diene[14] were investigated by matrix-isolation techniques at a relatively early date and certainly before reliable computational methods for IR transitions were available. As an example, both IR and UV-visible spectroscopy were employed to monitor the photoreaction of cyclohexa-1,3-diene at 240–270 nm in Ar matrices at 20 K.[13] It was discovered that the diene photolyzed irreversibly to *Z*-hexa-1,3,5-triene, which photolyzed more slowly but still irreversibly to *E*-hexa-1,3,5-triene and several other thermally unstable products. The latter could not be identified with certainty, but hexa-1,2,4-triene and *exo*-2-vinylbicyclo[1.1.0]butane were proposed as possibilities.

When *E*-2,5-dimethyl-1,3,5-hexatriene (**16**) was isolated in Ar matrices, it was found to exist almost exclusively as the *tEt* rotamer, but UV irradiation led to the formation of thermodynamically less stable rotamers (Scheme 4).[15] The various rotamers could be identified by comparison of their experimental and computed IR transitions. When the *Z* triene (**17**) was isolated in Ar matrices, it existed predominantly as the *cZt* rotamer, but it could also be generated in the *cZc* form by matrix photolysis of 1,4-dimethylcyclohexa-1,3-diene (**18**). In contrast to the *E* isomer, the *Z* isomer underwent photo-induced double bond isomerization, generating rotamers of the *E* form. It should be noted that matrix isolation provides



SCHEME 4

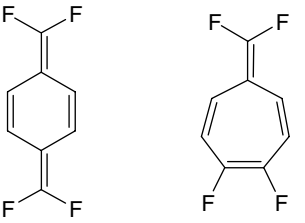


SCHEME 5

a generally applicable means of stabilizing the individual rotamers of flexible molecules and is thus an ideal way to identify their spectra and study their interconversions.

The 248 nm photolysis of butatriene (**19**) in Ar matrices at 10 K produced vinylacetylene (**20**), methylenecyclopropene (**21**), and acetylene (as a dimeric complex) (Scheme 5).[16] The rearrangement of **19** to **21** could be reversed by irradiation at long wavelengths ($\lambda > 420$ nm). The conversion of **19** to **21** was most likely to have proceeded by a [1,2]-H migration, forming allenylcarbene (**22**), and theoretical calculations suggest that this species is an energy minimum on both the singlet and triplet potential energy surfaces. Careful analysis of the matrix IR spectra revealed two sets of absorptions that could be attributed either to the *syn* or *anti* forms of singlet **22** or to a mixture of singlet and triplet **22**. Thus, the rearrangement of **19** to **21** appeared to proceed in a stepwise manner on either the singlet or triplet energy surface, with **22** as the intermediate.

Tetrafluoro-*p*-xylylene **23** has been matrix isolated by flash vacuum pyrolysis of the corresponding octafluoro[2.2]paracyclophane followed by condensation at 30 K with a large excess of argon.[17] This is a further example of the use of matrix isolation to stabilize a highly reactive species produced in a thermal reaction, which then becomes the starting material for photochemical studies. Irradiation of **23** at 248 nm resulted in partial conversion to a new species, which was identified as the tetrafluoroheptafulvene **24** by comparison of the experimental and computed IR transitions. Several possible reaction mechanisms for this rearrangement were proposed, but no intermediate species was detected in the matrix photolysis experiments, so a final conclusion as to the mechanism could not be drawn.



23 **24**

The UV photolysis of the [2,2]paracyclophan-ene **25** in Ar at 10 K resulted in cleavage of the ethano bridge and formation of **26**, which was identified by means of its IR and UV-visible absorption spectra.[18] The absence of an electron paramagnetic resonance (EPR) signal showed that the new species had a singlet ground state, while comparison of the IR and UV-visible spectra with those of *p*-xylylene and the benzyl radical suggested that the electronic structure of the photoproduct was predominantly quinonoid (**26a**) but with a substantial biradical contribution (**26b**). Related studies of a benzoannelated analogue of **25** gave similar results.

12.3 Photochemical Generation of Alkenes in Matrices

Cyclobutadiene

The story of the generation, detection, and determination of the structure of cyclobutadiene isolated in low temperature matrices is one of the most celebrated and long running in the history of matrix isolation, and it illustrates both the strengths and pitfalls of the technique.

The generation of cyclobutadiene (**30**) by matrix photolysis of α-pyrone (**27**) (Scheme 6) was reported independently in 1972–73 by two research groups.[19,20] Irradiation of matrix-isolated **27** with 313 nm light[21] or with $NiSO_4$-filtered[19] or Pyrex-filtered[22] Hg arcs resulted quickly in a reversible ring-opening to the aldehyde-ketene **28** and its rotamers, which could be interconverted photochemically. More prolonged irradiation, however, gave the β-lactone **29**, recognized by its characteristic high frequency ν(C=O) bands at 1850 and 1826 cm^{-1}. After a sufficiently long period of irradiation, quite high conversion of **27** into **29** could be achieved. Prolonged further irradiation, or irradiation with the filter removed, caused the disappearance of the IR bands of **29** and the appearance of those of CO_2 and another species, presumed to be cyclobutadiene (**30**). IR absorptions at or near 3040, 1240, 650, and 570 cm^{-1} were attributed to the latter species, which decomposed to acetylene on even more prolonged photolysis. A weak electronic absorption with λ_{max} at 405 nm was also attributed[19] to **30**. These experiments provided for the first time an IR spectrum of cyclobutadiene on which to base discussions of its structure. The crucial first question was whether the ring is square or rectangular.

Symmetry considerations predict four infrared-active fundamental vibrations for a square planar (D_{4h}) structure for **30** and seven for a rectangular planar (D_{2h}) structure. The simplicity of the observed IR spectrum, with only four absorptions, led one group[20] to the tentative conclusion that **30** has a square planar structure, in contradiction to nearly all previous theoretical predictions. The difficulty, of course,

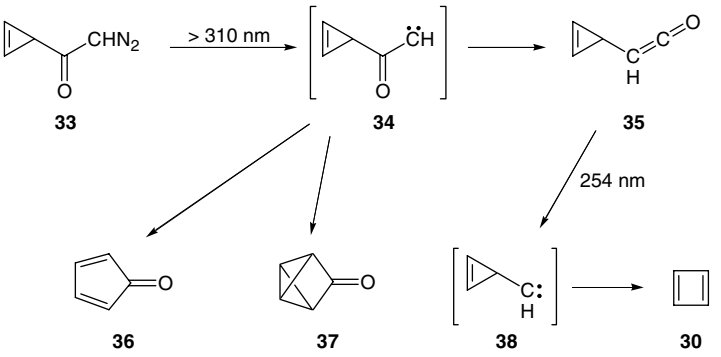
32d: X = Y = D

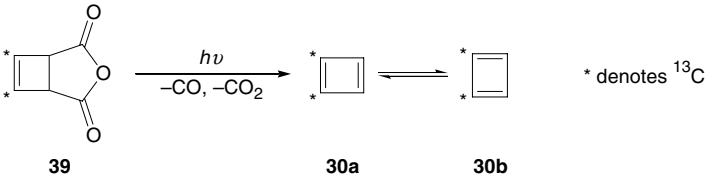
SCHEME 7

was that some fundamental IR bands might have remained undetected simply because they were too weak. In an effort to gain more structural information, mono- and dideuteriocyclobutadienes were generated in matrices by photolysis of the appropriate deuteriated α-pyrones,[23,24] but these experiments still left the question of the geometry of **30** unresolved. The uncertainty intensified when, a few years later, cyclobutadiene was generated in matrices from several different precursors,[25,26] in particular **31a**, from which cyclobutadiene was obtained along with phthalan (**32a**) but without the simultaneous formation of CO_2 (Scheme 7). In these studies, it was shown that the IR band at 650 cm^{-1} did not belong to **30** but was rather due to a complex between molecules of **30** and CO_2, which had remained together in the matrix cage after the photolysis of **29**. The 650 cm^{-1} band was apparently due to the bending mode of CO_2 perturbed slightly by interaction with **30**. This assignment of the 650 cm^{-1} band was confirmed by matrix photolysis of α-pyrone isotopically labeled with ^{13}C at the carbonyl carbon.[27] The product band normally at 650 cm^{-1} exhibited a substantial isotope shift to 636 cm^{-1}, showing that it belonged to CO_2 and not to the diene. Furthermore, after photolysis of α-pyrone ^{13}C-labelled at the 6-position, the 650 cm^{-1} IR band had no detectable isotope shift, whereas the 1240 cm^{-1} band of **30** was shifted to lower frequency by about 4 cm^{-1}. These observations left only three IR bands that could be reliably attributed to cyclobutadiene, and the inevitable conclusion was that at least one IR band of this compound had not been detected. If one such band, why not more than one?

The main question concerning the geometry of cyclobutadiene was eventually resolved when two additional IR bands of this molecule were observed at 1523 and 723 cm^{-1}, thus demonstrating that the molecule is not square.[28] The diene was generated by photolysis of precursors **31a-d** in argon matrices at 7 K. Although the IR absorptions of the byproduct, phthalan (**32a**), masked several regions of the matrix IR spectra, the IR bands of the isotopomers **32b-d** were significantly shifted, thus permitting careful scrutiny of the entire mid-IR region from 4000 to 400 cm^{-1}.



SCHEME 8



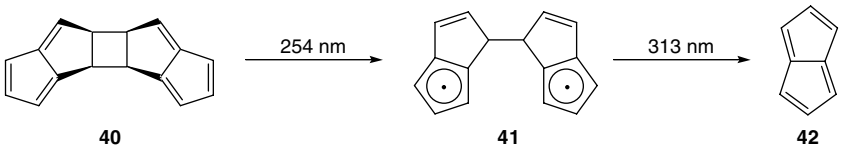
SCHEME 9

A thorough and critical review of cyclobutadiene chemistry[29] was published in 1980. A theoretical study of possible interactions between cyclobutadiene molecules and the various byproducts formed when **30** is generated photolytically in matrices appeared later.[30] Weak complexes between **30** and CO, CO_2, HCN, benzene, and phthalan (**32a**) were predicted, but no attempt was made to evaluate the effects of such complex formation on the IR absorptions of **30**.

Since the early work, the matrix chemistry of cyclobutadiene has attracted less attention, although some interesting results have been obtained. Diazoketone **33** gave cyclopropenylketene **35**, cyclopentadienone (**36**), and tricyclopentanone **37** when photolyzed at >310 nm in argon matrices, presumably via the ketocarbene **34**, which was not, however, observed directly (Scheme 8).[31] Ketene **35** was then further photolyzed at 254 nm, yielding cyclobutadiene (**30**), presumably via carbene **38**. At this shorter wavelength, **36** was photostable, but the tricyclopentanone **37** also gave mainly **30**, but in a very slow reaction.

Once it appeared certain that cyclobutadiene had a rectangular structure with alternating single and double bonds, it became interesting to consider the interconversion of the two valence tautomers. This was first probed by polarized IR spectroscopy coupled with one of the rare examples of the use of ^{13}C NMR spectroscopy of matrix isolated species.[32] Linearly polarized UV light was used to generate a matrix sample of partially oriented **30** from the unlabelled version of anhydride **39**, and the resulting matrices were then probed with linearly polarized IR light to determine the linear dichroism of each product IR band.[33] These studies were made with Ne and Ar matrices at temperatures down to 2.8 K. Although persistent IR dichroism was observed for six IR bands of **30**, the pattern of dichroism did not allow a conclusion to be drawn with regard to the rate of interconversion of the valence tautomers. On the other hand, ^{13}C NMR spectra of the matrix photolysis products of the vicinally ^{13}C-dilabelled anhydride **33** showed that the rate of interconversion of the two cyclobutadiene tautomers **30a** and **30b** exceeded 10^3 sec^{-1} at 25 K (Scheme 9). It was not possible to distinguish between thermally activated and tunneling interconversion, but the theoretically predicted energy barrier for the reaction (40–60 kJ mol^{-1}) was consistent only with a tunneling process.

A subsequent investigation using matrix Raman spectroscopy confirmed the submillisecond timescale for tautomer interconversion but led to the conclusion that even this was slow compared to theoretical expectations.[34] It was therefore suggested that the matrix environment, including the CO and CO_2



SCHEME 10

byproducts, might have a hindering effect on the tunneling process. In a further study of the UV and polarized IR spectra of matrix isolated cyclobutadiene and its *1-d*-, *1,2-*d_2-, *1,4-*d_2-, *1*–^{13}C-, *1,2*–$^{13}C_2$-, and *1,4*–$^{13}C_2$-labelled derivatives,[35] it was found that the two tautomers interconverted on a time scale of minutes even at 10 K. It was moreover discovered that the presence of CO_2 in the same matrix site inhibited the photodecomposition of cyclobutadiene to acetylene, probably because the CO_2 molecules enhanced the rate of vibrational relaxation in competition with fragmentation.

Pentalene

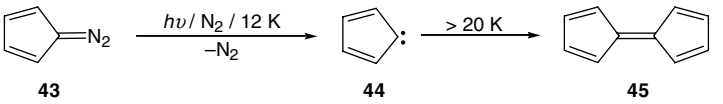
Although sterically shielded or electronically stabilized derivatives of pentalene (**42**) had been characterized previously, the first convincing spectroscopic evidence for the parent molecule was obtained when the *syn-cis* dimer **40** was photolyzed in argon and N_2 matrices (Scheme 10).[36] The cleavage took place in two steps: the first with 254 nm light leading apparently to the biradical **41**, while the subsequent cleavage to **42** occurred with 313 nm light. Pentalene was thus observed for the first time by electronic and vibrational absorption spectroscopy and was identified positively by an excellent agreement between the experimental IR spectrum and IR transitions computed by DFT theory. A C_{2h} structure for **42**, with pronounced alternation of single and double bonds, was indicated by both theory and experiment. In addition, a reinterpretation of the previously reported electronic spectra of pentalene derivatives emerged from this work.

Carbene Dimerizations

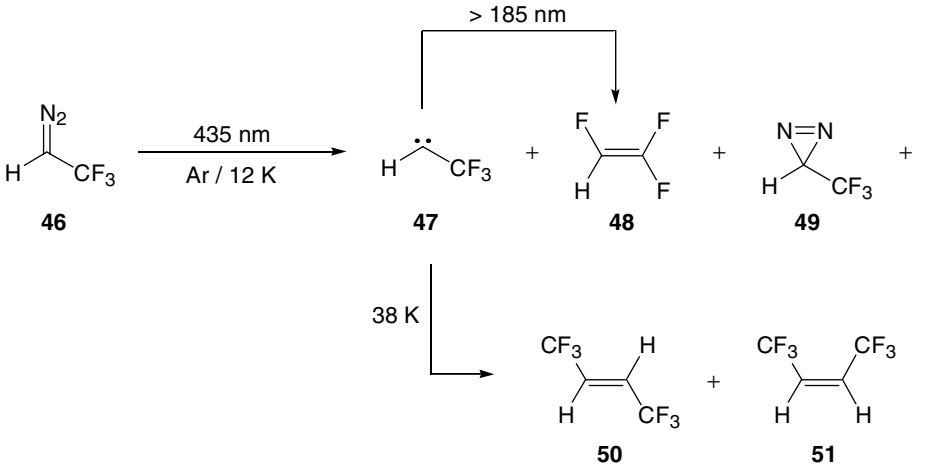
In principle, the dimerization of a carbene or the addition reaction of two different carbenes should provide a fundamental method for double bond formation. In practice such reactions are rare, primarily because carbenes are highly reactive species and are seldom generated in concentrations high enough to favor dimerization; they therefore usually undergo reactions with other species present, e.g., solvent or precursor molecules. The matrix-isolation technique, however, provides a means of generating carbenes in high concentration before the matrix is allowed to warm sufficiently to allow diffusion. This should permit the observation of genuine carbene dimerizations, and some such cases have been reported.

The simplest of all carbenes, methylene (CH_2), initially proved difficult to observe in low temperature matrices, owing to its small size and high mobility. One of the first indications that methylene had been generated in matrices was the observation of the supposed chemiluminescence of ethene following photolysis of diazomethane in solid argon or nitrogen.[37] The luminescence exhibited a distinct isotope effect when CD_2N_2 was photolyzed and was presumed to arise from excited ethene molecules formed by the dimerization of methylene. Nevertheless, a reinvestigation of this reaction[38] led to the conclusion that the excited ethene could have arisen either from the dimerization of CH_2 or from the reaction of CH_2 with the precursor CH_2N_2.

One of the first unequivocal examples of carbene dimerization in matrices seems to have been that of cyclopentadienylidene (**44**) (Scheme 11).[39,40] Photolysis of diazocyclopentadiene (**43**) in N_2 matrices produced the carbene **44**, which could be detected directly through both its UV and IR absorptions, provided that very dilute matrices were employed. When matrices containing **44**, but little or no **43**, were warmed to 20–25 K, fulvalene (**45**) was produced, which was recognized by its highly structured and distinctive UV absorption spectrum. Several carbenes analogous to **44**, e.g., tetrachloro- and tetrabromocyclopentadienylidene and fluorenylidene,[41,42] failed to undergo similar dimerizations even at 30–35 K.



SCHEME 11



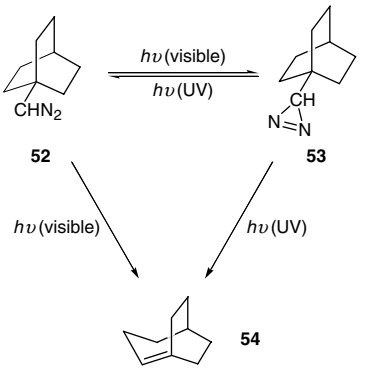
SCHEME 12

This was assumed to be a result of the increased size of the molecules compared with **44**, which would hinder diffusion within the matrix and also increase the energies of the transition states leading to the corresponding fulvalenes through unfavorable steric interactions.

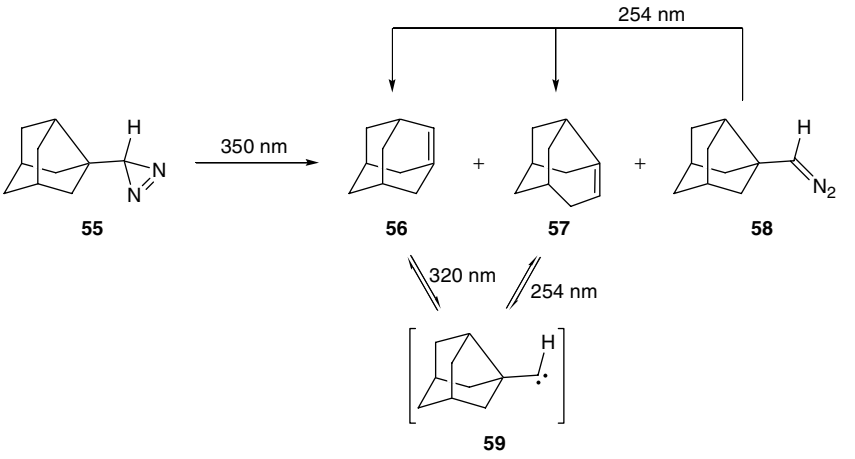
Many carbenes undergo rapid isomerizations when generated in matrices, especially via hydrogen or alkyl shifts. These unimolecular reactions compete very favorably with the bimolecular carbene dimerizations unless suppressed, e.g., by fluorine substitution. For example, 435 nm photolysis of 2,2,2-trifluorodiazomethane (**46**) in Ar matrices at 12 K generated significant amounts of the triplet carbene **47** as well as trifluoroethene (**48**) and small amounts of diazirine **49** and the hexafluorobut-2-enes **50** and **51** (Scheme 12).[43] Shorter-wavelength irradiation converted the carbene into trifluoroethene, whereas warming the matrix to 35–38 K increased the yields of the hexafluorobut-2-enes **50** and **51**, with a concomitant decrease in the concentration of the carbene.

Carbene Rearrangements

The rearrangements of carbenes via CC bond shifts have afforded routes to a number of matrix isolated strained bi- and tricycloalkenes of the *anti*-Bredt type. The inherently high energy of the carbene provides the driving force for the rearrangement to the strained product. As an example, the moderately strained bridgehead alkene bicyclo[3.2.2]non-1-ene (**54**) was generated in low temperature matrices and in fluid solutions by photolysis of the diazo precursor **52** and its diazirine isomer **53** (Scheme 13).[44] The diazo compound **52** was matrix isolated in argon by flash vacuum pyrolysis of the corresponding tosylhydrazone, followed by condensation of the pyrolysate in an excess of argon at 28 K. UV irradiation of **52** at 248 or 254 nm resulted in rapid decomposition, but slower and more selective photolysis occurred with visible light (488 or 514 nm). Under the latter conditions, **52** was converted into a mixture of products, which were identified as the diazirine isomer **53** (major) and the bridgehead alkene **54** (minor). The diazo compound and the diazirine could be photochemically interconverted by suitable choice of irradiation wavelength: 308 nm light favoring **52**, while 514 nm light favored **53**. Alternate irradiation of the



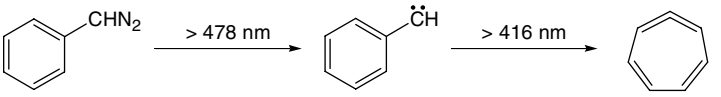
SCHEME 13



SCHEME 14

matrix sample at 514 and 308 nm eventually caused all the UV and IR absorptions of **52** and **53** to disappear, leaving an IR spectrum that could be assigned to **54** by comparison with a calculated spectrum.

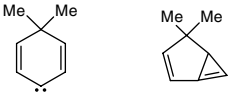
Matrix photolysis of 3-noradamantyldiazirine **55** at 350 nm produced adamantene **56** and protoadamant-3-ene (**57**), together with some of the diazo isomer **58**, which gave the same two bridgehead alkenes when irradiated at 254 nm (Scheme 14).[45] The two alkenes **56** and **57** could be photochemically interconverted with 320 and 254 nm light. The intermediacy of the carbene **59** was proposed for these processes, but the carbene was not detected directly, either in low temperature matrices or in parallel flash-photolysis studies. In an earlier investigation,[46] it had been found that 2-adamantylidene (**60**) rearranged to the tetracyclic tautomer **61** rather than the bridgehead alkene **62**. Computations suggested that formation of **61** from **60** is a much more exothermic process than formation of **62** and that the [1,2]-hydrogen shift that would lead to **62** is effectively prevented by the geometry of the carbene, which keeps the empty *p* orbital perpendicular to the migrating CH bond.



65 **66** **67**

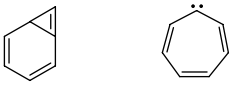
SCHEME 15

The triplet carbene **T-63** was generated in argon matrices by photolysis of the corresponding diazo precursor and characterized by UV-visible and IR spectroscopy.[47] On further irradiation with light of $\lambda > 515$ nm, this carbene rearranged irreversibly to the strained cyclopropene **64**. This reaction most probably occurred on the singlet energy surface, after excitation of **T-63** to the singlet state via excited triplet states.

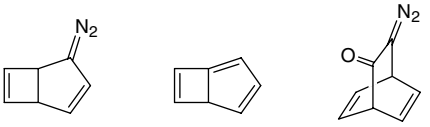


T-63 **64**

Matrix isolated aryl carbenes have yielded routes to a number of strained polyenic systems, including strained cyclopropenes and cyclic cumulenes. For example, photolysis of phenyldiazomethane (**65**) with visible light ($\lambda > 478$ nm) gave phenylmethylene (**66**), which was characterized by its highly structured UV absorptions and its IR spectrum (Scheme 15).[48] Further irradiation of **66** at shorter wavelengths ($\lambda > 416$ nm) produced a new species with a broad UV absorption with $\lambda_{max} = 271$ nm and IR absorptions which seemed considerably more complex than those usually encountered with phenyl groups. It was concluded that the new species was the cyclic allene cyclohepta-1,2,4,6-tetraene (**67**), and IR bands at 1824 and 1816 cm^{-1} were identified as belonging to the $\nu(C{=}C{=}C)_{as}$ stretch of the strained allenic system. In a detailed extension of this first study,[49] the identity of **67** was further supported by deuterium labeling and photolysis of fluoro and chloro derivatives of **65**, which ruled out the bicycloheptatriene **68** and the carbene **69** as alternative possibilities for the photoproduct of **66**. It was also discovered that diazobicycloheptadiene **70**, rather surprisingly, gave **67** as the sole product when photolyzed in argon matrices, and neither the corresponding carbene nor bicycloheptatriene **71** was detected. The diazoketone **72** also yielded **67** as a matrix photoproduct, along with CO and other carbonyl-containing species. The cyclic allene **67** is thus a readily accessible species. A theoretical study of substituent effects on the interconversions of phenylmethylene (**66**), cyclohepta-1,2,4,6-tetraene (**67**), and bicyclo[4.1.0]hepta-2,4,6-triene (**68**) has been published very recently.[50]

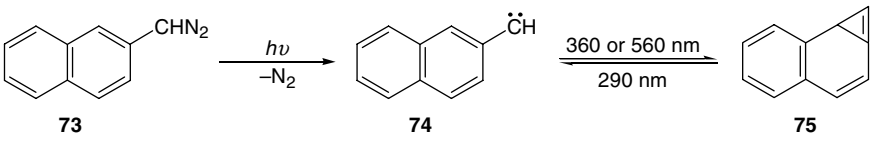


68 **69**

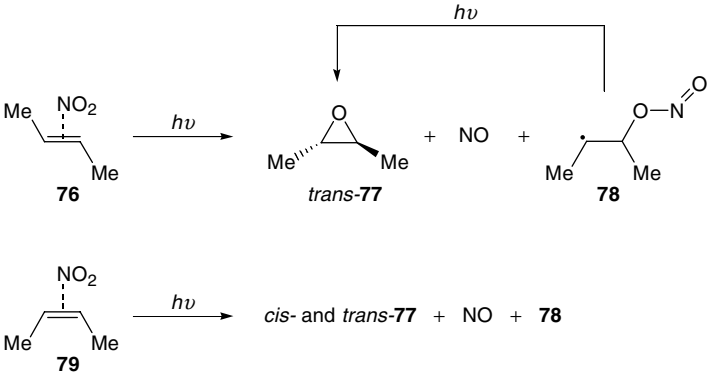


70 **71** **72**

In contrast to phenyldiazomethane, matrix photolysis of the naphthyldiazomethanes produced benzobicyclo[4.1.0]heptatrienes in photoequilibrium with the corresponding carbenes, rather than cyclic allenes.[51–53] For example, photolysis of 2-naphthyldiazomethane (**73**) ($\lambda > 300$ or $\lambda = 480$ nm) in argon at 10 K gave a mixture of the carbene **74** and the benzobicycloheptatriene **75**, which could be interconverted photochemically by choice of suitable irradiation wavelengths (Scheme 16).[52] Broadly similar



SCHEME 16



SCHEME 17

results were obtained in an examination of the matrix photolysis of 1-naphthyldiazomethane and its diazirine isomer.[53] Cyclic allenes analogous to **67** were not observed in any of these matrix-isolation studies of naphthylmethylenes.

12.4 Matrix Photochemistry of Alkene Complexes

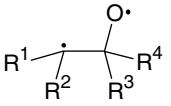
Alkene Complexes with NO_2

Charge transfer complexes between alkenes and NO_2 in low temperature matrices can be photolyzed with long-wavelength light, resulting in mild and selective oxidation of the alkene. For example, *E*-but-2-ene–NO_2 pairs (**76**) isolated in solid Ar were photolyzed with red, yellow, and green light, yielding *trans*-but-2-ene oxide (*trans*-**77**) and NO (Scheme 17).[54] In this reaction, the epoxide was formed with complete retention of stereochemistry. An addition product was also observed, and this was identified as the butyl nitrite radical **78**. With the isotope mixture $N^{16}O_2/N^{16}O^{18}O/N^{18}O_2$, the product IR spectrum revealed that the radical had nonequivalent O atoms, and this ruled out the analogous nitro radical, in which the O atoms would be identical. Analysis of the photolysis-wavelength dependence of the growth kinetics of *trans*-**77** + NO and the radical **78** showed that the epoxide was formed in two processes. In one, the epoxide, NO, and the radical **78** were generated upon absorption of a single photon by each reactant pair; in the other, *trans*-**77** arose by secondary photolysis of **78**. With *Z*-but-2-ene–NO_2 pairs (**79**) at low matrix concentrations, only 85% of the product epoxide retained the original stereochemistry, and this proportion decreased at higher concentrations.[55] Two conformers of the butyl nitrite radical **78** were also identified in these experiments: one *syn* and the other *anti* with respect to the position of the methyl groups about the central CC bond. Interestingly, on photolysis the *anti* conformer gave *trans*-**77** and NO at a threshold wavelength of 613 nm, while the *syn* conformer gave 2-methylpropanal and NO at 573 nm and shorter wavelengths.

Similar studies have been made of matrix isolated cyclohexene- and cyclopentene–NO_2 pairs.[56] At wavelengths greater than the dissociation threshold of NO_2 (398 nm), the corresponding cycloalkene oxides were the only final oxidation products, although two diastereomeric nitrite radicals were detected

as intermediates in the cyclohexene oxidation, and a single nitrite radical in the cyclopentene case. Comparable results have also been obtained for matrix-isolated complexes of NO_2 with propene.[57] With ethene- and tetradeuterioethene–NO_2 pairs, however, acetaldehyde was formed as well as ethylene oxide at wavelengths greater than 398 nm, and at wavelengths just above this NO_2 dissociation limit (385 and 355 nm), a new pathway leading to ketene was observed.[58] A carbonyl product, pinacolone, was also formed in the matrix photolysis of 2,3-dimethylbut-2-ene–NO_2 complexes alongside tetramethyloxirane.[59]

From these studies of the matrix photolysis of alkene–NO_2 pairs, it has been concluded that the primary process is a large amplitude O-atom transfer from NO_2 to the alkene, which occurs at photon energies below the dissociation threshold of NO_2. This transfer reaction is assumed to give biradicals **80**, which can undergo ring closure to the epoxides, rearrange to carbonyl products, or react with NO within the matrix cage to generate the nitrite radicals. So far, no example of a biradical of the type **80** seems to have been observed directly. In view of the retention of stereochemistry (partial or complete) observed in some of the reactions, it is likely that such biradicals have lifetimes that are short compared to rotation about CC bonds, so any difficulty encountered in detecting them spectroscopically would not be surprising.

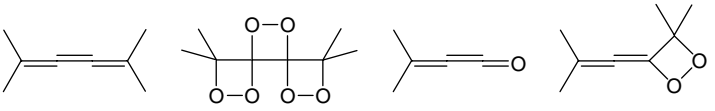


80

The matrix photochemistry of the 2,3-dimethylbut-2-ene complex with N_2O_4 (the NO_2 dimer) has also been investigated.[60] In this case the major product was 2,3-dimethyl-3-nitroso but-2-yl nitrate, a nitroso nitrate, and the minor product 2,3-dimethyl-3-nitrobut-2-yl nitrite, a nitro nitrite. The mechanism by which the observed products were formed appeared to be distinct from that previously suggested for the thermal reaction of alkenes with N_2O_4 in solution.

Other Alkene Complexes

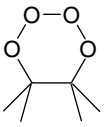
There have been a few studies of the matrix photolysis of complexes between alkene molecules and species other than NO_2. The charge transfer complex between O_2 and 2,5-dimethylhexa-2,3,4-triene (**81**) has been photolyzed in Ar matrices containing various amounts of O_2 and in pure O_2 matrices.[61] Oxidation products were formed even with visible light (543 nm), and these included the trisdioxetane **82**, which decomposed on further irradiation (slowly at $\lambda > 500$ nm, rapidly at $\lambda > 300$ nm) to acetone and CO_2. Identification of **82** was assisted by interpretation of its IR spectrum and the use of oxygen isotopes. At O_2 concentrations between 10 and 100%, the trisdioxetane was almost the sole product in these matrix reactions. At lower O_2 concentrations, a second product was observed, which was identified as dimethylpropadienone (**83**) and was probably formed from dioxetane **84**.



81 **82** **83** **84**

When 2,3-dimethylbut-2-ene was isolated in pure O_2 matrices, a broad charge-transfer band was observed, which tailed into the visible region to about 550 nm.[62] Irradiation of the matrices with visible light ($\lambda > \sim 520$ nm) gave a single product, which was tentatively identified as the tetraoxane **85** on the basis of the IR spectrum obtained with $^{18}O_2$. No product characteristic of the reaction of alkenes with singlet O_2 was detected. Two reaction mechanisms were proposed for the formation of **85**: one involved

stepwise addition of the two O_2 molecules via a triplet biradical, the other was a concerted mechanism in which two O_2 molecules participate in the excitation. The experimental results did not discriminate between these alternatives, however.



85

The complexes of ethene and cyclopropene with bromine were generated in argon matrices by co-condensation of alkene–argon and bromine–argon mixtures.[63] The structures of the complexes were determined by IR spectroscopy in conjunction with theoretical computations as complexes with the Br–Br bond perpendicular to the CC double bond, e.g., **86**. On photolysis with $\lambda > 300$ nm, the ethene–Br_2 complex gave 1,2-dibromoethane as the only detectable product, but apparently with an unusually high proportion of the normally disfavored *gauche* conformation. Similar photolysis of the cyclopropene complex **86** gave *cis*-1,2-dibromocyclopropane (**87**), 3-bromocyclopropene (**88**), and 1,3-dibromopropene (**89**) as the main products. The experimental results for both complexes fit well with a reaction mechanism in which initial cleavage of the Br–Br bond was followed by addition of one Br atom to the alkene to yield an intermediate monobromo radical.

Photorearrangement and Fragmentation of Alkenes

Paul J. Kropp
University of North Carolina

13.1 Photochemical Behavior

On direct irradiation in nonhydroxylic solvents, alkenes typically undergo several competing photoreactions. In addition to *E,Z*-isomerization, which is also exhibited on triplet sensitization, several processes occur that are usually observed only on direct irradiation: rearrangement via carbene intermediates, double bond migration, alkyne formation, and hydrogen atom abstraction. This chapter is concerned with these latter processes. Emphasis is given to developments since the topic was reviewed extensively in 1979.[1] Portions of this material are covered in reviews that have appeared since then.[2,3] The photobehavior of alkenes in hydroxylic media is discussed in Chapter 9.

Spectroscopic Properties

The ultraviolet absorption spectra of simple alkenes in solution typically consist of single, featureless bands with maxima at 185–195 nm ($\varepsilon = 5\text{–}10 \times 10^3$) and tails extending to 210–255 nm.[4] Absorption extends to longer wavelengths with increasing degrees of substitution. The spectra are deceptively simple, as they consist of several overlapping bands arising from close-lying transitions, two of which are generally accepted as being $\pi \rightarrow \pi^*$ and $\pi \rightarrow R(3s)$.[5] Weak absorptions attributed to $\pi \rightarrow \sigma^*$ transitions have also been reported for alkenes in the liquid state,[5c] although their presence has not been independently confirmed. Gas-phase absorption spectra are generally similar to those in solution except for the presence of some structure in the bands and somewhat longer absorption tails. Due to the diffuseness of Rydberg orbitals, bands corresponding to Rydberg transitions are severely reduced in intensity and blue-shifted in the condensed phase compared to the gas phase at low pressure.

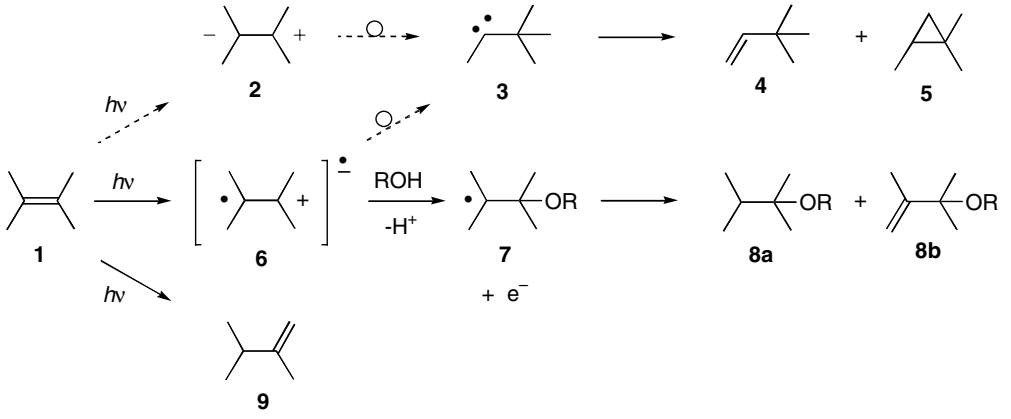
0-8493-1348-1/04/$0.00+$1.50

Alkenes exhibit only weak fluorescence, which is thought to involve emission from the π,R(3s) state.[6] On excitation at 185 nm, the emission maximum moves from 231 to 263 nm with increasing alkyl substitution, and the fluorescence quantum yield increases from 1×10^{-6} to 1.5×10^{-4}. Ethene itself does not fluoresce. The excitation maximum increases with increasing wavelength, moving from 195 nm for disubstituted to 229 nm for tetrasubstituted alkenes. The fluorescence lifetime is estimated at 15 psec.

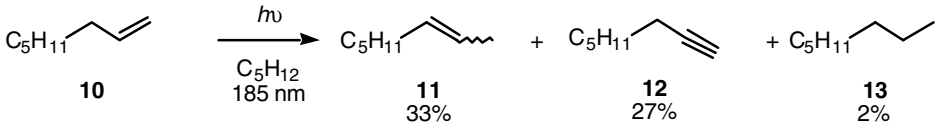
Owing to the large energy gap between the singlet and triplet manifolds, alkenes do not readily undergo intersystem crossing. Thus, their behavior on direct irradiation arises from singlet-excited states. The vertical excitation energy of the π,R(3s) singlet is generally below that of the ππ* singlet. Having a somewhat electron-deficient core, the ππ* excited state moves to lower energy with increasing alkyl substitution. But due to the large size of the 3s Rydberg orbital, the π,R(3s) state has an even more electron-deficient core and responds more strongly to alkyl substitution. Thus, the separation between the ππ* and π,R(3s) vertical levels increases with increasing substitution. However, the ππ* state undergoes substantial relaxation through pyramidalization and/or rotation about the central CC bond. Thus, in alkenes that are not highly substituted, the vertical levels are close, and the relaxed ππ* level is close to, if not lower than, that of the π,R(3s) state. With increasing substitution, there is increasing likelihood that the π,R(3s) state is lower lying. However, analysis of the ultrafast dynamics following irradiation of several alkenes in the gas phase has recently implied the presence of yet a third excited state somewhat lower lying than these two: the zwitterionic Z state (π^{*2}), which involves excitation of two π electrons.[7]

Principal Pathways

Irradiations of alkenes are generally conducted with a low-pressure mercury lamp (185 nm), an ArF excimer laser (193 nm), or a zinc resonance lamp (214 nm). Highly substituted alkenes can also be irradiated with a medium-pressure lamp and quartz optics (>200 nm). Because of the presence of two or more close-lying singlet excited states, irradiation of alkenes usually results in several competing photoprocesses. Thus, for example, irradiation of 2,3-dimethyl-2-butene (**1**) in hydrocarbon or ether solvent results in rearrangement to the carbene-derived products **4** and **5** and the double bond isomer **9**.[8] *E,Z*-Isomerization also occurs but is not apparent in this case because of the symmetry of alkene **1**. Similar behavior is exhibited in the gas phase.[9] In alcoholic or aqueous media, the nucleophilic trapping products **8** are formed in competition with the carbene-derived products **4** and **5**.[10]



The monosubstituted alkene 1-octene (**10**), on the other hand, affords the double bond migration products *E*- and *Z*-2-octene (**11**) but no products obviously derived from a carbene intermediate.[11] However, a new type of product, alkyne **12**, is formed, along with a small amount of the reduction product **13**. In addition to these general types of photobehavior, some alkenes exhibit behavior that is specific to particular systems, as outlined below.

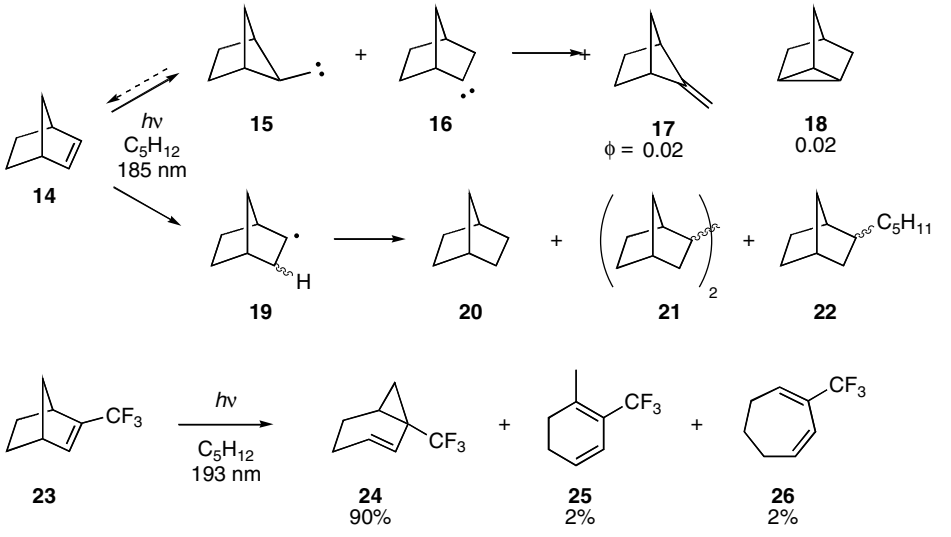


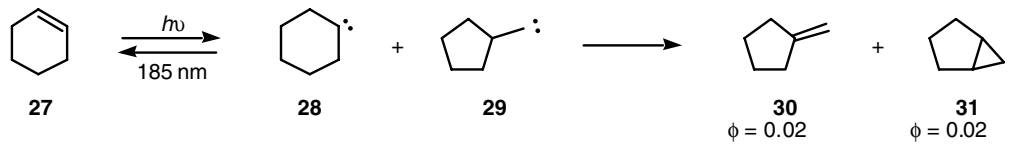
13.2 Mechanisms

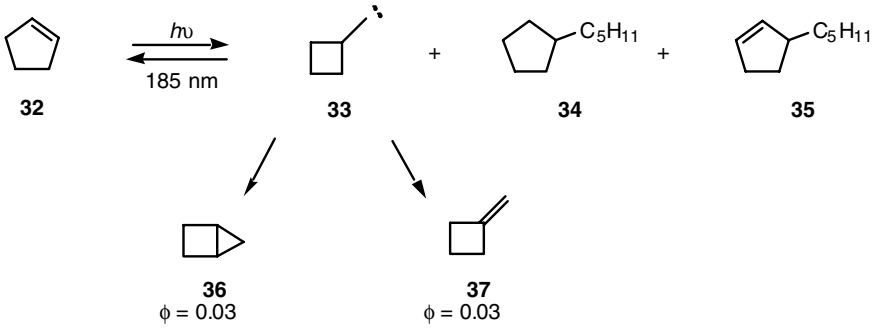
Rearrangement via Carbene Intermediates

There is general agreement with the proposal that products such as the rearranged alkene **4** and the cyclopropane **5** arise via competing 1,2 and 1,3 insertion of a carbene intermediate (**3**).[8] The involvement of carbene intermediates is supported by formation of the same products in similar ratios on independent generation of the corresponding carbenes for a wide range of alkenes. Formation of the carbene-derived products **4** and **5** relative to the double bond migration product **9** is wavelength dependent, being favored at higher wavelengths.[9,12]

2-Norbornene (**14**) affords products (**17** and **18**) derived from two carbene intermediates (**15** and **16**), along with small amounts of the radical-derived products **20–22**.[13,14] In the case of cyclohexene (**27**), deuterium-labeling studies showed that products **30** and **31** arise from carbenes **28** and **29**.[13] It was concluded that these intermediates are formed in a ratio of 14:1, respectively, but this does not take into account any reformation of starting material. Thus, in alkenes that are not fully substituted, hydrogen migration can compete with alkyl migration in carbene formation. However, hydrogen migration to form cyclopentylidene is at most a minor process in the photobehavior of cyclopentene (**32**), which affords the carbene-derived products **36** and **37** along with the radical-derived products **34** and **35**.[14,15]

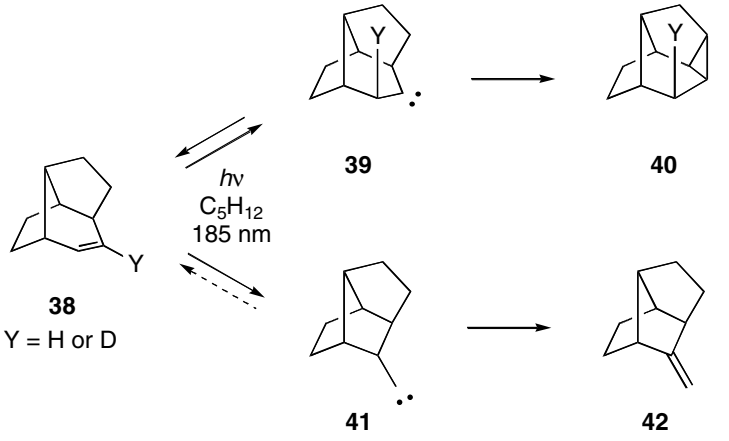






In contrast with 2-norbornene (**14**), the 2-CF_3 derivative **23** afforded no carbene-derived products but gave instead principally the 1,3-alkyl migration product **24** along with the related minor products **25** and **26**.[16] Spectroscopic studies of **23** showed that the strongly electron-withdrawing CF_3 substituent raises the energy of the π,R(3s) state, rendering the ππ* state lower lying in solution.[4b] The absence of carbene-derived products from **23** suggests that they normally arise from the π,R(3s) state. This would also be consistent with the preferred formation of the carbene-derived products **4** and **5** from alkene **1** at higher wavelengths, since the π,R(3s) state is lower lying than the ππ* state in tetrasubstituted alkenes. The electron-deficient core of the π,R(3s) state (**6**) could readily undergo [1,2]-sigmatropic rearrangement to a carbene. However, from analysis of the ultrafast dynamics following irradiation of 2-norbornene (**14**) and cyclohexene (**27**) in the gas phase, it was recently proposed that the carbene intermediates arise instead from the zwitterionic state Z (**2**), which crosses the ππ* surface.[7,17]

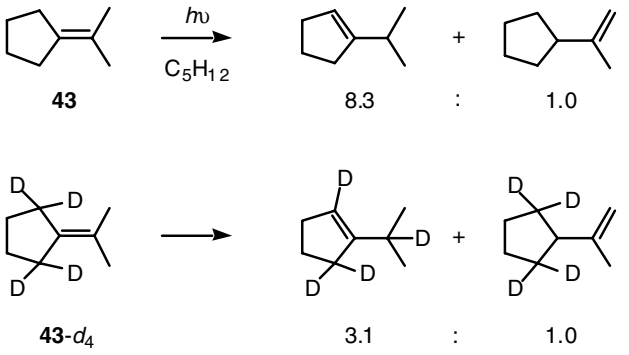
Labeling studies on the related homobrexene (**38**), which afforded the carbene-derived products **40** and **42**, revealed that the migrating hydrogen atom had a 2.3:1 preference for assuming the axial position.[18] Interestingly, deuterium had an even greater preference (10.2:1) for the axial pathway. Some scrambling of labeled **38** occurred, presumably because of competing return of one or both of the carbene intermediates **39** and **41**. On independent generation, carbene **39** afforded an approximately 3:1 mixture of the insertion product **40** and homobrexene (**38**).



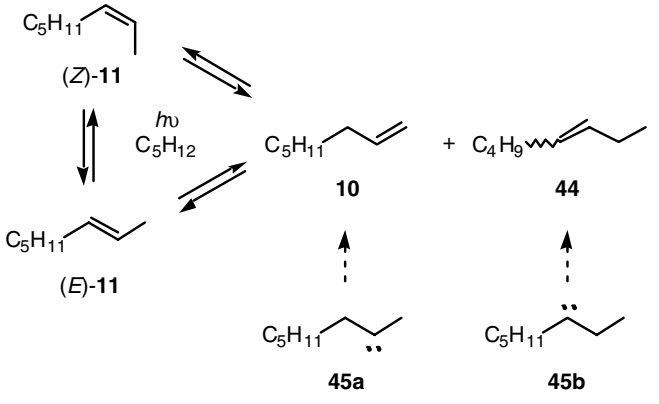
[1,3]-Sigmatropic Rearrangements

Double bond migration generally competes with *E,Z*-isomerization and the formation of carbene-derived products, unless it is structurally inhibited as in 2-norbornene (**14**) and homobrexene (**38**). It presumably occurs in cyclohexene (**27**) and cyclopentene (**32**) but is not observable. In an alkene such as **43**, in which the double bond is exocyclic to a five-membered ring, migration is the dominant photoprocess and occurs

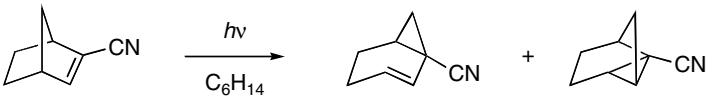
preferentially into, rather than away from, the ring.[19] Labeling studies with 43-d_4 showed that double bond migration involves an intramolecular [1,3]-sigmatropic migration of an allylic hydrogen atom and exhibits a deuterium isotope effect of 2.7.



No current agreement exists as to which excited state is responsible for [1,3]-hydrogen migration. As noted above, the ratio of double bond migration to formation of carbene-derived products from alkene **1** is wavelength dependent, being favored at shorter wavelengths. Thus, the π,R(3s) state is apparently not involved in [1,3]-hydrogen migration. Similarly, irradiation of *Z*-2-octene (*Z*-**11**) at 185 nm afforded competing *E,Z*-isomerization and rearrangement to a mixture of the double isomers **10** and *E*- and *Z*-**44**, whereas at wavelengths >200 nm only *E,Z*-isomerization was observed.[12] It was thus concluded that [1,3]-hydrogen migration does not involve the ππ* state either, and the $\sigma_\pi(CH_2)$,π* or π(C=C),σ_π*(CH_2) charge-transfer state was suggested as an alternative. However, it has been noted that the latter wavelength effect merely indicates that double bond migration does not involve the ππ* state in the case of a disubstituted alkene such as **11**.[16] It is conceivable that the double bond isomers **10** and **44** arise via the carbene intermediates **45** in this case and are thus derived from the π,R(3s) excited state, which is higher lying than the ππ* state in a disubstituted alkene.



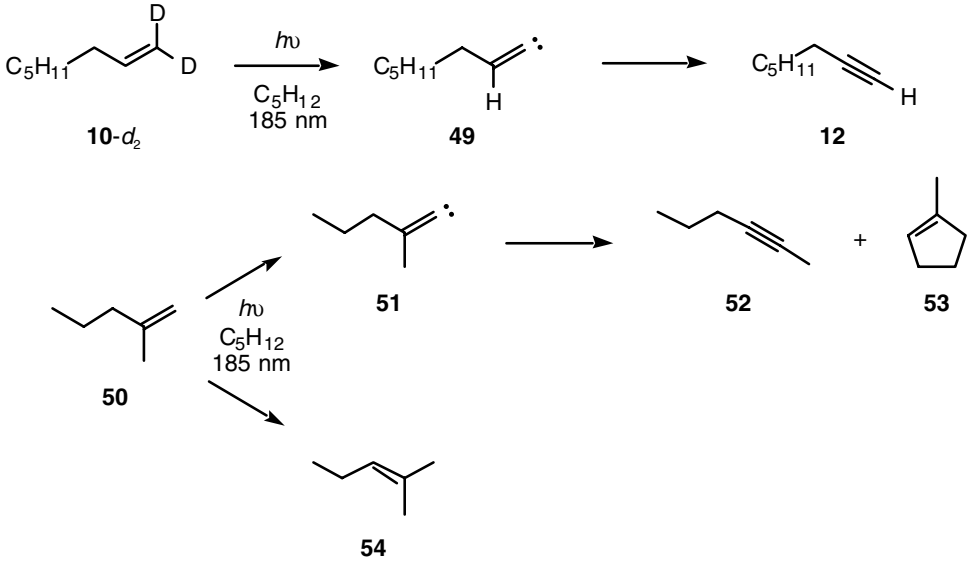
This leaves the possible involvement of the ππ* state in the direct [1,3]-hydrogen migrations in alkenes such as **1** and **43**. Some support for this assignment is provided by the formation of the analogous [1,3]-alkyl migration product **15** by the CF_3-substituted norbornene **23**, which has a low-lying ππ* state.[4b,16] Similar behavior was exhibited by the nitrile **46**, which afforded a 20:1 mixture of the [1,3]- and [1,2]-alkyl shift products **47** and **48**, respectively.[20] Since the lowest-lying excited singlet state of the conjugated alkene **46** is π,π*, it has been proposed that 1,3-alkyl migration in norbornene **23** also involves the ππ* state.[16]

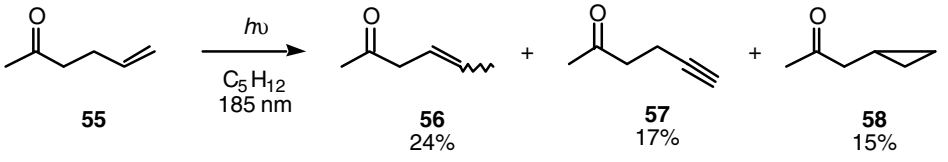


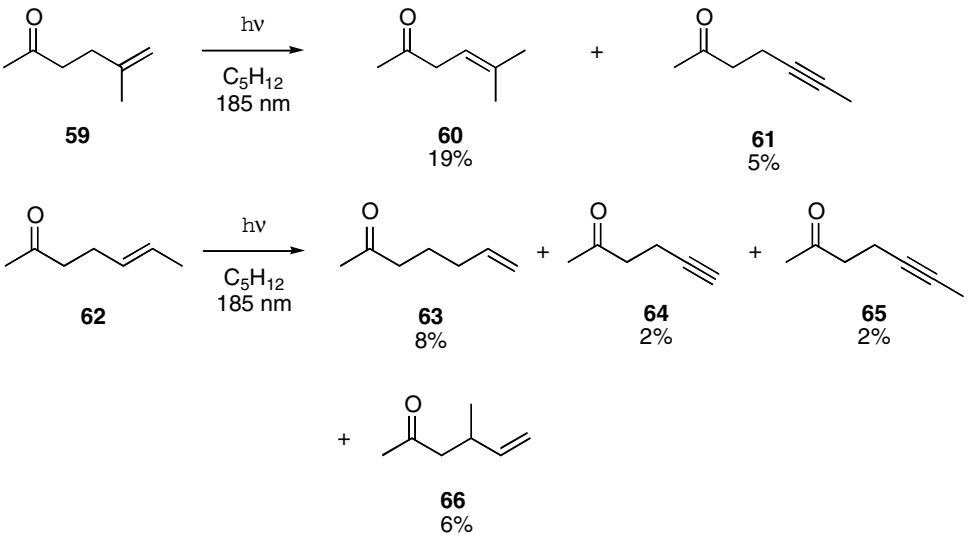
46 **47** 20 : **48** 1

Alkyne Formation

As noted above, irradiation of 1-octene (**10**) afforded a substantial amount of 1-octyne (**12**).[11] Similarly, the principal photobehavior of ethene is formation of ethyne and H_2.[21] Since the 1,1-d_2 derivative **10**-d_2 afforded alkyne **12** with an isotope effect ϕ_H/ϕ_D of 1.9 and almost complete loss of deuterium, the principal route to **12** apparently involves the vinylidene **49** as an intermediate. Alkyne formation is also a major pathway for the keto analog **55**.[22] Interestingly, the γ,δ-unsaturated ketones **55**, **59**, and **62** exhibit photobehavior typical of alkenes at 185 nm. Similar to alkene **10**-d_2, the terminally labeled derivative of enone **55** afforded alkyne **57** with 90% loss of deuterium. The 2,2-disubstituted alkene **50** afforded a mixture of the alkyne **52** and 1-methylcyclopentene (**53**), expected products from the vinylidene intermediate **51**, along with the double bond migration product **54**, and the keto analog **59** similarly afforded alkyne **61** and the double bond migration product **60**. Alkyne formation has also been observed in the 1,2-disubstituted analog **62**, which afforded a mixture of alkynes **64** and **65**, along with the double bond migration product **63** and the 1,3-acyl migration product **66**. It has been proposed that alkyne formation involves the ππ* excited state, since it has not been observed for highly substituted alkenes, in which the π,R(3s) state is lowest lying.[11,22]







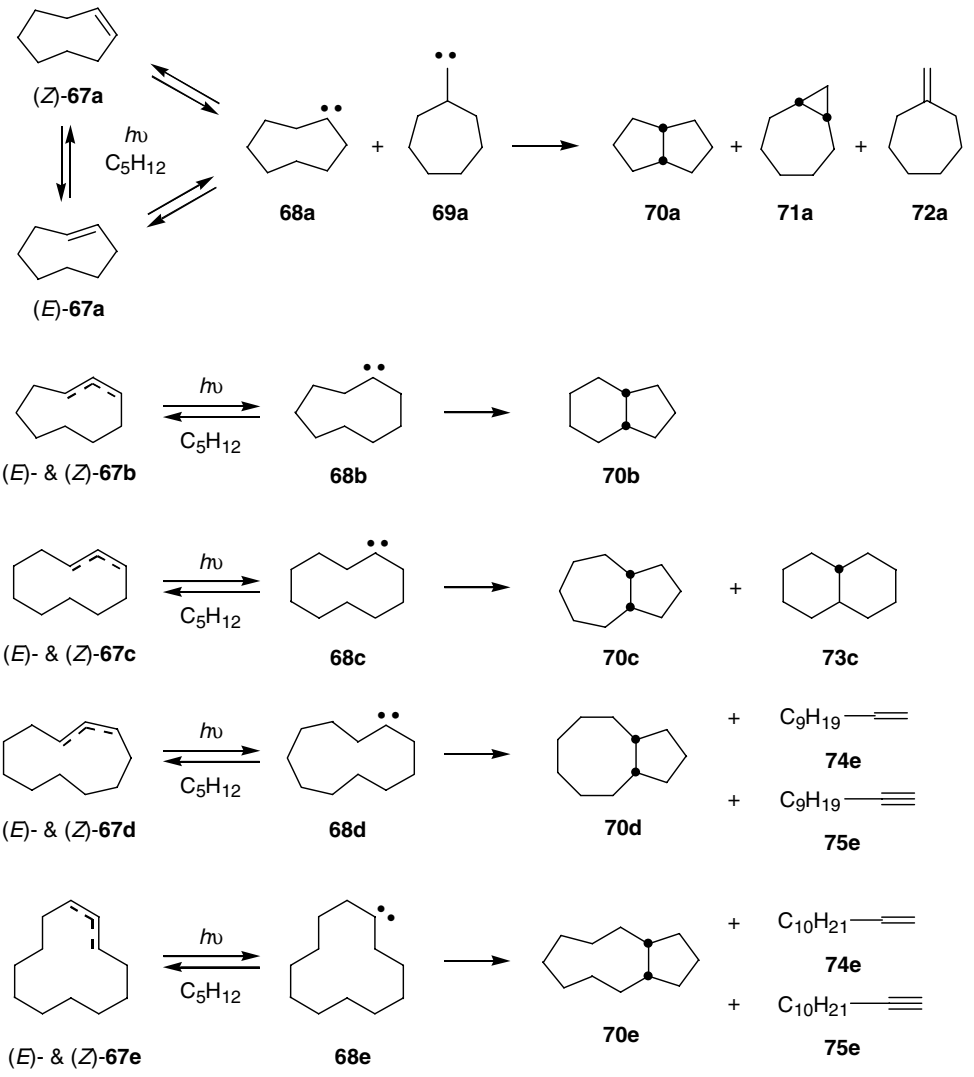
Hydrogen-Atom Abstraction

As noted above, irradiation of 2-norbornene (**14**) in pentane afforded, in addition to the carbene-derived products **17** and **18**, a mixture of alkanes **20–22**, which appear to be derived from the radical **19**, formed by hydrogen atom abstraction from the solvent.[14] Analogous behavior was observed for 1-octene (**10**), which afforded the reduction product octane (**13**), and cyclopentene (**32**), which afforded the radical-derived products **34** and **35**.[11,14] In each case, a mixture of branched decanes arising from coupling of solvent-derived pentyl radicals was also obtained. Hydrogen-atom abstraction has also been attributed to the $\pi\pi^*$ excited state.[14]

13.3 Further Examples

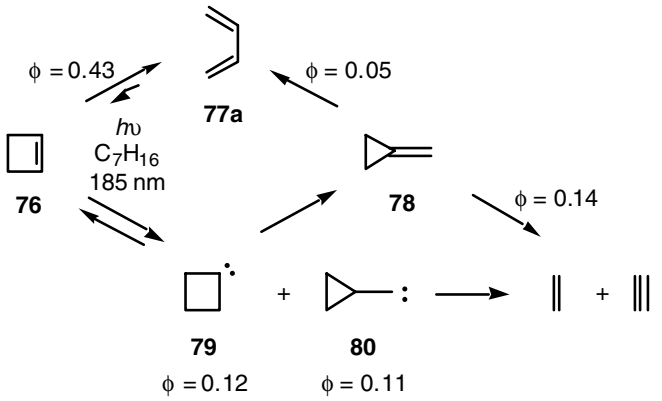
Medium and Large Cycloalkenes

Medium- and large-ring systems are noted for undergoing transannular reactions. This is seen in the cycloalkenes **67**, which afforded, in addition to *E,Z*-isomerization, the *cis*-bicyclo[*n*.3.0]alkanes **70** resulting from 1,5-transannular insertion of the corresponding cycloalkylidene intermediates **68**.[23] Only the smallest member of the series of cyclic alkenes, **67a**, afforded a product, which was identified as (**72a**). Apparently, this product arises from a ring-contracted cycloalkylmethylene intermediate (**69a**). The largest members of the series, **67d** and **67e**, gave small amounts of the fragmentation products **74** and **75**. Double bond migration presumably also occurs but is an identity process in these cases. When generated independently, cycloalkylidenes **68** undergo substantial 1,2-insertion to form cycloalkenes **67**. This is particularly true for the two largest members of the series, **68d** and **68e**, which give only a small amount of transannular insertion when generated independently. Transannular insertion is magnified when the cycloalkylidene intermediates are generated by irradiation of the corresponding cycloalkenes, since any 1,2-insertion simply regenerates the cycloalkene, which is recycled, whereas the bicyclic products **70** are photostable and accumulate in the irradiation mixture.

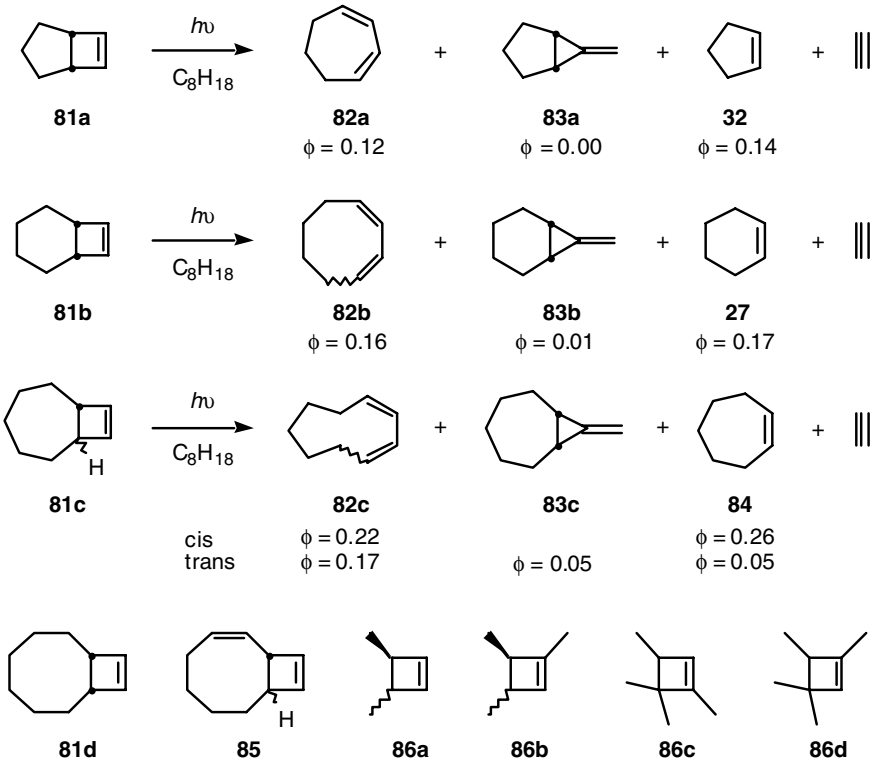


Cyclobutenes

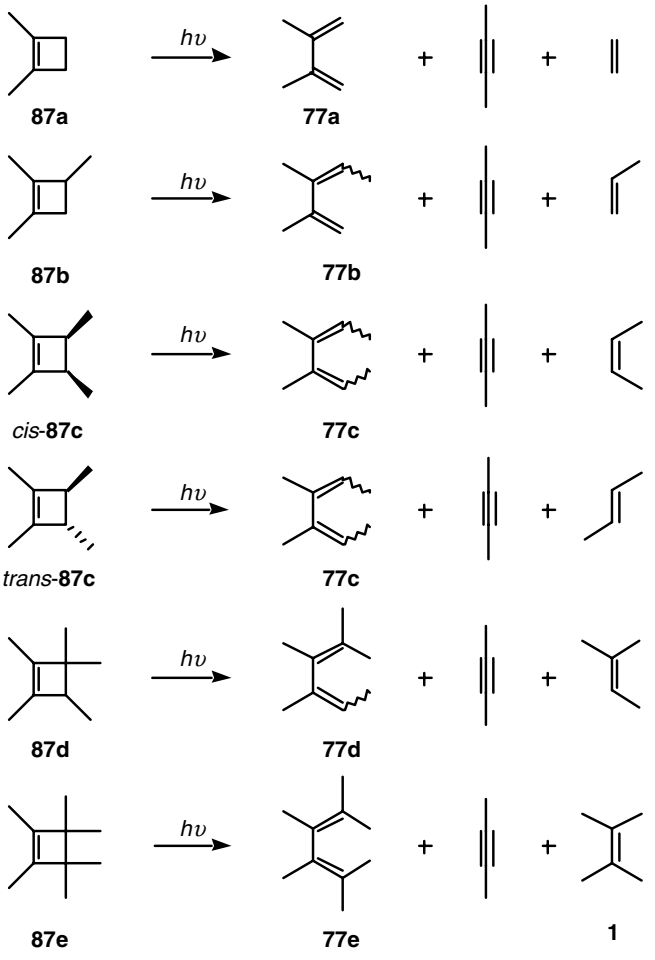
Leigh and co-workers have studied the photochemical reactions of cyclobutenes. A rather complex picture has emerged, which may not yet be fully understood. Irradiation of cyclobutene (**76**) itself afforded principally the ring opening product 1,3-butadiene (**77a**), accompanied by smaller amounts of methylenecyclopropane (**78**) and the fragmentation products ethene and ethyne.[24] Under the irradiation conditions, 1,3-butadiene (**77**) underwent a small amount of reversion to cyclobutene (**76**), and methylenecyclopropane (**78**) underwent secondary conversion to 1,3-butadiene (**77a**) and the fragmentation products ethene and ethyne. It was proposed that 1,3-butadiene (**77a**) arises via electrocyclic ring opening of the $\pi\pi^*$ excited singlet state and that the minor products are derived from the carbene intermediates **79** and **80** formed by rearrangement of the π,R(3s) state.



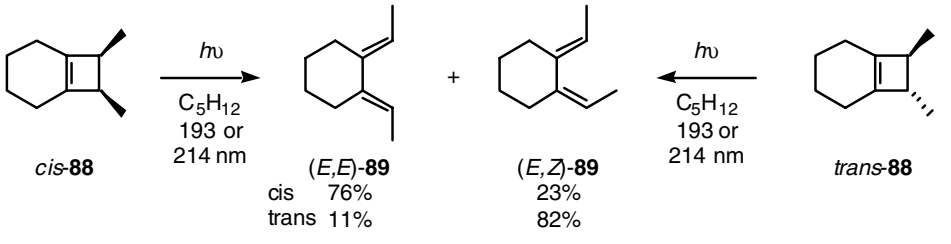
Similar behavior was exhibited by the bicyclo[*n*.2.1]alkenes **81**, except that the highly strained methylenecyclopropane **83a** was not formed.[25] Surprisingly, **81b** and **81c** afforded an *E,Z*-mixture of the 1,3-dienes **82b** and **82c** under conditions in which the dienes do not undergo interconversion.[4c,25b,26] Thus, ring opening of cyclobutenes is not stereospecific.

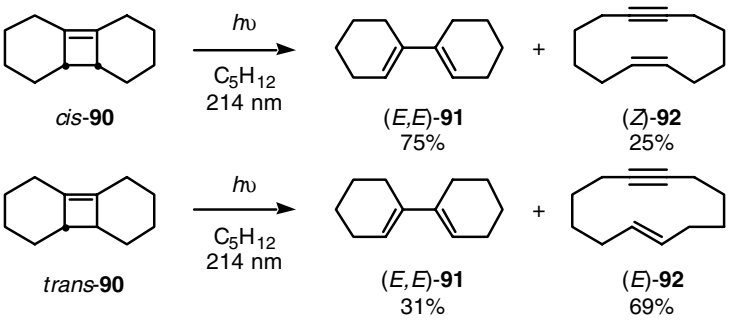


Similar lack of specificity has been observed for the bicyclo[6.2.1]octenes **81d** and **85**,[26] as well as the *cis*- and *trans*-isomers of cyclobutenes **86a–b** and the pair of tetrasubstituted cyclobutenes **86c–d**.[4a,4c,25b] On irradiation at 214 nm, the 1,2-dimethylcyclobutenes **87** also afforded all possible stereoisomers of the ring-opening products **77** (combined quantum yields 0.05–0.26), along with the usual fragmentation products (combined quantum yields 0.010–0.032).[27]

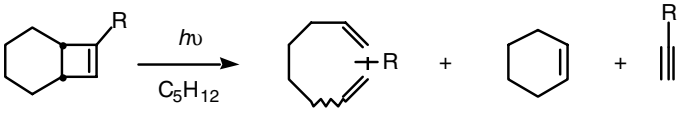


The bicyclo[4.2.0]oct-1(6)-ene system **88** comes closest to affording the disrotatory opening expected by orbital symmetry, with the *cis*-isomer giving mainly diene *E,E*-**89** and the *trans*-isomer even more predominantly diene *E,Z*-**89**.[28] Similarly, cyclobutene *cis*-**90** undergoes ring opening to diene *E,E*-**91** with a substantially higher quantum yield than *trans*-**90**, which would have to afford the highly strained *E,Z*-isomer of diene **91** to open in a disrotatory fashion.[29] Indeed, the *E,Z*-isomer may be formed initially and undergo rapid isomerization to *E,E*-**91**. These observations suggest that orbital symmetry plays a role in the photochemical ring opening of cyclobutenes. From analysis of steric effects on the efficiency of ring opening of the 1,2-dimethylcyclobutenes **87**, along with time-resolved resonance Raman studies of cyclobutene,[30] it was concluded that ring opening begins with disrotatory stereochemistry, as orbital symmetry selection rules predict for an excited-state process, but that stereospecificity is lost because ring opening proceeds adiabatically, yielding the disrotatory diene in an excited state, from which it decays by *E,Z*-isomerization.[27]





The assignment of the ππ* singlet excited state for ring opening has been supported by a study of the bicyclo[4.2.0]octenes **81b**.[4e] Spectroscopic studies indicate that the ππ* singlet excited state is higher lying than the π,R(3s) excited state in the parent **81b** (R = H) and the methyl derivative **81b** (R = CH_3) but the π,R(3s) excited state is raised to a higher energy than the ππ* state in the trifluoromethyl derivative **81b** (R = CF_3). Accordingly, fragmentation predominates over ring opening for the methyl and unsubstituted derivatives, whereas ring opening is more efficient for the trifluoromethyl-substituted derivative. Moreover, ring opening is enhanced over fragmentation on going from 214 to 193 nm for the first two compounds but is favored at the longer wavelength for the trifluoromethyl derivative.

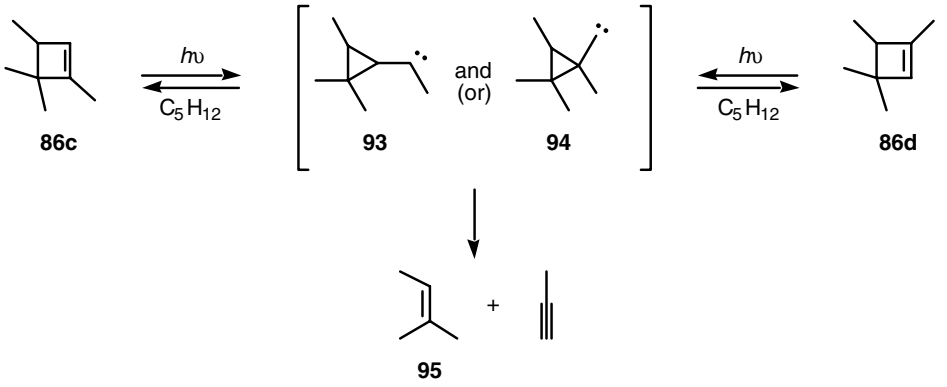


R = CH_3	193	1	:	1.49
	214	1	:	2.84
H	193	1	:	0.80
	214	1	:	1.10
CF_3	193	1	:	0.10
	214	1	:	0.06

However, it has recently been found that the stereochemical course of ring opening is wavelength dependent. The 1,2-dimethylcyclobutenes **87c** undergo stereospecific conrotatory ring opening at 228 nm, in contrast with the almost complete lack of stereospecificity at 193 and 214 nm.[31] The *cis*-isomer (***cis*-87c**) afforded stereospecifically the conrotary product (*E,Z*-**77c**), whereas the trans isomer (***trans*-87c**) afforded a mixture of the two conrotatory products *E,E*-**77c** and *Z,Z*-**77c** — those that would be allowed by thermal electrocyclic opening. The quantum yields for electrocyclic ring opening were significantly higher than those estimated for ring opening via a hot ground-state mechanism, suggesting that ring opening at 228 nm is a true excited state process.[30] Thus, ring opening proceeds by at least two mechanisms depending on excitation wavelength. The first, which dominates at short wavelengths, involves the ππ* excited state and occurs nonstereospecifically, as discussed above. Since absorption by the cyclobutenes **87c** at 228 nm involves the π,R(3s) excited singlet state, this state is apparently responsible for the observed stereospecific conrotatory opening.

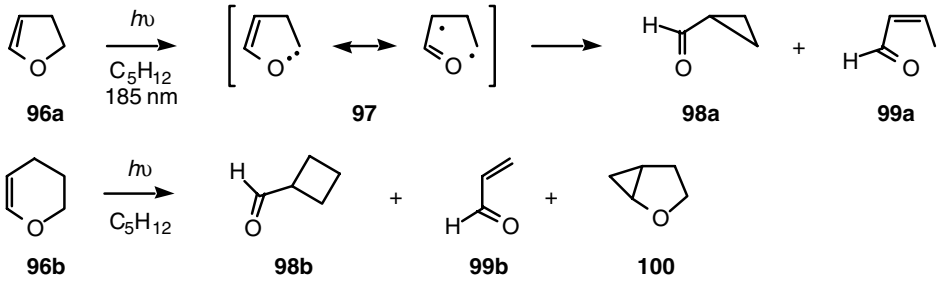
In contrast with ring opening, fragmentation is consistently stereospecific. For example, the *cis*- and *trans*-epimers of cyclobutene **90** afford exclusively the *Z*- and *E*-isomers of enyne **92**, respectively.[27,29] Similarly, the *cis*-isomers of cyclobutenes **86a–b** afford *Z*-2-butene and the *trans*-isomers afford *E*-2-butene with >90% stereospecificity.[4c] Moreover, cyclobutenes **88**, which would have to afford the highly strained cyclohexyne, give only ring-opening products.[28] Although fragmentation is formally a retro [2 + 2]-cycloaddition, it apparently occurs, at least in part, stepwise via a cyclopropylmethylene intermediate, as noted above for cyclobutene (**76**). Some evidence that the required carbene intermediates are indeed formed has come from cyclobutenes **86c–d**, which undergo some interconversion on

irradiation.[4a] Presumably the cyclopropylmethylenes **93** and/or **94** are involved in the interconversion as well as in fragmentation. As noted above, since fragmentation predominates when the π,R(3s) excited state is low lying and at wavelengths at which absorption involves principally the π,R(3s) band, it has been assumed that fragmentation involves this state. However, the recent proposal that carbene intermediates arise instead via rearrangement of the zwitterionic state Z must now be evaluated as an alternative pathway for fragmentation.



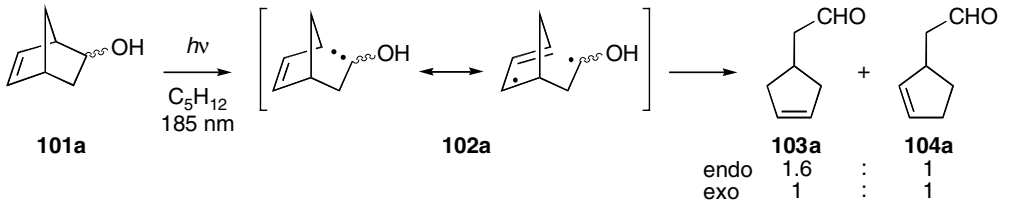
3-Oxacycloalkenes

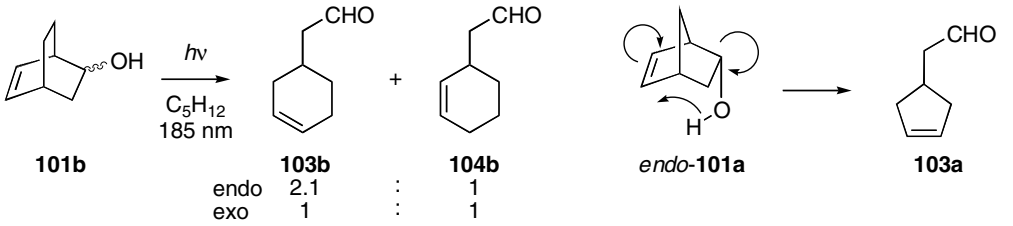
The oxacycloalkenes **96** afforded aldehydes **98** and **99**, which apparently arise from the diradical intermediate **97** formed via cleavage of the allylic OC bond.[32] The dihydropyran analog **96b** also afforded the carbene-derived product **100**. It was suggested that bond cleavage involves a πσ* excited state.



Homoallylic Alcohols

The homoallylic alcohols **101** afforded a mixture of aldehydes **103** and **104**.[33] Deuterium labeling showed that rearrangement occurs intramolecularly, presumably via the diradical **102**. Since in each case the endo epimer afforded an excess of the Δ^3 isomer **103**, it was proposed that the *endo*-epimers undergo a competing concerted rearrangement as shown for *endo*-**101a**.





13.4 Summary

The photochemistry of alkenes is exceptionally rich, arising from two or more closely lying excited states that appear not to communicate well between themselves. In addition to undergoing nucleophilic trapping in hydroxylic media (Chapter 9),[10,34] the π,R(3s) singlet excited state has been implicated in stereospecific long-wavelength ring opening of cyclobutenes,[29c,31] as well as undergoing rearrangement to carbene intermediates, although the closely related Z state has also been proposed for this latter process.[7,17] The resulting carbene intermediates, in turn, undergo intramolecular insertion to afford isomers of the starting alkene or, in the case of cyclopropylmethylenes derived from cyclobutenes, fragmentation to an alkene and alkyne. A variety of behavior has been ascribed to the π,π* singlet excited state. In addition to its widely recognized role in *E,Z*-isomerization, the π,π* state has been implicated in 1,3-alkyl migration,[16] alkyne formation,[11,22] hydrogen-atom abstraction,[14] and nonstereospecific ring opening of cyclobutenes.[4e] By analogy to 1,3-alkyl migration, 1,3-hydrogen migration may also involve this state. However, much remains to be done to place these assignments on a firmer basis.

Matrix Photochemistry

Ian R. Dunkin
University of Strathclyde

14.1 Introduction

In matrix-isolation experiments, stable molecules or reactive species are trapped as *guests* in rigid *host materials* and then examined spectroscopically. A common way of generating reactive species in matrices is by photolysis of photolabile precursors (Figure 14.1). The resulting matrix-isolated species are prevented from diffusing and undergoing bimolecular reactions (except with the host). They are therefore stabilized and can usually be characterized by standard spectroscopic techniques, such as IR or UV-visible absorption spectroscopy. Matrix isolation thus provides one of the many methods for the study of reactive intermediates.

The host material can be a crystalline solid, a polymer, or a glass formed by freezing a liquid or solidifying a gas. The term *matrix isolation* is, however, most commonly used in a more restricted sense to refer to the technique of trapping guest species in solidified inert gases, such as neon, argon, krypton, or nitrogen. In this form, the technique requires very low temperatures — typically 4 to 20 K. Occasionally, when it is desired to observe specific host–guest reactions, reactive gases such as methane, carbon monoxide, or oxygen are utilized as matrix hosts.

This chapter provides a brief description of the matrix-isolation technique and then gives some examples of its applications in the study of organic photochemistry. The topics that have been included have been selected from areas of photochemical research to which matrix isolation has made an important and sustained contribution. The choices have been made from among many possibilities and inevitably reflect the author's personal interests, but, in addition to this more general chapter, two specific areas of matrix photochemistry, alkenes and small ring compounds, are covered in Chapters Y and Z, respectively.

Although the technique of matrix isolation was first reported nearly fifty years ago[1] and has been employed in the study of organic photochemistry for at least the last thirty years, the contribution made by matrix studies to our understanding of structure, bonding, and reaction mechanisms is probably still

0-8493-1348-1/04/$0.00+$1.50

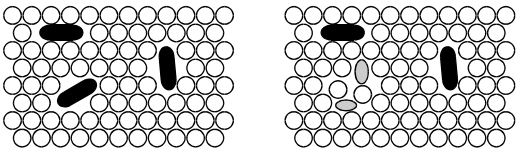

FIGURE 14.1 (a) Precursor molecules (shown in black) matrix isolated in an excess of the host material (white circles). (b) The same matrix after photolysis of one of the precursor molecules, and the formation of fragment species (grey ellipses).

not as well known among organic chemists as it should be. Perhaps this is due to the fact that specialized equipment is required, which is not very widely available, or that many key papers have been published in journals of physical chemistry or chemical physics.

A comprehensive review of matrix-isolation studies of organic photochemistry is not possible in a work of this type, because it would run to many hundreds — possibly thousands — of references. Fortunately, two useful bibliographies have been published: the first[2] covers the literature from the invention of the technique up to about 1985, while the second[3] extends this period to about 1997. These bibliographies are not free of omissions and errors, nor will they be found in every library, but both contain formula and author indexes and are valuable sources of information on matrix-isolation research. An earlier bibliography, which covered IR spectra at sub-ambient temperatures, including matrix-isolation IR spectra.[4] and an associated review of IR spectra of reactive species trapped in matrices[5] give useful entry points to the literature up to about 1968. Also, various aspects of matrix studies in organic photochemistry have been reviewed.[6–16]

14.2 The Matrix-Isolation Technique

Solidified Gas Matrices

Polymers or frozen solvents have several disadvantages as trapping media for the spectroscopic study of reactive species. First, they are often not chemically inert to very reactive species, such as metal atoms and carbenes. Second, they absorb strongly over large regions of the IR spectrum. Since much more structural information about trapped molecules can usually be derived from IR than from UV-visible or electron paramagnetic resonance (EPR) spectroscopy, the latter is a severe problem.

Solidified noble gases and nitrogen have three advantages when used as trapping media for reactive species: chemical inertness, complete transparency throughout the normal IR-visible-UV regions of the spectrum, and a tendency to form clear glasses. To make rigid matrices from the noble gases and nitrogen, very low temperatures are necessary — typically 4–20 K — and nowadays these are usually attained by means of closed-cycle helium refrigerators.

Matrices are formed by deposition from the gas phase onto a cold window. Any species that is to be trapped in a matrix must therefore be volatile, at least to a small extent. The guest species can be mixed with the host gas in either of two ways. If the guest has a high enough vapor pressure, it can be mixed with the host gas on a vacuum line by standard manometric techniques. This produces a gas mixture of guest and host, usually of known proportions; the ratio of host to guest is known as the *matrix ratio*. The gas mixture is then allowed into the vacuum chamber of the cold cell at a controlled rate and is deposited as a solid matrix. Figure 14.2 shows the important features of a suitable cold cell.

If the guest has low volatility, it is usual to evaporate it from a side arm attached to the vacuum chamber of the cold cell, while the host gas is deposited simultaneously. It is difficult to measure the matrix ratio in these conditions. To assist volatilization, the host gas can be passed directly over the solid or liquid guest material in the side arm and the guest can be heated, provided it does not decompose thermally at the necessary temperature.

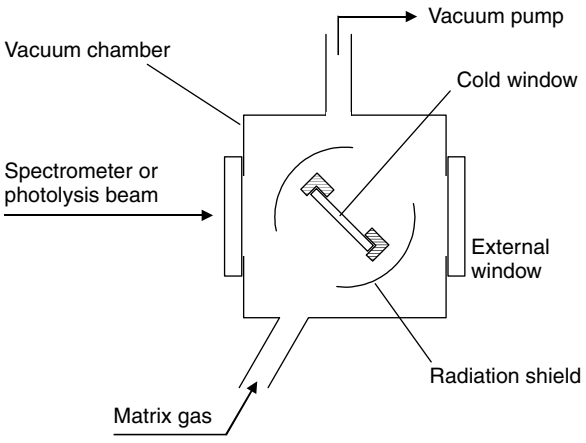

FIGURE 14.2 Top view of a cold cell for matrix isolation. The cold window in a metal holder is located inside a vacuum chamber fitted with an inlet port for the matrix gas, external windows, and a port for connection of the vacuum pump. The cold window can be rotated to face the inlet port or the external windows, and it is usual to incorporate a metal radiation shield around it (cooled to *ca.* 80K) to minimize warming. Matrices are formed by allowing a gas mixture to enter the vacuum chamber through the inlet port, whereupon it will condense on the cold window.

After matrix deposition, the vacuum chamber is maintained at very low pressure — typically 10^{-6} mbar or less. This provides a *Dewar vacuum,* which thermally insulates the matrix and cold window from the atmosphere outside and also prevents the deposition of appreciable amounts of extra material on top of the matrix.

The material from which the cold window is made is chosen to suit the spectroscopic techniques to be employed. For IR studies, CsBr or CsI are preferred. These are softer and less prone to cracking than NaCl or KBr and can better withstand repeated cooling and warming cycles. Although also transparent in the UV and visible regions of the spectrum, CsBr and CsI tend to deform and become scratched, which results in scattering of the shorter wavelengths. For this reason, CaF_2 or sapphire windows are often preferred for UV-visible studies. The external windows of the vacuum chamber do not have to be cooled, so KBr, which is inexpensive, is a popular choice for both IR and UV-visible experiments.

In principle, there could be another approach to forming matrices: first dissolving the guest material in a liquefied gas, such as argon or nitrogen, and then freezing the resulting solution. Usually, this does not work well. Liquefied gases at their normal boiling points are poor solvents for most organic materials, so only extremely dilute solutions can be prepared in this way. Moreover, when the solutions are cooled and frozen, guest molecules can aggregate or even crystallize out, so proper isolation of the molecules is unlikely. Until techniques like this can be utilized reliably, however, really involatile materials such as polypeptides or polysaccharides cannot be studied by the matrix chemist or spectroscopist.

Generation of Reactive Species in Matrices

As a consequence of the way in which matrices are deposited, the generation of reactive species can be carried out either (a) by photolysis or radiolysis of precursors already trapped in the matrices or (b) by gas-phase or surface (gas-solid) reactions prior to deposition. The second category can include flash vacuum pyrolysis, microwave excitation, or reactions of organic precursors with metals. After the reactants have passed through the region where the reaction takes place, the resulting product mixture is diluted with a large excess of the host gas and condensed as quickly as possible on the cold window as a matrix.

In whatever way reactive species are generated and trapped in the matrix, further reactions can be induced by photolysis or by annealing the matrix, i.e., warming to allow softening and then re-cooling.

TABLE 14.1 Strengths and Limitations of Matrix Isolation in Comparison with Flash Photolysis

Matrix Isolation	Flash Photolysis
Solid-phase reactions only, but precursor must be volatile	Reactions in gas, liquid or solid phases
Reactive species stabilized in the abnormal conditions of a matrix cage	Reactive species observed in the normal conditions of a reaction medium
Reactive species long lived — often indefinitely	Reactive species transient, and lifetimes can be measured
Spectra recorded normally, and in favorable cases, different types of spectra can be recorded for the same matrix	Spectra usually recorded at one wavelength per flash; multiple flashes are needed
Many types of spectroscopy applicable including far-, mid-, and near-IR absorption, Raman, UV-visible absorption, ESR, and various type of emission spectroscopy	Detection of transient species by UV-visible or IR absorption, but only part of the IR region is accessible at present
Reactive species can be generated by a range of methods including photolysis, vacuum pyrolysis, microwave discharge, and chemical reaction	Reactive species generated by photolysis

Spectroscopic Techniques for Matrix Studies

A wide range of spectroscopic techniques can be used with low-temperature matrices, and fairly routine spectrometers will usually suffice. Nevertheless, NMR spectroscopy is, for all practical purposes, unavailable. A few research groups have developed special forms of NMR for matrices, but the solid-state spectra obtained are of low resolution, lacking the coupling information that makes conventional NMR in liquids such a powerful structural tool. Usually, matrix chemists make do with IR and UV-visible spectroscopy, supplemented where appropriate with less common techniques such as Raman spectroscopy, laser-induced emission, and EPR.

Throughout the history of matrix-isolation studies of reactive intermediates, IR spectroscopy has undoubtedly played the most important part in the identification of reactive species and the determination of their structures. Recently, the interpretation of matrix IR spectra has been greatly enhanced by the development of reliable computational methods for predicting vibrational transitions — both frequencies and intensities — and then by the incorporation of these methods in commercially available software packages such as Gaussian and Spartan. In general, matrix IR frequencies are not greatly shifted from gas-phase values, so experimental and computed spectra usually agree well. Density functional theory (DFT) seems to have been particularly successful in predicting the IR spectra of matrix isolated species.[17]

The Matrix Isolation Laboratory

The preceding paragraphs have given a brief description of the essential features of matrix-isolation equipment and the way in which matrix experiments are conducted. It is hoped that this will assist readers previously unfamiliar with matrix isolation to understand the experimental constraints.

The use of matrix isolation on a preparative scale has been advocated by several workers and is an attractive idea for reactions that follow different pathways in low-temperature matrices and normal, ambient conditions. In these cases, matrix isolation could result in greater selectivity or even completely different products. There is no great difficulty in scaling up a cold cell to handle hundreds of milligrams or even gram quantities of guest materials, nor is it hard to monitor the progress of the reactions or to recover stable products from scaled-up matrix reactions.[18] Nevertheless, matrix isolation for synthesis has not yet become established and nearly all the studies reported in this chapter involved spectroscopic investigations carried out on a small scale, usually to characterize reactive intermediates. The strengths and limitations of matrix isolation as a technique for studying reaction mechanisms are summarized in Table 14.1, where there is also a comparison with flash photolysis.

A practical guide to the matrix-isolation technique has been published fairly recently.[19] This should be consulted for more details about cold cells, the scope of the technique, and how to carry out matrix experiments.

14.3 Radicals

The term *radicals* will here be applied exclusively to molecular fragments with single unpaired electrons, e.g., alkyl radicals (R·) and alkoxy radicals (RO·), as distinct from other hypovalent species such as carbenes and nitrenes. Radicals are conveniently studied by means of EPR spectroscopy, a sensitive technique that can, for example, be applied to photochemical reactions occurring in flow cells or in frozen organic glasses. Although there have been numerous matrix-isolation studies of radicals utilizing EPR, an important advantage of matrix hosts such as argon or nitrogen is the opportunity that they provide to obtain IR spectra of reactive species. This section will therefore concentrate on matrix IR studies of radicals. Not only have IR spectra been obtained for a range of radicals, but it has also been possible to investigate the photochemical reactions of some of these species. IR spectroscopy, unlike EPR, has the advantage of allowing both radical and non-radical products to be detected and characterized.

An obvious route to matrix-isolated radicals is by photo-induced bond homolysis of a suitable precursor. Such a reaction, however, will generate a pair of radicals within the same matrix cage, and in many cases efficient recombination can occur, resulting in a very low persistent yield of the desired radical. For instance, near-UV-photolysis of methyl iodide in matrices does not normally result in a sufficient concentration of methyl radicals to be detected by IR spectroscopy. Fortunately, as described below, several ways of circumventing this problem have been found.

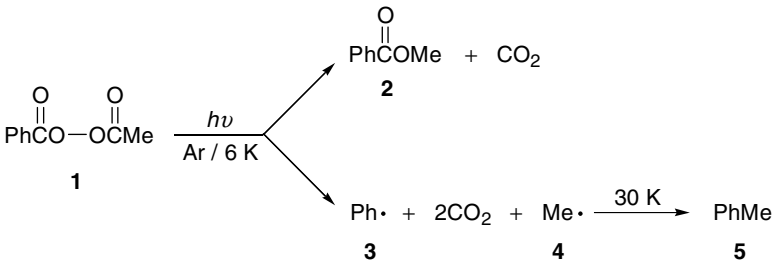
Matrix IR Spectra of Radicals

Photolysis of haloalkanes or alkanes with vacuum-UV light, which has considerably higher photon energies than near-UV light, seems to produce radicals with enough thermal energy to escape the matrix cage. This is particularly true when one of the radical fragments is a hydrogen atom, which has high mobility. Thus, the out-of-plane deformation IR band of the methyl radical at 611 cm^{-1} and the equivalent bands for several isotopomers ($^{13}CH_3$, $^{12}CH_2D$, $^{12}CHD_2$, $^{12}CD_3$ and $^{13}CD_3$), were observed following photolysis of normal and isotopically substituted methane in Ar and N_2 matrices with light from Kr-He or H_2-He helium discharge lamps.[20] Similar studies with halomethanes as the precursors provided the matrix IR spectra of a range of halomethyl radicals, e.g., CH_2F from CH_3F,[21] CH_2Cl from CH_3Cl,[22] and CF_3 from CHF_3, CF_3Br, and other precursors.[23] As an illustration of the value of matrix IR spectroscopy in giving structural information, two IR bands of CF_3 were found in the ν(C–F) region, and this indicated that CF_3 is nonplanar. Nevertheless, these high-energy photolyses did not produce the radicals cleanly, and other products, such as carbenes and dimeric species, were formed as well. Only with simple molecules such as methane derivatives was there much chance of disentangling the matrix IR spectra, so this approach was likely to encounter difficulties with much larger radicals.

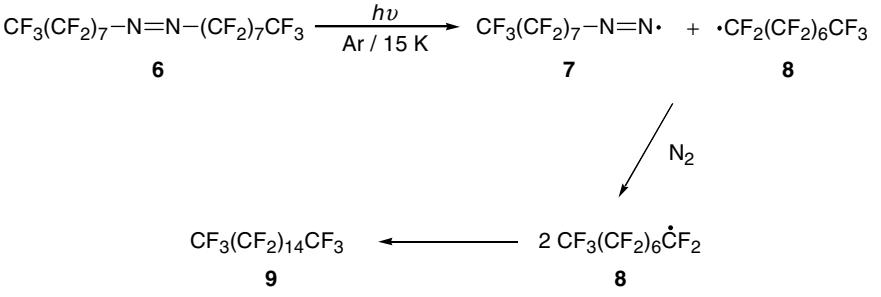
Nonetheless, various isotopomers of the vinyl radical (CH_2=CH·) have since been generated in Ar matrices by vacuum-UV photolysis of D- and ^{13}C-substituted ethenes and detected by IR spectroscopy.[24] These were identified through their ν_7 IR absorptions near 900 cm^{-1}; *ab initio* computations satisfactorily accounted for the observed isotope shifts in the frequencies.

An alternative method of minimizing radical recombination in matrices is to generate a pair of radicals separated by one or more inert molecules. For example, photolysis of acetyl benzoyl peroxide (**1**) in Ar matrices resulted in elimination of CO_2, producing methyl benzoate (**2**), but also phenyl radicals (**3**) and methyl radicals (**4**) in sufficient amounts to be detected by IR spectroscopy (Scheme 1).[25] The radicals were apparently kept apart by the eliminated molecules of CO_2. On warming the matrix to 30 K, the matrix softened, allowing diffusion of the radicals and the formation of toluene (**5**). The matrix photolysis of diacyl peroxides such as **1** proved a rich vein of research, and in analogous experiments matrix IR spectra were obtained for a range of alkyl radicals, e.g., ethyl,[26–28] isopropyl,[28] *n*-butyl,[29] isobutyl,[30] *n*-pentyl,[29] and neopentyl.[30] Enough data were collected in these investigations to permit the identification of characteristic differences in the IR spectra of primary, secondary, and tertiary alkyl radicals.[30,31]

Much more recently, the use of solid parahydrogen as a matrix host has been advocated for spectroscopic studies of radicals.[32] Its extreme softness, compared with the more usual matrix materials, allows



SCHEME 1



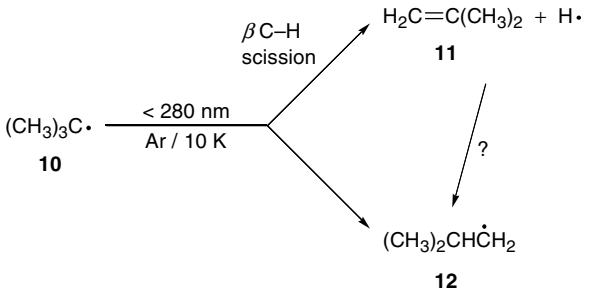
SCHEME 2

easy separation of radical pairs and, for example, photolysis of ethyl iodide in a parahydrogen matrix afforded the ethyl radical in amounts quite sufficient for IR detection.[32]

It might be thought that the photolysis of azoalkanes should also generate alkyl radical pairs, separated, in this case, by extruded N_2 molecules. There do not appear to have been many matrix-isolation studies of azoalkane photochemistry, but a recent example showed a more complicated and more interesting pattern of behavior. Photolysis of *cis*-enriched perfluoroazooctane (**6**) (Scheme 2) in argon matrices with a low-pressure Hg arc led to the IR and EPR observation of perfluorooctyl radicals (**8**), as expected, but a second reactive species was also detected.[33] This disappeared on warming to 30 K, accompanied by an increase in the yield of **8**. The thermally labile species was identified as the diazenyl radical **7**, thus confirming the view that azo photolyses normally proceed in a stepwise fashion. In this study, *cis*-enriched **6** was used as the starting material in order to avoid complications in the interpretation of IR spectra due to *cis-trans* isomerization of the *trans* isomer.

In addition to the photolysis of benzoyl peroxides (see Scheme 1), the phenyl radical (**3**) has also been generated by matrix photolysis of nitrosobenzene monomer.[34] Nitrosobenzene (PhNO) exists as a yellow *cis*-dimer (PhN(O)=N(O)Ph) in the solid state at room temperature but forms the blue monomer when sublimed and trapped in solid argon. Irradiation with light of $\lambda > 300$ nm of matrices containing the monomer decomposed the nitroso compound, while new species were formed. Among these were the phenyl radical and its triplet radical-pair complex with NO. On warming the matrix, PhNO was regenerated. Photolysis of PhNO provided an IR spectrum of the phenyl radical, which was less obscured by the absorptions of other species (principally CO_2, $PhCO_2Me$, and the methyl radical) than was the case in the earlier study of the matrix photolysis of **1**. Thus, seven previously unreported IR bands belonging to Ph· could now be observed for the first time.

The value of generating a reactive species by several independent routes is well illustrated in the case of the phenyl radical. Very recently, a thorough matrix-isolation and theoretical study has been made of the electronic absorption spectrum[35] and IR spectrum[36] of Ph·, in which the radical was generated by photolysis (193 or 248 nm) of phenyl iodide and other precursors, as well as by thermolysis reactions. Several D-substituted isotopomers of the radical were also investigated, and polarized light was used to



SCHEME 3

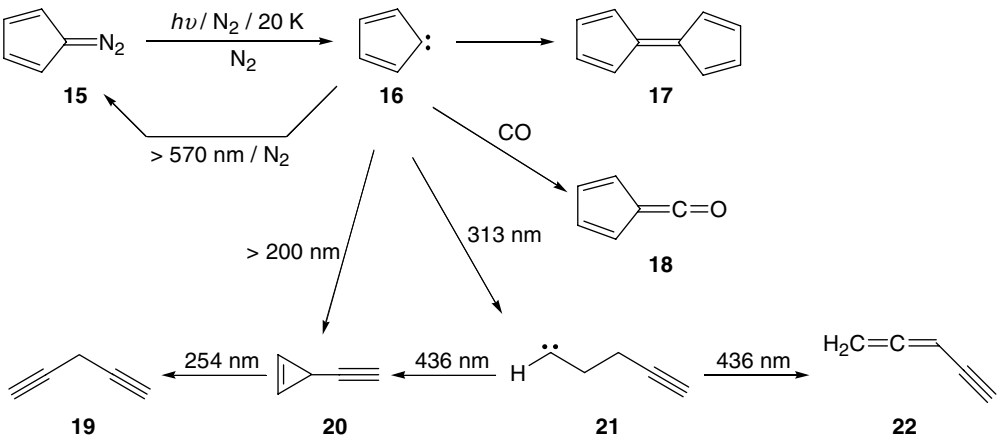
produce oriented samples from which band symmetries could be derived. The result was an impressively full description of the IR spectrum of the phenyl radical, with experiment and DFT calculations in good agreement.

In addition to alkyl and phenyl radicals, IR spectra of certain oxygen-centered radicals have also been obtained by matrix isolation. As an example, the trifluoroperoxy radical ($CF_3OO\cdot$), with IR absorptions at 1174 and 1094 cm^{-1}, was identified amongst the products of the UV-photolysis of CF_3OOF and bistrifluoromethyl trioxide (CF_3OOOCF_3) in Ar matrices.[37] Isotopic labeling experiments with $CF_3{}^{16}O^{16}O^{16}OCF_3$, $CF_3{}^{16}O^{18}O^{16}OCF_3$, $CF_3{}^{18}O^{16}O^{18}OCF_3$ and $CF_3{}^{18}O^{18}O^{18}OCF_3$ demonstrated the non-equivalence of the two O atoms in $CF_3OO\cdot$ through the observation of four distinct isotopic absorptions for the ν(O–O) band at 1094 cm^{-1}. This helped to confirm the identity of $CF_3OO\cdot$ by ruling out the possibility that the IR bands assigned to this radical belonged instead to its F-atom loss product, difluorodioxirane (CF_2O_2), in which the two O atoms are equivalent. More recently, the phenoxyl radical ($PhO\cdot$) has been matrix isolated in argon by photolysis of several different precursors, including phenol and diphenyl carbonate.[38] All but one of the IR-active fundamentals of $PhO\cdot$ were identified, and with the aid of DFT computations, a detailed assignment of its vibrational spectrum was made. Significant shifts of vibrational frequency were noted compared with previous data obtained from resonance Raman studies in polar solutions. In particular, the ν(C–O) frequency was found to be very susceptible to the polarity of the environment, apparently owing to an increase in quinoidal character of the radical in more polar media.

Photochemistry of Matrix-Isolated Radicals

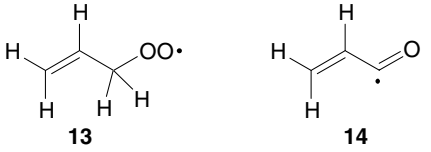
Matrix isolation provides the chance of investigating the photochemistry of radicals, irrespective of their mode of generation – thermal or photochemical. When the ethyl radical was formed in matrices, along with CO_2, by photolysis at $\lambda > 280$ nm of dipropionyl peroxide (*cf.* Scheme 1), subsequent photolysis at $\lambda < 280$ nm produced ethyl propionate, propionic acid, ethane, and ethyne.[39] It thus appeared that, upon excitation, $Et\cdot$ either reacted with CO_2 to yield propionic acid and ethyl propionate, or lost a hydrogen atom, or a hydrogen molecule and a hydrogen atom, to give ethene and ethyne, respectively. Similar behavior was observed for the isopropyl radical, which gave isobutyric acid, isopropyl isobutyrate, and propene, when photolysed under analogous conditions.[40]

The matrix photochemistry of the *t*-butyl radical (**10**) was examined following generation of this radical by flash vacuum pyrolysis of a gaseous mixture of azoisobutane and argon and subsequent condensation of the pyrolysate as a matrix.[41] Irradiation of the resulting sample with light of $\lambda < 280$ nm yielded two major photoproducts: isobutene (**11**) and the isobutyl radical (**12**) (Scheme 3). The former apparently arose in a β C–H scission reaction, eliminating a hydrogen atom; the latter probably was the result of a photoinduced rearrangement, but the possibility of a recombination of **12** and an H atom could not be completely ruled out. Since H atoms were being produced, it was also thought possible that some isobutene might have been produced in a disproportionation reaction of H atoms and the *t*-butyl radical.



SCHEME 4

Methylperoxy radicals (MeOO·) were formed when methyl radicals, generated by the gas-phase pyrolysis of azomethane or methyl iodide, were trapped in Ar matrices containing a few percent of oxygen.[42] Subsequent 254 nm irradiation resulted in destruction of these radicals, while IR absorptions of H_2O, CO, CO_2, formaldehyde, and probably HO_2 were seen to grow in intensity. A theoretical study suggested that the primary photochemical step was likely to have been O–O bond cleavage to give MeO· and an oxygen atom, but the experimental reaction pathways were not fully elucidated. Allylperoxy radicals (**13**) have been similarly trapped in Ar matrices and photolyzed.[43] The vinylacyl radical **14**, with a characteristically high ν(C=O) frequency at 1823 cm^{-1}, was identified in the product IR spectrum, seemingly resulting from elimination of H_2O from **13**.



Carbenes and Their Reactions

Of the various types of reactive organic species, carbenes have been the most extensively studied by matrix-isolation techniques. A comprehensive review of carbenes in matrices, with more than 400 references, was published in 1993 and is an excellent entry point into the literature on this subject.[44]

Methylene (CH_2) was generated from diazomethane in some of the earliest matrix studies of organic reactions, and its dimerization to ethene was observed, although its IR spectrum proved somewhat elusive.[45–47] Various halomethylenes were also observed among the products from the vacuum-UV irradiation of halomethanes in matrices. Examples are CHF from photolysis of methyl fluoride[21] and CCl_2 from dichloromethane.[22]

Simple carbenes such as the halomethylenes were comparatively easy to identify by IR spectroscopy, even when present in mixtures of photoproducts. With larger carbenes, however, identification often had to rely on the observation of characteristic reactions, e.g., dimerization or addition of CO to give ketenes. Cyclopentadienylidene (**16**) was one of the first carbenes to be investigated in this way.[48,49]

Cyclopentadienylidene and Related Carbenes

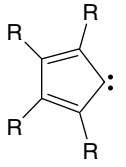
When diazocyclopentadiene (**15**) was photolyzed in N_2 matrices at 12–20 K, the product that was first identified was fulvalene (**17**) (Scheme 4), which has a highly structured and easily recognizable UV

spectrum.[48,49] Only in exceptionally dilute matrices (matrix ratio N_2/**15** = 1.5×10^6) was formation of fulvalene completely suppressed, and then UV and IR absorptions of another photoproduct were observed. This species was identified as the carbene, cyclopentadienylidene (**16**) on the basis of its reactions. Thus, warming matrices containing **16** (but little or none of the diazo precursor) to 30 K, produced fulvalene; also, when **16** was generated in matrices containing CO, warming to 24 K gave a ketene, assumed to be **18**.

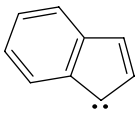
In the original investigation, an attempt was made to observe the back reaction of the carbene with N_2 to regenerate diazocyclopentadiene: unlabelled **15** was photolyzed in a $^{15}N_2$ matrix, but no $^{15}N_2$-substituted **15** was formed. It was therefore concluded that the elimination of N_2 from **15** was irreversible. It was also observed that, on photolysis of the carbene **16** with an unfiltered medium-pressure Hg arc, a secondary photoproduct appeared with IR absorptions near 3315 cm^{-1}, characteristic of a terminal alkyne. The secondary product was shown not be either ethyne or penta-1,4-diyne (**19**), but no further identification could be made at that time.

A later study, benefiting from DFT computations and the skilful use of various irradiation wavelengths, has considerably extended our knowledge of the photochemistry of cyclopentadienylidene.[50] First, it was shown that the back reaction of **16** with N_2 could be induced with long-wavelength light ($\lambda > 570$ nm). Second, several products from the photolysis of **16** at shorter wavelengths were identified. These included the ring-opened carbene **21**, a minor amount of ethynylallene (**22**), 3-ethynylcyclopropene (**20**), and penta-1,4-diyne (**19**). The photoreactions are summarized in Scheme 4.

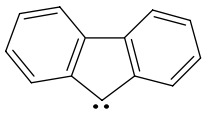
Several other cyclopentadienylidenes have been similarly investigated, including the tetrachloro[51] and tetrabromo[52] derivatives (**23**: R = Cl, Br), indenylidene (**24**),[51] and fluorenylidene (**25**).[51] These carbenes all reacted thermally with CO in matrices, generating the corresponding ketenes, but none could be induced to dimerize to the corresponding fulvalenes. The greater bulk of the carbene molecules compared with the unsubstituted parent **15** could inhibit diffusion within the matrix or simply prevent dimerization through adverse steric effects.



23



24



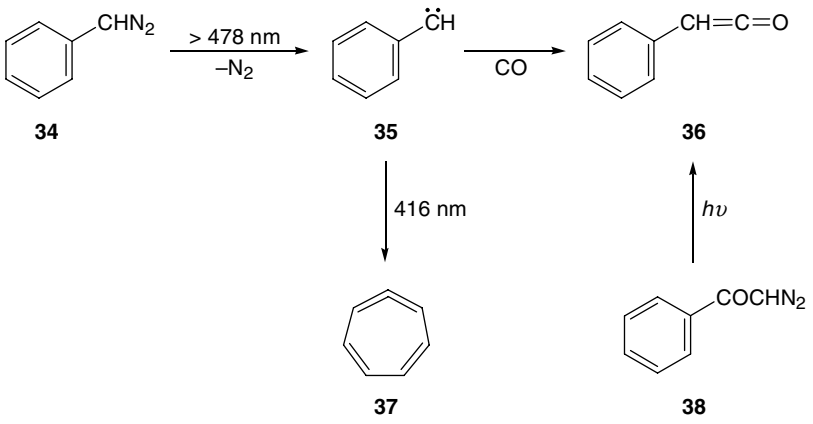
25

Interesting parallels with the photochemistry of cyclopentadienylidene have been discovered for some heterocyclic analogues. 2*H*-Imidazol-2-ylidene (**26**), for example, was trapped in argon matrices by photolysis of the corresponding diazo precursor, 2-diazo-2*H*-imidazole.[53] As with other carbenes, **26** reacted with CO in CO-doped matrices, yielding the corresponding ketene. Upon photolysis with light of $\lambda > 570$ nm, **26** was transformed into 1-cyano-1*H*-azirine (**27**), which in turn was efficiently converted into *N*-cyanoketenimine (**28**) by 254 nm irradiation. Interestingly, carbene **26** could not be trapped under thermal conditions, and flash vacuum pyrolysis of 2-diazo-2*H*-imidazole gave only imidazole.

26

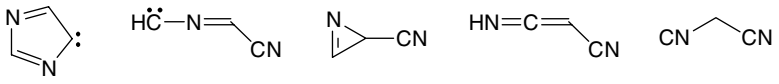
27

28



SCHEME 5

4*H*-Imidazol-4-ylidene (**29**) was similarly generated in argon matrices by photolysis of 4-diazo-4*H*-imidazole and was converted into the ring-opened carbene **30** when irradiated at >570 nm.[54] Further photolysis of **30** at > 310 nm produced 2-cyano-2*H*-azirine (**31**), which decomposed when irradiated at 254 nm to products with IR absorptions at 2067 and 2155 cm^{-1}. These were thought to belong to ketenimine **32** and isocyanoacetonitrile (**33**), respectively.

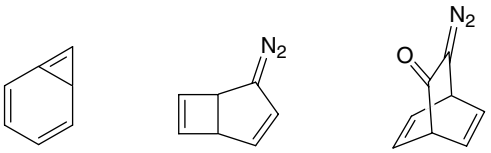


29 **30** **31** **32** **33**

Carbenes **26** and **29** both underwent facile reactions with N_2 to regenerate their diazo precursors, and neither could be detected when the diazo compounds were photolyzed in N_2 matrices. Moreover, when 2-diazo-2*H*-imidazole, the precursor of **26**, was photolyzed in a matrix of ^{15}N-labelled nitrogen, IR bands due to [$^{15}N_2$]-2-diazo-2*H*-imidazole were observed to arise after a very short irradiation time, providing a positive demonstration of the recapture of nitrogen from the matrix material.

Aryl Carbenes

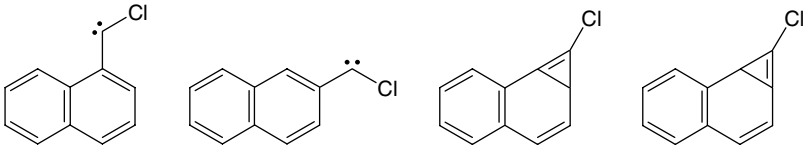
The triplet ground state of phenylcarbene (**35**) was first observed by EPR spectroscopy, but a matrix-isolation study of the photolysis of phenyldiazomethane (**34**) provided IR and UV spectra of this species and allowed an investigation of its photochemistry (Scheme 5).[55,56] When generated in matrices containing CO, carbene **35** gave phenylketene (**36**) on warming. The same ketene was also generated by photolysis of diazoacetophenone (**38**), thus confirming its identity. Irradiation of carbene **35** with light of $\lambda > 416$ nm produced a new species with a considerably altered IR spectrum, including bands at 1824 and 1816 cm^{-1}. This species did not react with CO to give a ketene and was therefore not another carbene. After the exclusion of other possibilities, such as bicyclo[4.1.0]hepta-2,4,6-triene (**39**), with the help of deuterium-labeling studies, it was identified as the cyclic allene, cyclohepta-1,2,4,6-tetraene (**37**). Subsequently, **37** was generated from a number of other precursors, including 2-diazobicyclo[3.2.0]hepta-3,6-diene (**40**) and 8-diazobicyclo[2,2,2]octa-2,5-diene (**41**). Several substituted derivatives of **37** were also investigated.[56] It was moreover shown that cyclic allene **37** and phenylcarbene (**35**) could be interconverted photochemically by appropriate choice of wavelengths. Thus, irradiation of matrix isolated **37** with light of $\lambda > 279$ nm produced a small, steady-state concentration of **35**.



39 **40** **41**

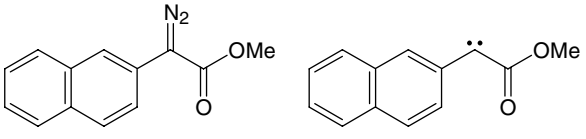
The mechanism for the formation of **37** is not completely clear, however. There is a question of whether it is formed directly from carbene **35** or via the bicyclic triene **39** as an intermediate. So far, the triene has not been detected, and calculations have suggested that it may not correspond to a local energy minimum on the ground-state singlet C_7H_6 energy surface.[57] On the other hand, in matrix studies of naphthylcarbenes, cyclopropene derivatives analogous to **39** have been observed, but not the corresponding cyclic allenes.[58–60]

In contrast to phenyl- and naphthyl carbenes, which have triplet ground states, 1- and 2-naphthylchlorocarbenes (**42** and **43**) exist as ground-state singlets; their matrix IR and UV-visible spectra were reported recently.[61] In the case of **43**, two distinct conformations were observed, and these could be interconverted by selective irradiation. Both **42** and **43** underwent cyclization upon prolonged UV-irradiation, yielding the chlorotricycloheptatrienes **44** and **45**, respectively. No ring-expanded cyclic allene products were detected. It therefore seems that both triplet and singlet naphthyl carbenes have similar photochemistry, which contrasts with that of phenylcarbenes.



42 **43** **44** **45**

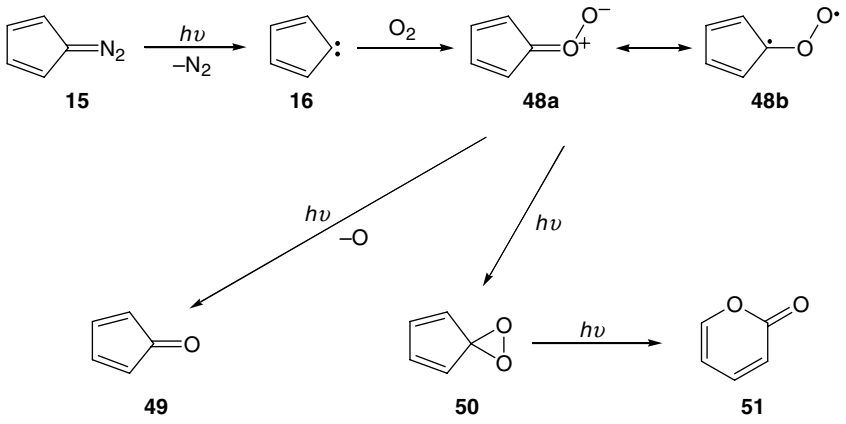
Matrix photolysis of methyl α-diazo-(2-naphthyl)acetate (**46**) at 450 nm gave primarily the triplet ground-state carbene **47**, which was characterized by its UV-visible, IR, and EPR spectra and by its reactions with carbon monoxide and oxygen.[62] Bleaching the weak visible bands of triplet **47** ($\lambda > 515$ nm) led to the disappearance of the triplet EPR signals, while a new absorption arose in the near-UV. Thereafter, however, the spectra of triplet **47** were almost fully recovered in the dark at 12 K. The species generated by visible irradiation of triplet **47** had IR and UV spectra consistent with singlet **47** and not a tricyclic cyclopropene analogous to **45**. Theoretical exploration of the potential energy surfaces for triplet and singlet **47** showed that a barrier between the two states is created by a pronounced change in conformation of the methoxycarbonyl group; for singlet–triplet interconversion, the necessary conformational change is likely to be hindered in the matrix environment.



46 **47**

Carbonyl Oxides

The reaction of matrix-isolated carbenes with carbon monoxide, as noted above, gives ketenes, even if the ground state of the carbene is a triplet. For triplet carbenes, the process is formally spin-forbidden;



15 **16** **48a** **48b** **49** **50** **51**

SCHEME 6

so it is remarkable that it proceeds readily in the temperature range 20–30 K. It might be supposed that the reaction of triplet carbenes with dioxygen, which also has a triplet ground state, would be even more favorable than the reaction with CO. This indeed appears to be the case and has provided a convenient means of investigating carbonyl oxides (R^1R^2COO), reactive species that were first proposed as intermediates in the ozonolysis of alkenes.

The first IR spectrum of a carbonyl oxide was obtained when diazocyclopentadiene (**15**) was photolysed in Ar or N_2 matrices containing O_2 (Scheme 6).[63] Under these conditions, a new species was observed to arise, either directly or on annealing the matrices, which appeared to be an adduct of the carbene **16** and O_2 and which was supposed to be the carbonyl oxide **48**. The matrix photolysis of **15** was reported independently by two research groups, and at first there was a discrepancy between the two IR spectra attributed to the carbonyl oxide.[63,64] This was resolved by studies utilizing mixtures of $^{16}O_2$, $^{18}O_2$, and $^{16}O^{18}O$ as the source of oxygen.[63,65] These showed that the initial product had nonequivalent oxygen atoms and could be identified as **48**, but that this species was very photolabile, either losing an O atom to give cyclopentadienone (**49**) or rearranging to α-pyrone (**51**) via the dioxirane **50**, which has equivalent O atoms.

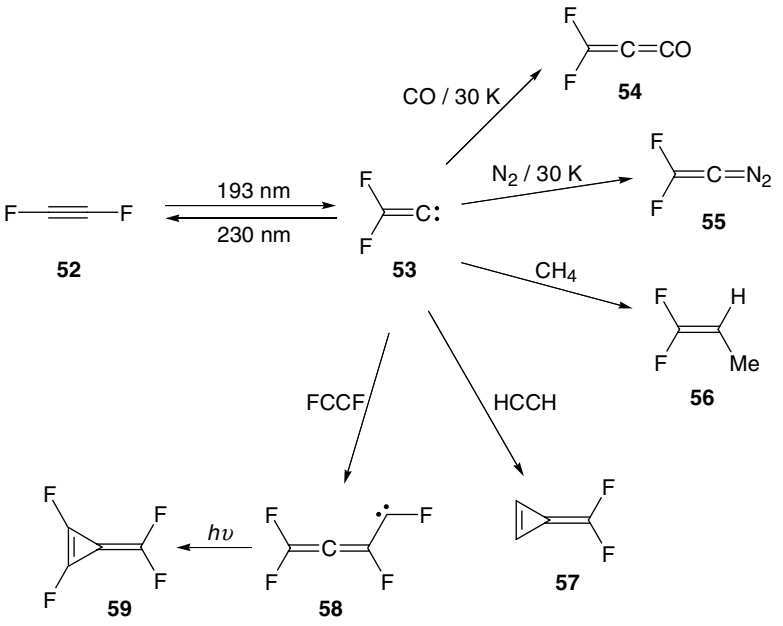
Several analogues of **48** were also investigated soon after the initial study. These included the tetrachloro derivative[66] of **48** and the adducts of O_2 with the carbenes, indenylidene and fluorenylidene.[67] In each case, both the O-atom loss and the rearrangement reactions (*cf.* Scheme 6) were observed to occur on further photolysis of the carbonyl oxides. Subsequently, many other examples were generated in similar fashion, and the formation and photolysis of carbonyl oxides, exemplified by **48**, turned out to be reasonably general.[68–70] Moreover, the trapping of an α–carbonylcarbene[71] and an α-sulfonylcarbene[72] by reaction with O_2 competed efficiently with the Wolff or hetero-Wolff rearrangements of these species, thus confirming the intermediacy of discrete carbenes in these reactions.

Before these matrix-isolation studies, it had been usual to denote carbonyl oxides as zwitterions (*cf.* **48a**), but the experimental IR spectra of **48** and its analogues did not exhibit absorptions that could be assigned to C=O bonds. It was therefore concluded that carbonyl oxides are better represented as polar singlet biradicaloids (*cf.* **48b**).[68]

Other Carbenes

Matrix-isolation studies of carbenes have been numerous and their scope extensive. Many interesting results have, of necessity, been left out of this review.

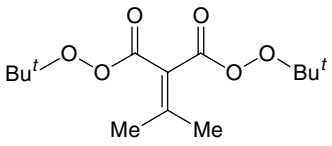
A notable case, which does not fit into the reaction types discussed in the earlier parts of this section, is that of the extremely electrophilic carbene difluorovinylidene (**53**), which has recently been isolated in argon matrices by 193 nm photolysis of difluoroethyne (**52**) (Scheme 7).[73,74] Carbene **53** thermally



SCHEME 7

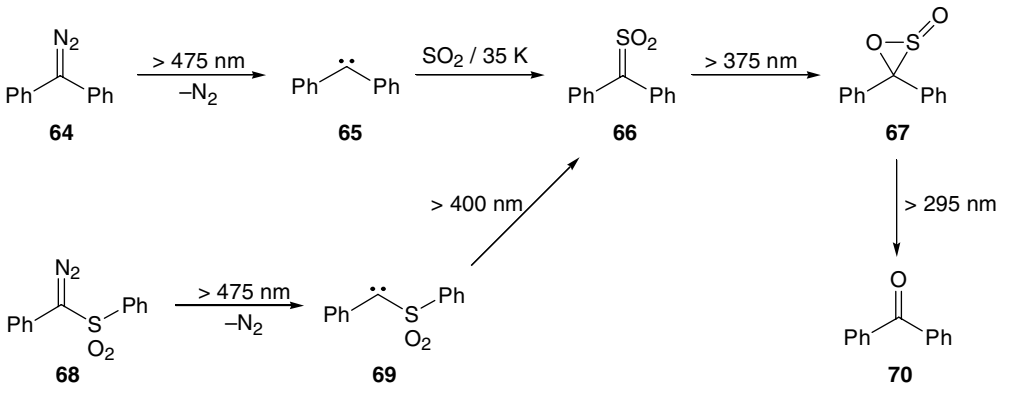
added CO and N_2 to give ketene **54** and diazoethene **55**, respectively. These reactions occurred so efficiently that carbene **53** could not be trapped in matrices by photolysis of either **54** or **55**. Carbene **53** also inserted into CH_4 at temperatures below 40 K to give **56** and added to ethyne to give cyclopropene **57** and to difluoroethyne to give the allenyl carbene **58**, which rearranged to the cyclopropene **59** when irradiated with visible light. Difluorovinylidene even underwent a thermal reaction with Xe to produce a distinct charge-transfer complex with characteristic IR absorptions.

The careful selection of suitable precursors is obviously needed for the study of such reactive species as vinylidenes, which rearrange to the corresponding alkynes very easily. Dimethylvinylidene ($Me_2C{=}C{:}$) has recently been trapped in matrices by photolysis of the bisperoxyester **60** and was identified by its reaction with CO and by comparison of the matrix IR spectrum with DFT computations of the IR transitions.[75] It was suggested that this approach could provide a convenient and general route to other vinylidenes in low-temperature matrices.



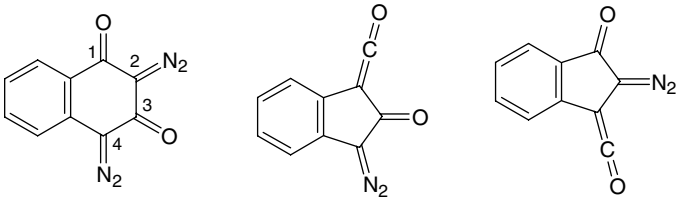
60

Matrix isolated α-carbonylcarbenes generated by photolysis of various α-diazocarbonyl compounds in low-temperature matrices have been investigated, among other reasons, in the hope of detecting oxirenes. A very interesting variation has been found in the photochemistry of **61**, which has two nonequivalent diazo groups.[76,77] Photolysis of **61** was investigated in Ar matrices and in liquid solutions. The product distribution was found to be remarkably dependent on irradiation wavelength. In Ar matrices, photolysis of **61** with light of $\lambda > 350$ nm produced mainly **62**, by selective elimination of N_2 from C2, whereas light of $\lambda > 420$ resulted mainly in N_2 elimination from C4, to give **63**. It was proposed that the wavelength effect in these photoreactions was probably due to selective excitation of **61** into the lowest excited singlet state (S_1) at longer wavelengths and the participation of higher excited states at



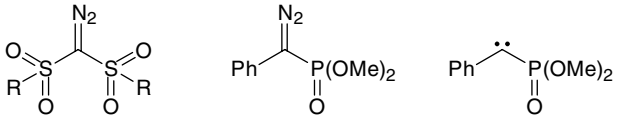
SCHEME 8

shorter wavelengths. Nevertheless, the involvement of different vibrational states of S_1 could not be ruled out.

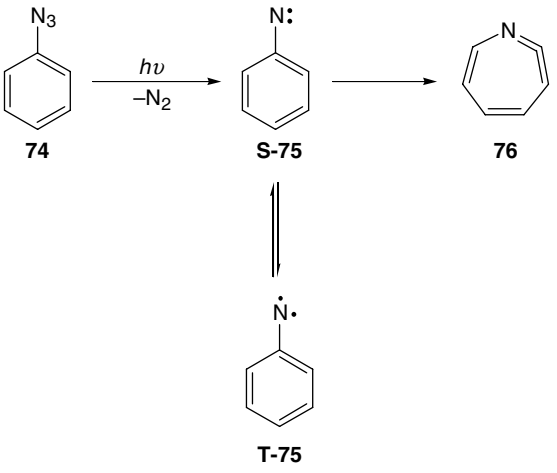


Matrix investigations of sulfur and phosphorus analogues of αcarbonylcarbenes have also been reported. For example, diphenylsulfene (**66**) and diphenyl-α-sultine (**67**) were isolated in low-temperature matrices following the thermal reaction of SO_2 and diphenylcarbene (**65**) and the stepwise photolysis of phenyl(phenylsulfonyl)diazomethane (**68**), as summarized in Scheme 8.[72] The ultimate photoproduct was benzophenone (**70**).

For a series of bis(sulfonyl)diazomethanes (**71**: R = Me, cyclohexyl, Ph, 4-MeC_6H_4, 4-ClC_6H_4), the corresponding carbenes could be trapped chemically in solution, but attempts to isolate them in Ar matrices were unsuccessful, and only sulfenes and other rearranged products were observed.[78] This failure, however, was in accord with theoretical computations, which predicted that the singlet carbenes correspond to saddle points on the potential energy surfaces, while the triplet carbenes lie at higher energies and are therefore not expected to have prolonged lifetimes even in matrices.



Photolysis of dimethyl α-diazobenzylphosphonate (**72**) in Ar matrices gave the corresponding carbene **73**.[79] Prolonged irradiation of **73**, even with short-wavelength light (254 nm), did not result in any appreciable photoreaction, but it underwent the normal thermal reactions with CO and O_2 in appropriately doped matrices.



SCHEME 9

14.5 Nitrenes

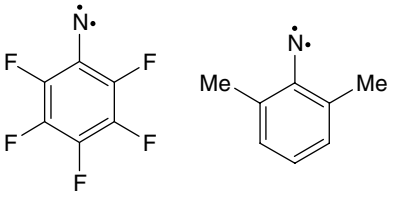
Phenyl Nitrenes

The matrix photochemistry of phenylnitrene (PhN) has many similarities to that of phenylcarbene, but also some significant differences. A comparison between the two, including flash-photolysis as well as low-temperature, matrix-isolation studies, can be found in a 1995 review.[57]

Any account of matrix studies of aryl nitrenes should begin with some early reports of the photolysis of aryl azides in frozen organic solvents, in which UV-visible absorptions of the photoproducts were assigned to the corresponding nitrenes.[80–82] It was therefore expected that IR spectra of the nitrenes should be readily obtainable by similar photolyses in Ar or other similar matrices. However, the nitrenes proved more elusive.

When phenyl azide (**74**) was photolyzed in Ar matrices, phenylnitrene (**75**) was not detected in the resulting IR spectrum, but a product with an intense absorption at 1895 cm^{-1} was formed.[83] It was concluded that the only plausible candidate for the observed product was the strained cyclic ketenimine **76** (Scheme 9), with the 1895 cm^{-1} IR band corresponding to the $\nu(C{=}C{=}N)_{as}$ vibration. The identity of **76** received further support when it was found that the ^{15}N-isotopomer had this IR band shifted to lower frequency by about 15 cm^{-1}.[84] At the same time, it was found that a series of 3- and 4-substituted phenyl azides gave the same type of ketenimine products when photolyzed in Ar and N_2 matrices, all with IR bands in the 1910–1880 cm^{-1} region.[84]

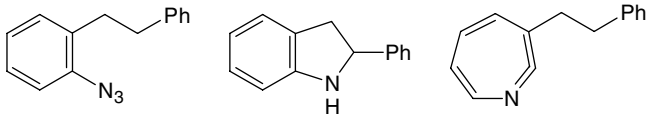
It was next discovered that when the *ortho* positions were substituted, the ring-expansion reaction was suppressed, and the direct observation of an aryl nitrene by matrix IR spectroscopy became possible. The first two examples were pentafluorophenylnitrene (**77**)[85] and 2,6-dimethylphenylnitrene (**78**).[86] Both these nitrenes underwent reaction with CO to give the corresponding isocyanates (ArNCO), but, unlike the situation with carbenes, the addition of CO did not proceed thermally at temperatures up to 35 K, requiring instead further irradiation ($\lambda > 330$ nm). The fluorinated nitrene **77** showed no tendency to undergo ring expansion to the corresponding keteninime on further irradiation, but the dimethylphenylnitrene **78** seemed to undergo an inefficient rearrangement on prolonged irradiation to give the corresponding ketenimine, with an IR absorption at 1899 cm^{-1}. The effect of *o*-fluorine substitution in suppressing the ring expansion of phenylnitrene has been examined theoretically.[87] The increase in energy barrier seems to derive principally from steric repulsion in the transition state when nitrogen approaches the fluorine-bearing ring carbon.



77 **78**

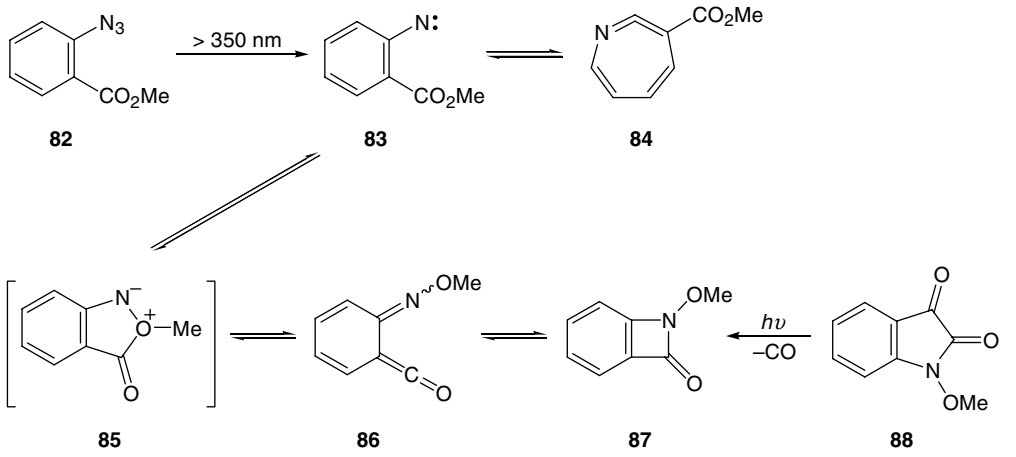
The question now arose as to why aryl nitrenes were apparently the major products when aryl azides were photolyzed in frozen organic solvents, but cyclic ketenimines were the major products in Ar and N_2 matrices, unless the ring expansion was suppressed by *ortho* substitution. One possible explanation lay in the differing abilities of the two types of media to dissipate excess vibrational energy following excitation of the precursor azides and generation of the nitrenes. Organic solvents with many molecular vibrations could couple more effectively with the initial, vibrationally hot, nitrene and cool it quickly, thus minimizing further reaction. On the other hand, matrices such as Ar or N_2 would probably be less effective in removing excess vibrational energy, so that further reaction of the nitrene would be more likely.[88] This idea has received some support from a comparison of the rates of disappearance of phenyl azide (**74**) and formation of ketenimine **76** in Ar, CH_4, and 3-methylpentane matrices.[89] With 280 nm light, the rate of appearance of **76** was significantly less than the rate of disappearance of **74** in both CH_4 and 3-methylpentane, but not in Ar. This indicated that an intermediate — presumably the triplet phenynitrene (**T-75**) — was accumulating in the hydrocarbon but not in the Ar matrices. This intermediate then required a second photon to rearrange to the ketenimine.

In fact, the key to obtaining a matrix IR spectrum of triplet phenylnitrene was the careful choice of photolysis wavelength, not of matrix host material. It was found that photolysis of phenyl azide in Ar or N_2 matrices with 334 nm light produced only a small amount of ketenimine **76**, and the IR bands of another species were then observable.[90] These disappeared on further irradiation with light of $\lambda > 450$ nm, while the IR absorptions of **76** increased. Clearly, **76** was being formed in a two-step process. It was concluded that **76** could be formed directly only from the singlet nitrene **S-75** and that the observed intermediate species was the triplet nitrene **T-75**, which required further excitation to the singlet manifold, presumably via higher triplet excited states, before being converted into **76**. A fuller study of phenyl azide photolysis, utilizing organic glasses at 77 K in conjunction with a variety of spectroscopic techniques, revealed that the preferred reaction pathway at ambient temperatures was different from that at 77 K and provided further examples of *ortho,ortho´*-disubstituted phenyl nitrenes.[88] It was concluded from this study that rearrangement of singlet phenylnitrenes to cyclic ketenimines is strongly dependent on temperature and substituent effects and that the competing process of intersystem crossing to the triplet nitrene is favored at low temperatures. In matrix-isolation conditions, it is quite possible that all the ketenimine observed comes from secondary photolysis of the triplet nitrene.



79 **80** **81**

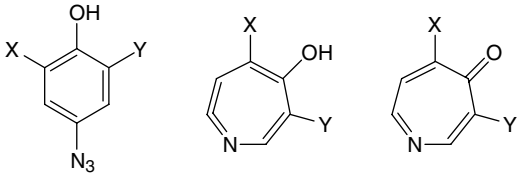
The matrix photochemistry of phenyl nitrenes becomes more complex when substituents are present that can take an active part in the reactions. For instance, irradiation of azide **79** in Ar matrices gave a product (**80**) from nitrene insertion into an adjacent CH bond as well as the ring-expanded ketenimine **81**.[91] The nitrene center can also react by attack on oxygen. Thus, the photolysis of 2-(methoxycarbonyl)phenyl azide (**82**) in Ar matrices gave rise to at least five major products: nitrene **83**, cyclic ketenimine **84**, the two geometrical isomers of ketene-oxime **86**, and *N*-methoxyazetinone **87** (Scheme 10).[92] Products



SCHEME 10

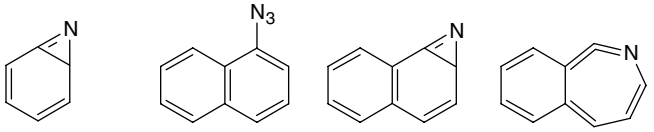
86 and **87** were proposed to arise via the oxonium ylide **85**, which was not itself directly detected. All the observed products were shown to be photochemically interconvertible, and the same mixtures could be generated by photodecarbonylation of *N*-methoxyisatin (**88**).

When 4-azidophenols such as **89** (X = Y = Cl) were photolyzed in N_2 matrices, azepin-4-ones (**91**) were the major products, presumably arising by tautomerization of the corresponding hydroxy-substituted cyclic ketenimines (**90**).[93,94] In some cases, the ketenimine was observed directly in the IR spectra. Tautomerization to give the azepinones was favored in more concentrated matrices, suggesting that this process involved intermolecular proton transfer between pairs or aggregates of ketenimine molecules. Matrix photolysis of 4-azidophenols held out the promise of a synthetic route to the elusive azepin-4-ones under exceptionally mild conditions and was tried on preparative scales up to 50 mg or more in a specially constructed matrix-isolation cell. Unfortunately, the azepinones did not survive warm-up at the end of the experiments, and only polymeric products were ultimately obtained.



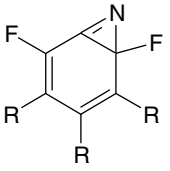
Azirine Intermediates

As with phenylcarbene (**35**) (*cf.* Scheme 5), the ring expansion of phenylnitrene (**75**) could occur directly on the singlet potential energy surface or via a bicyclic intermediate, in this case azirine **92**. Such azirines were first detected in the matrix photolysis of 1- and 2-azidonaphthalene.[95] For example, photolysis of **93** generated a photoproduct with an IR absorption at 1730 cm^{-1}, which in turn gave a cyclic ketenimine [ν(C=C=N)$_{as}$ at 1926 cm^{-1}] on further photolysis. It was proposed that the intermediate with the 1730 cm^{-1} IR band was the tricyclic azirine **94**, which subsequently rearranged to **95**. At the time of these experiments, however, reliable computations of IR transitions were not available, so a definitive identification of the azirines was scarcely possible. Nevertheless, a clear parallel was found here with the behavior of aryl carbenes, which give detectable cyclopropenes in the naphthalene series (*cf.* **44** and **45**) but not with the monocyclic carbenes (see the brief discussion of this point in Section 14.4).



92 **93** **94** **95**

It was later discovered that azirines **96** (R = H, F) could be generated in amounts sufficient for IR detection when the corresponding phenyl nitrenes were photolyzed with 444 nm light.[96] The azirines had prominent IR absorptions in the range 1680–1660 cm^{-1}, which could be assigned as ν(C=C + C=N) vibrations. Theoretical calculations of the IR transitions were in reasonable agreement with experimental results. Both of these azirines reverted to the corresponding nitrenes when irradiated at 366 nm but showed no tendency to rearrange to the seven-membered cyclic ketenimines.

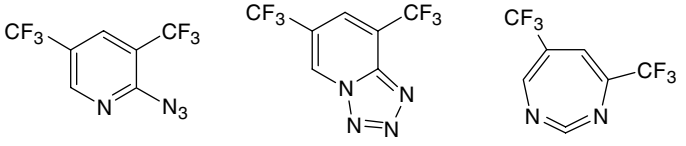


96

Heterocyclic Nitrenes

Matrix-isolation studies of the photochemistry of heterocyclic analogues of phenylnitrene have been reported at various times. The following are some recent examples.

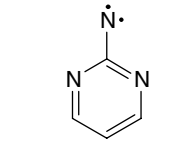
A number of trifluoromethyl-substituted 2-pyridyl azides, e.g., **97**, have been matrix-isolated and photolyzed in Ar at 12–18 K.[97] Like other 2-pyridyl azides, **97** exists in equilibrium with the tetrazole valence tautomer **98**, but sublimation for the purpose of matrix isolation usually causes significant ring opening to the azido forms. In any case, the tetrazole forms as well as the azides eliminate N_2 when photolyzed. All the 2-pyridyl azides or tetrazoles investigated underwent conversion into the corresponding 1,3-diazacyclohepta-1,2,4,6-tetraenes, e.g., **99** from **97**, and these ring expanded products, which are cyclic carbodiimides, had $\nu(N{=}C{=}N)_{as}$ bands at about 2000 cm^{-1} in their IR spectra. In the case of **97**, the triplet nitrene was also observed by both IR and EPR spectroscopy, and it was seen to give **99** on further photolysis.



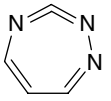
97 **98** **99**

Triplet ground-state 2-pyrimidylnitrene (**100**) has similarly been observed by EPR and UV-visible absorption spectroscopy in ethanol glasses at 77 K and by UV-visible and IR spectroscopy in Ar matrices, following 254 nm photolysis of the equilibrium mixture of 2-azidopyrimidine and its tetrazole tautomer.[98] The matrix IR spectrum of **100** was in good agreement with that predicted by DFT theory. The matrix IR spectra also revealed that a second, unidentified product, which might have been a photoproduct of the tetrazole tautomer of the starting azide, accompanied **100**. On continued exposure of the matrix to 254 nm light, the IR bands of **100** and the unidentified product disappeared and a new band arose at 2045 cm^{-1}, which was assigned to the carbodiimide **101**. In accord with theoretical predictions, no

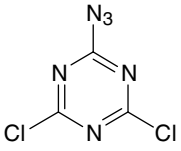
benzodiazirine, analogous to **96**, was detected. In a comparable reaction, 2-azido-4,6-dichloro-*s*-triazine (**102**) yielded both the corresponding triplet nitrene and the cyclic carbodiimide **103** when photolyzed in Ar matrices.[99]



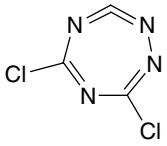
100



101



102

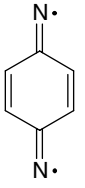


103

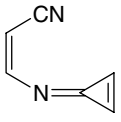
Di- and Trinitrenes and Carbenonitrenes

In the past few years, a growing interest in the investigation of reactive species with more than one nitrene or carbene center has developed.

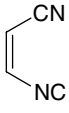
Photolysis of *p*-diazidobenzene in Ar matrices led to the IR detection of *p*-phenylenebisnitrene (**104**), which decomposed to **105** and then to ethyne and 1-cyano-2-isocyanoethene, most probably in its *Z* form (**106**), on further irradiation.[100] The identification of the reaction products from the matrix IR spectra relied greatly on DFT computations of IR transitions. The dinitrene **104** was predicted to have a singlet ground state with a small S–T splitting, which is in accord with the experimental results and is best described as a bisiminyl diradical. Owing to its high symmetry, only one C=N bond stretch of **104** is IR active, and this was observed at 1576 cm^{-1} with a weak intensity.



104

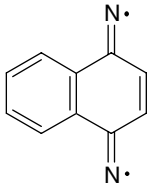


105

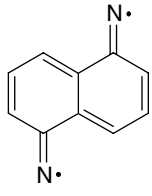


106

Related studies of the photolysis of 1,4-diazidonaphthalene[101] and 1,5-diazidonaphthalene[101,102] have afforded UV-visible, IR, and EPR spectra of the corresponding bisiminyl diradicals (dinitrenes), **107** and **108**, respectively. These also seem to have singlet ground states with quinonoidal character rather than aromatic dinitrene structures.

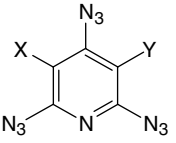


107

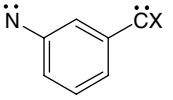


108

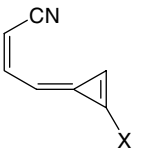
Matrix photolysis of 3,5-dichloro- and 3-chloro-5-cyano-2,4,6-triazidopyridines (**109**: X = Cl, Y = Cl, CN) gave in rapid succession mono-, di-, and trinitrenopyridines, which were identified by agreement of the matrix IR spectra with DFT calculations.[103] The 3,5-dicyano analogue (**109**: X = Y = CN), however, did not yield an identifiable trinitrene. The quintet dinitrenes and septet trinitrenes in this series have also been examined by EPR spectroscopy.[104]



109



110



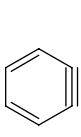
111

As a final example, *m*-phenylene–coupled carbenonitrenes **110** (X = H, F, Cl, Br) have recently been the subject of theoretical and experimental studies, the latter utilizing matrix IR, UV, and EPR spectroscopy.[105] At the highest level of theory, the unsubstituted species (**110**: X = H) should have a quintet ground state, whereas the halogen derivatives should have triplet ground states. Attempts to detect **110** (X = H) by matrix photolysis of 3-azidophenyldiazomethane did not yield detectable amounts of the carbenonitrene. Instead, an excellent match was found between the photoproduct IR spectrum and the cyclopropene derivative **111** (X = H). In the case of the three halogen derivatives, however, the triplet carbenonitrenes were detected and characterized. The matrix IR spectra indicated that all three isomerized to cyclopropenes **111** (X = F, Cl, Br) on further irradiation.

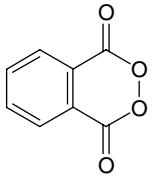
14.6 Arynes

o-Benzynes

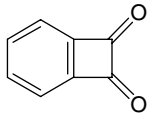
An account of the matrix-isolation studies of *o*-benzyne (**112**) provides a cautionary tale. This species was first isolated in matrices by the stepwise photochemical elimination of two molecules of CO_2 from **113** or two molecules of CO from **114**, and its IR spectrum was thereby observed.[106] IR bands at 1627, 1607, 1451, 1053, 1038, 849, 736, and 469 cm^{-1} were attributed to **112**. Although none of these bands appeared in the ν(C≡C) region of the spectrum and although the experimental band at 1672 cm^{-1} proved troublesome to fit, force-field calculations based on the matrix IR spectrum of **112** suggested that this molecule had a cycloalkyne structure, i.e., with a genuine triple bond.[107] On the basis of the force field, it was predicted that **112** should have IR absorptions with ν(C≡C) character at 2450 and 2083 cm^{-1}. In further experiments, an IR band at 2085 cm^{-1} was observed and assigned to **112**, in excellent agreement with the predicted ν(C≡C) band at 2083 cm^{-1}, thus seeming to provide firm confirmation of the triple bond character of **112**.[108] No band near 2450 cm^{-1} was observed, but it seemed likely that this other ν(C≡C) band could have very low intensity.[107]



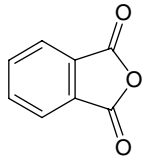
112



113



114

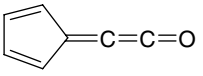


115

It was later found that *o*-benzyne could also be generated in matrices by photoelimination of CO and CO_2 from phthalic anhydride (**115**), a more convenient precursor than **113** or **114**.[109] This provided an alternative route to **112** and also the matrix IR spectrum of its tetradeuterio isotopomer. The problematical IR band at

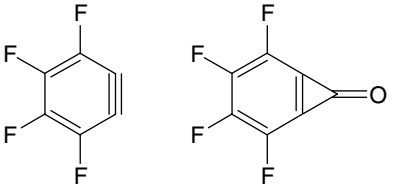
1627 cm^{-1} was not present in the matrix spectrum of **112** produced from **114** and was therefore due to a byproduct. Otherwise, the agreement in the IR spectra of **112** obtained from different precursors remained good, including the 2085 cm^{-1} band assigned to the C≡C stretch. On the other hand, the IR spectrum of tetradeuterio-*o*-benzyne did not fit as well as expected with predictions made from the force-field calculations for **112**. Some doubts as to the bonding in *o*-benzyne therefore remained, especially with respect to the surprising conclusion that the bond between C1 and C2 had full triple bond character.

Only much later, with the help of more modern theory, did the true picture emerge.[110] It was shown that the 2085 cm^{-1} band, previously assigned as ν(C≡C), belonged not to *o*-benzyne but to cyclopentadienylideneketene (**116**), which was formed in a remarkable, reversible photochemical reaction of *o*-benzyne with CO. A complete set of vibrational frequencies was obtained for *o*-benzyne and two of its isotopomers, C_6D_4 and 1,2–$^{13}C_2C_4H_4$, and symmetries were assigned for most of the transitions from the linear dichroism exhibited by matrices containing photo-oriented *o*-benzyne. From these results, the ν(CC) IR absorption of the bond between C1 and C2 in **112** was identified at 1846 cm^{-1}, indicating a bond somewhere between a double and a triple bond. Later, the ^{13}C NMR spectrum of *o*-benzyne isolated in Ar matrices was reported.[111] Simulation of the spectrum gave an estimated bond length of 124 ± 2 pm for the bond between C1 and C2, in good agreement with geometry optimizations carried out by *ab initio* methods and with the qualitative finding of a bond lying somewhere between double and triple in character. The introduction sections of these definitive IR[110] and NMR[111] papers should be read for their excellent critiques of the numerous previous investigations of *o*-benzyne.



116

Recently, tetrafluoro-*o*-benzyne (**117**) has been isolated in Ar matrices, together with CO and CO_2, by photolysis of tetrafluorophthalic anhydride.[112] On subsequent irradiation at 350 nm, **117** was carbonylated to give the cyclopropenone **118**. The C≡C stretching vibration in **117** could not, however, be identified. DFT computations predicted that the ν(C≡C) IR band should be found at 1936 cm^{-1}, but with very low intensity.

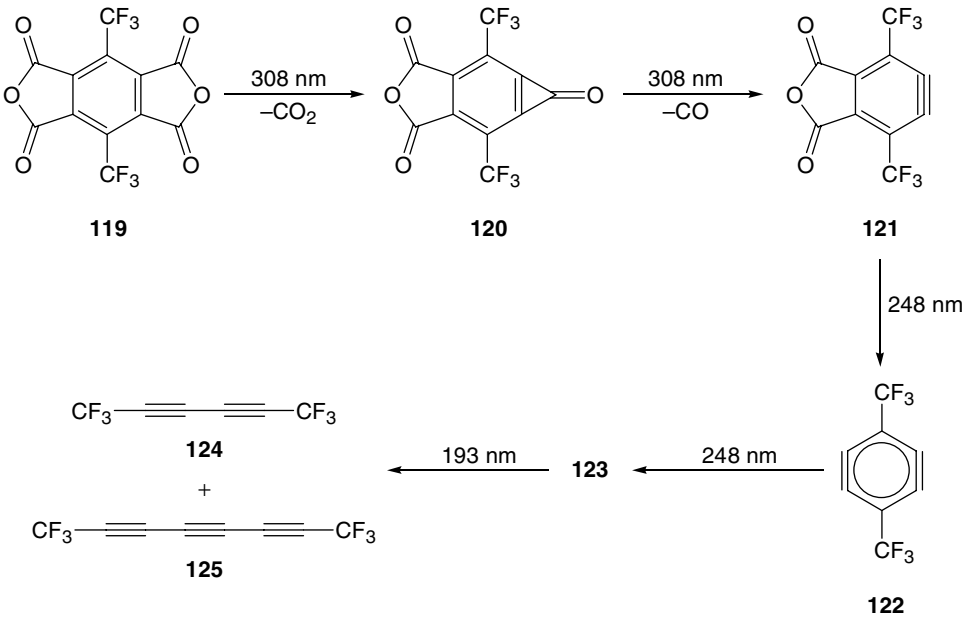


117 **118**

Benzdiynes and Analogues

The convenience of aromatic dicarboxylic anhydrides as precursors for benzynes has encouraged the search for benzdiynes. So far these efforts have provided some, but by no means universal, success. Much interesting chemistry has emerged, nonetheless.

Sequential photolysis of dianhydride **119** in Ar matrices, as shown in Scheme 11, resulted first in the elimination of CO_2 and then CO from one of the anhydride groups, giving cyclopropenone **120** and benzyne **121**.[113] The identity of benzyne **121** was confirmed by generating this species in argon matrices containing furan, allowing the argon to evaporate by gentle warming and finally analyzing the residue by GC-MS, which revealed the presence of the furan adduct of **121** (M^+ = 350). Further irradiation of matrices containing **121** at 248 nm led to a decrease in its IR absorptions, increases in the IR absorptions of CO and CO_2, and the appearance of a new species with IR bands at 1466, 1183, 1127, and 798 cm^{-1}.



SCHEME 11

On the basis of its IR spectrum and subsequent photochemistry, this new species was identified as the 1,4-benzdiyne **122**. With 248 nm light, **122** decomposed to an intermediate **123**, which could not be identified, but which in turn was transformed by 193 nm light into diyne **124** and triyne **125**.

Attempts to observe unsubstituted 1,4- and 1,3-benzdiynes (**126** and **127**) by similar wavelength-selective photolyses of 1,2:4,5- and 1,2:3,4-benzenetetracarboxylic dianhydrides were unsuccessful.[114] The corresponding cyclopropenone and benzyne photoproducts (*cf.* **120** and **121**) were observed in the initial stage in each case, but only ring-opened final products, such as hexa-1,3,5-triyne, were detected thereafter. Comparable results were obtained in attempts to observe naphthdiynes such as **128**.[115,116] Most recently, a second example of a 1,4-benzdiyne has been identified: the 3,6-difluoro derivative, which like the 3,6-bis(trifluoromethyl) analogue **122**, was converted into a hexatriyne on secondary photolysis.[117]

Matrix Photochemistry of Small Ring Compounds

Ian R. Dunkin
University of Strathclyde

15.1 Introduction

This chapter covers photochemical studies of three- and four-membered ring compounds isolated in very low temperature matrices, typically solidified noble gases or nitrogen at temperatures of 10–20 K. Under the conditions of such *matrix isolation*, reactive species are stabilized because they are prevented from diffusing and therefore from undergoing bimolecular reactions. Matrix-isolated species can be characterized by a variety of normal spectroscopic methods; IR spectroscopy usually provides the greatest amount of structural information. In the study of small ring compounds, the matrix-isolation technique has allowed the characterization and identification of previously elusive compounds such as thiirenes and highly reactive small ring species such as cyclopropenylidenes.

In addition to the stabilization of reactive species, an important advantage of matrix isolation is that IR bands tend to be very narrow. This means that overlap between the IR bands of different compounds in product mixtures is minimized, which facilities identification of the individual species present. Moreover, matrix IR frequencies are generally not greatly shifted from gas-phase frequencies, so experimental IR spectra can be expected to be in good agreement with IR spectra predicted theoretically. In recent years, density functional theory (DFT) has been highly successful in predicting the IR spectra of matrix-isolated species and has extended the scope of matrix isolation as a technique for the study of organic photochemistry.[1]

0-8493-1348-1/04/$0.00+$1.50

Although in a handbook of this type, comprehensive coverage of each topic is rarely possible, this chapter endeavors to represent the scope of matrix-isolation studies of the photochemistry of small-ring compounds over an extended period of time. In addition, attempts have been made to give examples of work by most of the research groups that are, or have been, active in the area and to give a sufficient number of key references to facilitate further searches.

15.2 Photochemical Generation of Three-Membered Rings in Matrices

Three-membered ring compounds have been generated photochemically in low-temperature matrices using three general reaction types:

1. Addition of reactive species, such as NH or an oxygen atom, to double or triple bonds, i.e., [1 + 2]-cycloaddition reactions
2. Elimination of small molecules, most commonly N_2, from suitable precursors
3. Photorearrangement, e.g., of carbenes and nitrenes or of compounds with larger rings

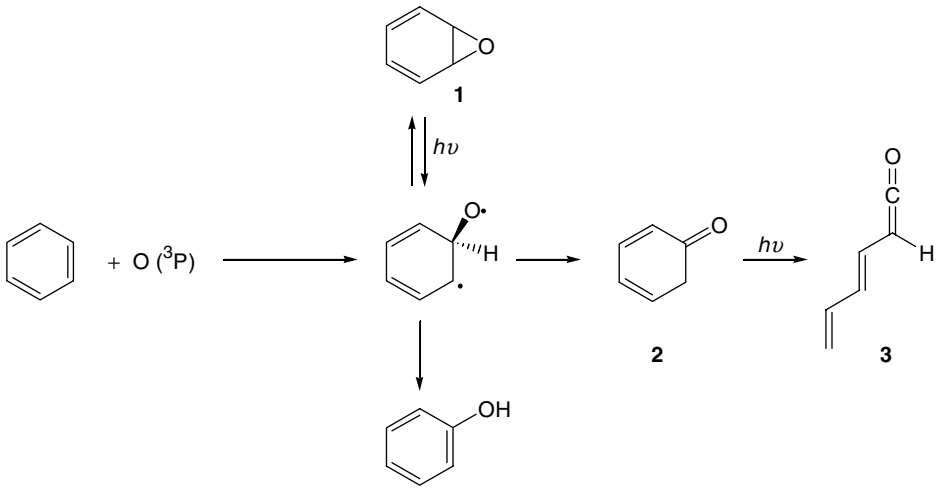
[1 + 2]-Cycloadditions

The reactions of ethene and ethyne with imidogen (NH) from photolysis of HN_3 and of ethyne with methylene (CH_2) from CH_2N_2 were among the first organic systems to be studied by the matrix-isolation technique.[2] The IR spectra for argon matrices at 4 K showed that the [1 + 2]-cycloadduct, aziridine (ethyleneimine), was the main product from NH and ethene, but no other cyclic products were detected. Instead, allene was formed from CH_2 and ethyne, and probably ketenimine from NH and ethyne. It was suggested that at least some of the NH and CH_2, generated initially as singlets, underwent deactivation to the triplet ground states before reaction.

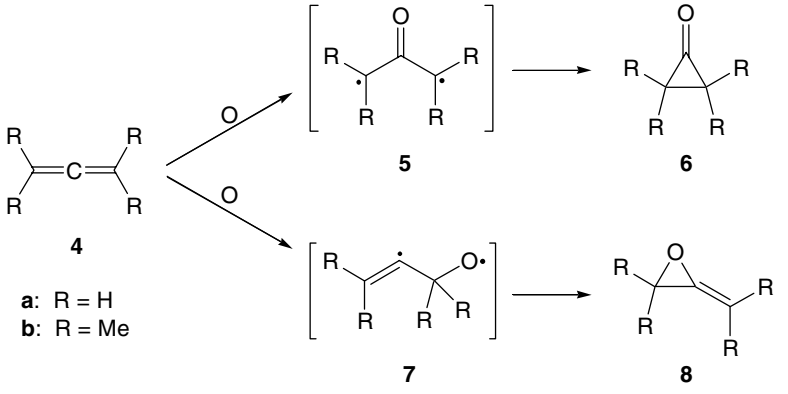
Similar studies have been made of the reactions of various unsaturated compounds with atomic oxygen, generated by the photolysis of ozone in argon matrices. It is generally assumed that the reactions involve ground-state O (^3P) atoms. The primary products from ethene included the [1 + 2]-cycloadduct, oxirane (ethylene oxide), along with acetaldehyde, ketene, and vinyl alcohol.[3] In similar conditions, benzene gave phenol, benzene oxide (**1**) (the [1 + 2]-cycloadduct), cyclohexa-2,4-dienone (**2**), and a ring-opened product, hexa-1,3,5-trienone (**3**).[4] The reaction mechanism shown in Scheme 1 was proposed to account for these observations. In contrast, the alkynes, dimethylacetylene[5] and hexafluorobut-2-yne,[6] did not give the corresponding [1 + 2]-cycloadducts, which would have been oxirenes. (See below for further attempts to generate and characterize these species.)

The photolysis of matrix-isolated complexes of alkenes with NO_2 has provided an alternative method for adding oxygen atoms to alkenes, thus generating oxiranes.

An interesting variation in the addition of oxygen atoms to alkenes in low-temperature matrices has been discovered for allenes. Photoinduced transfer of O atoms to allene (**4a**), either from ozone[7] or in a separate study,[8] from N_2O, gave cyclopropanone (**6a**) and methyleneoxirane (allene oxide) (**8a**) (Scheme 2), along with CO, formaldehyde, acrolein, and ketene. Similarly, tetramethylallene (**4b**), with ozone, gave **6b** and **8b**, together with acetone and dimethylketene.[9] It seemed possible that the initial attack of the O atom could occur either at the central carbon of the allene, to give biradical **5**, leading to a cyclopropane, or at a terminal carbon of the allene, to give an allenoxy biradical **7** and ultimately an allene oxide. Biradicals such as **5** and **7** were not observed directly, however. Moreover, generation of the biradical **5b** in an independent reaction from a pyrazolinone[9] (see below), led to the production of both tetramethylcyclopropanone (**6b**) and the allene oxide **8b**. The latter product could conceivably arise from **5b** by attack of one radical center on the carbonyl oxygen. Some questions still remain, therefore, over the exact mechanism of the addition of O atoms to allenes.

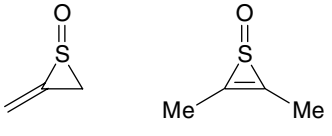


SCHEME 1

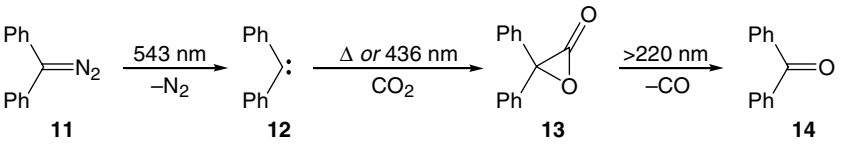


SCHEME 2

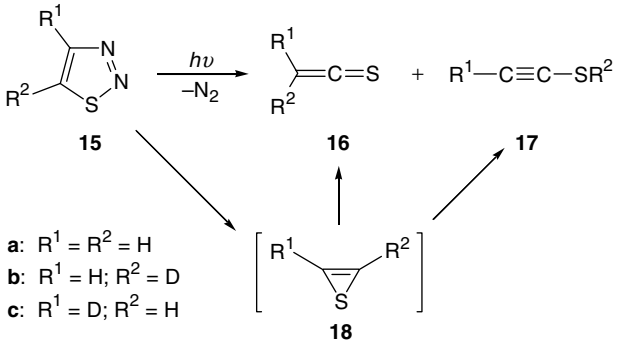
Complexes of sulfur monoxide (SO) with allene and dimethylacetylene in Ar matrices have been irradiated with near-infrared light.[10] Two novel episulfoxides (**9** and **10**, respectively) were the products identified by IR spectroscopy. No such 1 + 2 cycloadducts were detected in earlier studies of triplet reactions of SO; hence, it was concluded that **9** and **10** were formed in reactions of singlet-state SO. Near-infrared light apparently excites the reactant complexes to an electronic energy surface different from that of the ground state, while the long wavelength of the exciting photons ensures that the products, once formed, carry the least possible amount of excess vibrational energy, thus minimizing the chances of ring opening.



9 **10**



SCHEME 3



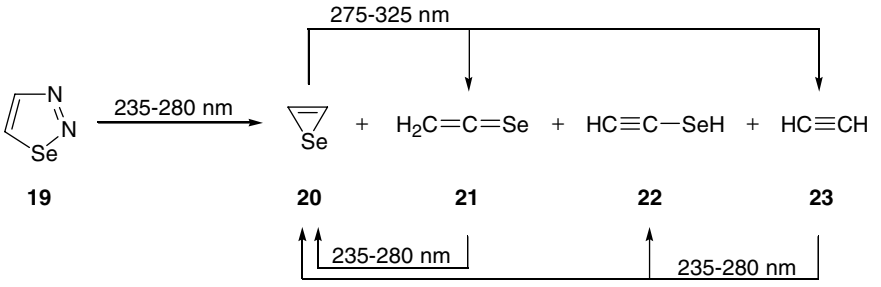
SCHEME 4

Photolysis at 543 nm of diphenyldiazomethane (**11**) in Ar or Xe matrices containing CO_2 resulted in the cycloaddition of the carbene **12** and CO_2, yielding the oxiranone (α-lactone) **13**, which was identified by means of strong ν(C=O) absorptions at 1890 and 1878 cm^{-1} (Scheme 3).[11] The IR assignments were supported by isotopic labeling studies utilizing [1–^{13}C]-**11**, $^{13}C^{16}O_2$, and $^{12}C^{18}O_2$. On further photolysis at wavelengths >220 nm, **13** lost CO to give benzophenone (**14**). Carbene **12** was not carboxylated thermally at 10 K and only slowly at higher temperatures, but irradiation into the long wavelength $\pi \rightarrow \pi^*$ (triplet-triplet) absorption of **12** (λ_{max} = 454 nm) gave **13** in a rapid reaction, even at 10 K. Since the formation of **13** from triplet **12** and CO_2 is formally spin forbidden, this provided evidence that excited triplet carbene **12** reacts like a singlet carbene, a possibility that had first been noted for **12** in alcohols at 77 K.

Photoeliminations

Only a few photoeliminations yielding three-membered ring products have been investigated by matrix-isolation techniques. Nonetheless, one of these — the generation of thiirene and its selenium analogue — was probably one of the most significant contributions made by matrix isolation to the study of organic reactive intermediates.

Photolysis of 1,2,3-thiadiazole (**15a**) in argon or nitrogen matrices gave thioketene (**16a**) and ethynyl mercaptan (**17a**) as the main products (Scheme 4).[12] When the singly labeled deuterium isotopomers **15b** and **15c** were similarly photolyzed, the two isotopomers of ethynyl mercaptan, **17b** and **17c**, were formed in the same ratio from each precursor. Since the isomeric deuterium labeled mercaptans were not interconverted under the matrix photolysis conditions, it was concluded that an intermediate was involved in their formation — probably thiirene (**18b,c**) — in which the deuterium label became scrambled. The same conclusion was reached when ^{13}C labeled isotopomers of **15a** were also photolyzed in matrices.[13] In this second study, a new species was detected that arose on initial photolysis of the thiadiazole at 300 nm and decomposed on further photolysis, with concomitant production of ethynyl mercaptan. It seemed likely that this species was thiirene (**18a**), but an unequivocal identification could not be made on the basis of the few IR bands observed.



19 **20** **21** **22** **23**

SCHEME 5

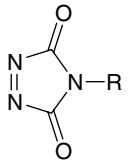
The definitive identification of thiirene was eventually made following careful matrix studies involving a number of isotopically labeled precursors and a range of substituted derivatives.[14–17] From the scrambling of ^{13}C labels, it was shown that the formation of both thioketenes (**16**) and ethynyl mercaptans (**17**) probably involved the same intermediate thiirenes (**18**). This work was carried out before reliable methods for theoretically predicting IR spectra became available, but it provided the IR spectra of a number of thiirenes, which could be analyzed and compared in detail. Convincing identifications of **18a** and some analogues were then possible. It was found that thiirene itself, trifluoromethylthiirene, and benzothiirene were all highly unstable, but ethoxycarbonylmethylthiirene (**18**: $R^1 = CO_2Et$, $R^2 = Me$) appeared to be relatively stabilized by the electron withdrawing substituent and persisted in Xe matrices up to at least 73 K, the softening point of the matrix. A thiirene with two ester groups, bis(methoxycarbonyl)thiirene (**18**: $R^1 = R^2 = CO_2Me$), proved to be even more stable.[18] This species was generated almost quantitatively from the corresponding thiadiazole by irradiation at 254 or 265 nm and was itself photolyzed only slowly and at short wavelength (210 nm). Moreover, the secondary photolysis resulted mainly in extensive fragmentation rather than the formation of bis(methoxycarbonyl)thioketene. A more detailed discussion of the chemistry of thiirene, including matrix-isolation studies, can be found in a 1980 review.[17]

In parallel with the matrix isolation investigations of thiirene, more limited studies of the selenium analogue, selenirene, were also carried out.[13,14] In its details, the matrix photochemistry of 1,2,3-selenadiazole differed significantly from that of 1,2,3-thiadiazole. The various reactions are summarized in Scheme 5. Photolysis of 1,2,3-selenadiazole (**19**) at 235–280 nm in argon at 8 K gave a mixture of products, which were identified by their IR absorptions as selenoketene (**21**), ethynyl selenol (**22**), acetylene (**23**), and a species with an IR spectrum strikingly similar to that of thiirene, which was therefore concluded to be selenirene (**20**). Further photolysis of this mixture at 275–325 nm led to the decomposition of selenirene,while the IR bands of **21** and **22** grew. Thereafter, if irradiation was continued at 235–280 nm, the IR bands of **21** and **23** were reduced in intensity, while those of selenirene (**20**) reappeared and those of **22** were enhanced. It was suggested that the conversion of acetylene back into **20** and **22** could have occurred by reaction of acetylene with photoexcited Se atoms. Following this initial study of selenirene, the analogue, benzoselenirene (**24**), was observed in matrices following 254 nm photolysis of 1,2,3-benzoselenadiazole.[19] On further irradiation, **24** rearranged to fulvene-6-selone (**25**).

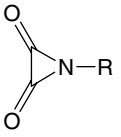
24 **25**

The photolysis at 310 or 335 nm of *N*-substituted 1,2,4-triazoline-3,5-diones **26** (R = Me, Ph) in Ar matrices gave the corresponding isocyanates (RNCO) as the most abundant products, resulting from the elimination of N_2 and CO.[20] Nevertheless, aziridine-2,three-dimensionaliones (**27**: R = Me, Ph) were also detected as minor products. These were identified by their IR absorptions, interpreted with the assistance

of *ab initio* calculations. The aziridinediones **27** were further photolyzed with light of $\lambda \geq 230$ nm to give the isocyanates (RNCO) and CO.

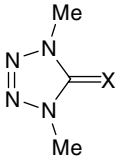


26

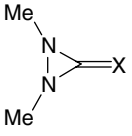


27

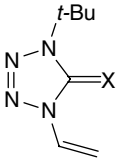
Matrix photolysis of the dimethyltetrazolinone **28** (X = O) gave the diaziridinone **29** (X = O) and methyl isocyanate (MeNCO).[21] The isocyanate was seemingly produced by the elimination of methyl azide (MeN_3) from **28**, in a process that had not been previously observed for the photolysis in solution. The *t*-butylvinyl derivative **30** also gave the corresponding diaziridinone and *t*-butyl isocyanate when photolyzed in matrices, even though in solution the imidazolone **31** was the sole isolable product. In the same study, it was also found that the imino analogue **28** (X = NMe) similarly gave the iminodiaziridine **29** (X = NMe) and the carbodiimide MeN=C=NMe. Analogous thiones, such as **28** (X = S), however, did not give diaziridinethiones, but rather eliminated sulfur atoms to yield the corresponding carbodiimides, e.g., MeN=C=NMe from **28** (X = S).



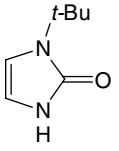
28



29

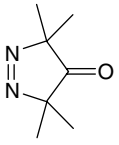


30

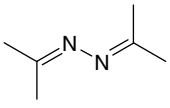


31

Photolysis of the tetramethylpyrazolinone **32** at 193 nm in Ar matrices resulted in high yields of tetramethylcyclopropanone (**6b**) (see Scheme 2) and allene oxide **8b**, the same products observed from the addition of O atoms to tetramethylallene (**4b**).[9] The primary photoproduct was presumably the biradical **5b**, so it seems likely that the allene oxide and the cyclopropanone arose from a common intermediate. In the case of **32**, a minor amount of the ketazine **33** was also formed, a result of the elimination of CO.

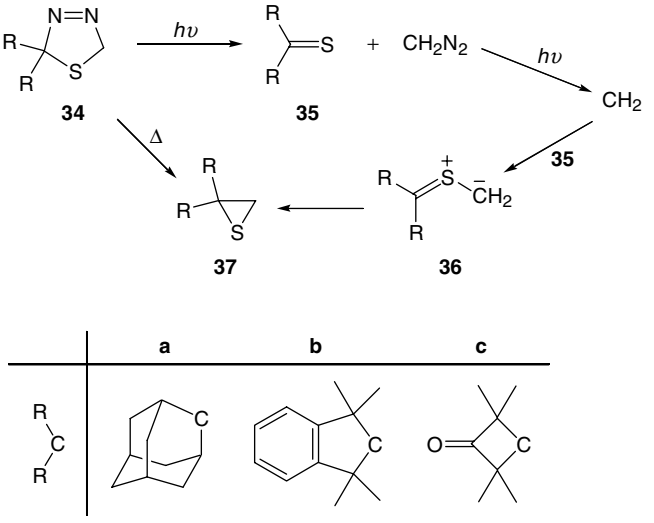


32



33

Although thermolysis of thiadiazolines **34a-c** gave the corresponding thiiranes **37a-c** exclusively, matrix photolysis in an organic glass at 77 K or in argon at 10 K allowed detection of the thiocarbonyl ylides **36a-c** (Scheme 6).[22] Surprisingly, in the photochemical reaction these ylides did not appear to arise directly from the thiadiazolines by elimination of N_2, but instead were formed via initial elimination of diazomethane (CH_2N_2), yielding thioketones **35a-c**. Photolysis of the diazomethane then gave methylene (CH_2), and this carbene reacted with the thioketones to give the thiocarbonyl ylides **36a-c**. Finally, the thiiranes **37a-c** could be produced from the thiocarbonyl ylides by further irradiation at 366 nm.

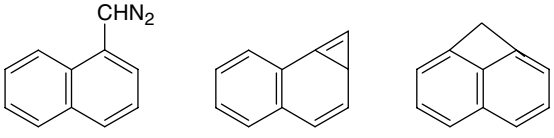


SCHEME 6

For an unusual generation of the CC double bond in a cyclopropenone by double photoelimination of nitrogen from an α,α'-bis diazoketone, see Scheme 12 in Section 15.3. Examples of photoeliminations of CO from a cyclobutanedione (**109**) and a cyclobutenedione (**112**), to afford a cyclopropanone and a cyclopropenone, respectively, are given in Section 15.4. The latter reaction appeared to proceed by a two-step mechanism involving an initial ring opening,

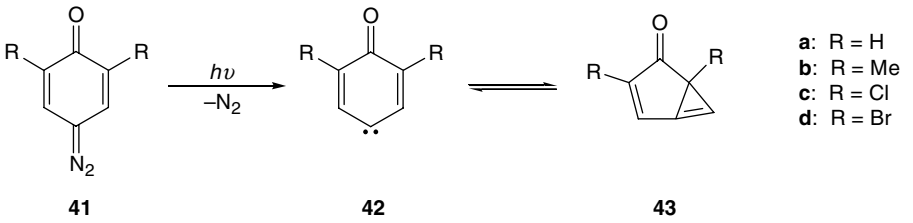
Photorearrangements

Several types of carbenes undergo rearrangements to cyclopropenes when generated photolytically in low-temperature matrices, either immediately or upon further irradiation. Early examples were found when naphthyldiazomethanes were photolyzed at 15 K in argon matrices.[23] For example, 1-naphthyldiazomethane (**38**) produced the cyclopropene derivative, 4,5-benzobicyclo[4.1.0]hepta-2,4,6-triene (**39**), when irradiated with light of $\lambda > 510$ nm (slowly) or $\lambda > 336$ nm (more rapidly), together with a small amount of the cyclobuta[*de*]naphthalene **40**. This behavior contrasted with the flash vacuum thermolysis of **39**, which gave mainly **40**. Both **39** and **40** were presumed to arise by rearrangement of the carbene resulting from the photoelimination of N_2 from **38**, but the carbene itself was not detected in the early studies. In a more recent study, utilizing DFT calculations of IR spectra, the original identifications were confirmed and the triplet carbene identified by IR and UV-visible spectroscopy.[24] It was moreover shown that the carbene and **39** could be interconverted photochemically. The analogous formation of azirines from aryl nitrenes has also been observed in certain cases.



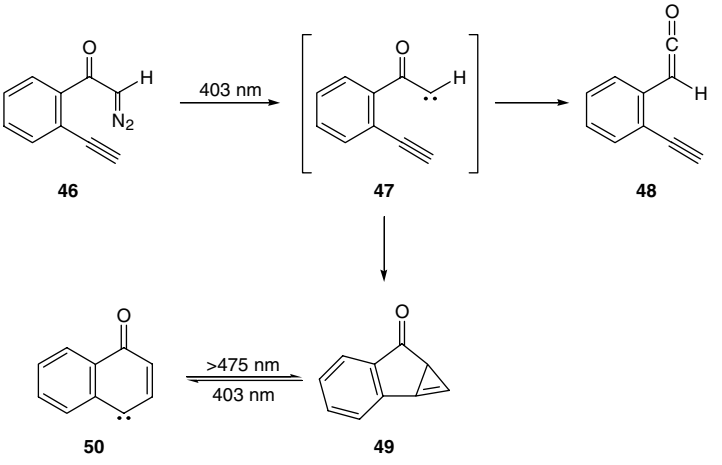
38 **39** **40**

The interconversion of vinylcarbenes and cyclopropenes has been directly observed in the case of the 4-oxocyclohexa-2,5-dienylidenes **42**, several examples of which were generated in Ar matrices by photolyzing the corresponding quinone diazides **41** (Scheme 7).[25] On irradiation into their longest wavelength absorption bands (420–700 nm), the carbenes **42** rearranged to the corresponding bicyclo[3.1.0]hexadienones **43**. This



41 **42** **43**

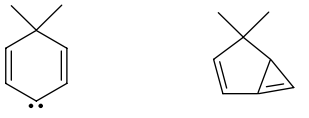
SCHEME 7



46 **47** **48** **50** **49**

SCHEME 8

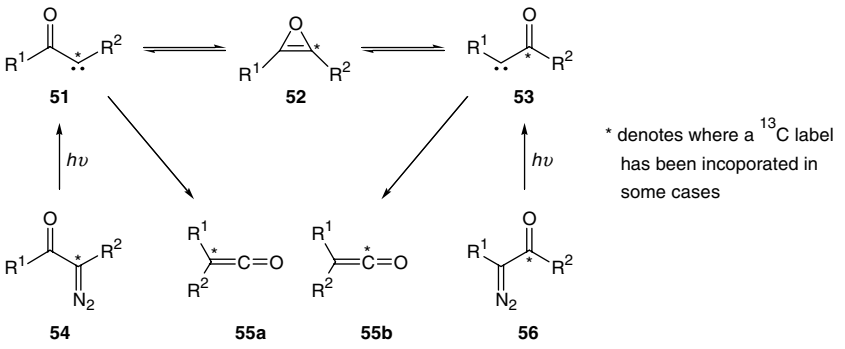
rearrangement could be reversed by IR irradiation or by visible light with $\lambda > 470$ nm. The related carbene **44** rearranged to the bicyclohexadiene **45** when irradiated at $\lambda > 515$ nm in Ar matrices, but in this case the rearrangement was irreversible.[26]



44 **45**

An intriguing alternative entry into this type of cyclohexadienylidene chemistry has been provided by matrix isolation studies of the photolysis of α-diazo-2-ethynylacetophenone (**46**) (Scheme 8).[27] Irradiation of **46** at 403 nm in solid argon gave the ketene **48** as the major product but also the carbene **50** as a minor product. Carbene **50** was reversibly converted into **49** on irradiation at $\lambda > 475$ nm. Thus, the Wolff rearrangement of ketocarbene **47**, which was not observed directly, competed with the intramolecular addition of the carbene center to the triple bond.

One of the main interests in matrix ketocarbene chemistry has been the quest for oxirene (**52**: $R^1 = R^2 = H$) and its derivatives. In principle, an oxirene should lie on the energy surface linking the two α-carbonylcarbenes **51** and **53** (Scheme 9), but whether as an intermediate or as a transition state has been much debated. Photolysis of diazoacetaldehyde (**51**: $R^1 = R^2 = H$) and ethyl diazoacetate (**51**: $R^1 = H$, $R^2 = CO_2Et$) in argon matrices was the first reported attempt to observe oxirenes.[28] Only the corresponding



SCHEME 9

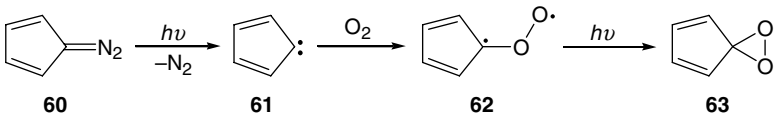
ketenes (**55**) were detected as products, however. Interestingly, the yield of ethoxyketene from ethyl diazoacetate was substantially reduced in methane, ethane, and ethylene matrices. This was taken as evidence that intermolecular reactions of the corresponding α-carbonylcarbene could compete with the intramolecular Wolff rearrangement, a conclusion that has since been drawn for other α-carbonylcarbenes, e.g., **47**.

Evidence for the involvement of oxirenes in the photolysis and thermolysis of α-carbonyldiazo compounds (**54, 56**) was obtained from the fate of isotopic labels, as indicated in Scheme 9.[17] Nevertheless, the goal of detecting an oxirene directly proved elusive. The problem was dealt with in a study of the matrix photolysis of diazoketones, from which it was concluded that oxirenes were, at best, intermediates lying in very shallow energy wells.[29]

Soon after, however, the detection and characterization of bis(trifluoromethyl)oxirene (**52**: $R^1 = R^2 = CF_3$) and perfluoromethylethyloxirene (**52**: $R^1 = CF_3$, $R^2 = CF_3CF_2$) in Ar matrices were reported, following photolysis of the corresponding diazoketones.[30] The species identified as oxirenes could be converted into the corresponding ketenes by irradiation at 360 nm and, in accord with predictions of very low stabilization energies for oxirenes, their spectra decayed substantially when the matrices were warmed to 35 K. In a later investigation of the matrix photolysis of the diazoketones **51** ($R^1 = R^2 = CH_3, CD_3$), the ketenes were always found to be more abundant, but species identified as oxirenes were detected as minor but well-defined products.[31] These were stable at temperatures below 25 K and isomerized to the ketenes when irradiated with light of $\lambda > 230$ nm.

Despite these seemingly reliable reports of oxirenes, doubts have recently been raised that any oxirene has been observed under matrix isolation conditions.[32] Most significantly, the computed IR spectrum of bis(trifluoromethyl)oxirene (**52**: $R^1 = R^2 = CF_3$) differed significantly from the experimental spectrum previously assigned to this species. Extraordinarily accurate agreements between experimental matrix IR spectra and those computed by modern theoretical methods are now routinely achieved. In view of this, a significant discrepancy has to be taken seriously. Therefore, the existence of oxirenes as reaction intermediates, which can be trapped in matrices, is still open to question.

The vinylcarbene–cyclopropene rearrangement, leading to cyclopropenes such as **39** and **43**, can be regarded formally as an addition of the carbene center across a flanking double bond. In contrast, (3-thienyl)methylene **57** (X = S) did not yield an analogous bicyclic compound, such as **58** (X = S), as the main product when generated in matrices, but underwent a more deep-seated rearrangement to give the methylenecyclopropene **59** (X = S).[33] It was plausibly suggested that **59** (X = S) arose by secondary rearrangement of **58** (X = S) and, indeed, a few weak IR absorptions in the matrix product spectra could be tentatively assigned to the latter species. Similarly, (3-furyl)methylene (**57**: X = O) gave α-formylmethylenecyclopropene (**59**: X = O); but no cyclopropene product was detected from the isomeric (2-furyl)methylene.[34]



60 **61** **62** **63**

SCHEME 10

57 **58** **59**

Although carbene rearrangements form the most numerous class of photorearrangements leading to three-membered rings, some other reaction types have been reported. The transformation of carbonyl oxides into dioxiranes is an example. This was first established for the photolysis of diazocyclopentadiene (**60**) in N_2 or Ar matrices doped with O_2 (Scheme 10).[35,36] Carbene **61** reacted readily with O_2 to give initially the carbonyl oxide **62**, which on subsequent irradiation with light of $\lambda > 420$ nm isomerized to the dioxirane **63**. The reaction with $^{16}O^{18}O$ demonstrated, from splittings in the IR spectra, that the two oxygen atoms were nonequivalent in **62** and equivalent in **63**. Subsequently, it has been discovered that this is a quite general reaction of carbenes.[37]

Matrix IR spectra of bicyclo[2.1.0]pent-2-ene (**64**: X = CH_2) and the heterocyclic analogues, Dewar furan (**64**: X = O) and Dewar thiophene (**64**: X = S), were obtained after UV-irradiation of cyclopentadiene, furan, and thiophene, respectively, in Ar matrices.[38] All three spectra contained a strong absorption in the region 700–800 cm^{-1}. Identifications on the basis of the matrix IR spectra alone would probably have remained somewhat tentative, but in the cases of cyclopentadiene and thiophene, the matrix products were distilled off the cold window at the end of the experiments, and ^1H NMR spectra were obtained. Dewar furan and Dewar thiophene were both produced along with other products, but **64** (X = CH_2) appeared to be the sole product of the matrix photolysis of cyclopentadiene. On further photolysis, Dewar furan gave cyclopropene-3-carboxaldehyde (**65**), whereas Dewar thiophene and the bicyclopentene **64** (X = CH_2) reverted to thiophene and cyclopentadiene, respectively.

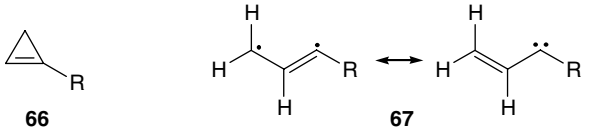
64 **65**

15.3 Matrix Photolysis of Three-Membered Ring Compounds

Cyclopropane, Cyclopropene, and Derivatives

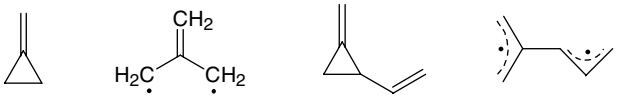
Cyclopropane does not absorb in the UV-visible region of the spectrum, but it has been discovered that cyclopropane isolated in a xenon matrix doped with a halogen, such as bromine, undergoes ring opening when irradiated at 254 or 270 nm.[39] The products have been identified by IR spectroscopy. At 254 nm, the main products were propene and the allyl radical, with allene, propyne, and small amounts of ethyne and methane appearing at high conversion. At 270 nm, however, propene was produced exclusively. It was suggested that the ring opening occurred in the vibrationally excited electronic ground state of cyclopropane, by energy transfer from Xe-halogen exciplexes.

In much the same way, triplet but-2-ene-1,3-diyl (**67**: R = Me) was generated on UV-irradiation of 1-methylcyclopropene (**66**: R = Me) in bromine-doped Xe matrices and was characterized by IR spectroscopy.[40] Under similar conditions, cyclopropene seemed to yield propene-1,3-diyl (**67**: R = H), although the interpretation of the spectral data was less certain in this case. Theoretical calculations accorded with the experiments in predicting that formation of the diyls is the lowest energy ground-state pathway for ring opening of each of the cyclopropenes.



66 **67**

The IR spectrum of the non-Kekulé hydrocarbon trimethylenemethane (**69**) was observed for the first time when methylenecyclopropane (**68**) was irradiated with a low-pressure Hg arc (254 nm) in solid Xe doped with Cl_2, Br_2, or I_2.[41] The conversion of **68** into **69** was even more efficient when carried out in Xe matrices doped with bromine or iodine *atoms*, prepared by heating Br_2 or I_2 with Xe at 750°C, followed by the simultaneous condensation of the pyrolysate and a gaseous mixture of **68** and Xe at 10 K. Previous attempts to generate **69** from several alternative precursors had produced only enough to allow detection by electron paramagnetic resonance (EPR) spectroscopy. Under similar conditions, 1-methylene-2-vinylcyclopropane (**70**) afforded 4-methylene-2-pentene-1,5-diyl (**71**).[42] The results for bicyclopropylidene (**72**), however, were considerably more complicated.[43] Irradiation of **72** in Xe matrices doped with Br_2 at 313 nm led to the formation of 1,2-dimethylenecyclobutane (**76**) almost exclusively, with a small amount of methylenespiropentane (**74**). The initial photolysis product was probably the biradical **73**, but this species was not detected spectroscopically. Likewise, there was no indication of the presence of tetramethyleneethane (**75**), although this was likely to be an intermediate in the pathway leading to **76**. On further irradiation at 254 nm, 3-methylenecyclopentene (**78**) was formed. The rationalization of these experimental observations is summarized in Scheme 11.



68 **69** **70** **71**

The photoextrusion of CO from cyclopropenones provides a convenient route to strained cycloalkynes. This approach seems to have been first exploited in low-temperature matrices in the formation of acenaphthyne (**83**) from cyclopropenone **82**, which was itself generated photolytically from the bisdiazoketone **81** by elimination of two nitrogen molecules (Scheme 12).[44] The ν(C≡C) IR bands of cycloalkynes are expected to be of low intensity, but a weak band at 1930 cm^{-1} was observed in the matrix IR spectrum of **83** and this was tentatively assigned to the C≡C stretch. The frequency is considerably lower than that for most normal disubstituted alkynes (2250–2200 cm^{-1}),[45] presumably as a result of the strain imposed by the distortion of the C–C≡C–C system from the ideal linear geometry. A number of other cycloalkynes have since been generated in matrices by photoelimination of CO from cyclopropenones. Examples are cycloheptyne [ν(C≡C) 2121 cm^{-1}] and the tetramethylcyclohexyne **84** [ν(C≡C) 2107 and 2116 cm^{-1}].[46] It is noteworthy that the ν(C≡C) frequencies reported for the six- and seven-membered ring cycloalkynes are appreciably higher than that for the more strained five-membered ring cycloalkyne **83**, but still lower than for unstrained alkynes. Note also that without the distortion of the C–C≡C–C moiety from linearity in cycloalkynes such as **83** and **84**, the ν(C≡C) vibration would be infrared inactive; the bent structure ensures that there is a small change of dipole moment during the vibration, *perpendicular* to the C≡C bond.

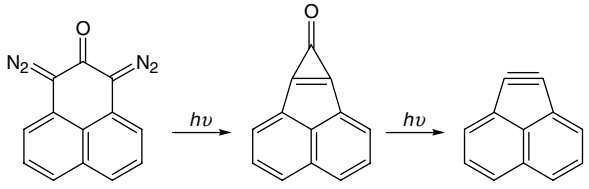
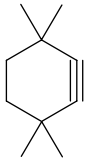
SCHEME 11



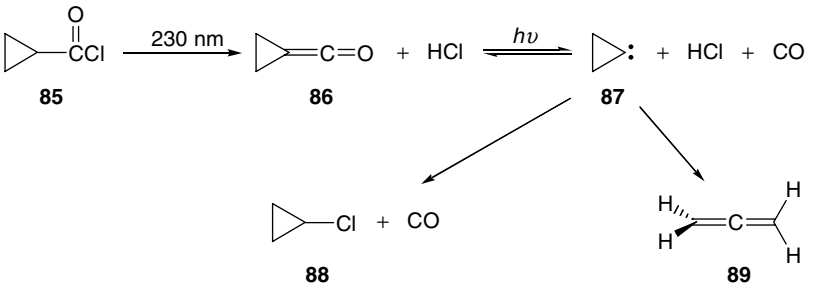
81 **82** **83**

SCHEME 12



84

The carbene cyclopropylidene (**87**) has been generated in Ar matrices by the route shown in Scheme 13.[47] UV-irradiation ($\lambda \geq 230$ nm) of the acid chloride **85** resulted first in the elimination of HCl, yielding ketene **86**, which then underwent reversible photoelimination of CO. The ultimate products of this process were identified by IR spectroscopy as chlorocyclopropane (**88**) and allene (**89**), but an intermediate in their formation was also detected. This intermediate was identified as cyclopropylidene (**87**), primarily on the basis of its further reactions to give **88** and **89**.

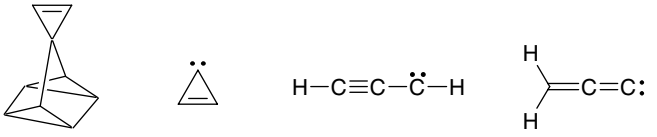


85 **86** **87** **88** **89**

SCHEME 13

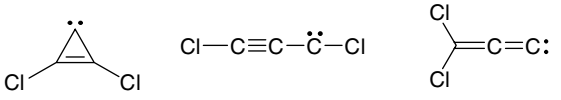
Cyclopropenylidenes and Related Species

One of the advantages of the matrix-isolation technique is that it affords opportunities to study photochemical reactions not only of stable compounds but also of highly reactive species. A good example is provided by the carbene, cyclopropenylidene (**91**), which was first trapped in Ar matrices, together with benzene, following gas-phase pyrolysis of the quadricyclane **90**.[48] Four IR bands of the carbene were observed, and these were in good agreement in both frequency and intensity with the computed IR transitions of **91**. When matrices containing carbene **91** were irradiated at >360 nm, only these four IR bands disappeared, while the IR bands of propynylidene (**92**) arose. Later, it was found that both propynylidene (**92**) and its isomer, vinylidenecarbene (**93**), were produced in the photorearrangement of **91**, with **93** arising from **92** in a secondary photolysis step.[49] By changing the wavelength, the back reaction of **93** to **92** could be induced.



90 **91** **92** **93**

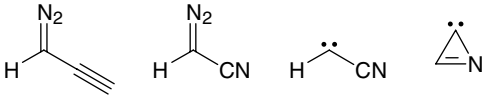
Mono- and dichlorocyclopropenylidene have been generated by flash pyrolysis of di- and trichlorocyclopropenes and trapped in argon matrices.[50] As with the parent carbene **91**, subsequent photolysis (254 nm) of the carbenes, e.g., **94**, led to the formation of the corresponding propynylidenes, e.g., **95**, and the isomeric vinylidenecarbenes, e.g., **96**. The photochemical back reaction (**95**, **96** → **94**) could be induced by changing the irradiation wavelength to 280–310 nm.



94 **95** **96**

In a later study utilizing ^{13}C labeling, the mixture of C_3H_2 isomers was accessed via the direct generation of propynylidene (**92**) by photolysis of the corresponding diazo precursor, diazopropyne (**97**).[51] Three ^{13}C-isotopomers of **97**, with each carbon singly labeled, were photolyzed in argon matrices at 8 K, and the experimental investigations were accompanied by theoretical computations of the geometries, energies, and IR transitions of the various species of interest. The products identified by IR spectroscopy included triplet propynylidene (**92**), singlet vinylidenecarbene (**93**), and singlet cyclopropenylidene (**91**). At 313 nm, **91** and **92** photoequilibrated, but the process did not seem to occur by a simple ring-closure or ring-opening mechanism because hydrogen migration accompanied the interconversion. At $\lambda > 444$ nm, isotopomers of **93**, $H_2C{=}C{=}{}^{13}C$: and $H_2C{=}{}^{13}C{=}C$: rapidly equilibrated; it was suggested, on

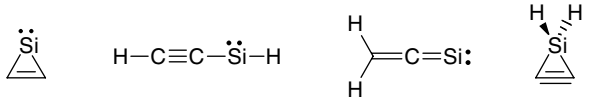
the basis of the parallel theoretical studies, that this equilibration could involve a cyclopropyne transition state.



97 **98** **99** **100**

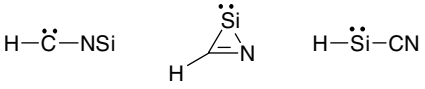
Azacyclopropenylidene (**100**), as well as cyanocarbene **99** and its isocyano isomer, were produced when diazoacetonitrile (**98**) was photolyzed in matrices.[52] Ring opening of **100** to regenerate **99** occurred on irradiation with light of $\lambda > 345$ nm.

Matrix isolated 1-silacyclopropenylidene (**101**) was generated by pulsed flash pyrolysis of 2-ethynyl-1,1,1-trimethyldisilane ($HC{\equiv}CSiH_2SiMe_3$).[53] Upon 254 nm photolysis, **101** first isomerized to ethynylsilanediyl (**102**) and then, on more prolonged irradiation, to vinylidenesilanediyl (**103**) and silacyclopropyne (**104**). Identifications were made by comparison of experimental and calculated IR spectra and the employment of ^{13}C labeling. On irradiation with longer wavelength light ($\lambda > 395$ nm), silacyclopropyne (**104**) regenerated **101**. Calculations suggested that the bonding in silacyclopropyne is unusual, having one electron pair in a CC nonbonding orbital. This molecule was an unexpected product because the all-carbon analogue cyclopropyne is unstable. A subsequent high-level theoretical study confirmed the identification of **104** and also indicated that this molecule has a relatively high energy barrier to isomerization, whereas cyclopropyne corresponds to a high-lying saddle point on the C_3H_2 potential energy surface.[54]



101 **102** **103** **104**

Silacyclopropylidene **101** has also been generated by evaporation of silicon atoms and co-condensation of these with acetylene and an excess of argon.[55] Similar reaction of Si atoms with hydrogen cyanide gave a mixture of CHNSi and CNSi isomers.[56] The product IR spectra, in comparison with computations, showed that the initial species formed was (silaisocyano)carbene (**105**). This rearranged to 2-aza-1-silacyclopropenylidene (**106**) and a small amount of cyanosilylene (**107**), when irradiated with light of $\lambda > 700$ nm.



105 **106** **107**

15.4 Matrix Photochemistry of Four-Membered Ring Compounds

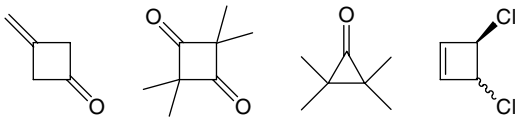
Cyclobutanes, Cyclobutenes, and Derivatives

As in the case of cyclopropane (see Section 15.3), cyclobutane does not absorb at wavelengths in the normally accessible UV region of the spectrum and is photostable in argon matrices. Nevertheless, cyclobutane was found to undergo photoinduced reactions in bromine-doped xenon matrices when irradiated with a low-pressure Hg arc (254 nm) and even in undoped xenon, provided a KrF laser (248 nm) was used.[57] The main products were found to be but-1-ene and ethene, although in the doped

matrices, 1-methylallyl radical was also detected. In these reactions, the energy of irradiation was absorbed by the matrix host material and transferred to the cyclobutane molecules.

When cyclobutanone was photolyzed in Ar, CO, and N_2 matrices with UV or vacuum-UV light, photodecomposition occurred by at least two and possibly three primary processes.[58] Photolysis with the 302 nm Hg line produced only CO and cyclopropane, while photolysis with the full Hg arc, with major lines at 302, 297, 289, and 280 nm, gave ketene and propene as IR detectable products, as well. It was concluded that the processes operating were (1) *c*-$C_3H_6CO \rightarrow$ *c*-C_3H_6 + CO, (2) *c*-$C_3H_6CO \rightarrow C_2H_4$ + CH_2=C=O, and possibly (3) *c*-$C_3H_6CO \rightarrow CH_3CH{=}CH_2$ + CO. Additional secondary photolysis products were detected when the matrices were irradiated in the vacuum-UV.

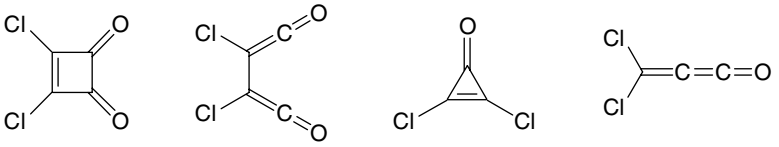
3-Methylenecyclobutanone (**108**) gave a small yield of trimethylenemethane (**69**) when irradiated at 300 nm in argon at 10 K, but a more efficient source of **69** was later found in the photolysis of methylenecyclopropane (**68**) in halogen-doped xenon matrices (see Section 15.3).[41] As also noted earlier in this chapter, 1,2-dimethylenecyclobutane (**76**) was amongst the products observed in the matrix photolysis of bicyclopropylidene (**72**). When incorporated into matrices independently, **76** afforded an alternative entry into the photoprocesses summarized in Scheme 11 and gave both tetramethyleneethane (**75**) and 3-methylenecyclopentene (**78**) when irradiated at 248 nm.[43] When **76** rather than **72** was employed as the starting material, tetramethyleneethane (**75**) could be detected directly in the IR spectrum, although only through a single absorption near 790 cm^{-1}.



108 **109** **110** **111**

The photolysis of tetramethylcyclobutane-1,3-dione (**109**) was followed by IR spectroscopy in N_2 matrices at 4 K in one of the earliest matrix isolation studies of an organic photochemical reaction.[59,60] The products identified included tetramethylcyclopropanone (**110**), from elimination of CO, and dimethylketene, from [2 + 2]-cycloreversion.

The stereochemistry of the thermally and photochemically induced ring opening of *cis*- and *trans*-3,4-dichlorocyclobutene (**111**) has been studied using matrix isolation.[61] Dichlorocyclobutenedione (**112**) also underwent ring opening when irradiated in matrices with light of $\lambda > 335$ nm, giving the dichlorobisketene **113** as the primary photoproduct.[62] On further photolysis, **113** eliminated CO and gave dichlorocyclopropenone (**114**) and dichloropropadienone (**115**) in a ratio of 93:7, probably via a common intermediate carbene. Both **114** and **115** finally gave dichloroacetylene when irradiated with light of $\lambda > 230$ nm.

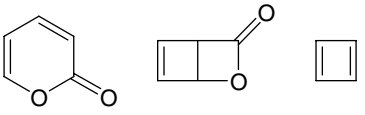


112 **113** **114** **115**

Cyclobutadiene

Cyclobutadiene (**118**) has been the subject of numerous matrix isolation investigations over a long period. It was first generated in matrices from α-pyrone (**116**), which gave β-lactone **117** on photolysis, from which CO_2 was subsequently eliminated to yield cyclobutadiene.[63,64] At first, an insufficient number of IR bands of **118** were observed to settle the question of whether the molecule has a square or rectangular geometry, but eventually a fuller spectrum was obtained, which contained too many bands to be consistent

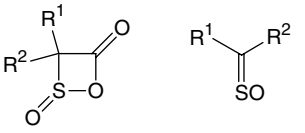
with a square structure.[65] The history of matrix isolation studies of cyclobutadiene is presented in more detail in another chapter, and a 1980 review of cyclobutadiene chemistry gives a very full account of the literature up to that time.[66]



116 **117** **118**

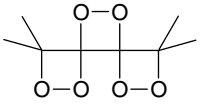
Heterocyclic Four-Membered Rings

In Ar or N_2 matrices containing SO_2, ketene underwent a [2 + 2]-cycloaddition reaction when irradiated with Pyrex-filtered light from a medium-pressure Hg arc ($\lambda > 300$ nm), affording 1,2-oxathietan-4-one 2-oxide (**119**: $R^1 = R^2 = H$).[67,68] On further irradiation with an unfiltered arc lamp ($\lambda > 200$ nm), **119** underwent a retrocycloaddition in the opposite sense, to give CO_2 and, presumably, the sulfine **120** ($R^1 = R^2 = H$). The latter, however, was not detected directly, but decomposed to formaldehyde (CH_2O) and sulfur atoms, which were evident from an intense blue chemiluminescence when the matrix was warmed at the end of each experiment. The retrocycloaddition of **119** was taken as reasonable evidence for the regiochemistry of the addition of SO_2 to ketene, but this work was carried out before the era of reliable computations of IR transitions, which might have settled the question more satisfactorily. Exactly similar reactions were observed for other ketenes ($R^1 = Me$, $R^2 = H$; $R^1 = Ph$, $R^2 = Et$; and $R^1 = R^2 = Ph$).[68]



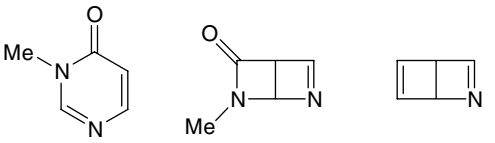
119 **120**

The trisdioxetane (**121**) was an observed product of the addition of dioxygen to 2,5-dimethylhexa-2,3,4-triene ($Me_2C{=}C{=}C{=}CMe_2$), when the latter compound was irradiated with visible light in Ar matrices containing O_2.[69] At O_2 concentrations between 10 and 100%, the trisdioxetane was almost the sole product. It decomposed on further irradiation to acetone and CO_2. Identification of **121** from its matrix IR spectrum was aided by the use of oxygen isotopes.



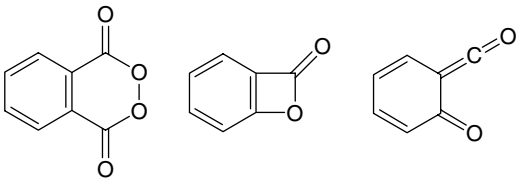
121

The Dewar isomer, **123**, of 3-methyl-4(3*H*)-pyrimidinone (**122**) was generated in argon matrices by 308 nm irradiation of the parent molecule and identified by comparison of the experimental matrix IR spectrum with spectra computed for **123** and other possible products.[70] For several 4(3*H*)-pyrimidinones not methylated at N3, two other types of matrix photoreactions were observed in addition to the isomerization to the Dewar isomer: phototautomerism and ring opening. Somewhat later, matrix isolated Dewar pyridine (**124**) was produced by UV-irradiation of pyridine in solid argon and was identified with the aid of DFT computations.[71] On further photolysis, **124** produced cyclobutadiene (**118**) and HCN.



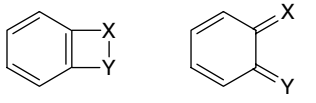
122 **123** **124**

Photolysis of phthaloyl peroxide (**125**) in argon at 8 K resulted in the elimination of CO_2 and produced a mixture of benzpropiolactone (**126**) and the *o*-quinoid ketoketene **127**.[72] The two product species could be interconverted photochemically, with long-wavelength light ($\lambda > 340$ nm) favoring **126** and shorter wavelengths ($\lambda > 310$ nm) favoring **127**. Subsequently, there have been periodic attempts to generate benzannelated four-membered ring compounds (**128**), which could be interconverted with their *o*-quinoid isomers (**129**), particularly if the latter could be generated easily, thus providing convenient routes to the four-membered ring compounds.

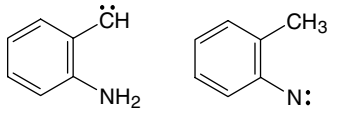


125 **126** **127**

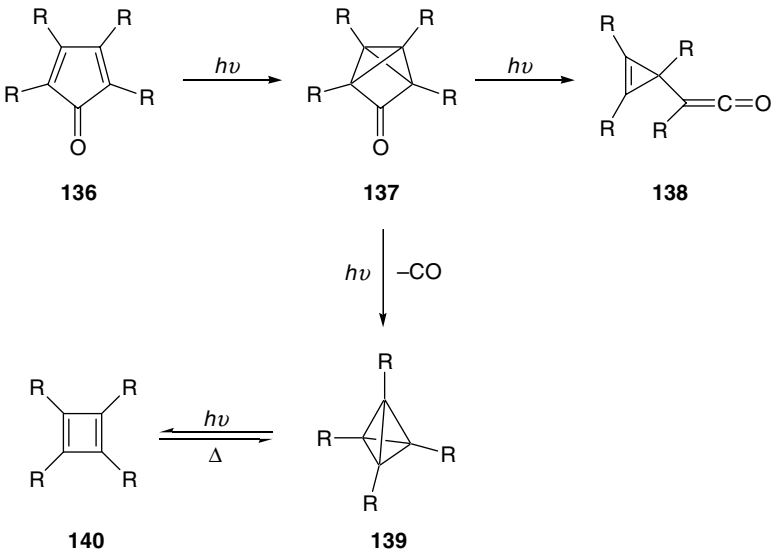
A fruitful approach has been to generate phenylcarbenes or -nitrenes with suitable *ortho* substituents, from which a hydrogen atom can be transferred intramolecularly. For example, 6-methylene-2,4-cyclohexadien-1-imine (**129**: X = CH_2, Y = NH) was generated in low-temperature matrices by intramolecular H-transfer in either (2-aminophenyl)carbene (**130**) or 2-tolylnitrene (**131**), following flash vacuum pyrolysis or matrix photolysis of the corresponding diazo and azido precursors, respectively.[73] The imine **129** (X = CH_2, Y = NH) was converted into benzoazetine (**128**: X = CH_2, Y = NH) when irradiated with light of $\lambda > 385$ nm, and the reverse, ring-opening reaction occurred at shorter wavelengths ($\lambda > 280$ nm). Similarly, benzoxete (benzoxetene) (**128**: X = CH_2, Y = O) and its photointerconversion with *o*-quinone methide (**129**: X = CH_2, Y = O) have been observed in Ar matrices, following photoelimination of CO from benzofuran-2-one (isophthalide) (**132**) or the generation of (2-hydroxyphenyl)carbene (**133**) from 2-(diazomethyl)phenol.[74] It has subsequently been shown that the methyl groups in 4,6-dimethylbenzoxete (**134**) stabilize this molecule to the extent that it could be observed to persist when warmed to room temperature in the solid state.[75]



128 **129**

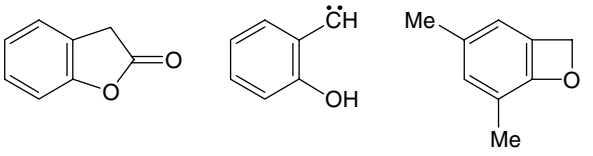


130 **131**



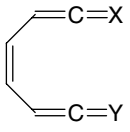
136 **137** **138** **140** **139**

SCHEME 14



132 **133** **134**

At the present time, it seems that ring closure of *o*-quinoids (**129**) can be achieved only when one of the terminal groups (X or Y) is a CH_2 group.[76] Thus, neither *o*-benzoquinone imine (**129**: X = NH, Y = O) nor *o*-benzoquinone diimine (**129**: X = Y = NH) forms the corresponding ring closed compounds (**128**) when photolyzed in matrices; instead, they undergo ring opening to compounds of structure **135**.



135

15.5 Tetrahedrane Derivatives and Related Compounds

The quest for tetrahedrane and its derivatives forms a fascinating chapter in the history of organic chemistry in which matrix isolation played a crucial part, at least in the initial stages. In spite of discouraging theoretical predictions of the instability of tetrahedranes and earlier failures, an example of a tetrahedrane was eventually generated photochemically in low-temperature matrices.[77,78] Photolysis of tetra-*t*-butylcyclopentadienone (**136**: R = *t*-Bu) in solid argon gave exclusively the criss-cross adduct **137** (R = *t*-Bu) (Scheme 14). On further photolysis, the criss-cross adduct rearranged to the cyclopropenylketene **138** (R = *t*-Bu) or lost a molecule of CO to give tetra-*t*-butyltetrahedrane **139** (R = *t*-Bu).

Matrix IR spectra would not have been sufficient to identify the tetrahedrane, but fortunately and perhaps surprisingly, the same photochemistry could be carried out in frozen solvents at 77 K and in liquid solutions up to room temperature, so the processes could also be monitored by ^{1}H and ^{13}C NMR spectroscopy. Even more surprisingly, it was found that tetra-*t*-butyltetrahedrane could be isolated from the solution product mixture by chromatography and was stable up to about +135°C. At this temperature, it was isomerized to tetra-*t*-butylcyclobutadiene (**140**: R = *t*-Bu), UV-irradiation of which, in Ar at 10 K or in solution at room temperature, regenerated **139** (R = *t*-Bu).

The possibility of isolating tetra-*t*-butyltetrahedrane as a stable compound allowed its full characterization by ^{1}H and ^{13}C NMR, IR, Raman, and photoelectron spectroscopy, by mass-spectrometry,[79–82] and ultimately by means of an x-ray crystal structure.[83] Nevertheless, related attempts to directly observe other tetrahedranes with smaller or fewer substituents, e.g., dimethyltetrahedrane,[84] tetramethyltetrahedrane,[85–87] bis(trimethylsilyl)tetrahedrane,[88] and tetrahedrane itself,[89,90] were uniformly unsuccessful. With bulky substituents, however, as in the case of the recently reported tetrakis(trimethylsilyl)tetrahedrane (**139**: R = $SiMe_3$),[91] tetrahedrane derivatives seem stable enough to be studied without the need for low-temperature matrix isolation techniques. This is not to say that such chemistry is easy. The photoisomerization of tetrakis(trimethylsilyl)cyclobutadiene (**140**: R = $SiMe_3$) to the corresponding tetrahedrane was achieved only after many unsuccessful experiments, with variations of wavelength, temperature, and solvent. Nearly all attempts led to fragmentation of the cyclobutadiene into two molecules of bis(trimethylsilyl)acetylene, but one set of conditions — prolonged 254 nm irradiation in deuteriated methylcyclohexane at −130°C — eventually afforded the desired tetrahedrane.

Two recent theoretical studies, one of the C_4H_4 isomers[92] and the other of tetramethyl- and tetra-*t*-butyl-substituted cyclobutadiene and tetrahedrane,[93] give further insights into the stabilities of tetrahedrane derivatives.

Photochemical Isomerization of Cycloalkenes

Tadashi Mori
Osaka University

Yoshihisa Inoue
Osaka University and ICORP/JST

16.1 Introduction

A number of reviews have been devoted to the photoisomerism of alkenes,[1–4] with the photochemistry of cycloalkenes treated as a subcategory.[5–10] The geometrical photoisomerization of alkenes was reviewed also in the previous edition.[11] However, the photobehavior of cycloalkenes is not a simple extension of that of acyclic alkenes, particularly in the cases of small- and medium-sized cycloalkenes. Medium-sized (*E*)-cycloalkenes produced photochemically are highly constrained and rapidly react with alcohols in the presence, or even in the absence, of dilute acid. An account of the photoprotonation-driven cationic reactions, such as addition, isomerization, rearrangement, and fragmentation of cyclohexenes and cycloheptenes, in protic solvents has been published.[12] The protonation of strained (*E*)-cycloalkenes was also reviewed in the previous edition.[13]

In this review, we will concentrate on the *E-Z*-photoisomerization and subsequent (photo)chemical transformations of cycloalkenes caused by direct and sensitized excitation. Valence isomerization, rearrangement, and fragmentation, observed upon irradiation of cyclopropene, cyclobutene, and cyclopentene, are only briefly described, as they have been extensively reviewed elsewhere.[3,4,8,9] Although the photochemistry of acyclic alkenes will not be included in this chapter, we will refer to the photobehavior of conjugated cycloalkenes, such as cyclic dienes, enones, and styrenes, as far as it relates to the cycloalkene functionality. As the photochemical formation of labile (*E*)-cycloalkenes is one of the major topics in this chapter, the physical properties of the (*E*)-isomers will be tabulated and discussed in detail. Recent studies on enantiodifferentiating photoisomerization of cycloalkenes are summarized in one section in view of the rapidly growing interest in asymmetric photochemistry.[14]

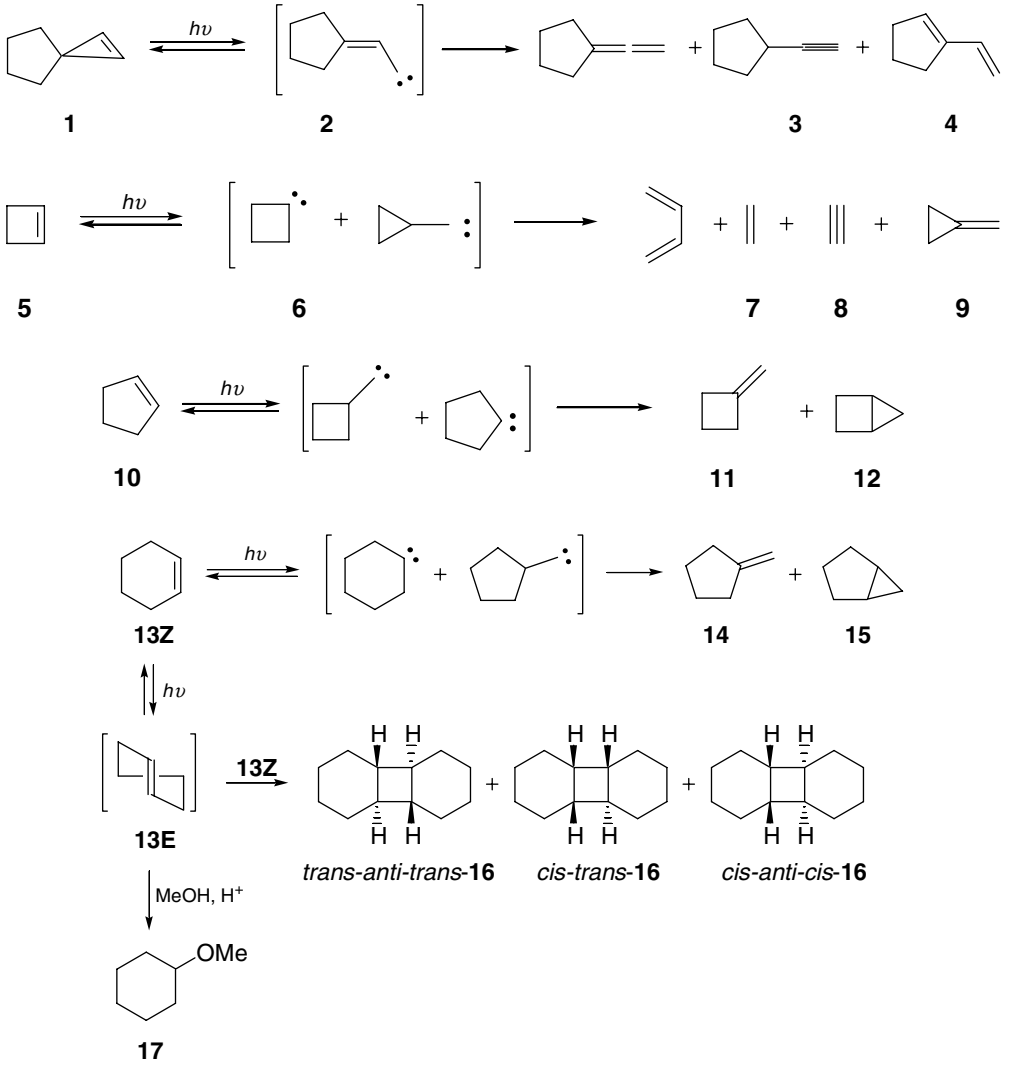
16.2 Simple Cycloalkenes

Direct Irradiation

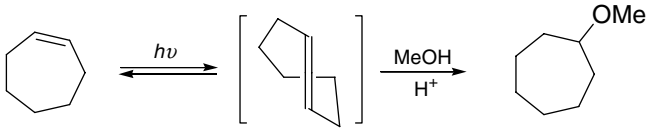
In direct photolysis of cycloalkenes, rearrangement and decomposition are the major reactions observed. Spiro-substituted cyclopropene (**1**) undergoes rearrangement upon direct irradiation to afford allene (**2**), acetylene (**3**), and vinylcyclopentene (**4**).[15,16] Cyclobutene (**5**) gives a ring-opening product, 1,3-butadiene (**6**), as the major product, and decomposition products, ethylene (**7**) and acetylene (**8**), together with rearranged methylenecyclopropane (**9**).[17–20] Cyclopentene (**10**) and cyclohexene (**13Z**) give the ring-contracted rearrangement products, i.e. methylenecyclobutene (**11**) plus bicyclo[2.1.0]pentane (**12**) from **10** and methylenecyclopentane (**14**) plus bicyclo[3.1.0]hexane (**15**) from **13Z**.[21,22] Most of the products are considered to be derived from the carbene intermediates.[3,4,8,9]



As is the case with acyclic alkenes, cycloalkenes undergo geometrical isomerization upon direct excitation. Thus, irradiation at ~200 nm of cyclohexene (**13Z**) in aprotic media affords a stereoisomeric mixture of [2 + 2]-cyclodimers (**16**), in 1.6:2.3:1 ratio.[23] This photocyclodimerization is interpreted in

terms of a successive photo/thermochemical process, which involves the initial photo-induced *Z*-to-*E* isomerization of **13Z** and the subsequent ground-state cycloaddition of photo produced **13E** to **13Z**.[23] Highly strained **13E** can be trapped by acidic methanol to give adduct **17**.

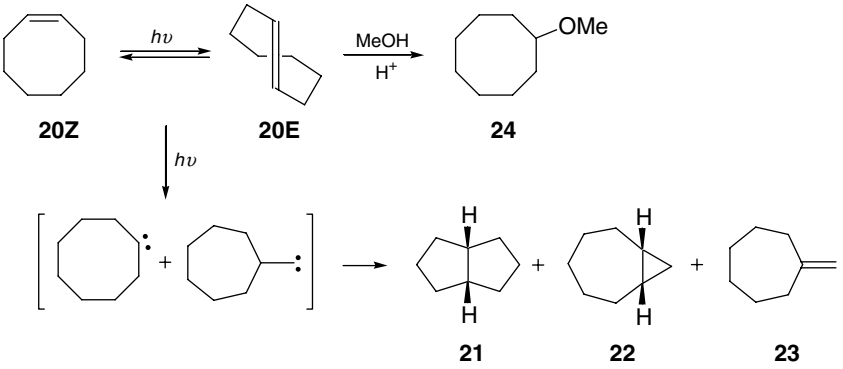
The photobehavior of cyclohexene (**13Z**), cycloheptene (**18Z**), and cyclooctene (**20Z**), upon direct irradiation at 185 nm, was studied comparatively in vapor and liquid phases.[24] In the vapor phase, direct excitation leads to decomposition and rearrangement reactions, affording those products that are obtained upon pyrolysis of each cycloalkene. This coincidence indicates that the excited singlet π,π^* state produced suffers rapid internal conversion to give hot (vibrationally excited) ground-state molecules, which in turn undergo thermal decomposition and rearrangement in the absence of effective collisional deactivations in the vapor phase.[13,24] In solution, the formation of these pyrolysis products is completely suppressed, and carbene-derived rearrangement products (see below) and the (*E*)-isomer become the major products.



18Z **18E** **19**

Formation of highly constrained (*E*)-cyclohexene (**13E**) and (*E*)-cycloheptene (**18E**) upon direct irradiation has been claimed and/or proven as precursors to the corresponding methanol adducts, **17** and **19**, in acidic methanol.[24]

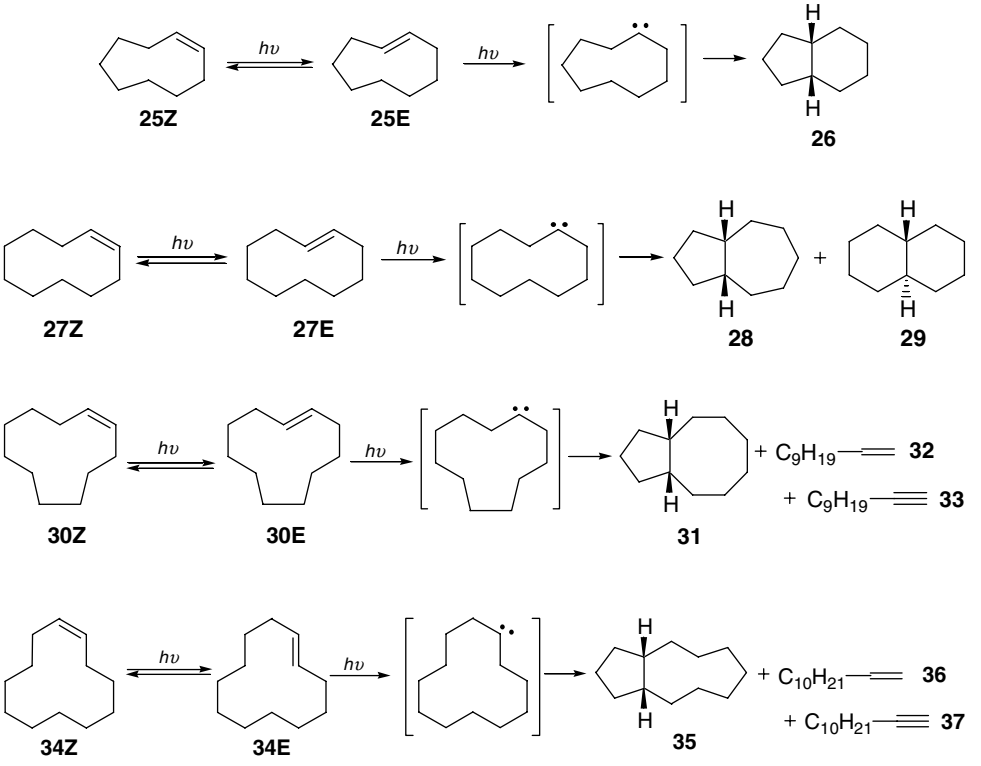
(*E*)-Cyclooctene (**20E**) is the smallest member of the (*E*)-cycloalkene series that can survive at room temperature. Hence, the conventional synthesis of **20E**, though tedious, has long been known.[25,26] Direct irradiation at 185 nm of (*Z*)-cyclooctene (**20Z**) in pentane or methanol affords **20E**, together with small amounts of *cis*-bicyclo[3.3.0]octane (**21**), *cis*-bicyclo[5.1.0]octane (**22**), and methylenecycloheptane (**23**). The latter three products are derived from the carbene intermediate(s) formed via the π,Rydberg(3s) excited state.[27] The direct photoisomerization of **20Z** has been compared with the sensitized one. A high photostationary-state *E/Z* ratio of 0.96 is obtained upon irradiation at 185 nm,[28,29] while the sensitization by benzenepolycarboxylates gives *E/Z* ratios of <0.32.[30] The formation of **20E** upon direct irradiation of **20Z** involves the π,π^* singlet.[31] The direct photoisomerization of **20Z** in pentane can be used as a chemical actinometer at 185 nm;[32] the photoisomerization quantum yield of **20Z** to **20E** is 0.32, while that of **20E** to **20Z** is 0.44.[33] This direct photoisomerization can be used for the practical synthesis of (*E*)-cycloalkene that is thermally stable and isolable. Thus, in a typical preparative-scale photoisomerization, a pentane solution (350 ml) of **20Z** (0.12 *M*) is irradiated at 185 nm for 6 h under a nitrogen atmosphere, and the irradiated solution is concentrated and extracted with aqueous silver nitrate. The aqueous extract is washed with pentane and then added to ammonium hydroxide to give **20E** of 99.6% purity in 26% yield.[29]



20Z **20E** **24**

21 **22** **23**

In the vapor-phase photolysis of larger (*Z*)-cycloalkenes, the photoisomerization to the (*E*)-isomer has not been described explicitly in the literature.[34] It is believed, however, that, analogous to **20Z**, cyclononene (**25Z**), cyclodecene (**27Z**), cycloundecene (**30Z**), and cyclododecene (**34Z**) afford not only the carbene-derived products but also the (*E*)-isomers (though not yet isolated) as intermediates upon irradiation in solution. Direct irradiation of (*Z*)-cycloundecene (**30Z**) in pentane affords *cis*-bicyclo[6.3.0]undecane (**31**) as the major photoproduct, together with ring-opened products **32** and **33**, and the *Z-E* isomerization appears to occur during the photolysis. (*Z*)-Cyclononene (**25Z**) is also believed to undergo the *Z-E* isomerization upon irradiation in solution, but the final product, after prolonged irradiation, is the carbene-derived *cis*-ocathydro-1*H*-indene (**26**).[35] Direct irradiation of (*Z*)-cyclodecene (**27Z**) and (*Z*)-cyclododecene (**34Z**) give similar carbene-derived products (**2829** and **3537**). The *E-Z* photoisomerization of these cycloalkenes is reported to occur, although no further examinations have been made.[27]

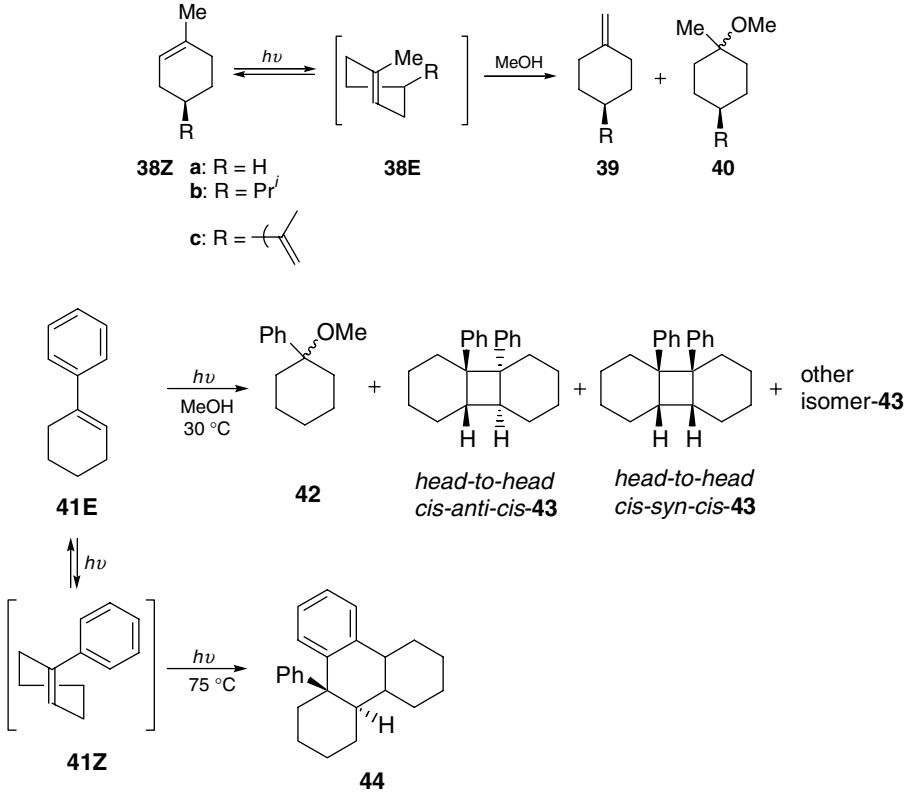


Sensitized Irradiation of Cycloalkenes

Cyclohexenes

A more commonly employed photochemical procedure to obtain (*E*)-cycloalkenes is the photosensitized isomerization of the (*Z*)-isomers, where conventional light sources can be used. Although (*E*)-cyclohexene (**13E**) has never been isolated, various chemical and spectroscopic observations strongly support its formation as a labile intermediate upon direct and sensitized irradiations of cyclohexenes. Thus, the triplet-sensitization of (*Z*)-cyclohexene (**13Z**) with benzene derivatives in aprotic media gives a stereoisomeric mixture of [2 + 2]-cyclodimers (**16**) via the initial *Z-E* photoisomerization.[23,36] A longer-wavelength irradiation of **13Z** in the presence of copper(I) leads to the formation of the same cyclodimers but in a quite different ratio. 1-Methylcyclohexene (**38a**) and *p*-menth-1-ene (**38b**) are converted to the corresponding exocyclic isomer (**39**) and the methanol adduct (**40**) upon alkylbenzene sensitization in methanol. In aromatic hydrocarbons used as sensitizing solvents, only the exocyclic isomer is obtained.[37]

Xylene sensitization of limonene (**38c**) in the presence of acidic methanol leads to photoprotonation, affording a mixture of (*Z*)- and (*E*)-*p*-menth-8-en-1-yl methyl ether (1.6:1) in 56% yield.[38–41] Cyclohexene (**13Z**) and 1-phenylcyclohexene also undergo photoinduced addition of methanol in the presence of acid.[42] In the photoreaction of (*E*)-1-phenylcyclohexene (**41E**)* in methanol at 30°C, 1-methoxy-1-phenylcyclohexane (**42**) and three [2 + 2]-cyclodimers (**43**) in a 55:40:5 ratio are formed. At –75°C, the [4 + 2]-cyclodimer (**44**) is obtained upon direct and/or acetophenone-sensitized irradiation, which is taken as evidence for the formation of the highly strained "*trans*" or (*Z*)-isomer (**41Z**).[43] X-ray crystallographic analysis of **44** supports the mechanism that involves **41Z**, as the stereochemistry is consistent with the addition of photogenerated **41Z** to **41E** as allowed by the Woodward–Hoffmann rule.[44] The quantum yield (Φ) of disappearance of **41E** at 300 nm amounts to 0.12,[45] whereas the intersystem crossing of **41E** is very inefficient (Φ = 0.001).[46] Hence, the singlet-excited state is most plausible as the precursor to **41Z** in the direct photoisomerization. A flash photolysis study of **41E** in methanol clearly reveals the intervention of **41Z** as a transient species.[47] In deuterium-labeling experiments, an exceptionally large secondary kinetic isotope effect (k_H/k_D) of up to two was observed upon thermal isomerization of **41Z** to **41E**. This was attributed to the changes in the torsion angle around the C=C bond and also in the bending angles of vinylic CH (or CD), both of which are seriously deformed during the geometrical isomerization.[48]



Cycloheptenes

(*Z*)-Cycloheptene (**18Z**) and (*E*)-1-phenylcycloheptene (**45a**) both undergo photoinduced methanol addition in the presence of acid, suggesting the intervention of (*E*)-cycloheptene (**18E**) and (*Z*)-1-phenylcycloheptene, respectively.[42] In sharp contrast to (*E*)-cyclohexene (**13E**), which has never been

* Note that the prefix (*E*)" represents the *cis* configuration in this compound.

isolated, **18E** has been identified and characterized by several spectroscopic methods. Irradiation of **18Z** in the presence of methyl benzoate as sensitizer in dimethyl ether-d_6 at −90°C affords the (*E*)-isomer **18E**, which has been characterized *in situ* by ^{1}H NMR spectroscopy. Upon warming to −30°C, **18E** quickly reverts to **18Z** with an energy barrier of 10 kcal/mol.[49] Upon irradiation of **18Z** at −78°C in the presence of methyl benzoate, **18E** is produced in the high *E/Z* ratio of 0.24. Triplet sensitization with toluene or xylenes affords **18E** in low yield with *E/Z* ratios of 0.065 or 0.094.[50,51] (*Z*)-1-Methylcycloheptene (**45b**) gives the exocyclic isomer (**46b**) and the methanol adduct (**47b**), both of which are derived from the (*E*)-isomer, upon alkylbenzene sensitization in methanol.[37] Low-temperature laser flash photolysis of (*E*)-1-phenylcycloheptene affords the transient absorption ascribable to the (*Z*)-isomer.[52] Irradiation of (*E*)-1-methoxycarbonylcylcoheptene (**45c**) in pentane gives the *head-to-head* cyclodimer (**48c**) in high stereoselectivity of 86:14 (the *trans-anti-cis* isomer is dominant), suggesting the intermediacy of the (*Z*)-isomer produced photochemically.[53]

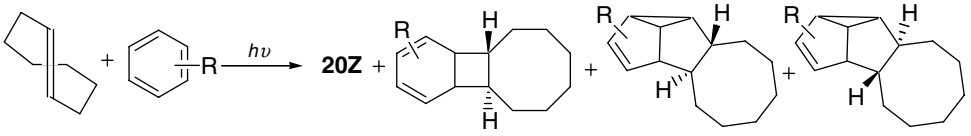
46b **47a**, **b** *head-to-head trans-anti-cis* and other isomers, **48c**

Cyclooctenes

Since (*E*)-cyclooctene (**20E**) is the smallest member of the (*E*)-cycloalkenes isolable under ambient conditions, its photochemical behavior has been studied intensively as a prototype or model system of the cycloalkene family; selected results are summarized in Table 16.1. When (*Z*)-cyclooctene (**20Z**) is irradiated with an equimolar amount of benzene or naphthalene, 1:1 sensitizer–substrate adducts rather than the (*E*)-isomer are produced.[54–56] Upon xylene sensitization, however, the adduct formation is retarded and the geometrical isomerization dominates to afford **20E** in an acceptable isolated yield.[57] The triplet-sensitized photoisomerization of **20Z** has been studied in some detail and has established that the *E/Z* ratio depends on the alkene concentration. The concentration dependence observed is attributed to the involvement of the excited singlet state, which tends to give arene–cyclooctene adducts such as **49** and **50**.[58] Temperature and solvent-viscosity effects upon triplet-sensitized photoisomerization of cyclooctene have been studied in detail.[59] In the alkylbenzene-sensitized isomerization of **20Z** in pentane, the photostationary-state *E/Z* ratio is substantially affected by temperature, being doubled when the temperature is lowered from 20 to −78°C. This result is in contrast with the photoisomerization behavior of acyclic 2-octene.



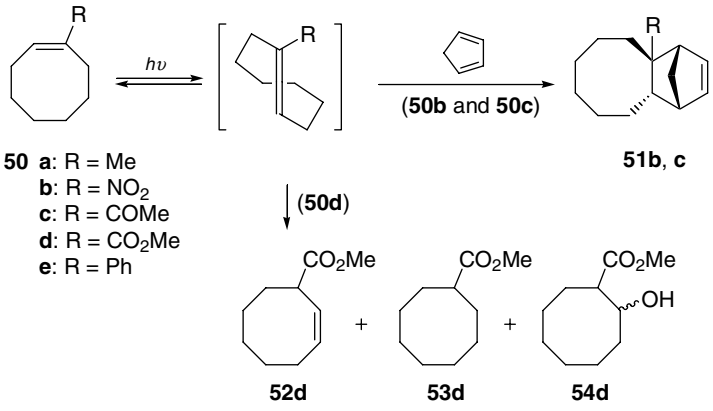
20E **49** **50**

Singlet sensitization performs better, as the photostationary-state *E/Z* ratios of 0.250.34 obtained from singlet sensitization with benzenepolycarboxylates are appreciably higher than those from triplet sensitization with alkylbenzenes.[30] Furthermore, benzenecarboxylates with electron-withdrawing group(s), such as trifluoromethyl, give much higher photostationary-state *E/Z* ratios of up to 0.6.[60,61] Singlet energies of the sensitizers employed are in a range 95–100 kcal/mol.[62]

The photobehavior of cycloalkene is significantly altered by the substituent introduced at the C-1; the alkyl substituent causes severe steric hindrance, and the aromatic functions as a built-in sensitizer. Direct irradiation of (*Z*)-1-methylcyclooctene (**50a**) at 214 nm leads to a photostationary-state *E/Z* ratio of 0.30,

while triplet-sensitization with alkylbenzenes affords smaller ratios of 0.03 to 0.26, which are slightly larger than those obtained with the parent cyclooctene. In contrast, singlet sensitization with alkyl benzoates gives *E/Z* ratios of 0.01 to 0.24, which are smaller than those for cyclooctene. This is attributable to the steric hindrance within the singlet exciplex.[63]

Irradiation of (*E*)-1-nitrocycloctene (**50b**) gives the (*Z*)-isomer, which is trapped by Diels–Alder reaction with cyclopentadiene to give an adduct (**51b**) in 40% yield; the (*Z*)-isomer content is estimated to be >28% at the photostationary state.[64] Irradiation at 337 nm of (*E*)-1-acetylcyclooctene (**50c**) in acetonitrile-d_3 affords a photostationary-state *E/Z* mixture in a ratio of 12:88; the strained (*Z*)-isomer produced is trapped by cyclopentadiene.[65] Irradiation of (*E*)-1-methoxycarbonylcyclooctene (**50d**) in pentane leads to the formation of deconjugated (*Z*)-3-methoxy derivative (**52d**) in 70% yield, along with the reduced and hydrated products (**53d** and **54d**) in 4 and 1% yields, respectively.[53] It is plausible that the reaction proceeds through the (*Z*)-isomer, in which the allylic hydrogen at C3 is readily accessible in space to the ester carbonyl.



16.3 Miscellaneous Cycloalkenes

Benzene-sensitized photoisomerization of (*Z*)-cyclododecene (**34Z**) affords **34E** in a 39:61 *E/Z* ratio at the photostationary state. Other triplet sensitizers such as benzophenone, acetophenone, and acetone, as well as copper salts, can also be used.[66] Sensitized photoisomerization of 1,5,9-cyclododecatriene has also been studied.[66] Direct irradiation of (*E*)-3-methylenecyclodecene (**55E**) affords **55Z**, which further photoisomerizes to yield **56**, **57**, and **58**. Triphenylene sensitization of **55E** affords a photostationary-state mixture of **55E** and **55Z** in a ratio of 94:6.[67] Doubly-bridged ethylene derivatives **59Z** (n = 8, 10), i.e., (*Z*)-bicyclo[8.8.0]octadec-1(10)-ene and (*Z*)-bicyclo[10.8.0]eicos-1(12)-ene, isomerize to the (*E*)-isomers upon xylene-sensitized or direct irradiation. An *E/Z* ratio of 0.42 is given upon sensitization of the latter,[68] while much higher *E/Z* ratios of 9 and 2 are attained upon direct irradiation at 254 nm of (*Z*)-bicyclooctadecene and (*Z*)-bicycloeicosene, respectively.[69]

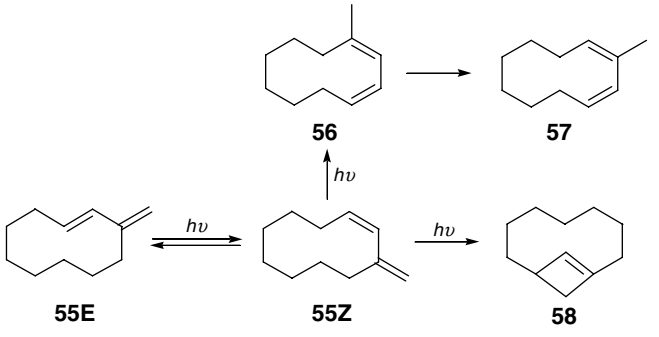


TABLE 16.1 Geometrical Photoisomerization of (*Z*)-Cyclooctene

59Z (n = 8, 10) **59E**

Irradiation of (*Z,Z*)-1,3-cyclooctadiene (**60ZZ**) affords the (*E,Z*)-isomer (**60EZ**), together with small amounts of bicyclo[4.2.0]oct-7-ene (**61**) and (*Z,Z*)-1,4-cyclooctadiene (**62**).[70] Upon direct irradiation of **60ZZ** and (*Z,Z*)-1,3-cycloheptadiene (**63ZZ**), the product distributions do not depend on the irradiation wavelength. (*E,Z*)-1,3-Cyclooctadiene **60EZ** is produced from **60ZZ** in 62 to 89% yields.[71] Low-temperature irradiation of **63ZZ** in a glassy matrix at −196°C affords the (*E,Z*)-isomer (**63EZ**), which is stable at that temperature and has been characterized spectroscopically.[72] Direct and triphenylene-sensitized irradiation of **63ZZ** in pentane or in neutral methanol at room temperature affords bicyclo[3.2.0]hept-6-ene (**64**) in excellent yields. In contrast, irradiation in acidic methanol gives 3-methoxycycloheptene (**65**) and 7-methoxybicyclo[4.1.0]heptane (**66**). All of these products are derived from the photochemically produced (*E,Z*)-isomer **63EZ**. Direct photolysis of (*Z,Z,Z*)-1,3,5-cycloheptatriene (**67**) affords bicyclo[3.2.0]hepta-2,6-diene (**68**) in an excellent yield. However, no experimental evidence for the *Z-E* photoisomerization has been obtained in this particular case; instead, the direct photocyclization allowed by the Woodward–Hoffmann rule appears to be operative.[73] Singlet photosensitization of (*Z,Z*)-1,5-cyclooctadiene (**69ZZ**) in pentane gives **69EZ**, along with tricyclo[3.2.0.0^{2,6}]octane (**70**), which arises from the thermal cyclization of **69EZ**.[74]

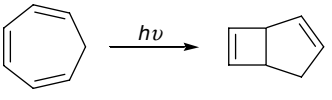
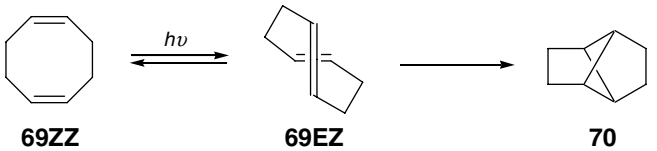
64



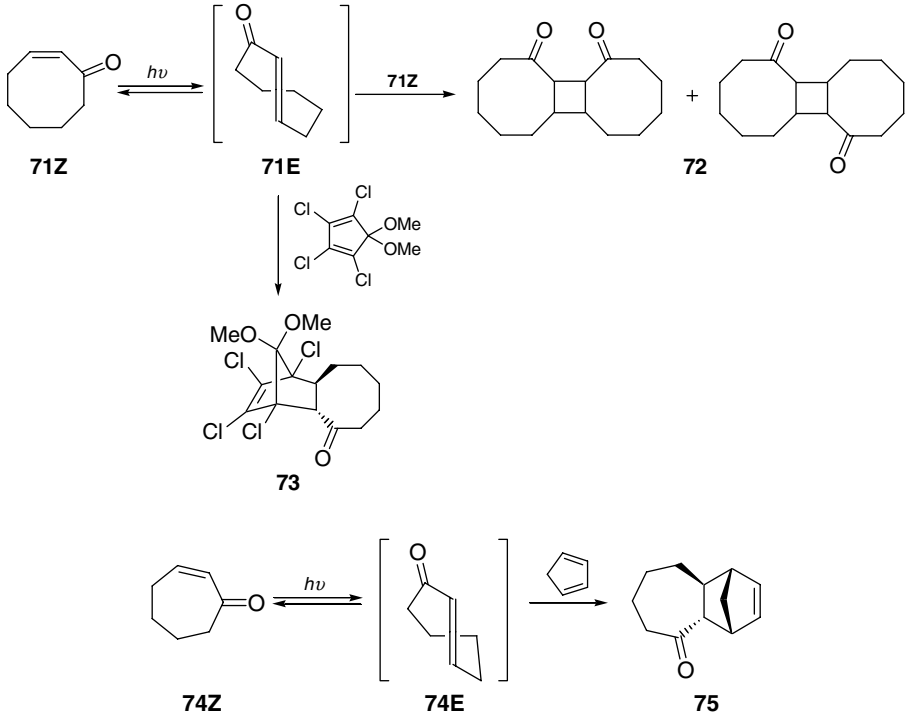
67 **68**

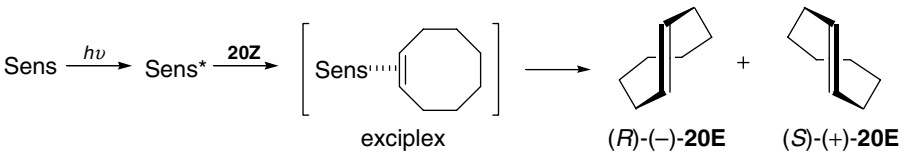


69ZZ **69EZ** **70**

(*Z*)-2-Cyclooctenone (**71Z**) isomerizes to (*E*)-isomer upon irradiation at 300 nm, affording an 80:20 *E/Z* mixture. The (*E*)-isomer **71E** can be trapped by **71Z** or by 5,5-dimethoxy-1,2,3,4-tetrachlorocyclopentadiene at room temperature to afford adducts **72** or **73**, respectively.[75] Similarly, (*E*)-2-cycloheptenone (**74E**) is produced upon irradiation of **74Z** at −50°C and trapped by cyclopentadiene to yield adduct **75**.[76] The formation of **74E** as a transient species has been proven by IR spectroscopy at −160°C, although this species is not stable above −120°C.[77] Laser flash photolysis revealed that **74E** has a lifetime of 45 sec in cyclohexane at room temperature.[78] A variety of alcohols and amines are known to add to the photochemically produced (*E*)-cycloheptenone, (*E*)-cyclooctenone, and (*E*)-cyclononenone.[79] Smaller-sized (*Z*)-cyclohexenone affords a similar adduct only in low yield (0.7%) upon irradiation in methanol, implying inefficient formation and/or trapping of the (*E*)-isomer. Photoinduced methanol additions to 2-cycloheptenone, 2-cyclooctenone, and 2,3-benzo-2,6-cycloheptadienone are also considered to involve the corresponding (*E*)-isomers as reactive intermediates on the basis of a deuterium-labeling experiment.[80]

Photochemical isomerization of cycloalkenes via copper(I) complexes is only briefly described here, as practically no additional studies have been published since the previous edition.[10] In copper(I) trifluoromethanesulfonate-sensitized photodimerizations of (*Z*)-cyclopentene, (*Z*)-cyclohexene, and (*Z*)-cycloheptene, the major products are a stereoisomeric mixture of cyclodimers, which may be derived from the initial *Z-E* isomerization of cycloalkenes.[81] Irradiation at 254 nm of (*Z*)-cyclooctene with copper(I) chloride affords the (*E*)-isomer in 19% isolated yield, the photostationary-state *E/Z* ratio being 20:80 after 24 h irradiation.[82] Photobehavior of (*Z*)-cyclohexene and (*Z*)-cycloheptene in the presence of copper(I) trifluoromethanesulfonate has also been examined.[83] Copper(I)-catalyzed photoreaction of cyclohexene in the presence of 1,3-butadiene affords Diels–Alder adducts.[84] Irradiation of the (*Z*)-cycloheptene-copper(I) triflate complex in hexane affords a stable (*E*)-cycloheptene-copper(I) complex, which can be isolated and identified by conventional analyses.[85] The xylene-sensitization of cycloheptene gives the 1:1 arenecycloheptene adduct in good yield; the cycloheptene dimer is obtained in 57% yield upon irradiation at 254 nm in the presence of copper(I)-benzene complex.[81] Mercury-sensitized photolyses of cyclohexene,[86] 3-methylcyclohexene,[86] and cycloheptene[87] in vapor phase lead to decomposition via biradicals.





16.4 Physical Properties of (*E*)-Cycloalkenes

Highly constrained (*E*)-cycloalkenes, generated readily through the photoisomerization of (*Z*)-isomers, are known to possess unique physical and (chir)optical properties. These properties are of particular interest and importance from both the experimental and theoretical points of view. For example, the experimental barriers of thermal *E*-to-*Z* isomerization of cycloalkenes are compared with the theoretical values obtained by semiempirical calculations. Among the calculations reported, the PM3 method appears to give good fits to the experimental results; e.g., the experimental strain energy of (*Z*)-cyclooctene (**20Z**) is 11.37 kcal/mol, which is close to the value (10.55 kcal/mol) obtained by PM3.[88] The relevant experimental (chir)optical properties, such as specific rotations and absorption maxima and thermodynamic parameters for isomerization, are summarized in Table 16.2.

16.5 Asymmetric Photoisomerization of Cycloalkenes

Cyclooctene

Enantiomeric (*E*)-cyclooctene (**20E**) was first resolved in 1963 through its diastereomeric platinum(II) complex.[89] Synthesis of optically active **20E** has been the subject of intensive study since 1968.[90] The first preparation involves the treatment of enantiopure (*E*)-cyclooctane-1,2-thiocarbonate with triisooctyl phosphate or of (*E*)-cyclooatane-1,2-trithiocarbonate with 1,3-dibenzyl-2-methyl-1,3,2-diazaphospholidine.[91] Following analogous synthetic routes, enantiomeric (*E*)-cycloheptene (**18E**) can be produced and trapped by 2,5-diphenyl-3,4-isobenzofuran as an optically active adduct. In 1973, the circular dichroism spectrum of enantiopure **20E** vapor was recorded in the vacuum UV region down to 150 nm.[92] The first enantiodifferentiating *Z-E* photoisomerization of cyclooctene sensitized by chiral benzenecarboxylates appeared in 1978.[93] Transfer of chiral information from sensitizer to substrate occurs within the exciplex intermediate.[30]

A few comprehensive reviews on asymmetric photochemistry in solution[94,95] and on asymmetric photosensitization[96,97] have been published. An account of the multidimensional control of asymmetric photoreaction by environmental factors appeared recently.[98]

Enantiodifferentiating *Z-E* photoisomerization of cyclooctene (**20Z**) sensitized by chiral polyalkyl benzenepolycarboxylates has been extensively studied; some of the results are summarized in Table 16.3.[99] The crucial enantiodifferentiating step is the rotational relaxation of prochiral **20Z** to enantiomeric perpendicular singlets within the exciplex of the chiral sensitizer with **20Z**. In order to elucidate the detailed mechanism and to obtain higher enantiomeric excess (*ee*), the steric and electronic effects of the sensitizer and its chiral substituent as well as the involvement of the intra/intermolecular triplex have been studied extensively. Thus, the sensitizations with bulky 8-phenylmenthyl and 8-cyclohexylmenthyl 1,2,4,5-benzenetetracarboxylates afford good *ee*s of up to 50% even at room temperature. The *ee* is improved at lower temperatures to reach 64% at −89°C.[62] In contrast, chiral triplet sensitizers afford much lower *ee*s, which are not appreciably improved even at low temperatures (at least in this system).[100] The enantiodifferentiating photoisomerization can also be effected by chiral aromatic amides,[101] phosphoryl esters,[102] and phosphoramides.[103]

Temperature effects do not appear to have been seriously considered or examined in the studies of photoisomerization, except for the purpose of stabilizing strained (*E*)-cycloalkenes, before the recent finding of the dramatic inversion of product chirality by changing temperature in the enantiodifferentiating

photoisomerization of cyclooctene **20Z** sensitized by chiral benzenepolycarboxylates.[104] More recent studies demonstrate that not only temperature[105] but also other entropy-related factors such as pressure,[106] magnetic/electronic fields,[107,108] and solvent[109] play vital roles in determining the product's *ee* and chiral sense in the excited-state interactions within the exciplex. Indeed, the chiral sense of photoproduct **20E** is switched from *R* to *S* either by lowering the temperature under atmospheric pressure (0.1 MPa) or by increasing pressure at 25°C in the enantiodifferentiating photosensitization of **20Z** with tetra-(−)-menthyl 1,2,4,5-benzenetetracarboxylate. When saccharide esters are used as the chiral sensitizer, the product chirality is inverted by simply changing the solvent from nonpolar to polar. In fact, the major product is (*S*)-(+)-**20E** in pentane but is switched to (*R*)-(−)-**20E** in diethyl ether in the photosensitization of **20Z** with tetrakis(diacetoneglucosyl) 1,2,4,5-benzenetetracarboxylate at low temperatures.[109]

Supramolecular asymmetric photoisomerization of cyclooctene has also been performed in native[110] and modified cyclodextrin cavities,[111,112] in zeolite supercages modified with chiral sensitizers,[113] and in DNA grooves.[114]

Cyclooctene Derivatives

Photoisomerization of (*Z*)-1-methylcyclooctene (**50a**) sensitized by hindered chiral benzene(poly)carboxylates affords photostationary-state *E/Z* ratios much lower than those obtained for unsubstituted cyclooctene, probably as a consequence of the steric hindrance of the 1-methyl functional group. However, the steric hindrance does not enhance the product *ee* in this particular case.[115]

Enantiodifferentiating photoisomerization of (*Z,Z*)-1,3-cyclooctadiene (**60ZZ**) is sensitized by chiral benzene(poly)carboxylates.[116] Upon sensitization with hexa-(−)-menthyl benzenehexacarboxylate in pentane at −40°C, the (*E,Z*)-isomer (**60EZ**) is obtained in 18% *ee*. Photoisomerization of (*Z,Z*)-1,5-cyclooctadiene (**69ZZ**) sensitized by (−)-menthyl benzoate affords (−)-(*E,Z*)-isomer (**69EZ**) in only 1.6% *ee*.[74]

Self-sensitized photoisomerization of (*Z*)-3-benzoyloxycyclooctene (**76Z**) affords diastereomeric (1*R**,3*R**)- and (1*S**,3*R**)-**76E** in moderate diastereomeric excess (*de*). Intriguingly, the product chirality is switched by changing the substrate concentration. Thus, irradiation of a 1 m*M* pentane solution of **76Z** at 25°C gives (1*R**,3*R**)-**76E** in 17% *de*, but the product *de* gradually decreases with increasing substrate concentration to ~0% at 10 m*M*, and eventually the epimeric (1*S**,3*R**)-**76E** becomes dominant at higher concentrations to give 11% *de* at 100 m*M*.[117] This unprecedented observation is rationalized in terms of the competing intra- and intermolecular sensitization mechanism, provided that each process gives the opposite product. In contrast, diastereodifferentiating photoisomerizations of 4- and 5-benzoyloxycyclooctenes (**77Z** and **78Z**) do not show such concentration dependence.[118] For the 4-benzoyl derivative, both intra- and intermolecular sensitizations give the same diastereomers, while essentially no intramolecular sensitization occurs in the 5-benzoyloxycyclooctene case due to the steric inaccessibility.

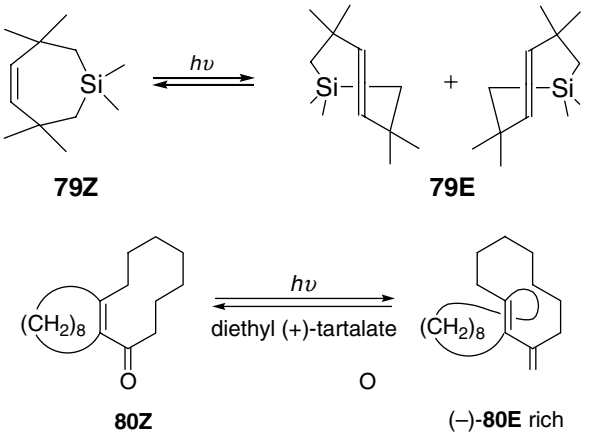
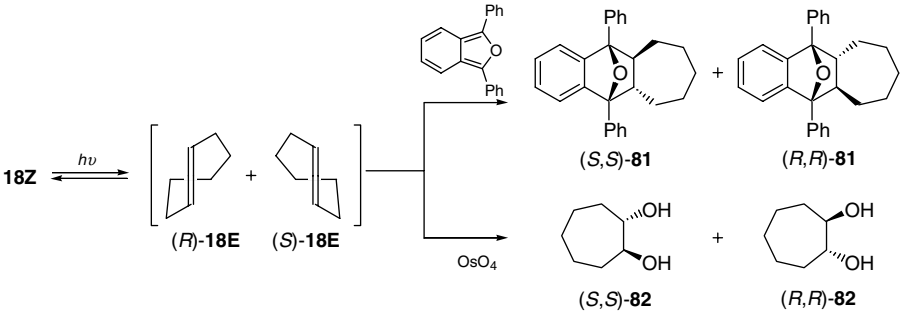
In the presence of (+)-ephedrine, (*E*)-1-acetylcyclooctene (**50d**) photoisomerizes to enantiomeric (*Z*)-isomer, which is trapped by cyclopentadiene to give a Dies-Alder adduct in 22 %ee.[65] A stable sila analogue of (*E*)-cycloheptene (**79E**) was prepared,[119] and its enantiomers were resolved by chiral HPLC.[120] However, direct and sensitized asymmetric photoisomerizations afford the (*E*)-isomer in low chemical and optical yields.[121] Direct irradiation at >280 nm of doubly bridged (*Z*)-D_{2h}-1(10)-bicyclo[8.8.0]octadecen-2-one (**80Z**) in diethyl (+)-tartrate as solvent affords the levorotatory (*E*)-isomer with an *E/Z* ratio of 7.[122,123]



Cyclohexene and Cycloheptene

In spite of the thermal instability of the (*E*)-isomers, the enantiodifferentiating photoisomerization of smaller-sized cycloalkenes has been investigated to some extent. Photosensitization of (*Z*)-cyclohexene (**13Z**) with chiral benzene(poly)carboxylates affords *trans-anti-trans*-, *cis-trans*-, and *cis-anti-cis*-[2 + 2]-cyclodimers (**16**). Interestingly, only the *trans-anti-trans* product is optically active, and the *ee* reaches up to 68% *ee*, for which the enantiodifferentiating photoisomerization of **13Z** to optically active (*E*)-isomer **13E** and the subsequent stereospecific concerted addition to **13Z** are responsible. In contrast, the *cis-trans* photoadduct is formed through the stepwise cyclization via a biradical intermediate, losing the original chiral information in **13E**.[36]

Enantiodifferentiating photoisomerization of (*Z*)-cycloheptene (**18Z**) was also studied in detail.[124] Low-temperature irradiation of **18Z** in the presence of a chiral aromatic ester as sensitizer gives the labile (*E*)-isomer **18E**, which is trapped by 1,3-diphenylisobenzofuran or oxidized by osmium tetraoxide to afford adduct **81** or diol **82**, respectively. The *ee* of **18E** can be evaluated from that of the adduct. The photostationary state is reached after 25–40 min irradiation, giving an *E/Z* ratio of ca. 0.1, which is comparable to or slightly lower than that obtained for the singlet-sensitized photoisomerization of cyclooctene **20Z**. The *ee* of **18E**, which is higher than that of **20E** obtained under the comparable conditions, is sensitive to the solvent polarity and reaction temperature. Upon sensitization with tetra-(–)-bornyl 1,2,4,5-benzenetetracarboxylate in hexane at –80°C, **18E** is obtained in 77% *ee*, the highest value ever obtained for enantiodifferentiating photosensitization.



16.6 Conclusions

As can be recognized from the above discussion, the photochemistry of cycloalkenes is not a simple extension or subcategory of the photochemistry of acyclic alkenes, but rather constitutes a distinct new area that provides a variety of mechanistic insights, novel reactivities, and useful synthetic methodologies. Direct irradiation of (*Z*)-cycloalkenes, mostly in or near the vacuum UV region, leads to a broad spectrum of photoreactions, including valence and geometrical isomerization, rearrangement, cyclization, and decomposition reactions through the π,π^* and π,R(3s) excited states. Both singlet and triplet sensitizations are useful strategies for effecting the photoisomerization of cycloalkenes. However, the singlet manifold is more advantageous in obtaining high photostationary-state *E/Z* ratios, particularly when the *trans* isomer is highly constrained. Environmental factors, such as temperature, pressure, solvent, and phase, can affect the photostationary-state *E/Z* ratio in the sensitized photoisomerization of cyclooctene.

Recent studies on enantiodifferentiating photoisomerization reveal that the photosensitization of C_6C_8 (*Z*)-cycloalkenes with optically active aromatic esters affords chiral (*E*)-cycloalkenes in good to excellent *ee*s. The mechanism involves enantiodifferentiating rotational relaxation within the exciplex intermediate formed from the excited singlet state of chiral sensitizer and prochiral substrate. The exciplex structure and hence the stereochemical outcome are very sensitive not only to the *internal* factors, such as sensitizer energy and structure, but also to the *external* entropy-related factors such as temperature, pressure, and solvent. This leads to a novel idea of multidimensional control of product chirality by several environmental factors. The asymmetric photosensitization can be applied to the photochemical asymmetric synthesis and also be used as a powerful tool for exploiting the reaction mechanisms in the excited-state chemistry.

The Photochemical Reactivity of the Norbornadiene–Quadricyclane System

Alexander D. Dubonosov
Rostov State University

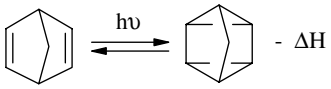
Vladimir A. Bren
Rostov State University

Vladimir I. Minkin
Rostov State University

17.1 Introduction

Photochemical valence isomerization involving the intramolecular (2 + 2)-cycloaddition that converts bicyclo[2.2.1]hepta-2,5-diene **1** (norbornadiene, N) to tetracyclo[3.2.0.0.^{2,7}0^{4,6}]heptane **2** (quadricyclane, Q) has been the subject of much investigation from a mechanistic point of view.[1–4] The N/Q system has found diversified applications as an efficient abiotic system for solar energy storage,[5–7] in molecular switching,[8–10] in optoelectronic devices,[11–14] as a data storage material,[15,16] as a photodynamic chemosensor for metal cations,[17,18] as a potential photoresponsive organic magnet,[19–21] and as an energetic binder for solid rocket propellants.[22]

0-8493-1348-1/04/$0.00+$1.50



1 **2**

The principal drawback of the N/Q system is a very low (~0.05) quantum yield (**Φ**) of the direct photoconversion **1**→**2**.[6,16] It has been established that the N→Q rearrangement occurs via the triplet state of N.[23,24] Consequently, this reaction can be photoinitiated by various sensitizers (S). Electron-donating and electron-withdrawing substituents attached to one or both double bonds of N can also increase the **Φ** value, providing a long-wavelength shift of the edge of the N absorption (λ_e, $\varepsilon \sim 1$).[25–27] The reverse Q→N reaction is thermally forbidden by the Woodward–Hoffmann rules, but this transformation can be readily accomplished via a radical-cation chain reaction pathway[24] initiated by chemical, electrochemical, or photosensitized single-electron oxidations.[4] The metastable Q structure contains a highly strained cyclobutane and two cyclopropane rings, and the enthalpy of the **2**→**1** isomerization in the pure liquid state has the value of $\Delta H = -89$ kJ mol^{-1}, as obtained from direct calorimetric measurement.[28] Results of other experiments and computed values vary in the range of –81 to –112 kJ mol^{-1}.[3,29,30]

17.2 Photosensitization of the Norbornadiene–Quadricyclane Rearrangement

Two distinct mechanisms are conceivable for the photosensitized N→Q isomerization.[31–35] The first one is characterized by the formation of ground-state adducts of S with N that can be selectively irradiated to release Q:

$$S + N \rightarrow \left[S\text{---}N\right] \xrightarrow{h\nu} S + Q$$

The alternative pathway involves interaction of excited S with ground state N either via formation of excited-state charge-transfer complexes (exciplexes) that collapse to Q:

$$S \xrightarrow{h\nu} {}^*S \rightarrow {}^*\left[S^{\delta-}\text{---}N^{\delta+}\right] \rightarrow S + Q$$

or via triplet–triplet energy transfer:

$$S \xrightarrow{h\nu} {}^1S \rightarrow {}^3S + N \rightarrow S + {}^3N \rightarrow Q.$$

Triplet–Triplet Energy Transfer

As mentioned in the Introduction, triplet photosensitizers can be used to increase efficiency of the **1**→**2** reaction.[2,23,24,34,36] This process is considered to consist of the following stages:

1. Photoexcitation of S into the singlet state: $S \xrightarrow{h\nu} {}^1S$
2. The intersystem crossing: ${}^1S \rightarrow {}^3S$
3. Triplet-triplet energy transfer: ${}^3S + N \rightarrow S + {}^3N$
4. Adiabatic isomerization of N to the triplet state of Q: ${}^3N \rightarrow {}^3Q$
5. Formation of the ground state of quadricyclane: ${}^3Q \rightarrow Q$

The energy levels of the electronic excited states[2,23,37] of N are relatively high, for which reason this mechanism of energy transfer is thermodynamically favorable (exothermic) only when the energy level of ${}^3S$ is higher than that of ${}^3N$, i.e., $E_T > 257$ kJ mol^{-1}, and even a small value of the singlet–triplet splitting of S corresponds to $\lambda_e \leq 400$ nm.[38] Only a small number of sensitizers S meet this condition; the range of sensitizers is mainly limited to carbonyl-containing compounds such as acetophenone, propiophenone,

TABLE 17.1 Quantum Yields of the Isomerization **1**→**2** in Acetonitrile

Sensitizer	E_T, kJ mol^{-1}	$\Phi_{1\rightarrow2}$	Ref.
Acetophenone	309.6	>0.9[a]	34
4,4′-Dimethylbenzophenone	290.1	0.59	43
4-Methylbenzophenone	289.7	0.50	43
Benzophenone	289.7	0.45	43
4-Cyanobenzophenone	280.5	0.33	43
1,2,4,5-Tetracyanobenzene	271.3	0.34[a]	34
Michler's ketone	259.6	0.04	43
2-Naphtaldehyde	249.1	0.06	6, 36
10-Methylacridinone	246.0	0.11[b]	42
2,7-Dibromo-10-methylacridinone	231.0	0.06[b]	42
Benzil	227.3	0.009	43
Benzoquinone	221.9	0.0[a]	34

[a] In CH_2Cl_2.
[b] In DMF.

benzophenone and its derivatives, benzoylpyridines, triphenylene, Michler's ketone, and some others.[34,37,39–43] (Table 17.1). The highest values of Φ for the N/Q transformation were found with acetophenone and benzophenone. This is due to the high values of E_T of these sensitizers, with λ_e equal to 366 and 388 nm, respectively. In the cases of other sensitizers, the classical triplet energy transfer mechanism is coupled with the formation of exciplexes. Formation of the ^{3}N species with a lifetime of about 7 nsec in the presence of triplet acetophenone as sensitizer was detected by photoacoustic calorimetry.[34] By contrast, reaction of N with the triplet benzoquinone does not yield ^{3}N, as no energy transfer was found to occur.

Adducts of Norbornadiene with Sensitizers

Due to the presence of two double bonds in norbornadiene and its derivatives, these compounds readily form π-complexes with transition metal salts and coordination compounds. The latter may serve as photosensitizers S for the N/Q transformation and can also be designated as photocatalysts.[32] Photoexcitation of the stable ground state adducts [S---N], results in the formation of quadricyclanes:

$$\left[\text{S}\text{---}\text{N}\right] \xrightarrow{h\nu} \text{S} + \text{Q}.$$

A suitable metal-containing photosensitizer S should satisfy the following requirements:[44]

1. The metal center in S must be in its low oxidation state with only one coordination site available for binding N in order to avoid undesirable dimerization processes.
2. The [S---N] complex must absorb in the visible region.
3. The compound S must be resistant to oxidative addition reactions and must not catalyze the reverse Q → N reaction.
4. The whole catalytic system must not promote side reactions.

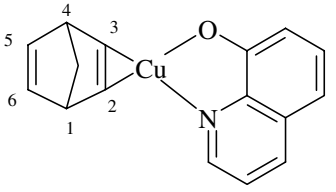
Although many transition metals are capable of forming complexes with N, only univalent copper compounds comply with the above requirements.[31–33,45,46] The initial ligand N and copper salts S (CuX, X = Cl, Br, I, OCOMe) do not absorb light with $\lambda > 300$ nm, whereas their adducts [S---N] display an intense charge-transfer absorption band with $\lambda_e \sim 370$ nm. Irradiation of these complexes by light of $\lambda =$ 313 nm results in the formation of Q as the sole product with reasonably high quantum yields ($\Phi =$ 0.2–0.4).

Photoexcitation ($\lambda = 313$ nm) of the charge-transfer adducts of N with $CuBr(Py)(PPh_3)$ or $Cu[HB(Pz)_3]$ in hexane (Py = pyridine, Pz = 1-pyrazolyl) gives rise to Q with $\Phi = 0.37$–0.65.[47,48] The photorearrangement of the complexes of N with halo(ferrocenyl-diphenylphosphine)copper(I) tetramers

$[CuX(PFcPh_2)]_4$ (X = Cl, Br) under irradiation (λ = 366 nm) in tetrahydrofuran (THF) solutions occurs with lower quantum efficiency ($\Phi \sim 0.01$).[49] With chloro(tertiary phosphine)copper(I) oligomers[32] $[CuCl(PR_3)]_n$ (R = 2-MeC_6H_4, 4-EtC_6H_4Me) as photocatalysts, the N $\rightarrow$ Q transformation (THF, λ = 366 nm) is characterized by quantum yields in the range of 0.11–0.49.

The highest value of $\lambda_e \leq 405$ nm has been achieved in the case of dinuclear complexes of norbornadiene $[Cu_2L_2(\mu\text{-N})]$, $[Cu_2L'_2(\mu\text{-N})]$, $[Cu_2L''_2(\mu\text{-N})]$, and $[Cu_2L'''_2(\mu\text{-N})]$ [L = 2-methyl-8-oxoquinolinato, L′ = 2-methyl-5,7-dichloro-8-oxoquinolinato, L″ = 4-oxoacridinato, L‴ = 2-(2-oxo-3,5-di-*tert*-butylphenyl)benzothiazole)],[31] whose structures were determined by x-ray crystallography. Absorption spectra of these adducts show metal-to-ligand charge-transfer bands in the visible region. Their photoisomerization (λ_{irr} = 405 nm) in methanol solution results in the formation of Q with Φ = 0.029. The **1**$\rightarrow$**2** turnover number (moles of Q produced by a mole of S) of 5000 was obtained. An increase in the temperature of the solution leads to significant enhancement of the quantum yield.

To gain insight into the energy and geometric characteristics of the experimentally studied $[Cu_2(2\text{-methyl-8-oxoquinolinato})_2(\mu\text{-N})]$ system, *ab initio* (the B3LYP hybrid exchange-correlation functional) calculations on the model ground state adduct [Cu(8-oxoquinolinato)N] **3** have been performed.[50]



3

The computed C2=C3 distance of 1.409 Å in **3** is strongly elongated compared with 1.339 Å in uncomplexed N. Complexation with S reduces the HOMO-LUMO gap in N due to donation of electron density from the metal center to the π^*-antibonding orbital of N. The decrease in the HOMO-LUMO gap is the main factor that causes narrowing of the gap between the ground and the first excited singlet state of [S---N]. This makes it possible to initiate the **1**$\rightarrow$**2** photoisomerization under irradiation with λ_{irr} = 405 nm.

Complexes of Norbornadiene with Photosensitizers in Their Excited Electronic States

Most metal salts and complexes do not form stable adducts with N, and for a large number of the triplet sensitizers with E_T < 257 kJ mol^{-1}, the energy transfer from ^{3}S to N is thermodynamically unfavorable (endothermic). Another way of promoting **1**$\rightarrow$**2** photoisomerization is to accomplish it in the complexes formed by N with photosensitizers S in their excited states.[24,34,35] Such a process includes the following stages:

1. Photoexcitation of S to the singlet excited state ^{1}S
2. The intersystem crossing: $^1S \rightarrow {}^3S$
3. Formation of the excited-state complexes [^{3}S ---N] (usually of charge-transfer or exciplex nature)
4. The dark reaction that leads to formation of Q in its ground state

Carbonyl-containing compounds or transition metal complexes used as photosensitizers must meet the following requirements:[44]

1. Metal-containing S must be inert towards ligand substitution and must not coordinate with N.
2. S must intensely absorb light in the visible region.
3. The lifetime of the excited state ^{3}S must be long enough for the bimolecular reaction to proceed.
4. S must not promote any reverse or side photoreactions.

Substituted acridinones act by this type of mechanism (E_T = 239–260 kJ mol^{-1}) and absorb in the long-wavelength region (λ_e = 360–420 nm). They bring about the **1**→**2** rearrangement to yield Q with Φ = 0.4–0.7.[42] A number of Cu(I) complexes do not react with N in the ground state and are capable of sensitizing the Q formation. The values of λ_e 330 nm and Φ 0.56–0.88 were achieved for the N → Q transformation in benzene with $Cu[PPh_2Me]_3BH_4$, $Cu[PPh_3]_2BH_4$, and Cu(prophos)BH_4 (prophos = 1,3-bis(diphenylphosphino)propane) as photosensitizers.[51,52]

The use of copper(I)-nitrogen ligand complexes, such as Ph_3PCuXL (X = Cl, Br; L = 2,2′-bipyridine, 1,10-phenantroline, phthalazine, pyridine) enables the **1**→**2** isomerization to occur upon irradiation of the solutions of the components in the spectral region $\lambda > 350$ nm (Φ 0.008–0.011 in THF and 0.03–0.13 in ethanol).[53] With another group of photosensitizers $[Cu(PPh_3)_2(dpk)]NO_3$, $[Cu_2I_2(PPh_3)_2(dpk)]$, $[Cu_4I_4(dpk)_3]$ (dpk = di-2-pyridyl ketone) (Φ 0.17–0.36 in CH_2Cl_2), it is possible to conduct the **1**→**2** photoreaction on exposure to light with wavelengths $\lambda_e \leq 600$ nm.[46]

Some of the compounds S are capable of forming adducts with N in both their excited and ground states. A high quantum yield (Φ = 0.75) for the **1**→**2** conversion was achieved upon illumination of concentrated chloroform solutions of N containing $Cu_2Br_2(AsPh_3)_3$ and $[CuCl(AsPh_3)]_4$[54] as the sensitizers of the reaction. Sensitization with the complexes $(Ph_2PCH_2CH_2PPh_2)CuCl$, $(Ph_3P)_3CuX$ and $(MePh_2P)_3CuX$ (X = Cl, Br, I) made it possible to achieve the maximum value Φ = 1.0 in a highly concentrated solution.[55] Dilution sharply reduced the quantum yield.

Transition metal complexes of other than Cu(I) metals are less frequently used for sensitizing the **1**→**2** transformation: $[Ru(bpy)_3]^{2+}$, $[Ru(phen)]^{2+}$, $[cis\text{-}Ir(phen)_2Cl_2]^+$, $[Ir(bpy)_3OH]^{2+}$, $[Rh(phen)_3]^{2+}$, $[Rh(phen)_3]^{3+}$, and $[Rh(phi)_2(phen)]^{3+}$ (bpy = 2,2′-bipyridine, phen = 1,10-phenanthroline, phi = 9,10-phenanthrenequinone diimine).[44,56–59] However, in these cases quantum yields of the conversion are rather low. An exception is the use of $[Ir(bpy)_2(bpy')]^{2+}$, in which case Φ = 0.72.[57]

A triplex electron-transfer mechanism involving interaction of dibenzoylmethanatoboron difluoride (DMB) and an aromatic co-sensitizer (A — toluene, ethylbenzene, biphenyl, and durene) with N was suggested based on the results from a chemically induced dynamic nuclear polarization study of the reaction:

$$\mathrm{DMB} \xrightarrow{h\nu} {}^1\mathrm{DMB} + \mathrm{A} \rightarrow {}^1\left[\mathrm{DMB\ A}\right] + \mathrm{N} \rightarrow {}^1\left[\mathrm{DMB}^{-\cdot}\left(\mathrm{A\ N}\right)^{+\cdot}\right] \rightleftharpoons$$

$$ {}^3\left[\mathrm{DMB}^{-\cdot}\left(\mathrm{A\ N}\right)^{+\cdot}\right] \rightarrow \mathrm{DMB} + \mathrm{A} + {}^3\mathrm{N} \rightarrow \mathrm{Q}.$$ [60]

An efficient electron-transfer mechanism of the **1**→**2** photoisomerization without intermediate formation of the triplet ^{3}N was shown to be involved in the presence of 3,3′,4,4′-benzophenonetetracarboxylic dianhydride (BTDA):

$$\mathrm{BTDA} \xrightarrow{h\nu} {}^1\mathrm{BTDA} \rightarrow {}^3\mathrm{BTDA} + \mathrm{N} \rightarrow {}^3\left[\mathrm{BTDA}^{-\cdot}\,\mathrm{N}^{+\cdot}\right] \xrightarrow{\mathrm{BCET}} \mathrm{BTDA} + {}^3\mathrm{Q} \rightarrow \mathrm{Q}.$$

The abbreviation BCET (bond coupled electron transfer) has been employed to describe such a mechanism.[34]

N-(α-Naphthyl)carbazole (N-C) has been shown to form a twisted intramolecular charge transfer (TICT) excited singlet state. It was used as a sensitizer to produce Q by the following mechanism:

$$\text{N-C} \xrightarrow{h\nu} {}^1\left[\text{N-C}\right] \rightarrow {}^1\left[\text{N}^{-\cdot}\text{-C}^{+\cdot}\right]\left(\text{TICT}\right) \rightarrow {}^3\left[\text{N-C}\right] + \text{N} \rightarrow {}^3\left[\text{N-C}\cdots\text{N}\right] \rightarrow \text{N-C} + \text{Q}.$$ [61]

Photoinitiated Quadricyclane and Norbornadiene Cycloaddition Reactions and Rearrangements

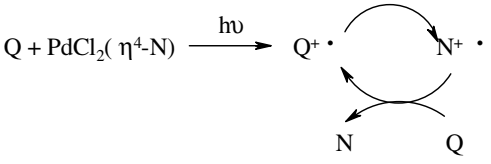
The reverse photochemical conversion **2**→**1** can be efficiently brought about via a radical-cation chain reaction $Q^{+\cdot}\rightarrow N^{+\cdot}$.[3,4] The stability of the two distinct isomeric radical cations with energy differences between $N^{+\cdot}$ and $Q^{+\cdot}$ of about 35.6–46.1 kJ mol^{-1} was confirmed by various experimental methods and theoretical calculations.[3, 62–66]

Carbonyl-containing compounds such as acetophenone, benzophenone, and chloranil can sensitize not only the **1**→**2** rearrangement but also the back reaction, though quantum yields for the latter (Φ 0.05–0.10) are much less than those for the direct photoreaction.[36,43,67,68] Photogenerated catalysis of the **2**→**1** reaction with some metal complexes is a more effective process, since a single photon may produce several molecules of N according to the sequence

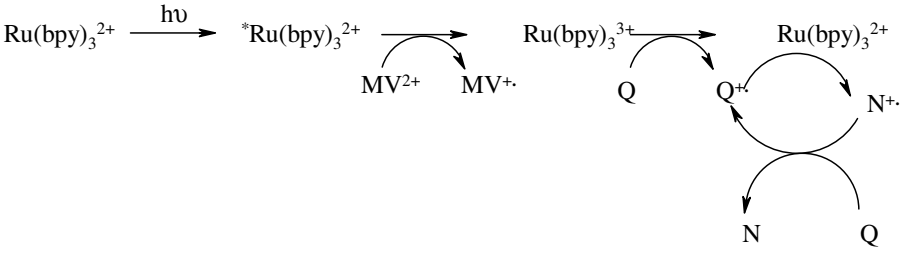
$$S \xrightarrow{h\nu} {}^{*}S \xrightarrow{Q} S^{-} + Q^{+\cdot} \rightarrow S^{-} + N^{+\cdot} \xrightarrow{Q} N + Q^{+\cdot};\ Q^{+\cdot} + S^{-} \rightarrow Q + S.$$

This mechanism operates upon irradiation of solutions Q and $Ru(bpy)_3^{2+}$ (bpy = 2,2′-bipyridine) or $PdCl_2(\eta^4\text{–N})$ with 436 nm light and produces N with quantum yields above 1.0 and a turnover number greater than 10^2.[69,70]

Such efficiency is the result of the intermolecular redox process in which Q reductively quenches the metal-to-ligand charge-transfer (MLCT) excited state of the palladium complex. The resulting radical cation $Q^{+\cdot}$ rearranges to its most stable isomer $N^{+\cdot}$, which then oxidizes another molecule Q to restart the cycle.



In the presence of methylviologen MV^{2+}, the $Ru(bpy)_3^{2+}$ complex is oxidized to $Ru(bpy)^{3+}$, which serves as a catalyst for the Q→N conversion, with the quantum yield (Φ) > 1.0.



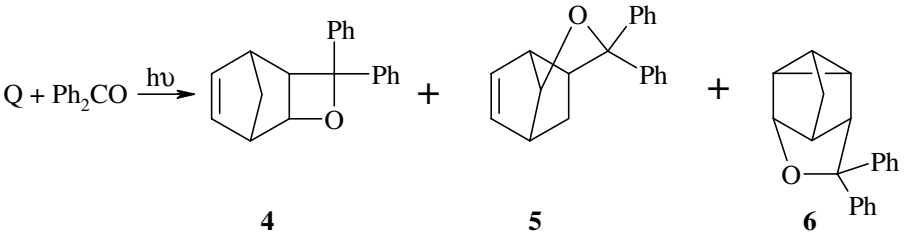
When the bipyridine ligands in the ruthenium complex are replaced by 1,10-phenanthroline analogues, the quantum yield of the reaction is drastically decreased to <0.01.[35]

Much like the **1**→**2** photoisomerization, the back **2**→**1** reaction may be catalyzed by complexation of Q with *N*-(α-naphthyl)carbazole (NC) in its TICT excited state. The following reaction scheme was suggested[61]:

$$N\text{-}C \xrightarrow{h\nu} {}^{1}N\text{-}C \rightarrow {}^{1}\left[N^{-\cdot}\text{-}C^{+\cdot}\right]\left(TICT\right) + Q \rightarrow \left[N^{-\cdot}\text{-}C\cdots Q^{+\cdot}\right] \rightleftharpoons \left[N^{-\cdot}\text{-}C\cdots N^{+\cdot}\right] \rightarrow N\text{-}C + N$$

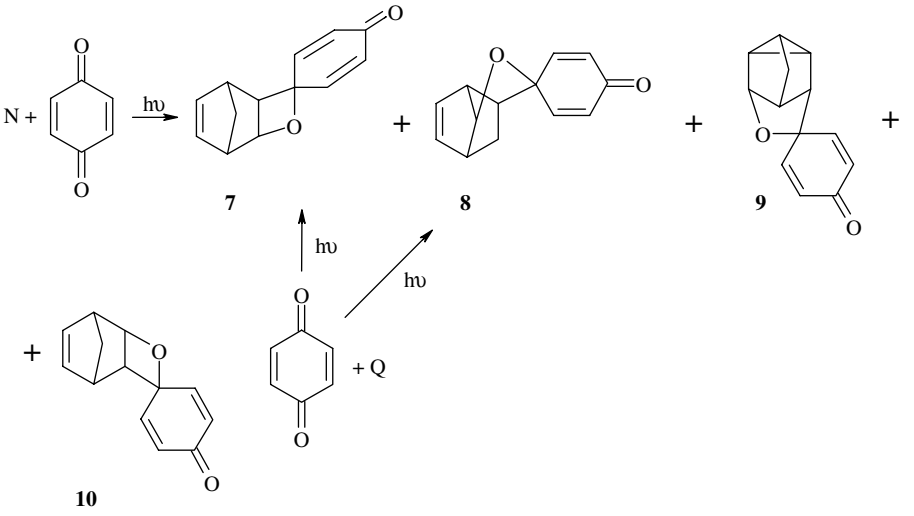
The main disadvantage of using carbonyl-containing compounds for sensitization of the **1**→**2** or **2**→**1** photoreactions is the formation of products of the side reaction of their photoaddition to N and Q.[71–73]

Irradiation of a benzene solution of benzophenone and N affords the adducts **4–6**[74] even though, in the triplet state, the ketone was shown to add only to Q.[75]



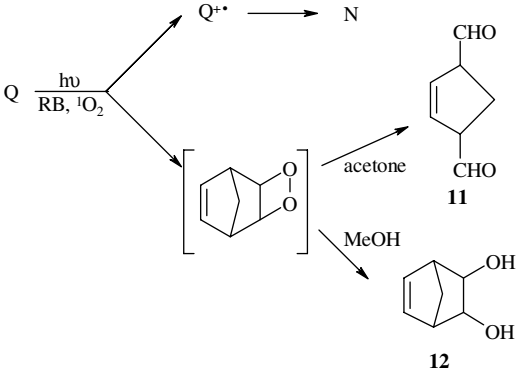
4 **5** **6**

Photoreaction of N with *p*-benzoquinone in benzene yielded a mixture of four isomeric 1:1 adducts **7–10**, whereas Q, under similar conditions, afforded only two *exo* adducts **7** and **8**.[76]



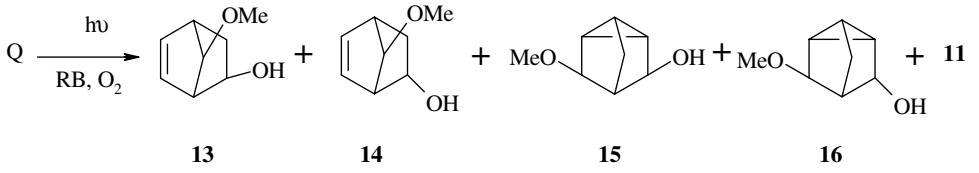
7 **8** **9** **10**

Photolysis of a benzene solution of chloranil and N gave rise to the norbornene analogues of **7**, **8**, and **10** and the tricyclene derivative **9**. By contrast, in acetonitrile solution, formation of only small amounts of type **8** and **9** adducts was detected.[71] The photoreaction of chloranil and Q gave rise to the type **7** adduct as the sole product. Irradiation of Q in acetone or methanol solution under Rose Bengal–sensitized (RB) conditions generated about 70% of N and adducts **11** and **12**.[77]



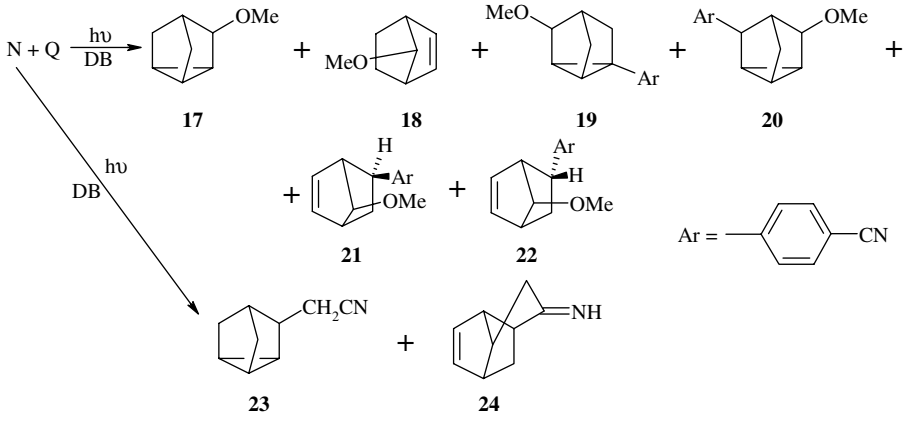
11 **12**

When a methanol solution of Q and RB was irradiated in the presence of NaOMe in an oxygen atmosphere, the epimeric pairs of methoxynorbornenols **13**, **14** and methoxynortricyclanols **15**, **16** were obtained along with the bis-aldehyde **11**.



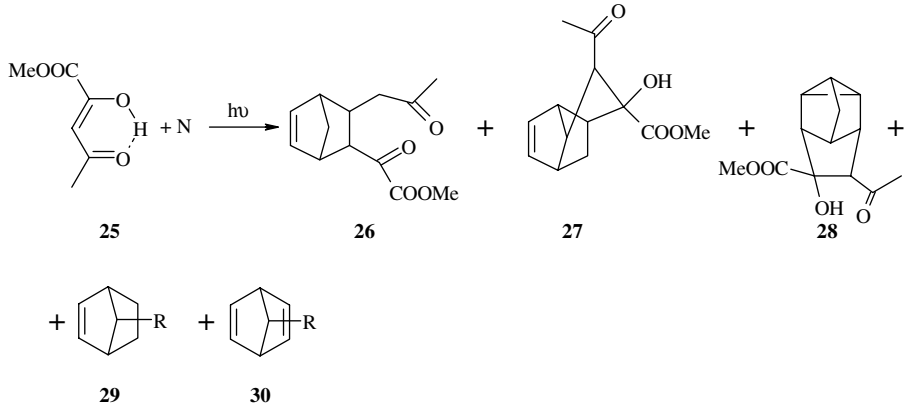
13 **14** **15** **16**

The photoinduced charge-transfer reactions between N or Q and 1,4-dicyanobenzene (DB) in acetonitrile/methanol lead to adducts **17** and **18**, photoinduced nucleophile-olefin-combination-aromatic-substitution (NOCAS) products **19–22** and two acetonitrile adducts, **23** and **24**, which are formed only from N.[78]



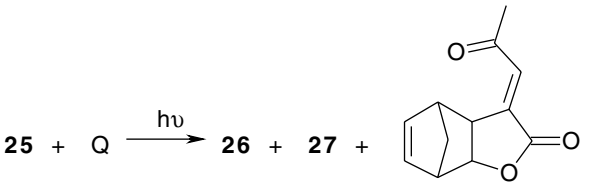
17 **18** **19** **20** **21** **22** **23** **24**

The photocycloaddition of methyl 2,4-dioxopentanoate (DOP) **25** to N afforded the esters **26** and **27**, the adduct **28**, the 7-substituted norbornene **29**, and the norbornadiene **30**. The analogous reaction of **25** with Q gave **26**, **27**, and the oxetane **31**.[72] The presence of **27** in the reaction mixture is evidence for the formation of zwitterions arising via single electron transfer.



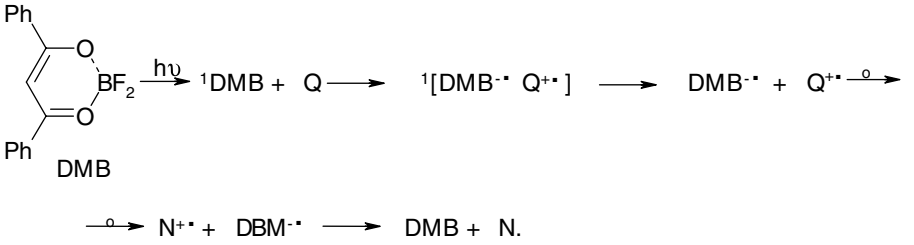
25 **26** **27** **28** **29** **30**

R = 3-DOP

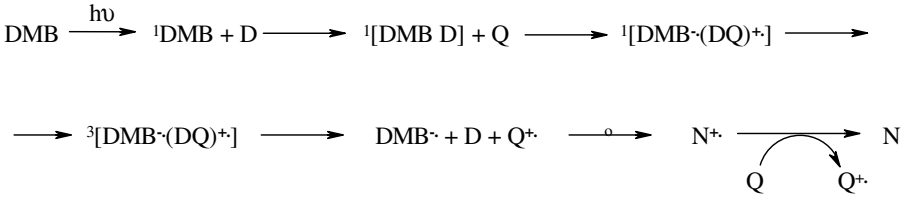


31

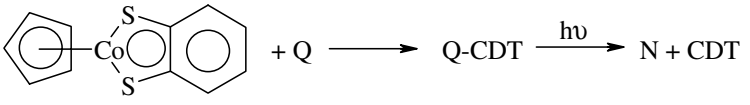
No photosensitized processes **1**→**2** and **2**→**1** took place in the presence of DOP, although dibenzoylmethanatoboron difluoride (DMB) readily sensitized the conversion of Q to N via an electron transfer mechanism.[60]



In the presence of durene (D), the participation of triplexes in the co-sensitized reaction is possible.[79]



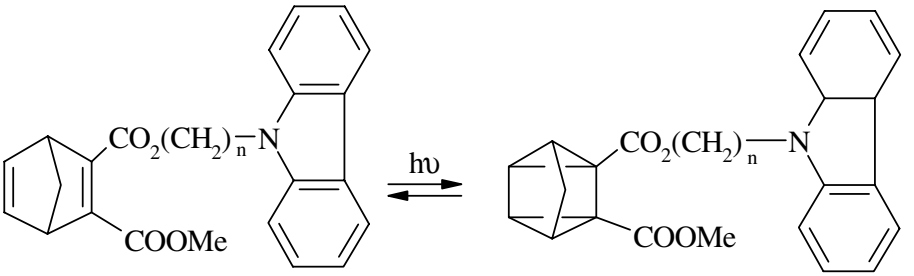
Cobaltadithiolenes (CDT) and rhodiadithiolenes react with Q to give adducts **32** in which the norbornadiene-5,7-diyl group bridges the metal atom to one of the sulfur atoms. UV-irradiation of the complex **32** in acetonitrile solution gives rise to the formation of the free metaladithiolene and norbornadiene in almost 100% yield.[80]



CDT **32**

Photosensitizers Covalently Bonded to Norbornadiene

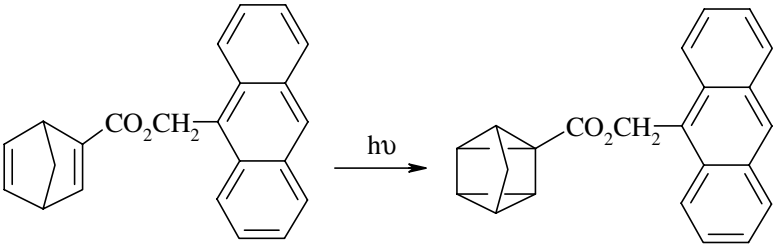
In order to avoid undesirable photoreactions, some of the suitable sensitizers S may be covalently linked to the norbornadienyl moieties N. Intramolecular photosensitized isomerization of norbornadienes **33** containing a carbazole (CZ) fragment produces the Q derivative **34** through a photoinduced electron transfer between the CZ ring and the olefinic fragment of N ($\lambda_{irr} \geq 350$ nm).[81]



33 **34**

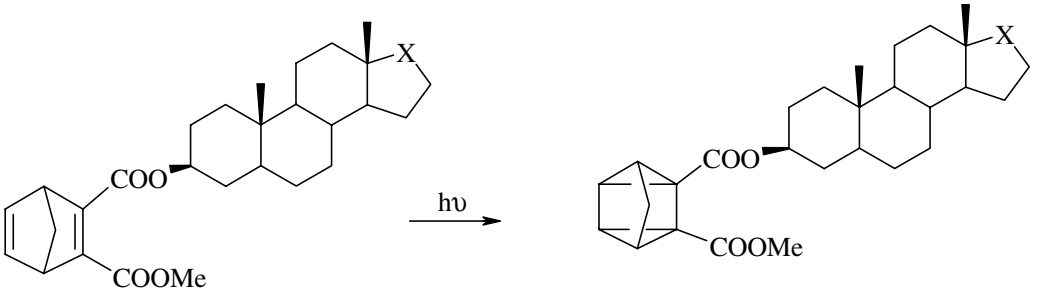
n = 2, 6

Intramolecular energy transfer from the second triplet of the anthracene moiety in **35** is exemplified by the **35**→**36** valence isomerization initiated by the stepwise two-color two-photon excitation method.[82] The energy transfers from the first excited singlet and triplet states of the anthryl group are highly endothermic, whereas that from the second triplet is exothermic. The quantum yield (Φ) of the reaction performed under argon has been determined to be 0.029.

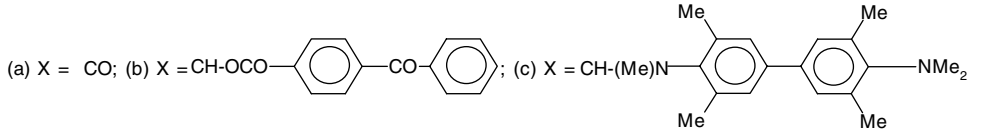


35 **36**

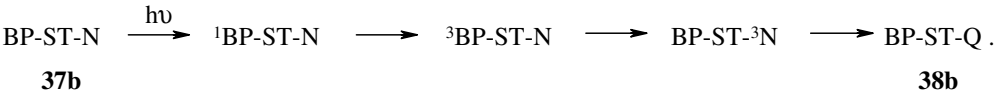
The photophysical and photochemical characteristics of the norbornadiene-steroid-sensitizer systems **37** were investigated by steady-state and time-resolved techniques.[83–86]



37 **38**

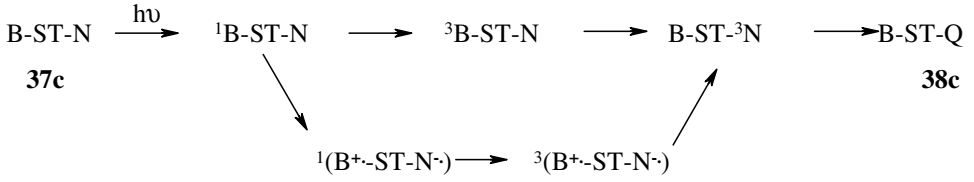


Selective excitation of the benzophenone or benzidine chromophores results in **37**→**38** isomerization. The long-distance intramolecular triplet-energy transfer is proposed to proceed via a through-bond exchange mechanism. For the benzophenone derivative **37b** (BP-ST-N), this process involves the following steps:



37b **38b**

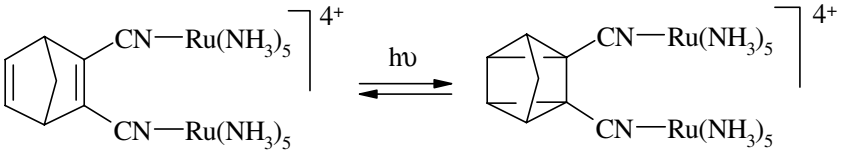
For the benzidine derivative **37c** (B-ST-N), the photorearrangement occurs via one long-distance triplet energy transfer process and two long-distance electron transfer processes (the electron transfer from the singlet benzidine and the recombination of the radical-ion pair).



37c **38c**

17.3 Valence Photoisomerization of Derivatives of Norbornadiene

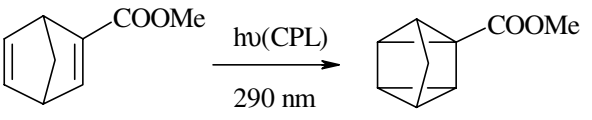
An alternative way of increasing the quantum yield (Φ) of the **1**→**2** photoreaction, as well as achieving a bathochromic shift of the long wavelength edge of N absorption λ_e, is by the substitution of the hydrogen atoms at one or both double bonds of N by suitable electron-withdrawing and electron-donating substituents. The push–pull type of substitution is required due to the well-established fact that for the majority of N derivatives with simple electron-withdrawing groups (COOH, COOMe, CN, SO_2Bu^t) at the 2- and 3-positions, λ_e is not greater than 365 nm.[87–90] The only known exception[8] is that of the bis[pentaammineruthenium(II)] complex of 2,3-dicyanonorbornadiene **39,** which absorbs at $\lambda_e \leq$ 700 nm; the quantum yield of the **39**→**40** rearrangement is, however, very low (8.3×10^{-4}).



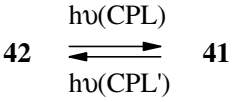
39 **40**

Mono- and 2,3-Disubstituted Norbornadienes

The process of synchronous enantiomeric enrichment of both reactant and product using circularly polarized light (CPL), for which the term new absolute asymmetric synthesis (NAAS) has been coined, was studied in detail for the case of methyl norbornadiene-2-carboxylate **41**.[91–93] This photorearrangement (irreversible NAAS) of racemic **41** produces the chiral product **42**. When **41** was irradiated with *r*-CPL at 290 nm, enantiomeric enrichment by (+)-**41** and (+)-**42** occurs. The inverse process was observed for *l*-CPL. The enantiomeric enrichment of **41** increases up to 100% enantiomeric excess (*ee*) at nearly 100% conversion, and the *ee* of **42** gradually decreases to zero at the end of reaction. These results suggest that one can obtain about 40% *ee* of **41** and **42** at 50% conversion if a starting material with an anisotropy factor *g* ($g = \Delta\varepsilon/\varepsilon$) of unity is used.

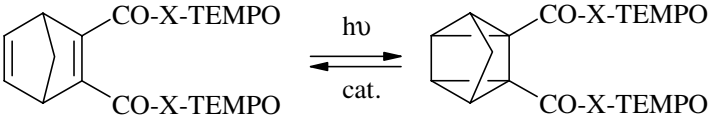


41 **42**



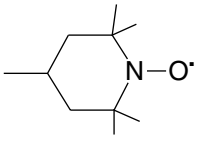
For the reversible photoisomerization, it was found that the *ee* of **41** and **42** concurrently increased by using CPL irradiation in such a way that if the *g* factors of **41** and **42** are large enough, the sign of the *g* factor of **41** is opposite to that of **42**, and the photochemical equilibrium constant is less than unity.[93]

With the aim of developing photoresponsive organomagnets, norbornadienes **43** with tetramethyl piperidine oxide (TEMPO) radical substituents were prepared and investigated.[19–21] Antiferromagnetic behavior was observed in the *bis*-amide-substituted valence isomers **43a** and **44a**. Intermolecular ferromagnetic interactions in the lower temperature region manifest themselves in **43b**. However, no substantial difference in magnetic properties of **43b** and **44b** has been found in spite of the difference in their Weiss temperatures.

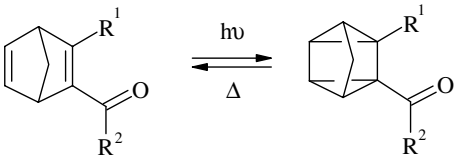


43 **44**

(a) X = NH (b) X = O; TEMPO =



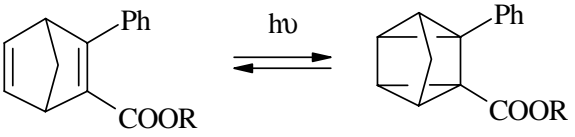
2-Aroyl-3-arylnorbornadienes **45**,[94] in which charge transfer occurs from the aryl to the aroyl group, thus helping to increase Φ and long-wavelength shifting λ_e, absorb at $\lambda_e \leq 450$ nm. Irradiation of their solutions with light of $\lambda_{irr} = 350$ nm yields the corresponding quadricyclanes **46** in high quantum yields ($\Phi = 0.30–0.60$). Electron-donating groups in the aroyl moiety favor an increase in both λ_{max} and Φ values, while a nitro group, although such substitution increases the λ_{max}, markedly reduces the quantum efficiency of the photoisomerization.



45 **46**

R^1 = Ph or 4-$R^3C_6H_4$, R^3 = Me, OMe, Cl or NO_2; R^2 = Ph or 4-$R^3C_6H_4$, R^3 = Cl or NO_2

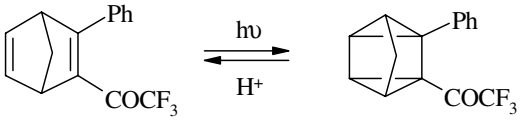
The photoisomerization of aromatic derivatives of N **47** into **48** was studied in different solvents.[95,96] These compounds absorb at λ_e < 360 nm, and quantum yields (Φ) are in the range of 0.18 to 0.36. The increase in fluorescence intensity during the irradiation of **47** was found and attributed to the formation of Q derivatives **48**. This peculiarity is probably due to the intramolecular or intermolecular self-quenching of the phenyl-ester fluorophore emission provoked by the N cycle.



47 **48**

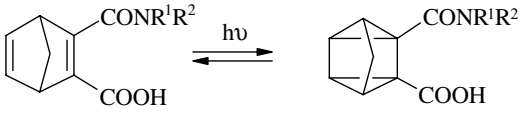
R = H, $PhCH_2$, 4-$MeOC_6H_4CH_2$ or 4-$MeOC_6H_4(CH_2)_6$

2-Trifluoroacetyl-3-phenylnorbornadiene **49** absorbs at $\lambda_e \leq 460$ nm, and the photoinitiated reaction **49**→**50** proceeds quantitatively in benzene with quantum yields of 0.62–0.86, depending on the concentration of the initial compound.[97]



49 **50**

The presence of amide and carboxyl groups at the 2- and 3-positions of N in **51** shifts λ_e up to the 365–415 nm range. The photoisomerization **51**→**52** can be performed not only in organic solvents but also in weakly alkaline aqueous solutions.[26,98–101] *N*-Alkylamides absorb at longer wavelengths than do *N,N*-dialkylamides. On irradiation of **51** in aqueous solutions, quadricyclanes **52** are formed with quantum yields of 0.1–0.6. An important photochemical behavioral principle[26] was postulated based on the study of the **51**→**52** photorearrangement: displacement of λ_e to longer wavelengths in the spectrum results in the decrease in quantum yields (Φ) of the photocyclization.

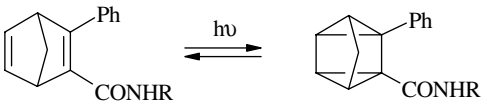


51 **52**

R^1 = H, Me, Ph CH_2, Ph, Ar, *t*-Bu; R^2 = H, Me, Ph; R^1-R^2 = -$(CH_2)_4$-, or 2-$(CH_2)_2C_6H_4$

The amides of 3-phenylnorbornadiene-2-carboxylic acid **53** absorb in the 280–305 nm spectrum region (λ_e = 375–435 nm).[27,102] Irradiation of their solutions with light of 313 nm results in the formation of **54**. Quantum yields for this photoisomerization (Φ = 0.15–0.71) depend on the nature of substituents in the amide fragment of **53**. Their values are increased for compounds with electron-withdrawing

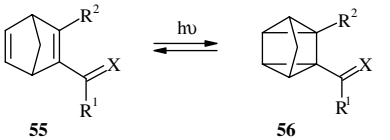
substituents and decreased for those containing electron-donating groups in the phenyl ring, when compared with unsubstituted *N*-phenyl-3-phenylnorbornadiene-2-carboxamide.



53 **54**

R = Ph, 4-MeC_6H_4, 2-MeC_6H_4, 4-$MeOC_6H_4$, 4-AcC_6H_4, 4-$CO_2EtC_6H_4$, 3-$NO_2C_6H_4$, α-$C_{10}H_7$ or β-$C_{10}H_7$

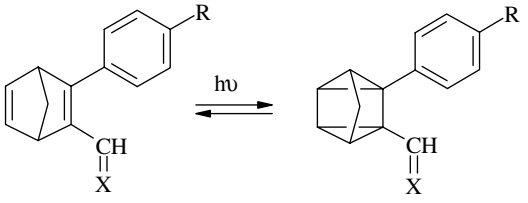
The carbonyl-containing norbornadienes **55** readily convert into the corresponding quadricyclanes **56** under irradiation with either light of 313 nm or 365 nm.[27,103–106] The compounds **55** have $\lambda_e \leq 500$ nm, and the quantum yields (Φ) of the **55**→**56** interconversion vary from 0.12 to 0.60. Of all these compounds, aroylvinylnorbornadienes **55** (R^1 = H, X = CHCOAr) possess the most suitable spectral characteristics for application to solar energy storage. At the same time, the unsubstituted 2-phenyl-3-(2-benzoylvinyl)norbornadiene **55** (R^1 = H, X = CHCOPh) (λ_{max} = 377 nm, λ_e = 450 nm) exhibits a low quantum efficiency (Φ 0.1) for the photocyclization. Substituents in the phenyl groups have little influence on the position of λ_{max} but significantly affect the values of the quantum yields. Thus, an electron-donating methyl substituent decreases Φ whereas introduction of electron-withdrawing substituents (Cl, Br, NO_2) increase Φ up to the value of 0.25. The quadricyclanes **56** easily revert to starting material **55** in the presence of homogeneous (CF_3COOH) and heterogeneous (MoO_3) catalysts.



55 **56**

R^1 = H, Me, OMe, CH=CHPh; R^2 = Br, 4-$R^3C_6H_4$, R^3 = H, Br, NO_2, NH_2; X = O, $CHCOC_6H_4R^4$-4, R^4 = H, Me, Cl, Br, NO_2, Ph

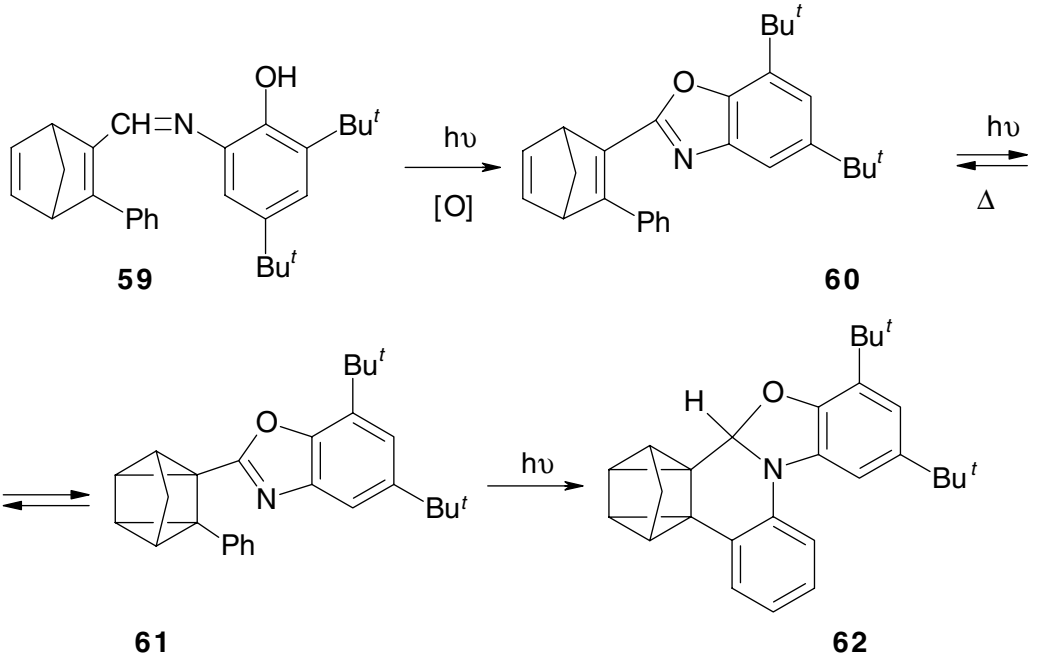
The long-wavelength absorption bands of 3-arylnorbornadiene-2-carbaldehyde derivatives **57** are shifted to the 340–505 nm region ($\lambda_e \leq 620$ nm).[27,104,106,107] Quadricyclanes **58** are readily formed by irradiation of isopropanol or acetonitrile solutions of **57** with light of 313, 365, or 436 nm (Φ = 0.10–0.75). The reverse reaction of the oximes **58** (X = NOH, NOMe) proceeds spontaneously at 293 K in the absence of catalysts. On the contrary, other compounds **58** are stable and form norbornadienes **57** only in the presence of MoO_3 ($k = 5 \times 10^{-3}$–10^{-3} sec^{-1}).



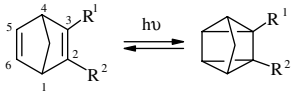
57 **58**

R = H, NO_2, NH_2; X = NOH, NOMe, NAr, N-NHPh, $C(CN)_2$, C(CN)COOEt, $C(COOEt)_2$

Irradiation of the imine **59** in methanol solution (λ_{irr} = 356 nm) causes oxidative photocyclization to give 2-(3-arylnorbornadien-2-yl)-benzo-1,3-oxazole **60**, which then converts to the quadricyclane isomer **61**.[108] The back thermal reaction **61**→**60** proceeds on heating the solution. Under prolonged UV-irradiation further (2 + 2 + 2)-photocyclization of **61**, followed by a 1,5-sigmatropic migration of a hydrogen atom, occurs. The resulting photoproduct **62** possesses intense fluorescence (λ^{fl}_{max} = 390 nm).



In order to study the influence of substituents on the geometry of the norbornadienyl moiety, x-ray structures of the compounds **63**, **64** have been investigated[109] and compared with the literature data for the parent norbornadiene **1**[4] and for 2-(2,2-diphenylvinyl)norbornadiene-3-carboxylic acid **65**.[110]

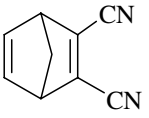


1, 63, 64, 65 **2, 66, 67, 68**

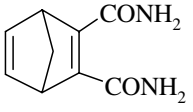
$R^1 = R^2 = H$ (**1**, **2**); R^1 = Ph, R^2 = CH=NPh (**63**, **66**); R^1 = Ph, R^2 = C=C(CN)$_2$ (**64**, **67**); R^1 = COOH, R^2 = CH=CPh$_2$ (**65**, **68**)

In **63**, the single bonds have normal lengths (average value 1.57 Å), whereas the C2=C3 double bond is lengthened to 1.342 Å, and the C5=C6 bond is shortened to 1.310 Å, as compared with the C=C bonds in unsubstituted norbornadiene **1** (1.339 Å). The C2=C3 double bond in **64**, to which a strong electron-withdrawing group C=C(CN)$_2$ is attached, shows additional lengthening up to 1.38(1) Å accompanied by shortening the C5=C6 bond to 1.29(2) Å. In accordance with these data, the quantum yields increase in the following sequence: 0.05 (**1**) < 0.15 (**63**) < 0.74 (**64**). Similar results were obtained earlier for **65**: the C2=C3 double bond is lengthened to 1.359(4) Å due to the π-conjugation with the substituent, and the C5=C6 double bond is shortened to 1.271(4) Å.[110]

The presence of two electron-withdrawing substituents attached to one of the ethylenic bonds of N (**69**, **70**) has a substantially less pronounced effect on the bond lengths.[111,112] For example, in **69**, the lengths of C2=C3 and C5=C6 double bonds are 1.341(3) Å and 1.285(4) Å, respectively. It may be assumed that push–pull substitution of hydrogens in one of the ethylenic bonds with electron-donating and electron-withdrawing substituents causes lengthening of the bond accompanied by the increasing of Φ and λ_e values of the corresponding N/Q system.



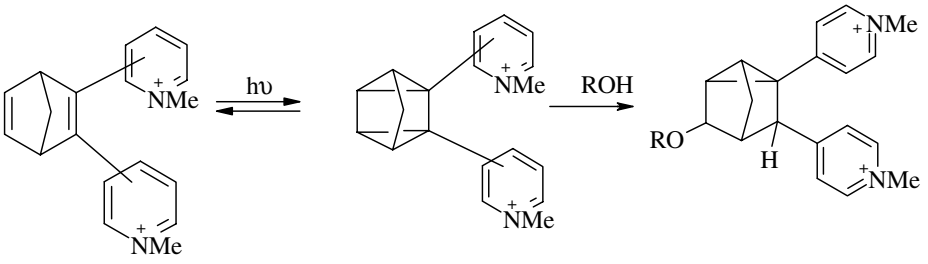
69



70

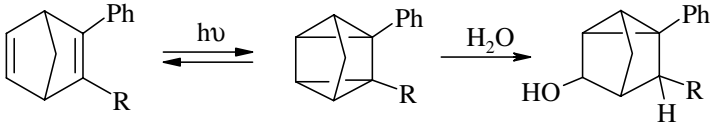
Norbornadienes Possessing Cationic Electron-Withdrawing Groups

In accordance with the above conclusion, organic cationic substituents in N cause significant changes in spectral and photochemical properties of the N/Q system. Quaternary salts of dipyridylnorbornadienes **71** absorb up to $\lambda_e \leq 470$ nm.[113,114] However, the **71**→**72** conversion is incomplete. Upon irradiation of solutions of **71** in acetonitrile with the light of $\lambda_{irr} = 350$ nm, a photostationary state is established between **71** and **72** containing about 70–88% Q. In the presence of water and methanol, the adduct **73** is obtained as the sole product of the photoreaction.



71 **72** **73** (R = H, Me)

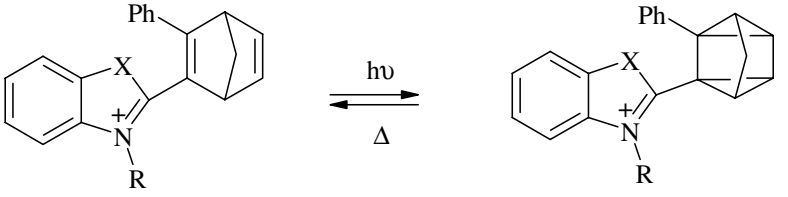
In some instances, there is instability of the cyclopropane rings in the quadricyclanes. This instability manifests itself when strong electron-withdrawing groups are attached to the system. Thus, the photorearrangement of norbornadienes **74** with pyrylium cation substituents[114] follows the usual path, but the product **75** is unstable and undergoes ring-opening to yield **76.** The value of λ_e reaches 580 nm, and the quantum yields (Φ) are 0.10–0.50. The reaction **74**→**75** is very sensitive to traces of moisture.



74 **75** **76**

R =  ; R^1, R^2 = H, Me

Benzoxazolyl derivative **77a** exhibits irreversible photoisomerization into the quadricyclane **78a**. The presence of an electron-donating NMe-group in the heterocyclic fragment of **77b** makes this process reversible.[27,115] The value of λ_e reaches 410 nm (**77b**), and Φ = 0.41–0.45. The reverse reaction **78b**→**77b** takes place upon heating the solution at 70°C.

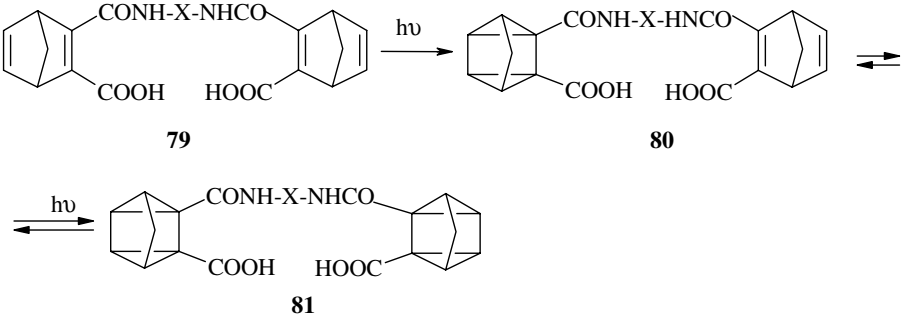


77 **78**

(a) X = O, R = H (b) X = NMe, R = Me

Biphotochromic Norbornadiene Derivatives

Compounds **79** containing two norbornadiene chromophores absorb at different wavelengths (a: λ_e = 370 nm; b: λ_e = 430 nm; c: λ_e = 475 nm). Upon irradiation with the light of the long-wavelength absorption band, they undergo stepwise isomerization first to monoquadricyclanes **80** and then to diquadricyclanes **81**.[26] N and Q moieties in all these systems do not interact with each other in either the ground or in the excited states. The quantum yields (λ_{irr} = 313 nm) of **79**→**80** and **80**→**81** decrease in the following order: **a** (0.58 and 0.56) > **b** (0.16 and 0.19) > **c** (0.035 and 0.034).

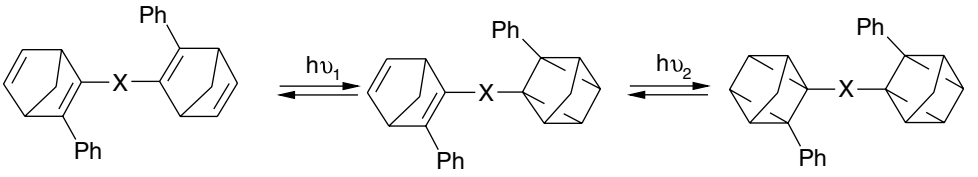


79 **80**

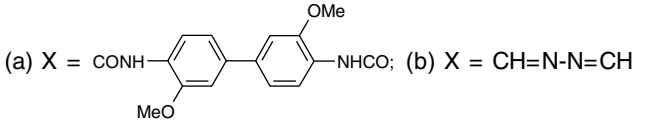
81

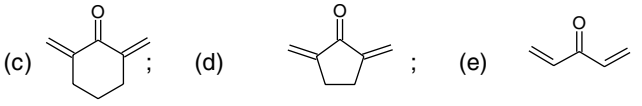
(a) X = $-(CH_2)_2-$; (b) X =  ; (c) X = 

Dinorbornadienes **82** absorb at long-wavelength spectral region $\lambda_e \leq 560$ nm. On irradiation of solutions of **82** in isopropanol with light of 365 nm (a) and 436 nm (b–e), valence isomerization into corresponding monoquadricyclanes **83** and then into the diquadricyclanes **84** occurs. The two-stage character of this reaction, postulated for the compounds **79**, is exemplified by the evolution of the UV spectra of **82b** as well as the NMR spectra. A new absorption band appearing at 380 nm characterizes the mono product **83b**. On prolonged irradiation with light of 365 nm, the formation of diquadricyclane **84b** (λ_{max} = 300 nm) is observed. The total quantum yields of **82**→**84** conversion are rather low, in the range 0.011–0.039.



82 **83** **84**





Two types of photochemical processes were found in dinorbornadienes **85**: *E/Z*-isomerization and valence isomerization into the diquadricyclanes **86**.[106] Quantum yields of the formation of **86** are about 0.025. The electronic absorption spectrum of **86** (λ_{max} = 340 nm) resembles that of 4,4′-dimethylazobenzene.[117] Diquadricyclanes **86** can revert into **85** with the aid of the heterogeneous catalyst MoO_3.

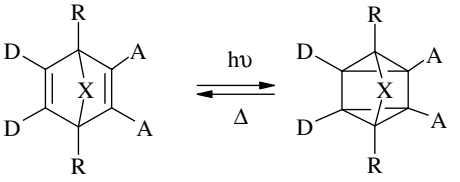
2,3,5,6-Tetrasubstituted Norbornadienes

Due to steric strain, the double bonds in N are pulled close together, which leads to the through-space interaction of their π-orbitals. This results in a considerable convergence of the energy levels of the frontier molecular orbitals.[1,118,119] This interaction manifests itself in the notably longer wavelength

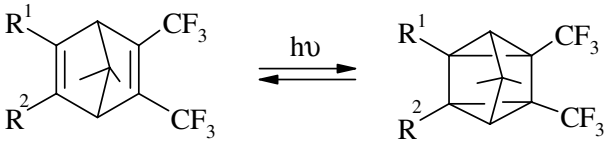
absorption than that expected for a compound with two isolated C=C bonds. A similar interaction is seen with electron-donating substituents attached to one of the double bonds of N, while electron-withdrawing substituents on the another C=C bond can lead to the appearance of a charge-transfer band in the visible spectral region. Such molecular systems as **87** have been called "donor–acceptor" norbornadienes.[25]



87 **88**

R = H, Me; X = CH_2, CMe_2; D = H, Me, Ph, C_6H_4OMe-4; A = CN, COOMe, COOEt, CONHPh

Depending on the nature of the substituents D and A in **87**, λ_e can vary from 345 to 558 nm, but the quantum yields of the N/Q photorearrangement remain high (0.26–0.96). Bathochromic shift of the long-wavelength absorption band of **87** is observed[16,25,120] with the increase of the electron-donating and electron-withdrawing capacities of D and A. The most important characteristic of "donor–acceptor" norbornadienes is that this shift of λ_e is not usually accompanied by a significant decrease in the quantum yield of the photoreaction **87**→**88**. The thermally reversible valence isomerization **87** $\rightleftharpoons$ **88** can be carried out in polymethylmethacrylate films, and the number of the cycles occurring without tangible changes in the initial absorption approaches 10^3. In solution, however, about 20% of **87** is decomposed.[16] However, despite the high Φ values, the visible light absorption is of low optical density with an extinction coefficient of the long-wave charge-transfer band of ε ~ 1000. Some of the quadricyclanes **88** are not stable enough at room temperature and gradually revert to the starting material. In order to stabilize "donor–acceptor" systems, trifluoromethyl substituted norbornadienes **89** were prepared and investigated.[121–123] The CF_3-substituted compounds **89** possess larger absorption coefficients (ε = 5000–20000) in the visible spectral region as compared with **87** and have $\lambda_e \leq 580$ nm. The absorption maxima of **89** tend to be red-shifted with increase in the electron-donating capacities of R^1 and R^2 groups, and the corresponding quadricyclanes **90** are thermally stable at 293 K. Due to these properties, "donor–acceptor" norbornadienes represent useful materials for energy and optical data storage.

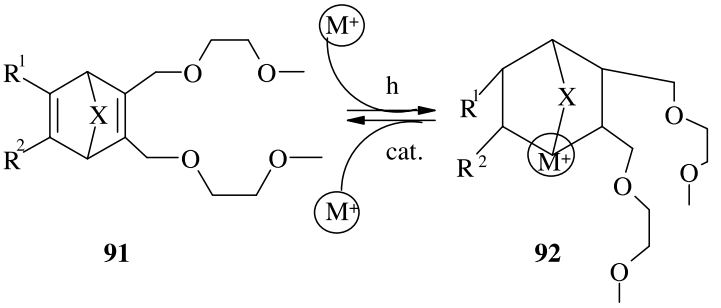


89 **90**

R^1, R^2 = 4-$MeOC_6H_4$, 4-$NMe_2C_6H_4$, 2-thiophenyl or 2-benzofuryl

Another application of 2,3,5,6-tetrasubstituted norbornadienes is their design as photoresponsive sensors for metal cations. The complexing ability of **91** is relatively low, but the corresponding quadricyclanes **92** with long-chain ether ligands containing six or eight oxygen donor atoms are able to extract Na^+ and K^+ from the aqueous phase into chloroform due to a grab or pincer-like movement of ligands

upon photoisomerization.[17,18] The systems **91b/92b** and **91c/92c** can be viewed as photochemically switchable polypodants.



91 **92**

(a) X = C=CMe$_2$; R^1 = H, R^2 = H;

(b) R^1 = CH$_2$O(CH$_2$)$_2$OMe, R^2 = H;

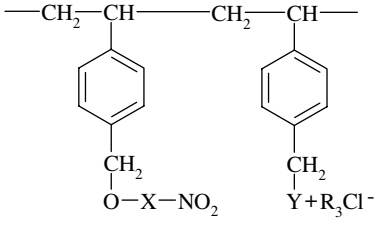
17.4 Photoresponsive Polymers Containing Norbornadiene and Photosensitizer Moieties

The N/Q isomerizations were studied for various polymeric materials containing norbornadienyl fragments in the main chain of the macromolecules or pendant N moieties and photosensitizers. These materials are designed mainly for solar energy storage and also for optical waveguides[11–14] and energetic binders for solid rocket propellants.[22]

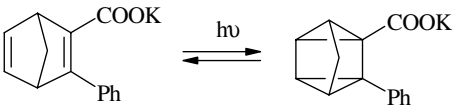
Polymers Containing Photosensitizer Units

Immobilized benzophenone or acetophenone molecules can be used as effective photosensitizers of the **1**→**2** conversion.[124,125] However, photostability of such polymeric systems is rather low. A new type of multifunctional polymeric photosensitizers **93** containing both pendant nitroaryloxy group functioned as the interposed sensitizer, and pendant ammonium or phosphonium salts as the substrate-attracting groups were applied for initiating the photoconversion of substituted N **94**→**95**.[126] Quantum yields of this reaction occurring in water solution under irradiation with 366 nm light were found to be 0.19 and 0.42 in the absence and in the presence of the sensitizers **93**, respectively. This result indicates that the energy transfer occurs effectively from the multifunctional S **93** to **94**.



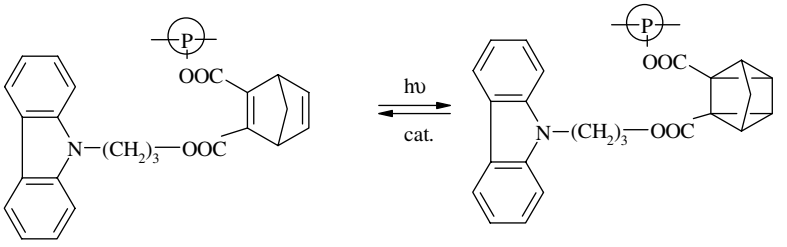
93

X =  ; Y = P, N; R = Pr, Bu, Hex

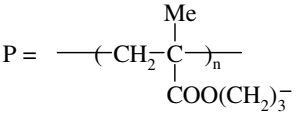


94 **95**

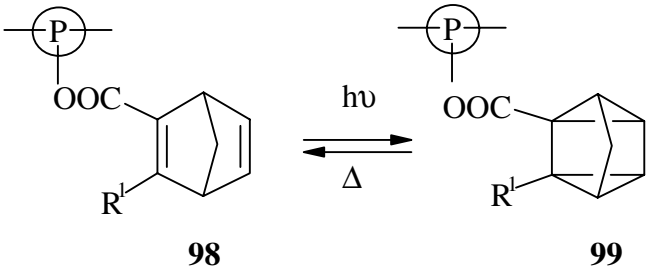
When irradiated with visible light (λ_{irr} > 350 nm), polymeric systems **96** containing N and carbazole pendants (S) undergo the valence N→Q isomerization.[127] The electron transfer mechanism: S–N (**96**) $\xrightarrow{h\nu}$ ^{1}S–N → ^{1}[S$^+$–N$^-$] ⇌ ^{3}[S$^+$–N$^-$] → S–^{3}N → S–Q (**97**) was proposed for this transformation. The reverse reaction proceeded smoothly under the action of catalytic amounts of cobalt porphyrin or trifluoroacetic acid.



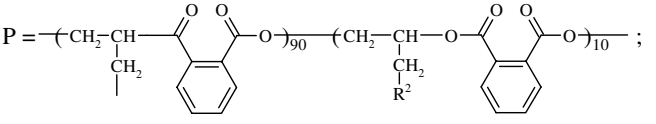
96 **97**

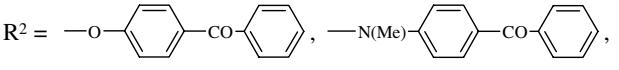


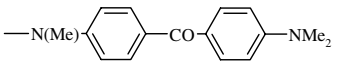
The valence isomerization **98**→**99** photosensitized by energy transfer from the benzophenone groups proceeds smoothly and in high quantum yields (Φ = 0.62–0.84) not only in polymeric films, but also in dichloromethane solution.[128] All the compounds **99** had good stability and can release about 90 kJ mol^{-1} of stored thermal energy.



98 **99**

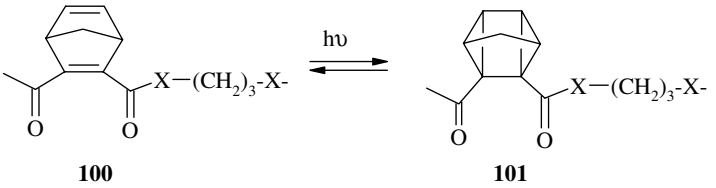




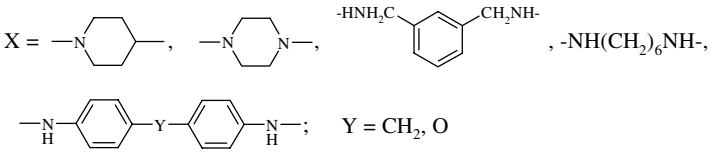


Polymers Containing Norbornadiene Residues in the Main Chain

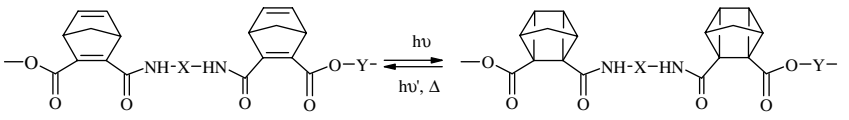
The photoconversion of N residues in polyamides **100** occurs selectively without any side reactions in the polymeric film as well as in a dichloromethane solution.[129–131] 4-(*N*,*N*-Dimethylamino)benzophenone and Michler's ketone strongly sensitize this photoreaction in the films.



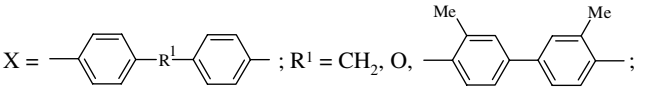
100 **101**



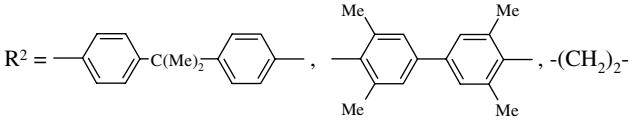
The photochemical valence isomerization of N residues in poly(ester-amide)s **102** occurs smoothly to give the corresponding quadricyclane-containing polymer **103** upon irradiation with sunlight in films or in THF solution.[132] The back-photochemical reaction proceeds also in the polymeric films **103** under irradiation with 272 nm light. The value of the stored thermal energy in such systems is about 84 kJ mol^{-1}.



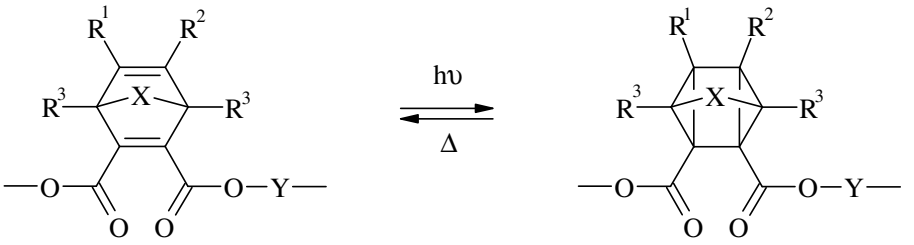
102 **103**



Y = -CH_2-CH(OH)-CH_2-O-R^2-O-CH_2-CH(OH)-CH_2-;



Photoresponsive polyesters containing donor–acceptor norbornadienyl residues in the main chain of the macromolecule were obtained and investigated.[133,134] The long-wavelength absorption of the compounds **104** with λ_e at nearly 500 nm is due to the appearance of the charge-transfer absorption band.[134] The back dark reaction proceeds at room temperature, and its rate can be controlled by structure of the polymer.



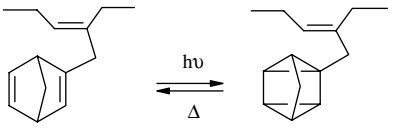
104 **105**

X = CMe_2; R^1 = 4-$MeOC_6H_4$; R^2 = Me, 4-$MeOC_6H_4$; R^3 = H, Me;

Y = -CH_2-CH(OH)-CH_2-O-R^4-O-CH_2-CH(OH)-CH_2-;

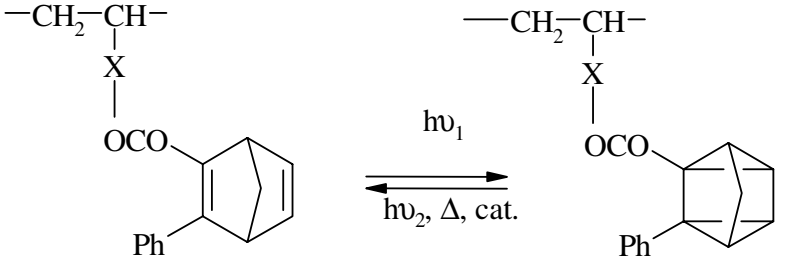
R^4 = 
Polymers Containing Pendant Norbornadiene Moieties

The poly-isoprene derivative **106** readily undergoes photochemical isomerization to quadricyclane **107** in the presence of $(PPh_3)_2CuBr$ in benzene solution.[22] The reaction in the solid state is thermally reversible at 180°C.



106 **107**

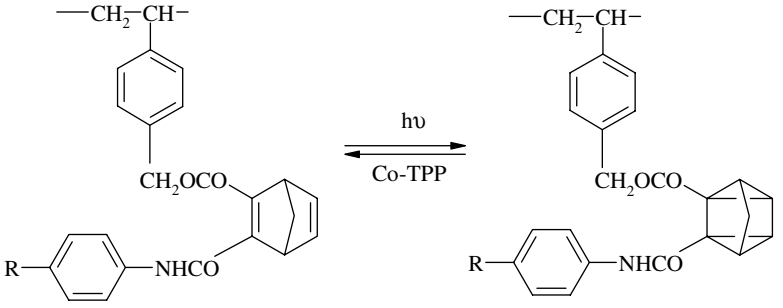
Under irradiation with 313 nm light, polymers **108** bearing 3-phenylnorbornadiene-2-carboxylic acid residues readily isomerize into the corresponding quadricyclanes **109**.[135–137] For **109b**, the back photoreaction (λ_{irr} = 248 nm) also occurs on heating the polymeric films at 100°C or in the presence of (5,10,15,20-tetraphenyl-21H,23H-porphine)cobalt(II) catalyst (Co-TPP) in a dichloromethane solution.



108 **109**

(a) X = 
(b) X = -O-$(CH_2)_2$-

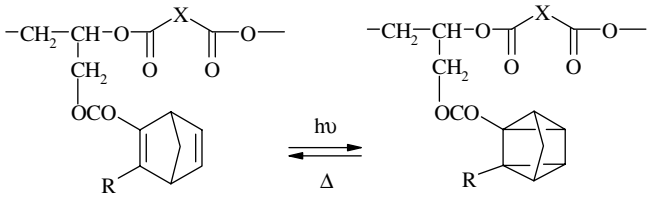
The red shift of λ_e up to 425 nm is achieved for the polymers **110** in comparison with **108**.[138] The rate of the **110**→**111** conversion is strongly affected by *para*-substituents in the benzene rings in the order of rate constants: **110e** < **110d** ≤ **110a** < **110b** < **110c**. The storage energy of Q moieties in **111** was determined to be about 60 kJ mol^{-1}. By replacing the carbamoyl group in the 3-position of N moieties of **111** by *N,N*-disubstituted amide groups, the stored energy can be increased up to 80–86 kJ mol^{-1}.[139] Poly(glycidyl methacrylate-co-methylmethacrylate)s containing the same pendant N moieties as in **108** and **110** produce under UV-irradiation the corresponding Q derivatives, which can gradually release thermal energy when Co-TPP is present in the solid films.[140]



110 **111**

(a) R = H, (b) R = Me, (c) R = OMe, (d) R = Cl, (e) R = COMe, (f) R = NO_2

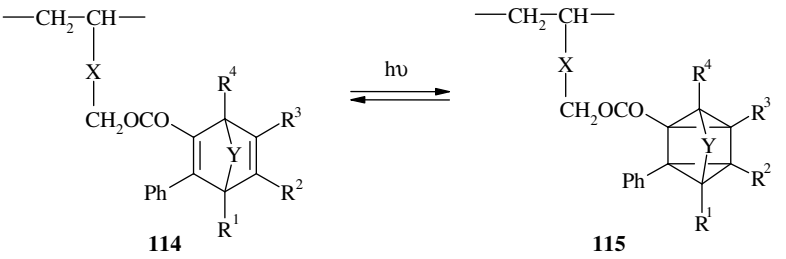
Under UV-irradiation, polyesters **112** with N moieties readily form the photoproduct **113** with quantum yields in the 0.33–0.41 range.[141] The reverse reaction occurs thermally. The stored thermal energy is about 90 kJ mol^{-1}.



112 **113**

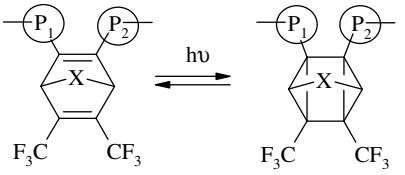
X =  ; R = Ph, $CONPr_2$, COOMe

Enhancement of the photoreactivity and cyclicity of the N/Q transformations of N-containing polymers is very important for their use in solar energy storage processes. With this purpose in mind, the polymers **114** with pendant donor–acceptor type N moieties were prepared.[142] Unexpectedly, these compounds were found to absorb light only up to $\lambda_e \leq 350$ nm. The polymers **114** isomerize quantitatively to **115** and show good repeatability of the N/Q interconversion. Methyl groups in the N moieties decrease the durability of the N-containing polymers **114**. Heating of the polymers **115** releases 55–74 kJ mol^{-1} of thermal energy.

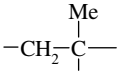


X =  , -O-CH_2- ; Y = CH_2, CHMe; $R^1 = R^2 = R^3 = R^4$ = H, Me

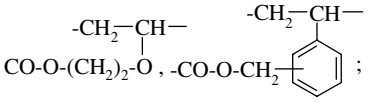
Excellent values of $\lambda_e \leq 505$ nm were achieved in the polymers **116** containing trifluoromethyl substituents in the N moieties.[143]



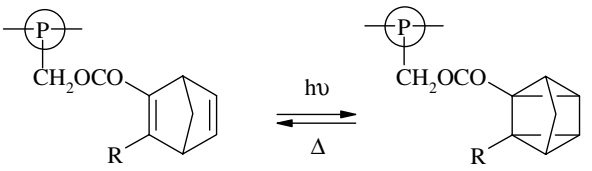
P_1 =  , R^1 = H, CO-; P_2 =  ,



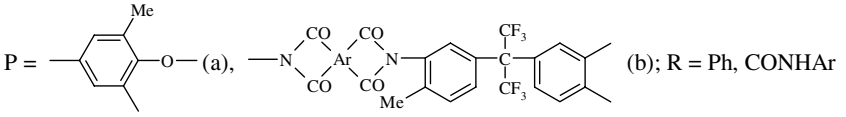
R^2 = CO-$(CH_2)_6$-O-,  , CO-O-CH_2-CH(OH)-CH_2-OCO,



; X = CMe_2

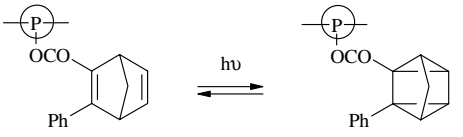


118 **119**

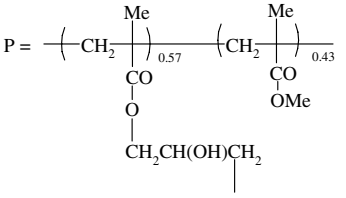


Polymers for Optical Devices

The highly efficient and low-cost procedures for the direct production of channel polymeric wave guides utilizing photochromic reactions have many advantages since such systems do not need to use photoresists and etching.[11–14] The requirements for a suitable material are substantial change in the refractive index triggered by irradiation with light and high transparency as well as thermal and chemical stability. The polymer **120** meets these requirements. The **120**→**121** valence photoisomerization occurs with 50% quantum yield.[147]



120 **121**



The refractive index change produced by this rearrangement is about 0.01 in the spectral region far outside of the absorption band (~ 633 nm). The polymer **120** has a good potential for application in channel wave guides and photo-optical switching devices.

Copper(I)-Catalyzed Inter- and Intramolecular [2 + 2]-Photocycloaddition Reactions of Alkenes

Subrata Ghosh
Indian Association for the Cultivation of Science

18.1 Introduction

Photoinduced [2 + 2]-cycloaddition of alkenes to form cyclobutanes is one of the most well-studied and synthetically useful reactions among all the photochemical processes. The utility of this reaction in organic synthesis stems from its ability to create in a single step a complex multicyclic carbon network[1,2] with up to four asymmetric centers on the cyclobutane ring in a regio- and stereoselective fashion. The scope of this photoreaction has been widened further by the proclivity of the cyclobutane ring to undergo facile ring expansion and carbon–carbon bond fragmentation. A sequence of [2 + 2]-photocycloaddition and ring expansion or C-C bond fragmentation has been extensively employed for the construction of five-[3] to eight[4]-membered rings.

The generally accepted mechanism[5] that accounts for the majority of the $2\pi + 2\pi$ photocycloaddition reactions involves excitation of the alkene on UV irradiation either directly or sometimes with sensitizer to the triplet-excited state. Quenching of the triplet-excited state by a ground-state alkene leads to an excited-state complex or exciplex that either directly or through biradical intermediates gives rise to cyclobutanes. The actual mechanism involved in a cycloaddition process depends on the substrates and the reaction conditions employed. Alkenes conjugated to a π-system, such as enones having UV absorption maxima around 300 nm, easily lead to triplet-excited states on direct irradiation, and these add to a ground state alkene to give cyclobutanes. A classic example of enone–olefin cycloaddition[6] is the addition of isobutylene to cyclohexenone **1** to produce the adduct **2** (Scheme 1).

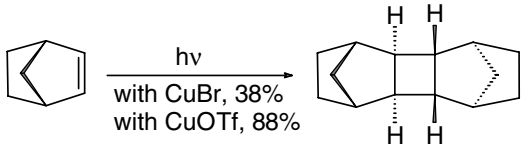
1 **2**

SCHEME 1



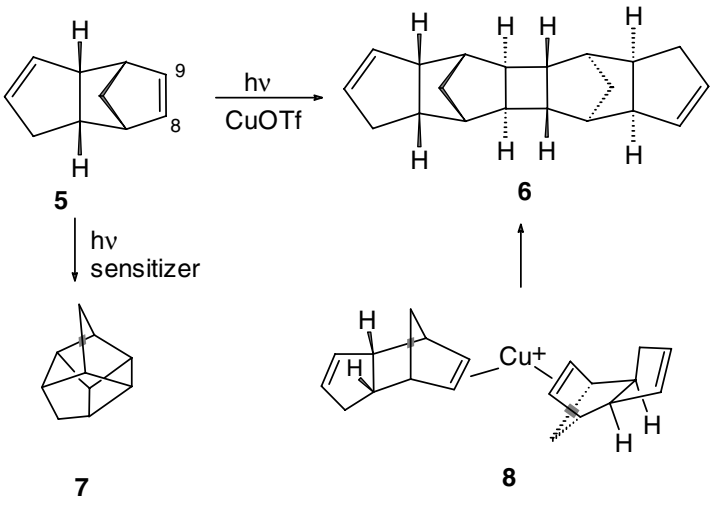
3 **4**

SCHEME 2

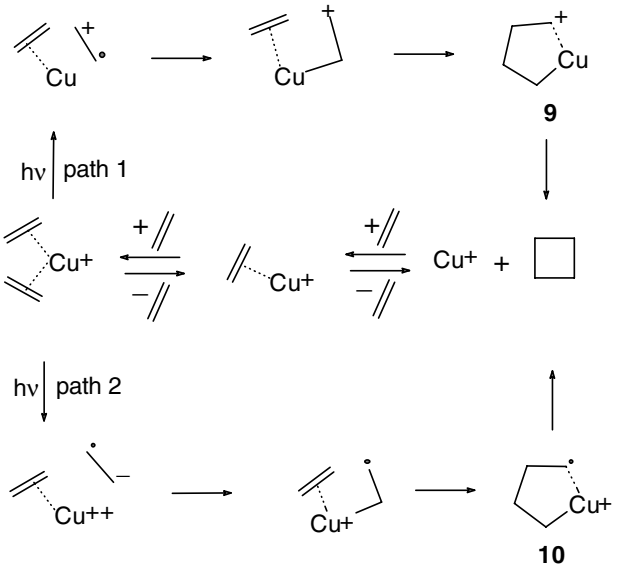
Nonconjugated alkenes have UV absorption maxima at 190–200 nm and thus require high energy for excitation not available from conventional photochemical equipment. Triplet energies are also relatively high. Thus, photocycloaddition between simple alkenes is difficult to attain through direct irradiation or sensitization. However, in the presence of transition metal salts, such alkenes exhibit UV absorption maxima around 240 nm. Thus, nonconjugated alkenes can be raised to the excited state when irradiated in the presence of transition metal salts[7] and undergo [2 + 2]-photocycloaddition. Although there are reports of the use of several transition metals,[7] copper(I) salts, especially copper(I) trifluoromethane sulfonate(CuOTf), first reported by Salomon and Kochi[8] as the 2CuOTf C_6H_6 complex, has been found to be the most efficient and selective for [2 + 2]-cycloaddition. The remarkable feature of the Cu(I)-catalyzed photocycloaddition reaction of the alkenes is the stereochemical outcome that leads preferentially to a single diastereoisomer especially in case of intramolecular reactions. A brief account of the mechanism, stereochemical aspects, and synthetic applications of Cu(I)-catalyzed [2 + 2]-photocycloaddition reactions is presented here.

18.2 Mechanism of Catalysis

Copper(I)-catalyzed [2 + 2]-photocycloaddition between two nonconjugated alkenes involves coordination of both the reacting alkene units in their ground states with a single copper(I). Photoexcitation of this bis-alkene-Cu(I) complex leads to a cyclobutane with regeneration of the Cu(I) catalyst. That Cu(I) forms complexes with alkenes was evidenced by isolation of several olefin-Cu(I) complexes.[8–10] The involvement of a bis-alkene-Cu(I) complex in [2 + 2]-photocycloaddition was obtained from dimerization of norbornene **3** when irradiated in the presence of CuCl or CuBr to afford mainly the dimer **4** in 38% yield (Scheme 2).[11] While norbornene and CuBr separately are almost transparent in the UV, an intense UV absorption band at 239 nm was observed for a solution containing norbornene and CuBr. A 1:1 norbornene-Cu(I) complex was also isolated. No dimer formation was observed on irradiation of this complex in ether solution. However, irradiation of the complex in the presence of excess norbornene provided[12] the dimer **4**. Thus, dimer formation presumably involves a complex having one Cu bonded to two norbornene units. Irradiation of norbornene in the presence of CuOTf affords the dimer **4** in 88% yield.[13] NMR investigations[14] have shown that with CuOTf, both 1:1 and 1:2 Cu(I)-alkene complexes with the same UV absorption spectra are formed. Quantum yield experiments confirmed that it is the 1:2 complex that leads to dimer production. Thus, copper(I)-catalyzed [2 + 2]-photocycloaddition of alkenes requires ground-state coordination of both reacting alkene bonds with a single Cu(I).[7] The requirement of a 1:2 Cu(I)-alkene complex is confirmed further by the almost exclusive formation of the



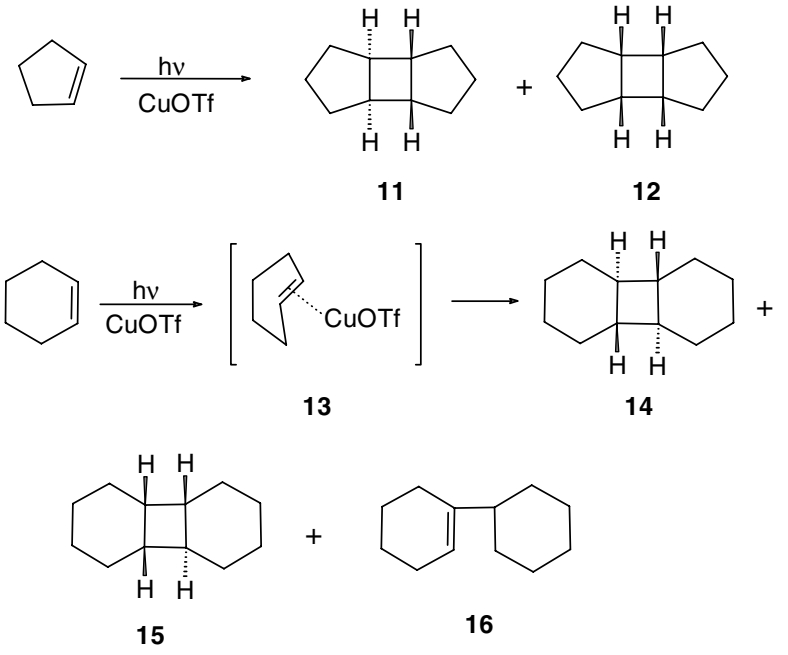
SCHEME 3



SCHEME 4

dimer **6**[14] from CuOTf-catalyzed photocycloaddition of *endo*-dicyclopentadiene **5**, which on sensitized irradiation[15] undergoes intramolecular cycloaddition to afford **7** (Scheme 3). A 1:2 Cu(I)-dicyclopentadiene complex **8** involving the more strained $\Delta^{8,9}$-bond has also been isolated.

The CuOTf-norbornene complex shows two UV absorption maxima at 236 nm (ε 3400) and 272 nm (ε 2000). The shorter wavelength absorption possibly arises through a metal-to-alkene ligand charge transfer (MLCT) excitation[16], while the longer wavelength absorption is assumed to be due to an alkene ligand-to-metal charge transfer (LMCT) excitation. The relative contribution of these two interactions is dependent on the olefin involved, as determined by NMR investigation[17,18] of the metal–alkene complex. Assuming bond formation to be a sequential process, LMCT (Path 1) and MLCT (Path 2) (Scheme 4)



SCHEME 5

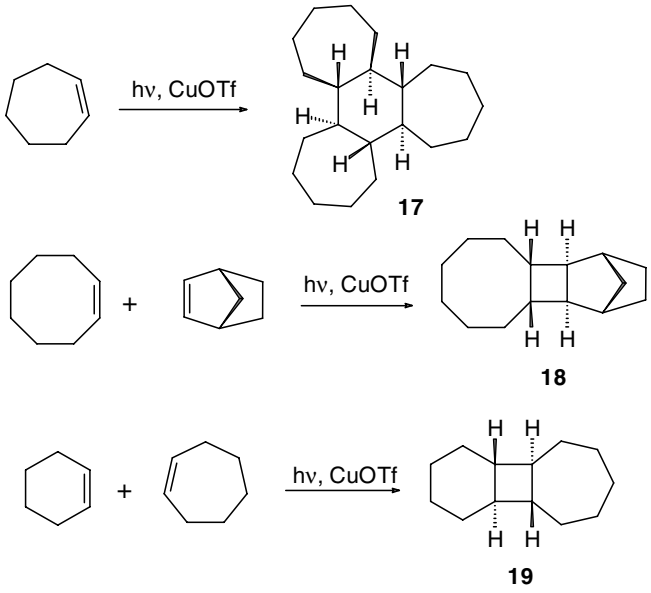
excitation may proceed through cyclization of either cationic or radical alkyl copper intermediates **9** or **10**, respectively. It has not yet been settled which of these processes actually leads to photocycloaddition. There is evidence in support of both radical[19] and cationic paths.[14,20,21] A concerted pathway[22] has also been supported by intermolecular cycloaddition studies.

Catalyst for [2 + 2]-Photocycloaddition

It is now well established that Cu(I)-catalyzed [2 + 2]-photocycloaddition of alkenes requires formation of a complex in which one copper is coordinatively linked with two alkene units. Among the various copper salts (CuCl, CuBr, CuOTf) used, the triflate anion in CuOTf has exceptional weak coordinating ability compared to halide ions, which compete with alkene for coordination with copper. Thus, CuOTf exhibits a strong tendency to form 1:2 Cu-alkene complexes compared to CuCl or CuBr. This is reflected in improved yields of adducts obtained with CuOTf rather than CuCl or CuBr (*vide infra*). In addition, CuOTf is soluble in most organic solvents and is stable under the photochemical reaction conditions. Hence, CuOTf is the catalyst of choice for [2 + 2]-photocycloaddition between two nonconjugated alkenes.

18.3 Intermolecular Photocycloadditions

Copper(I)-catalyzed intermolecular photocycloaddition requires that one of the reacting alkenes must be highly strained and reactive. It was already stated that norbornene **3** undergoes intermolecular addition to form the dimer **4** (Scheme 2) in 38% yield with CuBr and in 88% yield[13] with CuOTf as the catalyst. This is the first example of copper(I)-catalyzed intermolecular [2 + 2]-photocycloaddition.[11] Similarly, *endo*-dicyclopentadiene **5**, on irradiation in the presence of CuOTf, undergoes [2 + 2]-addition at the more stained 8,9-double bond to form the dimer **6**[14] (Scheme 3). Cyclopentene does not undergo dimerization with CuBr, while with CuOTf it forms the dimers **11** (30%) and **12** (2%) (Scheme 5).[22]



SCHEME 6

Irradiation of cyclohexene in the presence of CuOTf produces the dimers **14** (49%) and **15** (8%), along with the cyclohexylcyclohexene **16** (24%) (Scheme 5).[22] The stereochemical outcome in Cu(I)-catalyzed dimerization of cyclohexene may be the result of *cis-trans* isomerization on irradiation of the initially formed Cu(I)-cyclohexene complex to the *trans*-cyclohexene-CuOTf complex **13**, followed by a concerted ground state $2_{\pi a} + 2_{\pi s}$ cycloaddition of the highly strained *trans*-cyclohexene to another cyclohexene. Cycloheptene, on the other hand, produces the all *trans*-fused trimer **17** (Scheme 6) as the sole product.[23] A 1:3 CuOTf-*trans*-cycloheptene complex has been proposed to be the precursor of this product. No dimerization reaction has been observed for cyclooctene[14] and acyclic olefins.[22] However, mixed photocycloaddition occurs with cyclooctene if the other olefin is sufficiently reactive. Thus, cyclooctene adds to norbornene to produce the cyclobutane derivative **18** in 40% yield.[14] Codimerization was also observed when a mixture of cyclohexene and cycloheptene was irradiated in the presence of CuOTf to yield the adduct **19** (Scheme 6).[24]

Photocycloaddition of alkenes having allylic functional groups is of special significance, as the resulting cyclobutanes provide scope for further synthetic transformations. Allyl alcohol has been found to add to strained cycloalkenes only. Thus norbornene and *endo*-dicyclopentadiene, when irradiated in the presence of CuOTf with allyl alcohol as solvent, produce a pair of the cyclobutanes **20**, **21** and **22**, **23**, respectively (Scheme 7).[25] It is reasonable that the equilibrium between the complex **8** required for dimerization of dicyclopentadiene and the complex **24** required for the formation of **22** and **23** strongly favors the complex **24** in allyl alcohol due to additional coordinative interaction by the OH group of the allyl alcohol. No intermolecular cycloaddition between cyclohexene and allyl alcohol was observed, as the required mixed ligand complex having Cu(I) linked to both cyclohexene and allyl alcohol is not formed due to weak coordinating ability of cyclohexene with copper. Even cycloaddition between two units of allyl alcohol was not observed. However, irradiation of a dilute solution of allyl alcohol in dioxane in the presence of CuOTf does lead to photocycloaddition yielding 3-oxabicyclo[3.2.0]heptane **26** through intramolecular cycloaddition of *in situ* generated diallyl ether **25** (Scheme 8).[26] Interestingly, while acyclic olefins fail to undergo intermolecular [2 + 2]-photocycloaddition,[22] intramolecular cycloaddition of acyclic dienes proceeds smoothly. This observation has added a new dimension to copper(I)-catalyzed [2 + 2]-photocycloaddition of alkenes.

18.4 Intramolecular [2 + 2]-Photocycloadditions

Copper (I)-catalyzed intramolecular photocycloaddition between two acyclic double bonds was first observed by Evers and Mackor in 1978.[26] They demonstrated that although 3-oxabicyclo[3.2.0]heptane **26** is formed from diallyl ether **25** (Scheme 8), 4-hydroxy-1,6-heptadiene **27** produces an *endo,exo* (3:2) mixture of 3-hydroxy bicyclo[3.2.0]heptanes **28** (Scheme 9) on irradiation in presence of CuOTf. The generality and scope of this reaction were investigated in great detail by Salomon et al.[27] The acyclic dienes

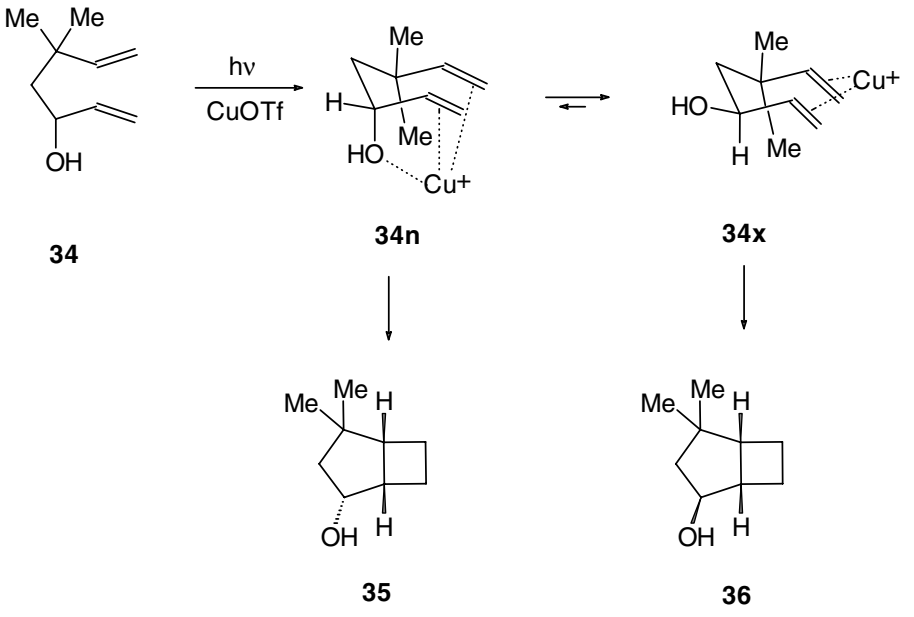
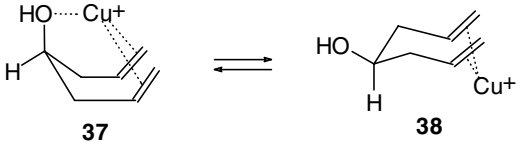
investigated so far include 1,6-heptadienes, diallyl ethers, homoallyl vinyl ethers, and *N,N*-diallyl carbamates.

[2 + 2]-Cycloaddition of 1,6-heptadienes

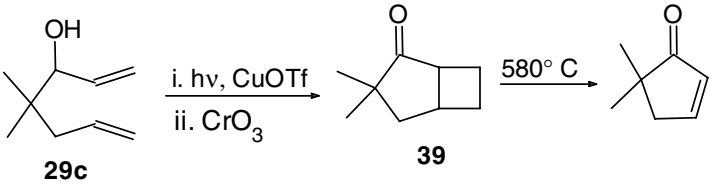
Copper(I)-catalyzed intramolecular photocycloaddition of 1,6-heptadiene-3-ols **29** provides an efficient route for the synthesis of bicyclo[3.2.0]heptan-2-ols **30** and **31** (Scheme 10).[27–30] Generally, a great preference for stereoselective generation of the thermodynamically less stable *endo*-2-hydroxy diastereoisomer **30** (Table 18.1) was observed. The observed selectivity is attributed to the behavior of the dienols **29** acting preferentially as a tridentate ligand shown in structure **32** rather than a bidentate ligand as in structure **33**. In contrast to the strong preference for *endo*-selectivity in the photocycloaddition of the dienes **29**, the dienol **34** produces *endo*-**35** and *exo*-**36** in a ratio of 3:4 (Scheme 11). The complex **34x** producing the *exo*-alcohol **36** is favored over the tri-coordinated Cu(I)-complex **34n** due to unfavorable steric interference by a Me substituent in the 5-position. The Cu(I)-catalyzed photocycloaddition of 1,6-



SCHEME 11



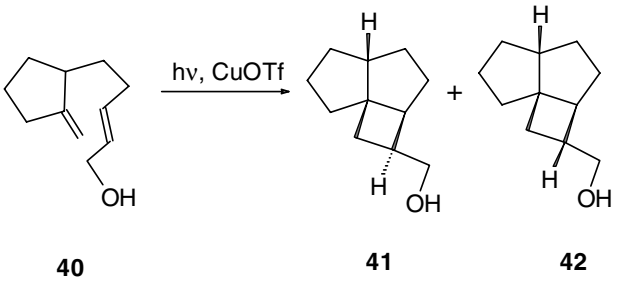
SCHEME 12



SCHEME 13

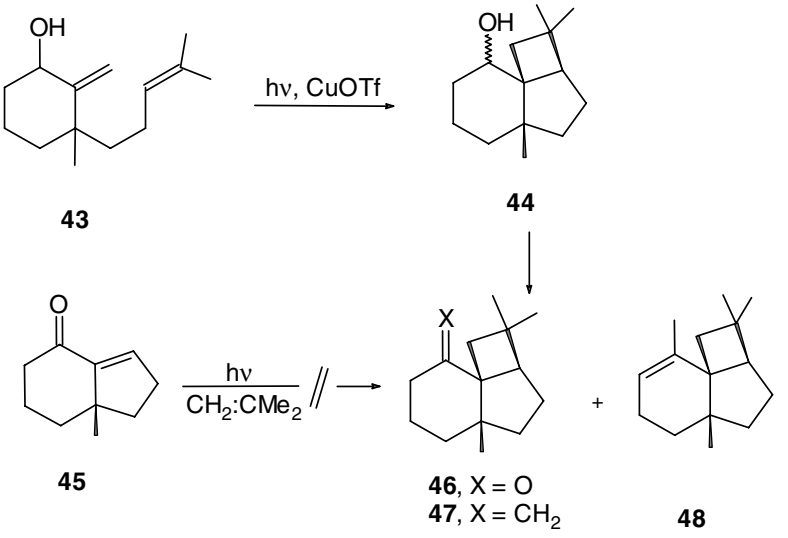
heptadien-4-ol **27**, with the OH group at the homoallylic position, is nonstereoselective producing a 3:2 *endo-exo* mixture of bicyclo[3.2.0]heptane-3-ols **28** (Scheme 9). In this case the *exo*-alcohol formation requires a tri-coordinated complex **37**[28] having a boat-like conformation that is disfavored in comparison to the chair-like arrangement in the complex **38** (Scheme 12). Thus, the presence of a hydroxyl group at the allylic position in 1,6-heptadiene plays a crucial role in determining the stereochemical outcome during the photocycloaddition.

The copper(I)-catalyzed photocycloaddition of 1,6-heptadien-3-ols **29**, in conjunction with oxidation of the resulting bicyclic alcohols to bicyclo[3.2.0]heptan-2-ones, as illustrated by the transformation of **29c** to **39** (Scheme 13), provides an alternative route to $2\pi + 2\pi$ intermolecular photocycloaddition of



40 **41** **42**

SCHEME 14



43 **44** **45**

46, X = O
47, X = CH_2 **48**

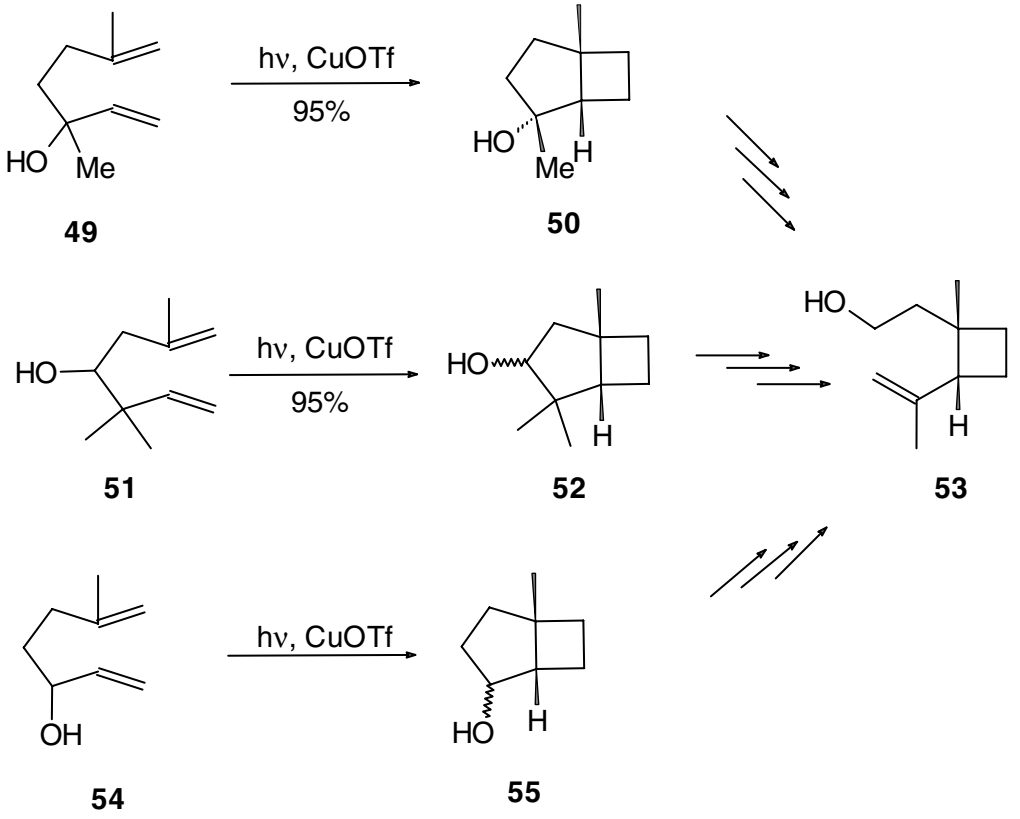
SCHEME 15

olefins to cyclopent-2-en-1-ones. Pyrolysis of the bicyclo[3.2.0]heptan-2-ones provides a new route to cyclopentenones also.[27] For example, the bicyclic ketone **39** on pyrolysis provides 6,6-dimethylcyclopent-2-en-1-one (Scheme 13).

Tricyclic ring systems can also be constructed when one of the alkene units of the 1,6-heptadiene is part of a ring. For example, the dienol **40** leads to the tricyclic products **41** (68%) and **42** (23%) (Scheme 14).[29] The loss of stereospecificity in the products probably arises due to competing copper(I)-catalyzed geometric isomerization of the *trans*-allylic alcohol during photocycloaddition.

Stereoselective copper(I)-catalyzed [2 + 2]-photocycloaddition of 1,6-heptadienols has been used as a key step in the synthesis of several natural products. The total synthesis of the sesquiterpenes α-panasinsene **47** and β-panasinsene **48** has been achieved by CuOTf catalyzed photocycloaddition of the dienol **43** as the key step (Scheme 15).[31] The resulting bicyclo[3.2.0]heptanol **44** was then converted to the natural products through the ketone **46**. It is noteworthy that direct access to the requisite intermediate **46** involving photoaddition of isobutylene to the enone **45** failed, illustrating the importance of the copper(I)-catalyzed photocycloaddition of 1,6-heptadienols.

The bicyclo[3.2.0]heptanols obtained through this cycloaddition process can be exploited for the stereocontrolled synthesis of 1,2-disubstituted cyclobutanes. The concept is demonstrated by the synthesis of grandisol **53** (Scheme 16), the pheromone of the male cotton boll weevil. Rosini et al. have described

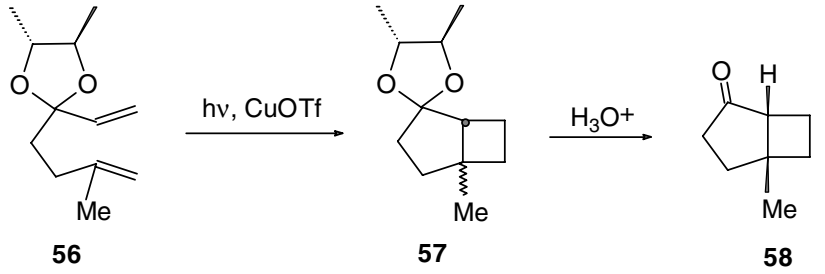


SCHEME 16

two stereoselective routes involving bicyclo[3.2.0]heptanols **50** and **52** as the intermediates.[32,33] These were obtained in excellent yields from CuOTf catalyzed photocycloaddition of the 1,6-heptadienols **49** and **51**, respectively. The functionalized cyclopentane ring in **50** and **52** was then cleaved to provide, finally, (±)-grandisol. Rosini et al.[34,35] have also achieved enantiomerically pure compound (EPC) synthesis of both enantiomers of grandisol through resolution of the bicyclo[3.2.0]heptanol **50**. Langer et al.[36] have also accomplished a racemic synthesis of grandisol through the bicyclo[3.2.0]heptanol **55** obtained through copper(I)-catalyzed photocycloaddition of the 1,6-heptadien-3-ol **54**. Later, this group completed enantioselective synthesis of (+)- and (–)- grandisol using enantiomerically pure dienol **54**.

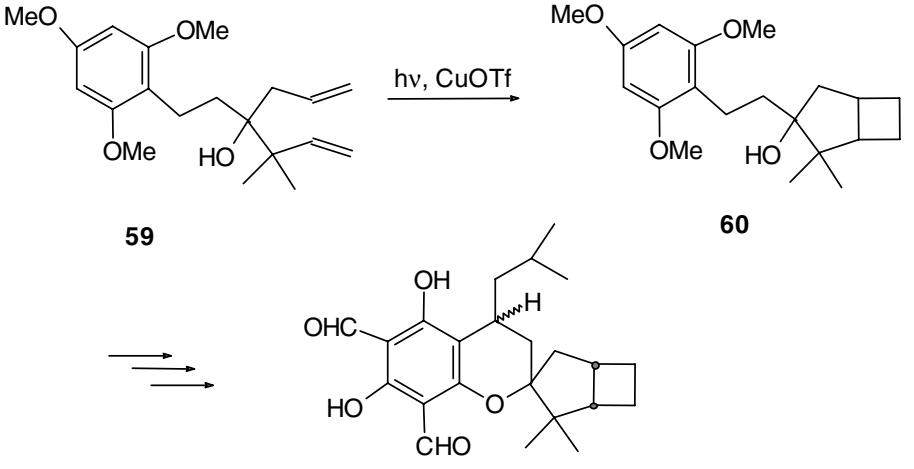
In connection with the enantioselective synthesis of grandisol, Langer and Mattay[37] explored several different approaches for asymmetric induction during [2 + 2]-photocycloaddition of 1,6-heptadienols. One of these approaches involves the use of chiral Cu(I)-complexes as the catalyst. This has resulted in photoadducts with very low enantiomeric excess (ee) (<5%). The low *ee*s have been attributed to the poor coordinating ability of the Cu(I) of the chiral Cu-complexes with alkenes. The other approach investigated involves photocycloaddition of dienes having a chiral auxiliary. Thus, reaction of 1,6-heptadien-3-ol having a chiral auxiliary attached to the 3-hydroxy group afforded bicyclo[3.2.0]heptan-2-ols with *ee*s of up to 15%. In another approach, the diene **56**, having a ketal made of a chiral diol, gives on CuOTf catalyzed photocycloaddition and auxiliary removal from the photoadduct **57**, the bicyclic ketone **58** with *ee*s of up to 60% (Scheme 17).

The Cu(I)-catalyzed photocycloaddition of 1,6-heptadien-4-ol **59** (Scheme 18) was employed by Lal and co-workers[38,39] for the synthesis of the sesquiterpenes robustadials for which the structures **61** were proposed. The bicyclo[3.2.0]heptane **60** obtained from this reaction was converted to three of the four



56 **57** **58**

SCHEME 17



59 **60** **61**

SCHEME 18

possible diastereoisomers of the structure **61**. None of these structures corresponds to the natural product, disproving the proposed structure.

A sequence of Cu(I)-catalyzed [2 + 2]-photocycloaddition–cyclobutyl carbinyl cation rearrangement has been employed for the construction of novel carbocyclic compounds. Thus, cycloaddition of the dienol **40** to the hydroxymethyl cyclobutane **41** followed by solvolysis of its tosylate **62** afforded the triquinane **63** after reduction (Scheme 19).[29] An efficient route[40] to *exo*-1,2-polymethylene-7-hydroxy norbornanes **66** has also been developed based on this protocol. Photocycloaddition of an epimeric mixture of the dienols **64** to 2-hydroxybicyclo[3.2.0]heptanes **65** followed by treatment with trifluoroacetic acid (TFA) affords the 7-hydroxynorbornanes **66** in overall good yields.

Ghosh et al[41] have recently demonstrated that the CuOTf-catalyzed [2 + 2]-photocycloaddition can be successfully carried out when 1,6-heptadienes are incorporated in a carbohydrate derivative, thus widening the scope of the Cu(I)-catalyzed photocycloaddition. The diene **67a**, on irradiation in the presence of CuOTf, afforded the thermodynamically less stable *cis-syn-cis* adduct **68a** (Scheme 20). Initially, this unexpected stereochemical outcome was thought to arise through the tri-coordinated Cu(I) complex **69**. However, photocycloaddition of the analogous diene **67b** (with benzophenone as sensitizer) in the absence of a Cu(I) catalyst also produced the *cis-syn-cis* adduct **68b**, excluding the possibility of the involvement of the Cu(I)-complex **69**. Possibly, the observed stereoselectivity arises through the Cu(I)-

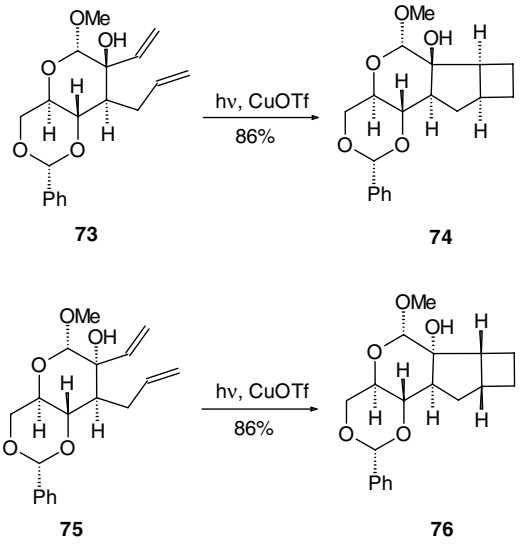
SCHEME 20

alkyl radical intermediate **71** rather than the more sterically crowded intermediate **72** derived from the Cu(I)-complex **70**. In contrast to this observation, irradiation of the 1,6-heptadienes **73** and **75** incorporated in a pyranosugar produced the expected adducts **74** and **76**, respectively (Scheme 21)[42], in accord with Salomon's earlier observation on photocycloaddition of 1,6-heptadien-3-ols.



73 **74** **75** **76**

SCHEME 21

[2 + 2]-Photocycloaddition of Diallyl Ethers and Homoallyl Vinyl Ethers

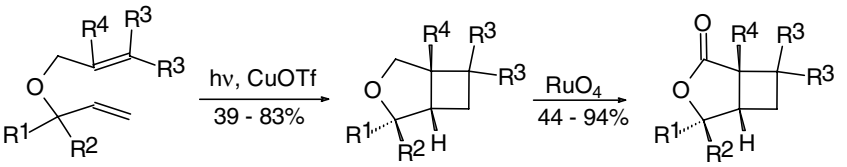
Copper(I)-catalyzed intramolecular [2 + 2]-photocycloaddition of diallyl ethers and homoallyl vinyl ethers provides a new route to 3-oxabicyclo- and 2-oxabicyclo[3.2.0]heptanes, respectively.[43,44] Different structural variants of diallyl ethers have been investigated. UV irradiation of diallyl ethers **77a–f** in the presence of CuOTf catalyst produces 3-oxabicyclo[3.2.0]heptanes **78a–f** in moderate to excellent yields (Scheme 22). The diallyl ethers **77c** and **77d** having alkyl substitution at the allylic position produce exclusively the 2-*exo*-alkyl-3-oxabicyclo[3.2.0]heptanes **78c** and **78d**, respectively. The observed stereoselectivity arises through photocycloaddition of the Cu(I)-diene complex **80,** which is sterically less crowded than the complex **81** with an axial alkyl group. The bicyclic ethers **78** can be oxidized smoothly to the lactones **79** with RuO_4. Cu(I)-catalyzed photocycloaddition of homoallyl vinyl ethers **82** also proceeds smoothly, producing 2-oxabicyclo[3.2.0]heptanes **83** (Scheme 22).

Using the sequence of Cu(I)-catalyzed photocycloaddition of diallyl ethers or homoallyl vinyl ethers and RuO_4 oxidation, a variety of novel multicyclic compounds such as **86** and **89** can be synthesized (Scheme 23) starting with the dienes **84** and **87**, respectively.

Copper(I)-catalyzed intramolecular [2 + 2]-photocycloaddition is selective for 1,6-dienes only. The 1,5- and 1,7-dienes do not react. Thus, the trienes **90, 92**, and **94** produce only the adducts **91**,[43] **93**,[45] and **95**[43] (Scheme 24), arising from reactions of 1,6-dienes only.

CuOTf-catalyzed photocycloaddition of the tetraene **96** produces a mixture of the compounds **98**, **99**, and **100** (Scheme 25).[46] The 1,2-divinyl cyclobutanes **97** initially formed from [2 + 2]-addition of the tetraene **96** undergo further reaction on prolonged irradiation in the presence of CuOTf to form these products. The tricyclic compound **100** arises from intramolecular $2\pi + 2\pi$ addition of cyclooctadiene derivative **99**. In fact, the transformation of *cis,cis*-1,5-cyclooctadiene **101** to the tricyclic compound **102** on irradiation in the presence of CuCl was the first example of an intramolecular Cu(I)-catalyzed photocycloaddition reaction.[47,48]

Panda and Ghosh[49] have recently reported the Cu(I)-catalyzed $2\pi + 2\pi$ addition of 1,6-dienes, where the alkene units are tethered through an acetal oxygen. For example, the mixed acetal **103** produces stereoselectively the bicyclic lactol **104** in 50% yield (Scheme 26). Chromic acid oxidation of the lactol **104** produces the lactone **105**. The advantage of this protocol is the exclusive synthesis of the lactone **105**, which was obtained as a mixture with its regioisomeric lactone **79e** by using the protocol involving



77 **78** **79**

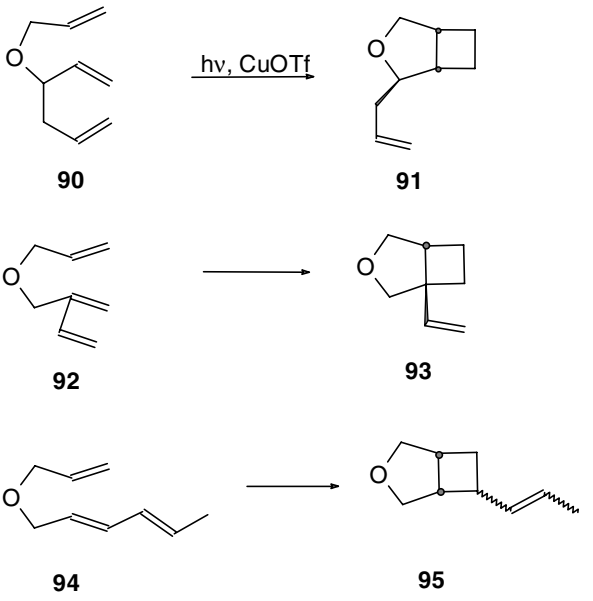
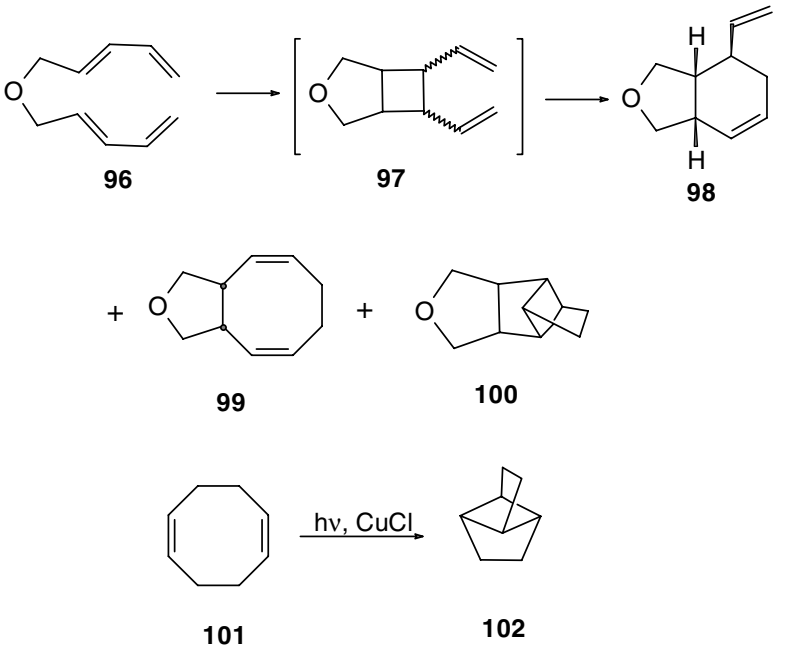
SCHEME 23

photocycloaddition of the diallyl ether **77e** followed by RuO_4 oxidation (Scheme 22). This protocol has been employed for a formal synthesis of grandisol (Scheme 27), beginning with the mixed acetal **106**.[49] Very recently, a synthesis of cyclobut-A **111**, an inhibitor of HIV, has been accomplished,[50] using the CuOTf catalyzed $2\pi + 2\pi$ addition of the acetal **109** (Scheme 28) as the key step.

CuOTf catalyzed $2\pi + 2\pi$ addition of diallyl ethers to form 3-oxabicyclo[3.2.0]heptanes has been elegantly employed for a novel stereoselective approach to the construction of vicinally substituted



SCHEME 24



SCHEME 25

cyclopentanones with a quaternary Me, rudimentary synthons for the synthesis of complex natural products. The protocol[51–53] involves (Scheme 29) intramolecular $2\pi + 2\pi$ addition of the diene **113**, derived from reaction of the ketone **112** with ethoxyvinyl lithium followed by allylation of the resulting carbinol. CuOTf catalyzed photocycloaddition of the dienes **113** then provides the cyclobutane derivatives **114**. The strategic placement of the alkoxy group on the oxabicyclo[3.2.0]heptanes **114** permits facile rear-

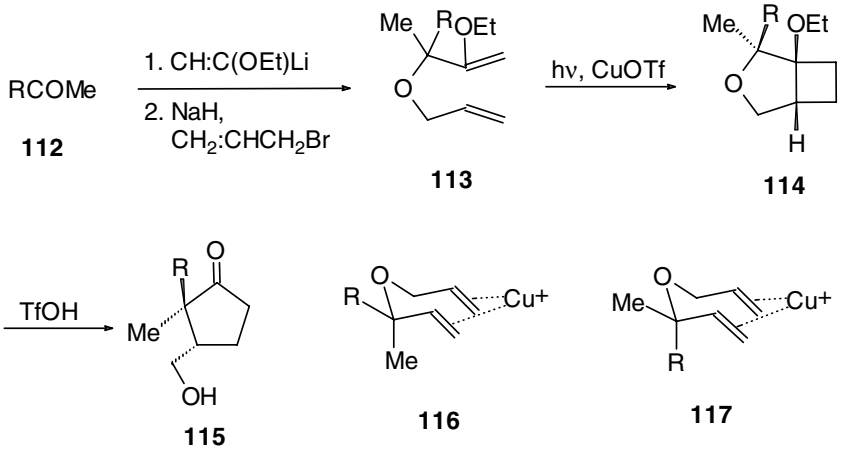
rangement, on treatment with trifluoromethane sulfonic acid (TfOH), to the substituted cyclopentanones **115**. During photocycloaddition, a strong preference for the formation of the adduct **114** with the alkyl group R occupying an *exo* position increases with an increase in the bulk of the substituent R (Table 18.2).[53] Cycloaddition takes place through the less sterically crowded Cu(I)-diene complex **116** in preference to the more crowded complex **117** with a bulky substituent (R) in the axial position. Thus, any acyclic ketone can be converted to a cyclopentanone through this protocol.

The cyclopentanone derivative **115a** (R = Me) has been used as an intermediate in the total synthesis of β-necrodol **118**,[52] an insect repellent isolated from the defensive spray of the red-lined carrion beetle, *Necrodes surinamensis,* and the sesquiterpene herbertene **119**.[54]

This methodology has also been extended to the construction of cyclopentanones with substituents at three contiguous centers.[55] Thus, the diene **120a** afforded the photoadduct as a mixture of *exo*-**121a** and its *endo*-isomer in a ratio of 2.5:1 (Scheme 30). In contrast, the diene **120b** afforded exclusively the *exo*-cyclobutane **121b**. The difference in stereochemical outcome in the photocycloaddition of the dienes **120a** and **120b** is explained as follows. Cycloaddition of these dienes is expected to proceed through the



SCHEME 29

[a] Photoadducts with R occupying *exo* position.

Cu(I)-diene complex **123**, as well as the complex **124** arising from the competing geometric olefin isomerization. In case of the diene **120b**, photocycloaddition takes place only through the Cu(I)-diene complex **123b**, as the alternative complex **124b** is sterically crowded due to the bulky Ph group, producing exclusively the *exo*-adduct **121b**. Acid treatment of the cyclobutanes **121** then leads to the cyclopentanones **122**. A synthesis of the diquinane **125**, an intermediate in the synthesis of the sesquiterpene $\Delta^{9,12}$-capnellene, has also been accomplished from the cyclobutane derivative **121c** obtained from photocycloaddition of the diene **120c** (Scheme 30).[56]

Employing this protocol, spirocyclopentanones can be obtained when cyclic ketones are used, as illustrated in Scheme 31.[57,58] The spirocyclopentanone **129**, obtained from 4-methylcyclohexanone **126**, has been converted to the spiro ketone **130**, which was earlier transformed to the sesquiterpene α-cedrene **131** (Scheme 31). Thus, CuOTf catalyzed photocycloaddition of 1,6-heptadienes provides a novel route to spiro cyclopentanones, also.

The Cu(I)-catalyzed $2\pi + 2\pi$ addition of diallyl ethers in conjunction with cyclobutyl carbinyl cation rearrangement has also been used for the construction of densely functionalized substituted cyclopentanones **135** from the ketones **132**, as illustrated in Scheme 32.[59]

An interesting application of CuOTf-catalyzed intramolecular $2\pi + 2\pi$ addition is the synthesis of isomers not formed in the corresponding intermolecular process. For example, the tricyclo[5.2.1.$0^{2,6}$]decene **136** undergoes dimerization when irradiated in the presence of CuOTf to form only

the *exo-trans-exo* isomers **137** and **138** (Scheme 33). However, when two such units are linked through tethers such as the diester **139**, photoreaction under identical conditions produces a 1:1 mixture of the unknown *exo,cis,exo*-dimer **141**[60] originating from the (R,S/S,R) diastereoisomer of the diester **139** and the *exo,trans,exo*-isomer **140** originating from the (R,R/S,S) diastereoisomer (Scheme 33).

The efficiency of this reaction depends on the length and rigidity of the tether. The tether can be removed easily through $LiAlH_4$ reduction to provide the dimers.

[2 + 2]-Photocycloaddition of Diallyl Carbamates

The *N,N*-diallyl carbamates **142a–c** undergo smooth $2\pi + 2\pi$ photocycloaddition in the presence of CuOTf catalyst to produce 3-azabicyclo[3.2.0]heptanes **143a–c** in excellent yields.[61] *exo*-Selectivity was observed for photocycloaddition of **142c** with a Me group at an allylic position to produce exclusively **143c**, as observed in photocycloaddition of the corresponding diallyl ethers. Multicyclic compounds **145** containing a N atom in the ring can also be prepared from $2\pi + 2\pi$ addition of the carbamates **144**. It is important to note that *N,N*-diallyl acetamide and *N,N*-diallyl formamide do not undergo [2 + 2]-photocycloaddition under these conditions. The failure of these photoreactions is possibly due to excitation of the amide functional groups rather than photoactivation of the Cu(I)-diene complex.

18.5 Conclusion

Copper(I)-catalyzed [2 + 2]-photocycloaddition of alkenes yields cyclobutanes in high yields in regio- and stereoselective fashion. A variety of functional groups are tolerant to the reaction conditions. Both carbo- and heterocyclic rings can be easily constructed. This reaction has been used as a key step in the synthesis of several natural products and molecules of novel architecture. The synthetic utility of this reaction would be greatly enhanced if asymmetric induction during cycloaddition could be achieved. Further investigation in this direction is greatly needed.

Photochemical Synthesis of Cyclophanes

19.1 Introduction

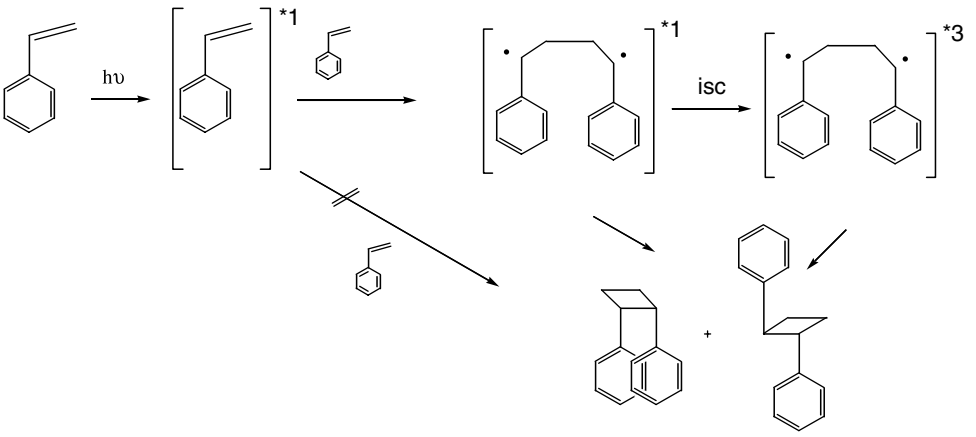
In 1949, [2.2] paracyclophane[1] was prepared by the pyrolysis of *p*-xylene.[2] This intriguing event highlighted the birth of cyclophane chemistry, a name that was coined by Cram.[3] Recently, a member of the cyclophane family that has some cytotoxicity to LoVo tumors was isolated from a species of marine blue-green algae.[4,5] This general field of cyclophane chemistry was extended to host–guest chemistry, again coined by Cram,[6] applying the rigidity and planarity of the arene rings in cyclophanes as shaping or building blocks.[7]

In this chapter, the term cyclophane is used as the family name or general name for phanes as well as for the standard phanes composed of benzene nuclei.

Unless they have considerable strain in their ring systems, cyclophanes can be formed by most conventional bond-forming reactions. The first photochemical approach was applied by Schönberg et al. to prepare cage compound **1**, a cyclophane, in 1968.[8] Moreover, styrene photocyclodimerization (Scheme 1) was also published in the same year,[9,10] although it took almost two decades before we first successfully applied the reaction to cyclophane synthesis.[11] The mechanism (Scheme 1) of [2 + 2] cycloaddition with direct photoirradiation of vinylarenes and their derivatives has been published.[12]

Since then, several phanes have been prepared by photoirradiation as a key step for CC bond formation (Table 19.1).[13–15] Until the mid-1980s, stilbene, vinyl ether, and cinnamic acid moieties were used for the [2 + 2] cycloaddition, avoiding the use of labile vinylarenes. Thus, the phanes formed had some additional substituents at the tethers. This sometimes made their characterization complex. Other techniques were developed for the photochemical transformation of the simplest starting materials with vinyl groups directly attached to arene nuclei.

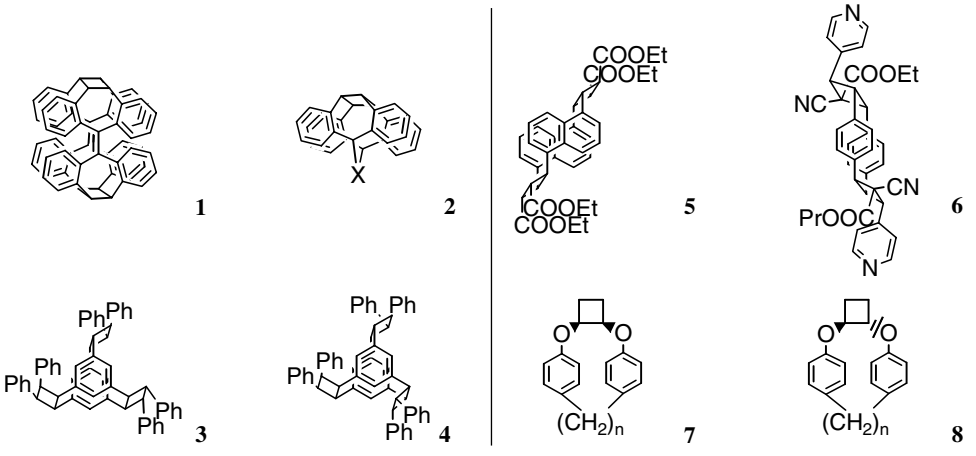
0-8493-1348-1/04/$0.00+$1.50



SCHEME 1

TABLE 19.1 Cyclophanes Prepared from Stilbene, Vinyl Ether, and Cinnamic Acid Derivatives in Solution and Solid-State Reactions

Cyclophane	Reaction Conditions	Yield, %	Isomer Ratio	Ref.
1	In benzene	—	—	9
2 (**X** = **O**)	In benzene	70	—	16
3 + **4**	In benzene	30	—	13,14
5	In benzene	47	—	17
6	Solid state	100	—	18
7 + **8**	In acetonitrile; sensitized by DCA	n = 4, 25 n = 20, 66	n = 4, 96: 4 n = 20, 42:58	15



In 1986, it was recognized for the first time that the [2 + 2] photocycloaddition of styrene moieties was efficient if proper conditions were chosen.[11] After this discovery, many simple phanes were prepared from styrene derivatives or from vinylarenes by using the [2 + 2] photocycloaddition in solution.[19,20] This photochemical approach to cyclophanes is reviewed in this chapter, which focuses on the scope and limitations of the process.

19.2 Experimental

The vinylarenes are prepared from the corresponding bromides and from 1-arylethanols, such as phenethol, using Pd-catalyzed vinyl couplings including the Kosugi–Migita–Stille reaction[21] and dehydration methods including the acid-DMSO (dimethyl sulfoxide) system.[22]

Irradiation at around 300 nm under a nitrogen atmosphere is achieved using a high-pressure mercury lamp. A Pyrex filter that also serves as the reaction vessel is recommended to eliminate wavelengths <280 nm. Short wavelength irradiation sometimes forms undesired complex products via other reaction processes occurring before and/or after the [2 + 2] cycloaddition. In most cases, the polymerization of vinylarenes accompanies the cycloaddition. This affords polymers that do not have cyclobutane units in the main chains. Moreover, the phanes produced are generally photoreactive and can be degraded on prolonged irradiation. It is important to monitor the reaction to ensure maximum yields of the desired products.

Sensitizers and/or electron acceptors are not always necessary for the [2 + 2] cycloaddition of vinylarenes, which generally react from their excited singlet states. If sensitizers are used, the isomer ratios obtained are often different, and the process can yield more of the stable isomers. This occurs because of the intervention of longer-lived less active species such as triplet biradicals and ion radicals.[23]

Many different solvents can be used, although nonpolar benzene is recommended for most purposes. Generally speaking, simple distillation is adequate for the purification of solvents when singlet excited states are involved. Metal ion templates for the synthesis of crown-type phanes or crownophanes help to increase product stabilities but do not necessarily increase the efficiency of the cyclization.[24] The concentration of substrates should be in the 10^{-4} to 10^{-1} *M* range. The intermolecular reaction needs more concentrated solutions to raise the yield of adduct, but the intramolecular reaction occurs efficiently in more dilute conditions.

Products are isolated with a combination of column chromatography, GPC, and HPLC. Most isomers can be separated easily by HPLC. The most difficult cases may require recycled GPC and HPLC to achieve separation.[25] The phanes formed are stable if they are stored in a refrigerator or in a dark cool place in the solid or the crystalline state.

Structures are determined by many spectroscopic methods including ^{1}H NMR.[26] Methine proton signals around $\delta 4$ to $\delta 5$, as well as the high-field shifted aromatic proton signals, are used for the structural determination. So far only *cis*- and *trans*-1,2-diarylcyclobutane moieties have been found in the cyclophane structures obtained in solution, although 1,3-diarylcyclobutane moieties are often formed in solid-state addition reactions.[27]

19.3 Scope and Limitations of [2 + 2] Photocycloaddition as a Cyclophane Synthetic Method

The photochemical method has been successfully carried out in solution to make cyclophanes,[11] biphenylophanes,[11] cyclonaphthalenophanes,[11] naphthalenophanes,[11,21] binaphthylophanes,[28] phenanthrenophanes,[25,29–32] biphenylophenanthrenophane,[33] thiophenophanes,[34] and carbazolophanes.[35] Although the cycloaddition approach is quite general, some limitations exist as a result of strain and other competitive photoprocesses.[19,20]

In the following sections, the scope is summarized for inter- and intramolecular reactions. The limitations are discussed as a whole, combining some solid-state photoreactions listed in Table 19.1.

Intermolecular Reactions

Details of the yields of cyclophanes, naphthalenophanes, and phenanthrenophanes are summarized in Table 19.2. All phanes possess more than two cyclobutane rings, although they are described simply as [2.2]- and [2_n]phanes in this chapter.[1]

TABLE 19.2 Intermolecular Cyclization to Prepare Cyclophanes from Polyvinylarenes

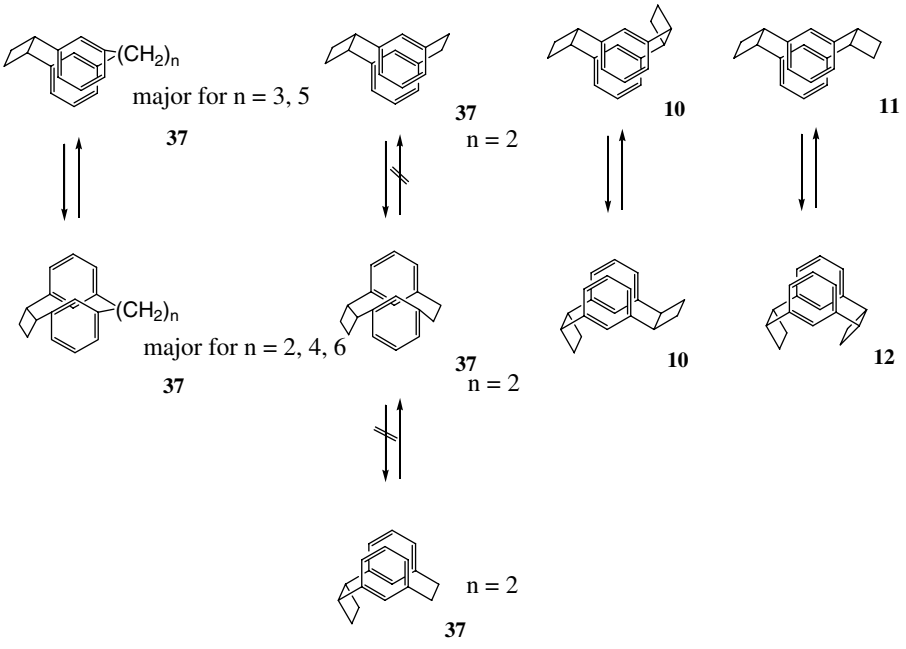

SCHEME 2

[2_n]Cyclophanes

[2.2]Orthocyclophane **9**,[36] [2.2]metacyclophane **10–12**,[37] [2_3](1,3,5)cyclophane **13–14**,[38] and [2_4](1,2,4,5)-cyclophane **15**[36] were successfully prepared by irradiation through a Pyrex filter of the appropriate di-, tri-, and tetravinylbenzene in benzene solution at room temperature. The yields obtained were not optimized at that time (Table 19.2). It is clear that the more strained the cyclophane is, the less product is formed. [2.2]Paracyclophane was not obtained by this route, although [2_4](1,2,4,5)cyclophane **15**, which contains the paracyclophane moiety, was prepared. It is likely that a zipper effect could be operative in this cycloaddition following the first metacyclophane formation.[36]

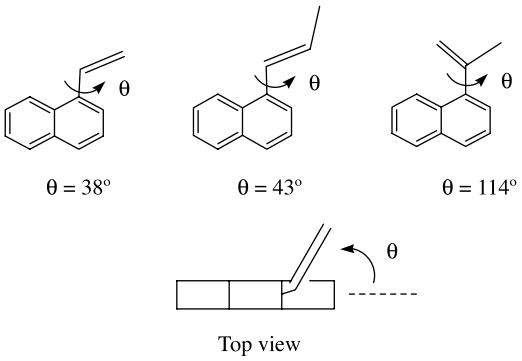

FIGURE 19.1

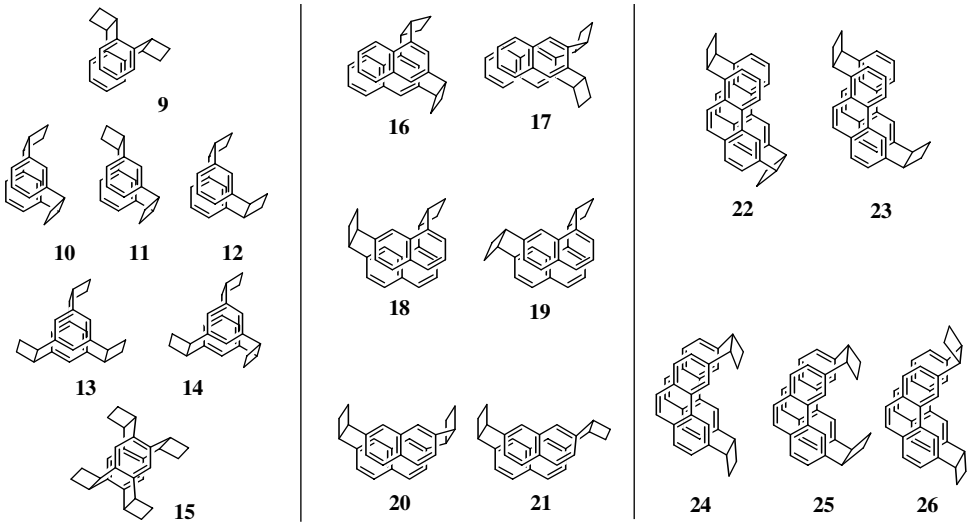

The [2.2]orthocyclophane formed has a pair of considerably tilted benzene nuclei, but the $[2_4](1,2,4,5)$cyclophane has a perfectly stacked pair. The difference in structure is seen in the UV-Vis spectra; i.e., the latter shows a bathochromic shift of 40 nm from durene, but the former is similar to *o*-xylene.[36]

[2.2]Naphthalenophanes

Many regioisomeric divinylnaphthalenes were examined, and some were found to produce [2.2]naphthalenophanes (Table 19.2).[21] They are the 1,3- **16**, 2,3- **17**, 1,7- **18–19**, 1,8-, 2,6-, and 2,7-isomers **20–21**. Again, the method failed to produce any [2.2](1,4)naphthalenophane, whose structural elements are the same as those of [2.2]paracyclophane.

A 1:1 mixture of two different divinylnaphthalenes was irradiated, but only homocycloadducts **16–21** were obtained in yields that were similar to those obtained by irradiation of the pure divinylnaphthalene.[21]

The synthetic route possesses an interesting stereochemical character: i.e., if the vinyl group is attached at the α-position of the naphthalene (and the 1- or 8-position of the phenanthrene) nucleus, the molecule is conformationally rigid because of the steric hindrance of the peri-hydrogen. The vinyl group always faces the *exo*-direction. This fact has been verified by ^{1}H NMR spectroscopy (Figure 19.1).[39] As a consequence, the naphthalenophane produced always has *exo*-cyclobutane ring(s), and moreover, a *syn*-conformation around the naphthalenophane (see **16**, **18**, **19**).[11] This selectivity had not been attained using

TABLE 19.3 Fluorescence Spectroscopic Data of [2.n]Phenanthrenophanes

Phenanthrenophane	Conformation	Origin of Emission	Emission, λ_{max}, nm	Ref.
23	*syn*	Excimer	410	25
27	*syn*	Excimer	405	30

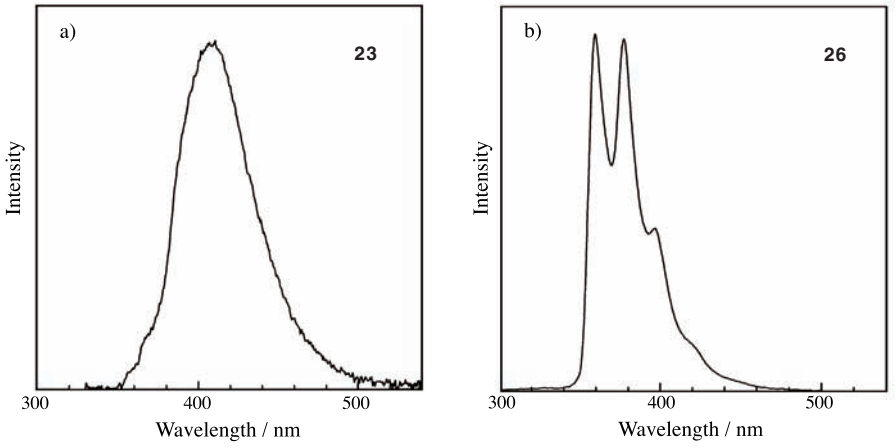

FIGURE 19.2

other synthetic methods reported previously.[21] Generally speaking, most CC bond formations used for the synthesis of naphthalenophanes are apt to give *anti*-isomers exclusively or largely with a minimal yield of the *syn*-isomer. When α-(2-propenyl)naphthalene is used, the situation is changed completely, and the *endo,cis,syn*-isomer is obtained as the major product.[17]

[2.2]Phenathrenophanes

Several phenanthrenophanes listed in Table 19.2 were prepared after a structural examination of strain within the molecule using molecular mechanics (MM2) calculations.[25,29–32] Their predicted three-dimensional structures look much the same, but they actually are considerably different in reality. Evidence for the structural differences can be seen in the excimer emission behavior that is summarized in Table 19.3. Two typical fluorescence spectra are depicted in Figure 19.2.

The same stereochemical control as that for the naphthalenophane mentioned above is operative in this synthesis. The vinyl groups attached at the 1- and 8-positions are conformationally rigid due to the peri-hydrogen, and therefore yield the phenanthrenophane stereoselectively to some extent, as seen for **22** and **23**.

Intramolecular Reactions

The yields of cyclophanes, naphthalenophanes, and phenanthrenophanes synthesized by the intramolecular photocyclization are summarized in Table 19.4. Again, although all the phanes have at least one cyclobutane ring, they are described here as [2.n]phanes for simplicity.

TABLE 19.4 Intramolecular Cyclization to Prepare Cyclophanes from Polyvinylarenes

35 (n = 6)	0.26	**47 (n = 14)**	0.10

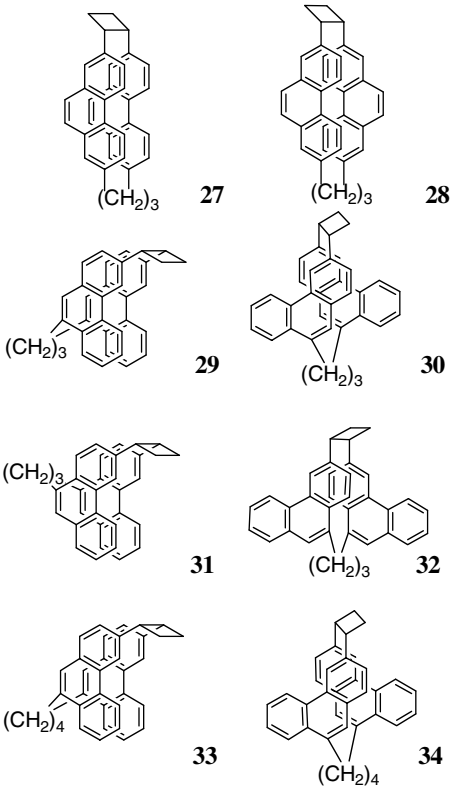
Note: For intramolecular reactions of vinylnaphthalene moieties ($\phi = 0.26$), see References 43 and 44.

[2.n]Cyclophanes

Unless much strain will be induced by the cycloaddition, the [2.n]paracyclophanes **35**, **36** ($n \geq 3$)[11] and metacyclophanes **37** ($n \geq 2$)[23,41,42] are easily prepared by intramolecular photocycloaddition. The quantum yield is usually as high as 0.4,[43–45] and sometimes the cyclophanes are isolated in quantitative yield. As shown in Table 19.5, the quantum yield tends to decrease with the increase of tether length, with the exception of the flexible oligooxyethylene unit (see **46** and **47**).[45]

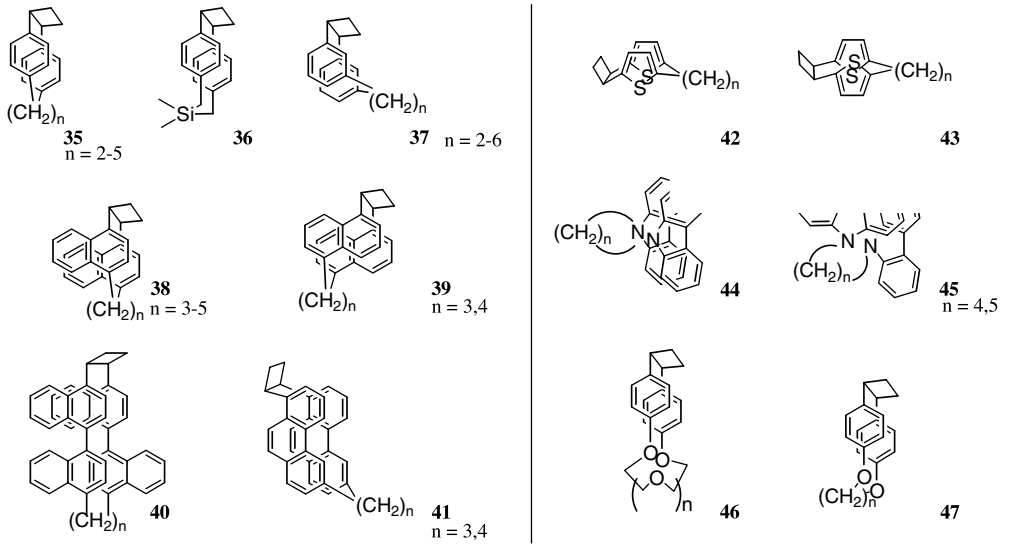
While the paracyclophanes synthesized have little stereochemical diversity, the metacyclophanes can be obtained as *syn*- and *anti*-isomers on the cyclophane substructure and *cis*- and *trans*-isomers around the cyclobutane ring system. When the [2.n]metacyclophanes where $n \geq 4$ ring flipping of the benzene moiety occurs. At the flipping equilibrium, [2.4]-, [2.5]-, and [2.6] phanes **37** possess mainly *anti*-, *syn*-, and *anti*-conformations, respectively. This is dependent to some extent on the tether conformation. The smaller [2.2]- and [2.3]metacyclophanes **37** showed no ring flipping and were obtained as *cis,anti*- and *trans,anti*-isomer mixtures. Note that the *cis,anti*-[2.2]metacyclophane was formed instead of the *cis,syn*-isomer. It is believed that the photocycloaddition gives initially the *cis,syn*-isomer, which then converts irreversibly to the more stable *cis,anti*-isomer.[46] This result, together with the conformation of bisethano[2.2]metacyclophane **10**, **11**, and **12** implies that a single cyclobutane linkage is insufficient to maintain the cyclophane in *syn*-conformation (see Scheme 2).

[2.n](4,4′)Biphenylophanes ($n \geq 3$) are also produced by the general method and usually in reasonable yields.[11,28]



[2.n]Naphthalenophanes

The intramolecular cycloaddition path can afford phanes with different aromatic nuclei. In fact, [2.3]paracyclo(1,4)naphthalenophane was prepared in 8% yield.[11] The method has been applied to prepare [2.n](1,4)- **38**, -(1,5)- **39**, and –(2,7)naphthalenophanes (n ≥ 3) in reasonable yields. [2.2](1,4)Naphthalenophane cannot be synthesized by this route.



It is important to note that the conformational rigidity of the α-vinyl group referred to earlier makes the reaction stereoselective. This control is also operative in the preparation of [2.n](4,4′)binaphthylophanes **40**, where a pair of naphthalene moieties is adjacent to the vinyl groups. Moreover, it is possible to synthesize the [2.6](4,4′)phane due to lessening of molecular strain, while the synthesis of the [2.5]phane fails. The length of the methylene tether (n ≥ 6) is important.[28]

[2.n]Phenanthrenophanes

Some phenanthrenophanes cannot be prepared by the intermolecular photocyclization pathway, mainly because of strain induced by the two carbon linkage (n = 2). However, some were prepared using longer methylene chains (-$(CH_2)_n$-, n ≥ 3). This is typically seen in the synthesis of [2.n](2,7)phenanthrenophanes **27** and **28**.

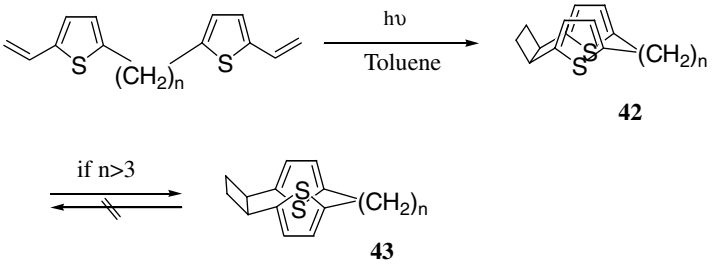
The same stereochemical selectivity induced by the α-vinyl group again operates in the reaction, and [2.n](1,6)phenanthrenophanes **41** are obtained.[25,29]

[2.n]Heterophanes

Among heterophanes, some thiophenophanes and carbazolophanes were successfully synthesized. Some [2.2]phanes with relatively small frameworks are too strained to be synthesized by this method. However, the photocycloaddition can afford some [2.n](2,5)thiophenophanes **42–43** (n ≥ 3),[34] [2.n](3,9)carbazolophanes **44–45** (n ≥ 4),[35] with the limitations shown in parentheses. These syntheses are also dependent on the large atomic radii of the hetero elements and on the electrostatic repulsive interaction between two co-facially arranged heteroatoms.

Conformationally stable *cis,exo,syn*- **42** (n = 3) and *cis,anti*-[2.3](2,5) thiophenophane **43** (n = 3) were obtained as shown in Scheme 3. However, the [2.4](2,5)thiophenophane **43** (n = 4) exists as a mixture of two *anti*-conformers that rapidly interconvert. It is believed that even larger [2.n](2,5)thiophenophanes (n ≥ 4) are first formed as *exo,syn*-isomers and then undergo a ring flip to the more stable and flexible *anti*-isomer.

[2.4]Carbzolophane **44–45** (n = 4) was produced as a mixture of *syn*- and *anti*-isomers. These did not undergo interconversion due to the short linkage. Interconversion occurs at a slow rate with the larger [2.5]carbazolophane.

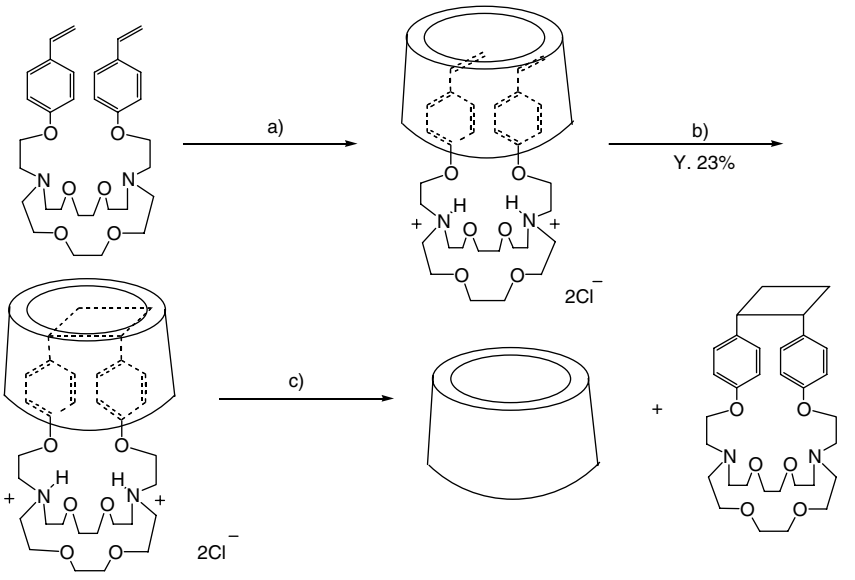


SCHEME 3

Limitations: Competing Photochemical Processes and the Influence of Strain at the Transition State

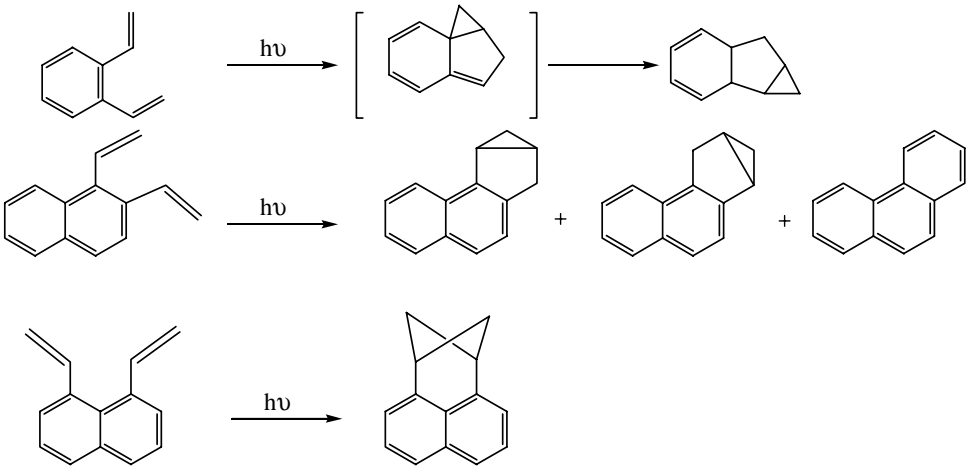
As mentioned above, the photochemical method has some limitations. These limitations are due to the variety of different photochemical processes involved and the strain at the transition state.

Vinylarenes can undergo several reactions on irradiation depending on the substitution involved. Sometimes the photoreactive compound is bichromophoric, with the possibility of interaction between the vinyl group and another substituent. In some instances, supramolecular techniques can be applicable. An example of this is shown in Scheme 4. The excited singlet styrene moiety could react with the tertiary- or



a) 1) HCl/H_2O, 2) γ-CD. b) hυ (>280 nm). c) $NaOH/H_2O$

SCHEME 4



SCHEME 5

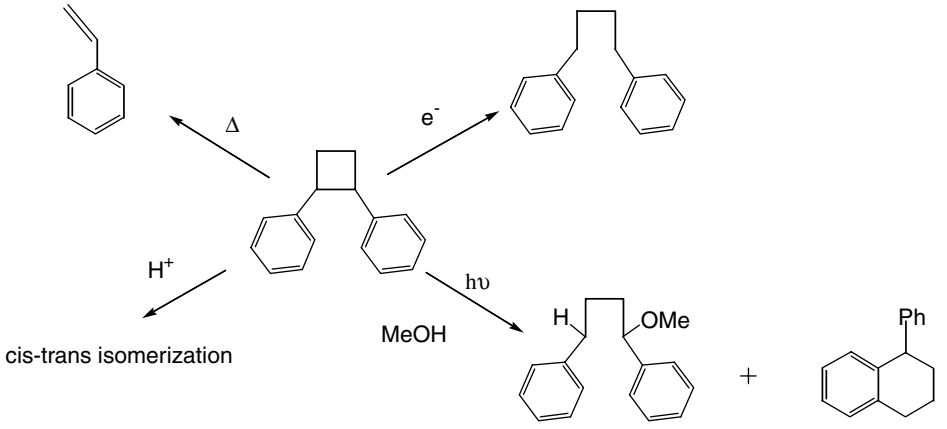
secondary-amino groups. To minimize this side reaction, γ-cyclodextrin is used to complex the vinylarene moieties. Under these conditions, the cycloaddition occurs normally.[47]

The two neighboring vinyl groups have to be in the proper conformational arrangement to react with each other. This type of reaction affords the cyclized compounds shown in Scheme 5.[48] However, the *exo,endo*-vinyl group arrangement shown for *o*-divinylbenzene is not preferred under thermal equilibrium conditions. The arrangement is present in ground-state 1,2-divinylnaphthalene, and irradiation of this gives, exclusively, the phenanthrene and its derivatives without any intermolecular cycloadditions leading to naphthalenophanes. In order to compete with these intramolecular reactions, the concentration of starting polyvinylarenes has to be increased to several hundred m*M*. Such a concentrated system easily produces polymeric byproducts.[36]

TABLE 19.6 Strain Energy of 1,2-Ethano[2.n]paracyclophanes

	1,2-Ethano[2.n]paracyclophane **35**	
n	Strain Energy (kcal/mol)[a]	Remarks[b]
2	52.0	Not obtained by the reaction
3	41.1	14% yield
4	33.9	61% yield

[a] Calculated by HDE method.
[b] Ref. 11.



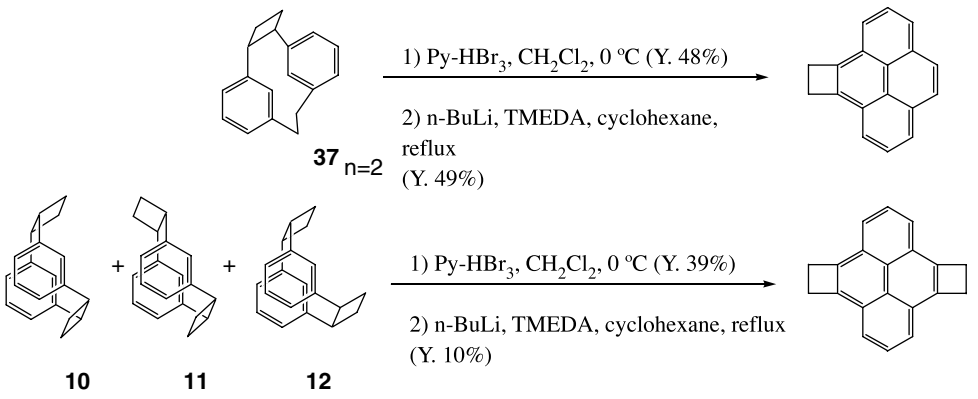
SCHEME 6

A typical cyclophane with short linkages, [2.2]paracyclophane, could not be prepared by this photochemical method in solution even though the strain calculated by the HDE (homodesmic destabilization energy) method at the *ab initio* (PM3) level is not too high, as shown in Table 19.6.[49] It was supposed that the wavelength used (300 nm) could supply sufficient energy to *p*-divinylbenzene. In fact, as shown in Table 19.1, a solid-state photoreaction successfully gave [2.2]paracyclophane in quantitative yield.[18,50,51] Therefore, it is proposed that in solution, monocyclized species are formed and undergo second photon excitation. However, the excited species may undergo bond fission or internal conversion before a second bond is made between the two free vinyl groups. Thus the cyclization fails. In the solid state, however, two molecules are arranged parallel and are constrained, and both cyclobutane rings can be formed. The limitation due to the strain can be seen in the syntheses of metapara-, orthopara-, and metaorthocyclophanes and several naphthalenophanes and phenanthrenophanes in which the two nuclei are connected with each other at different positions.

19.4 Transformation of Products

Diphenyl cyclobutanes can react in several ways, as shown in Scheme 6. The thermal ring cleavage of cyclobutane is not efficient unless there is considerable strain.[52] The most labile [2.2]metacyclophane among the phanes examined undergoes ring opening to the corresponding styrene derivative at 200°C with a rate constant of 1.0×10^{-1} sec^{-1}. Others do not ring open as fast as this and are in the range 1 to 50×10^{-5} sec^{-1}.

Yamamoto and coworkers have reported a photochemical ring-opening using electron transfer and the production of cation radical species.[53] One of the electron transfer reactions of this sort is the Birch reduction. This is quite useful to bring about ring enlargement. When it is applied to the phane systems,



SCHEME 7

the products obtained have linkages two methylene groups larger than the starting materials, i.e., [2.n]-phanes become [4.n]phanes.[54]

Cyclobutane rings can be converted to arene-fused cyclobutene rings as shown in Scheme 7. It should be noted that the largest homologue of benzocyclobutene was prepared for the first time by this transformation.[55]

19.5 Future Prospects

Many photoreactions on phane skeletons have not been included in this chapter, such as reports related to ring construction via sulfides and esters.[3,56] Several phanes have been examined as photochromic materials, but these molecules usually do not exhibit reversible photochromicity and decompose on repeated irradiation. It may be possible to carry out some asymmetric-induced formation of phanes. These studies are of value for practical and theoretical reasons.[44] Other work has used a supramolecular catalyst for the preorganization of vinylarenes.[47] The technique could be of considerable value.[57] Some additional photochemical syntheses of phanes have been described for the formation of sterically strained systems.[58] In order to make such highly strained phanes, solid-state reactions could play a key role.

The intramolecular photochemical synthesis of phanes can be applied to the construction of covalent templates. Moreover, the cyclobutane ring(s) formed by the cycloaddition reaction can act as a stereochemical control forcing the phane conformation to one side similar to a caliper system. Other work has been directed towards the synthesis of receptors and ionophores applicable to host–guest chemistry.[59]

19.6 Conclusion

The [2 + 2] photocycloaddition of vinylarenes in solution was successfully carried out to make cyclophanes, biphenylophanes, cyclonaphthalenophanes, naphthalenophanes, binaphthylophanes, phenantherenophanes, thiophenophanes, carbazolophanes, and other related systems.

Unless the reacting system leads to a highly strained molecule, phanes are easily prepared by inter- and intramolecular photocycloaddition.[21] The intramolecular method can afford phanes with different aromatic nuclei. It is stressed that the conformational rigidity of the vinyl group and/or the apparent difference of the product stability makes the reaction stereoselective.

Those [2.n]phanes possessing cyclobutane ring(s) can be transformed into [4.n]phanes by Birch reduction and can also be transformed into benzocyclobutene analogs.

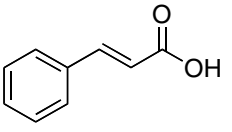
The Dimerization of Cinnamic Acid Derivatives

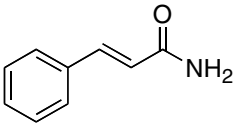
Dario M. Bassani
Laboratoire de Chimie Organique et Organometallique

20.1 Background

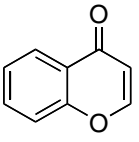
The photoinduced dimerization of cinnamic acid and its derivatives has sparked continued interest since its initial reports, nearly one hundred years ago.[1,2] The reasons for such a privileged position in the annals of photochemistry surely lie in its intriguing solid-state behavior and its versatility in a number of industrial applications, ranging from cosmetics to polymers for photoresists and lithography. With so much interest, an exhaustive review of all the pertinent literature would be overly lengthy and beyond the scope of this book. Therefore, greater emphasis is placed on more recent advances, particularly those dealing with reactions in complex or organized media (polymers, aggregates, and supramolecular architectures).



E-Cinnamic acid



E-Cinnamamide



Coumarin

Hydroxycinnamic acids are present in plants, where they play an important role in controlling the structure of cell walls.[3] It should come as no surprise, therefore, that cyclodimerization products of naturally occurring cinnamate and coumarin derivatives, such as *p*-coumaric acid and ferrulic acid, have been isolated from a variety of plants.[4] It has been postulated that dimers are formed by a photoinduced mechanism, causing cross-linking of the polysaccharide chains.[5,6] For example, sagerinic acid isolated from sage (*Salvia officinalis*) was identified as the uncommon μ-truxinate dimer **2**, presumably the result of the [2 + 2]-cyclodimerization of rosmarinic acid **1** present in the plant.[7]

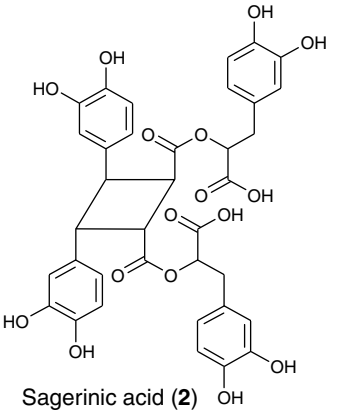
Rosmarinic acid (**1**)



Sagerinic acid (**2**)

In principle, the [2 + 2]-cyclodimerization of cinnamates can proceed to yield 11 different products, commonly divided between those arising from a head-to-head dimerization (truxinates) and those from a head-to-tail dimerization (truxillates).

Truxinates

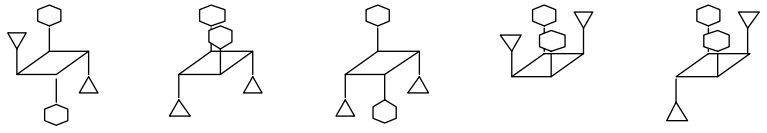
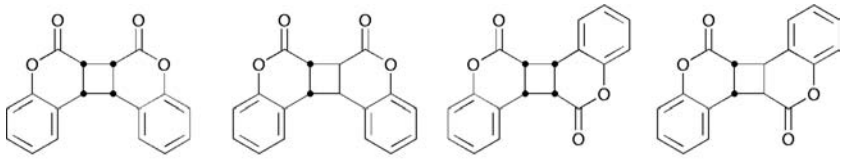
Truxillates



α ε γ peri epi

Whereas the preparation of the α- and β-truxinic acids from the solid-state irradiation of the corresponding crystals is straightforward,[8–10] the remaining cyclobutane structures are more complicated to prepare. The cross-photocycloaddition of stilbene to diethylfumarate can be used to prepare the μ-truxinate isomer,[11] and a similar procedure was used to prepare diethyl ξ-truxinate.[12] The preparation of the ε- and γ-isomers was described by Stoermer and Emmel.[13] To prepare the δ-isomer in good yields, a tetramethylene tether can be used to temporarily connect two cinnamoyl units during irradiation.[14]

The situation is considerably simplified in the case of coumarin due to the absence of *cis* and *trans* isomers of the exocyclic double bond. Only four isomers are possible, resulting from the head-to-head or head-to-tail dimerization in a *syn* or *anti* approach. Optically active coumarin dimers have found applications as chiral derivatizing agents for amines and alcohols.[15]



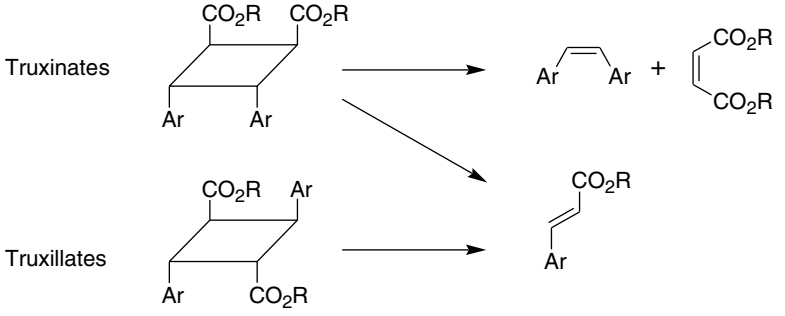
syn head-to-head anti head-to-head syn head-to-tail anti head-to-tail

20.2 Photodimerization in Solution

The photochemistry of cinnamate derivatives in solution has received comparatively less attention than in the solid state. In solution, dimerization must compete with fast *E,Z*-isomerization, and long irradiation times are required to achieve significant conversions. Reiser and co-workers[12] investigated the dimerization of thin films of neat ethyl cinnamate both as a liquid and as an amorphous solid. Their findings dispelled remaining doubts on the possibility of photodimerization outside of ordered crystalline matrices. High yields (>90%) of photodimers, predominantly the δ- and β-truxinate, were obtained in all cases, with the formation of the α-truxillate dimer favored at lower temperatures. Overall quantum yields for the photodimerization of ethyl cinnamate of 0.08 (neat) and $< 10^{-4}$ (0.2 *M* dichloromethane solution) were later determined by Lewis et al.[16,17] In this work, the authors also reported a significant increase in photodimerization efficiency through the use of Lewis acid catalysts such as BF_3 and $SnCl_4$, which is accompanied by a reduction in regiospecificity. In contrast, Cu(I) complexes of cinnamates were found to only undergo *E,Z*-isomerization without dimerization.[18] The photodimerization of a number of hydroxycinnamic acids,[19] methoxy-cinnamate esters,[20] and *p*-nitrocinnamate esters[21] has also been reported.

The low efficiency of photoinduced dimerization of cinnamates is in agreement with the short (< 3ps) fluorescent lifetime of methyl cinnamate estimated by Lewis et al.[22] using picosecond time-resolved spectroscopy. Inefficient intersystem crossing from the lowest $n\pi^*$ singlet excited state excludes the possibility that the photoinduced isomerization and dimerization reactions observed upon direct excitation originate from the excited triplet. Consistent with these observations, Herkstroeter and Farid[23] measured a bimolecular rate constant for the dimerization of triplet methyl cinnamate of $8.8 \times 10^6\ M^{-1}s^{-1}$ and a triplet lifetime of 10.6 ns (E_T = 229 kJ mol^{-1}), giving a limiting quantum yield of 0.5 — considerably higher than observed for dimerization from the excited singlet state. The isolated photoproducts were found to consist mainly of the δ–truxinate dimer (63%), with smaller proportions of the β-truxinate dimer (25%). Many other examples of sensitized dimerization of cinnamates have been reported (see, for example, refs. 20, 24) and more recently, the use of electron transfer sensitization has also been reported.[25]

Positive identification of the cycloadducts has vastly improved, thanks to advances in modern spectroscopy. Generally, ^{1}H-NMR provides the most information regarding the geometry of the cyclobutane ring (detailed NMR data of photoproducts may be found in refs. 17, 19, 21, and 26; for detailed analysis of cyclobutane NMR spectra, see references 27–29). This is frequently complemented by mass spectroscopy to identify the fragmentation pattern characteristic of truxinates, which, unlike truxillates, may fragment along one of two possible pathways to give stilbene and dicarboxylate fragments.[30]

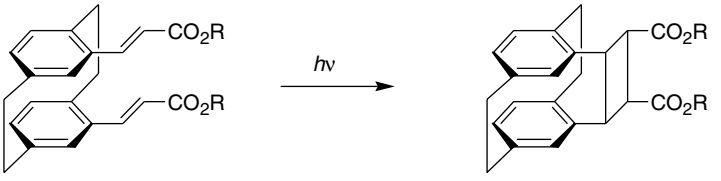


Moderately efficient photochemical scission of truxinates and truxillates is also possible via direct,[31,32] benzene-sensitized irradiation[33] and via an electron transfer mechanism[34] (γ irradiation in 2-methyltetrahydrofuran matrix).

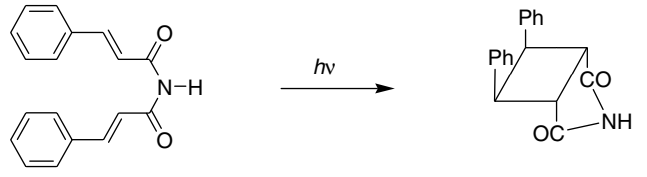
Like cinnamate esters, coumarin also dimerizes slowly under direct irradiation conditions to give a mixture of photodimers composed of the *syn* head-to-head (major product) and *syn* head-to-tail

dimers.[35–37] At low coumarin concentrations, intersystem crossing competes with dimerization to generate excited triplet coumarin, which undergoes dimerization to yield the *anti* head-to-head dimer.[38] Coumarin dimerization in the presence of BF_3 has been investigated in detail by Lewis et al.,[22] revealing uncommon complexity even under long-wavelength (313 nm) irradiation. Thiocoumarin also undergoes dimerization in solution, which, in marked contempt to all topological principles, is cleaner than in the solid, yielding principally the *anti* head-to-head dimer.[39,40]

Connection of two cinnamate chromophores has frequently been used to attain high local concentrations of reactants, thereby circumventing the inefficiency of the above-mentioned bimolecular dimerization reactions. An extreme example of this approach is embodied in the cyclophane structures **3**, in which two cinnamate moieties undergo photodimerization to give quantitatively the β-truxinate dimer with a quantum yield of 0.55.[41,42] Similarly, the bis-cinnamamide **4** furnished 48% of β-truxinimide upon irradiation through Pyrex.[43] Other cyclophanes have been prepared, including highly strained multibridged tricyclic phanes.[44,45]



3, R = H, Me



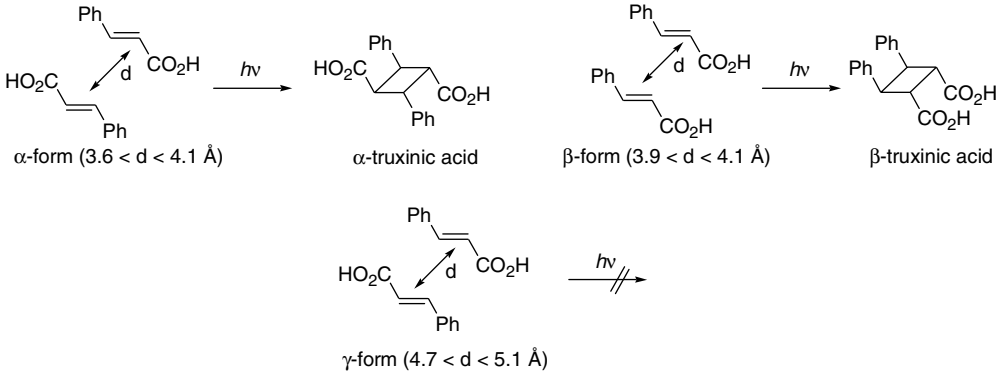
4

Many macrocyclic compounds have been prepared by the irradiation of α,ω-dicinnamates[46–48] and dicoumaryl derivatives (130, 130–16).[49,50] When the tether is a polyglycol unit, the photodimerization is sensitive to alkali metal ions, and crown-ether-like structures can be prepared.[51] Intramolecular dimerization reactions can find preparative importance as, for instance, in the preparation of the β- and δ-truxinate dimers from the irradiation of propylene-1,3-dicinnamate and *n*-butylene-1,4-dicinnamate, respectively.[14,52] The tether may also function as a chiral auxiliary, such as in the irradiation of L-erythritol 1,4-dicinnamate or mannitol hexacinnamate.[53,54] In the latter case, an excess of the (+)-δ–truxinate isomer was observed, along with several other isomers.

20.3 Photodimerization in the Solid

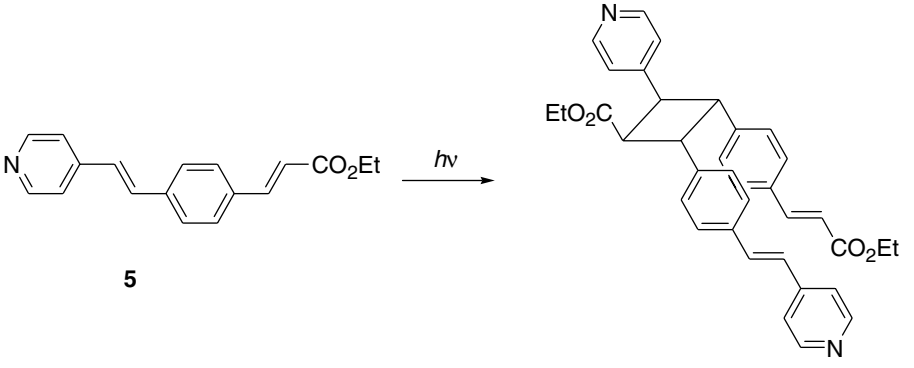
The solid-state photoreactivity of cinnamic acids is one of the most explored areas in organic solid-state photochemistry and holds considerable potential for preparative applications.[55] In a series of papers published in 1964, Schmidt and co-workers[56–59] elegantly established the principle of topochemical control of reactivity first expressed by Kohlshütter et al.[60] and Hertel et al.[61] The observation that one could relate the relative orientation of molecules in crystals to the geometry of the reaction products has since governed solid-state photochemistry. Cinnamic acid is the archetypical example of such processes, crystallizing in one of three morphologies. The stable α and metastable β forms are photoreactive, yielding the α- and β-truxinic acid dimers, respectively, with similar quantum yields of 0.7.[62] (Cohen,[63] however, has cast some doubts on this value.) The γ form, in which the olefinic double bonds are separated by a distance >4.7 Å, is unreactive. These findings are general for the wide variety of substitution patterns examined by Schmidt and co-workers and lead to the conclusion that the reactive double bonds must

be within ca. 4.2 Å for photodimerization.[64] Keating and Garcia-Garibay[65] have recently reviewed the physical aspects of several photochemical solid-to-solid reactions, including cinnamates.



In cases where irradiation of photoreactive crystals proceeded without destroying the crystal lattice, it has been possible to investigate the dimerization process by x-ray diffraction. Data from single crystal–to–single crystal transformations provide invaluable insight to the atomic movement during the cycloaddition step[66] and have been obtained for several cinnamate derivatives, including α-cinnamic acid[67] and its α-acetylamino derivative,[68] various cinnamamides,[69] co-crystals of *trans*-cinnamamide with phthalic acid,[70] coumarins in chiral hosts,[71] and cinnamic acid in clays.[72] In some cases, the presence of water[73,74] or hydrocarbons[75] in the crystal lattice has been noted. The dimerization of cinnamic acids in crystals has also been investigated by the use of atomic force microscopy,[76] scanning near-field optical microscopy,[77] and vibrational microspectroscopy.[78] It has been the subject of Monte Carlo simulation[79] and detailed mathematical analysis.[80]

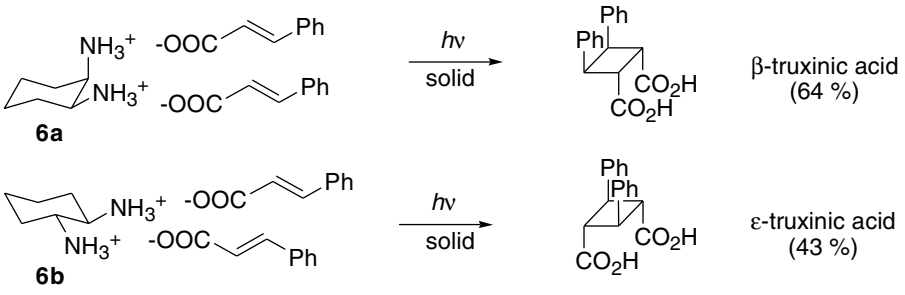
Irradiation of cinnamate derivatives in chiral host environments has long attracted attention as a gateway to asymmetric photochemical synthesis.[53,54,81–84] The use of a nonchiral host induced to crystallize in a chiral space group represents an example of absolute asymmetric synthesis, as described by Vaida et al.[85] for the cinnamamide/cinnamic acid host/guest system and by Hasegawa et al.[86,87] for the cross dimerization of **5** (which spontaneously crystallizes in a chiral space group). It should be noted that even apparently minor modifications, at times, have a profound impact on the outcome of solid-state reactions. In the previous example, the methyl ester derivative of **5** gives, upon irradiation, linear polymers.



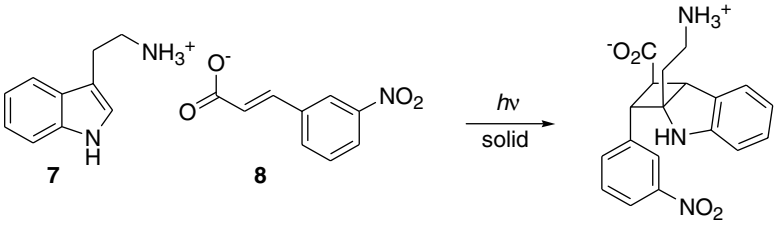
5

Noncovalent interactions, principally hydrogen bonding and electrostatics, have also been used in conjunction with mixed crystal environments in view of directing the outcome of the dimerization process.[88] This approach, which borders on the fields of supramolecular chemistry and crystal engineering, has at times proven very successful. Noteworthy examples include the use of linear or conformationally restricted diamines

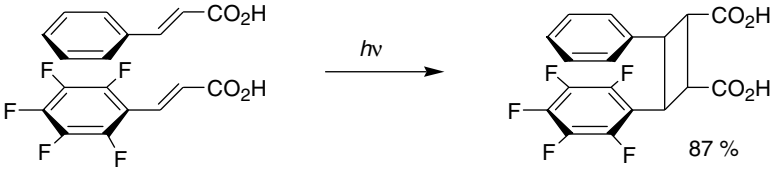
such as **6** to induce variation in the mutual orientation of cinnamic acid during crystallization.[89,90] Here, electrostatic interactions form the basis for driving the formation of 1:2 adducts in the solid phase. Hydrogen bonding between cinnamamides and dicarboxylic acids has also been used to achieve similar results.[91]



Electrostatic interactions probably also play a role in directing the unusual cross photocycloaddition between tryptamine (**7**) and 3-nitrocinnamic acid (**8**) in the solid as reported by Ito and Fujita.[92]



Coates et al.[93] used stacking interactions in the phenyl–perfluorophenyl system[93] to direct co-crystallization of mixed stilbene and cinnamic acid co-crystals, thereby directing the formation of the mixed β-truxinic acid derivative in very high yield. Ito has recently reviewed the solid-state organic photochemistry of mixed crystals.[94]

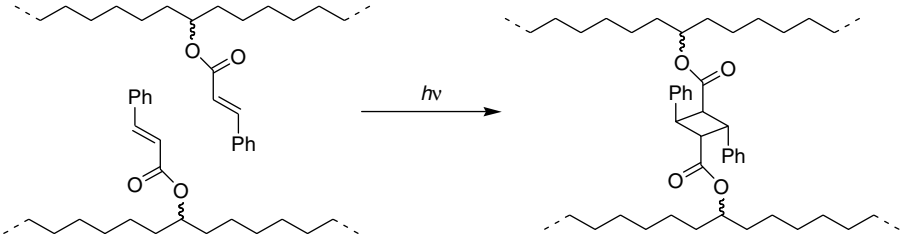


Many examples of dimerization of cinnamate derivatives in the solid exist, including thiocinnamate esters,[40,95–97] α-cyano-cinnamates,[98,99] and in the presence of BF_3.[16,17] It is frequently admitted that the outcome of the dimerization reflects the "prereaction" ordering of the chromophores.[12] This seems to hold true, with a few exceptions where rearrangement or isomerization (as in the case of crystalline *Z*-cinnamic acid) takes place prior to photodimerization.

The solid-state chemistry of coumarin has also received considerable attention, mainly due to the biological importance of coumarin derivatives, and has been summarized in several reports.[35,100,101] In a comprehensive study of nearly 30 coumarin derivatives in the solid state, Venkatesan, Ramamurthy, and co-workers[102] discuss the criteria for topochemical reactivity in the solid set forth 20 years earlier by Schmidt. Their results, though not invalidating previous guidelines for solid-state reactivity, indicate that caution, rather than rigor, is recommended in their application. The irradiation of coumarin within chiral inclusion complexes has also been used as a means to achieve enantioselective dimer synthesis.[71,103–105]

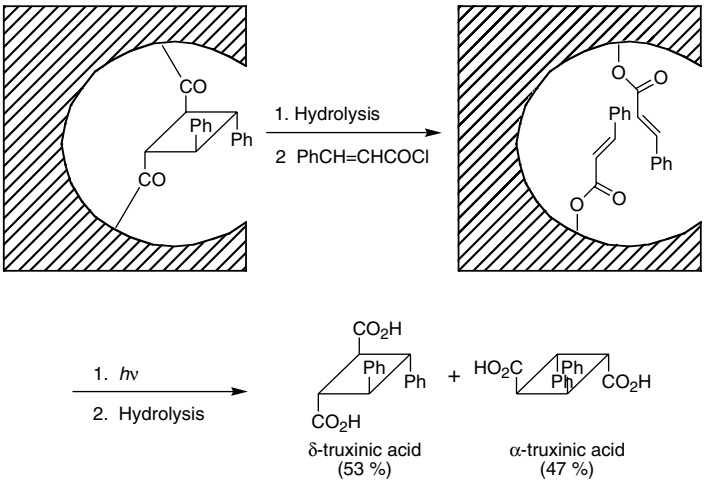
20.4 Polymer Systems

Photoresponsive polymers, in which light is used to bring about a change in a sample's physical or chemical properties, have found numerous commercial applications. A wealth of fundamental research has accompanied these developments, with the aim to shed light on the many parameters that influence the behavior and properties of such advanced materials. One of the most commercially successful examples in the field involves the use of pendant cinnamate moieties to induce cross-linking of polymer chains upon exposure to light. Discovered nearly 50 years ago,[106] polymers such as poly(vinyl cinnamate) function as negative photoresists in lithographic materials[14,107] and can also be used in photocurable coatings.[108] Photoreactive polymers combining crown ether and cinnamate units were shown to be active toward cation transport in liquid membranes.[109] Often, the progress of the photodimerization process can be conveniently followed by UV absorption spectroscopy by monitoring the disappearance of the cinnamate chromophore; this approach has often been used to obtain valuable kinetic data (see, for example, reference 110).

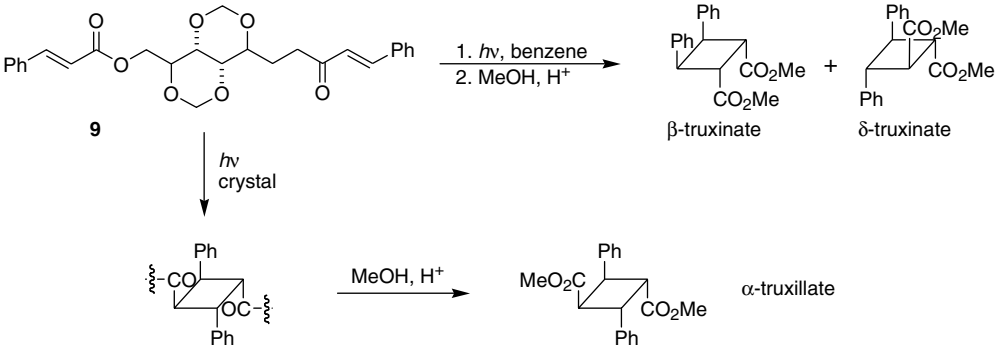


The photoinduced cross-linking of a number of polyacrylates and polymethacrylates containing substituted cinnamoyl groups has been reported.[111,112] Controlling the competition between intra- and interstrand dimerization is of paramount importance in achieving high degrees of cross-linking, as only the latter is productive. Blends of electron donor and electron acceptor substituted vinyl cinnamate polymers were shown to possess superior sensitivity, presumably as a result of the preordering of reactant pair sites due to donor–acceptor interactions.[113]

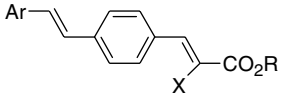
A photochemical template effect (footprinting) was demonstrated by Damen and Neckers[114] through the use of polystyrene networks that were prepared in the presence of monomers appended with truxinic or truxillic acids. Treatment of the hydrolyzed polymers with cinnamoyl chloride, followed by irradiation and hydrolysis, yielded dimers whose composition was biased in favor of the photoproduct with which the polymer had been molded.



Another promising application of photo-crosslinkable polymers is in the stabilization of nanospheres and other micellar assemblies formed from block copolymers.[115–117] Typically, the photosensitive cinnamates are included in one of the polymer blocks, and a block-selective solvent is used to induce its micellation. Irradiation causes photo-dimerization of nearby chromophores, thus covalently linking the aggregated polymer blocks. In their investigation of chiral bifunctional photopolymers, Bernstein et al.[118] showed that the chiral sugar ester **9** yields polymeric material incorporating exclusively α-truxillate linkages when irradiated in the solid state. In contrast, irradiation in benzene solution affords mixtures of mainly the β- and δ-truxinate isomers.



Numerous derivatives of arylethenylcinnamate ester **10** (Ar = 2- or 4-pyridine, pyrimidine; X = H, CN; R = alkyl) have been investigated by Hasegawa and co-workers.[87,119–121] These compounds are remarkable in their versatility, undergoing hetero- and homo-dimerization processes that are very sensitive to their environment. Various dimer and polymer structures can be formed, sometimes with high enantioselectivity.

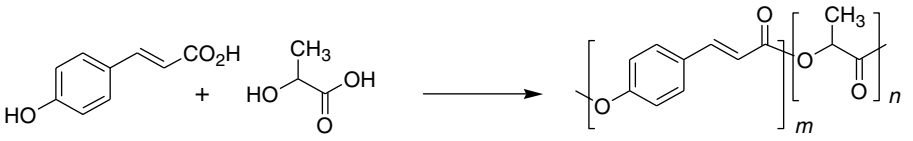


10

Ar = pyridine, pyrimidine
X = H, CN
R = Me, Et, Pr

An important breakthrough in the area of photoresponsive polymers came from the discovery that the use of polarized light in the cross-linking step results in birefringent materials that could be used to induce alignment of liquid crystals.[122] This provides an appealing alternative to the rubbing technique used in polyimide films. In addition to the extensive work on the use of azobenzene-containing polymers for such applications, much effort has focused on polymers containing photodimerizable units such as cinnamates and coumarins which, compared to azobenzene derivatives, can exhibit superior long-term thermal stability. Although it is generally assumed that the induced alignment is a result of the anisotropy of the cinnamoyl groups on the polymer chains, the mechanism by which this is brought about remains a topic of debate. Schadt et al.[123] proposed that alignment is a result of preferential dimerization perpendicular to the plane of the incident linearly polarized light.[124–127] This view has been questioned by Ichimura and co-workers, who proposed that both *E,Z*-isomerization and dimerization are, in fact, responsible for the observed photo-induced anisotropy.[128,129] This dual reactivity of the cinnamate chromophore was also evidenced by Olenik et al.,[130] using surface second harmonic generation. Other investigations of the photoinduced molecular orientation and liquid crystal alignment in cinnamate and coumarin thin films include phase-modulated IR[131,132] and Raman spectroscopy.[133] Coumarins have also been applied to the generation of photoinduced anisotropy.[134,135]

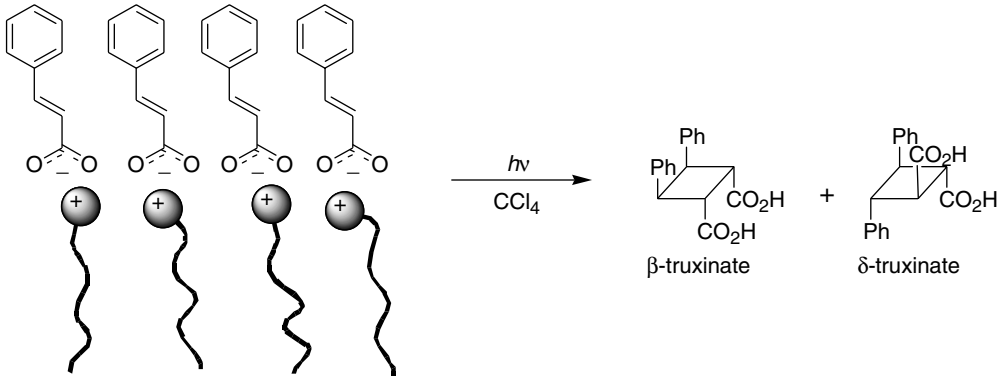
Yet another promising application of cinnamate- and coumarin-containing polymers is in the field of biocompatible or biodegradable materials. Due to their costs, these find use predominantly in medical applications, such as drug delivery systems and as scaffolds for tissue engineering. Thus, coumarin-containing peptides display photoresponsive behavior in their gelling ability.[136] Direct incorporation of *E*-4-hydroxycinnamic acid in poly(lactic acid) affords a polyester that is reported to be photoresponsive towards both *E,Z*-isomerization and dimerization, as evidenced by UV absorption spectroscopy.[137]



20.5 Organized Assemblies and Supramolecular Systems

For simplicity, the irradiation of cinnamate derivatives in various organized assemblies, ranging from self-assembled monolayers and micelles to discrete multi-component architectures, is grouped together. Whether all such structures are indeed "supramolecular" is left to the reader to decide, but it should be noted that many of the preceding examples, particularly those dealing with solid-state crystal engineering, could also belong here. Many photochemical reactions have been revisited in self-organized aggregates such as micelles or monolayers, sometimes with surprising results.[138–140] Cinnamate derivatives are no exception and present the added quality of supplying information on the morphological structure of the assembly, provided the results can be rationalized in terms of topochemical control set forth above.

In its deprotonated form, cinnamic acid already presents some prerequisites of surfactants and is easily incorporated in reversed micelles, as demonstrated by Sawaki and co-workers[141,142] and others.[143,144] Their results support the view that increased local concentration and alignment can be achieved at micellar interfaces. Substantially higher conversion of cinnamate to its photodimers is observed upon irradiation of reversed micelles formed by laurylammonium or hexadecyltrimethylammonium cinnamate in carbon tetrachloride.[142] The photoproducts are mainly the β- and δ-truxinates, consistent with the requirements imposed by the assembly for the formation of contact ion pairs. Unfortunately, these are also the main products observed by Reiser upon irradiation of ethyl cinnamate (albeit in different proportions).[12] Interestingly, however, the observed dimer distribution varies as a function of added water that is proposed to lie near the ion pair interface. Similar results were also obtained for indene-2-carboxylate[145] and using sodium dodecyl sulfate microemulsions in water.[146] The photodimerization of coumarin in micelles has been investigated by Ramamurthy and co-workers.[147–149]

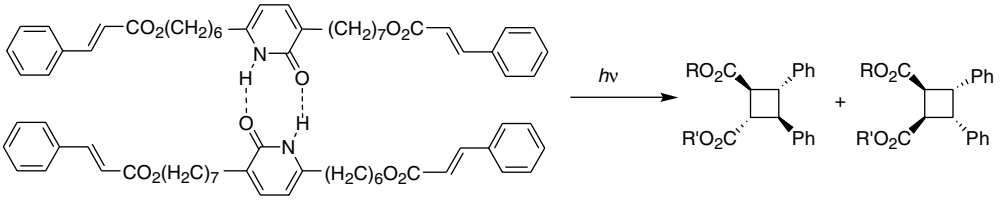


Interest in the study of photoresponsive liquid crystals has expanded tremendously with the advent of flat-panel displays, and the use of cinnamates and coumarin derivatives to orient liquid crystalline

materials has already been discussed (see also Mukkamala et al.[150] and Ramesh and Weiss[151]). It is also possible to use the photoinduced cycloaddition process to crosslink liquid crystalline polymers, thus imparting orientational anisotropy to the entire assembly. This, in turn, can be used to significantly improve such parameters as the viewing angle and contrast of the display.[134] The application of cinnamate derivatives to liquid crystalline polymers has been recently reviewed by Creed et al.,[152,153] who also established the presence of aggregates absorbing in the long-wavelength region,[154,155] and compared the temperature and phase dependence of photocycloaddition products upon triplet sensitization of arylcinnamate liquid crystalline polymers.[156] The photoreactivity of cholesteryl cinnamate in isotropic and mesomorphic phases[157–159] and of liquid crystals based on cinnamate-containing poly(methylmethacrylate)[160] have also been reported.

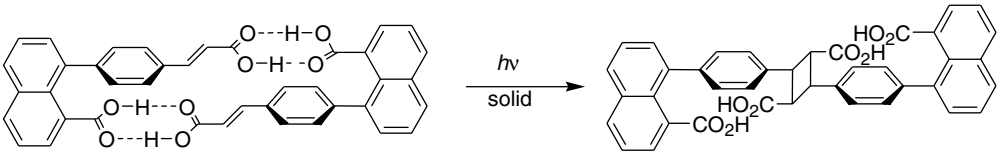
The irradiation of cinnamic acid and cinnamamides at the air/water interface was used by Lahav and co-workers to obtain structural information during the early stages of crystal growth.[161,162] Additionally, Langmuir–Blodgett (L-B) films also provide a facile means of controlling packing structures in two-dimensional assemblies, which can be used to direct dimerization.[163] A limiting factor, in some cases, occurs from disruption of the close packing of the molecules in the film from product formation.[164,165] Comprehensive studies of cinnamate dimerization in L-B films have also been undertaken by the group of Nakanishi[166–168] and by Itoh and co-workers.[169]

Since the mid-eighties, the term supramolecular chemistry has come to signify the programmed self-assembly of complex architectures through the interplay of noncovalent interactions.[170] In the case of the dimerization of cinnamate derivatives, Beak and Ziegler[171] presented, over 20 years ago, the first example of the use of hydrogen bonding in solution to accelerate the usually inefficient cycloaddition reaction. In their work, the self-complementary pyridone unit was used to direct the head-to-head dimerization of the appended cinnamate moieties.

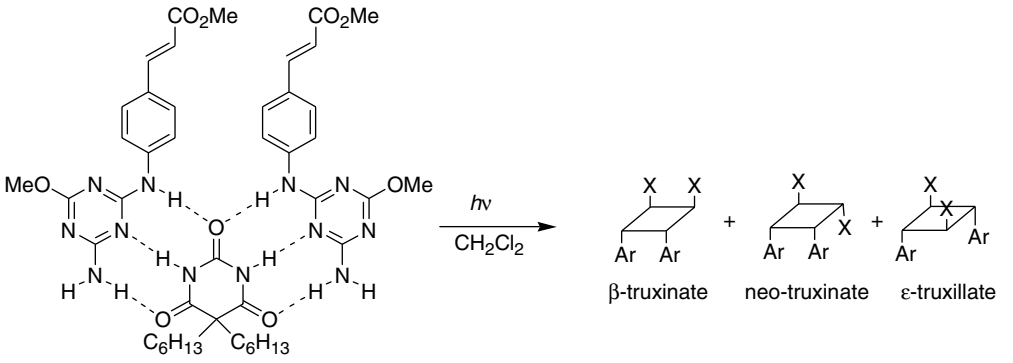


In their communication, however, the authors only reported overall yields of photoproducts, and no kinetic or binding data are available to characterize the intervention of the supramolecular assembly during the photocycloaddition step. In this regard, the choice of ethyl cinnamate as a model compound is also unfortunate, as it cannot be ruled out that the enhancement in yield results from an increase in the single state lifetime of the cinnamate chromophore due to hindered *E,Z*-isomerization. Although the observed products are the β- and δ-truxinate dimers, which are usually the major products from solution photodimerization,[12] the presence of methylene tethers of different lengths could, in principle, be used to provide evidence for the proposed hydrogen-bonded assembly.

Along similar lines, Feldman et al.[172] used a naphthalene scaffold to construct hydrogen-bonded assemblies in the solid state. Their results, which border on the field of crystal engineering, indicate that the dimerization occurs in a quasi-unimolecular fashion to afford the α-truxillate dimer in near-quantitative yield. The reported lack of photoreactivity in tetrahydrofuran (THF) solutions may be due to the weakness of the hydrogen-bonding interactions in those solvents suitable for solubilizing such compounds.



Recently, Bassani et al.[173] reported the use of hydrogen-bonded tape-like structures to assemble cinnamate derivatives in solution. In this work, a dialkylbarbiturate derivative serves to bind two diaminotriazine units appended with cinnamate chromophores. Of the several structures that may be formed, one places the reactive double bonds in close proximity. A nearly 100-fold enhancement in the dimerization rate constant with respect to solution (at identical concentration) is calculated based on the experimentally determined quantum yields and binding constants. The formation of the ε-truxillate dimer — unusual in solution — and control experiments in the absence of template or using a di-*N*-methylated barbiturate substantiate the proposed supramolecular control of photoreactivity.



Dendrimers decorated with peripheral cinnamoyl groups have been prepared to impart photoreactivity to the assembly. Boiko et al.[174] reported the synthesis and investigation of a liquid crystalline carbosilane dendrimer (second generation) containing eight *p*-methoxycinnamate ester chromophores. Irradiation of thin films results in *E,Z*-isomerization and cycloaddition between dendrimers to generate a covalent three-dimensional structure. Wang et al.[175] have shown that intra-dendrimer cycloaddition of the appended cinnamate units is possible upon irradiation of dilute solutions (ca. 10^{-4} *M*) of the dendrimers. Regrettably, in both examples only UV-Vis absorption was used to characterize the formation of photoproducts, and further structural characterization appears complicated due to the dendritic assembly.

An elegant example of the use of supramolecular interactions (hydrophobic forces in this case) to accelerate and direct photochemical cycloaddition reactions is embodied in the use of β-cyclodextrins as a reaction vessel in which to assemble two coumarin molecules in a geometry adequate for dimerization.[37] In the case of 4,7-dimethylcoumarin, recent investigations by Brett et al.[176] using x-ray crystallography to determine the structures of the inclusion complex before irradiation and of the photoproduct reveal that the latter is not the expected *syn* head-to-tail or *anti* head-to-head, but rather the *anti* head-to-tail photodimer. Single crystal–to–single crystal photoreaction was observed for the β-cyclodextrin-4-hydroxy-7-methylcoumarin complex and, in this case, the observed photoproduct is correctly predicted from the topochemical principles set forth by Schmidt[64] over 30 years earlier.

Katsumi Tokumaru
International Institute for Advanced Studies

21.1 Introduction

Acenaphthylene (ACN), which forms bright yellowish plates with a melting point of 93–94°C, is one of the simplest nonalternant aromatic hydrocarbons. Since its discovery by Dziewonski and Rapalski in 1912, the photochemical conversion of ACN into two isomeric dimers (*cisoid*-**1** and *transoid*-**1**) has been studied because of its unique photophysical properties and mechanistic interest.[1] ACN is very weakly fluorescent both from the S_1[2–6] and the S_2 states[5] and has an extremely low intersystem crossing efficiency, $\Phi_{S1\rightarrow T1}$.[6] Distortion in the S_1 state would lead to a large Frank–Condon overlap with higher vibrational levels of the S_0 state, resulting in rapid nonradiative decay from the S_1 state to the S_0 state with a very short lifetime (e.g., 1.2 nsec in *n*-hexane,[4] 3.5 nsec in cyclohexane,[5] 0.6 nsec in toluene[6]). Moreover, ACN is not phosphorescent at low temperatures.[7] Therefore, the S_1 state of ACN undergoes efficient internal conversion as a major pathway and is expected to be poorly reactive on irradiation. However, upon irradiation with UV or visible light, the alkene CC double bond of ACN undergoes various photochemical processes, including dimerization, as is the case with many other simple alkenes.

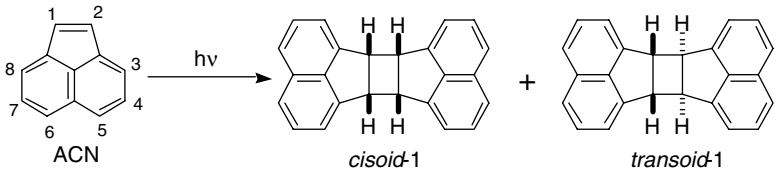
In this review, we will first describe the photochemical dimerization of ACN in solution, summarizing studies that have been carried out over the past 30 years, focusing on the mechanistic aspects and the reactivity of the S_1 and the T_1 states and of radical ions generated by photochemical electron transfer. Thereafter, reactions in the solid state and constrained media, including the crystalline state, silica gel surfaces, micelles, liquid crystals, zeolite, and other heterogeneous media will be described.

21.2 Physical Properties of Excited States of Acenaphthylene

The photophysical and electrochemical properties of ACN are summarized in Table 21.1. Data for naphthalene (NP) and acenaphthene (ACE), congeners of ACN with a naphthalene moiety, are included in the same table to emphasize the peculiarly short lifetime of the ACN S_1 state, the low efficiency of fluorescence, the low quantum yield for intersystem crossing (ISC), and the low efficiency for phosphorescence.



SCHEME 1

21.3 Photochemical Dimerization in Isotropic Solutions

Formation of the Two Isomeric Dimers of Acenaphthylene

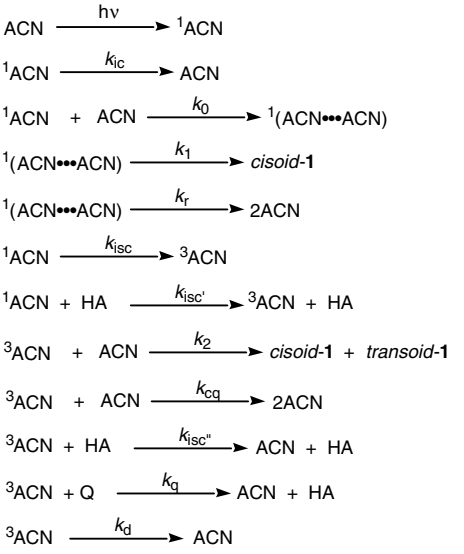
The first report on dimerization of ACN described its exposure to sunlight and its conversion into two dimeric products with higher melting point (305°C) for *transoid*-**1** and a lower melting point (233°C) for *cisoid*-**1** (Scheme 1).[1] Chemical conversion of these compounds into 1,2,3,4-tetracarbomethoxycyclobutanes by ozonolysis followed by esterification with diazomethane allowed the verification of their structures.[8] Direct evidence for the structure of *cisoid*-**1**[9] and *transoid*-**1**[10] was obtained from x-ray crystallographic analysis, where space group, lattice parameters, Z value, and observed density were determined, though lacking the atomic positions for the latter. The use of a nitrogen laser as a light source was also reported in the literature to give the dimers **1** on irradiation of ACN in methanol. This report lacked chemical yields and the *cisoid/transoid* ratio of **1**.[11]

Mechanism of Dimerization from the S_1 and T_1 States of ACN

In 1947, Bowen and Marsh determined quantum yields of the dimerization reaction of ACN at 436 nm (direct excitation of ACN) in toluene, varying the concentration of ACN in the range of 0.16 ~ 1.13 M, and suggested that the mechanism is probably not of a collisional type, but is dependent on the existence of van der Waals complexes in solution.[12] Schenck and Wolgast found that the dimerization can be sensitized by Rose Bengal on irradiation with light of $\lambda > 590$ nm and gives the dimers **1** in a *cisoid/transoid* ratio of 2.64 in methanol. The dimerization was inhibited by O_2 and cyclooctatetraene as triplet quenchers. The authors concluded that the dimers **1** were, for the most part, derived from the T_1 state of ACN.[13] Formation of the T_1 state of ACN by sensitization was also demonstrated in later work by White et al. They generated triplet states of simple ketones by thermolysis of trimethyl-1,2-dioxetane at 100°C and used these excited state ketones to transfer energy to the ground state of ACN. This afforded the dimers **1** from the T_1 state of ACN in a *cisoid/transoid* ratio similar to that mentioned above.[14]

Hartmann et al. studied the effect of ACN concentration [ACN] and the presence of cyclooctatetraene on direct or Rose Bengal–sensitized excitation in 16 solvents of varying polarity.[15] The logarithmic *cisoid/transoid* ratio of **1** showed a linear relationship with the dielectric constant of the solvent. Cyclooctatetraene suppresses the formation of *transoid*-**1**, whereas sensitization by Rose Bengal results in a decreased *cisoid/transoid* ratio. In line with these results, the authors made some important inferences on the reaction mechanism that have currently been proven to be correct in essence. Thus, an association of two ground state ACN molecules can form a molecular complex (van der Waals complex), which is stabilized in more polar solvents. The S_1 state of the molecular complex (an excimer) may give *cisoid*-**1** exclusively; this is in contrast to the T_1 state of the uncomplexed ACN molecule, which leads to both *cisoid*- and *transoid*-**1**, whose distribution depends on the nature of the solvent.

Livingston and Wei irradiated ACN at various concentrations in methanol and benzene (0.05 ~ 1.5 M) and found that both the quantum yield and the chemical yield of *cisoid*-**1** increase with the increase of [ACN] in degassed solutions.[16] Only *cisoid*-**1** was found in oxygen-saturated solutions. They determined the apparent

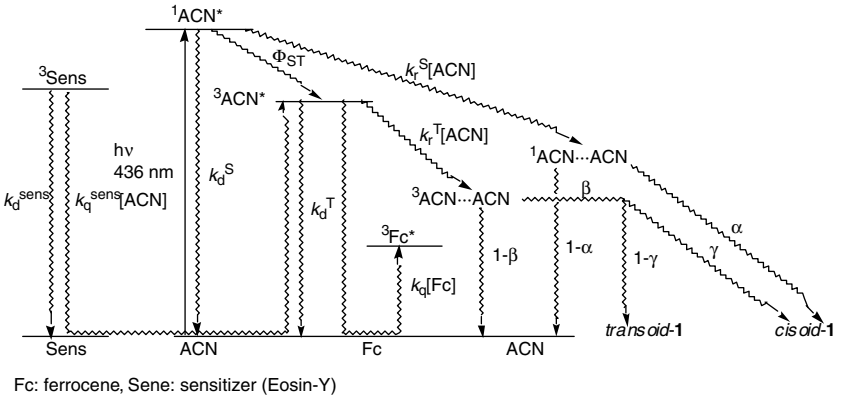


SCHEME 2

molecular weight of ACN in *n*-hexane as 154 using a differential vapor pressure method to give a value slightly higher than the formula weight of 152. This result was taken to support the proposal by Hartmann et al. that two ACN molecules in the ground state form a van der Waals dimer in a face-to face manner. Exclusive excitation of this molecular complex gives *cisoid*-**1** by a unimolecular reaction of an excimer, whereas excitation of the monomeric ACN affords both *cisoid*-**1** and *transoid*-**1**.[15]

A more detailed insight into the mechanism has been contributed by Cowan and Drisco.[17,18] Their results showed that both the quantum yield at 436 nm for the dimer formation and the *cisoid/transoid* ratio increased linearly with increase of [ACN] in the high concentration range of 0.22 ~ 1.34 *M*. Formation of *cisoid*-**1** was more dominant in polar methanol than in nonpolar cyclohexane and benzene. Ferrocene and O_2 quenched the precursor of *transoid*-**1** but only slightly reduced *cisoid*-**1** formation.[18] Sensitized dimerization experiments were utilized to bracket the energy of the T_1 state: E_T, as 170 ~ 180 kJ mol^{-1}.[18] Thus, energy transfer from excited sensitizer to the ground state ACN was successful with Rose Bengal (E_T = 187.0 kJ mol^{-1}) but failed with Crystal Violet (E_T = 163.2 kJ mol^{-1}). These results are also in accord with the mechanism proposed by Hartmann et al.[15]

Cowan et al., furthermore, investigated the dimerization of ACN from the T_1 state.[19–21] In studies that employed solvents that include heavy atoms such as chlorine, bromine, iodine, antimony, and tin, the chemical yields and the *cisoid/transoid* ratio of the dimers **1** were determined in each solvent; the relative quantum yields, **Φ**, for **1** were also determined. These solvents were found to promote formation of products originating from the T_1 state in comparison with solvents without heavy atoms, such as benzene and cyclohexane. Correlation of the yields of *transoid*-**1** with the square of the spin-orbit coupling parameters of these heavy atoms indicates that the heavy atom solvent effect is a result of spin-orbit coupling to enhance ISC from the S_1 state of ACN to the T_1 state.[19] Plots of 1/**Φ** increased linearly with increase of concentration of ethyl iodide [EtI] and [ACN]$^{-1}$.[20,21] Ethyl iodide apparently enhanced ISC from the S_1 to the T_1 state leading to predominant dimerization from the T_1 state with preference for *transoid*-**1** (*cisoid/transoid* ratio of 0.28) in cyclohexane. However, higher [EtI] resulted in a decrease of **Φ**, indicating a smaller but significant effect of the heavy atom to accelerate ISC from the T_1 to the S_0 state. On the basis of elegant analysis of kinetic data including Stern–Volmer quenching plots by ferrocene, the mechanism shown in Scheme 2 has been proposed, where ^{1}(ACN•••ACN) = singlet excimer, HA = EtI, Q = ferrocene. The triplet lifetime of ACN, τ_{T1}, the rate constant for dimerization from the T_1 state, k_2, the rate constant for concentration quenching, k_{cq}, the rate constant for unimolecular decay, k_d, and



Fc: ferrocene, Sene: sensitizer (Eosin-Y)

SCHEME 3

the rate constant for quenching by EtI, k_{isc}, were reported to be 2.15×10^{-6} sec, 6.58×10^5 M^{-1} sec^{-1}, 1.58×10^6 M^{-1} sec^{-1}, 9.20×10^4 sec^{-1}, and 6.71×10^4 sec^{-1}, respectively.[21]

Later studies by Koser and Liu also demonstrated that the heavy atom effect promoted the formation of **1** derived from the T_1 state of ACN in the presence of *p*-X-bromobenzenes (X = OCH_3, CH_3, H, CHO, CF_3) in methanol; however, the *cisoid/transoid* ratio does not vary linearly with Hammett's substituent constant, σ.[22]

According to the valid mechanism pictured in Scheme 2, the singlet excimer, whether coming from an encounter between the S_1 state of ACN and the ground state ACN or from the van der Waals dimer formed in the ground state, is converted into *cisoid*-**1**, while excitation of a monomeric ACN molecule leads to the T_1 state of ACN, which results in the formation of both of the isomeric dimers with a preference for *transoid*-**1**. Actually, the larger Mulliken electronic overlap population at the 1,1′ positions for the *cis* configuration of an excited molecular pair than for the *trans* configuration with a shorter distance of 3.5 ○ between the alkene moieties of ACN explains the preferred formation of *transoid*-**1** in the absence of aggregation of two ACN molecules prior to excitation.[23] Taking the electronic overlap population at the 6,6′ positions of ACN for excimer formation from an aggregated molecular complex in the ground state, the *cis* configuration can be favored over the *trans* configuration.

The above conclusions derived from the studies Hartmann et al.,[15] Livingston and Wei,[16] and Cowan et al.[17–21] were confirmed by the recent studies of Haga et al.[24] For the purpose of strict elucidation of the roles of the S_1 and the T_1 state of ACN, they scrutinized the dimerization under irradiation of a highly diluted solution. The quantum yields at 435.8 nm, Φ_R, and the *cisoid/transoid* ratios in several solvents over a wide range of concentration ($2.0 \times 10^{-4} \sim 2.0$ *M*) in the absence of additives and in the presence of 1,2-dibromoethane (a heavy atom solvent), Eosin-Y (a triplet sensitizer), and ferrocene (a triplet quencher) were measured. In dilute solution, where ISC from the S_1 state occurs in competition with rapid internal conversion because reaction from the S_1 state can be considerably suppressed, the resultant T_1 state reacts with ground state ACN to give the dimers **1** with the *cisoid/transoid* ratio depending on the solvent. In more concentrated solutions, the S_1 state reacts with ACN prior to ISC into the T_1 state leading to exclusively *cisoid*-**1**. In line with the mechanism depicted in Scheme 3, they have determined the following values (see Table 21.2):

Fraction survival from the singlet excimer leading to *cisoid*-**1**, α
Fraction survival from the T_1 state of ACN to **1**, β
Distribution between *cisoid*- and *transoid*-**1** from the T_1 state, γ
The rate constant from the singlet excimer to afford *cisoid*-**1**, k_r^S
Quantum yields from the S_1 into the T_1 state with and without the heavy atom solvent dibromoethane, Φ_{ST} and Φ_{ST}^{DBE}, respectively

TABLE 21.2 Selected Data for the Photochemical Process from the S_1 and the T_1 States

	1,2-Dichloroethane	Acetonitrile	Cyclohexane
α	0.257	0.286	0.385
k_r^S (M^{-1} sec^{-1})[a]	6.3×10^9	2.6×10^9	1.6×10^9

The rate constant from the T_1 state to afford **1**, k_r^T
The lifetime of the T_1 state, τ^T

It is clearly demonstrated that the small but nevertheless significant Φ_{ST} of 0.029 in acetonitrile and 0.045 in cyclohexane is the origin of *transoid*-**1**. The 10,000-fold longer lifetime of the T_1 state of 10^{-6} sec than that of the S_1 state of 10^{-10} sec, together with the larger β than α in each solvent, contributes to the higher Φ_R from the T_1 state at low [ACN]. The γ value depends on the solvent used, with preference for *transoid*-**1** in 1,2-dichloroethane (0.337) and in cyclohexane (0.361), but for *cisoid*-**1** in more polar acetonitrile (0.618).

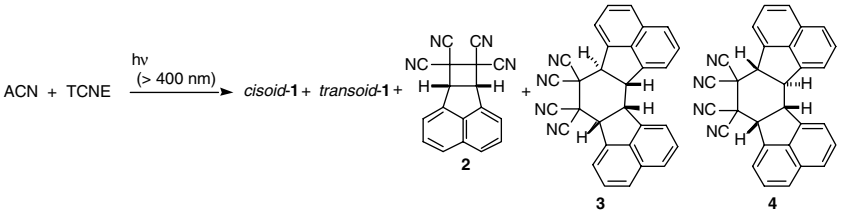
Preferred formation of *cisoid*-**1** from the T_1 state in polar solvents was observed in the reaction in aqueous solution. Sigman et al. irradiated very dilute solutions of ACN (5×10^{-5} *M*) in water both by direct excitation ($\lambda > 350$ nm) of ACN and by Rose Bengal–sensitization ($\lambda > 540$ nm).[25] It is worthy of note that the quantum yield for formation of **1** was greater in water than in methanol. Also, the *cisoid/transoid* ratio by direct excitation at lower conversion of ACN showed a small excess of *cisoid*-**1** (*cisoid/transoid* = 1.5), and upon further conversion the ratio changed to favor *transoid*-**1** (*cisoid/transoid* = 0.6). Rose Bengal sensitization afforded a large excess of *cisoid*-**1**. Moreover, irradiation at elevated temperatures gave rise to increased *cisoid*-**1** but with a lower quantum yield. The authors interpreted these unique phenomena as follows: not only the S_1 but also the T_1 state preferentially yields *cisoid*-**1** in water. On the other hand, *transoid*-**1** comes from crystalline ACN produced by co-precipitation on seed crystals of *cisoid*-**1** produced in the early stage of the irradiation. The enhanced quantum yield in water compared to that in organic solvents was due to the hydrophobic effect by co-precipitation of ACN with *cisoid*-**1** produced. High temperature will prevent the co-precipitation leading to the reduced quantum yield and increased *cisoid/transoid* ratio.

Ichimura and Watanabe also addressed the question of ISC to the T_1 state and found that, under 13 kG of magnetic field in benzene, the *cisoid/transoid* ratio of the dimers **1** increased from 0.05 to 0.10.[26] They attributed the increase of the *cisoid/transoid* ratio to the effect of the magnetic field in promoting ISC or to relaxation of complexes produced from the T_1 state.

Gáplovsky et al. conducted ultrasound irradiation of ACN.[27] Sonication at 35 or 20 kHz of ACN (0.09 *M*) solutions in benzene using reactors designed to allow simultaneous irradiation by UV light and ultrasound resulted in preferred formation of *cisoid*-**1** (*cisoid/transoid* = 45). This is marked contrast to the silent process (*cisoid/transoid* = 25). This fact showed that ultrasound did not affect the dimerization from the S_1 state of ACN but affected the dimerization from the T_1 state by quenching.

Dimerization in the Presence of an Electron Acceptor or Electron Donor

Shields et al. reported the reaction of ACN with maleic anhydride in dioxane, acetone, acetonitrile, dichloromethane, dibromoethane, and iodomethane.[28] On irradiation of the solution of ACN ($\lambda >$



SCHEME 4

330 nm), a 1:1-adduct between maleic anhydride and ACN with a cyclobutane ring was produced stereoselectively, along with the dimers **1** (no data for the *cisoid/transoid* ratio were reported), and the distribution among these products depended on the solvent used. They stated that both the S_1 and T_1 states of ACN undergo exergonic electron transfer to maleic anhydride to generate the radical cation $ACN^{+\cdot}$, which subsequently leads to dimerization with a neutral (ground state) ACN. No reference was made regarding the detailed mechanism for formation of **1**.

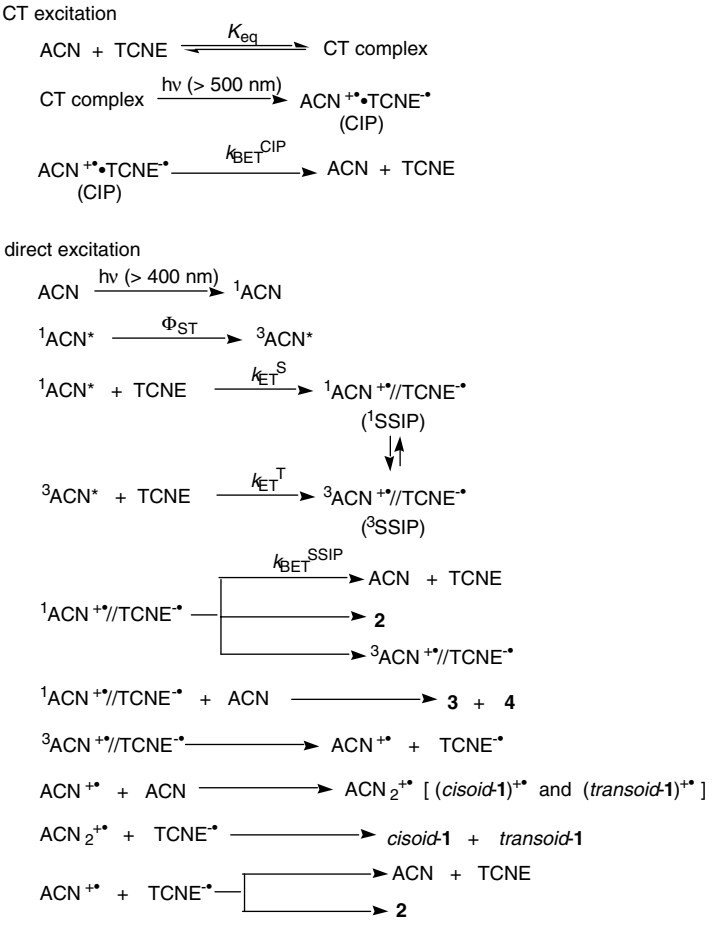
Recently, Jiang et al. conducted photochemical reactions of ACN sensitized by cyanoanthracene or dicyanoanthracene in the presence of O_2.[29] Irradiation ($\lambda > 300$ nm) of ACN (4×10^{-2} *M*) in the presence of the sensitizers (4×10^{-4} *M*) in acetonitrile or benzene gave *cisoid*-**1** as well as acenaphthone and acenaphthenequinone as primary photochemical products. It is quite obvious that the key intermediate leading to these primary products is $ACN^{+\cdot}$ produced by electron transfer to the sensitizers. Though the authors attributed this result to quenching of the T_1 state of ACN by O_2 and did not refer to participation of $ACN^{+\cdot}$, preferential formation of *cisoid*-**1** is in accord with the recent findings of Haga et al. involving $ACN^{+\cdot}$, as described below.[30]

Haga et al. have clearly demonstrated contrasting reactivities between different modes of photoinduced electron transfer from ACN to tetrcyanoethylene (TCNE).[30] That is, ACN and TCNE form a tan-brown charge transfer (CT) complex in equilibrium in acetonitrile or 1,2-dichloroethane. This complex has an absorption at wavelengths longer than 500 nm. Excitation of the CT complex ($\lambda > 500$ nm) did not give any reaction product. On the contrary, direct excitation of ACN ($\lambda > 400$ nm) in the presence of TCNE gave the dimers **1** as the major products as well as addition products (**2, 3, 4**) to TCNE as minor products (Scheme 4). This result is consistent with an early report by Shirota et al., who found that excitation of ACN in the presence of TCNE in 1,2-dichloroethane with $\lambda > 320$ nm light yielded the 1:1-adduct (**2**), but excitation of the CT complex with light of wavelengths in the 500 ~ 600 nm range failed to yield any product.[31]

On direct excitation of ACN, the resultant excited state of ACN acts on TCNE to undergo electron transfer affording the solvent separated radical ion pair (SSIP) of $ACN^{+\cdot}$ and $TCNE^{-\cdot}$, which subsequently undergoes diffusion from the pair to give free radical ions (FRIs) of $ACN^{+\cdot}$ and $TCNE^{-\cdot}$, competing with back electron transfer, BET, reverting to the ground state of ACN and TCNE (Scheme 5). The $ACN^{+\cdot}$ that escapes from the SSIP either adds to the ground state of ACN to give the dimeric radical cation, $ACN_2^{+\cdot}$, which then accepts an electron from $TCNE^{-\cdot}$ to produce the dimers **1** and regenerate TCNE, or encounters with $TCNE^{-\cdot}$ to produce the 1:1-adduct (**2**).

On the contrary, selective excitation of the CT complex affords the contact radical ion pair (CIP) of $ACN^{+\cdot}$ and $TCNE^{-\cdot}$, which undergoes charge separation by the way of SSIP competing with BET between $ACN^{+\cdot}$ and $TCNE^{-\cdot}$ within the CIP. Because SSIP undergoes BET much more slowly than CIP does, SSIP produced by direct excitation of ACN can dissociate to FRIs with a higher proportion leading to the dimers **1**, whereas CIP generated from selective excitation of the CT complex prefers deactivating BET without chemical change rather than dissociation to FRIs via SSIP.

Data pertinent to the mechanism of direct excitation of ACN are obtained from the effect of concentration of TCNE on quantum yields for products (Φ_R) and the *cisoid/transoid* ratio of **1**. These data rationalize the involvement of the singlet SSIP (^{1}SSIP) under high [ACN] and the triplet SSIP (^{3}SSIP) under low [ACN]; the former tends to undergo BET but the latter undergoes dissociation to FRIs leading to **1** (Scheme 5). The rate constant for electron transfer from the T_1 state of ACN to TCNE (k_{ET}^T), the



SCHEME 5

TABLE 21.3 Selected Data Relating to the Dimerization of ACN on Excitation in the Presence of TCNE

	1,2-Dichloroethane	Acetonitrile
k_{ET}^{T} (M^{-1} sec^{-1})	2.3×10^8	3.4×10^8
k_{ET}^{S} (M^{-1} sec^{-1})	3.3×10^{11}	5.8×10^{11}
x_T	0.023	0.11
x_S	0.017	0.015

fraction survival from the T_1 state of ACN to afford **1** (x_T), the rate constant for electron transfer from the S_1 state of ACN to TCNE (k_{ET}^{S}), and the fraction survival from the S_1 state leading to **1** (x_S) were established both in 1,2-dichloroethane and in acetonitrile (Table 21.3).

Haga et al. have subsequently studied photochemical reactions of CT complexes of ACN with a series of acceptors, including nitriles, acid anhydrides, and 1,4-benzoquinones (BQs), with varying reduction potential ($E_{1/2}^{Red}$), with the intention of quantitatively estimating the effect of the ease of BET from CIP on the efficiency of production of reaction products.[32,33] They found a clear trend indicating that the quantum yields for the formation of the dimers **1** by CT excitation (Φ_{CT}^{dimers}) tended to decrease with the decrease of the energy gap between the ground state and CIP ($-\Delta G_{BET}$) and finally became zero when

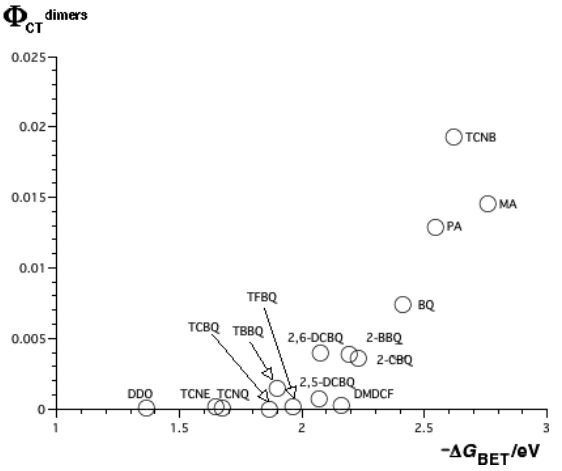


FIGURE 21.1

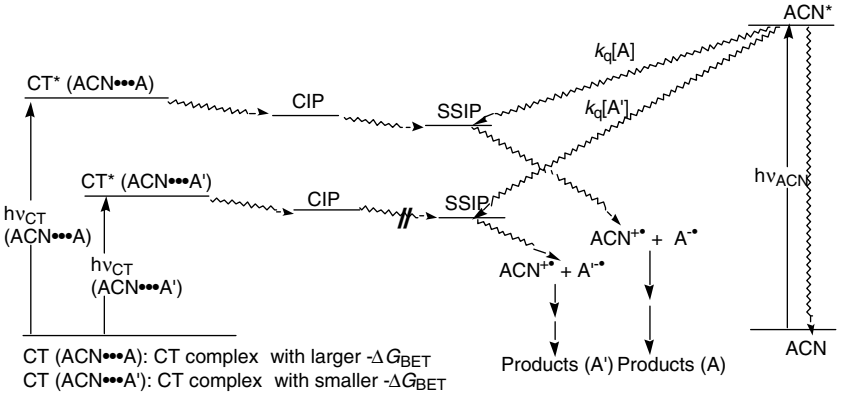
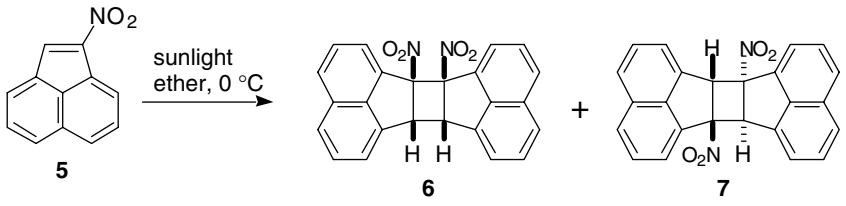


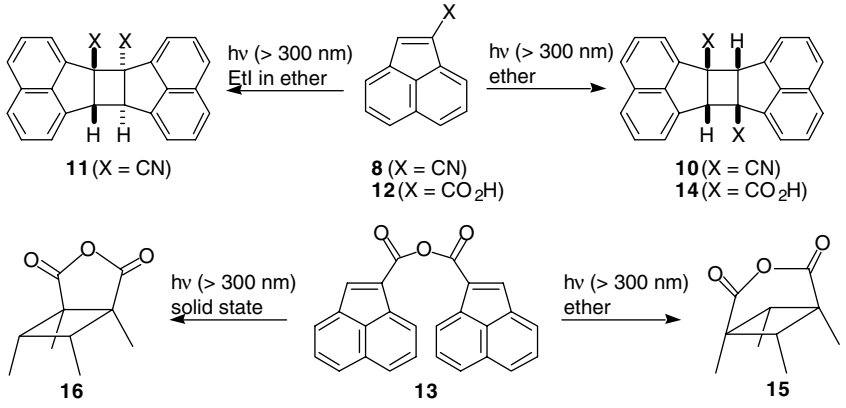
SCHEME 6

$-\Delta G_{BET}$ was smaller than a threshold of ca. 1.8 ~ 1.9 eV (Figure 21.1). On the contrary, direct excitation of ACN afforded products irrespective of the acceptor. It is undoubtedly clear that dissociation from CIP is almost nonexistent when $-\Delta G_{BET}$ is smaller than the threshold value referred to above, and dissociation from CIP to FRIs via SSIP tends to be enhanced with increase of $-\Delta G_{BET}$ and therefore enhances Φ_{CT}^{dimers} (Scheme 6). This is in keeping with the results of the transient spectroscopy by Mataga and co-workers showing that CIP produced by excitation of CT complexes of various aromatic hydrocarbons with nitriles or acid anhydrides tend to deactivate more rapidly with decrease of $-\Delta G_{BET}$.[34]

Compared to the production of $ACN^{+\cdot}$, the formation of the radical anion $ACN^{-\cdot}$ by photoinduced electron transfer has seldom been mentioned in the literature. Davidson has carried out irradiation of ACN in the presence of tertiary amines such as *N,N*-dimethylaniline and triethylamine in benzene and acetonitrile.[35] Reaction in benzene affords **1** in the *cisoid/transoid* ratio of 1.0. On the other hand, in acetonitrile *cisoid*-**1** was formed, as well as acenaphthene (ACE), without affording *transoid*-**1**. Interpretation for the solvent-dependent product distribution is that the T_1 state of ACN, produced from interaction



SCHEME 7



SCHEME 8

between the S_1 state of ACN with electron donors such as amines in benzene, is responsible for formation of both of the dimers, whereas the S_1 state can be produced in acetonitrile, which then undergoes dimerization with ground state ACN leading to *cisoid*-**1** or electron transfer with the amines to give $ACN^{-\cdot}$, followed by its further reduction to ACE.

Dimerization of Substituted ACN

Photochemical dimerization of substituted ACN is a relatively unexplored field, presumably in part due to synthetic difficulty. Substrates studied so far are limited to derivatives of ACN substituted at the alkene carbons (position 1 and 2); those with substituents on the aromatic rings have not been investigated. Cantrell and Shechter irradiated 1-nitroacenaphthylene (**5**), which was obtained by reaction of ACN with dinitrogen tetroxide (N_2O_4).[36] Sunlight irradiation of **5** in ether solution (0.046 *M*) at 0°C gave the *syn-cisoid*-dimer (**6**) and the *anti-transoid*-dimer (**7**) in isolated yields of 35 and 3.8%, respectively (Scheme 7). The stereochemistry of the two products was deduced on the basis of measured dipole moments of 5.82 ± 0.2 and 0.00 D for **6** and **7**, respectively. Castellan et al. performed irradiation of 1-cyanoacenaphthylene (**8**) and 1,2-dicyanoacenaphtylene (**9**) in the presence and the absence of a sensitizer such as Eosin-Y or ethyl iodide in methanol or benzene.[4] The E_S of **8** and **9** were determined to be 251.5 and 244.8 kJ mol^{-1}, respectively. Direct excitation of **8** in ether in the absence of ethyl iodide gave the *anti-cisoid*-dimer (**10**) predominantly, which shows that **10** arises from the S_1 state of **8** (Scheme 8). To the contrary, the T_1 state of **8**, produced in the presence of ethyl iodide or by sensitization, resulted in exclusive formation of the *syn-transoid*-dimer (**11**). The stereoselectivity and regioselectivity of these reactions are discussed in terms of a biradicaloid transition state stabilized by the ACN ring and the cyano group.

21.4 Photochemical Dimerization in Organized and Constrained Media

Dimerization of Acenaphthylene in the Crystalline or Solid State

Wei and Livingston published the first report of the photochemical dimerization of ACN in the solid state in 1969. They irradiated molten or crystalline ACN at 436 nm at 0 ~ 70°C.[37] At 0 ~ 25°C, *transoid*-**1** was exclusively produced with a low quantum yield (Φ_{trans} = 0.0029 at 0°C); however, at elevated temperatures over 60°C. both the Φ and the *cisoid/transoid* ratio gradually increased (Φ_{cis} = 0.0405, Φ_{trans} = 0.0041 at 70°C). These results allow us to estimate the activation energy, E_{act}, for formation of *transoid*-**1** and *cisoid*-**1** as 10.0 and 167 kJ mol^{-1}, respectively. Cohen et al. irradiated ($\lambda > 300$ nm) crystalline ACN at 0°C and also found *transoid*-**1** as the sole product.[38] Photomicrography of thin single crystals of ACN showed dislocation arrays within the monomer crystal; however, selective formation of *transoid*-**1** was not rationalized.

Attempts to elucidate the detailed crystal structure of ACN by x-ray diffraction, a crucial issue for exclusive formation of *transoid*-**1** at low temperature, have largely been unsuccessful[39,40] due to the high degree of disorder in the crystal at ambient temperatures.[41] It has been pointed out by pulse NMR technique that ACN undergoes an order–disorder phase transition at 130 K.[42] Furthermore, He and Welberry have demonstrated, using semiempirical potential energy calculations, that 10 out of 12 possible ordered structures of crystalline ACN with various molecular orientations had total potential energies within 2.5 kJ mol^{-1} of each other.[43] Therefore, poorer selectivity among the dimers **1** at room or higher temperature agrees well with promoted disorder of ACN molecules in the crystalline state with many different molecular orientations. A detailed crystal structure of ACN was accomplished by neutron diffraction at 80 K;[44] however, topochemical evidence for preferential formation of *transoid*-**1** at low temperature is, at present, not available.

In the recent work on photoinduced electron transfer of CT complex between ACN and TCNE by Haga et al., the crystalline CT complex with a 1:1 composition, ACN•TCNE, was prepared as tan-brown prisms.[30,45] Irradiation of ACN•TCNE either by CT excitation ($\lambda > 500$ nm) or by direct excitation of ACN moiety ($\lambda > 400$ nm) at 25°C afforded the 1:1-adduct **2** as the sole product in yields higher than 70% based on ACN consumed without giving the dimers **1**. X-ray crystallography shows, in the CT crystalline lattice, that the two alkene parts of ACN and TCNE are aligned parallel with the interatomic distances within 3.7 Å, which satisfies the requirements for the [2 + 2]-cycloaddition of ACN to TCNE in the solid state under the topochemical control in the crystalline lattice (Figure 21.2).[46] On the other hand, those of two ACN molecules are aligned unfavorably for the dimerization to give **1** with interatomic distances longer than 6 Å. This is reflected in no formation of **1** by irradiation of ACN•TCNE CT crystal. Instead of irradiation of the CT crystal, irradiation of the tan-brown ground powder of an equimolar mixture of ACN and TCNE with $\lambda > 500$ nm light (CT excitation) afforded **2** (75.8%) and **1** (12.5%) with a *cisoid/transoid* ratio of 0.71, which is much larger than the ratio, 0.19, from the irradiation of crystalline ACN without TCNE.[30] Production of both **1** and **2** from this mixed powder is attributed to the formation of microcrystalline ACN•TCNE by pulverization of the mixture, which under irradiation undergoes electron transfer to give $ACN^{+\cdot}$ leading to not only **2**, by coupling with $TCNE^{-\cdot}$, but also **1** by reaction with a proximate ground state ACN molecule in looser and randomly arranged molecules in the mixed powder. Furthermore, direct excitation of ACN ($\lambda > 400$ nm) in the mixed powder resulted in a decrease in the yield of **2** (12.2%) and an increase in **1** (78.7%) with a *cisoid/transoid* ratio of 0.20, which is close to that for the direct irradiation of crystalline ACN without TCNE. Therefore, in the mixed powder excited ACN dimerizes by reaction with neighboring ACN molecules and preferentially gives *transoid*-**1** without participation of $ACN^{+\cdot}$ competing with electron transfer to TCNE due to disordered arrangement of molecules.

Bouas-Laurent et al. undertook irradiation of 1-substituted ACN (**8**, **12**: X = CO_2H, **13**: X = CO-O-CO) in solution and in the solid state (Scheme 8).[47] Irradiation ($\lambda > 300$ nm) of **8**, **12**, **13** in ether at

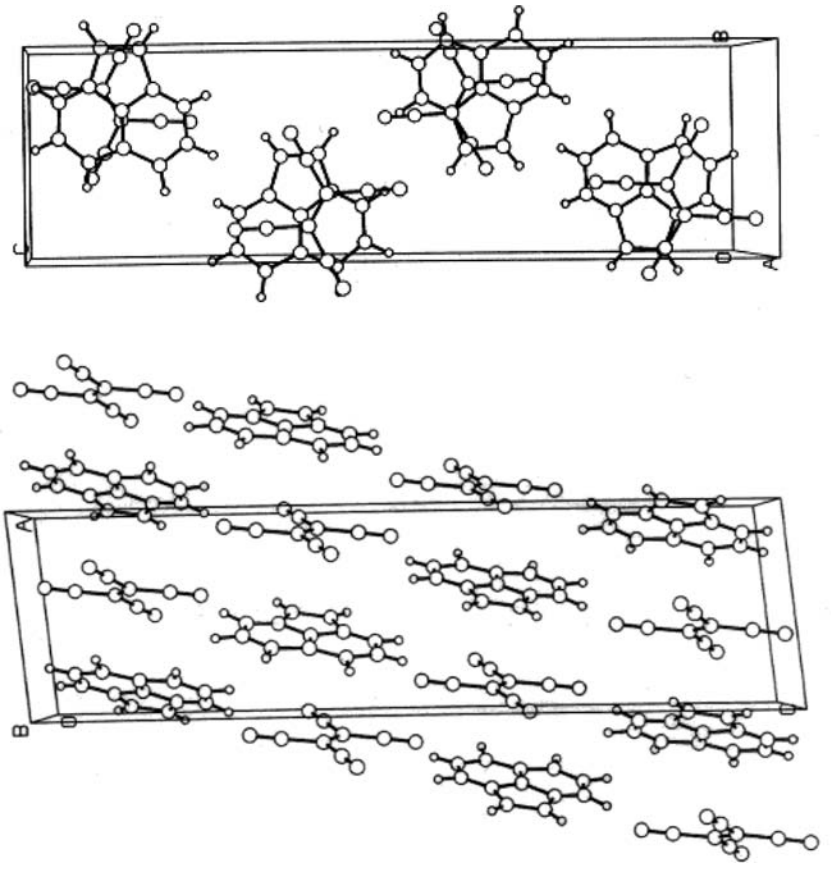


FIGURE 21.2

25°C leads to the *anti-cisoid* dimers (**10, 14, 15**) as major products in yields of 92, 35, and 40%, respectively. Compounds **10** and **15** were hydrolyzed to **14**, and final confirmation of the structure of **10** came from x-ray crystallographic analysis.[48] The dipole moments of **10** and **11** were determined to be 5.90 and 3.65 D, respectively, in benzene at 25°C. On the other hand, irradiation of **13** in both the crystalline and the molten state gave the *syn-cisoid*-dimer (**16**) as the sole product in a yield of 65%. X-ray crystallographic analysis of the monomer **13**[49] demonstrated stereo- and regioselective formation of **16** in the solid state irradiation of **13** according to the topochemical rules.

Dimerization on Silica Gel Surfaces

Photochemistry of ACN adsorbed on a silica gel surface has been reported by de Mayo and coworkers.[50–52] ACN with coverage of 0 ~ 100% on silica gel in the presence or absence of additives (alcohols, ACE, Rose Bengal) was irradiated with a xenon lamp under suitable filters. The major results are abridged as follows.[50,51] The *cisoid/transoid* ratio increased linearly with increase of ACN coverage up to 20%. At above 40%, the curve flattened to about 21 of the ratio. Stern–Volmer plots using ferrocene as a triplet quencher revealed that the formation of *transoid*-**1** is inhibited by the quencher, while efficiency for the formation of *cisoid*-**1** is independent of quencher concentration. Rose Bengal–sensitization produces **1** even at low coverage (0.1%) of the sensitizer. Intergranular movement of ACN molecules adsorbed on the silica gel surface across silica gel particles was directly demonstrated by elaborate experiments using two groups of silica gel particles with different particle sizes.

Essentially, photochemical dimerization on a silica gel surface proceeds by an identical mechanism to that in solution, the short-lived S_1 state leading to the *cisoid*-**1,** and the T_1 state, with a relatively long lifetime, leading to *cisoid*- and *transoid*-**1** with a preference for the latter; however, comparison of quantum yields for the dimerization in solution is not available. Three possible courses leading to **1** from excited ACN proposed by de Mayo et al. are: (a) bimolecular intragranular process, (b) reaction of nearest neighbors (reaction with ACN molecules on neighboring particle), and (c) molecular intergranular encounter. Reactions (a) and (b) could depend on the coverage and proceed mainly via the S_1 state of ACN, whereas reaction (c) comes from the T_1 state because interparticle migration of ACN molecules is sufficiently slow to permit S_1 to T_1 intersystem crossing. An increase in the coverage brings about increased contributions from both reactions (a) and (b), resulting in linear increases of the *cisoid/transoid* ratio. The plateau value of the ratio reflects saturated contribution from reactions (a) and (b) due to a sufficiently high concentration of ACN to allow dimerization from the S_1 state at a diffusion-controlled rate. Sensitization at low coverage (0.1%) of Rose Bengal suggests intra- and intergranular movement of the T_1 state of the sensitizer molecules to allow energy transfer to ground state ACN.

The effect of co-adsorbates such as alcohols and ACE was scrutinized by direct or sensitized excitation of ACN.[51,52] In the direct excitation, the *cisoid/transoid* ratio was reduced from 8.78 with additives to 1.6 ~ 2.8 without additives. In the Rose Bengal sensitization, the ratio remained relatively constant at 0.34 ~ 0.61. Co-adsorption of alcohols increased ACN mobility on the silica gel surface because of blocking of stronger binding sites and reduced the *cisoid/transoid* ratio because increased mobility by solvent molecules would be advantageous for dimerization from the T_1 state, rather than the S_1 state, over a longer time span. Moreover, the co-adsorbed alcohols would result in diminished formation of preferred pairs of ACN that would lead to *cisoid*-**1** from the S_1 state owing to the occupation of sites for pair formation by the co-adsorbate. When ACN is diluted with ACE as an inert counterpart, a hybrid pair of ACN with ACE that is unable to dimerize may be created, and therefore the *cisoid/transoid* ratio reflects the diffusional dimerization via the T_1 state.

Later, Barbas et al. performed irradiation ($\lambda > 350$ nm) of ACN on a dry silica gel–air interface with monolayer coverage of 0.3 ~ 9%.[53] The dimers **1** were produced along with oxidation products of ACN. These products included 1,2-acenaphthenedione, 2-hydroxy-1-acenaphthenone, 1,8-naphthalenedicarboxaldehyde, and 1,8-naphthalic anhydride. For formation of **1**, results derived by Barbas et al. support the validity of de Mayo's results. Thus, the yield of *cisoid*-**1** increased much more dramatically than that of *transoid*-**1** and rose from 2.4 to 13.2 as the surface coverage was increased from 0.3 to 8.6%, which indicates that the contribution from the S_1 state to *cisoid*-**1** formation is more significant than that from the T_1 state.

Dimerization in Micelles

In a pioneering study, Nakamura et al. have pointed out enhancement of photochemical dimerization of ACN in micelles compared to dimerization in solution phase.[54] They employed sodium dodecyl sulfate (SDS) as an ionic surfactant and polyoxyethylene–polyoxypropylene cetyl ether (PBC-34) as a nonionic surfactant. In general, the dimerization occurred efficiently in both of the micelles even with concentrations of ACN as low as 1.9 mmol, whereas dimerization in benzene solution was nil. Under concentrations of 5 ~ 30 mmol of ACN, the *cisoid/transoid* ratio in PBC-30 was ca. 0.8 and independent on the initial concentration of ACN, while that in SDS was as high as 2.7, showing dependence of the ratio on the surfactant used.

The presence of oxygen and the use of surfactants with heavy atoms in micellar systems show similar effects as in homogeneous solution.[55] Mayer and Sauer irradiated ($\lambda > 400$ nm) ACN and 1-substituted ACN (**8**: X = CN, **12**: X = CO_2H, **17**: X = CO_2CH_3, **18**: X = $CO_2C_4H_9$, **19**: X = $CO_2C_8H_{17}$) in the micellar systems of SDS and dodecyltrimethylammonium fluoride, chloride, bromide, and iodide with and without O_2. The reaction of ACN in the SDS micelle resulted in a higher *cisoid/transoid* ratio of ca. 9 under O_2 than that of ca. 1.5 under argon. The ratio decreased with increase of the atomic number of the

counterion of the dodecyltrimethylammonium salts: fluoride 3.54, chloride 2.57, bromide 1.12, and iodide 1.12. As in the case of reaction in homogeneous solutions, the effect of O_2 can be attributed to quenching of the T_1 of ACN leading to preferential dimerization from the S_1 state. Acceleration of ISC by spin-orbit coupling is apparently responsible for the lower *cisoid/transoid* ratio in the reactions in micelles with bromide or iodide anions. Irradiation of **8**, **12**, **17**, **18**, and **19** afforded an *anti-cisoid*-dimer (**10**, **14**, **20**, **21**, **22**) as a major product for each substitution (Scheme 9), the structures of which were deduced by means of ^{1}H- and ^{13}C-NMR.[56] Regio- and stereoselective formation of **10** from **8** and **14** from **12** is essentially identical to the results obtained from irradiation in solution.[47] The same authors compared the *cisoid/transoid* ratio in the reactions in micelles by direct excitation of ACN and by Rose Bengal sensitization with that in solutions with varying polarity of solvent.[57] The ratio in micelles (1.0 ~ 1.1) was independent of [ACN] (8.3 ~ 40.1 mmol) 1.04 and 0.48 for direct and sensitized excitation, respectively. The former ratio corresponds to that in polar solvents such as MeCN and DMF.

Tamura and Aida reported the unique influence of shape and volume of inner micellar space on product distribution.[58] They irradiated ACN in aqueous sodium octyl sulfate, decyl sulfate, dodecyl sulfate, and hexadecyltrimethylammonium bromide under pressures up to 150 MPa. Pressure enhanced the dimerization reaction in all micellar systems due to the formation of a van der Waals dimer in the ground state. Plots of the consumed ACN vs. concentration of micelles exhibited a minimum under constant concentration (9.7 mmol kg^{-1}) of ACN. Thus, the number of micelles in the solution increases with increase of surfactant concentration and, as a result, the number of ACN molecules solubilized per micelle decreases. This leads to a decrease of probability of collision between ACN molecules that undergo bimolecular reaction. Viscosity measurements indicate that spherical micelles start to aggregate and form rod-shaped micelles with larger volumes at ca. 9 wt% of micelle, which exactly coincides with the minimum concentration of micelles. At concentrations of micelles higher than the minimum, the number of ACN molecules included in a micelle increases due to aggregation of spherical micelles into rod-shaped micelles, leading to enhanced dimerization of ACN.

Ramesh and Ramamurthy demonstrated a dependency of the *cisoid/transoid* ratio on the mean occupancy number (S), which refers to number of ACN molecules per micelle.[59] Under constant concentration (0.05 *M*) of aqueous surfactant SDS, the *cisoid/transoid* ratio decreased with decrease of [ACN]; that is, the ratio was 4.6, 4.6, 4.0, 3.6, 2.0, and 1.7 under S of 9.0, 7.0, 6.0, 3.0, 2.0, and 1.0, respectively. When cetyltrimethylammonium bromide (CTAB) was employed in place of SDS, the ratio decreased from 4.6 to 1.3 at S of ca. 9. These results can be interpreted as follows. With a decrease of [ACN], the S value decreases. Since the probability for formation of S_1-derived *cisoid*-**1** increases at high [ACN], *cisoid*-**1** is favored under conditions of high S. With a decrease of S, the probability for the S_1 state to encounter a ground state ACN prior to ISC to the T_1 state decreases, and hence the *cisoid/transoid* ratio decreases. In CTAB micelles, the heavy atom effect of the bromide ion leads to promoted formation of T_1-derived *transoid*-**1**, whereas in micelles with atoms lighter than bromine, the S_1-derived *cisoid*-**1** predominates.

Dimerization in Liquid Crystals

Nerbonne and Weiss demonstrated that upon irradiation ($\lambda > 340$ nm), dimerization of ACN is enhanced in a 1:1 mixture of 5α-cholestan-3β-yl acetate and 5α-cholestan-3β-yl nonanoate as a cholesteric liquid crystal (LC), compared to that in isotropic solution such as benzene.[60] Thus, the quantum yield (Φ) for formation of the dimers **1** at 366 nm under 0.08 *M* of ACN in the LC was 0.23 ~ 0.28 in the temperature range of 10 ~ 40°C when the LC was in a cholesteric phase; however, above 50°C, when the ester was in an isotropic phase, the Φ dropped to 0.03, which is comparable to that in isotropic solution and in smectic phase such as *n*-butyl stearate. The enhanced Φ for the dimerization in the cholesteric LC can be ascribed to an ordering effect induced by alignment of LC molecules on collisions between excited and ground state ACN molecules. The *cisoid/transoid* ratio was, however, generally constant (0.7 ~ 1.0) in the concentration range 0.02 ~ 0.08 *M* of [ACN]. This is in contrast to the results by Nakano and Hirata described below.[61]

Nakano and Hirata found that the *cisoid/transoid* ratio of **1** increased from ca. 0.3 to 0.7 with an increase of [ACN] from ca. 7×10^{-3} to 7×10^{-2} *M* in cholesteric LC (cholesteryl oleyl carbonate, cholesteryl linolate, and cholesteryl oleate), whereas nematic LC or benzene as the reaction medium did not affect the ratio. These results suggest that the cholesteric LC structure makes the ACN molecules align in a phase-to-phase manner. For dimerization of ACN in the nematic phase, Oh-hashi et al. reported briefly the effect of electric fields on the *cisoid/transoid* ratio.[62] Upon irradiation ($\lambda > 300$ nm) of ACN in nematic LC (4-hexyloxyphenyl 4′-butylbenzoate, LC1), application of an electric field up to 5 kV cm^{-1} decreased the *cisoid/transoid* ratio from 0.33 to 0.15. They attributed this effect to the preferred formation of the T_1 state of ACN by "molecular stirring" under dynamic scattering of the nematic phase.

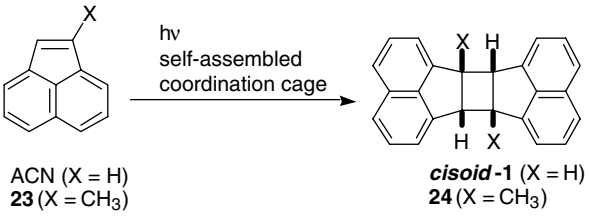
Dimerization in Zeolites

Like other constrained media, supercages in zeolites can offer reactivity and selectivity for products in photochemical reactions that cannot be expected in homogeneous solutions. Ramamurthy et al. have undertaken photochemical reactions in dry cation-exchanged Y zeolite (LiY, NaY, KY, RbY, CsY, TlY).[63] On irradiation ($\lambda > 300$ nm) of ACN, formation of *cisoid*-**1** was favored in zeolites with lower atomic number metals (Li and Na) and with a higher occupancy number (S). The *cisoid/transoid* ratios in NaY and CsY, for example, were 25 and 4.2, respectively, at S = 0.5 and decreased to 22 and 2.8 at S = 0.25. It is apparent that a higher S value is favorable for formation of *cisoid*-**1** derived from the S_1 state with a short lifetime, while heavy atom cations accelerate ISC from the S_1 to the T_1 state of ACN in the cage. Transient absorption of the T_1 state was observed at 470 nm with higher relative yield with the use of heavier cations.

Furthermore, the same authors compared the reactions in hexane slurry with those in the dry solid.[64] Employing LiY and NaY zeolites with occupancy numbers of 0.2 ~ 0.9, they showed that irradiation of ACN in slurry zeolite led to formation of **1** with *cisoid/transoid* ratios of 2.3, 3.5, and 7.2 for S of 0.2, 0.5, and 0.9, while the ratios in the solid zeolite were 0.6, 1.7, and 2.0 for the corresponding S values. Higher *cisoid/transoid* ratios in the slurry compared to the solid were interpreted in terms of mobility of ACN molecules between the zeolite supercage: that is, ACN molecules in single occupancy cages should migrate between cages to give **1** from the T_1 state with a long lifetime, which is comparable to the time for migration between cages, whereas ACN molecules in double occupancy cages react in the cages, affording *cisoid*-**1** from the short-lived S_1 state. Because the solvent inhibits or blocks migration of ACN molecules between cages, predominant migration of ACN molecules between supercages in the absence of solvents results in preferred production of the T_1 state, leading to a decrease in the *cisoid/transoid* ratio.

Dimerization in Miscellaneous Heterogeneous Systems

Recently, the nonpolar and flexible sites available between the alkyl chains of surfactant-intercalated graphite oxide were used as a noble reaction medium.[65] Matsuo et al. irradiated ($\lambda > 330$ nm) ACN in



SCHEME 10

graphite oxide as a layered material intercalated with myristyltrimethylammonium bromide $[C_{14}H_{29}N(CH_3)_3Br]$ as a surfactant. X-ray diffraction patterns of powdered ACN-surfactant graphite oxide before and after UV irradiation showed broadening of the interlayer spacing (d = 2.7 to 3.2 nm) because **1** is bulkier than ACN and this prevents dense packing of surfactant and **1**. The authors did not refer to the origin for the notably high *cisoid/transoid* ratio of 8.8 obtained in relation to molecular configuration in the layer of graphite oxide and nature of excited state of ACN, however.

Also quite recently, Yoshizawa et al. found that self-assembled coordination cages containing palladium can function as a medium of dimerization of alkenes.[66] Irradiation of ACN or 1-methyl-ACN (**23**) in coordination cages in D_2O resulted in efficient formation of the dimers with high stereoselectivity and regioselectivity with a preference for *cisoid*-**1** of > 49 (ACN) and the *anti-cisoid*-dimer of > 49 (**23**), which is in contrast with the less efficient reaction in benzene with the ratio of 1.1 (ACN) and no reactivity (**23**) (Scheme 10).

Tong and Zeng applied cyclodextrins, one of the most widespread microenvironmental media, to the photochemical dimerization of ACN and found an effect of cavity size on reactivity.[67] Thus, upon irradiation ($\lambda > 340$ nm) of ACN in γ-cyclodextrin, the formation of the dimers **1** was promoted, whereas no dimerization occurred in β–cyclodextrin. The distinction between γ- and β-cyclodextrin may be due to number of the guest molecules accommodated; γ-cyclodextrin includes two ACN molecules that may lead to **1** within the cage, while escape from the cage should be necessary for encounter of singly occupied ACN molecules in β-cyclodextrin.

Behymer and Hites carried out photolysis of ACN from the viewpoint of the polycyclic hydrocarbons formed by combustion of fuel and their transportation in the vapor phase and adsorption on particulate matter.[68] Using a rotary photoreactor to simulate environmental conditions in the atmosphere, they carried out irradiation ($\lambda > 300$ nm) on ACN adsorbed on 16 kinds of fly ashes with varying chemical and physical compositions. The half-life of ACN was determined as 1 ~ 125 h depending on the properties of the fly ash; however, no product analysis was performed.

21.5 Conclusions

In conclusion, this chapter details the photochemical dimerization of ACN. This reaction proceeds with relatively low quantum yields, since the S_1 state is short lived (ca. 1 nsec) and undergoes ISC to the T_1 state with low efficiency. On excitation of ACN in solution, the resultant S_1 state produces *cisoid*-**1** in competition with very fast internal conversion from the S_1 both in solution and in constrained media as far as movement of molecules is permitted. An excimer, where two ACN molecules are aligned in the same direction, is responsible for regioselective formation of the *cisoid*-dimer, whether the excimer originated from a van der Waals dimer in the ground state or from action of an S_1 state of ACN on ground state ACN. High concentration or aggregation of ACN molecules in a limited space is advantageous for dimerization from the S_1 state. In contrast, the T_1 state produces both *cisoid*- and *transoid*-**1**, whose ratio is seriously affected by polarity of the media of reaction. Because the T_1 state is produced in a low efficiency from the S_1 state and has a relatively longer lifetime (2 ~ 4 μsec) than the S_1 state, low concentrations or separated circumstances where long-distance migration is necessary for contact

between two ACN molecules are advantageous for dimerization from the T_1 state. Sensitized formation of the T_1 state, therefore, enhances efficiency of the dimerization. In the crystalline state under topochemical control, *transoid*-**1** is preferentially produced, presumably due to unfavorable arrangement of the ACN molecules in the crystalline lattice for formation of the *cisoid*-**1**. Properties and reactions of radical ions, especially radical anions of ACN generated by photoinduced electron transfer, are areas for future development from the viewpoint of reaction mechanisms and synthetic application.

Interest in alicyclic highly strained cage molecules has accelerated greatly during the past decade, and these compounds continue to fascinate chemists since their synthesis is a major challenge. These molecules also have useful physical and chemical properties and biological activity. The extensive efforts devoted to the synthesis of these molecules are described in this chapter. One of the most important components of the cage compounds is a highly strained cyclobutane ring (strain energy 26.4 kcal/mol). The first synthetic approach to a cyclobutane ring via a photochemical reaction was reported by Ciamician and Silber in 1908.[1] They found that exposure of an alcohol solution of carvone **1** to sunlight provided carvone camphor **2** via [2 + 2]-photocyclization of the carbon–carbon double bonds (Scheme 1). Since then, formation of a cyclobutane ring by a photochemical [2 + 2]-process has been one of the most important and useful methods for the synthesis of cage compounds. Accumulated experimental data on the synthesis of cage compounds indicate that the best method to construct highly strained molecules is to use photochemical reactions.

Light is one of the cleanest energy sources, and various light sources are now available for different types of reactions. In the [2 + 2]-photochemical reaction, the most widely used light source is the mercury (Hg) arc lamp. Three main types are designated as low, medium, and high pressure, and each has different spectral characteristics. The low pressure Hg lamp operates at room temperature and emits mainly 253.7 nm and weak 184.9 nm light. The so-called sterilizing lamps are coated with special filters and cut off below 200 nm to obtain only 253.7 nm light.

Monochromatic 253.7 nm light can be obtained from the low pressure Hg lamp using a Vycor filter. The spectral lines at 265.4, 313, and 365 nm have reasonably high relative intensity in the medium pressure Hg lamp. A stronger continuum is obtained with broadening of these emission lines in the high pressure Hg lamp.

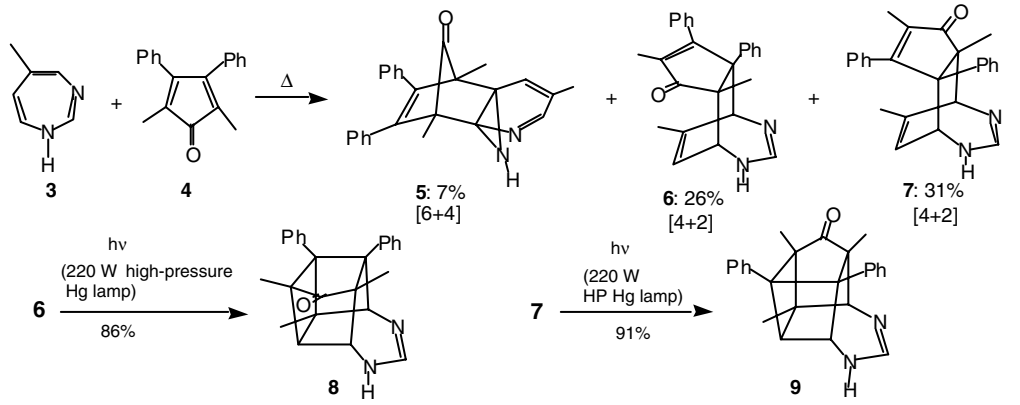

SCHEME 2 Photocycloadditions of the Diels-Alder adducts with cyclopentadienone and 1H-1,3-diazepine.

In this chapter, prototypes of the photochemical reactions useful for the synthesis of cage compounds are outlined first, and then photochemical approaches towards the synthesis of [n]prismanes as representative cage compounds are reviewed.

22.1 Prototypes of the Photochemical Reactions for the Synthesis of Cage Compounds

Prototypes of the photochemical reactions for the synthesis of cage compounds are classified as shown in Table 22.1. The most predominant examples are [2 + 2]-reactions of Diels–Alder adducts with an *endo*-configuration. Intramolecular photochemical [2 + 2]-, [6 +2]- and [6 + 6]-reactions in the rigid polycyclic framework have been increasingly employed for the synthesis of polycyclic cage compounds. Other photochemical reactions, such as [4 + 4]-cycloaddition and related processes, are also important. According to this arrangement, prototypes of the photocycloadditions and their important applications are described.

Photochemical [2 + 2]-Reactions of Diels–Alder Adducts

Diels–Alder Adducts of Cyclopentadiene and Cyclopentadienone with Cyclopentadienone and Cyclopentene-3,5-dione.

The cycloaddition reaction of 1*H*-1,3-diazepine **3** and 2,4-dimethylcyclopentadienone **4** in refluxing xylene resulted in the formation of three adducts: **5** ([6 + 4]), **6** ([4 + 2]), and **7** ([4 + 2]).

Irradiation (220 W high-pressure Hg lamp) of **6** in benzene for 30 min afforded cage compound **8** (86%) via intramolecular [2 + 2]-photocycloaddition. Similarly, the adduct **7** gave the regio-isomeric cage compound **9** (91%).[2]

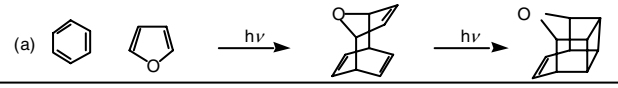
1.3. Photochemical [4+4]- and related reactions.



1,3-Bishomocubane acetate **12** was synthesized conveniently by the photocycloaddition of the Diels–Alder adduct **11** of cyclopentadiene with cyclopentene-3,5-dione **10**. Base induced homoketonization of the acetal of **12** led to the thermodynamically favored half-cage skeleton **13**.[3]

The Diels–Alder dimerization of 2-bromo-2,4-cyclopentadienone ethylene acetal **15** gave *endo*-2,7-dibromodicyclopentadiene-1,8-dione 1,8-bis(ethylene acetal) **16** as a minor product (4.5%), along with the major product **17** (91.5%). Adduct **17** is an important synthetic intermediate for the synthesis of cubane. Irradiation of the mono-acetal of the minor product **18** with a high-pressure Hg lamp in CH_2Cl_2

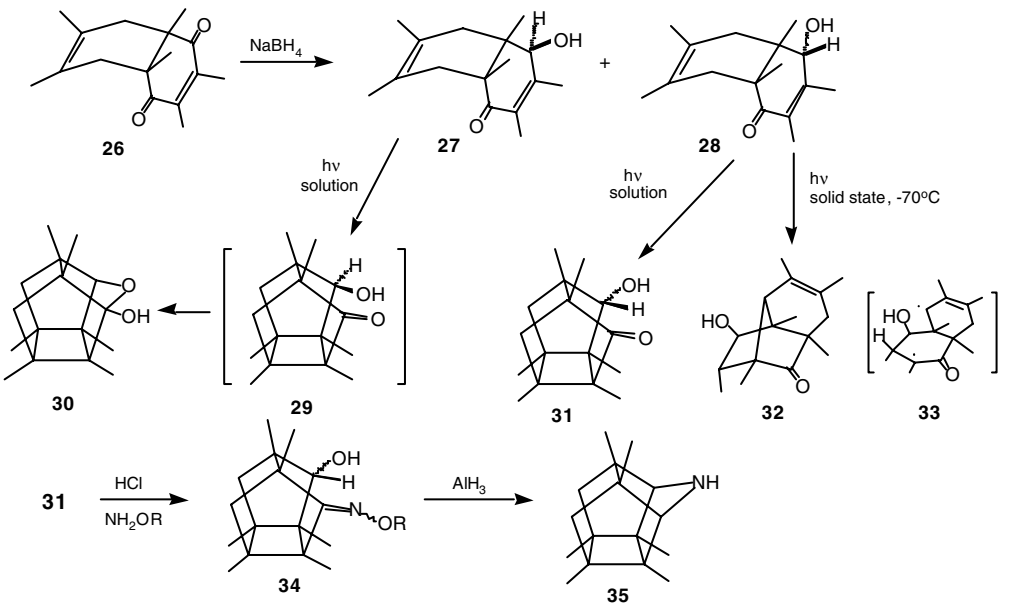
provided cage compound **19** (99%). Unexpectedly, Favorskii contraction of the diketone **20** in 5% aqueous KOH solution at 80°C gave lactone-carboxylic acid **21** with the pentacyclo[5.3.0.^{2,4}0.^{3,6}0^{5,8}]octane skeleton in place of the expected cubane-dicarboxylic acid (Scheme 4).[4]

The cyclopentadienones **22** are primarily known as building blocks of interesting structures, e.g., the dimers **23,** which are known to exist as reversibly dissociating or nondissociating dimers depending on whether or not the starting monomers bear substituents in both the 2- and the 5-positions; the effect is largely steric. The parent cyclopentadienone **22a** exists as a monomer at –196°C and dimerizes above –80°C to give the *endo*-dimer **23a**.[5] Fuch et al. first isolated the monomers **22b,c,d** bearing aryl substituents in the 3 and 4 positions and alkyl substituents in the 2 and 3 positions by sublimation *in vacuo* of the corresponding dimers **23** (Scheme 5).[6]

Direct irradiation ($\lambda > 290$ nm) of **23b** in dioxane for 94 h provided the dissymmetric cage **24b** (1%) and the symmetric cage **25b** (48%) at 67% conversion. The amount of **24b** was enhanced (**24b**: **25b** =



SCHEME 6 Differences in cyclohexenone photochemistry in solution and the solid state.

11:42) when the reaction was discontinued after 48 h of irradiation. Under similar conditions, **23e** gave a mixture of **24e** (22%) and **25e** (21%), whereas **23c** and **23d** did not afford photoproducts. Interestingly, irradiation of crystals of the monomer **22b** into any of its absorption bands resulted in efficient and quantitative cycloaddition to give **25b**.[6] The dissymmetric cages (**24b,c,e**) ring open on irradiation ($\lambda >$ 300 nm) back to the dimer **23**, whereas the symmetric cages **25** do not. While **24** is thermally stable, the symmetric dimer **25** undergoes a thermal reversion to **23**.

Diels–Alder Adducts of Cyclopentadiene and Cyclopentadienone with *p*-Benzoquinone and 2,4-Cyclohexadienone

p-Benzoquinones are potent dienophiles in the Diels–Alder reaction. The strong preference for *endo*-addition, together with the long-wavelength absorption of the enedione chromophore, has made these adducts very suitable for photocycloaddition. Scheffer et al. reported the photocycloaddition of the epimeric hydroxycyclohexenones (**27**, **28**), which were readily obtained from the tetrahydro-1,4-naphthoquinone derivatives **26**. Direct or benzophenone-sensitized irradiation ($\lambda >$ 330 nm) of **27** and **28** in benzene afforded a high yield of the [2 + 2]-cycloaddition products with the tetracyclo[5.3.0.0.^{2,6}0^{4,9}]decane skeleton (**30** and **31**). However, irradiation ($\lambda >$ 330 nm) of crystalline samples of **28** gave **32** via intermediate **33**, while no reaction was observed with the isomer **27**. Scheffer et al. concluded that solid phase photoreactions are crystal lattice–controlled, least motion processes, and the solid state/solution reactivity differences are the results of reaction from different conformational isomers in the two media.[7] The ketol **31** is a useful synthetic intermediate to the synthesis of a variety of cage compounds with bridging nitrogen atoms such as 11-azapentacyclo[6.2.1.0.0.^{2,7}0.^{4,10}0^{5,9}]decane **35**, which has antiviral activity.[8]

Cookson et al. first reported prior to 1965 that photochemical reaction of the Diels–Alder *endo*-adducts of cyclopentadiene or cyclohexa-1,3-diene with *p*-benzoquinone gave cage compounds by formation of a cyclobutane ring from the two double bonds.[9] Irradiation of an ethyl acetate solution of the cyclopentadiene adduct **36** with a medium pressure Hg lamp for 6 h afforded cage **37** (90%). This photoreaction proceeded even in the solid state, and the cage compound **37** was obtained in 80% yield after 80 h irradiation. Similarly, the 1:1 adduct **38** of cyclohexa-1,3-diene and *p*-benzoquinone was converted into cage **39** by irradiating the ethyl acetate solution for 10 h (80%) or the solid state for 90 h (90%). This reaction was successfully applied to the adduct **40** of cyclooctatetraene (COT) and *p*-benzoquinone (92%

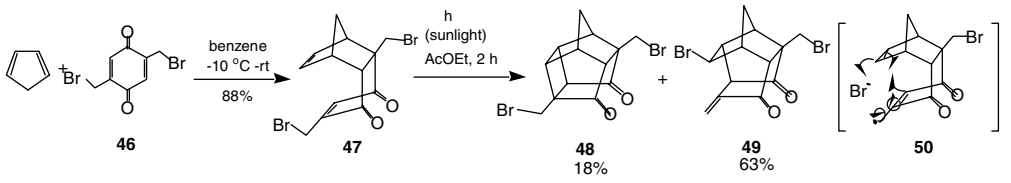
of **41** in ethyl acetate solution or 16% in the solid state) and **42** of cyclopentadiene and chloranil (54% of **43** in ethyl acetate solution). γ–Irradiation (^{60}Co) was used in place of a UV lamp for similar conversions (**36** to **37**, 33%).[10]

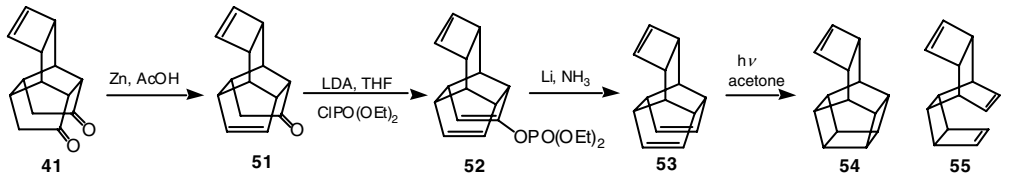
Wladislaw et al. examined the reactivity–substituent effect relationship in the photo-cyclization of the adducts **44** of cyclopentadiene with *p*-benzoquinone. Some substituted adducts **44h** and **44i** do not undergo photocyclization. Table 22.2 shows the quantum yield (Φ_{rel}) for photocyclization of the mono-substituted adducts **44a–i**, relative to that of the unsubstituted adduct **44j** for which Φ was assumed to be 1.00. These data show not only that the adducts **44h,i,j** do not photocyclize but also that adduct **44g** photocyclizes inefficiently. It is proposed that the factor that determines the photocyclization efficiency is the difference between the energy levels of the two interacting orbitals (HOMO-′HOMO′) since the cyclization is most probably initiated by a photochemical electron transfer (PET).[11]

The photocyclization of the Diels–Alder *endo*-adducts of cyclic dienes with *p*-benzoquinone has been successfully applied to the construction of polycyclic cages. Nair et al. reported that the photocyclization of the 2,5-bis(bromomethyl) compound **47** gave the unexpected cage compound **49** as a major product along with the anticipated product **48** (Scheme 9).[12] The formation of **49** can be explained through the initial photolytic cleavage of the bromine–allylic carbon bond (**50**) followed by radical reorganization and final bromine radical capture.

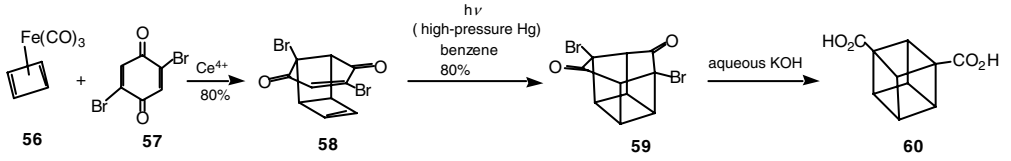
Fessner et al. developed a high yield route to the triene **53,** a new unsaturated member of the $(CH)_{14}$ family (Scheme 10 from the COT-*p*-benzoquinone adduct **41** described above [Scheme 7]).[13] This, upon



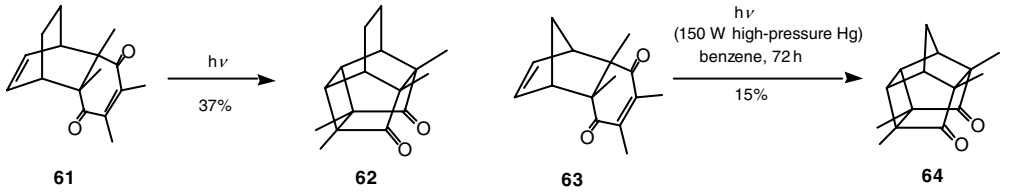
SCHEME 9 Photocycloaddition of a cyclopentadiene-*p*-benzoquinone adduct.



SCHEME 10 Synthesis and interconversion of new $(CH)_{14}$ isomers.



SCHEME 11 The covenient synthesis of the cubane system.

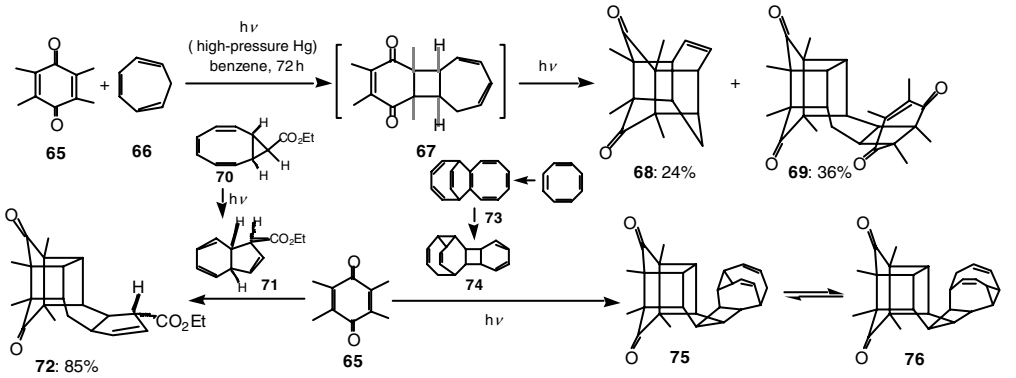


SCHEME 12 Photocycloaddition of the cyclohexa-1,3-diene and cyclopentadiene-duroquinone adducts.

triplet-sensitized photolysis (acetone) of **53** gave the cage **54**, while heating in solution to above 80°C induced a quantitative, regiospecific [3.3]-shift to **55**.

A convenient synthesis of a cubane system, in which the cyclobutadiene transfer reaction plays a key role, was reported by Pettit et al. (Scheme 11).[14] By the oxidative decomposition of cyclobutadiene-iron tricarbonyl **56** with Ce^{4+} ion in the presence of a dienophile, a molecule of cyclobutadiene can be transferred from the iron to the dienophile. Decomposition of **56** in the presence of 2,5-dibromobenzoquinone **57** yielded the Diels–Alder adduct **58** with *endo*-configuration. Irradiation of **58** in benzene with a high-pressure Hg lamp afforded the bishomocubane derivative **59**, which gave cubane-1,3-dicarboxylic acid **60** (80%) by treatment of **59** with aqueous KOH at 100°C.

Schenck et al. studied the photochemical reactions of the adducts of duroquinone with unsaturated compounds such as cyclic dienes, acenaphthylene, coumarin, and styrene (Scheme 12).[15,16] Formation of both oxetanes[17] and cyclobutanes was observed, depending on the substituents present in the quinone. From the theoretical and experimental investigations, *p*-benzoquinone reacts from its triplet $n\pi^*$ excited state to yield exclusively oxetane adducts, while its tetramethyl or tetrachloro derivatives, duroquinone



SCHEME 13 Photocycloaddition of duroquinone-cyclic polyene adducts.

or chloranil, whose lowest triplet should be $\pi\pi^*$, afford only cyclobutanes. These photocyclizations are one of the most convenient methods for the synthesis of cage compounds. For example, Ogino et al. reported the photoreaction of duroquinone with cyclic trienes.[18]

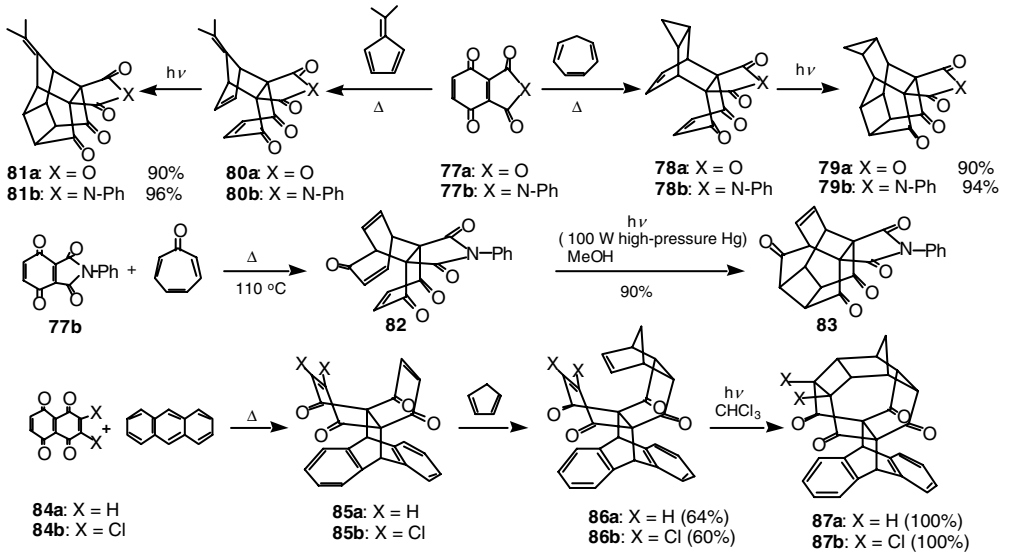
On irradiation of a benzene solution of duroquinone **65** and cyclohepta-1,3,5-triene **66** (**65**:**66** = 1:2), 1:1 adduct **68** (24%) and 2:1 adduct **69** (36%) were formed via the [2 + 2]-photoadduct **67** as the intermediate (Scheme 13).

Although only the formation of the dimer of tropone and the recovery of duroquinone were observed in the photoreaction of duroquinone and tropone, the photoreaction of ethyl bicyclo[6.1.0]nona-2,4,6-triene-9-carboxylate **70** with duroquinone afforded the 1:1 adduct **72** (85%). When a solution of duroquinone and COT in benzene was irradiated under similar conditions, a single product **75** was obtained in low yield (3–5%). COT is known to thermally dimerize to afford **73** and/or **74**, and these dimers should be reactive compounds for the photoaddition with duroquinone. In fact, duroquinone reacted with **74** to afford photoproduct **75** under similar conditions (63%). No reaction was detected with **73**. A Cope rearrangement of the dihydrobullvalene moiety interconverts **75** and **76**.

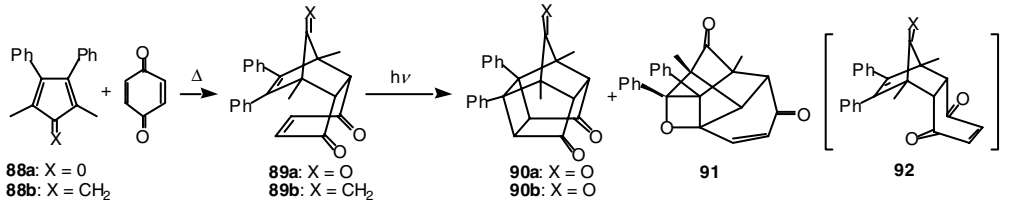
p-Benzoquinone behaves only as a weak dienophile in the Diels–Alder reaction and is rather inert to homodienes, conjugated medium-ring polyenes such as norbornadiene, cycloheptatriene, and tropone even under drastic conditions. Kanematsu et al. developed *p*-benzoquinone-2,3-dicarboxylic anhydride **77a** and *N*-phenylimide **77b** as powerful electron-withdrawing dienophiles for the cycloadditions. The reactions with 6,6-dimethylfulvene and cycloheptatriene gave the corresponding 1:1 adducts (**80** or **78**) with *endo*-configurations in quantitative yields.[19]

Irradiations of the adducts **80** and **78** in acetone solution (100 W high-pressure Hg lamp, Pyrex filter) afforded the cage compounds **81** and **79,** respectively, in quantitative yields. Tropone also reacted with **77b** smoothly to give adduct **82**, which was converted into cage compound **83** on irradiation. Kanematsu et al. also developed the site-selective Diels–Alder reactions of 1,4,5,8-naphthoquinone **84** with anthracene; the reaction of **84** with anthracene exclusively afforded the adduct **85** attached to the internal double bond.[20] Irradiation of the adduct **86** of **85** with cyclopentadiene in chloroform with a high-pressure Hg lamp (400 W) through a Pyrex filter resulted in the smooth formation of a cage compound **87**. By using this methodology, Kanematsu et al. also prepared caged crown ethers.[21]

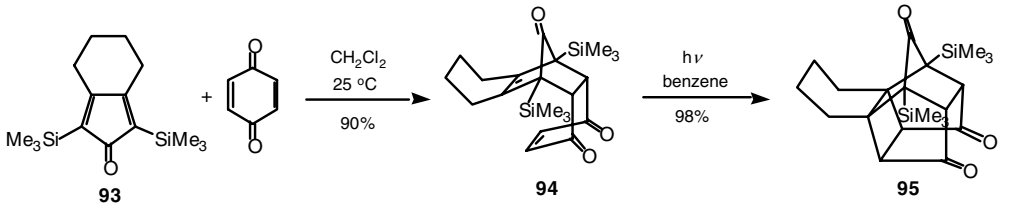
2,5-Dimethyl-3,4-diphenylcyclopenta-2,4-dienone **88a** and related 1,4-dimethyl-2,diphenylcyclopenta-1,3-diene **88b** readily formed adducts **89a** and **89b** on reaction with *p*-benzoquinone in refluxing chloroform. Irradiation of the adduct **89a** in benzene with a high-pressure Hg lamp (400 W) through a Pyrex filter afforded cage compound **90a** as a major product along with oxetane **91** (21%), while solid state irradiation with sunlight gave **90a** as single product (Scheme 15).[22] The cyclopentadiene **88b** was far less reactive than the dienone **88a** toward *p*-benzoquinone, the reaction requiring heating under reflux in benzene to yield the single adduct **89b**. The cage compound **90b** was formed in quantitative yield by high-pressure Hg lamp–irradiation of **89b** both in the solid state and in benzene solution. The oxetane



SCHEME 14 Photocycloaddition of highly reactive *p*-benzoquinone-tropone or cycloheptadiene adducts.



SCHEME 15 An unusual oxetane formed by intramolecular photocyclization within an enedione.

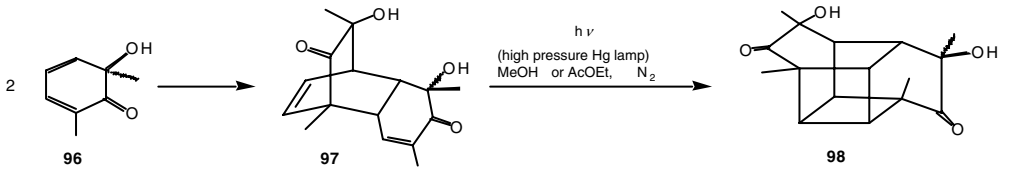


SCHEME 16 Cycloadditions of annulated 2,5-bis(trimethylsilyl)cyclopentadienones.

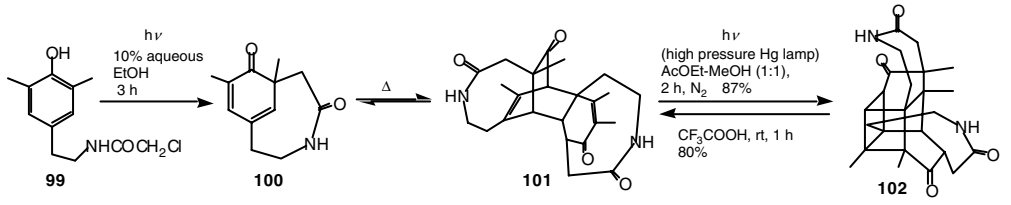
formation may be explained by the photochemical [2 + 2]-reaction between the CC and CO double bonds within a suitable conformation **92.**

The use of annulated 2,5-bis(trimethylsilyl)cyclopentadienone **93** in this reaction gave the hexacyclic cage compound **95** in high yield via consecutive [4 + 2]- and photochemical [2 + 2]-cycloaddition with *p*-benzoquinone (Scheme 16).[23]

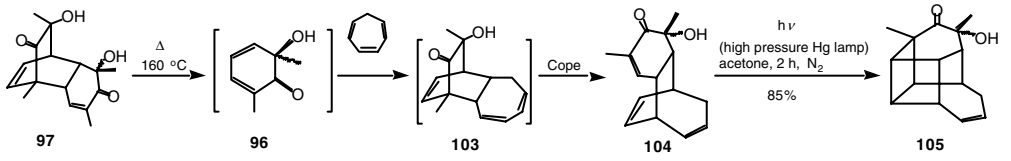
Becker et al.[24] and Yonemitsu and co-workers[25] independently found that dimerization of 2,4-cyclohexadienone **96** gave the adduct **97**, which upon photoirradiation ($\lambda > 300$ nm) in MeOH (91%) or ethyl acetate (64%) yielded cage **98** (Scheme 17).



SCHEME 17 Photochemical intramolecular cycloaddition of 2,4-cyclohexadienone Diels-Alder dimers.



SCHEME 18 The photocyclization of a pharmacodynamic amine.



SCHEME 19 A novel periselective cycloaddition of cycloheptatriene with cyclohexa-2,4-dienones.

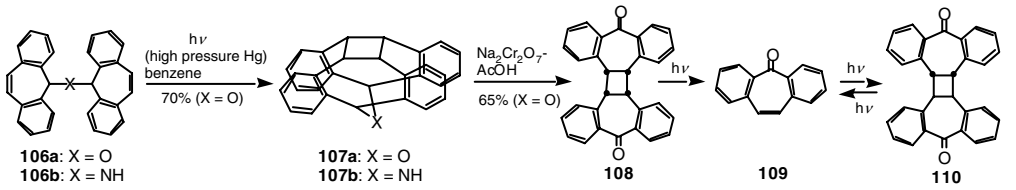
Yonemitsu et al. found that irradiation of the *N*-chloroacetyl derivative of dimethyltyramine **99** gave the dimeric cage compound **102** (Scheme 18). The presence of cyclohexa-2,4-dienone **100** as a transient species and its thermal dimerisation to the dimer **101** were proven by flash photolysis and also by trapping the intermediate with *N*-ethylmaleimide by a Diels–Alder addition. On treatment with trifluoroacetic acid, the cage compound **102** easily reverted to **101**.[26]

The highly periselective cycloaddition reaction of cycloheptatriene and cyclohexa-2,4-dienones to yield *endo*-tricyclic systems followed by their photocyclization to cage compounds have been reported.[27] The cyclohexa-2,4-dienones **96** were generated by pyrolysis (160°C) of the dimer **97**. Subsequent trapping with cycloheptatriene gave adduct **104** with *endo*-configuration as the exclusive product. The formation of the adduct **104** was ascribed to Cope rearrangement of the initially formed [4 + 2]-adduct **103**. Acetone-sensitized [2 + 2]-photocycloaddition of **104** gave the cage **105**.

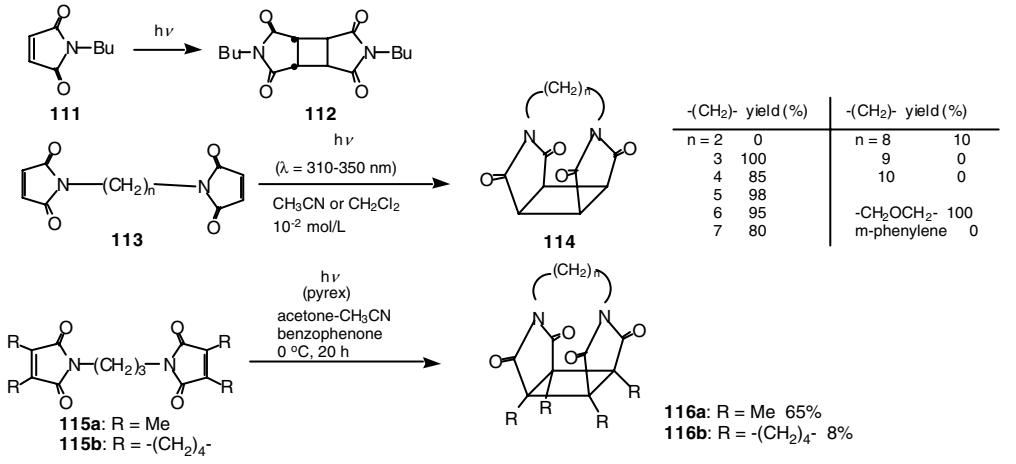
22.2 Photochemical [2 + 2]-, [6 + 2]-, and [6 + 6]-Reactions in Rigid Polycyclic Compounds

[2 + 2]-Reactions

The [2 + 2]-photocycloaddition of activated alkenes is the most useful route to cyclobutane derivatives, but the main impediment to the use of photoannelations in synthesis remains the generally poor regio- and stereochemical control. Some simple approaches to a *cis,cis,cis*-tetrasubstituted cyclobutane backbone have been reported. Although the photochemical dimerization of dibenzo[a,d]cycloheptane-5-one **109** yielded *trans*-cyclobutane dimer **110**[28], *cis*-cyclobutane dimer **108** can be prepared through a novel heterocyclic ring cage system **107** (Scheme 20).[29] Irradiation of **106a** in benzene with a high-pressure Hg



SCHEME 20 A new heterocyclic cage ring system; the preparation of the *cis*-cyclobutane dimer of benzo[a,d]cyclohepten-5-one.



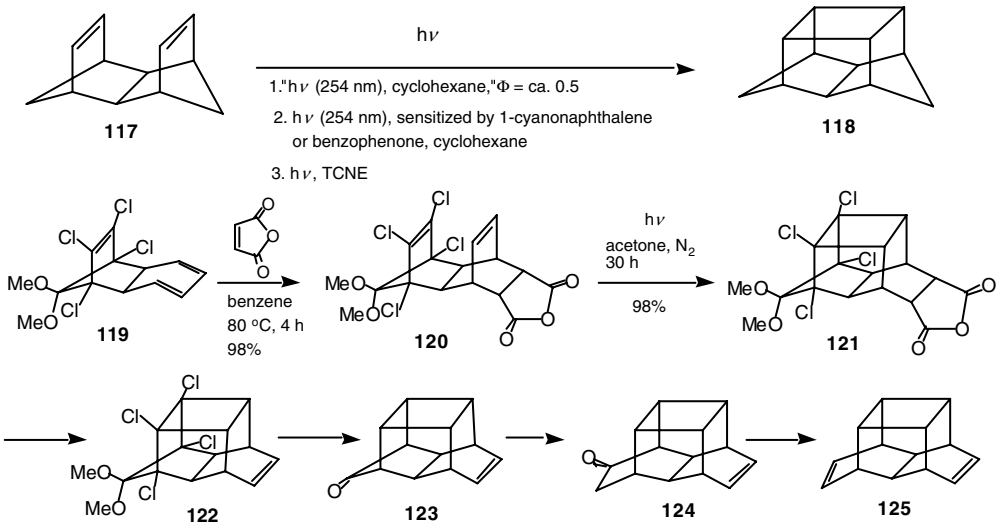
SCHEME 21 Intramolecular photocycloaddition of *N,N′*-alkylenedimaleimides.

lamp through a Pyrex filter gave the new cyclobutane cage **107a** (70%). Similarly, irradiation of **106b** (X = NH) in benzene gave *cis*-**107b**. Oxidation of the cage ether **107a** afforded *cis*-diketone **108**. The *cis*- and *trans*-diketones **108** and **110** reverted to **109** on photoirradiation ($\lambda > 200$ nm).

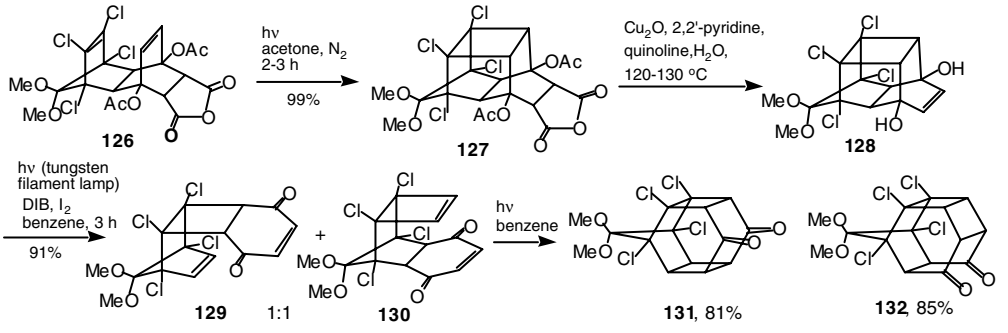
The biacetyl-sensitized photoreaction of *N*-butylmaleimide **111** in methylene chloride afforded only the *trans*-isomer **112** in which the two rings lie *anti* to each other (Scheme 21). Upon irradiation of dimaleimide **113**, an intramolecular cycloaddition to tetracyclic compound **114** occurs.[30] The reactions were carried out in solution in acetonitrile or methylene chloride at a concentration of 10^{-2} mol/l using 310 or 350 nm light. Almost quantitative intramolecular reactions occur for dimaleimides with three to six methylene units. Increasing the chain length from seven to eight methylene units causes a marked drop in the yield of products. With chain lengths longer than eight methylene units, no reaction is observed. Sensitized irradiation of dimaleimide **115** affords the cage diimide **116**.[31]

Photochemical [2 + 2]-reactions of two olefinic double bonds in rigid polycyclic compounds have been widely examined. The photocycloaddition of the isodrin-type compound **117** to give the cage compound **118** was studied in detail by Jones et al.[32] Both direct irradiation and triplet-sensitized reaction of **117** gave **118** exclusively (Scheme 22). In addition, on irradiation in polar solvents in the presence of an electron acceptor sensitizer, **117** gave **118** with quantum yield greater than unity. It is suggested that the formation of a polar exciplex between the sensitizer (e.g., 2-cyanonaphthalene; electron affinity EA = 0.68 eV) and **117** is the first step of this reaction, and the resulting exciplex finally gives **118** by excitation energy transfer from naphthalene to the diene.

Chou et al. successfully applied this [2 + 2]-photocycloaddition to the synthesis of hexacyclotetradecadiene **125** (30% overall yield from **119**).[33] On irradiation (450 W medium-pressure Hg lamp, 130 h) of an acetone solution of the diene **120**, the reaction proceeds slowly but efficiently to give the photoproduct **121**. Decarboxylation of **121** and subsequent ring expansion of **123** afforded the desired novel cage



SCHEME 22 Photochemical enelene cycloaddition reactions: The synthesis of hexacyclo[6.5.1.$0^{2,7}$, $0^{3,11}$, $0^{4,9}$, $0^{10,14}$]tetradeca-5,12-dienes.

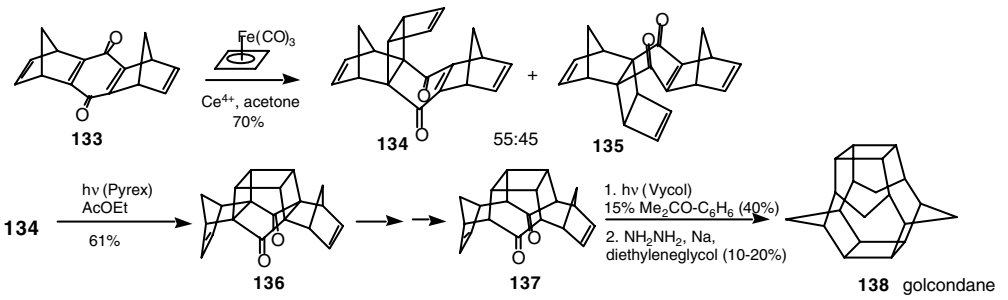


SCHEME 23 A fragmentation-photocyclization approach to the homosecoprismane skeleton.

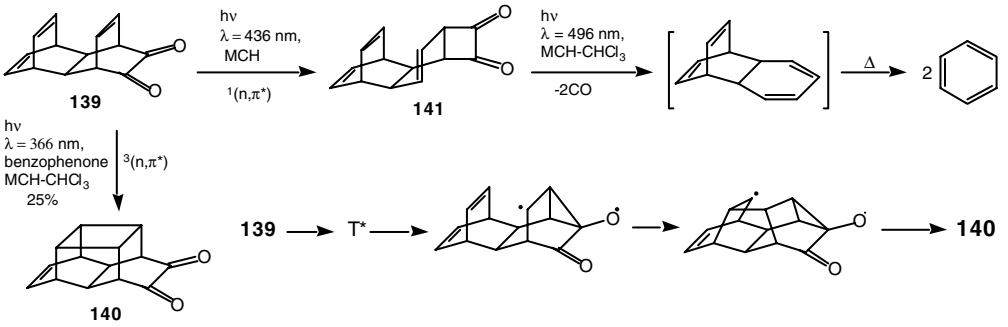
compound **125**. Similar [2 + 2]-photocycloaddition of **126** and decarboxylation of the photoproduct **127** give the diol **128**, which is converted to tetracyclic dienes **129** and **130** by oxidative fragmentation. [2 + 2]-Photoreaction of the mixture of **129** and **130** affords the hexacyclic cage compounds **131** and **132** with homosecohexaprismane skeleton (Chou et al., Scheme 23).[34]

Mehta et al. also employed this type of [2 + 2]-photocycloaddition for the synthesis of novel, caged, nona-cyclic $C_{20}H_{24}$-hydrocarbon of D_{2d} symmetry, golcondane **138**, named after the old name for Hyderabad.[35] On irradiation of **134** with a 450 W high-pressure Hg lamp through a Pyrex filter, smooth intramolecular [2 + 2]-ring closure takes place to give the nona-cyclic annulated bishomocubane dione **136**. Finally acetone-sensitized photocyclization of **137** affords golcondane **138**.

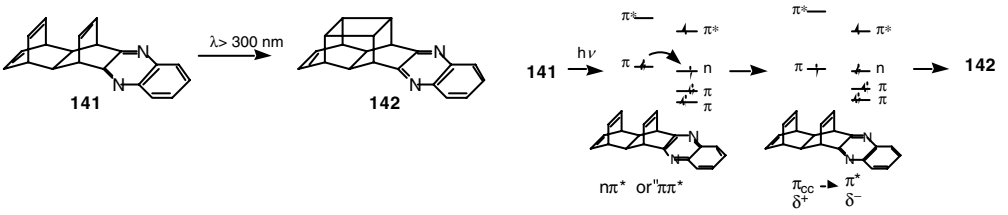
Behr et al. studied the photoreaction of tetracyclic trienedione **139**,[36] which was prepared by the thermal addition of *o*-benzoquinone to barrelene (15%). Irradiation of **139** in deoxygenated methylcyclohexane (MCH) or chloroform with benzophenone at 366 nm afforded the cage compound **140** (25%). The first step of this cycloaddition may be the formation of a biradical by a pathway similar to that of the oxa-di-π-methane rearrangement from the lowest $^3(n\,\pi^*)$ state (Scheme 25). Since the excitation energy of the α-dicarbonyl unit in **139** [EA (biacetyl) = 0.72 eV] is similar to that of 2-cyanonaphthalene, intramolecular excitation energy transfer from dione to diene similar to that from 2-cyanonaphthalene



SCHEME 24 Golcondane: novel, caged, nonacyclic $C_{20}H_{24}$-hydrocarbon of D_2d symmetry.



SCHEME 25 Photoreaction of trienedione.

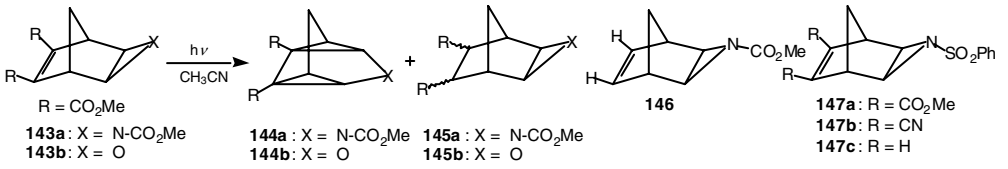


SCHEME 26 Photoreaction of multichromophoric polycyclic compound in which the dicar bonyl moiety of **139** is replaced by the quinoxaline.

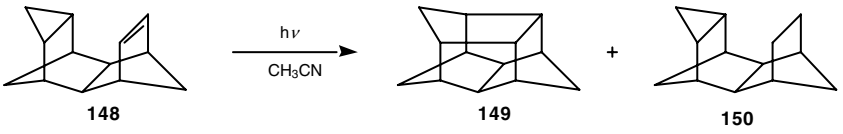
to **117** might occur. Irradiation of **139** at 436 nm ($n\pi^*$ excitation) in MCH gave the rearrangement product **141**. Subsequent irradiation of **141** at 496 nm or with broad spectrum light in MCH at room temperature resulted in bisdecarbonylation and formation of benzene. The intramolecular [2 + 2]-cycloaddition did not occur within the excited $^1(n\pi^*)$ state of **139** since intramolecular energy transfer might be possible; the process does not seem to able to compete with the faster 1,3-acyl shift and rearrangement of **139** to **141**.

In consideration of the above results, Behr et al. examined the photoreaction of the multichromophoric compound **141** in which the dicarbonyl moiety of **139** was replaced by the quinoxaline (Scheme 26).[37] The irradiation of **141** with $\lambda > 300$ nm, which brings about $n\pi^*$ or $\pi\pi^*$excitation localized in the quinoxaline chromophore, afforded the cage compound **142** as the sole product in high yield.

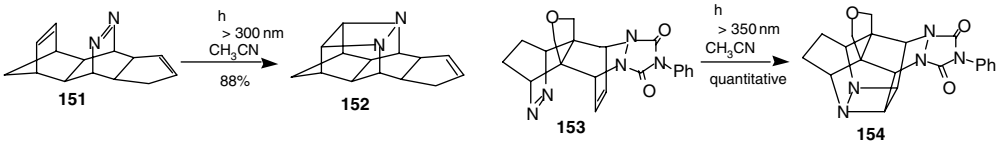
It is suggested that intramolecular [2 + 2]-cycloaddition of **141** is sensitized by the quinoxaline chromophore, since the π_{cc},π_{cc}^* isodrin transition of **141** is presumably not excited by $\lambda > 300$ nm by analogy with the corresponding transition of **117**. Behr et al. proposed two reaction mechanisms. The



SCHEME 27 Intramolecular photocycloaddition between an alkene double bond and a three-membered ring.



SCHEME 28 Photocycloaddition between an ethylene moiety and a three-membered ring.



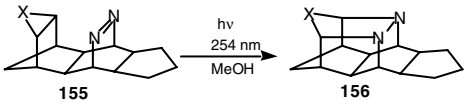
SCHEME 29 Photocycloaddition of C=C and N=N double bonds.

intramolecular cycloaddition is induced by the energy transfer from $n\pi^*$ or $\pi\pi^*$-excited quinoxaline to isodrin. The other possible mechanism would involve singlet–triplet intersystem crossing followed by an aza-di-π-methane rearrangement similar to the oxo-di-π-methane rearrangement of **139** to **140**.

Intramolecular $[2\pi + 2\sigma]$-photocycloaddition between an ethylene unit and a three-membered ring for the construction of a cyclopentane ring is a valuable synthetic step. Klaus and Prinzbach reported that the direct irradiation of **143** resulted in the formation of the cage compounds **144** (Scheme 27).[38] Irradiation of the aziridine derivative **143a** with Vycor-filtered light in oxygen-free acetonitrile at –20°C afforded the cage compound **144a** (50–55%) along with a small amount of hydrogenated product **145a** and polymeric material. Under similar irradiation conditions, the oxirane **143b** afforded cage compound **144b** as a major product (16–20%) along with hydrogenated analogue of **145b**. No cage compound such as **144** was formed in ether, cyclohexane, or acetone. Since the unsubstituted **146** does not undergo $[2\pi + 2\sigma]$-cycloaddition, it was suggested that this reaction was initiated by excitation of the maleic acid ester chromophore of **143**. Analogous results were reported by Umano et al. from the photoreaction of **147**.[39] Compounds **147a** and **147b** gave the corresponding cage compounds in moderate yields, while unsubstituted **147c** afforded no cage product.

Prinzbach et al. reported the formation of a cyclopentane ring via photochemical alkene–cyclopropane cycloaddition (Scheme 28). Direct irradiation of **148** in acetonitrile in a quartz vessel resulted in the formation of the cage product **149** (65%) along with the hydrogenated product **150** and polymeric material.[40] In the photoreaction of rigid polycyclic compounds, a CC double bond can be replaced by a NN double bond, and this change constitutes a remarkable extension of the intramolecular photocycloaddition system. Photocycloaddition between parallel CC and NN double bonds in a rigid polycyclic framework gives the corresponding cage compounds. For example, irradiation of **151** in acetonitrile brings about ring closure to give **152** in a [2 + 2]-process (Scheme 29).[41] Because of its rigid framework, this reaction proceeds without elimination of nitrogen. In a similar way, propellane **153** gave **154** quantitatively.[42]

Similar to the CC double bonds mentioned above, the cycloaddition reactions between NN double bonds and three-membered rings takes place and gives the corresponding cage compounds. On irradiation of **155** at 254 nm ($\pi\pi^*$ excitation) in methanol, the cycloaddition between three-membered rings



155 **156**

substrate	irradiation time (min)	product (yield %)	
155a<X = CH_2	120	**156a**<X = CH_2	63%+
155b<X = NH	120	**156b**<X = NH	80%+
155c<X = O	360	**156c**<X = O	30%+[a)]

a) in addition to **156c** , transannular product was obtained in 35%.

157 **158**

solvent	irradiation time (min)	product (%)
MeOH	600	**158** (75%)
2-PrOH	180	**158** (<10%) + **157** (>90%)
2-PrOH:acetone (1:1)	270	**158** (90%)
2-PrOH + piperylene(1.7 mmol)	180	**157** (100%)

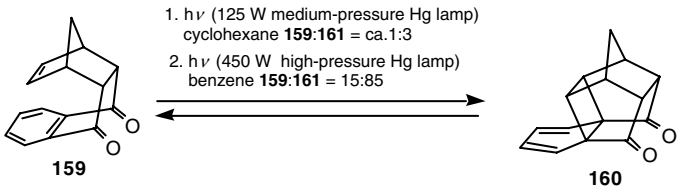
SCHEME 31 Photoreaction between an aziridine and an azo group.

(cyclopropane, aziridine, and oxirane) and the azo groups proceeded and yielded the corresponding cage compounds **156** in a [σ2s + π2s]-process (Scheme 30).[43] These cycloadditions proceeded without elimination of nitrogen. The reactivity order of the three-membered rings toward photocycloaddition at 254 nm, i.e., aziridine > cyclopropane >> oxirane, corresponds well with the energy order of the e_s orbitals measured from their photoelectron spectra, –8.50, –9.15, and –9.40 eV. This order is also reflected in the solvent dependence of the photoreaction. Cycloaddition of **157** (X = N–CO_2Et) occurred smoothly in solvents less polar than acetonitrile and even occurred in hexane, whereas the cycloaddition of **155a** or **155c** did not take place under the same conditions. On irradiation at 350 nm ($n\pi^*$ excitation), these cyclizations did not occur. Irradiation at 350 nm in methanol gave the transannular product **158** instead of cage compounds. The slow transformation of **157** into **158** in 2-propanol (a better proton donor than methanol) by irradiation at 350 nm was accelerated dramatically by the addition of acetone (triplet sensitizer) or suppressed by the addition of piperylene (triplet quencher). These observations clearly show that the transannular reaction occurs via the $^3(n\pi^*)$ state of the azo group and not by the $^1(n,\pi^*)$ state. In contrast, on irradiation at $\lambda > 300$ nm, [2 + 2]-cycloaddition of an olefin to azo bridges occurred smoothly. In aprotic solvents, this type of reaction does not occur on $n\pi^*$ excitation.

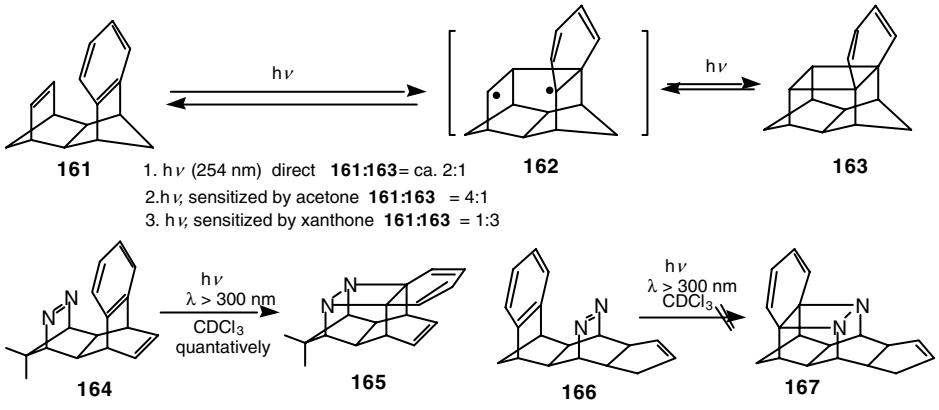
[6 + 2]- and [6 + 6]-Cycloaddition Reactions

Irradiation of a cyclohexane solution of the adduct **159**, formed by addition of cyclopentadiene to 1,4-naphthoquinone, led to a photostationary 1:3 mixture of **159** and **160** (Scheme 32). This reaction was sensitized by xanthone, benzophenone, and di-4-pyridyl ketone.[44] Direct irradiation of the adduct **159** in benzene for 1 h afforded **160** (80%) along with recovered **159** (15%).[45]

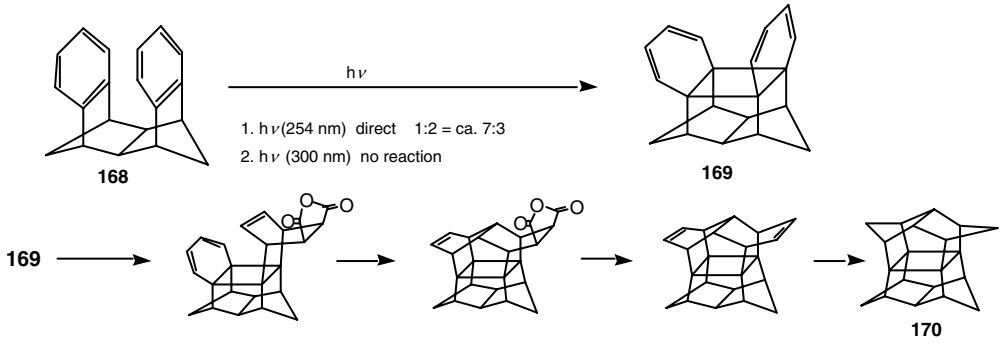
Prinzbach et al. reported that direct irradiation with monochromatic 254 nm light from a low-pressure Hg lamp or sensitized excitation (acetone or xanthone) produced ca. 2:1, 4:1, and 1:3 photoequilibrium mixtures of **161** and **163**, respectively. The cage compound **163** was stable up to 250°C in benzene solution (Scheme 33).[46] The [6 + 2]-cycloaddition between the *o*-phenylene bridge and a NN double bond also takes place. Irradiation of **164** at $\lambda > 300$ nm afforded cycloadduct **165** quantitatively. In contrast,



SCHEME 32 Photochemical [6+2]-cycloaddition.



SCHEME 33 Photochemical [6+2]-cycloadditions.



SCHEME 34 Photochemical [6+6]-cycloadditions.

compound **166**, in which the chromophores are interchanged, failed to cyclize under the same irradiation conditions. The difference in photochemical behavior of **164** and **166** is due to the different interaction between parallel π systems observable in the UV spectrum; the interaction of the NN double bond and the *o*-phenylene bridge is stronger in **164** than in **166**.

The dibenzo compound **168** was inert toward acetone-sensitized excitation, probably because the triplet energy for the isolated chromophoric xylene units is too high, whereas irradiation of **168** with monochromatic 254 nm light slowly gave a ca. 7:3 equilibrium mixture of **168** and the [6 + 6]-photoaddition product **169**.[47] The key step for the successful synthesis of "Pagodane," the $C_{20}H_{20}$ polyquinane, is this type of benzo/benzo [6 + 6]-photocycloaddition and a domino Diels–Alder reaction.

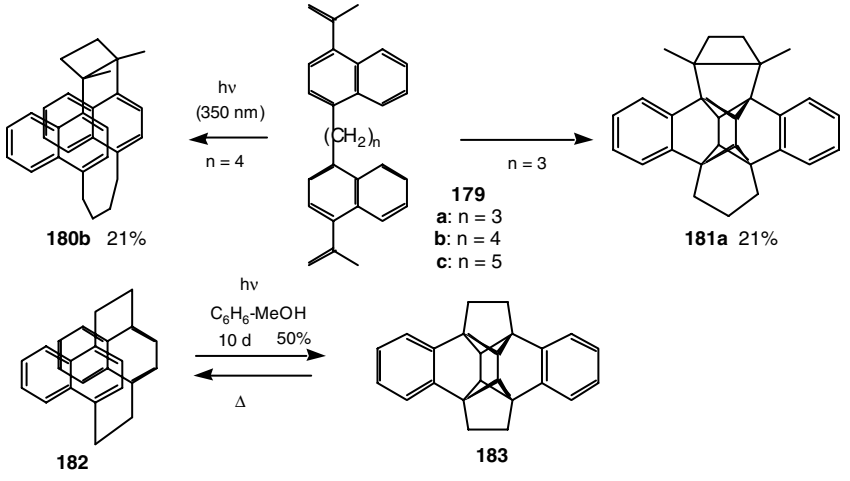

SCHEME 37 Photocycloaddition of naphthalenophanes.

Photochemical [4+4]-Cycloadditions and Related Reactions

Irradiation (low-pressure Hg lamp) of an equimolar mixture of benzene and furan gives fulvene together with a mixture of five 1:1 photoadducts and some material of higher molecular weight. The major component has the 2,5–1′,4′-structure **171**, which rearranged very cleanly both photochemically and thermally to the isomeric adduct **172**. This compound proved to be identical to the second most abundant component of the original mixture of photoproducts. Thermal Cope rearrangement of **171** to **172** occurred readily at 60°C. Acetone-sensitized photochemical cyclization of the maleic anhydride adduct **173** gave the cage compound **174**.[48]

Kimura et al. prepared the naphthalene-1,4-difluorobenzene adduct **177** by a [4 + 4]-photocyclization followed by oxidative decarboxylation of **176**. They named this type of [4 + 4]-adduct "biplanemer."[49] The direct irradiation of **177** gave 1,4-difluorobenzene and excited naphthalene in both singlet and triplet

states at 77 K in EPA. In the triplet-sensitized reaction, **177** underwent an intramolecular [2 + 2]-reaction to give the cage compound **178** instead of forming triplet naphthalene.

Through their studies on the synthesis of naphthalenophanes via [2 + 2]-photocycloaddition,[50] Nishimura et al. found that the irradiation of diolefin **179a** gave cage compound **181a**,[51] structurally similar to dibenzoquinene **183**, which was obtained from *anti*-[2.2](1,4)naphthalenophane **182** by photoirradiation.[52] Interestingly, the diolefin **179b,c** having longer tethers showed different photochemical behaviors from those of **179a**. Under the same irradiation condition, **179b** gave the expected [2 +2]-photocycloadduct (naphthalenophane) **180b**. On the other hand, **179c** gave no photoproduct. It is assumed that **181a** is formed through twofold [π4s + π2s]-photocycloaddition during the [π2s + π2s]-photocycloaddition of 2-propenyl groups, although there is no conclusive evidence on whether this reaction occurs by a concerted or a stepwise mechanism. This reaction is an uncommon examples of the photochemical reactions of naphthalenophanes, which tend to give a [π4s + π4s]-cycloadduct by irradiation. The [4 + 4]-photochemical cycloaddition and related reactions of cyclophanes have been the subject of a review by Misumi.[53]

23.1 Synthesis of [n]Prismanes (n = 3–5)

Prismanes constitute an infinite family of $(CH)_n$ polyhedra that chemists find aesthetically appealing because of their molecular architecture (Figure 23.1).[1] Notwithstanding their structural regularity, many years of effort were needed before the first three members, prismane ([3]prismane) **1**,[2] cubane ([4]prismane) **2**,[3] and pentaprismane ([5]prismane) **3**,[4] could be successfully synthesized. Recently, attention has been focused on the challenging objective of constructing the higher prismanes, in particular, hexaprismane ([6]prismane) **4**. The molecules in the prismane family are highly strained due to their unusual structural features, extended CC bond lengths, and deformed bond angles. Their strain energies are estimated to be 140–178 kcal/mol based on *ab initio* MO calculations (6–31G*).[5] Pentaprismane has the smallest strain energy, while hexaprismane has the highest. Although several approaches have been tried, hexaprismane **4** has eluded synthesis so far. In this section, strategies for the synthesis of [n]prismanes (n = 3–5) are outlined, where the key steps of the synthesis are the [2 + 2]-photocyclization and Favorskii contraction. In the next section, photochemical synthetic approaches toward hexaprismane and its derivatives are introduced as a hot topic in this area.

Scheme 1 illustrates the synthesis of prismane ([3]prismane) **1** by Katz and Acton[2] Benzvalene **5** reacts with the powerful dienophile, 4-phenyltriazolinedione **6**, in diethyl ether–dioxane to give the 1:1 adduct **7** (60–70%). Refluxing **7** with KOH in MeOH/H_2O, followed by treatments with acidic $CuCl_2$ and aqueous NaOH, gives azo compound **8**. Irradiation of **8** through Pyrex in isobutane at 35°C affords prismane **1** (1.8%) as an explosive colorless liquid. Prismane is stable at room temperature. One of the key steps of this synthesis is a photochemical nitrogen extrusion (Scheme 1).

The ethylene ketal of 2-bromocyclopentadienone undergoes spontaneous dimerization to give the dimeric adduct **10**, which is converted to the cage compound **11** by ultraviolet irradiation in benzene (95%). The bishomocubane system **11** is contracted to the homocubane system **12** by the Favorskii rearrangement. Decarboxylation of **12** via perester **13** gives **14**, and subsequent similar ring contraction (**14** to **15**) and decarboxylation of **15** provide the desired cubane **2** as glistening rhombs (mp 130–131°C).[3] In this synthesis, the critical steps are the [2 + 2]-photochemical reaction and subsequent Favorskii ring contractions (Scheme 2).

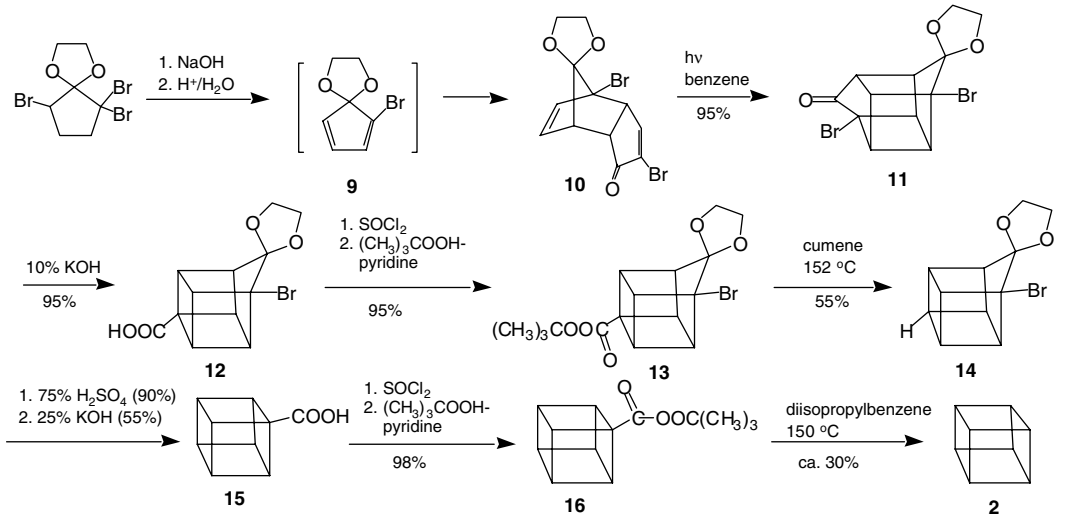
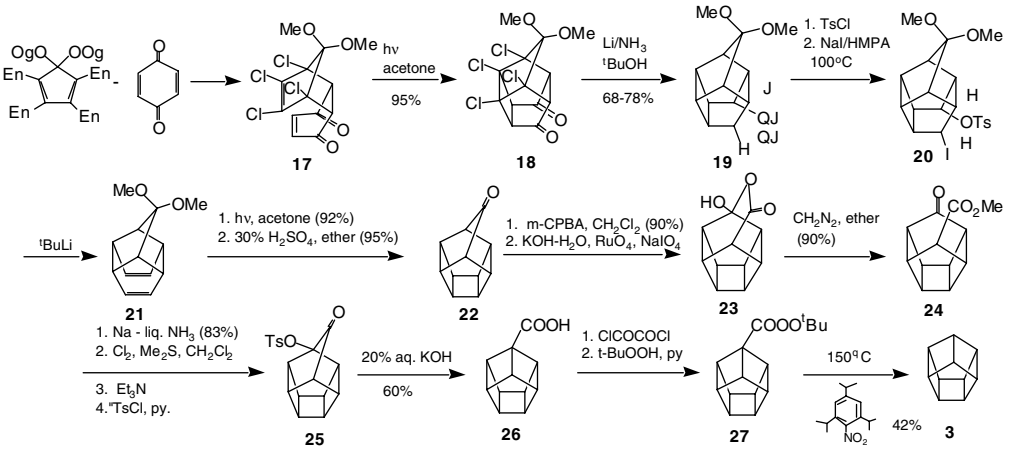


SCHEME 2 Synthesis of [4]prismane (cubane). (From Reference 3.)

Acetone-sensitized [2 + 2]-photocycloaddition of the adduct **17** of 1,2,3,4-tetrachloro-5,5-dimethoxycyclopentadiene with *p*-benzoquinone gives the cage compound **18** effectively (95%) (Scheme 3). Dechlorination and reduction of the carbonyl groups of **18** with Li in liquid NH_3 and tosylation of the *endo-endo*-diol **19**, is followed by treatment with NaI to give a mixture (1:3) of diiodide and iodotosylate **20**. Reaction of the mixture with *t*-butyl lithium gives dimethoxyhomohypostrophene **21**, which is photocyclized to give homopentaprismanone **22**. A tosyl group is introduced α to the bridging carbonyl



SCHEME 3 Synthesis of [S] prismane (pentaprismane). (From Reference 4.)

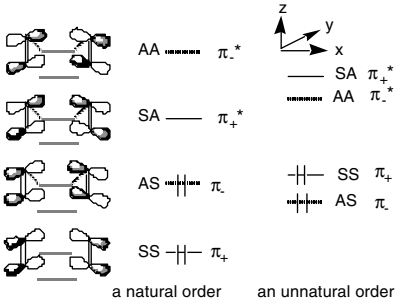


FIGURE 23.2 In a diene with juxtaposed double bonds, the natural frontier molecular orbitals (FMO) in the absence of through bond interaction is $\pi^{+} < \pi^{-} < \pi^{+*} < \pi^{-*}$.

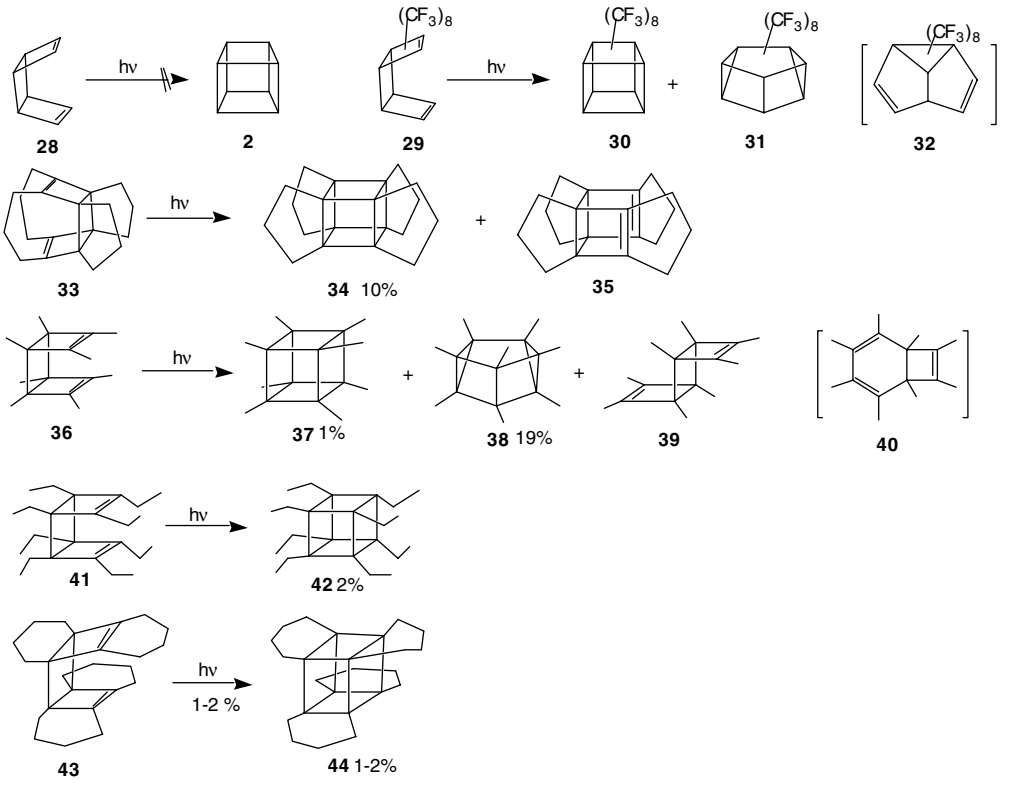
group (**22** to **25**), and the Favorskii ring contraction of **25** followed by decarboxylation of **26** affords the desired pentaprismane **3** as glistening crystals (mp 127.5–128.5°C).[4,6]

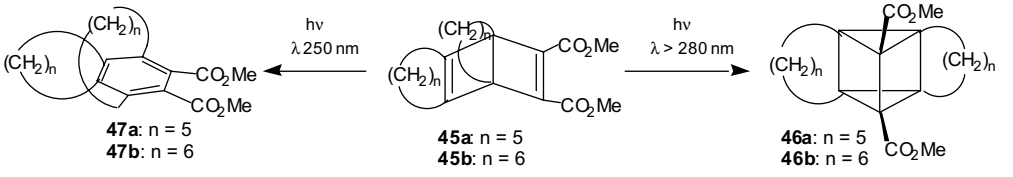
Gleiter et al. suggested an alternative simple approach to the synthesis of cubane derivatives. Osawa et al. reported that the failure to produce the cubane skeleton from *syn*-tricyclo[4.2.0.0^{2,5}]octa-3,7-diene **28** was rationalized by assuming that the sequence of the frontier orbitals was π_{+} above π_{-} and π_{+}^{*} above π_{-}^{*} as a result of strong through-bond interaction between the cyclobutene ring and the π orbitals (an unnatural order). As a result of this orbital sequence, photochemical [2 + 2]-cycloaddition of **28** to cubane is a symmetry-forbidden process (Figure 23.2).[7]

However, Polesi and Miller reported in 1976 that irradiation (450 W high-pressure Hg lamp) of a perfluoro-derivative of *anti*-tricyclo[4.2.0.0^{2,5}]octa-3,7-diene in a fluorocarbon solution yielded perfluorooctamethylcubane **30** (ca. 20%) and perfluorooctamethylcuneane **31** (15%) (Scheme 4). They postulated that the cubane **30** and cuneane **31** were formed from the *syn*-isomer **29** and the semibullvalene **32**, respectively.[8]

Gleiter et al. found that the alkyl-substituted *syn*-tricyclo[4.2.0.0^{2,5}]octa-3,7-dienes **33**, **36**, **41**, and **43** afforded the cubane derivatives **34**, **37**, **42**, and **44** via photoirradiation (high-pressure Hg lamp) of the pentane solution.[9] In the case of octamethyl-diene **36**, six different photoproducts were isolated, but the main product was octamethylcuneane **38**. The cubane **37** may be formed directly via photoirradiation, whereas a mechanism involving either a biradical intermediate or the triene **40** was proposed for the formation of other products (**38**, **39**). Although the parent **28** is photochemically inactive, Gleiter et al. revealed that its octaalkyl derivatives have a rich photochemistry.



SCHEME 4 Photochemistry of *syn*-tricyclo[4.2.0.0^{2,5}]-octa-3,7-dienes.



SCHEME 5 Synthesis of doubly bridged prismanes.

Gleiter and Treptow reported the synthesis of the first doubly bridged prismane derivatives **46a** (n = 5) and **46b** (n = 6).[10] Irradiation (500 W high-pressure Hg lamp) of the Dewar benzene derivatives **45a** (n = 5) at 250 nm in diethyl ether under Ar yields only polymeric material because of the instability of the initially formed [5]paracyclophane **47a**, whereas irradiation at 280 nm gives the prismane **46a** (15%, 72 h). When **45b** (n = 6) was irradiated at 250 nm, rapid isomerization to the [6]paracyclophane **47b** (100%, 1 h) took place; increasing the wavelength to 280 nm led to the prismane **46b** (30%, 24 h).

23.2 Photochemical Approaches to the Synthesis of Hexaprismane and Its Derivatives

Many diverse synthetic strategies have been developed, and significant progress toward the synthesis of hexaprismane has been made. Through these efforts, bissecohexaprismane **48** (Eaton and Chakraborty),[11] secohexaprismane **49** (Mehta and Padma)[12] 1,4-bishomohexaprismane (garudane) **50** (Mehta and Padma),[13] 1,4-bishomohexaprismane dione **51** (Dailey and Golobish),[14] and homosecohexaprismane skeleton **52** (Chou et al.)[15] have been synthesized (Figure 23.3).

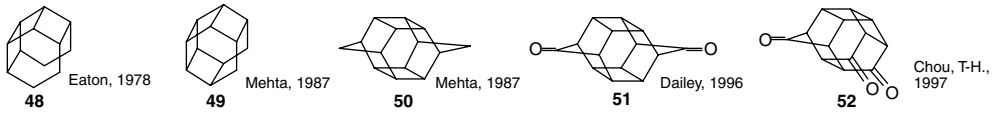


FIGURE 23.3

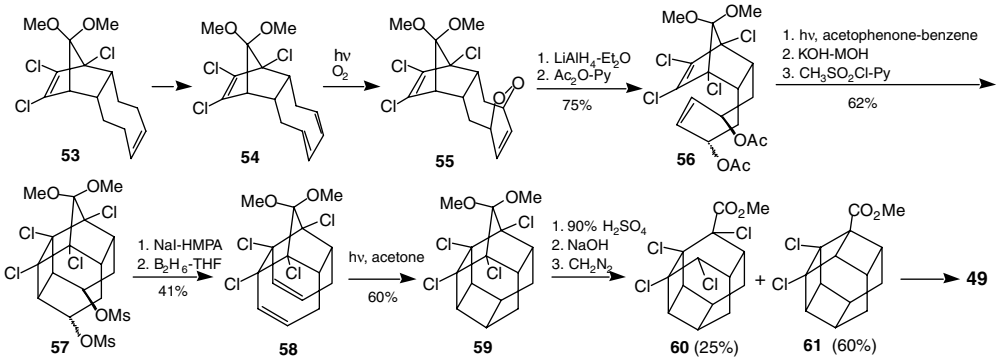
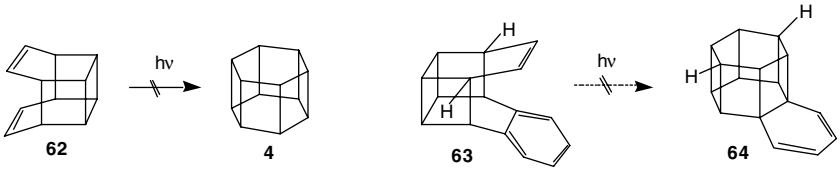


SCHEME 6 Synthesis of secohexaprismane. (From Reference 12.)

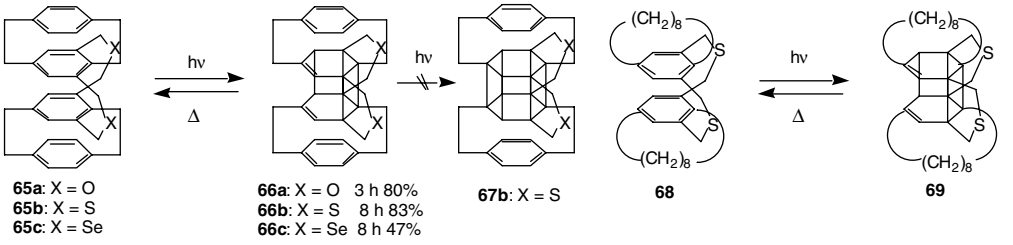


SCHEME 7 Photochemistry of pentacyclo[6.4.0.0^{2,7}.0^{3,12}.0^{6,9}]dodeca-4-10-dienes.

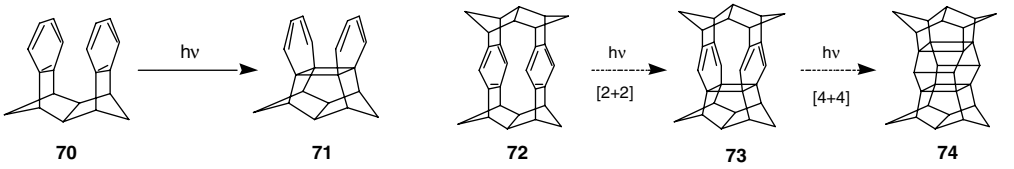
The synthesis of secohexaprismane **49** is outlined in Scheme 6.[12] The Diels–Alder adduct **53** of 1,5-cyclooctadiene and 5,5-dimethoxy-1,2,3,4-tetrachlorocyclopentadiene was readily available. It was converted into the diacetate **56** via the cyclic peroxide **55**, which was formed through stereoselective [4 + 2]-addition of singlet oxygen to the diene moiety of **54**. Acetophenone-sensitized photocyclization gave the caged pentacyclic *endo,endo*-diacetate, which was converted into the diene **58** by conventional methods (Scheme 3, **19** to **21**) via the dimesylate **57**. Acetone-sensitized photocyclization provided **59**, and deprotection of the carbonyl group of **59** and Favorskii ring contraction gave a 2:5 mixture of **60** and **61**. Alkaline hydrolysis, Hunsdiecker reaction, and reductive dehalogenation of **61** provided secohexaprismane **49** as a highly volatile waxy solid (mp > 250°C). It should be noted that the [2 + 2]-photocyclization of the Diels–Alder adduct and Favorskii contraction play pivotal roles in the synthesis of these cage compounds. However, hexaprismane and its derivatives have not yet been synthesized.

An alternative approach is the photochemical dimerization of benzene and its equivalent. Yang and Horner synthesized pentacyclododecanediene **62** as a logical precursor of hexaprismane **4**,[16] but the [2 + 2]-photocyclization did not occur (Scheme 7). A similar approach was reported by Kimura et al. Acetone-sensitized irradiation of the benzene solution of diene **63** did not give the desired hexaprismane derivative **64**; only naphthalene and *p*-difluorobenzene were formed.[17] In principle, the [2 + 2]-photocyclization of the pentacyclododecanediene skeletons **62** and **63** may be a symmetry-forbidden process.[7]

Misumi and co-workers reported the first example of photodimerization of benzene rings incorporated into a *syn*-quadruple-layered diheteracyclophane **65**. A benzene solution of **65a** (X = O) was irradiated with a high-pressure Hg lamp under N_2 for 30 min to give the cage compound **66a** (Scheme 8).[18] In a



SCHEME 8 A novel photodimerization of benzene moieties in the *syn*-quadruple-layered diheteracyclophanes.



SCHEME 9 Benzo/benzo [6+6]-photocycloaddtion.

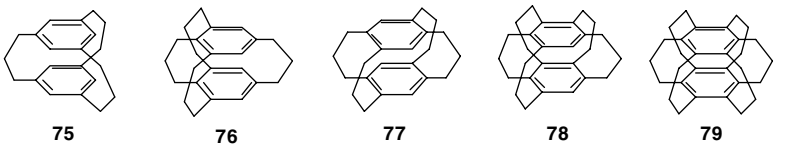


FIGURE 23.4 [3_n]cyclophanes (n = 3-6).

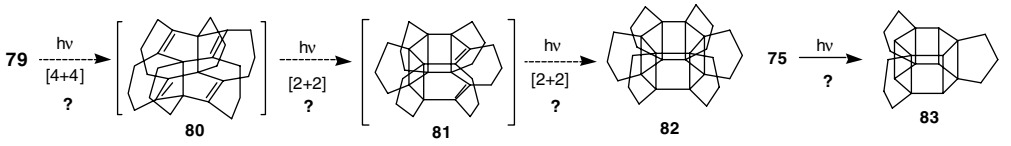
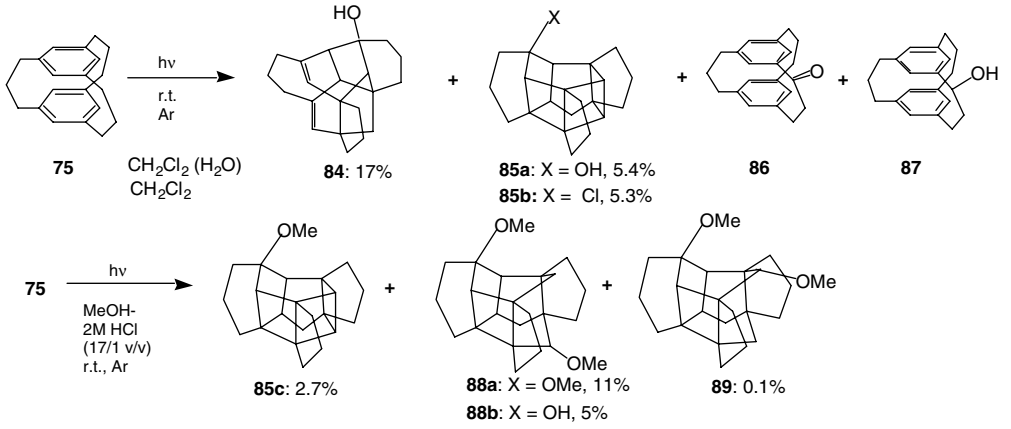
similar manner, **65b** (X = S) and **65c** (X = Se) were converted into the cage compounds **66b** and **66c**, respectively. These cage compounds reverted thermally to the starting cyclophanes. In dithia compounds with an [n]paracyclophane framework, the compound **68** (n = 8), which is as strained as **65b**, also gave the photoisomer **69** (17% at room temperature, 31% at –78°C), whereas no photoisomer was obtained with the compound (n = 10), with much less strain. A [2 + 2]photocycloaddition of the remaining two double bonds of **66b** was attempted by irradiating with a low-pressure Hg lamp at various temperatures, but only formation of a small amount of dimethyl[2.2]-paracyclophane was observed. They concluded that the face-to-face stacking of two fairly strained benzene nuclei is responsible for the photodimerization, and the two outer benzenes are required for effective interconversion between quadruple-layered diheteracyclophanes and their isomeric cage compounds.

As already described (Chapter 22, Scheme 34), Prinzbach et al. reported benzo/benzo [6 + 6]-photodimerization of benzene rings (**70** to **71**), and this is the second example of the photodimerization of benzene rings.[19] Recently, they proposed a possible synthetic route of pagodane-condensed prismane derivatives **74** via a photochemical benzo/benzo [6 + 6]-photoreaction of **72** followed by a photochemical [4 + 4]-cycloaddition reaction of **73** (Scheme 9).[20]

Recently, we discovered a third example of the photodimerization of the benzene rings. In our photochemical approach to the construction of hexaprismane derivatives, we used the [3_n]cyclophanes ([3_n]CPs) **75–79** (n = 3–6)[21], in which two benzene rings are stacked at 3.0–3.2 Å transannular distances (Figure 23.4), as precursors.[22] We expected that the photocyclization of the [3_n]CP would proceed via the first [4 + 4]-photoreaction (**79** to **80**), followed by successive [2 + 2]-reactions (**80** to **81** then **81** to **82**) (Scheme 10). We describe here the photochemical reactions of [3_3](1,2,3)CP **75** and [3_4](1,2,3,5)- and (1,2,4,5)CPs **76** and **77**.



SCHEME 10 Expected photochemical isomerizations.



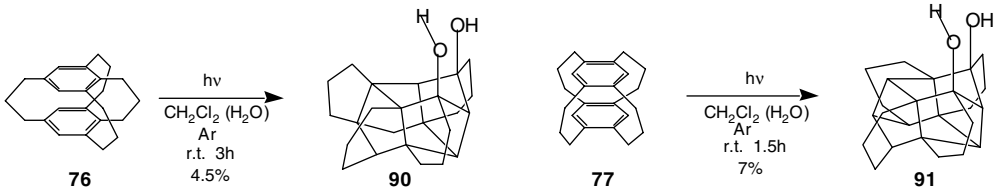
SCHEME 11 Photochemical reactivity of [3_3](1,3,5)cyclophane.

Irradiation of the [3_3]CP **75** by a sterilizing lamp (254 nm) in cyclohexane, methanol, or benzene left **75** intact although some polymerization occurred. However, two types of products were formed when methylene chloride was used as a solvent. A dry methylene chloride solution of **75** (4.90 mmol/l) in a quartz vessel was irradiated by a sterilizing lamp for 2.5 h at room temperature under Ar to give a new cage compound, the bridged hexacyclic chlorododecane **85b** (5.3%), with a bishomopentaprismane skeleton and the recovery of the starting compound **75** (40%) (Scheme 11).[23a] Irradiation of **75** under the same conditions, but in a methylene chloride solution saturated with water (14.5 mmol/l), for 2.5 h under Ar gave, in addition to **75** (18%), two photoproducts: diene–alcohol **84** and caged alcohol **85a** with the same skeleton as **85b**.[23a,24]

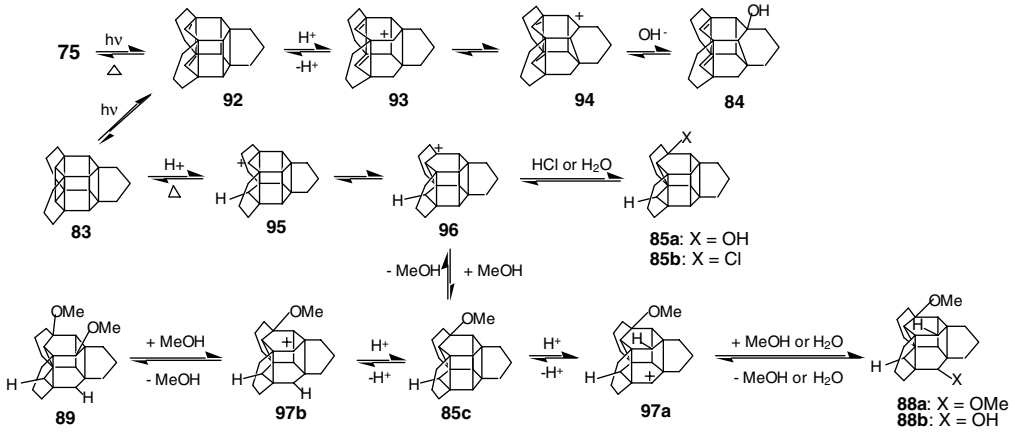
In order to examine the photochemical reaction mechanism, photolysis in acidic and basic conditions was examined. A d_4 methanol or d_3 acetonitrile solution of **75** containing 2 mol/l aqueous HCl solution in a quartz NMR tube was irradiated with a sterilizing lamp for 2.5 h at room temperature under Ar. The reaction proceeded in acidic conditions, whereas the reaction in dideuterio methylene chloride in the presence of triethylamine failed. In a preparative scale reaction, a mixture of MeOH and 2 mol/l aqueous HCl solution (17:1 v/v) (10.2 mmol/l) of **75** was irradiated with a sterilizing lamp in a quartz vessel for 80 min at room temperature under Ar to give recovered **75** (11%) and the methoxy compound **85c** (2.7%), as well as the dimethoxy and methoxy–hydroxy compounds **88a** (11%) and **88b** (5.9%), with a new cage skeleton. Prolonged irradiation gave the dimethoxy compound **88a** as a major product (57%).

In completely degassed nonpolar solvents such as hexane, pentane, and cyclohexane, no reaction apparently took place even on prolonged irradiation. On the other hand, in the presence of dissolved oxygen in the solvent, trace amounts of the photoproducts **86** and **87**, formed by oxidation at the benzylic carbon, were isolated.

The photochemical reactions of the [3_4](1,2,3,5)CP **76** and [3_4](1,2,4,5)CP **77** were also examined. A water-saturated methylene chloride solution of **76** or **77** was irradiated with a sterilizing Hg lamp for 1.5 h at room temperature under Ar to afford a new cage compound **90** (4.5%)[25] or **91** (7%),[26] respectively, along with the starting material (Scheme 12). We have failed to gather conclusive evidence for the reaction mechanism, but a proposal is shown in Scheme 13. The [3_3]CP **75**, on irradiation in methylene chloride,



SCHEME 12 Photochemical reactions of the $[3_4](1,2,3,5)$cyclophane and $[3_4](1,2,4,5)$ cyclophane.



SCHEME 13 Expected mechanism for the formation of the photoproducts.

first gives the highly strained hexaprismane derivative **83**. Protonation occurs at the unbridged carbon atom of a cyclobutane ring to give the secondary carbocation **95**, which rearranges to the more stable tertiary carbocation **96**. Finally, **96** is trapped by chloride or hydroxide ions to give the products **85b** (X = Cl) or **85a** (X = OH).

One of the driving forces in this series of reactions must be release of the steric strain. The formation of the diene–alcohol **84** is explained in a similar way. The protons may be generated upon photoirradiation of methylene chloride. In fact, the pH of the reaction mixture was ca. 2 after irradiating in the wet methylene chloride solution. The photochemical reaction of **75** did proceed in methanol in the presence of a proton source to give **85c**, as was the case in methylene chloride. Subsequent protonation to the unbridged carbon atom of the central bicyclo[2.2.0]hexane skeleton of **85c** from the upper side may give the secondary carbocation **97**, which is intercepted by MeOH or H_2O to give the products **88a** and **88b**, respectively. This trapping of the secondary carbocation occurred preferentially on the lower face. This preference is the result of a variety of factors such as steric hindrance by the methoxy group and repulsion by the lone pair of electrons on the oxygen atoms between the flagpole bonds if attack occurred on the upper face. In this reaction, isolation and characterization of the highly strained propella$[3_3]$prismane **83**, a possible intermediate, is impossible because **83** may be protonated under the acidic conditions.

Although we have not yet succeeded in the isolation of **83**, these photochemical reactions provide useful one-step synthetic methods leading to new polycyclic cage compounds with novel skeletons **98–101** from the $[3_3]$CP **75** and $[3_4]$CPs **76**, **77** (Figure 23.5). Further investigation of the photochemical reaction conditions via the excited singlet state of **75**, and modification of the benzene ring of **75** in order to stabilize the hexaprismane skeleton, may lead to the isolation of the hexaprismane derivative. The photochemical reactions of $[3_6]$CP **79** and fluorinated $[3_3](1,3,5)$CPs[27] are in progress. We believe that a successful synthesis of hexaprismane or hexaprismane derivatives will be realized in the near future.

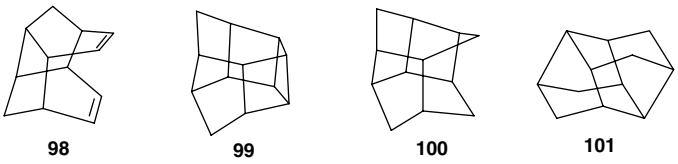


FIGURE 23.5 Skeleta of the new cage compounds.

Photochemistry of Allenes

Toshio Shimizu
Tokyo Metropolitan University

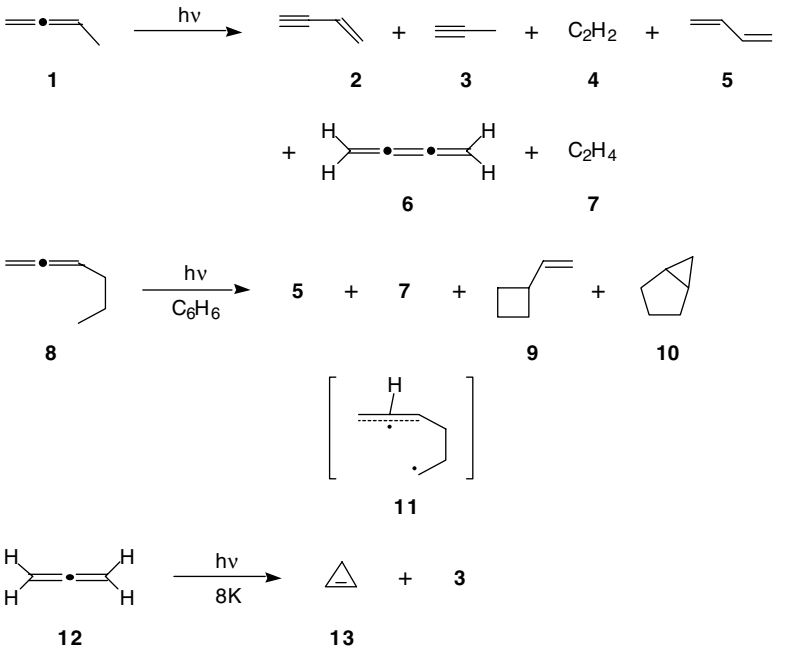
24.1 Introduction

Allenes are frequently used as building blocks for the synthesis of cyclic compounds by inter- and intramolecular photochemical cyclization reactions with ketones, thiones, enones, and related compounds. Most of the reactions, however, proceed between the ground state of the allenes and the excited state of the other reactants. Over the past 40 years, many photochemical reactions of allenes have been reported, and theoretical studies of the excited states have been conducted.[1–6] In this chapter, the fundamental photochemical reactions of allenes will be described.

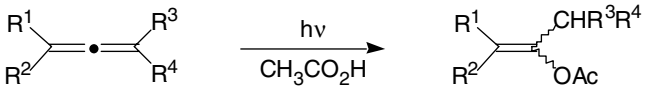
24.2 Photochemical Reactions of Acyclic Allenes

In 1957, Collin and Lossing reported that the mercury-photosensitized decomposition of allene in the vapor phase leads to the formation of a C_3H_3 radical, which was detected by mass spectrometry. This radical affords the corresponding dimer.[7] They proposed two modes of decomposition for the mercury-photosensitized decomposition of 1,2-butadiene: one is decomposition giving H_2 and C_4H_4, and the other path yields CH_3 and C_3H_3 radicals. Later, Doepker and co-workers studied the direct photochemical reaction of 1,2-butadiene.[8,9] Vacuum-ultraviolet photolysis (1470 and 1236 Å) of 1,2-butadiene **1** affords vinylacetylene **2**, methylacetylene **3**, acetylene **4**, 1,3-butadiene **5**, butatriene **6**, and ethylene **7**. Ward and Karafiath reported the photochemical reaction of 1,2-hexadiene.[10] Benzene-sensitized vapor-phase photolysis (2537 Å) of 1,2-hexadiene **8** leads to the formation of 1,3-butadiene **5** ($\phi = 0.16$), ethylene **7** ($\phi = 0.15$), vinylcyclobutane **9** ($\phi = 0.07$), and bicyclo[3.1.0]hexane **10** ($\phi = 0.005$) as the primary products, whereas direct vacuum-ultraviolet photolysis (1600–2100 Å) of **8** yields **5**, **7**, **9** and a further nine products. Products **5**, **7**, and **9** are suggested to be formed via the intermediate biradical species **11**, which is generated by a pathway similar to that of the Norrish type II reaction of ketones. The bicyclic product **10** may be formed by an allene–cyclopropylidene rearrangement followed by insertion into a CH bond. Chapman reported the photochemical reaction of the simplest allene.[11] Irradiation of allene **12** matrix-isolated in argon at 8 K affords cyclopropene **13** and methylacetylene **3**.

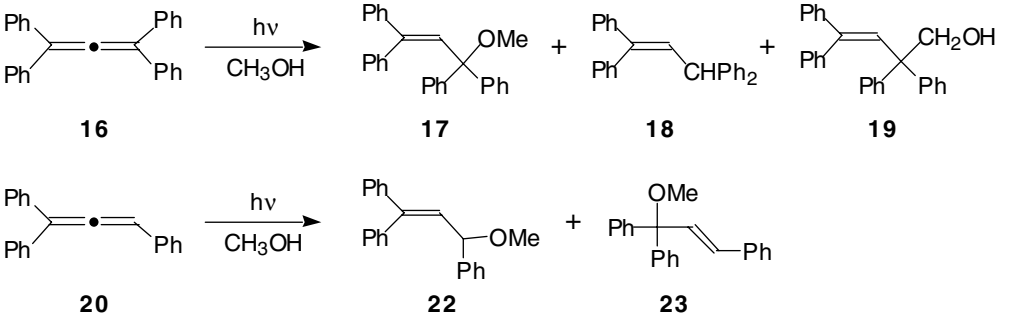
0-8493-1348-1/04/$0.00+$1.50

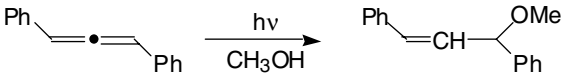


Fujita and co-workers reported the photochemical reaction of allenes in acetic acid.[12] Irradiation (254 nm) of **14a–e** affords the respective enol acetates **15**. In the reaction of **14b**, a triplet mechanism is proposed on the basis of quenching experiments. In methanol solution, on the other hand, the photochemical reaction of tetraphenylallene **16,** using Corex or Pyrex filters, was reported by Klett and Johnson to yield the allylic methyl ether **17** as the major photoproduct along with **18** and **19** (in ratios of 10:1:1).[13] Similar reactions of triphenylallene **20** and 1,3-diphenylallene **21** also afford allyl ethers **22**, **23** (5:1), and **24**, respectively. In these reactions, a mechanism involving a strongly polarized planar singlet excited state is proposed on the basis of triplet sensitization experiments.



14a $R^1 = n\text{-}C_6H_{13}$; $R^2 = R^3 = R^4 = H$ **15a**
14b $R^1 = Ph$; $R^2 = Me$; $R^3 = R^4 = H$ **15b**
14c $R^1 = Ph$; $R^2 = R^3 = Me$; $R^4 = H$ **15c**
14d $R^1 = m\text{-}MeOC_6H_4$; $R^2 = Me$; $R^3 = R^4 = H$ **15d**
14e $R^1 = m\text{-}CF_3C_6H_4$; $R^2 = Me$; $R^3 = R^4 = H$ **15e**

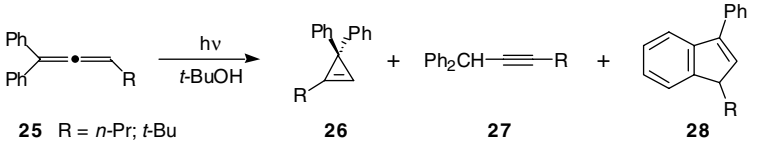




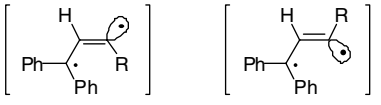
21 **24**

Several cyclopropene-forming reactions from allenes have been reported. Steinmetz and co-workers reported that the direct irradiation of 1,1-diphenylallenes **25** through a Vycor filter in *t*-butanol produces 3,3-diphenylcyclopropenes **26** and diphenylpropynes **27**, along with indenes **28**, as the major products.[14,15] The mechanism is proposed as follows. Vertical allene excited state **25*** forms the vinylmethylene biradical species **29** via 1,2-hydrogen migration. Further hydrogen migration within **29** affords propynes **27**. On the basis of deuterium labeling experiments, it is suggested that the second 1,2-hydrogen shift is the rate-determining step. Due to unfavorable steric interactions from bulky terminal substitution, the stereoisomerization of **29** to *anti*-**30** would provide a pathway for the formation of cyclization products **26** and **28**. An additional pathway for the formation of products **26** and **28** involving equilibration from **30** to vinylcarbene followed by cyclization is suggested on the basis of theoretical calculations.[16] Klett and Johnson also reported that irradiation (254 nm) of triphenylallene **20** in pentane at –10°C (to prevent thermal dimerization) rapidly forms **31–33** as the primary photoproducts.[17,18]

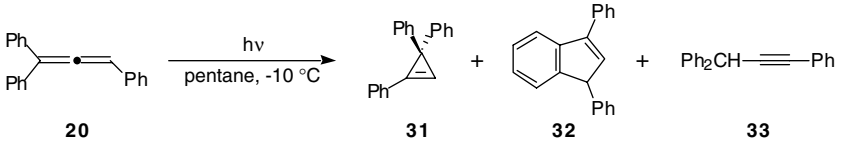
Irradiation (>220 nm) of tetraphenylallene **16** in cyclohexane very slowly yields indene **34** as the primary product, and no cyclopropene derivative is formed. In this reaction, triplet sensitization (xanthone, benzene, wavelengths >330 nm) gives unreacted **16** and the sensitizer. In these reactions in hydrocarbons, vinylcarbenes are proposed as the common intermediates. The direct photolysis of vinylidenecyclobutane **35** in pentane or hexane at 185 nm was reported by Steinmetz and co-workers to afford spiro[2.3]hex-1-ene **36**, ethynylcyclobutane **37**, 3-methylenecyclopentene **38**, butatriene **6**, and ethylene **7** as the primary products in quantum yields of 0.054, 0.044, 0.078, 0.12, and 0.14, respectively.[19] The reaction path to compounds **36** and **37** is thought to involve the biradical **39** generated by the 1,2-hydrogen shift of **35**. Compound **38** is formed via biradical **40** generated by 1,2-carbon migration. The reverse reaction from spiro compound to allene at 185 nm was also reported in the case of spiro[2.4]hept-1-ene **41** to yield vinylidenecyclopentane **42**.[20]



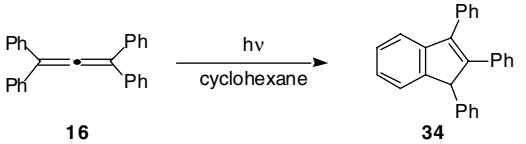
25 R = *n*-Pr; *t*-Bu **26** **27** **28**



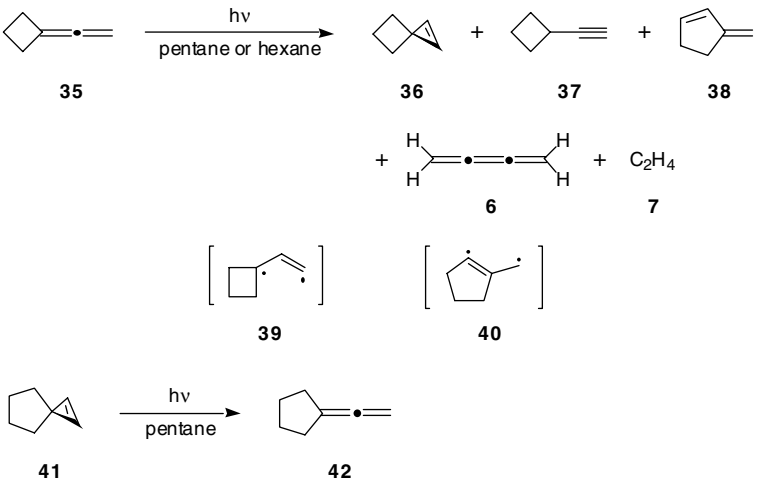
29 **30**



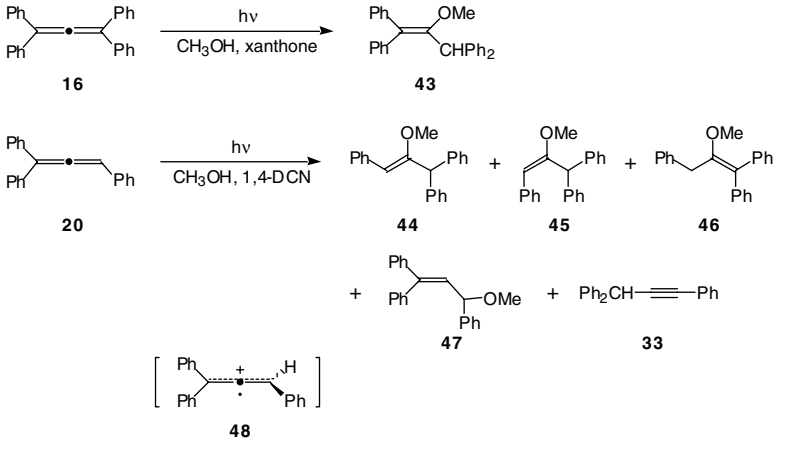
20 **31** **32** **33**



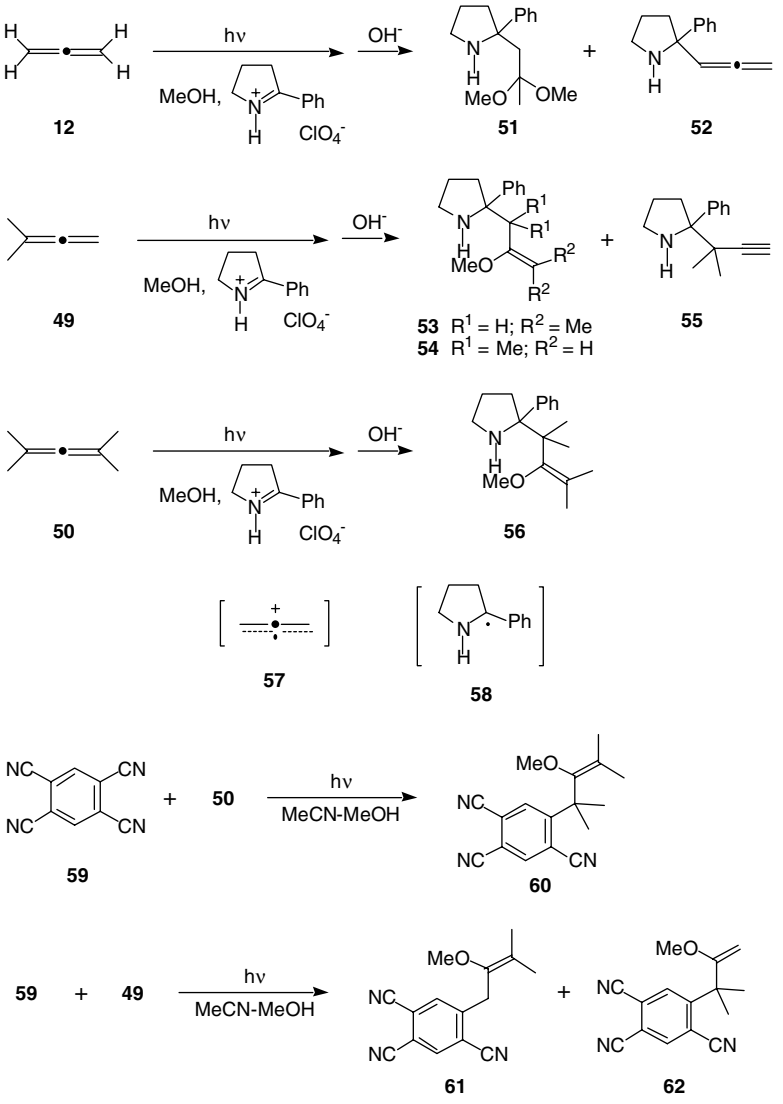
16 **34**



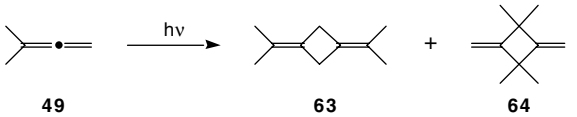
The photochemical reactions of allenes via an electron-transfer pathway have also been reported. The triplet-sensitized reaction of tetraphenylallene **16** in the presence of xanthone was reported by Klett and Johnson to afford only vinyl ether **43**.[13] They also reported that the photochemical reaction (λ >330 nm) of triphenylallene **20** in methanol in the presence of 1,4-dicyanonaphthalene (1,4-DCN) yields vinyl ethers **44–46** via an electron-transfer pathway, together with allyl ether **47** and alkyne **33**.[21] In this reaction, the radical cation of allene **48** is assumed to be the key intermediate.

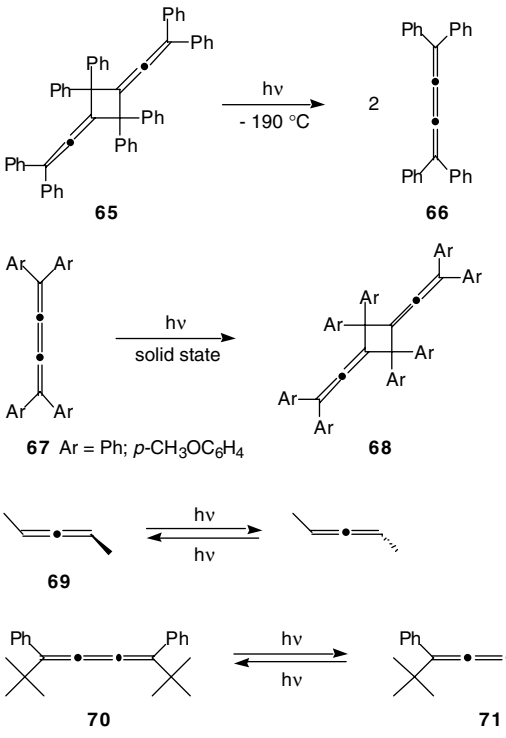


Mariano and co-workers also reported the photochemistry of allenes using an electron-transfer sensitizer.[22,23] Irradiation of allenes **12**, **49**, and **50** in the presence of 2-phenylpyrrolinium perchlorate affords adducts **51** and **52**, **53** to **55**, and **56**, respectively. In these reactions, the radical cation of allene **57** and pyrrolidinyl radical **58** are assumed to be the key intermediates. Mangion and co-workers reported the photochemical reactions of allenes with cyanoarenes.[6] For example, irradiation of 1,2,4,5-tetracyanobenzene **59** and tetramethylallene **50** in acetonitrile–methanol (3:1) through a Pyrex filter leads to 1:1:1 arene–allene–methanol adduct **60**. Similar reaction of 1,1-dimethylallene **49** also affords adducts **61** and **62**.



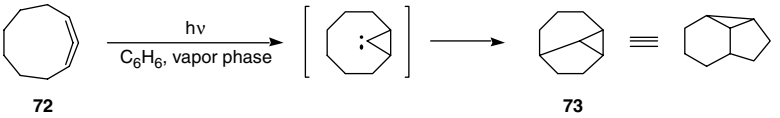
Slobodin reported the photodimerization reaction of allene.[24] Irradiation of 1,1-dimethylallene **49** affords dimers **63** and **64**. The ring-opening reaction of cyclic bisallene **65** was reported by Kaupp to yield butatriene **66** on irradiation in a low-temperature matrix,[25] and the reverse reaction from butatriene **67** to cyclic bisallene **68** in the solid state was also reported by Berkovitch-Yellin and co-workers.[26] The photochemical racemization of optically active penta-2,3-diene **69** in hexane was reported by Rodriguez and Morrison.[27] Kuhn and Schulz reported the photochemical *cis,trans*-isomerization reaction between *cis*-butatriene **70** and *trans*-butatriene **71** and also reported a 39.5%:60.5% *cis-trans* ratio at equilibrium upon irradiation at 313 nm.[28]

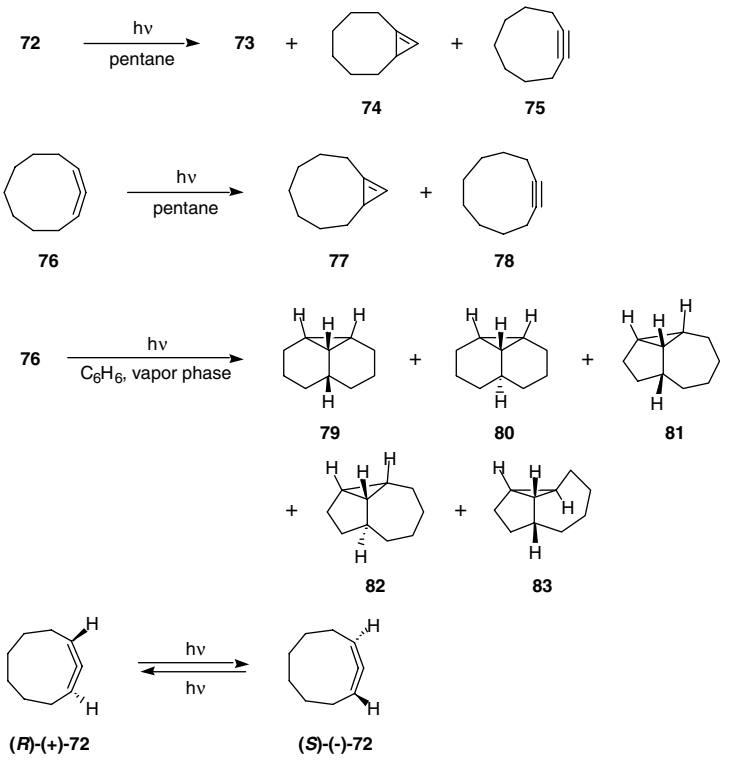




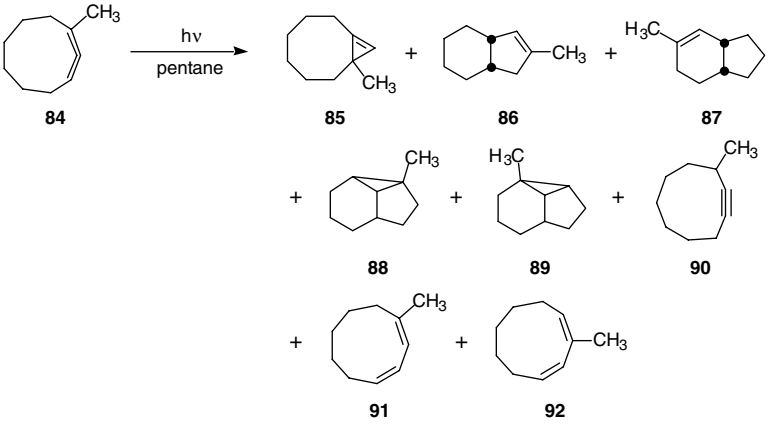
24.3 Photochemical Reactions of Cyclic Allenes

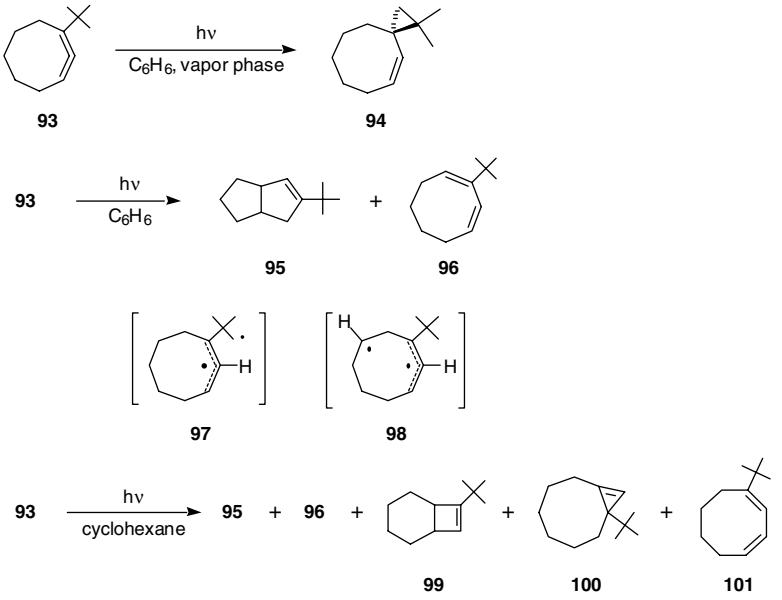
Cyclic allenes are also interesting subjects for photochemistry. In the late 1960s, Ward and Karafiath reported the photolysis of 1,2-cyclononadiene.[29] Benzene-sensitized photolysis (2537 Å) of 1,2-cyclononadiene **72** in the vapor phase affords tricyclo[4.3.0.0^{2,9}]nonane **73** as the primary product ($\phi = 0.17$). The closing of the allene to form the cyclopropylidene and the subsequent transannular insertion of the species into a C–H bond are surmised to be the most reasonable pathway for the formation of **73**. Direct irradiation of **72** in the vacuum-ultraviolet region also forms **73** along with three other isomers.[10] Later, Stierman and Johnson investigated the photochemistry of this system in solution.[30,31] Irradiation ($\lambda > 220$ nm) of a dilute pentane solution of **72** affords tricyclic compound **73**, bicyclo[6.1.0]non-1(9)-ene **74**, and cyclononyne **75** as the primary photoproducts in ratios of 3:94:3. In the formation of **74** from **72**, the authors propose a concerted [$\sigma 2_a + \pi 2_a$] electrocyclization process. Direct irradiation ($\lambda > 220$ nm) of a dilute pentane solution of the larger cyclic allene, 1,2-cyclodecadiene **76**, also yields a cyclopropene derivative **77** and cyclodecyne **78** (5:1) as the primary photoproducts at low conversion (<1%).[32] At high conversions, a complex mixture is obtained from the secondary reactions of **77**. On the other hand, benzene-sensitized irradiation (254 nm) of **76** in the vapor phase yields five major tricyclic products **79–83**. The photochemical reaction of a chiral cyclic allene was also reported.[31] Irradiation of optically active 1,2-cyclononadiene (R)-(+)-**72** or (S)-(–)-**72** yields racemic **72**.





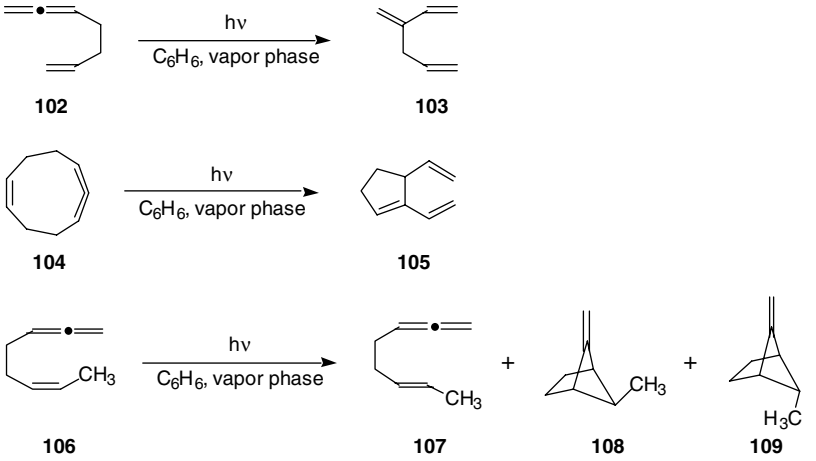
The photochemical reactions of substituted 1,2-cyclononadiene, 1-methyl-1,2-cyclononadiene **84**, were also reported by Stierman and co-workers.[33] Direct irradiation ($\lambda > 220$ nm) of **84** in pentane solution affords seven isomers **85–91** as the primary products, along with the secondary product **92**. Methyl derivative **84** seems to favor vinylcarbene intermediates, in contrast to the concerted reaction of **72**. Benzene-sensitized irradiation of strained 1-*t*-butyl-1,2-cyclooctadiene **93** affords the spiro compound **94** in the vapor phase, and irradiation (254 nm) of a dilute benzene solution of **93** yields 3-*t*-butylbicyclo[3.3.0]oct-2-ene **95** and 2-*t*-butyl-1,3-cyclooctadiene **96** in a 1:1 ratio.[34] The difference in reactivity between the vapor phase and the solution is explained as follows: the vapor-phase reaction proceeds through biradical **97**, whereas selective hydrogen abstraction from C7 yields biradical **98** in solution. On the other hand, direct irradiation (254 nm) of **93** in cyclohexane solution affords five photoproducts: **95**, **96**, and **99–101**.

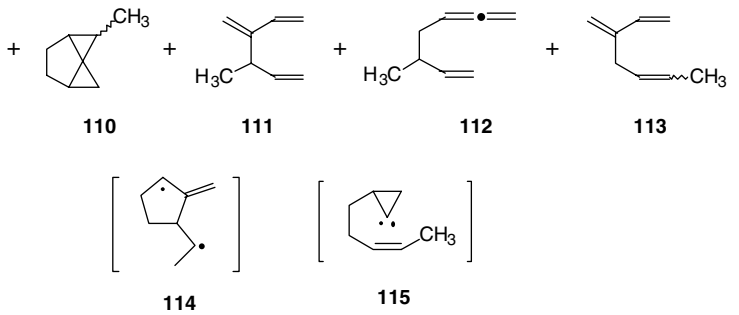




24.4 Intra- and Intermolecular Photochemical Reactions between Allenes and Olefins

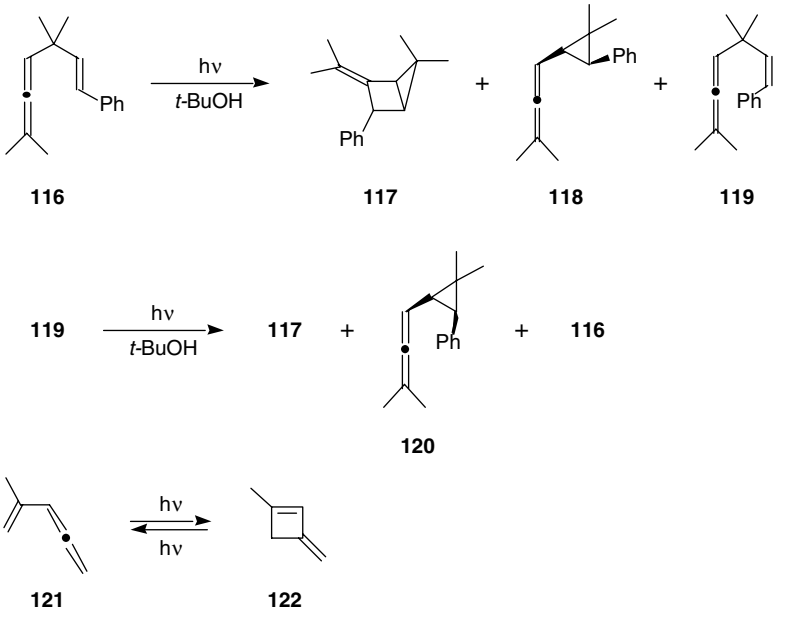
1,2,6-Heptatriene **102** was reported by Ward and Karafiath to afford the Cope rearrangement product, 3-methylene-1,5-hexadiene **103** ($\phi = 0.24$), as the primary product by benzene photosensitization at 2537 Å in the vapor phase.[10,35] This rearrangement is not reversible. Similarly, 2,3-divinylcyclopentene **105** is also obtained from 1,2,6-cyclononatriene **104** ($\phi = 0.02$). 1,2-Cyclononadiene is known to give tricyclo[4.3.0.$0^{2,9}$]nonane via the cyclopropylidene intermediate under similar conditions.[29,30] However, in this reaction, the compound that is expected to be obtained from the cyclopropylidene is not produced. The gas-phase benzene-sensitized photolysis (2537 Å) of *cis*-1,2,6-octatriene **106** was reported by Karan to lead to the formation of the *trans*-isomer **107** and six other primary products **108–113** with quantum yields of 0.150, 0.013, 0.023, 0.006, 0.007, 0.042, and 0.011, respectively.[36] At higher conversion, compounds **108–110** become the major products. One reasonable reaction pathway from **106** to **108** and **109** is proposed to proceed in a stepwise manner through an α,δ–biradical intermediate **114** formed from the excited state of the starting material. The intermediate **114** undergoes ring closure to form **108** and **109**. 2-Methyltricyclo[4.1.$0^{1,3}$]heptane **110** is considered to be formed via cyclopropylidene **115**.



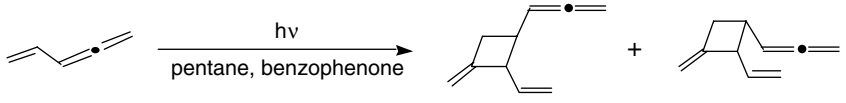


110 **111** **112** **113** **114** **115**

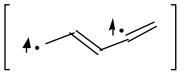
Lankin and co-workers reported the photochemical reaction of allylallene.[37,38] Direct irradiation (254 nm) of *trans*-7-phenyl-2,5,5-trimethylhepta-2,3,6-triene **116** in *t*-butyl alcohol leads to the formation of methylene bicyclo[2.1.0]pentane **117** and allenic cyclopropane **118**, along with *trans,cis*-isomerization product **119**. Similarly, the irradiation of the *cis*-isomer **119** also affords **117** and **120** with *cis,trans*-isomerization product **116**. No di-π-methane rearrangement to cyclopropanes is observed in these reactions. On the basis of quenching studies, the triplet states of *trans*- and *cis*-trienes **116** and **119** are indicated to be chemically significant excited states in the formation of bicyclo[2.1.0]pentane **117**. The photochemical reaction of vinylallene **121** was reported by Maier and co-workers to afford intramolecular cyclization product **122**, and **122** also yields allene **121** photochemically.[39]



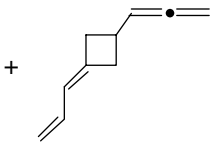
The intermolecular photochemical reaction of allene and olefin was also reported by Schneider and co-workers.[40] The benzophenone-sensitized reaction of 1,2,4-pentatriene **123** in pentane leads to the formation of cyclobutane derivatives **124–126** as the primary photoproducts. These products are suggested to be formed via biradical intermediate **127** followed by intermolecular addition to **123**.



123 **124** **125**



127



126

24.5 Photochemical Reactions of Allenes Containing Heteroatoms

α-Allenic halides **128** were reported by Troyanowsky and co-workers to undergo photorearrangement in solution to yield 1,3-dienes **129**.[41–43] A mechanism involving a free radical derived from the cleavage of carbon–heteroatom bonds is proposed, and the reactions proceed via bimolecular rearrangement on the basis of crossover experiments. Ueda and Toda reported the photochemical reaction of bromoallene.[44] Irradiation of a benzene solution of bromoallene **130** affords intermolecular cyclization product **131**, whereas the fluorenone-sensitized reaction of **130** yields **132**. In this sensitized reaction, radical **133** is thought to be the intermediate.

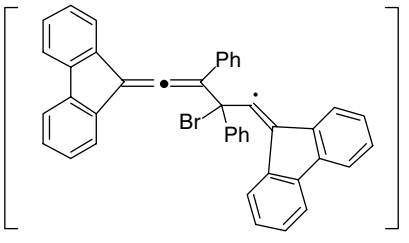
132



133

Recently, we reported the photochemical reactions of sulfur- and selenium-substituted allenes. Irradiation (λ >300 nm) of benzene solutions of 1,3-bis(alkylthio)allenes **134** affords rearrangement products **135** together with secondary products **136**.[45] A mechanism involving photoinduced 1,2-rearrangement of the alkylthio group to yield carbene **137** via biradical **138** is suggested. Irradiation (λ >300 nm) of cyclic bisallenes *dl*- and *meso*-**139** also causes similar rearrangement to give products **140** and **141**, together with the stereoisomer of the starting materials. The photoisomerization of **139** is assumed to be a result of a reverse reaction from the carbene or the biradical. In the case of selenium-substituted allenes, on the other hand, irradiation (λ >300 nm) of 1,3-bis(methylseleno)allene **142** affords enediynes **143** and **144**, along with rearrangement product **145**.[46] In this reaction, enediynes **143** and **144** are secondary products of propyne **145**. Irradiation (λ >300 nm) of 1,3-bis(benzylseleno)allene **146** also yields enediynes **143** and **144** together with dibenzyldiselenide **147**. Cyclic allenes **148** also form enediynes **143** and **144** with rearrangement product **149**.

25.1 Introduction and Definition of the Reaction

Since the early period of steroid chemistry, when the first photooxygenation of a 1,3-diene was reported by Windaus and Brunken[1] with an ergosteryl derivative as substrate, hundreds of examples of this reaction type have been described. Similar to the (thermal) reaction of 1,3-dienes with electron-deficient dienophiles, the Diels–Alder reaction mode ([4 + 2]-cycloaddition) is one of several possibilities when 1,3-dienes are subjected to photooxygenation conditions (light, oxygen, a dyestuff, and the substrate). In contrast to ground-state reactions, physical quenching of the electronically excited species (the dyestuff or singlet oxygen) may compete. The electronically excited dyestuff interacts with the diene to produce an electronically excited diene (energy transfer), a diene radical cation (electron transfer), or a pentadienyl radical (hydrogen abstraction) that subsequently is trapped by triplet oxygen. Another possibility is energy transfer from the excited dye (the sensitizer) to triplet oxygen with formation of singlet oxygen. The subsequent reaction of singlet oxygen with an acceptor molecule is termed a Type II process, whereas oxygenation reactions through an activated substrate molecule (radicals) are called Type I processes. In addition to this historically valuable nomenclature,[2] electron-transfer processes that involve alkene radical cations or superoxide radical anion have been designated as Type III photooxygenation reactions.[3] Most reactions discussed in this chapter are Type II reactions of singlet oxygen, the latter in its first electronically excited singlet state ($^1\Delta_g$).

Numerous alternatives exist for performing photooxygenation reactions with respect to solvent, sensitizer, and reaction temperature. Some of the most useful sensitizers for singlet oxygen generation are rose bengal (RB), polymer-bound RB, methylene blue (MB), and eosine for aqueous or alcoholic solvents and haematoporphyrin (HP) or tetraphenylporphin (TPP) for nonpolar organic solvents; recently, C_{60}[4] was also introduced as an efficient sensitizer for nonpolar organic solvents. The triplet energy of these sensitizers is low enough to guarantee selective energy transfer to molecular oxygen; however, in some cases the use of methylene blue may be critical because of electron transfer reactions. As light sources, sodium lamps are most convenient, but "traditional" light sources such as high-pressure mercury lamps

0-8493-1348-1/04/$0.00+$1.50

may be employed if appropriate filters are used to cut off the short-wavelength region ($\lambda >$ ca. 400 nm). Radical scavengers such as 2,5-di-*t*-butyl-phenol may be added in order to suppress radical reactions. Furthermore, typical singlet oxygen quenchers such as DABCO (diazobicyclo[2.2.2]octane) are useful as indicators for the nature of the reactive electronically excited species. Important reviews, which cover recent developments in a greater detail, are helpful for the reader as background material.[5]

25.2 Mechanism of the Singlet Oxygen Diene Photooxygenation

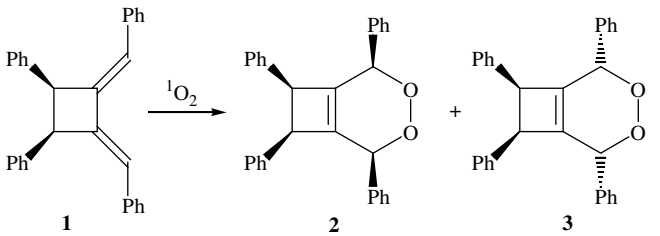
Theoretical Models

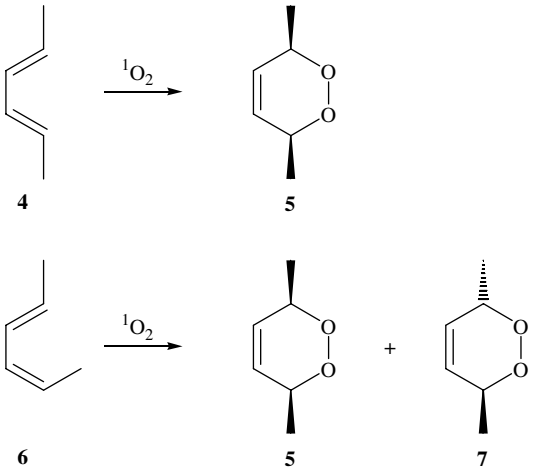
Several possibilities exist for the primary interaction of singlet oxygen with 1,3-dienes. As with monoalkenes, the reversible formation of an exciplex possibly precedes product formation. This exciplex collapses to a perepoxide, a 1,4-biradical, or a 1,4-zwitterion. Alternatively, the formation of the [4 + 2]-cycloadduct may take place in a concerted fashion without the involvement of an intermediate. Should intermediates such as those mentioned above participate, other reaction pathways such as hydrogen transfer to give allylic hydroperoxides (ene reaction) or cycloaddition to give 1,2-dioxetanes ([2 + 2]-cycloaddition) compete. MINDO/3 calculations suggested that a stable perepoxide intermediate for the butadiene/singlet oxygen reaction is feasible.[6] Orbital correlations characterize the [4 + 2]-cycloaddition reaction of singlet oxygen with 1,3-dienes as a stepwise process.[7] The role of charge-transfer (CT) interactions in these reactions and a detailed discussion of the various theoretical aspects are given in the review by Yamaguchi.[8]

Sevin and McKee[9] have computed the reaction of singlet oxygen with 1,3-cyclohexadiene at the B3LYP76–31G(d) and CASPT2(12e,10o) levels. They found a stepwise biradical pathway, in which a biradical is formed in the first step with an activation barrier of 6.5 kcal/mol (experimental value: 5.5 kcal/mol). The second transition structure has a lower energy than the biradical intermediate and for this reason the reaction could also be considered as a nonsynchronous concerted reaction. Bobrowski et al.[10] studied the 1,4-cycloaddition of singlet oxygen with both s-*cis*-1,3-butadiene and benzene by CAS MCSCF/CAS MCQDPT2 *ab initio* methods with a 6–31G* basis set. They propose a biradical intermediate on the lowest energy pathway (MCQDPT2/6–31G(d)) of the reaction of singlet oxygen with s-*cis*-butadiene to the endoperoxide. In the case of benzene, the reaction occurs in a concerted manner with an activation energy of 25.3 kcal/mol.

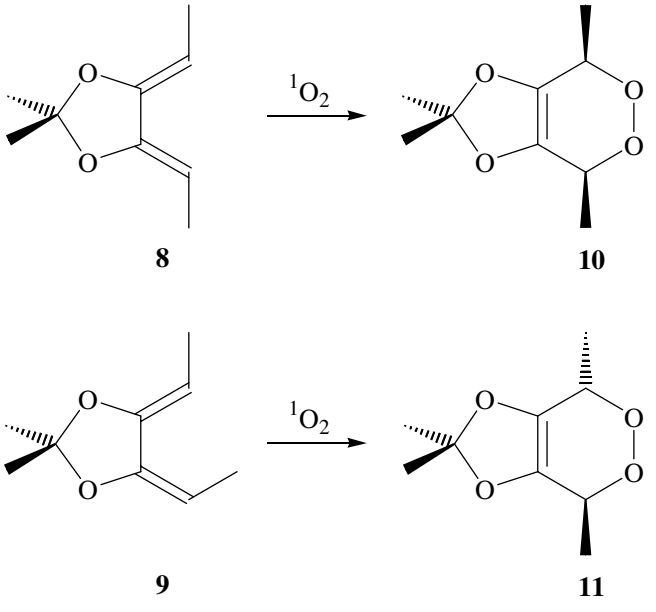
Experimental Results

Rigaudy et al. originally investigated the stereoselectivity of addition of the singlet oxygen to 1,3-dienes[11] with the s-*cis*-1,3-diene **1**. In agreement with the high degree of stereoselectivity observed in this case, Gollnick and Griesbeck[12] have found that *trans,trans*-2,4-hexadiene **4** reacts with singlet oxygen chemo- and stereoselectively to yield the *cis*-disubstituted endoperoxide **5**. The stereoisomeric *cis,trans*-2,4-hexadiene **6**, however, gave a mixture of the *trans*-endoperoxide **7** and its *cis*-isomer **5**. This result was confirmed by NMR studies that clearly showed that singlet oxygen induces *cis-trans* isomerization of the starting 1,3-diene.[13] Such isomerization was also observed for the *cis,cis*-2,4-hexadiene isomer. A time profile of the photooxygenation of the (*E,Z*)-1-aryl-1,3-pentadiene showed that singlet oxygen adds exclusively to the (*E,E*)-isomer that is generated from the (*E,Z*)-isomer by photoinduced isomerization; the rates of both isomerization and photooxygenation increased with increasing electron-donating ability of the aryl ring.[14]





Clennan has investigated two s-*cis*-fixed 1,3-dienes.[15] These compounds, the *trans,trans*- and the *cis,trans*-dioxolanes **8** and **9**, reacted with a high degree of stereoselectivity, besides appreciable amounts of dioxetane formation (*vide supra*). Therefore, it may be deduced that the interaction between singlet oxygen and 1,3-dienes with conformationally flexible 2,3 single bonds leads to intermediary 1,4-biradicals or 1,4-zwitterions. These may undergo retrocleavage to triplet oxygen (physical quenching) with concomitant *cis-trans* isomerization, whereas s-*cis*-fixed 1,3-dienes give endoperoxides highly stereoselectively. From a detailed investigation of the kinetics for a series of Diels–Alder reactions between singlet oxygen and symmetrically and unsymmetrically substituted furans, it was concluded that these reactions proceed concertedly but asynchronously (at least for unsymmetric substrates), with an exciplex involved as the primary reaction intermediate.[16]



The intervention of an exciplex is in agreement with the nearly zero activation energies for the singlet oxygen [4 + 2]-cycloadditions[17] and with the solvent insensitivity of the reaction rates.[18] Paquette and

coworkers have shown that the facial selectivity for the [4 + 2]-reaction with tricyclic cyclopentadiene derivatives is unusual compared to other [4 + 2]-cycloadditions, which indicates that the mechanism may be different from that of most Diels–Alder reactions.[19] De Lucchi and co-workers have shown that the cycloaddition of $^1O_2$ to 3,3′,4,4′-tetrahydro-1,1′-binaphthalene occurs with a preference for antarafacial addition, which is consistent with the intermediacy of a perepoxide.[20]

25.3 Substrates for Diene Photooxygenation

Carbocyclic Substrates

Unsubstituted Compounds

One of the most reactive substrates for endoperoxide formation is 1,3-cyclopentadiene. Rate constants of 1×10^8 (in chloroform)[21] and 3.9×10^7 (in toluene)[17] mol^{-1} sec^{-1} have been determined. The kinetics and the solvent dependence of the singlet oxygen [4 + 2]-cycloaddition with 1,3-cyclohexadiene have been investigated in detail.[18,21] The rate constant decreases about tenfold when the ring size is increased by one methylene unit (Table 25.1).

Except for the endoperoxide from 1,3-cyclopentadiene,[22] the higher homologues are thermally stable compounds, which have been isolated in moderate to good yields under various photooxygenation conditions.[23–25] Cyclic 1,3,5-trienes, which can undergo valence tautomerization, give the respective cycloaddition products (Table 25.2).

From 1,3,5-cycloheptatriene[26] and 1,3,5-cyclooctatriene,[27] the respective bicyclic and tricyclic endoperoxides were obtained in 93:7 and 80:20 ratios, respectively. From cyclooctatetraene, no adduct with the bicyclic valence tautomer was obtained, but 26% of the bicyclic [4 + 2]-adduct was isolated.[28] The valence tautomer of cyclooctatetraene, however, could be prepared independently and afforded the expected tetracyclic endoperoxide with singlet oxygen.[29]

Substituted Compounds

Electron-donating substituents activate the 1,3-cyclodiene towards electrophilic attack by singlet oxygen, which clearly demonstrates that the [4 + 2]-cycloaddition is controlled by HOMO (diene)–LUMO (singlet oxygen) interaction. For 1,3-cyclopentadiene derivatives, alkylation or arylation at positions 1 to 4 did

TABLE 25.2 Photooxygenation of Unsubstituted 1,3,5-cyclotrienes

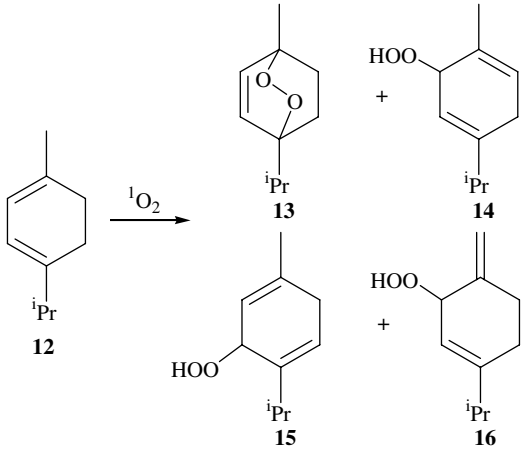
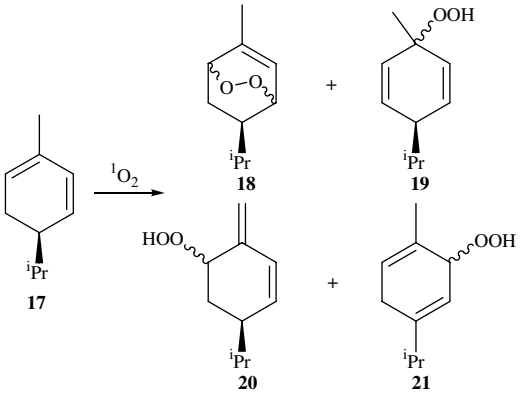
not change the chemoselectivity, i.e., only bicyclic endoperoxides were formed.[30] This was not the case for the higher homologues: even α-terpinene **12**, a classical singlet oxygen acceptor[31] and of similar reactivity as 1,3-cyclopentadiene,[21] led to 90% of the [4 + 2]-cycloadduct ascaridole **13** and about 5% of ene products **14–16** (besides 5% *p*-cumene).[32]



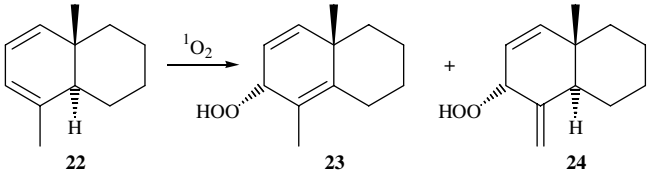
13 /14 /15 /16 = 90 / 2.2 / 2.2 / 0.5

More illustrative was the photooxygenation of the optically active terpene R-(–)-α-phellandrene **17**.[33] In this case, a 3:2 facial selectivity (*cis* predominates) was observed for all products, namely for 65% of the [4 + 2]-cycloadduct **18** and 30% of the ene products **19–21**.[34] The methyl group at position 2 is only marginally involved (ene product **20**) in the reaction but activates the trisubstituted double bond towards the ene reaction (ene product **19**). Alkoxy substituents have been reported to have the same effect.[35]

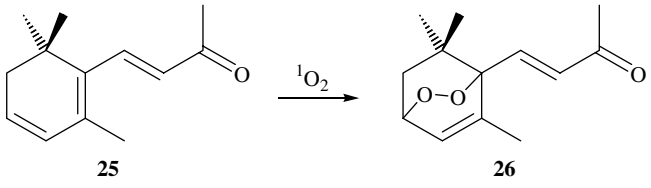


18 /19 / 20 /21 = 65 / 23 / 3.0 / 5.8

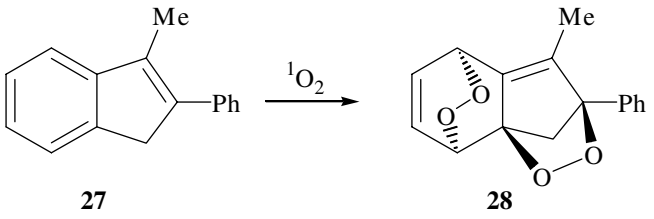
An extreme example is the photooxygenation of a hexahydronaphthalene **22** from which only the ene products **23** and **24** were isolated.[36] The latter case constitutes a combination of steric shielding and substituent activation that leads to high loco- and stereoselectivity. The photooxygenation of chiral 1,2-dihydronaphthalene derivatives with additional allylic hydroxy groups proceeds with moderate chemoselectivity ([4 + 2] versus ene reaction) but a high degree of stereoselectivity, which may be rationalized in terms of attractive interactions between the terminal oxygen of $^1O_2$ and the allylic hydroxy group in an intermediate with perepoxide geometry.[37]



A synthetically useful example for perfect regioselective control was reported for furan photooxygenation in the presence of a tricarbonyliron-protected cyclohexadiene.[38] Numerous examples are known for terpene and steroid substrates with 1,3-cyclohexadiene subunits in which endoperoxides have been isolated in good to excellent yields, e.g., dehydro-ß-ionone **25** gives the endoperoxide **26** in 50% yield by using rose bengal as the sensitizer in methanol.[39]

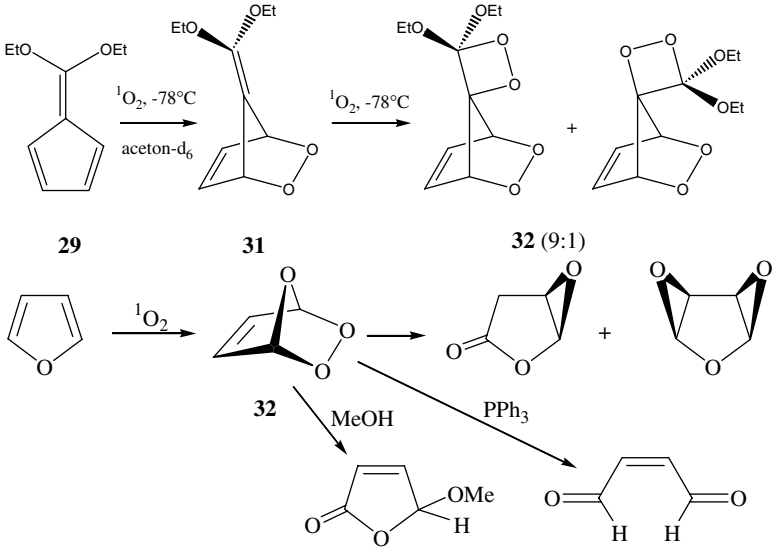


Substituted 1,3,5-cycloheptatrienes and 1,3,5-cyclooctatrienes afford mixtures of bicyclic and tricyclic endoperoxides in ratios that are highly dependent on the electronic nature of the substituent.[27,28,40,41] Indene[42] and 1,2-dihydronaphthalene[43] derivatives were shown to add two equivalents of singlet oxygen to give rise to *bis*-endoperoxides or their corresponding rearrangement products.[44] The photooxygenation of 6-methyl-5-phenylindene **27** in Freon 11/TPP gave the *bis*-endoperoxide **28** in 82% yield.[42]



27 **28**

Photooxygenation of pentafulvenes afforded the corresponding endoperoxides[45] as primary products (which rearrange subsequently to allene oxides). The 6,6-dialkoxy-substituted pentafulvene **29** generates the [4 + 2]-cycloadduct **30** and, after further photooxygenation, the diastereoisomeric oxetanes **31** are prepared by subsequent [2 + 2]-cycloaddition.[46]



Heterocyclic Substrates

The photooxygenation of furans was investigated initially by Schenck in the mid-forties.[47] A crystalline and highly explosive material **32** was isolated from the parent furan by Schenck and Koch.[48] This secondary ozonide rearranges thermally to an epoxybutanolide and a *bis*-epoxide; reduction with triphenylphosphine leads to maleic dialdehyde, methanolysis to a methoxy butenolide.

The rate constants of singlet oxygen reactions have been determined for a series of substituted furans by Koch,[49] Clennan et al.,[16] and Gollnick and Griesbeck.[50] Only a moderate solvent dependence was observed, which implies a concerted (possibly asynchronous) [4 + 2]-cycloaddition. More thermally persistent endoperoxides were obtained from alkyl-substituted furans, e.g., 2,5-dimethylfuran[51] or furans with electron-withdrawing substituents.[52] A few representative examples of furan endoperoxides together with their thermal stability are given in Table 25.3.

TABLE 25.3 Photooxygenation of Furans

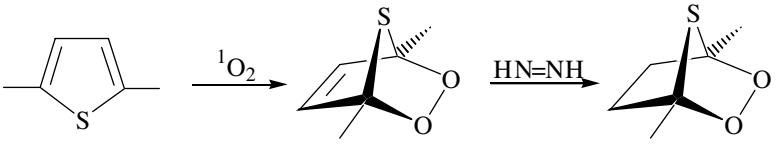
These furan endoperoxides are valuable building blocks for the synthesis of di- and tetrahydrofuran derivatives, e.g., *bis*-epoxides, epoxy lactones, ene diones, *cis*-diacyloxiranes, enol esters, butenolides,[53] and others. Furthermore, the primary [4 + 2]-cycloadducts may rearrange into 1,2-dioxetanes[54] or 1,2-dioxolenes.[55]

Unlike furan, thiophene was found to be unreactive under photooxygenation conditions. The alkylated derivative 2,5-dimethylthiophene **33**, however, is reactive[56] and the structure of the endoperoxide **34** was unambiguously proven by low-temperature NMR studies,[57] as well as by diimide reduction to the saturated thermally persistent endoperoxide **35**.[58]



33 **34** **35**

The heterocyclic 1,3-dienes such as pyrroles,[59] thiazoles,[60] and oxazoles[61] are also reactive and afford endoperoxides on photooxygenation. Most of these ozonide-type cycloadducts have neither been isolated nor detected but have been postulated as plausible reaction intermediates.

Acyclic/Cyclic Substrates

Mode Selectivity

As mentioned in the introduction, two main pathways compete with the singlet oxygen [4 + 2]-cycloaddition, the ene reaction and [2+2]-cycloaddition. The formation of carbonyl products during the photooxygenation of dienes is due to the decomposition of the intermediary dioxetane in many cases. Another route to these fragments is a Hock-type cleavage of the allylic hydroperoxides formed by the ene reaction.[62] Three predominant factors control the mode selectivity in the photooxygenation of substrates that possess one (or more) endocyclic C=C double bond(s) and one conjugated exocyclic C=C double bond: (i) the amount of s-*cis* conformer in the equilibrium necessary for a *concerted* [4 + 2]-cycloaddition, (ii) the relative reactivity difference of the C=C double bonds, e.g., an alkoxy substituent activates an exocyclic double bond strongly for [2 + 2]-addition, and (iii) the appropriate alignment of the allylic hydrogens for the competing ene reaction. Even a small amount of the s-*cis* conformer in the conformational equilibrium may give rise to an appreciable amount of endoperoxide due to the very low activation energy of this reaction mode.

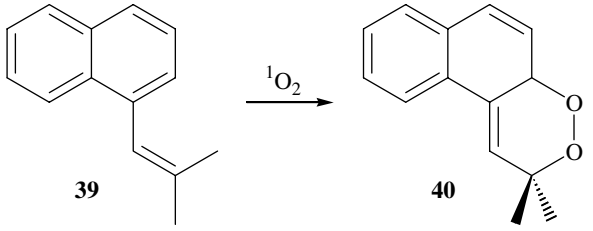
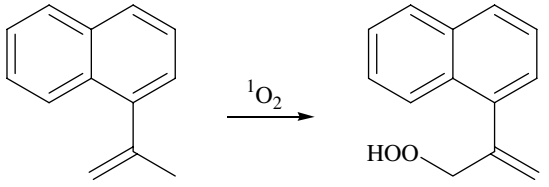
Substituted Compounds

A series of 1-vinylcycloalkenes **36** with ring sizes from 3 to 8 has been investigated.[63] For these substrates, factor (iii) controls the ratio of [4 + 2] versus ene product (**37/38**) (Table 25.4). It may be safely assumed that the s-*cis*/s-*trans* ratio is similar for all starting materials, and the decisive difference comes from the alignment of the allylic hydrogens in the central ring. Analogous to the ene reactions of singlet oxygen with cyclopentene and cyclohexene, the ene path is largely preferred for the five-membered versus the six-membered ring.



39 **40**



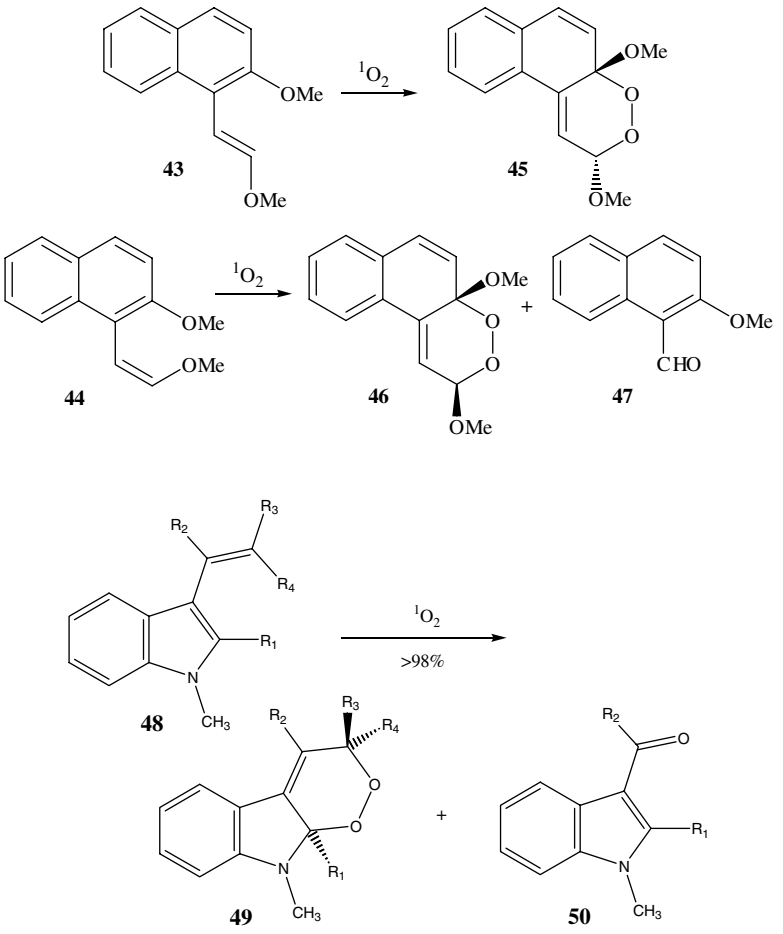
41 **42**

1-Vinylnaphthalenes preferentially undergo [4 + 2]-cycloadditions when alkyl-substituted at the vinylic positions,[64] e.g., the dimethyl substrate **39** gives **40** in 78% yield.[65] In contrast, the geminally dimethyl-substituted substrate **41** is prone to ene reaction because of steric (*peri*) interactions that depopulate the s-*cis* conformer. In this case, controlled by factor (i), the allylic hydroperoxide **42** is formed in 90% yield.[64]

An example in which the relative reactivity of the C=C double bond (factor ii) depends on the population of the s-*cis* conformer (factor i) is the photooxygenation of the *E*- and *Z*-2′-methoxy-1-vinylnaphthalenes **43** and **44**. The *Z*-isomer affords the [4 + 2]- and [2 + 2]-cycloaddition/cleavage products **46** and **47** in nearly equal amounts, whereas the *E*-diastereomer **43** generates, nearly quantitatively,

the endoperoxide **45**.[66] Presumably, the s-*cis* conformer of **44** is present only in small amounts, and even the rapid [4 + 2]-cycloaddition does not compensate for this disadvantageous situation.

For similar substrates, such as substituted styrenes,[67] stilbenes,[68] or 1-vinylthiophenes,[69] in some cases *bis*-endoperoxides have been isolated similar to the indene and dihydronaphthalene cases (*vide infra*). Also, terpene derivatives are a treasure house of polyfunctional substrates for which all types of reaction modes have been observed.[70] Substituted 3-vinylindoles **48** without allylic hydrogens give with $^1O_2$ the endoperoxides **49** by [4 + 2]-cycloaddition unless the s-*cis* conformation is disfavored due to the substituent pattern.[71] Product **50** is formed presumably by [2 + 2]-cycloaddition of singlet oxygen and subsequent 1,2-dioxetane cleavage.



Acyclic Substrates

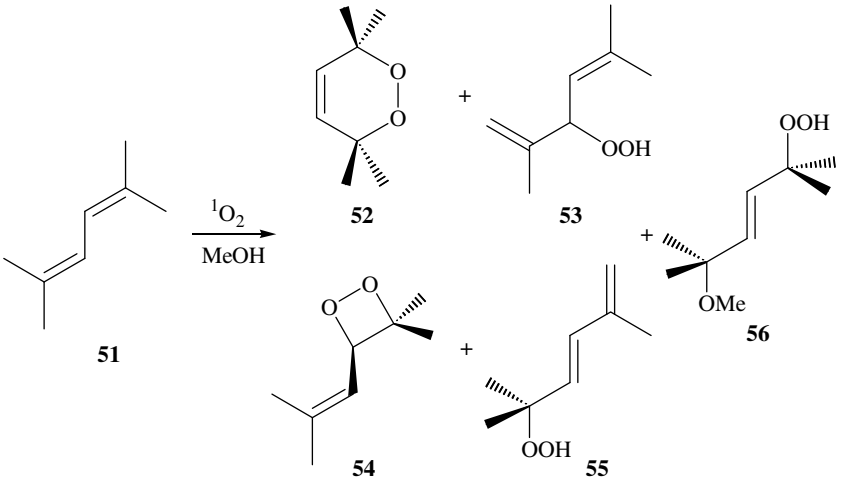
Mode Selectivity and Regioselectivity

According to the guidelines described previously, the mode selectivity and regioselectivity of singlet oxygen reactions with acyclic 1,3-dienes may be controlled and predicted. The parent compound, 1,3-butadiene, leads to the endoperoxide in 20% yield.[72] Electron-donating substituents activate 1,3-butadienes in the reaction with the electrophilic singlet oxygen. As already discussed, alkyl substituents with allylic hydrogens favor ene reactions with singlet oxygen, whereas alkoxy substituents activate the diene for [2 + 2]-cycloadditions. A fact that is often ignored is that in many cases the main reaction pathway is efficient physical quenching of singlet oxygen by the diene.[73]

Another way to control mode selectivity is by solvent polarity. The photooxygenation of 2,4-dimethyl-1,3-pentadiene in different polar and nonpolar solvents gave in all cases the [4 + 2]-cycloaddition product as the major product. In CCl_4, the [4 + 2]-mode selectivity is as high as 97%, but it drops in polar and especially in protic solvents such as methanol to 65%.[74] From the dependence of the [4 + 2]-cycloaddition of substituted naphthalenes on the solvent structure and polarity, exciplex formation was suggested especially in the highly polar solvent dimethylformamide (DMF).[75]

Substituted Compounds

As a model substrate, 2,5-dimethyl-2,4-hexadiene **51** has been intensively investigated by several research groups.[73,76–79] Depending on the solvent polarity, five peroxidic products have been isolated in varying relative yields: the endoperoxide **52** (from [4 + 2]-cycloaddition), the allylic hydroperoxide **53** (from ene reaction), the 1,2-dioxetane **54** (from [2 + 2]-cycloaddition), the diene hydroperoxide **55** (either from a vinylogous ene reaction or a radical-induced rearrangement of **53**),[78] and the methoxy-substituted hydroperoxide **56** (a methanol trapping product) were observed. A maximum of 23% of the [4 + 2]-cycloaddition product **52** was detected in tetrachloromethane, whereas the dioxetane **54** dominated in polar acetonitrile.



For a series of methyl- and phenyl-substituted 1,3-butadienes, the proportion of [4 + 2]-cycloaddition to ene products was shown to be determined by the factors mentioned previously (Table 25.5).[79] The relative amount of [4 + 2]-cycloaddition products may be explained by assessing the number of appropriate allylic hydrogens and the s-*cis*/s-*trans* ratio for the 1,3-diene system.

The terpenes α- and ß-myrcene are classical examples of substrates controlled by factor (ii). In these polyenes the relative reactivity of the nonconjugated C=C double bond (di- versus trisubstituted) controls the first reaction event. ß-Myrcene, a monoterpene triene with a trisubstituted nonconjugated double bond, undergoes preferentially the ene reaction with subsequent [4 + 2]-cycloaddition,[80] whereas α-myrcene **57** solely reacts in a [4 + 2]-mode to give the endoperoxide **58**.[81] Alkoxy-substituted 1,3-dienes, which cannot undergo ene reaction, have been shown to be excellent substrates for [2 + 2]-cycloaddition.[82,83] The 1,4-di-*t*-butoxy-1,3-butadienes were the first substrates that showed nonstereoselective [2 + 2]-cycloaddition reactions. Formation of the endoperoxide **60** was observed only from the *E,Z*-isomer **59**, which indicates a pronounced activation effect by the alkoxy groups for dioxetane formation.

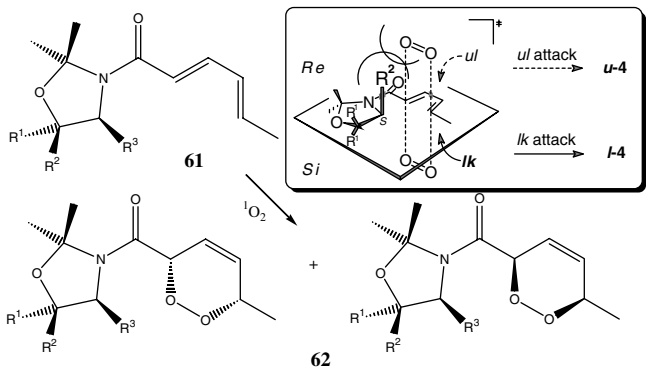
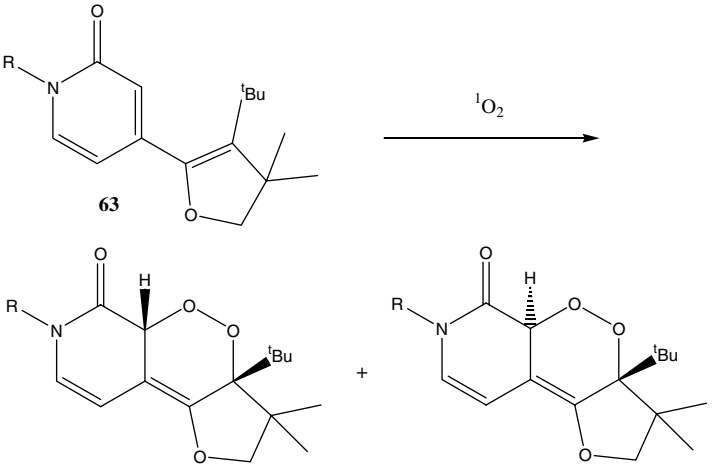
25.4 Diastereoselectivity in the [4 + 2]-Cycloaddition Reaction with Singlet Oxygen

The diastereoselectivity of the [4 + 2]-cycloaddition may be controlled with chiral auxiliaries, by directing the singlet oxygen attack from the less hindered side of the diene (steric control) through conformational effect of the substrate or by using electrostatic interactions between the substrate and the incoming singlet oxygen (electronic control). High facial selectivity (d.r. = 95:5 like versus unlike attack) has been achieved for the reaction of singlet oxygen with a 1,3-diene derived from 2,2-dimethyloxazolidine-substituted amides of sorbic acid **61**; such stereochemical control derives from the steric interactions between singlet oxygen and the shielding substituent in the chiral auxiliary.[84]



61 **62**

In the photooxygenation of chiral dienol ethers, the facial selectivity (maximum d.r. achieved was 74:26) depends both on the conformational preference of the dienol ether and on the ability of the chiral auxiliary to shield one face of the diene substrate. The modest diastereoselectivity that is observed for most cases is due to the lack of conformational control in the substrate.[85] The reaction of the isopropyl-substituted cyclohexadiene with singlet oxygen gave an endoperoxide that is derived from preferential attack on the sterically *more* hindered diastereotopic face of the diene. It was suggested that the less hindered face undergoes ene reaction preferentially rather than [4 + 2]-cycloaddition through a common perepoxide intermediate.[86] A surprising result was described for the photooxygenation of the 1,3-diene **63,** for which *E*/*Z*-isomerization of the enone double bond is not possible: a mixture of the diastereoisomeric 1,4-endoperoxides **64** (expected configuration) and **65** was isolated. This nonselective [4 + 2]-addition reaction was rationalized in terms of a two-step process through a perepoxide intermediate.[87]



Hydrogen-bonding substituents strongly influence the facial selectivity of the singlet oxygen [4 + 2]-cycloaddition, as shown by the hydroxy-directing effect with chiral naphthyl alcohols.[88] For facially unsymmetric dienes, e.g., the hexacyclo-[7.5.1.0.^{1,6}0.^{6,13}0.^{8,12}0.^{10,14}]pentadeca-2,4-diene-7,15-diones, the facial diastereoselectivity of the [4 + 2]-cycloaddition with singlet oxygen may be modulated by modification of protecting groups.[89]

25.5 Applications of the Photooxygenation of 1,3-Diene

Primary Products

The peroxide products obtained in the photocycloaddition of 1,3-dienes with singlet oxygen are of interest either as pharmaceutically active compounds, e.g., the legendary ascaridole **13**, or as model compounds for biochemical studies, e.g., prostaglandin biosynthesis,[90] allocolchicinoids synthesis.[91] These compounds were prepared directly from fatty acid precursors[92] or from 1,3-cyclopentadienes, followed by reduction of the resulting C=C double bond.[93] Other attractive target structures were antitumor-active cyclic peroxy ketals chondrillin and plakorin synthesis.[94] For most preparative purposes, however, the photooxygenation reactions have been designed in such a way that either *in situ* or by subsequent treatment of the initially formed peroxides synthetically valuable products and/or building blocks have been obtained for organic synthesis, e.g., the preparation of hydroxycodeinone from thebaine.[95]

Secondary Products

Endoperoxides (also 1,2-dioxetanes) are versatile starting materials for further transformations. In view of the weak O-O bond, these peroxides are thermally sensitive to homolytic cleavage, a feature that makes most of them **hazardous**. Ring opening opens up attractive opportunities for selective transformations that include reductions (diols), oxidations (dicarbonyl products), rearrangements (hydroxy carbonyl compounds, epoxy carbonyl compounds, *bis*-epoxides, ene diones, etc.) and additions (polycyclic dioxanes[96] or trioxanes,[97] some of which display antimalarial activity). The synthesis and the subsequent reactions of the 2,3-dioxabicyclo[2.2.2]oct-7-en-5-one skeleton have been studied by Adam et al.[98] An impressive number of chemical transformations and examples for applications in organic synthesis have been collected in several reviews.[5c,59,99]

Hula-Twist: A Photochemical Reaction Mechanism Involving Simultaneous Configurational and Conformational Isomerization

Robert S.H. Liu
University of Hawaii

George S. Hammond
University of Hawaii

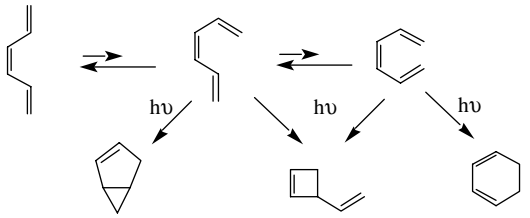
26.1 The Need for New Mechanisms for Photoisomerization

A well-known generalized observation for photochemical reactions of conjugated systems is the absence of conformational changes during photoexcitation. It is known as NEER, or nonequilibration of excited rotamers. Havinga and colleagues formulated the concept through an incisive examination of structural properties of reactants and photoproducts of compounds in the vitamin D series.[1] Later, the same concept was demonstrated with the simpler *cis*-1,3,5-hexatriene as shown below. Only products retaining the original conformation were observed.[2] (It should be pointed out that the same group was aware of the fact that ground state product analysis may not produce unambiguous information related to the excited species.[2,3])

Independently, from product analyses of triplet-sensitized dimerization of dienes, Hammond and Liu recognized the absence of interconversion of conformers in the triplet state. Thereby, the term isomeric triplets was coined.[4]

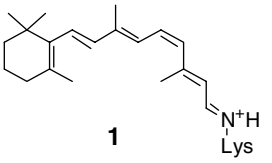
However, the NEER behavior was not without exceptions. As early as 1975, Squillacote et al. showed that butadiene, under argon matrix isolation conditions, undergoes ready s-*trans*,s-*cis* photo-equilibration.[5] Also, for several larger arylethenes where the excitation energy was largely localized in the aryl ring,

0-8493-1348-1/04/$0.00+$1.50



conformational reorganization was detected in the excited singlet state[6] as well as the longer lived triplet state.[7]

Ever since the first picosecond time-resolved spectroscopic study was carried out in 1972,[8] the question how the seemingly volume-demanding 11-*cis* to all-*trans* isomerization of the retinyl chromophore can take place within 6 psec was raised. The question is particularly relevant when one considers that photochemical isomerization is highly sensitive to medium viscosity. Thus, in the typical case of *trans*-stilbene, the quantum yield of isomerization under direct irradiation decreases with an increase of solvent viscosity and with a simultaneous increase in fluorescence efficiency.[9] This trend is attributed to the presence of a viscosity-dependent barrier that impedes the volume-demanding torsional relaxation (or the one-bond-flip, OBF) process. Fluorescence, being relatively insensitive to solvent viscosity, becomes the only observable deactivation process in a frozen medium. Also, it is known that rhodopsin formation is a stereospecific reaction — only one of 16 possible isomers of retinal is known to give the visual pigment.[10] Hence, there must be close interaction between a well-defined protein pocket and the centrally bent 11-*cis* retinyl chromophore (**1**). How, then, can the volume-demanding isomerization process take place within 100 fsec (based on the better time-resolved apparatus that have since become available),[7,11] a time scale clearly too short for protein reorganization?



1

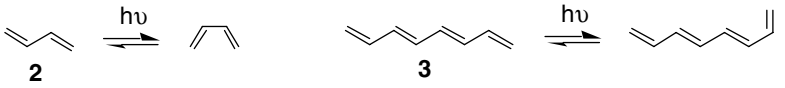
26.2 Volume-Conserving Mechanisms for Photoisomerization

Warshel first postulated the bicycle-pedal (BP) mechanism as a volume-conserving mechanism for photoisomerization.[12] In it, two alternating double bonds rotate concertedly with only the two CH units turning in and out of the plane of the molecule.

However, the stereochemical consequence of one-photon–two-bond isomerization for this model is not in agreement with experimental fact. Subsequently, the model was modified to one that involved small twists at various double and single bonds (none greater than 90°),[13] thus leading to one-bond isomerization only. The revised model appears to us a refined OBF process (i.e., a modified version of the conventional torsional relaxation) rather than a modified BP, as claimed.

In 1985, Liu and Asato proposed the Hula-twist (HT) concept, in which two adjacent double and single bonds are rotated concertedly.[14] The motion involves only one CH unit moving in and out of the plane of the molecule, with the remaining parts of the molecule sliding roughly in the original plane. It is also a volume-conserving process. The stereochemical consequence is simultaneous isomerization of a double bond and an adjacent single bond. In 1998, this concept met direct experimental confirmation when Fuss et al. reported the observation that photoisomerization of pre-vitamin D in an organic glass

at liquid nitrogen temperature takes place with simultaneous double bond and single bond isomerization[15] (for structures, see below). What was evident to us was its disagreement with the NEER phenomena when products with altered conformation were obtained. A quick survey of the literature revealed three more cases of photoreactions in apparent contradiction of NEER: the photochemical interconversion of s-*trans* and s-*cis* conformers of 1,3-butadiene (**2**) in an argon matrix,[4] the photochemical interconversion of all-s-*trans* and 2-s-*cis* 1,3,5,7-octatetraene (**3**) in a *n*-octane matrix at 3.5 K,[16] and the postulated HT process for the primary process of rhodopsin.[14,17,18]



2 **3**

None of these papers referred to each other or to their apparent deviation from NEER. However, since they were the only exceptions to NEER (not counting the large aryl systems mentioned above), we suspected that there must be a shared common feature. After much deliberation, it suddenly dawned on us that these four examples share common reaction conditions in that all four photoisomerization studies were conducted in rigid media. This feature differs from numerous other photoisomerizations that obeyed NEER and were carried out either in fluid solutions or under other unconstrained conditions.[19]

Following this line of thought, we postulated the following generalization for all photoisomerization reactions.[19]

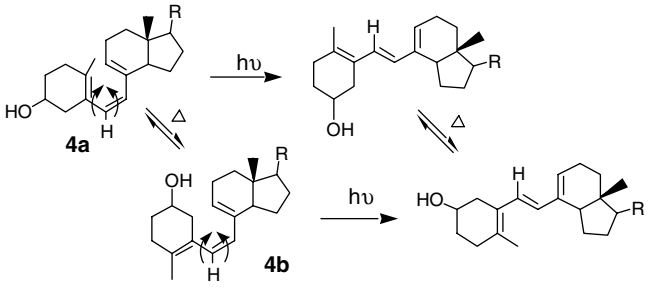
> Under unconstrained conditions (e.g., in fluid solutions or gaseous conditions), the conventional one-bond-flip (OBF) process is the dominant process with the HT being an undetectable higher energy ($\Delta G^{\dagger}$) process. Under confined conditions (whether in a solid matrix or solution or in a protein binding cavity), the additional viscosity-dependent barrier makes OBF a less favorable process, allowing the volume-conserving HT to be the dominant process for photoisomerization.

26.3 Examples of Hula-Twist

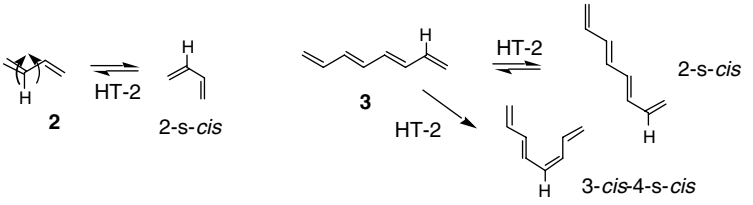
A subsequent survey of literature revealed many previously unexplained photoisomerization examples that can now be explained by this generalization.[20,21] The number of such examples has continued to increase.[22] However, they can be categorized into two groups.

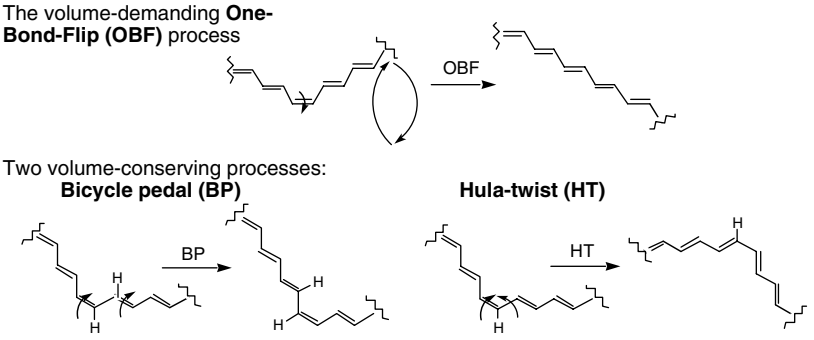
Conjugated Polyenes

Possible photoisomerization of compounds in the vitamin D series in organic glass at liquid nitrogen temperature was first reported by Havinga more than 40 years ago.[23] Stereospecific photoisomerizations of pre-vitamin D (**4a, b**) in an organic glass were demonstrated only recently.[15] The results are consistent with HT at the vinylic centers shown below.

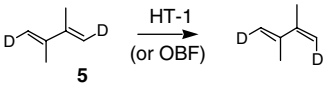


The ready interconversions of s-*trans*,s-*cis* conformers of 1,3-butadiene[5] and 1,3,5,7-octatetraene[16] in argon or *n*-octane matrix are consistent with HT-2. In the case of the octatetraene, the absence of products derived from HT at central carbons must be due to incompatibility of such products with the cavity provided by the host. For example, HT-4 would lead to the highly bent structure (3-*cis*-4-s-*cis*-**3**) shown, one not likely to fit in the linear *n*-octane matrix.



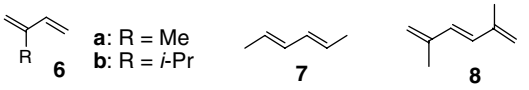


This leaves the interesting possibility of HT-1. Such a reaction is observable only after selective isotope labeling. In fact, a relevant experiment was carried out years ago. Irradiation *of trans,trans*-1,4-dideutero-2,3-dimethylbutadiene (**5**) in an argon matrix was reported not to result in any conformational changes around the central single bond.[24] Rather, the only facile reaction observed was *trans* to *cis* isomerization at the 1 or 4 centers. These results can be readily accounted for by the HT mechanism. Conformational changes at the 2,3-bond would involve HT of a CCH_3 unit, a much more hindered process than flipping a CH unit as in butadiene. Instead, the molecule will likely channel its excitation energy to the HT-1 process where either flipping of the CH or the CD unit leads to the observed products. Alternatively, a diene molecule might be all along undertaking a competing OBF at the terminal carbons by rotating a small methylene unit.[24] Only when HT-2 is hindered and D-labels are introduced can this process reveal itself.



Additionally, conformational equilibrations upon irradiation in argon matrix were reported for 2-methyl-1,3-butadiene (isoprene) **6a** and 2-isopropylbutadiene, **6b**.[25] These results suggest that the size of the 2-substituent is not an important factor in controlling HT while the retention of at least one vinyl hydrogen (at C3) apparently is. However, there appear to be other limitations because conformational equilibration was not observed for *trans,trans*-2,4-hexadiene, **7**.[26] The latter observation suggests that

under these very stringent reaction conditions (low temperature and argon matrix), the sideways movement of the remaining portions of the molecules is also sensitive to steric hindrance. Apparently, methyl groups at the two ends are sufficiently bulky to stop the HT motion. On the other hand, in another matrix isolation study on isomers of 2,5-dimethyl-1,3,5-hexatriene (**8**), two-bond isomerized products were not detected, although IR analysis for this triene system is obviously more complex than for the dienes.[3]



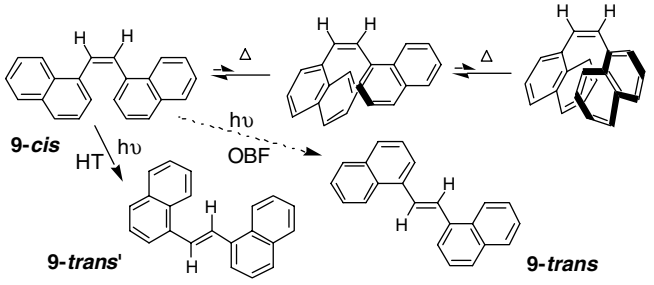
6 **7** **8**

1,2-Diarylalkenes

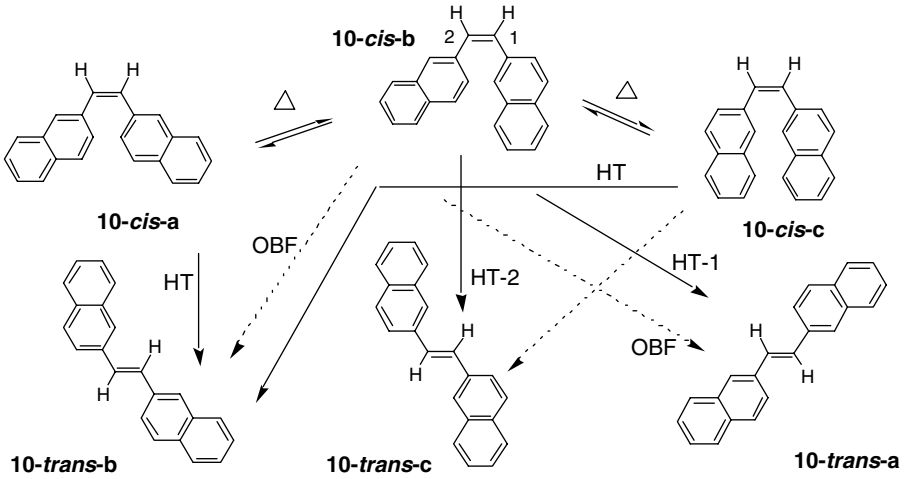
For diarylalkenes, the *trans* to *cis* isomerization is either completely inhibited or becoming very inefficient in low-temperature organic glasses. However, the *cis* to *trans* conversions remain moderately efficient.[27] (Photocyclization products are usually not observed in low temperature glasses.) However, in general the product *trans* isomers are formed as high-energy conformers. While no explanation was offered for formation of the unstable conformers, the method is widely recognized as a photochemical procedure for preparation of high-energy conformers of the *trans* isomer.[28]

These observations are now understandable within the context of the HT mechanism.[19–21] Two examples are illustrated below.

cis-1,2-α,α′-Binaphthylethene (**9**) should be conformationally homogeneous when cooled to liquid nitrogen temperature, existing in the least congested conformation shown. Photoisomerizations by way of HT and OBF are expected to lead to different conformers of the *trans* isomer as shown below. Of the two, only HT gives the less stable conformer that is in agreement with the low temperature photochemical results.[27] Therefore, one might muse at the conclusion that HT was, in fact, first detected in 1983,[27a] two years before postulation of the concept.[14]

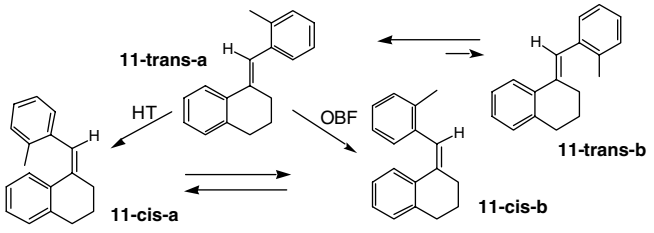


When conformational homogeneity is not ensured in a *cis*-diarylethene, the photoisomerization pathways could be rather complex. For example, for 1,2-β,β′-dinaphthylethene (**10**), the *cis* isomer should exist in three possible conformations (*cis*-**10a**, *cis*-**10b**, *cis*-**10c**), as shown below. HT of these conformers should lead to three conformers of the *trans* products (*trans*-**10a**, -**10b**, and -**10c**) (solid lines) with comparable internal steric strain. The same conformer products are also expected from OBF processes (dashed line), albeit not from the same starting conformers as in HT processes. While it is clear that the product ratio is dependent on a number of factors, this ambiguity renders such systems uninformative for elucidation of the exact nature of their photoisomerization pathways. On the other hand, it should be clear that photoisomerization, e.g., by HT, is not likely to produce the same equilibrated mixture of conformers of the *trans* isomer as in the equilibrated mixture, i.e., obtained from irradiation at room temperature. Thus, the claim of possible preparation of a nonequilibrated *trans* isomer in organic glass is also consistent with, but not a proof for, involvement of HT.



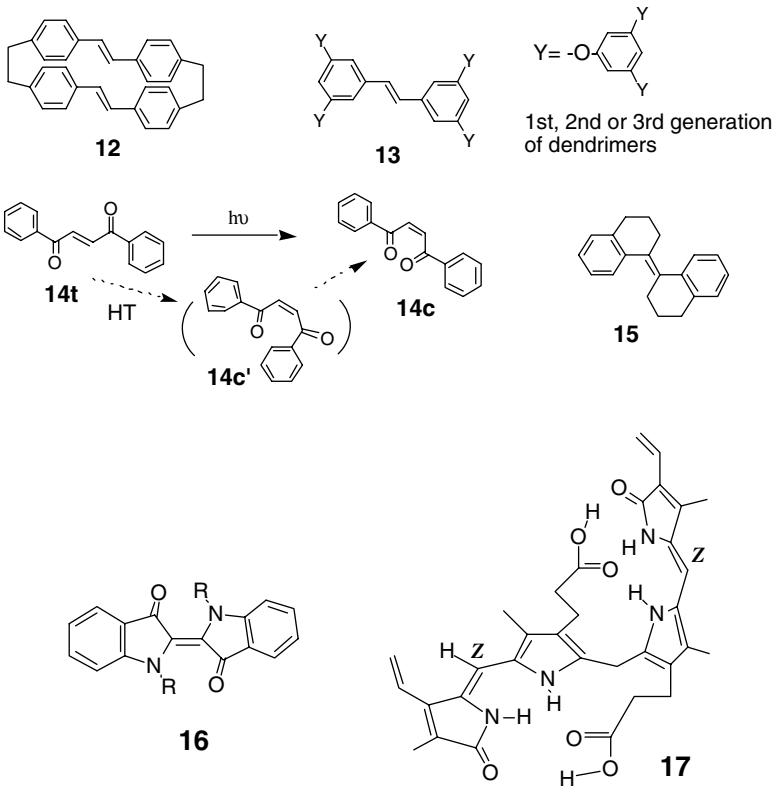
Other *cis*-diarylethene systems reported to give nonequilibrated *trans* products at low temperature in organic glasses[28] were: 1-naphthyl-2-phenylethenes,[27] 1-α-naphthyl-2-β-naphthylethene and 1-β-naphthyl-3-phenanthrylethene.[27b] But, none of these *cis* reactants is likely to be conformationally homogeneous.

With the new mechanistic insight on photoisomerization under confined conditions, we can now rationally design new systems for differentiation of HT from OBF. Several examples have been outlined in the literature.[19,20] Preliminary photochemical results have already been obtained for the stilbene analog **11**.[29] The additional fused 6-ring not only reduces the number of possible conformers, but also introduces sufficient steric strain making the *E* to *Z* isomerization also a facile process detectable at liquid nitrogen temperature. In an organic glass, photoirradiation led to an unstable product that differed from the *cis* (*Z*) product obtained from irradiation in solution at room temperature, but they become identical after the glass solution was warmed to room temperature. These observations are in agreement with the postulated dual mechanisms for photoisomerization. Interestingly, while the *Z* to *E* isomerization was also readily detected, the *Z* isomer apparently was not conformationally homogeneous even at low temperatures. Hence its photochemistry is more complex.



In other more complex diaryl systems, including the stilbene paracyclophane (**12**)[30] and stilbene dendrimers (**13**),[3] OBF is structurally impossible, yet efficient *trans* to *cis* photoisomerizations have been reported. The presence of vinylic hydrogens should allow the volume-conserving HT process to proceed, thereby initiating the *trans* to *cis* conversion. For dibenzoylethene (**14**), the *trans* to *cis* isomerization could be carried out with the *trans* crystals only.[32] An analysis of the shape of the crystal cavity of the starting *trans* isomer revealed that its dimensions are not sufficiently large for a OBF process, but an HT process is possible. The crystals of the *cis* isomer do not have a cavity sufficiently large for either the HT or the OBF process. Therefore, the relative photochemical reactivities of *cis* and *trans* isomers are different from those in frozen glass.

It is also interesting to recall that the ring-fused stilbene analog **15** behaves differently photochemically (obeying the Kramer equation throughout a wide range of solvent viscosity)[33] than *trans*-stilbene does (not obeying the Kramer equation at medium or high solvent viscosity).[34] This contrast is reminiscent of the difference between the indigo dye **16** (no photoisomerization)[35] and bilirubin **17** (efficient photoisomerization).[36] While both have constraints from internal hydrogen bonding, HT has been invoked for the latter, which contains key vinylic hydrogens[20,21] that are absent in **15** and **16**. The question is whether viscosity is a sufficient constraint to produce similar trends in stilbene and its ring-fused analog.



26.4 Theoretical Models Related to HT

A little-noticed theoretical paper interpreting the photochemistry of diazines recognized the concerted nature of the isomerization process.[37] However, somewhat bafflingly, it described the motion as a three-bond concerted twist process in the form of a "crank-shaft" motion. These inexact descriptions appeared to have distracted from what is distinctly an HT-like process as shown in an accompanying figure in the paper.

Interpreting photoisomerization of the visual chromophore, Seltzer[38] calculated the energy requirement of the isomerization process of the free retinyl chromophore by way of conventional torsional relaxation and the BP and the HT processes. BP was judged as an untenable, activated process while both the OBF and HT processes were considered energetically feasible.

The first direct connection of conical intersection (CI) calculations with HT was that of Fuss et al.[39] They pointed out that the geometry of the molecule at the CI in the minimum energy pathway of deactivation of an excited conjugated polyene corresponds to that from HT. Even though CI calculations are limited to isolated molecules, in a recent paper,[40] Fuss and co-workers argued that HT is general for all isomerization reactions including cases where one-bond isomerization is observed.

Recently, Wilsey and Houk[41] introduced a new detailed molecular reorganization process that more specifically describes the HT process and successfully accounts for formation of the observed products. It involves pyramidalization of a carbon and its bridging of the attached vinylic hydrogen with the adjacent carbon (in analogy with the minimized structure of excited ethene) for the CI structures of excited butadiene. They argued that pyramidal inversion of such a CI structure leads to the stereochemical consequence of HT.

25.5 A Word of Caution in Applying the HT Concept

The arguments presented above are applicable primarily to amorphous solids, where no or few specific interactions exist between the trapped molecule and the host system. If specific interactions are present, the energy required to break such interactions, rather than searching for empty space available for reaction, could become the controlling factor in determining directions of photoreactions. The situation is particularly acute when one considers a protein-bound substrate. It is usually anchored to the protein host at both ends. The motion associated with the isomerization reaction would have to be executed without moving (to any significant extent) the anchors within the short S_1 lifetime of the chromophore. Sometimes the movement is facilitated by the presence of a "rubber-band" (usually a saturated side chain of, e.g., a lysine residue to allow ready conformational reorganization) between the chromophore and the anchor(s).[42] The situation was first discussed in relation to the photochemistry of rhodopsin and recently elaborated in a discussion of the photoisomerization processes of photoactive yellow protein (PYP).[43]

Also, while conceptually it is easier to visualize HT as a higher energy process than OBF, we hasten to add that under confined conditions, the rate of HT does not necessarily have to be slowed. There could instead be specific medium assistance that might result in rate acceleration (e.g., through a favorable entropy factor). In this regard it is particularly relevant to point out that the 11-*cis*-retinyl chromophore when protein bound (i.e., in rhodopsin) isomerizes nearly 10 times faster[44] than the same free chromophore in solution.[45] Furthermore, the resonance Raman work of Mathies and Lugtenburg showed that the excess vibrational energy during relaxation of the Franck-Condon species produced immediately after light absorption of the 11-*cis* retinyl chromophore is largely localized in the hydrogen-out-of-plane (HOOP) vibrational mode of H_{12} of the first stable photoproduct, bathorhodopsin.[46] This appears to be a smoking gun for protein directed HT-12 for photoisomerization of rhodopsin as well as a mechanism for rate acceleration assisted by the surrounding protein residues. Whether the protein structure allows completion of the HT process, frequently involving substantial relocation of atoms associated with the expected change of the overall shape of the chromophore, remains a subject of further studies.[22]

We might also point out that our earlier thoughts on photochemical reactivity and radiationless transitions,[47] with the energy gap between the excited species and the corresponding ground state structure as a dominant factor, is not likely to be applicable to predicting HT reactivity. We suspect that the latter is controlled by kinetic factors such as entropy probability during relaxation of the Franck-Condon species. The latter topic will be dealt with in detail in a separate, future publication.[48]

25.6 Concluding Remarks

Hula-twist was postulated in 1985 to account for the unique photochemistry of the retinyl chromophore in retinal binding proteins.[14] In hindsight, it was probably too ambitious an attempt to tackle first the protein bound systems where direct experimental proof is difficult to obtain. The 1998 paper by Fuss and coworkers not only established unequivocally the first case of simultaneous configurational and conformational photoisomerization but also redirected our attention to molecules trapped in amorphous solids. The refocused thought process allowed the postulation of a simple generalization that led to rational design of new test systems. There is now a resurgence of interest and effort in examining scope and limitation of the hula-twist process, as indicated by the many publications that have appeared

recently.[22,26,31,32,40,41,43] Our recent activity in this area has also triggered our thoughts on factors controlling efficiency of diabatic processes such as HT.[48] But it is clear that the HT concept is still at a nascent stage awaiting new information from reliable experimental data and exact theoretical models. Nevertheless, we are hopeful that a more thorough understanding of the intricate details and scope and limitation of the process can be achieved in the near future.

27.1 Definition and Scope

Photochemistry in the vitamin D field has played a central role in the development of molecular photochemistry. Especially noteworthy have been the early contributions of Havinga[1] and Dauben[2] and their co-workers. Havinga introduced his principle of the nonequilibration of excited rotamers (NEER) to explain the excitation wavelength dependence of the photoproducts of the trienes previtamin D and tachysterol (Scheme 1).[3] The NEER principle is based on the idea, inspired by Hückel molecular orbital (MO) theory, that excitation of conjugated polyenes and related molecules to their lowest singlet or triplet excited states tends to reverse double/single bond character, preventing equilibration of ground state conformers. Thus, the ground state conformer equilibrium compositions, the individual spectra and excited state energies of the conformers, and the conformer-specific photochemical properties of the conformers control observed product quantum yields and distributions. The dependence of acyclic 1,3-diene photodimer distributions[4] and trans/cis photostationary states[5,6] on the triplet excitation energy of the sensitizer demonstrated by Hammond, Saltiel, and co-workers, soon thereafter, provided dramatic confirmation of this principle (Figure 27.1 and Schemes 2 and 3). Ground state conformer controlled photochemical ring opening of a substituted 1,3-cyclohexadiene to isomeric conjugated trienes was first reported in the case of α-phellandrene (Scheme 4).[7]

Demonstrations of photophysical manifestations of NEER include the resolution of the fluorescence of all-*trans*-1,6-diphenyl-1,3,5-hexatriene into s-*trans*,s-*trans* and s-*cis*,s-*trans* contributions[8] and analogous resolutions of fluorescence and absorption spectra of styrylarene conformers.[9,10] The conformer-specific adiabatic *cis*→*trans* photoisomerizations of 2-styrylnaphthalene[11] (*cis*- and *trans*-NPE) and 2-styrylanthracene[12] are especially striking examples. In each case, the more extended s-*trans*-like conformer undergoes adiabatic *cis*→*trans* photoisomerization whereas the less extended s-*cis*-like conformer undergoes selective photocyclization (Scheme 5).[13,14] In this sense, these *cis*-diarylethenes can be regarded as true previtamin D mimics.

Adherence to the NEER principle is expected in molecules with relatively short-lived excited states in which the electronic excitation is delocalized extensively over the conjugated π-system. In such molecules, torsional barriers about essential ground state single bonds are enhanced in the lowest excited states. Conversely, molecules that have long excited state lifetimes and in which there is pronounced localization of electronic excitation in parts of the π-system are likely to violate the NEER principle. Alkenyl-substituted anthracenes provide well-documented examples.[9,15–17]

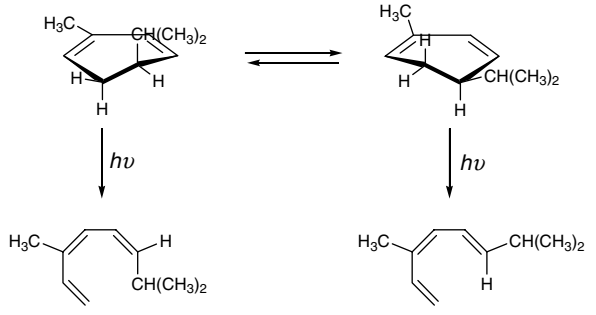
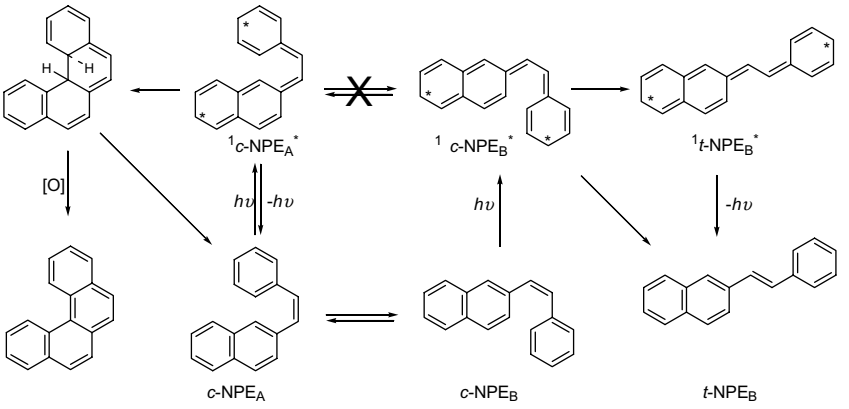


SCHEME 4 Conformer specific ring opening of α-phellandrene.

In recent years, it has been suggested that not all the excitation wavelength dependence of quantum yields in the vitamin D field can be accounted for by the NEER principle. We consider below the competing mechanisms that have been proposed to account for photochemical observations and describe some of the strategies that have been employed to improve the photochemical production of the previtamins from the provitamins. Optimization of the previtamin yields improves vitamin yields as the latter are formed thermally from the previtamins via 1,7-suprafacial hydrogen shifts.[18] Readers interested in the rich photochemistry leading to overirradiation products should consult previous reviews.[1a,2b]

27.2 Mechanism

Paradoxically, it was the dependence of product distributions and quantum yields in the interconversion of vitamin D precursors on the excitation wavelength that led Havinga to the postulation of the NEER principle and it was, subsequently, systematic confirmation of such dependence that led Dauben, Kohler, and co-workers and, more recently, Fuß and co-workers to propose alternative explanations.



SCHEME 5 Conformer specific photochemistry of *c*-NPE.

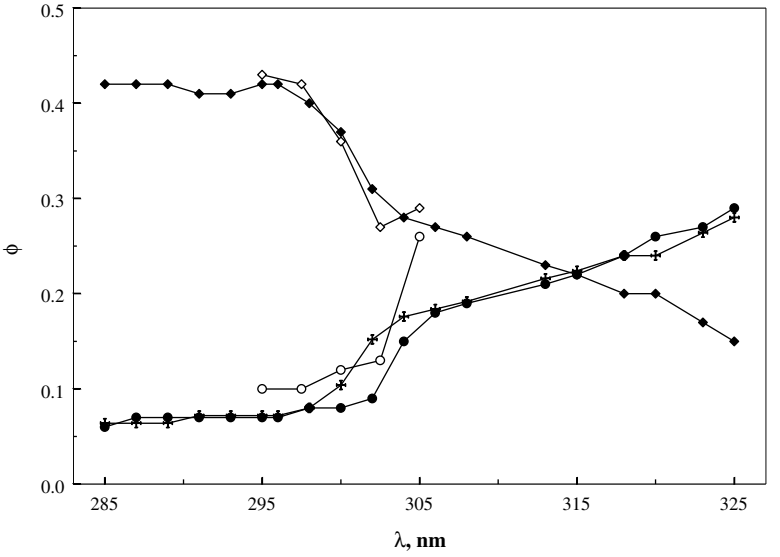


FIGURE 27.2 Excitation wavelength dependence of photocyclization (o,[19b] •[20]) and photoisomerization (◊,[19b] ♦[20]) quantum yields starting from previtamin D_2 in ether at 0°C; crosses designate calculated photocyclization quantum yields based on the NEER principle, see text.

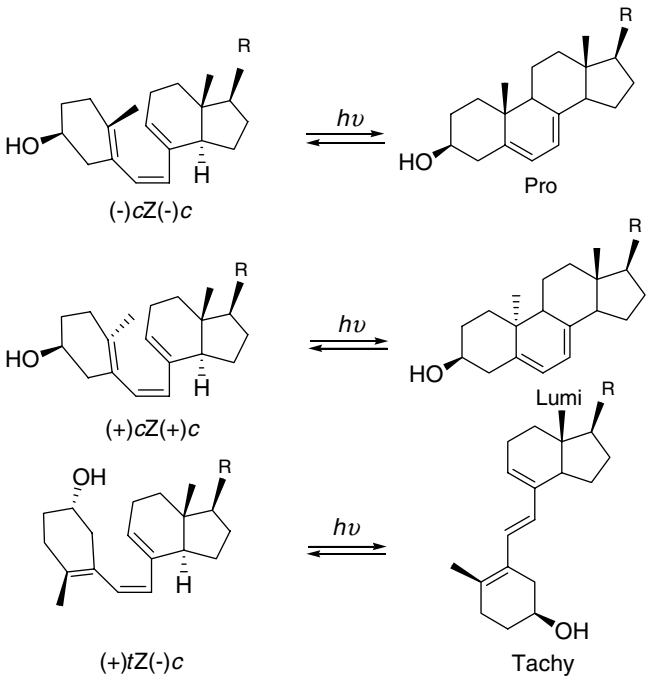
The experimental data that have been presumed to be incompatible with the NEER principle derive from studies by Dauben and co-workers of the λ_{exc} dependencies of *cis-trans*-photoisomerization (to tachysterol, ϕ_T) and photocyclization quantum yields (to provitamin D_3 and lumisterol, ϕ_{PRO} and ϕ_{LUMI}, respectively) starting from pure previtamin D_3.[19,20] Quantum yields were measured in reference 20 (de-aerated anhydrous diethyl ether, 0°C). In reference 19 relative quantum yields were estimated from quasi-photostationary states and molar absorptivities and were converted to absolute quantum yields on the basis of Havinga's measurements at 254 and 302.5 nm.[21] Photocyclization quantum yields ($\phi_{PRO} + \phi_{LUMI}$) increase and photoisomerization quantum yields (ϕ_T) decrease as λ_{exc} is increased (Figure 27.2). A study of the effect of λ_{exc} in the 225–400 nm range on the formation of "potential vitamin D_2" found that 295-nm light is most effective,[22] in good agreement with the earlier findings of Havinga and co-workers[23] and a more recent study by Braun et al.[24] The "sudden" increase in the photocyclization quantum yields and decrease in the photoisomerization quantum yields in the narrow 302–305 nm λ_{exc} range (ϕ_{PRO} = 0.02, 0.04, ϕ_{LUMI}



SCHEME 6 Conformer specific photochemistry of Pre in solution.

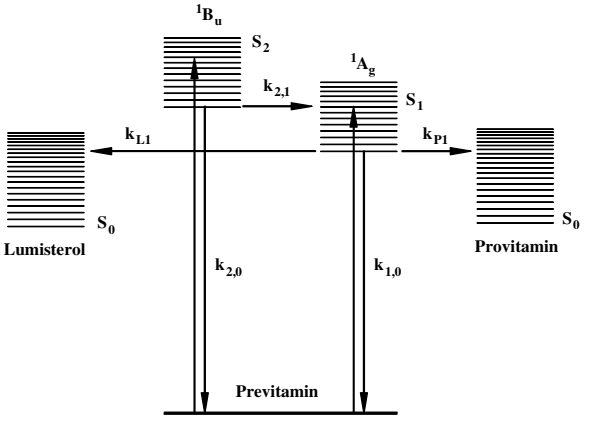


FIGURE 27.3 The Dauben-Kohler 1B/2A mechanism for *cZc*-previtamin D photochemistry (reproduced from Reference 19b with permission from the copyright owner, the American Chemical Society).[20]

= 0.07, 0.13, and ϕ_T = 0.31, 0.27 for 302 and 306 nm, respectively[20]) was judged to be inconsistent with changes in the absorption spectra of the previtamin conformers, potential specific precursors of the three photoproducts (Scheme 6).[19,20] It was suggested that $\lambda_{exc} \leq 302$ nm populates the lowest allowed 1B (S_2) excited state of the previtamin whose major reaction channel, photoisomerization, competes with internal conversion to 2A, the lowest (doubly) excited singlet state (S_1). Excitation at longer wavelengths, $\lambda_{exc} \geq$ 304 nm, directly populates S_1 whose major reaction channel, photocyclization, competes with radiationless decay to S_0 (Figure 27.3).[19,20] This interpretation was bolstered by low temperature (77 K) fluorescence measurements assigned to the $S_1 \rightarrow S_0$ transition in the previtamin that appeared to gain dramatically in intensity for $\lambda_{exc} > 300$ nm.[20] The latter result suggests poor communication between S_2 and S_1 excited

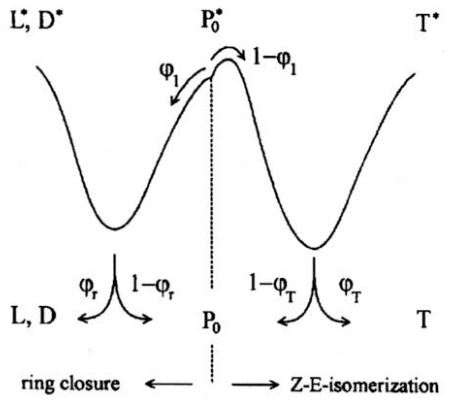

FIGURE 27.4 The Fuß hot excited state mechanism for *cZc*-previtamin D photochemistry in S_1 (2A) (reprinted from Reference 27, with permission from the copyright owner, Elsevier Science, Oxford, UK).

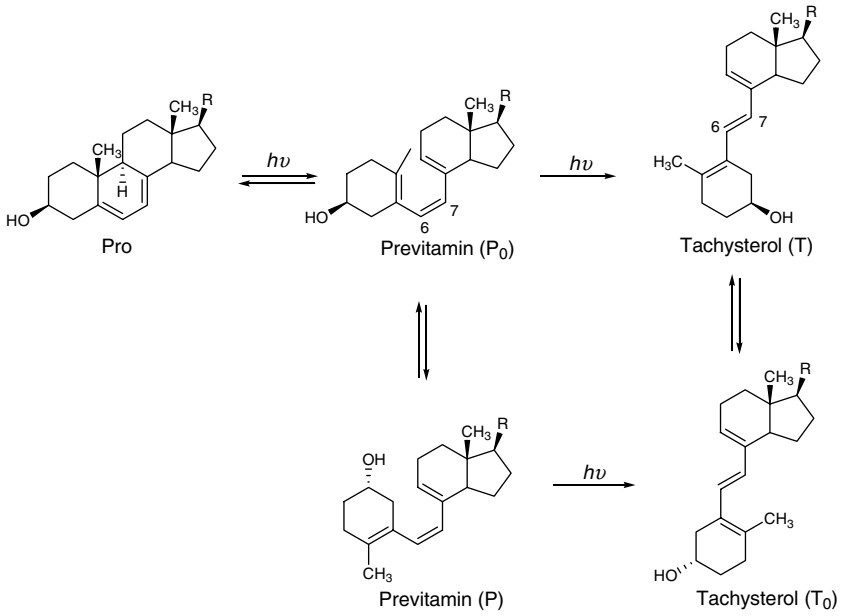
states in contrast to the very rapid $S_2 \rightarrow S_1$ in all-*trans*-1,6-diphenyl-1,3,5-hexatriene.[25,26] However, the relevance of the low temperature spectroscopic observations in a rigid medium to the interpretation of the high temperature photochemical observations in solution is questionable because different conformer equilibrium distributions are likely to be involved (see below).

Fuß and Lochbrunner have advanced an alternative interpretation of the λ_{exc} dependence of the quantum yields in Figure 27.2.[27] They retain Havinga's ground state conformer control at $\lambda_{exc} \leq 302$ nm but propose that the jumps in the quantum yields over the narrow wavelength range that follow are due to competing barrierless photocyclization and activated photoisomerization pathways in *cZc*-previtamin. Because of the short excited state lifetime, photoisomerization competes with vibrational relaxation, such that excitation over the torsional barrier favors cis→trans photoisomerization as a hot excited state reaction (Figure 27.4). Common features of the mechanisms in Figures 27.3 and 27.4 are that they attribute the sharp change in the quantum yields to the behavior of the excited states of a single conformer. Enhanced cis→trans photoisomerization efficiency with wavelengths shorter than 302 nm is assigned to the 1B state of the *cZc* (s-cis at C_5C_6, cis at C_6C_7, and s-cis at C_7C_8) conformer in the Dauben/Kohler mechanism and to a vibrationally hot S_1 (presumably 2A) state in the Fuß mechanism. Fuß argues in favor of his mechanism because it accounts for the monotonic increase in the overall cyclization quantum yield at the longer wavelengths that populate only S_1, whereas a constant quantum yield is predicted by the Dauben/Kohler mechanism.[27] However, the argument is not compelling because neither mechanism takes into account the fact that provitamin (Pro) and lumisterol (Lumi) have different (at least in a helical sense) *cZc*-previtamin (*cZc*-Pre) precursors. Thus, consideration of observed and expected changes in the spectra of the conformers of the previtamin indicates that the NEER principle still provides a viable explanation for the quantum yield variation in Figure 27.2,[28c] accounting also for the change in the ϕ_{LUMI}/ϕ_{PRO} ratio.[29]

Then, what is the relationship between photoisomerization and photocyclization quantum yields that would be predicted if the NEER principle were strictly adhered to throughout the λ_{exc} range? In view of the structural requirements of the two reactions, we assume that only cZc conformers undergo photocyclization and that the rest undergo only photoisomerization. For simplicity, we also assume that the cis→trans photoisomerization quantum yields of the cZc conformers are relatively small and can be neglected (this is not an essential assumption). Adopting the notation proposed by Fuß and Lochbrunner,[27] the previtamin conformers are divided into a set P that photoisomerizes and a set P_0 that photocyclizes. Since the sum $\phi_T + \phi_{PRO} + \phi_{LUMI}$ starts at 0.48 at the shorter wavelengths where ϕ_T dominates and decreases to 0.44 at the longer wavelengths where ϕ_{PRO} and ϕ_{LUMI} dominate (these are minimum values since back reaction corrections were not applied),[20] it is reasonable to assume maximum quantum yields of 0.50 and 0.40 for the photoisomerization of the P conformer set and the photocyclization of the P_0 conformer set,



SCHEME 7 Proposed conformer specific Hula-Twist photoisomerization of Pre in a rigid medium.

respectively, independent of λ_{exc}. It follows that the fraction of absorbed light that excites P conformers is $f_P = \phi_T/0.50$, and the remainder, $f_{P0} = (1 - f_P)$, is the fraction that excites P_0 conformers. This allows calculation of the sum of cyclization quantum yields from the photoisomerization quantum yields: $(\phi_{PRO} + \phi_{LUMI}) = 0.40(1 - f_P)$. Cyclization quantum yields obtained in this way, Figure 27.2, are in excellent agreement with observed values at short and long wavelengths. The quantum yield "jump" is reproduced satisfactorily but is predicted to occur at shorter wavelengths by about 2 nm, in better agreement with results from the earlier study.[19] Application of this procedure separately on the experimental ϕ_{PRO} and ϕ_{LUMI} values can be used to divide f_{P0} into excitation fractions of cZc conformers that differ in helicity. In view of the large number of potentially accessible conformers and the low absorbance of the system above 300 nm (see below), a 2 nm lag between the fall in ϕ_T and the rise in $(\phi_{PRO} + \phi_{LUMI})$ could be caused by the drop of tZc conformer absorption initially coinciding with competing absorption by conformers that have low photoisomerization and photocyclization efficiencies. Clearly, the NEER principle accounts for the data over the entire wavelength range and predicts that absorption by the P_0 conformer set is shifted to the red of the absorption of the P conformer set, becoming important at the onset of the previtamin D spectrum (see below)

27.3 Conformer Spectra Energies and Populations

Experimental verifications of the conformational dependence of the UV absorption spectra of the triene moieties in tachysterol ($Tachy_3$) and previtamin D_3 (Pre_3) were obtained by excitation of Pre_3 at 92 K in a rigid EPA-type glass[28] (5/5/1 solution of ether/isopentane/ethyl alcohol) and of Pro_3 in EPA[27,30] (5/5/2 solution of ether/isopentane/ethyl alcohol), respectively. The current interpretation of these results, advanced by Fuß and co-workers, is shown in Scheme 7.[30] Irradiation of Pre_3 gives a red-shifted relatively structureless spectrum assigned to the *cEc* conformer of tachysterol because on warming the mixture to 100–105 K in the dark, the spectrum slowly shifts to the blue and develops the well defined vibronic progression of the equilibrium conformer mixture of tachysterol (mainly the *tEc* conformer), as shown in Figure 27.5.[28] On the basis of these observations, Havinga and co-workers proposed that *cEc*-Tachy forms from excited *cZc*-Pre.[28a,b] Fuß questioned this proposal because irradiation of the provitamin under

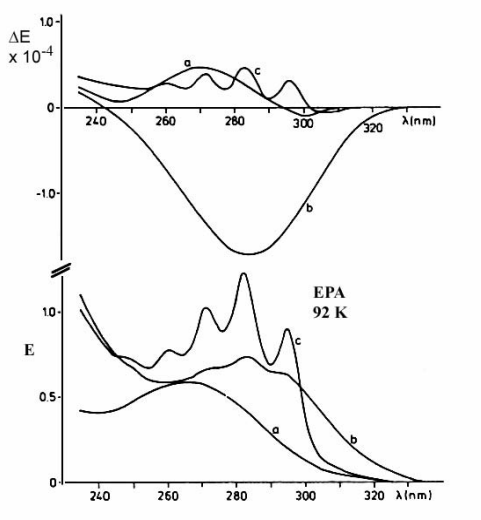


FIGURE 27.5 UV and CD spectra before (curves a) and after (curves b) irradiation of previtamin D_3 in EPA at 92 K. Curves c are for the irradiated sample after it was warmed to 105 K and re-cooled to 92 K (reproduced from Reference 28a with permission from the copyright owner, Wiley WCH Verlag GmbH, Weinheim, Germany).

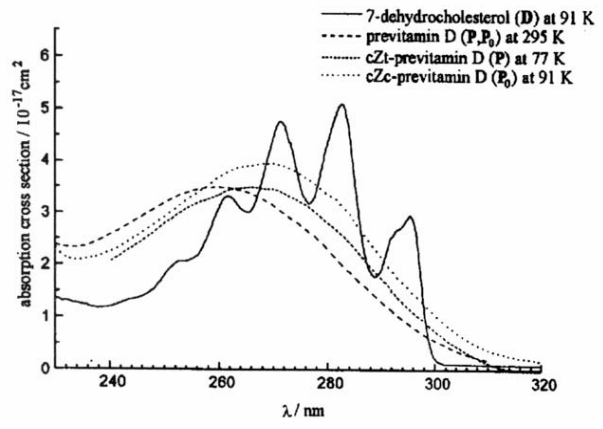

FIGURE 27.6 UV spectra of provitamin D_3 at 91 K, previtamin D_3 at 77 K (designated as conformer set P), previtamin D_3 formed *in situ* from provitamin D_3 at 91 K (designated as conformer set P_0), and previtamin D_3 at 295 K (designated as equilibrium P_0/P conformer mixture (reprinted from Reference 27, with permission from the copyright owner, Elsevier Science, Oxford, UK).

nearly identical conditions gives a red-shifted previtamin spectrum, presumed to be the cZc conformer, which, on further irradiation, gives the structured *tEc*-Tachy spectrum.[30]

The low temperature spectra of Pre[20] and of Pre formed photochemically from Pro are shown in Figure 27.6.[27] It was reasoned that the rigid medium prevents the nascent Pre from relaxing to an equilibrium conformer distribution and ensures that its initial geometry is retained, hence accounting for the red shift in the spectrum. Assignment of the red-shifted spectrum to the cZc conformer of Pre follows from least motion considerations in the highly viscous medium.[27,30] The conformer-specific photoisomerization outcomes in Scheme 7 are based on these spectroscopic structural assignments. No experimental mixture spectra have been published, and no clear description of the method used to derive

the pure component spectrum of the matrix-trapped *cZc*-Pre conformer, Figure 27.6, was provided. In accepting such assignments, it is important to establish that the initially observed transient arises from a one-photon process and that overirradiation was avoided. These precautions are essential because the sequence of light-induced s-trans to s-cis conformer equilibration followed by photochemical ring-closure of the s-cis conformer to the cyclobutene has been reported for Ar-matrix isolated 2,3-dimethyl-1,3-butadiene at 19.5 K.[31] Conformer interconversion under these conditions was first reported for 1,3-butadiene,[32] and Kohler et al. have shown that excitation of all-s-trans *trans,trans*-1,3,5,7-octatetraene in an *n*-octane matrix at 4.2 K leads to s-trans to s-cis conformer conversion[33] and that prolonged irradiation leads to formation of *cis,trans*-1,3,5,7-octatetraene even at this low temperature.[34]

If the assignments in Scheme 7 are correct, formation of the Tachy products involves rotations at adjacent double and single bonds, providing the first experimental verification of an outcome consistent with Liu's hula-twist mechanism for cis→trans photoisomerization.[30,35] They have stimulated the recent resurrection of this mechanism with special attention to the key role of the volume-conserving requirements of the rigid medium.[36]

Theoretical calculations at different levels of theory of the structures and energies of the ground state conformers of Pre have been carried out on the model compound with the side chain at the D ring replaced by a methyl group.[37–41] They generally predict a complex mixture of conformers in close energetic proximity. The order of conformer energies varies with the level of theory, but at least eight of them, four in the cZc family (P_0) and four in the tZc family (P), are predicted to lie within less than 2 kcal/mol of each other.[29] The *tZt* conformer set lies a little over 2 kcal/mol above the global minimum. Within each subset the conformers differ in helicity and in the quasi-axial or equatorial orientation of the OH group in the A ring. In such gas phase calculations, the interaction of the OH group in the axial orientation with the rest of the molecule has a pronounced stabilizing influence, which would be attenuated in solution.[41] At the B3LYP/6–31 G(d) level of theory, tZc conformers are generally predicted to lie roughly 1 kcal/mol below corresponding cZc conformers.[41]

In view of the above spectroscopic observations and theoretical predictions, Havinga's NEER principle appears to best account for the λ_{exc} dependence of the quantum yields of the products from Pre. The two competing mechanisms assign the change in the quantum yields at about 302 nm to the excited state behavior of the *cZc*-Pre conformers (P_0). The postulation of the 1B/2A origin of the effect[19b,20] by Dauben and Kohler was influenced by the finding that the 2A→1A fluorescence excitation spectrum of Pre_3 dissolved in a decalin/methylcyclohexane glass at 77 K extends well to the red of the absorption spectrum under the same conditions. However, although it is likely that this was correctly attributed to a strong fluorescence contribution by direct absorption into the highly forbidden 2A←1A transition in the 300–340 nm region,[20] the fact that the fluorescence intensity diminishes at shorter wavelengths where 1B←1A transitions are strongest cannot be taken as support for the conclusion of weak communication between 1B and 2A states of P_0. Transient spectroscopic observations have established that radiationless 1B→ 2A transitions occur in the fsec-timescale in trienes[25,26,42–44] and in cyclohexadienes,[42,45] including members of the vitamin D family.[45b] A much more likely interpretation is that the shorter excitation wavelengths are not effective because they excite the dominant tZc family of conformers (P), which do not fluoresce. Precisely such an interpretation applies to *cis*-NPE (Scheme 5).[46]

Fuß assigned the sharp quantum yield changes to hot excited state chemistry in P_0 because he also concluded, based on the spectra in Figure 27.6, that only P_0 absorbs above 300 nm. However, it seems to us difficult to predict from these spectra precisely where P absorption will stop and P_0 absorption will take over at 0°C. The low temperature spectra were taken in different solvents and at different temperatures. The spectrum assigned to the P set of conformers was measured at 77 K in a hydrocarbon glass[20] and that assigned to the P_0 set was for Pre prepared photochemically *in situ* from Pro in EPA glass at 91 K.[27] Not only are the spectra expected to shift to the blue with increasing *T*, but there is strong evidence in circular dichroism (CD) spectra that the conformer composition is strongly solvent dependent.[28] At the very least, the ethanol in EPA is expected to favor conformations with the 3-OH equatorial, whereas a hydrocarbon medium is expected to shift the equilibrium toward conformations with the 3-OH axial.[28c] We conclude that the Pre spectra in Figure 27.6 are consistent with strongly diminishing relative absorption

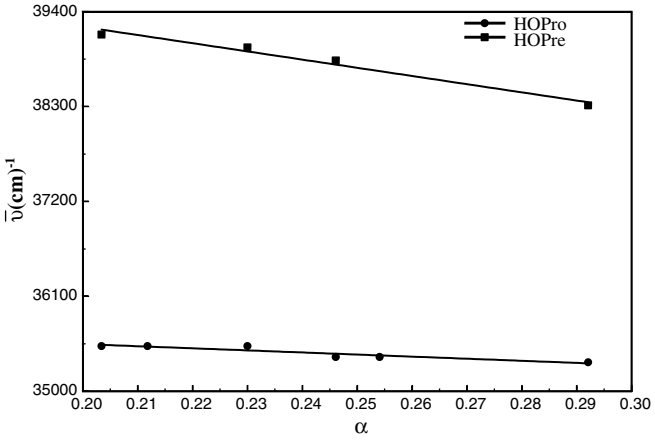

FIGURE 27.7 The dependence of the λ_{max} values of the UV spectra of HOPro and HOPre on solvent polarizability at 20°C;[48b] the solvents, in order of increasing polarizability are methanol, acetonitrile, isopropyl alcohol, tetrahydrofuran, dioxane, and toluene.

by P conformers (tZc) at 302 nm and substantial contribution at longer λ (the onset of the UV spectrum of Pre in ether at 0°C) by P_0 conformers (cZc). There is also the possibility, which may be remote due to the very viscous EPA medium, that following the ring opening of Pro, the hot Pre conformers equilibrate on the ground state surface, as has been reported for 1,3-cyclohexadiene in ethanol.[42]

27.4 Optimizing the Production of Vitamin D from Provitamin D

The production of vitamin Ds provides a rare example of an industrial scale synthesis in which, free radical chain reactions aside, photochemistry *in vitro* plays a crucial role.[47] The objective is to maximize the photochemical conversion of Pro to Pre and to follow this with the thermal rearrangement of the latter to the vitamin Ds (Vit). It is desirable to achieve optimum conversions to the Pre while minimizing the yields of the undesirable secondary photoproducts Lumi and Tachy.[1,2] Finally, the thermal Pre→Vit conversion must be carried out at an intermediate temperature in order to avoid competing thermal disrotatory cyclizations to pyro- and isopyrocalciferols, cyclohexadiene stereoisomers of the lumisterols and provitamins with cis ring B junctions, which occur at temperatures above 100°C.[47] The separation of photochemical and thermal steps is beneficial because it prevents formation of Vit photoproducts.[1,2]

Three strategies have been proposed to maximize the photochemical yields of Pre. They all have in common as a first step, roughly monochromatic UV-excitation of Pro in the absence of oxygen with the goal of approaching quasi-photostationary states (Q-PSS; Scheme 1). Overirradiation or even attainment of the Q-PSS is avoided because of slow, irreversible stoichiometric losses of the interconverting isomers to undesirable isomers transparent to the exciting light.[1,2] The success of the first strategy depends on the selection of an excitation wavelength that yields the largest previtamin contribution in the Q-PSS and employs no other photochemical step in the synthesis.[22–24] The optimum λ_{exc} selection has been based on the quantum yields of the interconversions and the absorption spectra of the contributing isomers. There is a general shift of the λ_{max} of the absorption spectra to the red with increasing solvent polarizability $\alpha = (n^2 - 1)/(n^2 + 2)$, where n is the index of refraction,[48] similar to that experienced by the α,ω-diphenylpolyenes.[49,50] More subtle changes are expected at the onsets of the absorption spectra due to the influence of solvent on the equilibrium distribution of the conformers.[28] Figure 27.7 shows the polarizability effect on the spectra of the Pro and Pre 25-OH analogues of vitamin D_3 ($HOVit_3$).[48] The effect is generally more pronounced for the trienes than for the cyclohexadienes.[48] The set of spectra for the 25-OH vitamin D_3 ($HOVit_3$) isomers in methanol, Figure 27.8,[48] is typical.

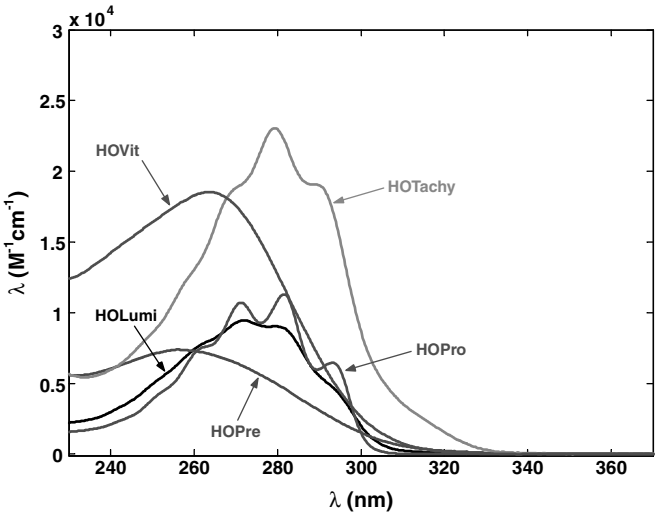

FIGURE 27.8 UV spectra of HOVit isomers in methanol at 20°C.[48]

Most quantitative determinations of the progress of the photochemical conversions, as Q-PSS relationships are approached, have been by high performance liquid chromatography (HPLC) analysis, a rather time-consuming method. The availability of an accurate set of absorption spectra, such as those in Figure 27.8, allows the product distribution to be conveniently determined directly from UV spectra of the reaction mixture taken during the course of the irradiation. Treatment of such spectral matrices by singular value decomposition (SVD) reveals the number of major components and stoichiometric losses due to the formation of photoproducts (i.e., toxisterols[1]) that do not contribute in the wavelength range of the spectra.[51,52] As an example, we present results from a 254 nm irradiation of HOPro (4.90×10^{-4} *M*) in methanol at 20°C. On the basis of the relative magnitude of the eigenvalues, the spectral matrix is a well-behaved three-component system (HOPro/HOPre/HOTachy). Pure component and mixture spectra are represented as linear combinations of the three major eigenvectors, and each is reduced to a point in the combination coefficient space. Figure 27.9 shows the time evolution of the spectra in the eigenvector combination coefficient space. Deviations from the stoichiometric plane defined by the combination coefficients of the three pure components (not obvious in Figure 27.9 but easily seen by rotating the plane to an edge view) are small. They reflect formation of very small amounts of HOLumi and HOVit (<1%) that are neglected in the analysis and stoichiometric losses to nonabsorbing products (≤3.3% at the end of this experiment). The results in Figure 27.9 correspond to the reaction profile in Figure 27.10.

Figure 27.11 shows the λ_{exc} dependence of Q-PSS compositions for the Vit_3 system in diethyl ether calculated by Braun et al.[24] based on absorption spectra and published quantum yields.[19a,53] The maximum contribution of the previtamin is predicted to occur for $\lambda_{exc} = 296$ nm,[24] in excellent agreement with the previous two studies[22,23] and in satisfactory agreement with experimental results (one glaring exception is the contribution of Lumi, which is found experimentally to be larger than that of Pro at nearly all wavelengths, and especially at wavelengths longer than 300 nm).[24] Excitation close to 296 nm is desirable in the one-step previtamin synthesis because it minimizes the formation of Tachy, the major undesirable secondary product for the $\lambda_{exc} \leq 296$ nm range. It was estimated that a 47% optimum conversion to Pre could be achieved by excitation of the provitamin at 296 nm. The process then requires separation of unreacted provitamin for recycling and of previtamin for the thermal conversion to the vitamin.

The other two strategies employ sequential photochemical steps. The excitation wavelength in the first step is chosen so as to maximize the conversion of Pro to Pre and Tachy, and a longer excitation wavelength, with or without an added triplet energy donor, is used in the second step to convert the initial Pre and Tachy mixture to a Pre-rich Q-PSS. The sequential direct excitation procedures mainly

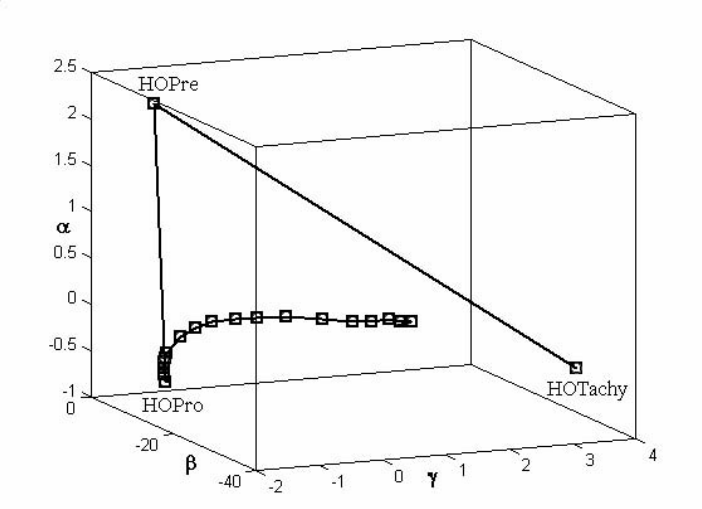

FIGURE 27.9 Stoichiometric plane (shown by the labeled pure component points) in SVD combination coefficient space for the 254 nm-irradiation of HOPro in methanol[48] (see text).

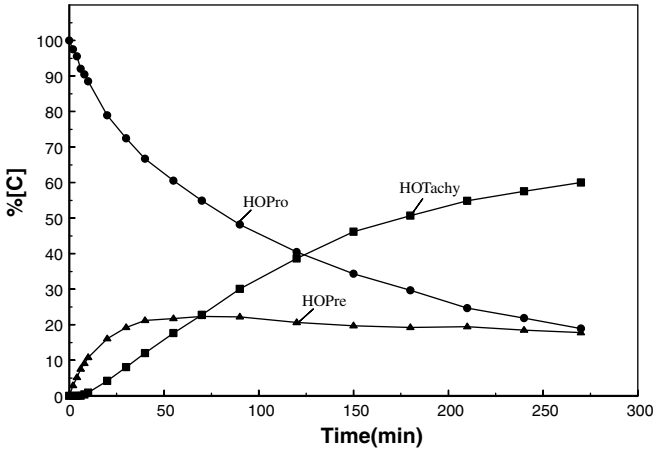

FIGURE 27.10 Product evolution according to Figure 27.9.

use a short wavelength (248 or 254 nm) for the Pro to Pre + Tachy step, followed by a second excitation wavelength in the 337–355 nm range to convert most of the Tachy to Pre.[54–56] These procedures have sought to take advantage of the fact that the Tachy UV spectrum extends to longer wavelengths than the Pre spectrum (Figure 27.8). However, the second wavelengths that have been suggested are barely absorbed by Tachy and, in addition, the desired selective excitation advantage is almost lost. For instance, the molar absorptivities of $Tachy_3$ and Pre_3 at 350 nm in diethyl ether are given as 100 and 25 $M^{-1}cm^{-1}$, respectively.[55] To make matters worse, wavelengths longer than 296 nm selectively excite *cZc*-Pre conformers (probably directly into the 2A state) and favor return to Pro and, especially, formation of Lumi (Figure 27.12).[19,20,24] Results from the Dauben and Phillips study are shown in Figure 27.12. They show that the Tachy→Pre conversion is the dominant process during the initial 350-nm irradiation period and that only when it is nearly complete do the Pre→Lumi and Pre→Pro photoreactions take over. The irradiation sequence in Figure 27.12 yielded up to 83% Pre at 95% Pro conversion.[55] The large Pre/Tachy Q-PSS ratios that were achieved with $\lambda_{exc} = 350$ nm indicate that the quantum yield in the Tachy→Pre

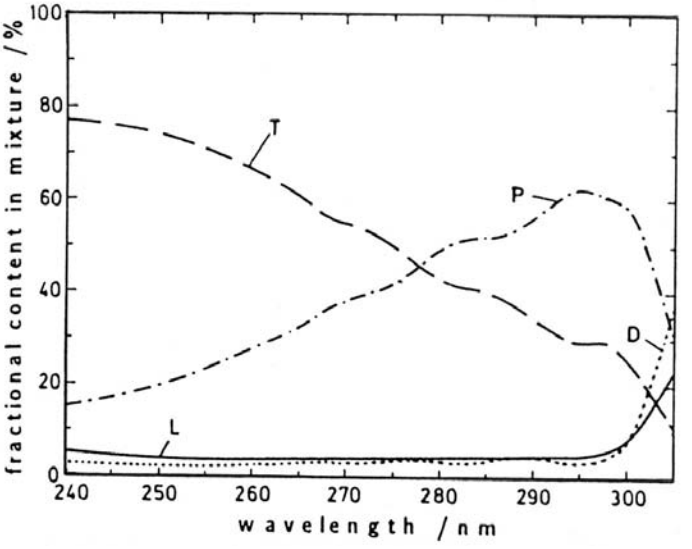

FIGURE 27.11 Calculated Q-PSS compositions for the Vit_3 isomers in ether as a function of excitation wavelength; T, P, L, and D are $Tachy_3$, Pre_3, $Lumi_3$, and Pro_3 (7-dehydrocholesterol), respectively (reprinted from Reference 24, with permission from the copyright owner, Elsevier Science, Oxford, UK).

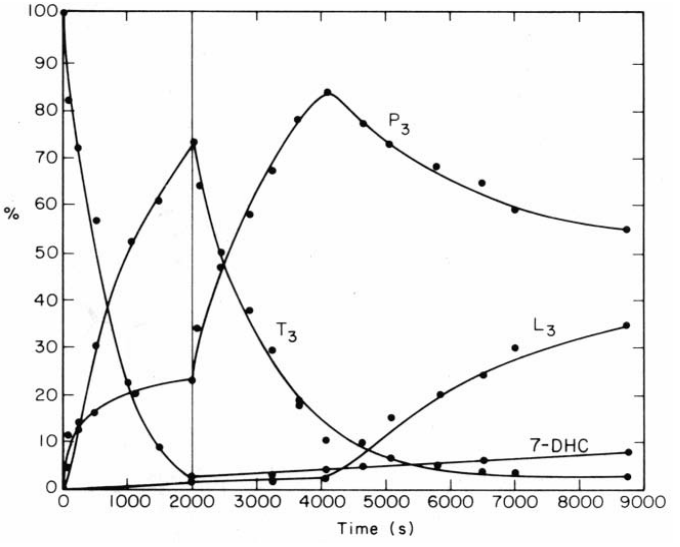

FIGURE 27.12 Product evolution from the irradiation of Pro_3 (7-DHC) in diethyl ether at 0°C at 254 and then (vertical line at 2000 min) at 350 nm (reproduced from Reference 55 with permission from the copyright owner, the American Chemical Society).

direction is at least four times larger than in the Pre→Tachy direction. Since, furthermore, Lumi becomes the major component in the Q-PSS at long irradiation times, it follows that the quantum yield trends in Figure 27.2 extend to longer wavelengths.

We have tested the use of the 313 nm Hg line to effect the HOTachy→HOPre conversion as an alternative wavelength in the second irradiation step.[48] This wavelength is absorbed more strongly and more selectively by the Tachy chromophore (Figure 27.8). Essentially identical Tachy→Pre quantum yields

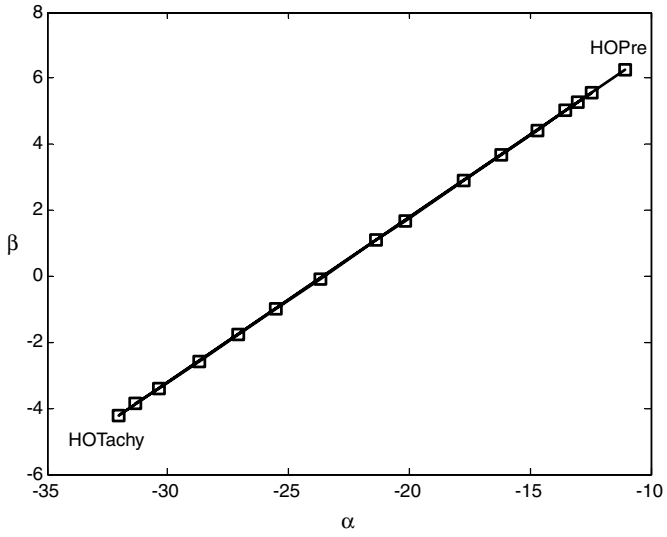

FIGURE 27.13 Stoichiometric line in 2-component SVD combination coefficient space for the 313 nm conversion of HOTachy to HOPre in methanol.[48]

of 0.10 at 254 and 313 nm in diethyl ether were reported by Jacobs and Havinga et al.[1a] Similar claims were made by Dauben and Phillips for 254 and 302 nm excitations,[19a] and by Gliesing and co-workers for excitation over the 254 to 313 nm range in ethanol.[57]

We used degassed methanol solutions and determined conversions by SVD analysis of UV spectra and by HPLC. The quantum yield for the HOTachy→HOPre direction in methanol at 20°C is 0.43. It is significantly larger than the 0.10 value at 254 nm[1a] (the 0.49 value for the Lumi→Pre quantum yield in ether at 313 nm[21] was assigned inadvertently to the Tachy→Pre process[47]).[48] Our value for the HOTachy→HOPre quantum yield in methanol at 254 nm is 0.14. The substantial λ_{exc} effect on the quantum yield for the Tachy→Pre process indicates that the two wavelengths excite different compositions of HOTachy conformers. SVD analyses of the UV spectra of product mixtures obtained in the course of the 313 nm irradiations of a degassed HOTachy solution in methanol are consistent with well-behaved 2-component systems. The excellent adherence of the combination coefficients points of individual spectra from the HOTachy/HOPre stoichiometric line in Figure 27.13 at up to an apparent 95% conversion to HOPre (see below) is typical. At the longer irradiation times, a three-component SVD analysis gives more accurate product compositions. The longer irradiation time spectra that were included in the two-component treatment in Figure 27.13, when treated as a three-component system give the product evolution shown in Figure 27.14. HPLC analysis of the final reaction mixture gave 5.7% (6.9%) HOTachy, 81.9% (82.4%) HOPre, 8.3% (7.8%) HOLumi, 2.4% HOPro, and 1.8% HOVit (values in parentheses are from the corresponding three-component SVD analysis). A filter solution was used to isolate the 313 nm Hg line, but nearly identical product compositions are attained much faster with the use of only Pyrex as the filter because 313 nm is the only transmitted Hg line that is absorbed significantly by the reaction mixture.[48]

Early discussions of the conformational equilibrium in Tachy have settled on the tEc and the tEt conformers as the most energetically favored, with the former being more abundant.[1a,58] A recent molecular mechanics-based (MMX) conformational search confirms the placing of tEc as the most abundant Tachy conformer (63%) but predicts cEc (18%) to be slightly more abundant than tEt (13%).[59] The weak structureless band at the onset of the UV spectrum of HOTachy, Figure 27.8, should then be assigned to either the cEc or the tEt conformer, or both, and 254 nm should favor *tEc*-HOTachy excitation (note that s-*cis* diene moieties normally absorb to the red of s-trans diene moieties).[60] The *s-cis*-butadiene moiety in *tEc*-HOTachy may explain the much lower HOTachy to HOPre quantum yield at 254 nm than

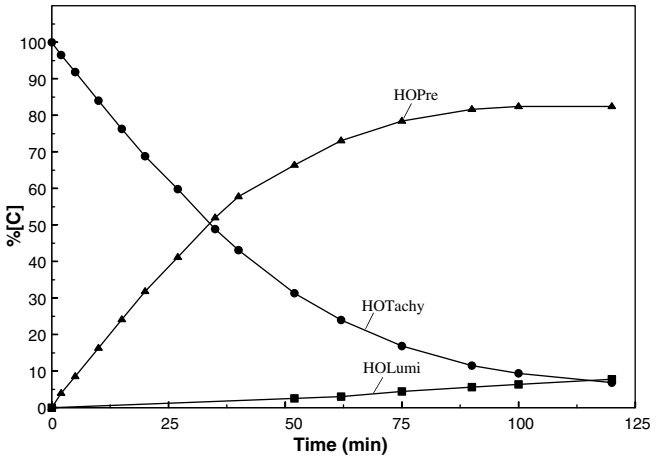

FIGURE 27.14 Product evolution for the 313 nm irradiation of HOTachy in methanol (2-component analysis up to 40 min and 3-component SVD analysis for longer times).[48]

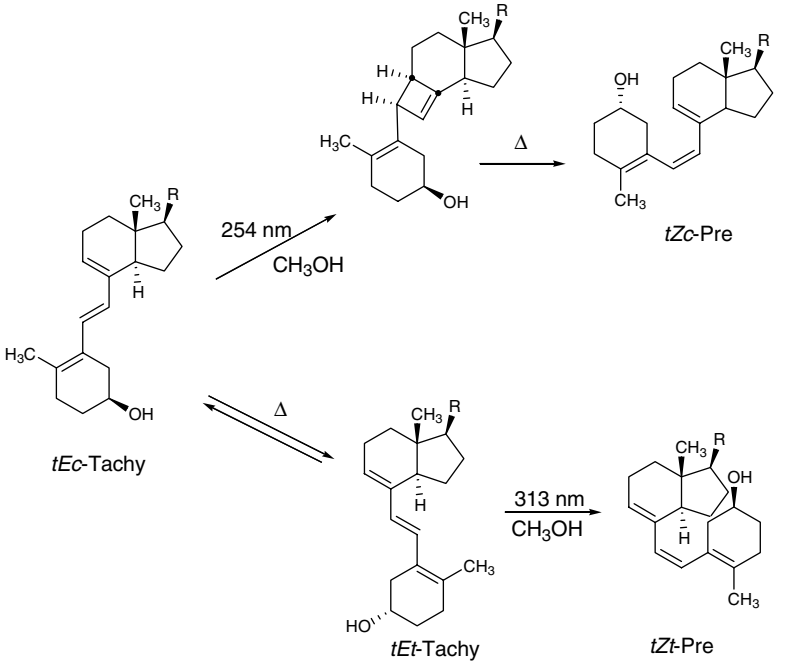

SCHEME 8 Proposed conformer specific photochemistry of HOTachy.

at 313 nm. Excited *tEc*-HOTachy has the potential of giving vinylcyclobutene[1a,61] (or deactivation along that reaction coordinate) in competition with trans→cis photoisomerization, whereas that reaction/deactivation channel is not available to excited *tEt*-Tachy, whose primary reaction may well be efficient trans→cis photoisomerization (Scheme 8).

The 254, 313 nm two-step sequence for Pro to Tachy conversion has advantages over the earlier sequences that employed longer wavelengths in the second step.[54–56] It achieves high, relatively clean Tachy to Pre conversion without requiring high excitation intensities or long irradiation times due to low absorbance in the second irradiation step and minimizes competing Pre photocyclizations to Pro and

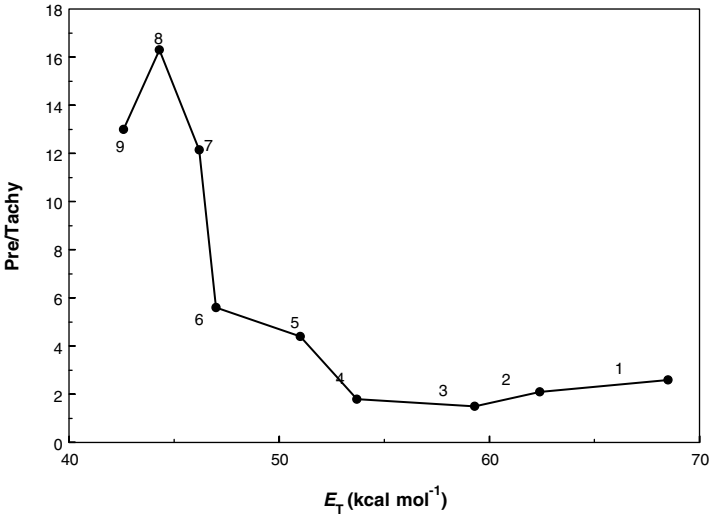

FIGURE 27.15 Saltiel plot for the sensitized Pre/Tachy interconversion. Photostationary Pre/Tachy ratios are given for benzophenone (1), anthraquinone (2), 2-naphthyl phenyl ketone (3), benzil (4), fluorenone (5), and benzanthrone (6) for the vitamin D_2 system,[66] 2-(6-hydroxy-3-oxo-3H-thioxanthene-9-yl)benzene-sulphonic acid[68] (7) and 7,12-dimethylbenzanthracene[70] (8), for the vitamin D_3 system, and anthracene (9) for both vitamin D_2 and D_3 systems.[67]

Lumi. The sequence employs a low-pressure Hg lamp for 254 nm irradiation in the first step, followed by the use of a medium pressure Hg lamp in the second step. Similar conversions to HOPre (82–84%) were attained starting from either HOTachy or HOPro.[48] In a variant of the sequential two excitation wavelength procedure, Reichenbächer and coworkers recommend simultaneous irradiation at 300 and 330 nm to enhance the conversion of Pro to Pre in a single photochemical step,[62] and they have recently refined this approach.[63]

Havinga and coworkers first reported the triplet sensitized Pre/Tachy interconversion for the trimethylsilyl ethers in the vitamin D_3 system,[64] and the idea of replacing the second direct excitation step with triplet sensitization using a sensitizer (fluorenone) to maximize the conversion to Pre was advanced by Eyley and Williams.[65] No side reactions compete in this second photochemical process, as efficient trans-cis interconversion is the only unimolecular triplet state reaction.[64] Efforts since then have been directed toward fine tuning the selection of the sensitizer.[66–70] The challenge here is to chose a triplet energy donor that yields a high PSS Pre/Tachy ratio by selectively exciting Tachy, is nontoxic, has no undesirable photochemistry of its own, and can be removed readily and completely from the reaction mixture. As is usually the case,[5,71] the cis/trans isomer ratio depends on the triplet energy of the sensitizer.[66–70] The Saltiel plot in Figure 27.15 is analogous to that shown in Figure 27.1 for the 1,3-pentadienes but is not as easily interpreted quantitatively due to the possibility of selectively exciting up to four different conformers of Pre and of Tachy in different sensitizer triplet energy regions. It is clear from the plot that very high conversions to Pre can be achieved with donors whose triplet energy is close to ~45 kcal/mol. The direct excitation of Pro followed by the sensitized conversion of Pre to Tachy has also been combined into a single step, simultaneous direct and triplet sensitized (fluorenone, benzanthrone) irradiation with promising results.[72]

Guillet and coworkers have reported very intriguing observations in a polymer medium (a "photozyme") in which the naphthalene chromophore is proposed to play a double role by sensitizing the singlet Pro→Pre→Tachy and the triplet Tachy→Pre conversions.[73] Aqueous solutions of poly(sodium styrenesulfonate-*co*-2-vinylnaphthalene irradiated at 313 nm or with solar light in the presence of Pro D_3 lead to very clean conversions of Pro to Pre. The proposed mechanism involves excitation of the polymer bound naphthyl groups followed by singlet excitation transfer to the polymer-solubilized Pro to effect the ring-opening reaction. Tachy is not observed, presumably due to its return to Pre via triplet sensitization

again from the pendant naphthyl group.[73] Extraction with chloroform separates the Pre-rich product mixture from the polymer-immobilized sensitizer. Formation of Pre, nearly free from Tachy, under these conditions is all the more remarkable when one considers that, based on Figure 27.15, the expected Pre/Tachy PSS ratio with a triplet energy donor having the triplet energy of naphthalene (61 kcal/mol) should be smaller than two. For the proposed Tachy→Pre conversion to be important, the polymer would have to control the conformational equilibria of Pre and of Tachy in ways that favor one-way triplet sensitization in the Tachy→Pre direction. In view of the fact that the Tachy UV spectrum extends well to the red of the Pro and Pre spectra, it is difficult to imagine why singlet energy transfer from naphthalene would not be enormously more efficient to Tachy than to Pro or Pre. Coupled with our finding of a significantly enhanced quantum yield for the trans→cis Tachy photoisomerization at 313 nm and the availability of 2A states that can be accessed directly with wavelengths as long as 355 nm,[54–56] we much prefer a singlet excitation transfer pathway for the proposed Tachy→Pre conversion. An alternative possibility is that excited naphthalene fails to sensitize the Pre→Tachy process in the first place. The selectivity achieved in an extension of this work using styrene-2-vinylnaphthalene copolymers in tetrahydrofuran to photosensitize the formation of Pre from Pro was again impressive, although less spectacular.[74] The observed 13:1 ratio of Pre:Tachy is again too high to be consistent with naphthalene triplet sensitized Pre/Tachy interconversion.

Differences between triplet-sensitized Tachy/Pre equilibration and analogous equilibrations of simpler conjugated trienes,[66,75] including the parent 1,3,5-hexatrienes,[76] are worth noting. In contrast to other acyclic trienes such as alloocimene,[75a] 1,3,5-hexatriene,[76] 1,6-diphenyl-1,3,5-hexatriene,[77] and 1,2-di-(1-cyclopentenyl)ethene,[65] there are no significant concentration or quencher effects on photoisomerization quantum yields or PSS ratios in the Pre/Tachy system.[65] Electronic and steric requirements of the steroid moieties apparently limit access to planar Tachy and Pre triplet states causing a shorter triplet lifetime and smaller effective T_1–S_0 energy gaps, effectively preventing their involvement as donors in excitation transfer steps.[65]

27.5 Conclusion

Its practical importance aside, photochemistry in the vitamin D field continues to claim its place at the forefront of the science. Its central role in the renewed interest in the hula-twist mechanism for trans-cis photoisomerization will no doubt prompt much research to test the validity and generality of that concept. Through it all, it provides a plethora of observations confirming Havinga's NEER principle.

Photochemical Reaction of Fullerenes and Fullerene Derivatives

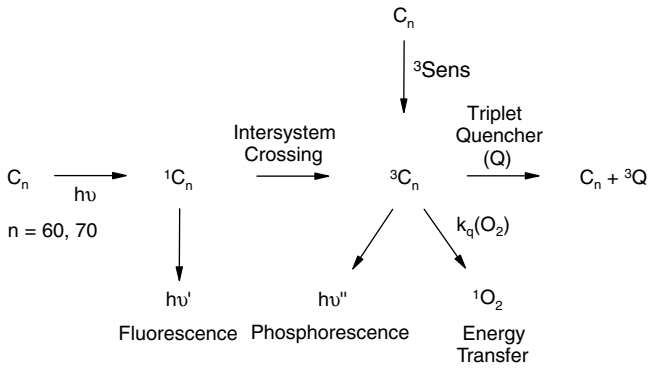
Andreas Kleineweischede
Universität Bielefeld

Jochen Mattay
Universität Bielefeld

28.1 Introduction

In 1985, the existence of a form of elementary carbon with a definite number of carbon atoms became certain with the discovery of the fullerenes by Kroto, Smalley and co-workers.[1] The development of a simple procedure for making fullerenes available in macroscopic quantities by Krätschmer et al.[2] induced a veritable flood of investigations in the last two decades leading to molecules and materials with interesting behavior such as superconductivity,[3] ferromagnetism,[4] biological activity,[5,6,7] and nonlinear optics.[8,9,10] As a result, a great number of reports and reviews have been published describing the full scope of fullerene chemistry, including functionalization (thermally or photochemically) and physical properties.[11–19] Recently, two reviews dealing with the photochemical functionalization of fullerenes have been published.[20,21] This review will focus on the photochemistry of the two most prominent fullerenes, C_{60} and C_{70}, and their derivatives. Photochemistry of higher fullerenes will not be discussed. Before the different photochemical reactions of the fullerenes and derivatives are described, the photophysical properties of C_{60} and C_{70} will be briefly discussed in Section 28.2.

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1 Photophysical processes in C_{60} and C_{70}.

TABLE 28.1 Photophysical Properties of C_{60} and C_{70}[22,23]

Property	C_{60}[a]	C_{70}[a]
E_S	46.1 kcal/mol[b]	44.1 kcal/mol[b]
E_T	37.5 ± 4.5 kcal/mol[c]	33.0 kcal/mol ≤ E_T < 42 kcal/mol[c]
ε_T (480 nm)	$(2.8 \pm 0.2) \times 10^3$ M^{-1} s^{-1}	$(1.4 \pm 0.1) \times 10^4$ M^{-1} s^{-1}
τ_T	40 ± 4 μs[d]	130 ± 10 μs[d]
k_q (O_2)	$(1.9 \pm 0.2) \times 10^9$ M^{-1} s^{-1}	$(9.4 \pm 1.5) \times 10^8$ M^{-1} s^{-1}
Φ $^1O_2$ (355 nm)	0.76 ± 0.05[e]	0.81 ± 0.15[e]
Φ $^1O_2$ (532 nm)	0.96 ± 0.04[f]	0.81 ± 0.15[f]
k_q ($^1O_2$)	$(5 \pm 2) \times 10^5$ M^{-1} s^{-1} [g]	not measurable[g]

[a] All measurements in C_6H_6 or C_6D_6 were taken at room temperature, with concentrations of $C_{60} \approx 3 \times 10^{-5}$ and 3×10^{-4} M (OD ≈ 0.5) at λ_{exc} = 355 and 532 nm; $C_{70} \approx 1 \times 10^{-5}$ and 4×10^{-5} M (OD ≈ 0.3) at λ_{exc} = 355 and 532 nm, respectively, unless otherwise noted. [b] Calculated from the presumed 0-0 band at 620 nm for C_{60}[24] and at 638 nm for C_{70}.[23] [c] Average of the triplet energy of TPP (33.0 kcal/mol) and anthracene (42 kcal/mol); however, the low quenching rate with TPP suggests the actual energy is closer to the level of TPP. [d] In argon-saturated solution. [e] C_{60}: average of the five determinations with TPP (Φ_Δ = 0.62) and acridine (Φ_Δ = 0.84)[22]; C_{70}: avarage of five determinations at varied laser energies (1-3 mJ/puls), OD = 0.3-0.5, with TPP (Φ_Δ = 0.62). [f] C_{60}: avarage of three determinations with TPP (Φ_Δ = 0.62); C_{70}: avarage of seven determinations, same conditions as for Φ^1O_2 (355 nm). [g] C_{60}: total of physical and chemical quenching of $^1O_2$ by C_{60} (TPP, 532nm). The maximum concentration of C_{60} was limited by saturation; C_{70}: No change in $^1O_2$ lifetime on adding C_{70} up to 4.9×10^{-4} M.[23]

28.2 Photophysical Properties of C_{60} and C_{70}

The first investigations of basic photophysical properties of pure fullerenes were carried out by Foote and co-workers in 1991.[22,23] Since then, research has led to an extensive knowledge about the photophysical behavior of the fullerenes in general.[24–91] Scheme 1 shows the main photophysical processes, and in Table 28.1 the most relevant photophysical properties are summarized.

UV/Vis-Absorption and Fluorescence

The electronic absorption spectra of both C_{60} and C_{70} show strong absorption bands in the UV region due to allowed $^1T_{1u} \rightarrow {}^1A_g$ transitions [$\varepsilon_{max} \sim 10^5$ M^{-1} cm^{-1}; λ_{max} (C_{60}) = 211, 256, 328 nm; λ_{max} (C_{70}) = 215, 236, 313].[24,25] The absorption in the visible region due to the low-lying electronic transitions is only weakly allowed because of the high degree of symmetry in the closed shell electronic configuration[28] (λ_{max} 540 nm, $\varepsilon_{max} \sim 710$ M^{-1} cm^{-1} for C_{60} and λ_{max} 468 nm, $\varepsilon_{max} \sim 15{,}000$ M^{-1} cm^{-1} for C_{70}).[24,25] The

longest wavelength absorption of C_{60} attributed to the $S_0 \rightarrow S_1$ transition appears at 620 nm.[24] The lower symmetry of C_{70} leads to stronger absorptions in the visible due to the fact that the longest wavelength transition is less forbidden.[23]

C_{60} shows very weak fluorescence with a low quantum yield (λ_{max} 720 nm, quantum yield $\Phi_F \sim 10^{-5}$–10^{-4}),[26–31] while fluorescence of C_{70} is somewhat stronger ($\Phi_F \sim 8.5 \times 10^{-4}$), and at 77 K structured fluorescence occurs with λ_{max} 682 nm.[22,32,34,35] It has been reported that fluorescence of C_{70} at 77 K strongly depends on the solvent matrix. This is most probably associated with deformations of the solute molecules.[33] The S_1–T_1 splitting of both C_{60} and C_{70} is small (~10 kcal/mol in C_{60}[49,51]; ~7 kcal/mol in C_{70}[31,33]). Surprisingly, the S_1–S_2 energy difference of C_{70} was found to be quite large, almost equal to the S_0–S_1 energy difference.[33] The low fluorescence of both C_{60} and C_{70} probably results from the short lifetime of the singlet excited state and from the symmetry forbiddeness of the lowest-energy transition. The decay rates k_F were determined to be 1.5×10^9 sec^{-1} for $^1C_{60}$* and 1.61×10^9 sec^{-1} for $^1C_{70}$*.[35,43] Both fullerenes display wavelength-independent photophysical properties both for absorption and emission and thus obey Kasha's rule.[52]

Excited State Spectroscopy and Phosphorescence

The singlet excited states (S_1) of C_{60} and C_{70} were characterized by transient absorption studies. The estimated lifetimes were 1.2 nsec for $^1C_{60}$* and 0.7 nsec for $^1C_{70}$*. The absorption maxima λ_{max} appear for C_{60} at 513, 759, and 885 nm and for C_{70} at 675 and 840 nm.[36–40] The reason for the very short singlet lifetimes of both C_{60} and C_{70} is related to the high intersystem crossing rate to the triplet excited state with triplet quantum yields close to 100%.[37,42–45] The intersystem crossing rates k_{ISC} for C_{60} and C_{70} are in good agreement with the values for the fluorescence decay rates [k_{ISC} (C_{60}): 1.5×10^9 sec^{-1}; k_{ISC} (C_{70}): 1.25×10^9 sec^{-1}].[35] These values were determined by spectroscopic and photothermal methods and agree with lower limits determined from singlet oxygen quantum yields.[22,23]

Triplet–triplet absorption spectra and extinction coefficients (C_{60}: λ_{max} = 330, 750 nm, ε_{max} 40,000, 20,000 M^{-1} cm^{-1}; C_{70}: λ_{max} = 335, 480, 690, 970 nm, ε_{max} 35,000, 12,000, 2250, 3800 M^{-1} cm^{-1}) were measured by several groups with varying details of the spectra because of difficulties of correcting the spectra for ground state depletion. The triplet lifetimes of both fullerenes in solution are quite short (50–100 μsec) due to triplet–triplet annihilation and ground state quenching.[22,23,35,38,40,44–48] However, Fraelich et al. reported significantly longer T_1 lifetimes of both fullerenes. For C_{60}, they determined a triplet lifetime of 133 μsec and for C_{70} 2.2 msec. In mixed solutions of C_{60} and C_{70}, they observed intermolecular energy transfer between nearly isoenergetic triplet states. The T_1–S_0 gap of C_{60} was estimated to be 102 ± 30 cm^{-1} greater than that of C_{70}.[41]

The triplet energy levels (E_T) of C_{60} and C_{70} were estimated to be close to 35 kcal/mol by triplet–triplet energy transfer.[22,23] Both compounds quench the triplet states of senzitizers with $E_T \geq 42$ kcal/mol with essentially diffusion-controlled rate constants. Quenching of the tetraphenylporphyrine (TPP) triplet (E_T = 33 kcal/mol)[49] is significantly slower (~2–4 – 10^7 M^{-1} sec^{-1}), probably because energy transfer with this sensitizer is slightly endothermic. Energy transfer from C_{60} and C_{70} triplets to acceptors with $E_T \leq 28$ kcal/mol is diffusion controlled. Despite the high quantum yield of triplet formation, no phosphorescence of C_{60} is observed, and C_{70} shows only weak phosphorescence at 77 K, which also confirmed the triplet energy of C_{70}.[39] Heavy-atom–induced phosphorescence can be observed and gives a triplet energy of 36.3 kcal/mol.[50] These values are in good agreement with those determined by photothermal [44,45,51] and spectroscopic methods.[25,38]

EPR studies of the triplet states of the fullerenes give much insight into rotational dynamics of the triplet. It could be shown that for both fullerenes two triplet states exist over a temperature range from T = 8 K to T = 213 K. The differences between them are in their relaxation rates, one type having a faster decay of magnetization (by one order of magnitude) than the other type. Additionally, a small difference exists in the resonance frequency (small shift in the g-value). The faster decaying triplet was found to have a stronger intensity. Also, triplet–triplet annihilation and quenching by nitroxide radicals was measured by EPR-technique.[39,53–61]

28.3 Photochemical Reactions of Fullerenes

In the early 1990s, the derivatization of fullerenes was based on thermal reactions, e.g., the Diels–Alder reaction of C_{60} with substituted dienes leading to cyclohexyl-fused fullerene derivatives, and only a few examples were known, where a fullerene adduct was obtained by photochemical reactions. The pioneering work in the field of photochemical derivatization of fullerenes was done by Wilson, Schuster, and colleagues who, for example, reported the [2 + 2]-photocycloaddition of enones to C_{60}. Nowadays, more and more fullerene derivatives are synthesized by photochemical reaction pathways.

The photoinduced functionalization of fullerenes can be achieved either by electron transfer activation leading to radical ions or by energy transfer processes, either by direct excitation of the fullerenes or the reaction partner (Equation 28.1). In the latter case both singlet and triplet species are involved. In the case of reactions proceeding via electronically excited fullerenes, the situation is somewhat different. As described in the previous section, the absorption features of fullerenes extend over the UV and visible region, and light of different wavelengths can be used for excitation. Depending on the frequency, various vibrational levels of singlet excited states are populated, followed by relaxation to the lowest vibrational level of S_1. This process is completed before efficient intersystem-crossing to the triplet excited state occurs.[19,35] Usually, the triplet excited state is then the starting point for the derivatization of the fullerenes. Before going into detail, a short summary of the principles of fullerene chemistry will be given.

Electron transfer activation:	Photochemical activation:	
$C_{60} \xrightarrow{+e^-} C_{60}^{\cdot -}$	$C_{60} \xrightarrow{hv} C_{60}* \xrightarrow{A} C_{60}A$	(28.1)
$C_{60} \xrightarrow{-e^-} C_{60}^{\cdot +}$	$A \xrightarrow{hv} A* \xrightarrow{C_{60}} C_{60}A$	

Principles of Fullerene Chemistry

The chemical behavior of C_{60} is largely governed by three properties attributable to the structure of C_{60}.[12,15,63] First, the bonds at the junctions of two hexagons ([6,6]-bonds) are shorter than the bonds at the junctions of a hexagon and a pentagon ([5,6]-bonds) (see Figure 28.1). Second, the highly pyramidalized sp^2 C-atoms in spherical C_{60} cause a large amount of strain energy within the molecule. Third, C_{60} is an electronegative molecule; it can easily be reduced, but it is difficult to oxidize.

The following rules of reactivity, which are based on these properties, can be deduced from the results obtained by the chemical transformation of fullerenes:

1. The reactivity of C_{60} is that of a fairly localized electron deficient polyolefin; thus, typical reactions are additions at a [6,6]-double bond.
2. The driving force is the relief of strain in the fullerene cage.
3. The regiochemistry of the addition reaction is governed by the minimization of [5,6]-double bonds within the fullerene framework.

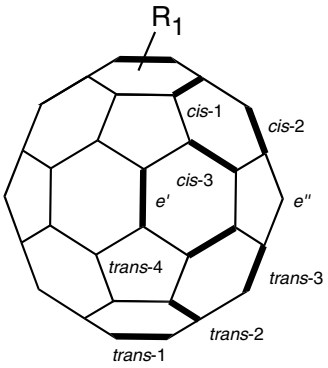

FIGURE 28.2 Positions of the ligand-carrying bonds in the eight possible regioisomers.

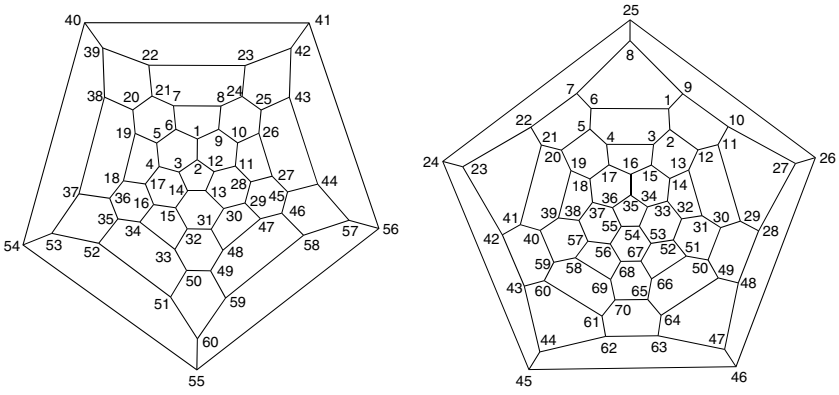

FIGURE 28.3 Schlegel diagrams with carbon atom numbering for C_{60} and C_{70}.

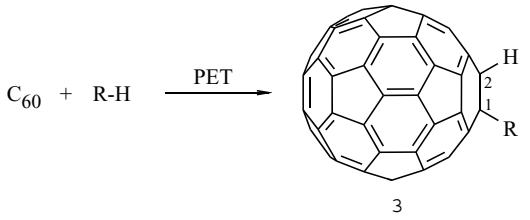
The chemical reactivity of C_{70} is very similar to that of C_{60}. While all positions in C_{60} are identical, and two different types of CC bonds exist, five sets of carbon atoms and eight distinct types of CC bonds are available in C_{70} (Figure 28.1). It can be anticipated that the different bonds will display different reactivity.[64]

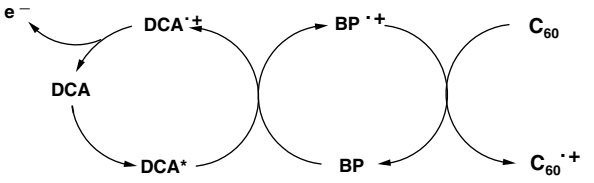
Since there are up to 30 reactive double bonds in the C_{60} molecule, a great number of polyadducts are possible. For a description of the spatial arrangement of the addends, the C_{60} molecule is divided into three sections with regard to the location of the second attack.[65] The second attack can take place on the same hemisphere (*cis*), at the equator (*e*), or on the opposite hemisphere (*trans*). For example, for the addition of an identical second addend, eight regioisomeric bisadducts are possible, as shown in Figure 28.2. To identify modified fullerenes, a numbering system for the carbon atoms is necessary. According to the IUPAC nomenclature,[66] based on the proposal of Robert Taylor in 1993,[67] the carbon atoms are numbered as outlined for C_{60} and C_{70} in Figure 28.3.

Photochemical Synthesis of Substituted 1,2-Dihydro[60]fullerenes

As a first example, the photochemical synthesis of substituted 1,2-dihydro[60]fullerenes of type **3** (Scheme 2) should be discussed. These compounds can be synthesized via either oxidative or reductive photoinduced electron transfer (PET). Whereas the oxidation to the fullerene radical cation is difficult to achieve, reduction of the fullerenes leading to radical anions should be much easily performed due to their electronic features.



SCHEME 2 Formation of dihydro[60]fullerenes under PET conditions.



SCHEME 3 Generation of $C_{60}^{\bullet+}$ by cosensitization (hv: 419 nm, DCA, BP: biphenyl).

Synthesis of Substituted 1,2-Dihydro[60]fullerenes by Oxidative PET

The preparation of 1,2-dihydro[60]fullerenes via oxidative photoinduced PET was investigated by several research groups. In Scheme 2, the general formation of 1-substituted 1,2-dihydro[60]fullerenes is shown.

In 1995, Schuster, Wilson, and co-workers reported the formation of C_{60} radical cations by photosensitized electron transfer that were trapped by alcohols and hydrocarbons to yield alkoxy- or alkyl-substituted fullerene monoadducts as major products.[68] As a sensitizer for the generation of $C_{60}^{\bullet+}$, Schuster et al. used 1,4-dicyanoanthracene (DCA).

Following the conditions developed by Schuster et al., Mattay et al. also generated $C_{60}^{\bullet+}$ using different sensitizers such as *N*-methylacridinium hexafluorophosphate (NMA^+) and 2,4,6-triphenyl-pyrylium tetrafluoroborate (TPP^+) in the presence of biphenyl.[69,70] The assumed mechanism of formation of $C_{60}^{\bullet+}$ by this cosensitization is shown in Scheme 3.

Quenching of $C_{60}^{\bullet+}$ with H-donors such as *t*-butylmethylether, propionaldehyde, and alcohols results in the formation of 1:1 adducts. The product structures support a H-abstraction process[71,72] rather than nucleophilic addition. Some examples of the products generated by this method are summarized in Table 28.2 (products 4–12).

Time resolved laser flash photolysis and ESR spectroscopic investigations clearly demonstrate the formation of $C_{60}^{\bullet+}$ using PET conditions.[73–75] Upon addition of H-donors, the signal of $C_{60}^{\bullet+}$ is quenched.[74] The oxidation of C_{60} is followed by H-abstraction from the H-donor, as shown in Scheme 4. Nucleophilic addition can be excluded because no alkoxyfullerenes were detected.[69] After reduction of $H\text{-}C_{60}^{+}$, e.g., by electron transfer from the reduced sensitizer molecule, $H\text{-}C_{60}^{\bullet}$ might recombine with $R^{\bullet}$ to give the final product. Decay experiments of $C_{60}^{\bullet+}$ by the addition of alcohols support the proposed mechanism of H-abstraction as a first step. The involved radical products reveal $C_{60}^{\bullet+}$ as an electrophilic radical.

The authors reported the formation of some unexpected products in the above-mentioned reaction. For example, when aldehydes were used as the H-donor reactants, the products depended on the reactivity of the intermediate radical. Propionaldehyde as the starting material did not lead to decarbonylation because a primary alkyl radical is less stable than a benzyl radical. Consequently, the decarbonylation during the addition of phenylacetaldehyde leading to **10** (Table 28.2) strongly suggests that this reaction involves an acyl radical that undergoes decarbonylation.

In addition, the reaction of $C_{60}^{\bullet+}$ with glycol, propionic acid, and *t*-butanol could only be explained by loss of the hydrogen from an OH bond, either from the neutral or from the oxidized substrate. For example, the reaction of *t*-butanol with C_{60} leading to the dihydrofullerene **6** (path A in Scheme 5) and

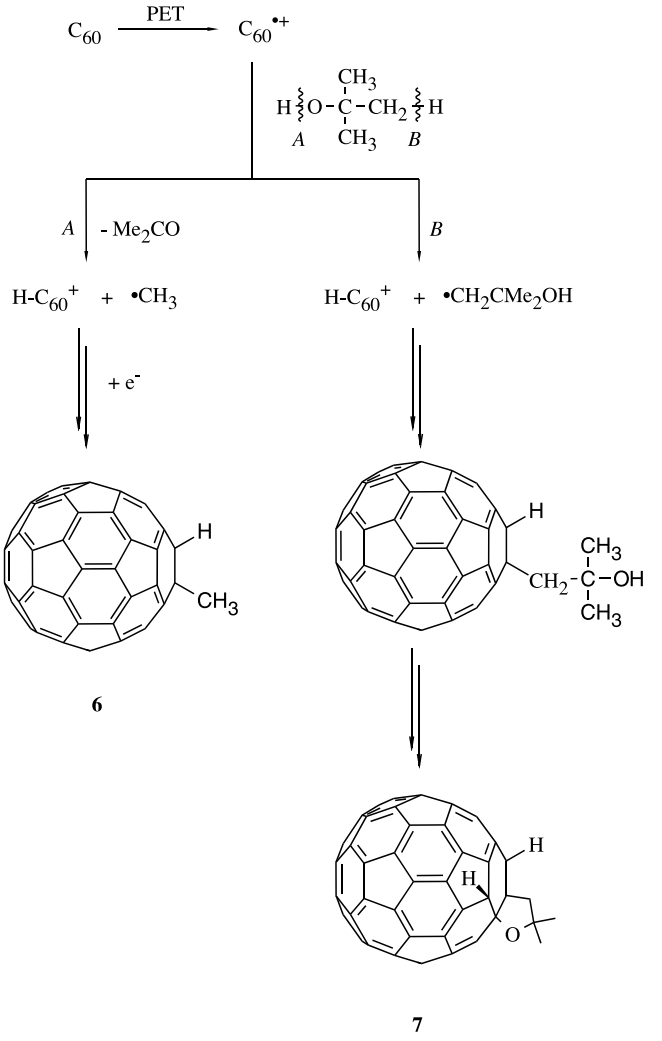
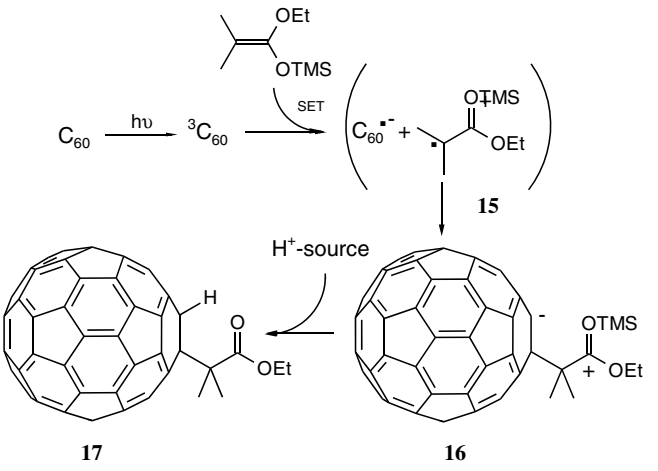


SCHEME 5 Reaction of *t*-butanol and C_{60} under PET conditions.

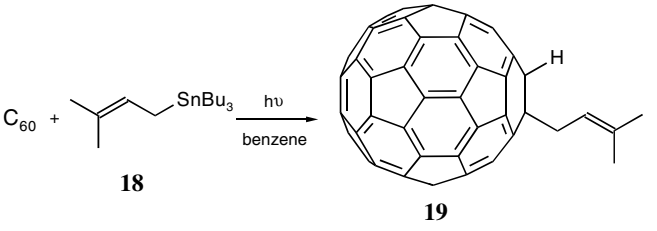
the tetrahydro[60]fullerene **7** (path B in Scheme 5) can be easily explained by homolytic bond breaking at the OH site in the former case and abstraction at the CH site in the latter. Reactions of alcohols and C_{60} under PET conditions yield hydroxylated dihydro[60]fullerenes. It was first considered that the α-centered hydroxyalkyl radicals were formed by direct abstraction of a hydrogen from a CH bond. Instead, it was shown that such radicals can be formed in a bimolecular process from O-centered radicals as a second step in a pseudo-[1,2]-shift reaction. Analogously, the product of the reaction with methoxyethanol can be explained. The primarily generated O-centered radical is transformed into the C-centered radical via a [1,5]-hydrogen shift in a six-membered transition state. Whether simple alcohols react with $C_{60}^{\bullet+}$ by direct H-abstraction from the α-position or via O-centered radicals in a two-step mechanism cannot finally be decided. Both reaction paths may operate.

Synthesis of Substituted 1,2-Dihydro[60]fullerenes by Reductive PET

Several examples are known in which formation of 1-substituted 1,2-dihydro[60]fullerenes occurs by reductive PET. In all these examples, single electron transfer between photoexcited $^3C_{60}$ and the electron donor to form the $C_{60}^{\bullet-}$-$D^{\bullet+}$ radical ion pair is suggested to be the key step in the synthesis of the 1,2-dihydro[60]fullerenes.



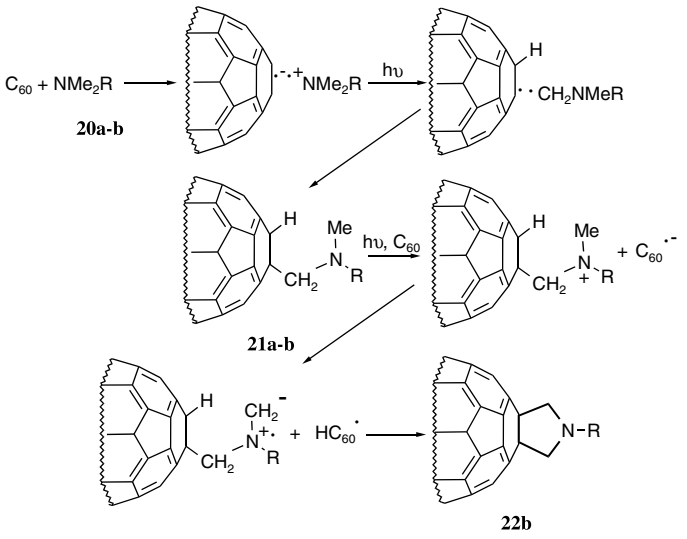
SCHEME 6 Reaction mechanism for the photo-induced CC bond formation of C_{60} with ketene silyl acetals.



SCHEME 7 Reaction of prenyltributyltin 18 with C_{60} upon irradition.

As a first example, irradiation of C_{60} with ketene silyl acetals (KAs), first reported by Nakamura et al., will be discussed (Scheme 6).[76] Interestingly, when unstrained KAs were used, this reaction did not yield the expected [2 + 2]-cycloaddition product either by the thermal pathway, as observed by the use of highly strained ketene silyl acetals,[77] or by the photochemical pathway. As mentioned above, single electron transfer between photo-excited $^3C_{60}$ and the electron-rich ketene silyl acetal leads to the formation of the radical ion pair **15**, followed by coupling to a zwitterionic species **16**, which finally leads to product **17**.[78] The active role of water in the photoaddition in relation to the TMS/TBDMS-dependent reactivity difference indicates that the oxonium intermediate **16** is the direct precursor of the photoproduct **17**, which is formed by the water-assisted loss of the silyl group from **16**. The radical ion pair **15** is the most plausible precursor to **16**, in light of the high electron affinity of excited [60]fullerene[22] and the excellent single-electron donating ability of silyl KA.[79] No free radical species are involved in the reaction since addition of a radical trap (6 equiv. TEMPO) has no effect on the photoreaction. At least, the formation of the [2 + 2]-cycloadduct as an intermediate, which undergoes photoassisted heterolytic CC bond cleavage via **16**, cannot be excluded. Mikami et al. also investigated the addition of ketene silyl acetals. In further studies, they found that addition of the silyl enol ether of acetone and allylic silanes did not result in the synthesis of substituted 1,2-dihydro[60]fullerenes.[78a,80]

In 1997, Mikami, Fukuzumi, and co-workers[81] reported the photoaddition of allylic stannanes, which leads to mono-allylation of C_{60}. The CC bond formation of C_{60} with group 14 organometallic compounds is attained through photoinduced electron transfer from group 14 organometallic compounds acting as electron donors to the triplet excited state of C_{60}. When an unsymmetric allylic stannane such as γ,γ-dimethyl substituted allyl stannane **18** (Scheme 7) is employed,[82,83] the allylic group is introduced selectively at the α-position to yield C_{60}–1,2-$CH_2CH{=}CMe_2$ **19**. Since the allylic group is introduced selectively



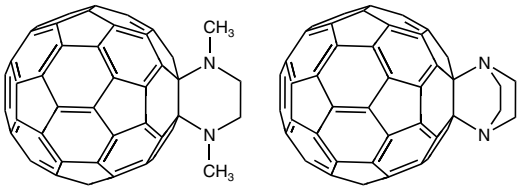
SCHEME 8 Mechanism for the reaction of C_{60} and tertiary amines $RN(Me)_2$ (R=CH_3, Ph) leading to monosubstituted 1,2-dihydro[60]fullerenes.

at the α-position and no γ-adduct has been formed, the SnC bond of the allylstannane radical cation formed in the photoinduced electron transfer may be nearly cleaved prior to the CC bond formation with $C_{60}^{\bullet-}$ in the radical ion pair.[83]

The reaction of fullerenes with amines has been the subject of considerable interest. Whereas primary and secondary amines readily add to C_{60} to give 1-H-2-(NR′R″)C_{60},[84] tertiary amines such as triethylamine, *N,N*-diethylaniline and *N,N*-dimethylaniline do not undergo the same type of addition due to the absence of an NH bond. Instead, weak charge transfer complexes with C_{60} are formed in the ground state.[85–87] Photoexcitation of amine [60]fullerene solutions leads to electron transfer from amines to the fullerene and the formation of C_{60}^{-} amine^{+} ion pairs.[22,31,53,88,89] For amines possessing α-hydrogens, proton transfer from amines to C_{60} is possible to give photochemical products.[90,91] When tertiary amines are reacted with C_{60} under PET conditions, these reactions usually result in the formation of pyrrolidinofullerenes (see the section below on [2 + 3]-photocycloaddition). Nevertheless, in some cases monosubstituted 1,2-dihydro[60]fullerenes are obtained. For example, Liou et al. reported the photochemical reaction of triethylamine and *N,N*-dimethylaniline with C_{60}.[92] Irradiation of C_{60} in the presence of an excess of amine **20a–b** in toluene slowly led to the isolation of **21a–b** (Scheme 8). No cycloadduct similar to the pyrrolidinofullerenes obtained from the irradiation of triethylamine and C_{60} was detected. In the case of **21b** (R = phenyl), further irradiation led to the pyrrolidinofullerene **22b** and a dihydrogen derivative, 1,2-H_2C_{60}, suggesting that **21b** is an intermediate for **22b**. Initial formation of the $C_{60}^{\bullet-}$-$D^{\bullet+}$ radical ion pair is followed by deprotonation of the amine cation by the fullerene anion to give an α-aminoalkyl and HC_{60} radical pair.[90] Subsequent combination of the radical pair leads to the final product. Formation of **22b** is likely to be initiated by PET from **21b** to C_{60}. This is then followed by successive intermolecular proton transfer, hydrogen abstraction, and ring closure to give 1,2-H_2C_{60} and **22** (Scheme 8).

Using diamines such as *N,N′*-dimethylethylenediamine or piperazine leads to the formation of heterocycle-fused fullerene derivatives **23** and **24** (Figure 28.4).[96] Again, the reaction proceeds via single elctron transfer to give the $C_{60}^{\bullet-}$-$D^{\bullet+}$ radical ion pair followed by successive intermolecular proton transfer, which completes the addition reaction with [60]fullerene.

Gan et al. used amino acids such as piperidino acetic acid or morpholino acetic acid in photochemical reactions with C_{60}.[93,94] Whereas the reaction of the ester derivatives of the amino acids results in the formation of pyrrolidine-fused C_{60} derivatives, the reactions of the free amino acids **25a–b** give the 1-substituted 1,2-dihydro[60]fullerenes **26a–b** (Scheme 9). The first step in the formation of the dihydrofullerenes is electron



23 **24**

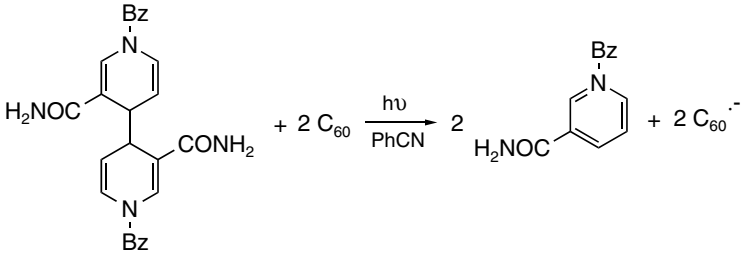
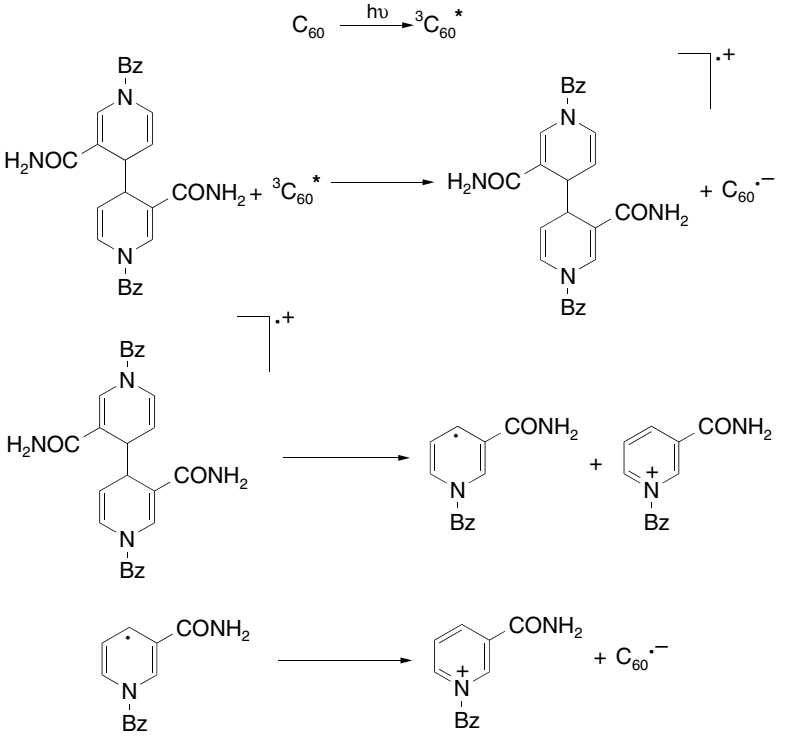


SCHEME 10 Generation of $C_{60}^{\bullet -}$ by selective one-electron reduction with $[(BNA)_2]$ in deaerated benzonitrile at $\lambda > 540$ nm.

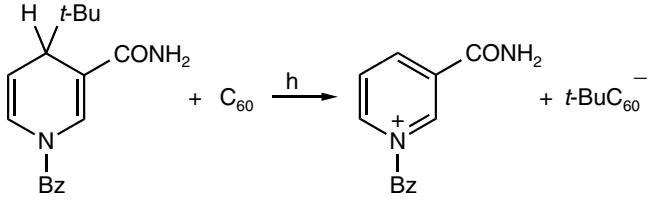
transfer and proton loss. The CO_2 loss from carboxyl radicals is well known.[95] The aminomethyl radical formed by this path then adds to C_{60}. The final step is the abstraction of hydrogen from the environment.

The radical anion $C_{60}^{\bullet -}$ can also be easily obtained by photoinduced electron transfer from various strong electron donors such as tertiary amines (*vide supra*), ferrocenes, tetrathiafulvalenes, and thiophenes. In homogeneous systems, back electron transfer to the reactant pair plays a dominant role resulting in an extremely short lifetime of $C_{60}^{\bullet -}$. In these cases, no net formation of $C_{60}^{\bullet -}$ is observed. These problems were circumvented by Fukuzumi et al. by using NADH analogues as electron donors.[97,98] Selective one-electron reduction of C_{60} to $C_{60}^{\bullet -}$ takes place by the irradiation of C_{60} in a deaerated benzonitrile solution upon the addition of 1-benzyl-1,4-dihydronicotinamide (BNAH) or the corresponding dimer $[(BNA)_2]$ (Scheme 10).[97] The formation of $C_{60}^{\bullet -}$ is confirmed by the observation of the absorption band at 1080 nm in the NIR spectrum assigned to the fullerene radical anion.

As shown in Scheme 11, the triplet excited state $^3C_{60}^*$ is quenched by electron transfer from $[(BNA)_2]$, generating the radical ion pair $[(BNA)_2^{\bullet +}$ and $C_{60}^{\bullet -}]$, in competition with the decay to the ground state. However, back electron transfer is reduced by the fast cleavage of the CC bond in the dimer $[(BNA)_2^{\bullet +}]$. Finally, a second electron transfer from $BNA^{\bullet}$ occurs leading to two molecules of $C_{60}^{\bullet -}$. The photoreduction of C_{60} with BNAH also proceeds via photoinduced electron transfer. In this case, C_{60} is also reduced



SCHEME 11 Mechanism for the generation of $C_{60}^{\bullet-}$ by selective one-electron reduction with [$(BNA)_2$].

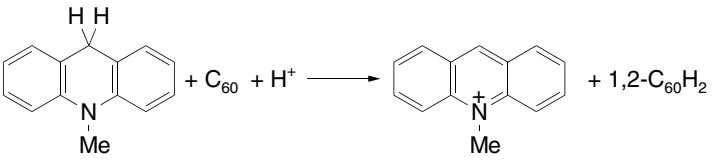


SCHEME 12 Selective two-electron reduction of C_{60} to t-BuC_{60}^-.

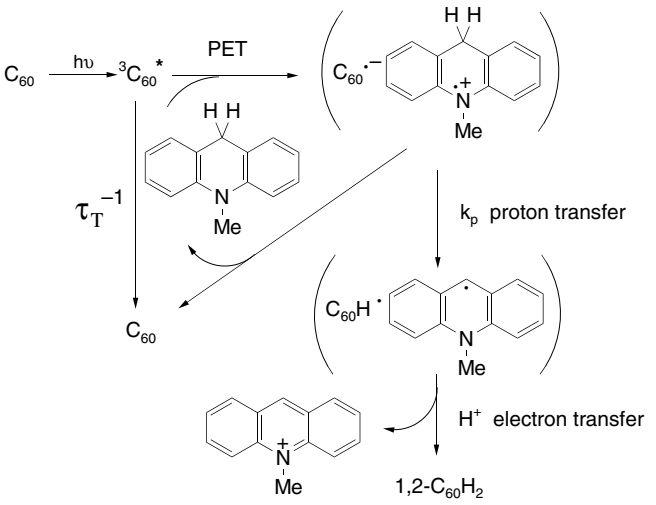
to the monoanion by $BNA^{\bullet}$, which is formed through deprotonation of $BNAH^{\bullet+}$. Formation of $C_{70}^{\bullet-}$ is also attained through photoinduced electron transfer from BNAH and [$(BNA)_2$] to the triplet excited state of C_{70}.[98]

In addition, Fukuzumi et al. observed selective two-electron reduction of C_{60} when BNAH is replaced by the 4-*t*-butylated BNAH (*t*-BuBNAH) in the above reaction, leading to the formation of *t*-BuC_{60}^- and the two-electron oxidation of BNAH to BNA^+ (Scheme 12). Subsequent trapping of initially formed t-BuC_{60}^- by CF_3COOH and $PhCH_2Br$ results in formation of the corresponding 1,2-substituted dihydrofullerene for the former and 1,4-substituted adduct for the latter.[99] The initial product of 1,4-*t*-$BuC_{60}H$ is rearranged to the 1,2-isomer during the isolation procedure to give the 1,2-adduct exclusively.[100]

Again, photoinduced electron transfer to the triplet excited state $^3C_{60}^*$ is the initial step to yield *t*-$BuBNAH^{\bullet+}$ and $C_{60}^{\bullet-}$. Upon C(4)-C bond cleavage of *t*-$BuBNAH^{\bullet+}$, the *t*-butyl radical is formed, which readily adds to the fullerene radical anion yielding *t*-BuC_{60}^-. In competition, back electron transfer takes place. Similar results are obtained in the photochemical reaction of C_{70} with the NADH analogues mentioned above. The reaction mechanism remains the same in the case of *t*-BuBNAH. However, there are some differences in the reaction mechanism for [$(BNA)_2$] and BNAH. After the photoinduced electron



SCHEME 13 Selective two-electron reduction of C_{60} to 1,2-$C_{60}H_2$.



SCHEME 14 Mechanism for the selective two-electron reduction of C_{60} to 1,2-$C_{60}H_2$.

transfer reaction from [$(BNA)_2$] to C_{70}, resulting in the formation of the radical ion pair, CC bond cleavage of the dimer leads to C_{70}^{2-}, which is followed by facile electron transfer from C_{70}^{2-} to C_{70} to give two equivalents of $C_{70}^{\bullet -}$. In the case of BNAH, CH bond cleavage occurs to give HC_{70}^- and BNA^+. Subsequent electron transfer from C_{70}^{2-}, which is in equilibrium with HC_{70}^-, to C_{70} leads to the formation of two equivalents of $C_{70}^{\bullet -}$.

Using 10-methyl-9,10-dihydroacridine ($AcrH_2$) in the photochemical reaction with C_{60} in the presence of CF_3COOH, 1,2-$C_{60}H_2$ is formed exclusively (Scheme 13).[97] The reaction mechanism is shown in Scheme 14. Proton transfer from $AcrH_2^{\bullet +}$ to $C_{60}^{\bullet -}$ is significantly exergonic and occurs efficiently in the radical ion pair to give $C_{60}H^{\bullet}$. The product 1,2-$C_{60}H_2$ is obtained by fast electron transfer from $AcrH^{\cdot}$ in the presence of CF_3COOH. Protonation of $C_{60}^{\bullet -}$ by the acid and subsequent hydrogen transfer from $AcrH_2^{\bullet +}$ to $C_{60}H^{\bullet}$ yielding the final products, are also possible.

Photocycloaddition

Among the reactions applied in the synthesis of fullerene derivatives, cycloaddition reactions such as [2 + 1]-, [2 + 2]-, [3 + 2]- and [4 + 2]-cycloadditions play a dominant role. In these reactions, ring-fused fullerene derivatives are obtained, at least, with incorporation of heteroatoms such as oxygen or nitrogen. Such reactions will be the topics of the following sections.

[2 + 1]-Photocycloaddition

In general, by [2 + 1]-photocycloaddition reactions methanofullerenes, fullerene epoxide, and aziridinofullerenes as the corresponding oxygen and nitrogen analogues with a [6,6]-closed structure are obtained as shown in Figure 28.5.

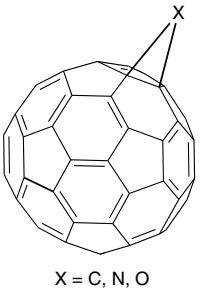


FIGURE 28.5 Fullerene derivatives obtained by [2+1]-photocycloaddition: methanofullerene, fullerene epoxide, and aziridinofullerene.

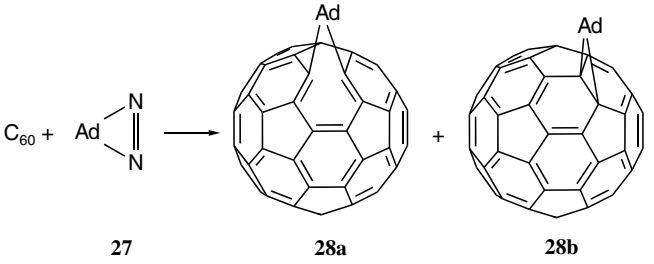
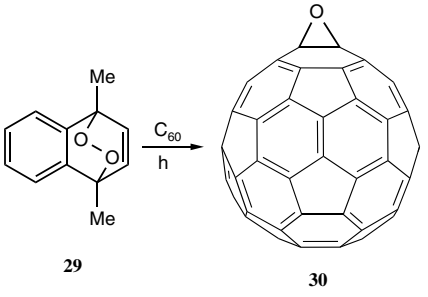


SCHEME 15 Photolysis of 2-adamantane-2,3′-[*3H*]-diazirine **27** and C_{60} with a high-pressure mercury lamp (cutoff <300 nm).



SCHEME 16 Irradiation of C_{60} and endoperoxide **29**.

Recently, Akasaka et al.[101] described the photochemical reaction of diazirine **27** with C_{60} resulting in the formation of a mixture of the isomers **28a** and **28b** in a ratio of 51:49 (Scheme 15). Structure elucidation by UV-vis spectroscopy and NMR investigations clearly demonstrates that isomer **28b** is the 6,6-adduct of C_{60} with C_{2v} symmetry, namely the methanofullerene. There is crucial evidence supported by ^{1}H and ^{13}C NMR that the isomer **28a** is the 5,6-adduct (fulleroid) of C_{60} with C_s symmetry. Isomerization of the pure fulleroid to the methanofullerene or *vice versa* upon photolysis, as reported by Wudl et al.,[102] is not observed; thus, the isomeric ratio of the two isomers reveals the formation ratio of carbene and diazo compound during the reaction.

Fullerene epoxide ($C_{60}O$, **30**), the oxygen analogue of the methanofullerene, can be obtained by the extended irradiation of C_{60} in an oxygen atmosphere as reported by Smith et al.[103] Irradiation of C_{60} with

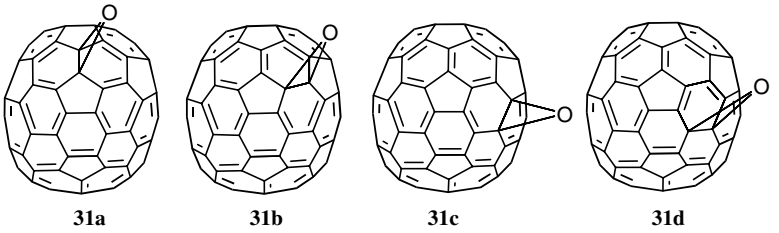


FIGURE 28.6 Possible C_{70} O isomers.

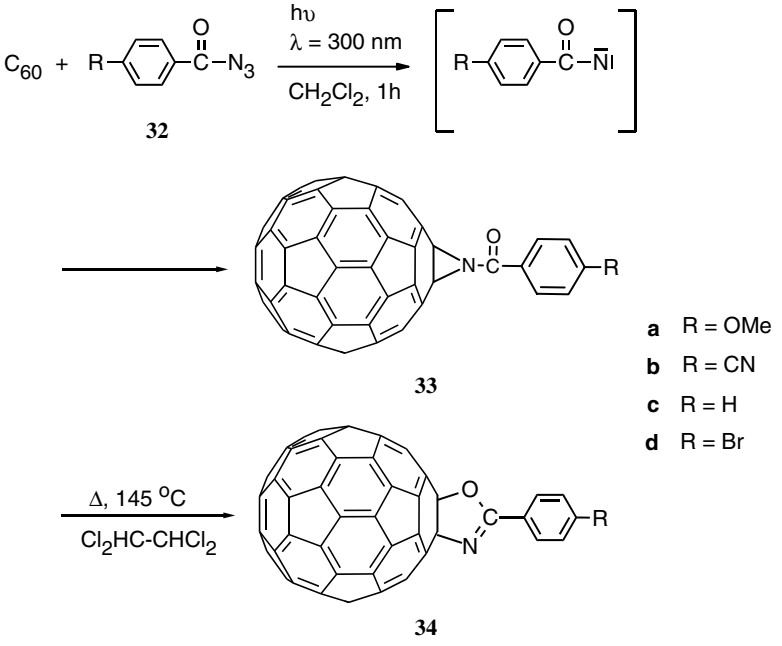
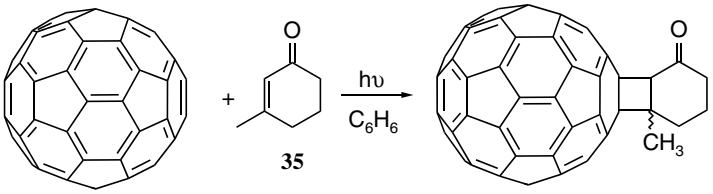


SCHEME 17 Photolysis of C_{60} and aroylazides **32a-d** in oxygen-free 1,1,2,2-tetra-chloroethane at $\lambda = 300$ nm.

endoperoxides **29**[104] leads to the formation of epoxide **30** in high yields (Scheme 16). Singlet oxygen $^1O_2$ released from the endoperoxides is the key species in the mechanism for fullerene oxide formation under photochemical reaction conditions and suggests that $C_{60}O$ results from reaction of $^1O_2$ with C_{60} triplet excited states as primarily suggested by Juha et al.[105]

Heymann et al.[106] as well as Smith et al.[107] reported the synthesis of $C_{70}O$ **31** by photo-oxygenation. Irradiation of an oxygenated toluene solution of C_{70} using rubrene as a sensitizer resulted in the formation of a nearly 1:1 mixture of two $C_{70}O$ isomers **31a** and **31b**, which cannot be separated (Figure 28.6). No evidence for the formation of isomers **31c** and **31d** was found.

The thermal reaction of nitrenes resulted in the formation of the nitrogen analogues of the fullerene epoxide, the aziridinofullerenes, and the 5,6-open azafulleroids.[108] Under photochemical reaction conditions, aziridinofullerenes are observed as the only addition product of nitrenes. Photochemical synthesis of aziridinofullerenes was first reported by Keana et al.[109] in low yields, probably due to the addition of the nitrene to the solvent chlorobenzene.[110] Averdung et al. also obtained several aziridinofullerenes by the reaction of C_{60} with acylnitrenes, generated by photolysis of aroylazides **32a–d**, leading to the fullerene adducts **33a–d** (Scheme 17).[111] The structures of the [6,6]-ring fused 1,2-dihydrofullerenes have been



35 **36**

SCHEME 18 Reaction of C_{60} with cyclic enone **35**.

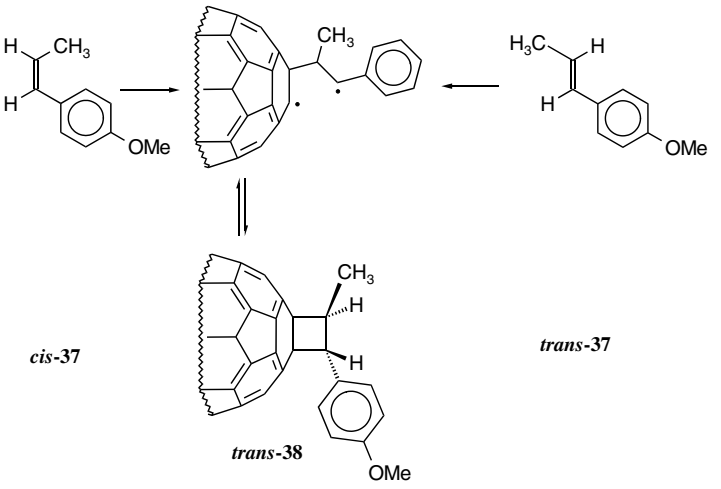
identified by standard spectroscopic methods. Irradiation at wavelengths >380 nm did not result in product formation. Thus, the formation of the acylnitrenes does not occur via excited C_{60}. The reaction of C_{60} and 4-cyanobenzoylazide **32b** in benzene at 300 nm did not lead to the expected fulleroaziridine **33b**. Instead, a 6,6-bridged dihydrofullerene was obtained as a main product. Mass spectral analysis and NMR spectroscopic investigations indicate an asymmetrical fullerene structure formed by reaction of the nitrene to C_{60} with incorporation of benzene, similar to the incorporation of benzene in the reaction of 1,8-dehydronaphthalene with C_{60}.[112] The exact structure still remains unknown. As a minor product, the fullerooxazole **34b** was observed. The formation of the corresponding fullerooxazoles **34a–d** was also observed by the thermal rearrangement of aziridinofullerenes.

[2 + 2]-Photocycloaddition

A very versatile method of formation of fullerene adducts is the [2 + 2]-photocycloaddition. The preparation and isolation of well-characterized [2 + 2]-monoadducts of C_{60} with alkynes,[113] arylalkenes,[114] dienes,[115] cycloenones,[116] acyclic enones,[117] and diones[118] has been reported. The pioneering work on this useful synthetic pathway was executed by Schuster and co-workers in 1993. In their first attempts, a crown-ether tagged fulleroid and various cyclohexen-2-one derivatives were used in the cycloaddition reaction.[62,119] Once the reaction was successfully performed, Schuster and co-workers synthesized cyclobutane–fullerene adducts by the irradiation of C_{60} (Scheme 18).[62] Up to seven enone units are incorporated on longer irradiation time. As shown by ^{1}H-NMR, IR and HPLC analysis, the isolated monoadducts consist of a mixture of two stereoisomers, the *cis*- and *trans*-isomers arising from the [2 + 2]-cycloaddition across the [6,6]-ring junction in C_{60}; the major product normally is *trans*. When 3-methyl-2-cyclohexen-1-one is used in the reaction, the obtained fullerene derivatives are chiral. Semipreparative HPLC analysis with a chiral stationary phase (*S,S*)-Whelk-O HPLC column results in the separation of the four stereoisomers.[118]

No product formation was observed upon irradiation at 532 nm where the fullerene is the only light-absorbing component. Thus, fullerene triplets do not undergo addition to ground-state enones. Instead, the reaction proceeds by the same mechanism operating in the photoaddition of enones to ordinary alkenes,[120] namely stepwise addition of enone triplet excited states to the fullerene via an intermediate triplet 1,4-biradical.

Orfanopoulos and co-workers studied the photochemical reaction of alkenes, aryalkenes, dienes, dienones, and acyclic enones with [60]fullerene to obtain various substituted cyclobutanofullerenes.[114,115,117,121] For example, the photocycloaddition of *cis*- and *trans*-1-(*p*-methoxyphenyl)-1-propene **37** to C_{60} gives only the *trans* [2 + 2]-adducts; thus, the reaction is stereospecific for the most thermodynamically stable cycloadduct (Scheme 19). A possible mechanism includes the formation of a common dipolar or biradical intermediate between $^3C_{60}$* and the arylalkene, followed by subsequent fast rotation of the aryl moiety around the former double bond leading to *trans*-**38**. Irradiation of this product yielded 90% *trans*-**37** and 10% *cis*-**37** as cycloreversion products. As the photocycloreversion is expected to give *trans*-**37** as the only product, a concerted mechanism can be excluded. Similarly, cycloreversion products from C_{60} and tetraalkoxyethylene adducts were also observed by Foote et al.[113b] As reported by this research group, the cycloreversion proceeds via the triplet excited state of the adduct because rubrene



SCHEME 19 Reaction of C_{60} and *cis*-37/*trans*-37 at $\lambda > 530$ nm and proposed mechanism for this reaction.

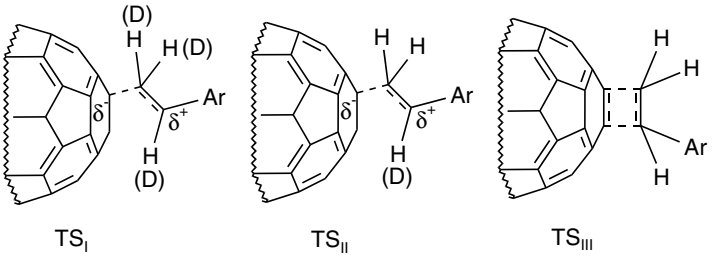


FIGURE 28.7 Possible transition states in the reaction of C_{60} with deuterated 1-(*p*-methoxyphenyl)ethylene.

and oxygen efficiently inhibit photocycloreversion. However, these results do not exclude an electron transfer or charge transfer mechanism with loss of stereochemical integrity.

Studies of the secondary isotope effect also confirmed the two-step mechanism, involving the formation of a dipolar or biradical intermediate in the rate-determining step. The observed isotope effects in the reaction of 1-(*p*-methoxyphenyl)-ethylene and its deuterated analogues 1-(*p*-methoxyphenyl)-ethylene-d_1 and 1-(*p*-methoxyphenyl)-ethylene-d_3 with C_{60}, when taken in conjunction, exclude the formation of transition state TS_{III} (concerted mechanism), because in that case substitution at either C_α or C_β would have given an inverse isotope effect (Figure 28.7).

Furthermore, addition reactions of alkyl-substituted 1,3-butadienes to C_{60}[115] supported the suggested two-step mechanism via a dipolar or biradical intermediate. The formation of this intermediate is responsible for the observed regioselectivity and the secondary isotope effects. The second step (collapse of the initial ion pair) dictates the diastereoselectivity that favors the more thermodynamically stable *trans*-cyclobutane products. The lifetime of the biradical intermediate is long enough to allow rotation around the C2C3 bond in the 1,3-butadienes, leading to loss of stereochemical integrity of the cycloadducts. However, the stereochemistry of the unreacted double bond of the dienes is retained, and this result is consistent with the known propensity of allylic radicals to resist rotation around the partial double bond. The regio- and stereoselectivity can also be observed in the reaction of acyclic enones to C_{60}.[117]

42

SCHEME 21 Photochemical reaction of sarcosine esters with C_{60}.

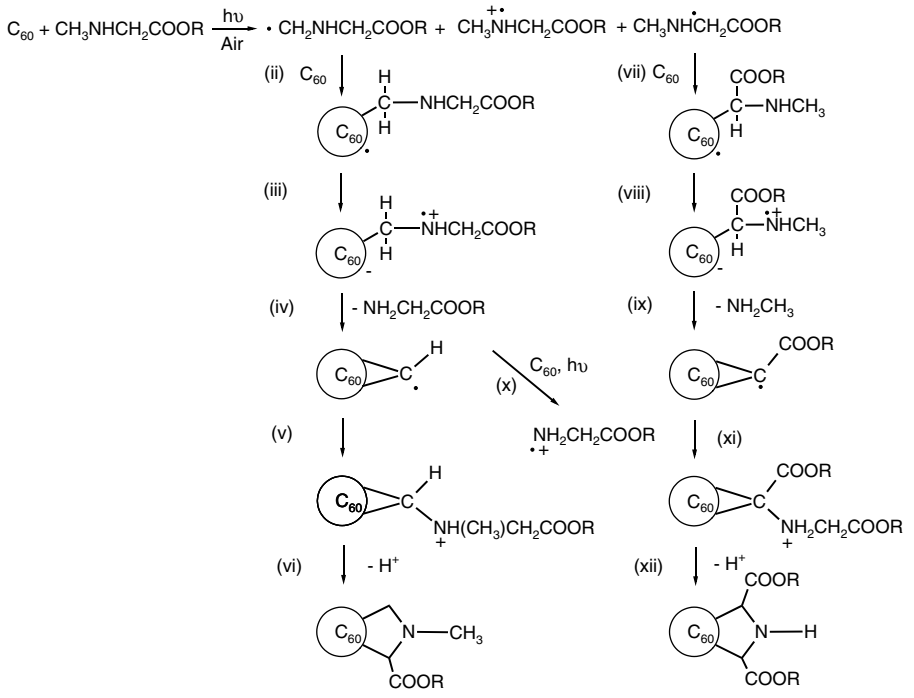
[2 + 3]-Photocycloaddition

The photochemical functionalization of fullerenes with amines leading to monosubstituted 1,2-dihydro[60]fullerenes has already been discussed in the section "Synthesis of Substituted 1,2-Dihydro[60]fullerenes by Reductive PET." In this context, formation of pyrrolidinofullerenes as the main reaction products, when tertiary amines are reacted with C_{60} under PET conditions, has already been mentioned. The synthesis of the pyrrolidinofullerenes via 1,3-dipolar cycloaddition of azomethine ylides has met a broad acceptance, probably due to the many ways to generate the reactive intermediates from a wide variety of easily accessible starting materials. The most successful approach has been the decarboxylation of iminium salts derived from condensation of α-amino acids with aldehydes.[122] An alternative way to pyrrolidinofullerenes was developed by Gan et al. using amino acid esters in both thermal and photochemical reactions with C_{60}.[123] For example, refluxing a mixture of C_{60} and glycine ethyl ester **39** afforded two products in a 4:1 ratio, with pyrrolidinofullerene **40** as the major product and **41** as the minor product, whereas upon photolysis **41** is the only isolated product indicating that the thermal and photochemical reactions follow different mechanisms (Scheme 20).

For the photochemical reaction, an air-assisted radical reaction mechanism was proposed, in which both CN bond breaking and bond formation processes are involved. Recently, Foote et al.[124] confirmed the involvement of singlet oxygen by a control experiment. The reaction of the glycine ester with C_{60} was performed thermally under the same reaction conditions using $DMNO_2$ as the singlet oxygen source, resulting in the formation of a product with identical ^{1}H-NMR and ^{13}C-NMR spectra to that reported by Gan et al.

When sarcosine esters are reacted with [60]fullerene, compounds **41**, bearing two ester functionalities, and **42**, containing only one ester functionality, are obtained (Scheme 21). Sarcosine has one more methyl group than glycine, which results in the amino group being more basic and also more crowded. Obviously, the electronic effect predominates leading to an increased rate compared to the glycine analogues.

The reaction mechanism for the sarcosine ester reaction is outlined in Scheme 22. In the first step three radicals are formed: the aminium radical cation (a) arising from single electron transfer from the amino group to C_{60} and the two carbon-centered radicals (b,c) produced by the interaction with $^1O_2$,



SCHEME 22 Mechanism for the photochemical reaction of sarcosine esters.

which is generated by C_{60} efficiently. Addition of the carbon-centered radicals to the fullerene is followed by electron transfer from the amine to the C_{60} fragment to form the zwitterionic radical (Step iii). The CN bond cleavage and the release of glycine at Step iv is unusual and may be due to the unique properties of C_{60}. Moderate heating is probably necessary due to the endothermic CN bond-breaking step. The driving force for the rearrangement in Steps vi and xii may be the more stable five-membered ring. Besides the main products **41** and **42**, several other products are possible, such as $C_{60}(CH_2)$, C_{60}(HCCOOR), and the amine addition product $C_{60}(H)(CH_3NCH_2COOR)$.

Photolysis of aminopolycarboxylates such as tetramethyl ethylenediaminetetraacetate (EDTA) **43** and pentamethyldimethylenetriaminepentaacetate (DTPA) **47** with C_{60} has been shown to be an effective method for the preparation of isomerically pure pyrrolidinofullerene derivatives, which can be used as complexones or polydentate ligands.[94] The presence of free acid functionalities leads to decarboxylation, and 1-alkylated 1,2-dihydro[60]fullerenes are formed as described by Zhang et al.[93] In case of esters, pyrrolidine-fused fullerenes are the major products. All reactions involve radicals as described for the photoaddition of glycine and sarcosine esters. Unlike primary amino acid esters, which undergo complicated bond-breaking and formation processes, amino acid esters with secondary and tertiary amino groups add to C_{60} simply by losing two H atoms. In comparison to the well-known synthesis of pyrrolidine ring-fused fullerene adducts in the above reaction, the use of aldehydes or ketones can be avoided. Table 28.3 gives a short overview of fullerene derivatives obtained by the photoreaction of EDTA and DTPA.

As a last example of fullerene functionalization leading to pyrrolidinofullerenes, the photoreaction of triethylamine (TEA) with C_{60} should be discussed. Fullerene C_{60} undergoes efficient photochemical reactions with TEA to form a complex mixture of addition products under ambient and deoxygenated conditions.[125] The reactions are initiated via photoinduced electron transfer between the excited singlet C_{60} and the amine. Three types of cycloadducts of fullerenes — **50**, **51**, and **52** — were obtained, whereas the formation of the mono-alkylated 1,2-dihydro[60]fullerene **53**, as described by Liou et al.[92] in the reaction of trimethylamine and *N*,*N*-dimethylaniline with C_{60}, was not observed (see Figure 28.8).

Compound **50** was formed in the deoxygenated solution, and compounds **51** and **52** were obtained by irradiation of air-saturated solutions. Sun and co-workers suggest that the simple adduct **53** should be the initial product formed in C_{60}-tertiary amine photochemical reactions regardless of whether the reaction is performed in deoxygenated or air-saturated solutions. The monoadducts isolated and identified by Sun et al. are completely different from those expected on the basis of the photoinduced

sequential electron transfer, proton transfer, and radical combination mechanism, which is well established in reactions of conventional aromatic molecules with tertiary amines. The complexity in the reactions involving fullerenes is attributed to the fact that the functionalized fullerenes remain electron acceptors for both inter- and intramolecular electron transfer reactions. The observed C_{60}-TEA photoadducts are likely from multistep processes, each of which may involve either inter- or intramolecular photoinduced electron transfer.

The photochemical [3 + 2]-cycloaddition of 2*H*-azirines with C_{60} has been intensively studied by Mattay et al.[126,127] Photolysis of a equimolar solution of C_{60} and **54a–c** leads to the corresponding monoadducts **55a–c**, which have a closed [6,6]-bridged 1,2-dihydrofullerene structure with C_1 symmetry as confirmed by UV spectroscopy and NMR investigations (Scheme 23). An open [1,6]-substituted [10]annulene structure can be excluded. Upon irradiation of a 10-fold excess of 2,3-substituted-2*H*-azirines **54a–c** with [60]fullerene, formation of mono- and oligoadducts is observed. In all cases a fraction of regioisomeric bisadducts can be obtained, which were not separated.

The formation of the [3 + 2]-cycloadduct **55** can be explained by two different reaction pathways (Scheme 24). Irradiation at 300 nm leads to ring opening of the azirine **54** to the nitrile ylide as an intermediate, which adds to C_{60} yielding the observed product **55**. No product formation is observed at wavelengths >400 nm. Instead, under photoinduced electron transfer conditions in the presence of 9,10-dicyanoanthracene (DCA), the [3 + 2]-cycloaddition reaction proceeds via the 2-azaallenyl radical cation.

[2 + 4]-Photocycloaddition

The thermal Diels–Alder reaction ([4 + 2]-cycloaddition) is widespread in the synthesis of fullerene derivatives. In contrast, only a few examples of photochemical Diels–Alder reactions in solution or in the solid state are known. Among the functionalization of C_{60}, Diels–Alder reactions with *o*-quinodimethanes as dienes are very versatile because they provide thermally stable adducts that are usually not subjected to cycloreversion to the original components. The photoirradiation of *o*-toluylaldehyde and related carbonyl compounds is known to give an *o*-quinodimethane species carrying a hydroxy group via the biradical generated by the intramolecular hydrogen abstraction of the carbonyl group in the excited triplet state ($n\pi^*$) from the neighboring methyl group.[128] Instead of the desired cyclohexyl-fused

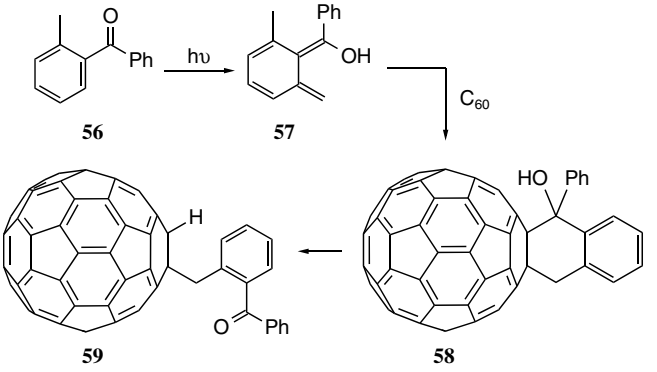
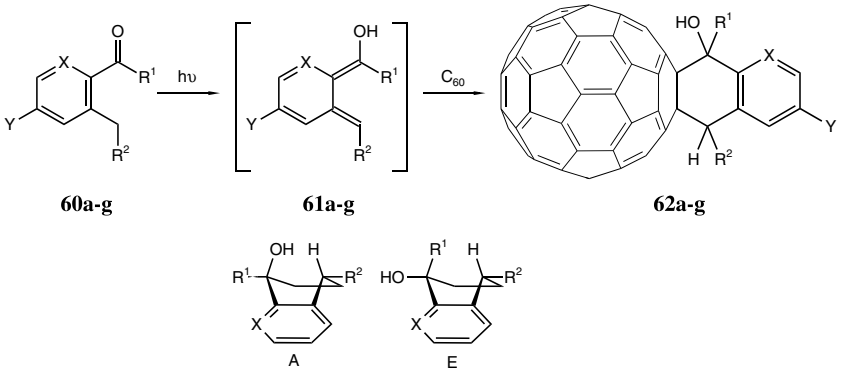


SCHEME 25 Irradiation of ketone **56** and C_{60} leading to monoalkyl-1,2-dihydro-[60]fullerene **59**.

fullerene derivative **58**, which is unexpectedly unstable, Tomioka et al. observed, in their study of the photoreaction of *o*-methylbenzophenone **56** with C_{60}, the formation of the monoalkyl-1,2-dihydrofullerene **59** by the cleavage of the CC bond connected to the fullerene core (Scheme 25).[129]

In contrast, Nishimura et al. obtained stable monoadducts **62a–g** possessing a hydroxy group suitable for further derivatization from the [2 + 4]-photocycloaddition of the corresponding carbonyl compounds **60a–g** and [60]fullerene (Scheme 26).[130] The adducts **62** were found to adopt one or both of two conformers **A** and **E**, which possess pseudoaxial and pseudoequatorial hydroxy groups, respectively (see Table 28.4). Two conformers existed for **62a**, **c**, **d**, and **f**, while **62b**, **e**, and **g** exclusively adopted **E**, **A**, and **E**, respectively. The comformer ratios remarkably depend on the bulkiness of the substituents attached to the aromatic nucleus and the cyclohexene ring.



SCHEME 26 [4+2]-photocycloaddition of C_{60} with *o*-quinodimethane derivatives generated from carbonyl compounds.

Mikami et al. investigated the photochemical Diels–Alder reaction of anthracenes with C_{60} in the solid state.[131] Irradiation of a mixture of C_{60} and 9-methylanthracene led to the formation of mono- and bisadducts. No formation of 9-methylanthracene dimers as in solution was observed. The reaction did not work with less bulky anthracenes. The reaction rate depends on the ionization potential of the anthracenes. With decreasing ionization potential, the Diels–Alder reaction of C_{60} proceeds much more easily. Therefore, the reaction may proceed via photoinduced electron transfer from anthracenes to the triplet excited state of C_{60}. The energetics for the photoinduced electron transfer in the solid state are significantly different from those in solution where solvation plays an important role. Such a difference leads to the different reactivity of the anthracene derivatives in the solid state as compared to that in solution.

Recently, Fukuzumi et al. reported the photochemical Diels–Alder reaction with Danishefsky's diene.[132] A mixture of C_{60} and the stereochemically defined (1*E*,3*Z*)-1,4 disubstituted Danishefsky's diene **63** was irradiated for 9 h at –30°C to avoid the thermal reaction. After work-up, two desilylated adducts **65** were obtained, the major being the *trans*-product, the minor the *cis*-product (Scheme 27).

TABLE 28.4 Photoreaction of [60]fullerene with **60**[130b]

	X	R_1	R_2	Y	Adduct	Yield/%[a]	Conformer ratio **A/E**[b]
60a	CH	H	H	H	**62a**	32 (63)	4:6
60b	CH	H	Me	H	**62b**	17 (80)	0:10[c]

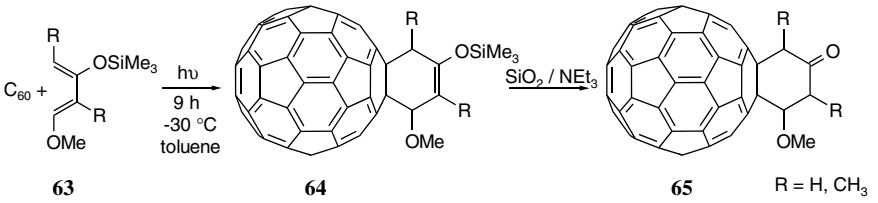
[a] Isolated yields are shown, although not optimized. Recovery of C_{60} is also shown in parenthesis.

[b] The symbols A and E denote conformers possessing pseudoaxial or pseudo-equatorial hydroxy group, respectively.

[c] Only a single isomer was obtained in which both the hydroxy and methyl groups adopt pseudoequatorial conformations.

[d] A trace amount of the decomposition product is included.



SCHEME 27 Irradiation of C_{60} and Danishefsky's diene **63**.

The same *trans*-product **65** is obtained as a single isomer after short irradiation, indicating that the *cis*-isomer may be formed by isomerization of the *trans*-adduct after a longer irradiation period, which is indicative of the Diels–Alder reaction proceeding by a stepwise mechanism rather than a concerted mechanism. Initially, the triplet radical ion pair (**A**) is formed by photoinduced electron transfer from **63** to triplet excited C_{60} (k_{et}) (Scheme 28), which then provides the singlet radical ion pair leading to a biradical intermediate (**B**) or a zwitterionic intermediate (**C**) in competition with back electron transfer to the reactant pair (k_b). In the latter case, the initial C–C bond formation should occur between the C4 carbon of **63**$^{\bullet+}$ and the $C_{60}^{\bullet-}$, while in the former it occurs betweenb the C1 carbon of **63**$^{\bullet+}$ and the $C_{60}^{\bullet-}$. Despite the fact that there are difficulties in distinguishing between the two possible reaction pathways, one can conclude that in any case the formation occurs stepwise, and thus there is no symmetry restriction for bond formation. Both *trans*-adduct and *cis*-adduct **65** are obtained as the final products.

28.4 Photochemistry of C_{60} and C_{70} Derivatives

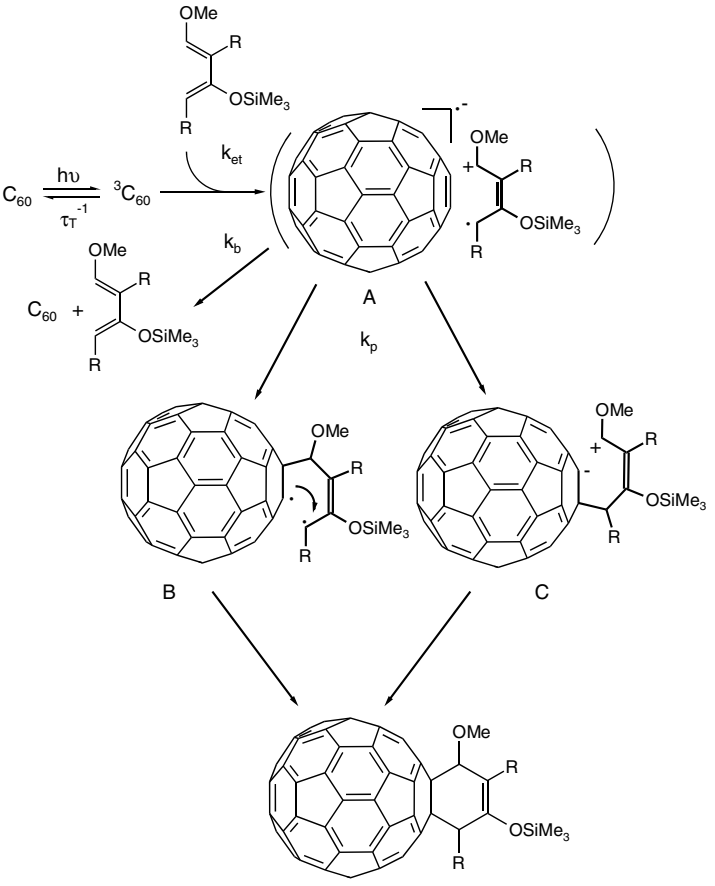
Addition of Singlet Oxygen

The triplet excited state of C_{60} is formed with a quantum yield close to unity,[22] and by energy transfer to molecular oxygen, it produces large quantities of singlet oxygen (Equation 28.2). This useful photochemical property makes C_{60} a potent sensitizer for the mild photooxygenation of simple alkenes and dienes.[133]

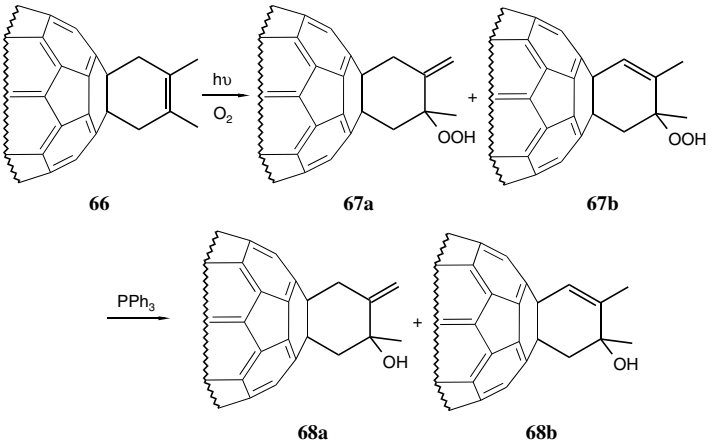
$$^3C_{60/70}{}^* + {}^3O_2 \rightarrow C_{60/70} + {}^1O_2 \qquad (28.2)$$

As fullerene adducts with an oxidizable group are sensitive to oxygen and light,[134] a variety of oxygenated derivatives are available by self-sensitized photooxygenation. This is a simple synthetic strategy for oxo functionalization leading to fullerene compounds with better solubility in more polar solvents.[135] This useful observation has been applied successfully in photosensitized studies of biological systems.[6,136] Rubin et al. reported previously an unexpected regioselectivity in the self-sensitized ene photooxygenation of several adducts prepared by [4 + 2]-cycloaddition to C_{60} (Scheme 29).[137] In almost all cases, the reactions resulted in the formation of allylic alcohols **68** with endocyclic double bonds after reduction of the corresponding hydroperoxides **67** with PPh_3.[137]

In contrast, reaction of alkyl-substituted cyclohexenes yields a majority of products with an exocyclic double bond.[138] The unexpected regioselectivity is explained in conformational and electrostatic terms. The boat conformation of the C_{60}-fused cyclohexenes confers a rigid framework to the six-membered ring in which two of the 3,6 hydrogens are pseudoaxial. Because of favorable interactions between the incoming $^1O_2$ and these axial hydrogens, the *endo*-perepoxide resulting from transition state $\mathbf{TS_I}$ is formed, rather than the *exo*-isomer derived from transition state $\mathbf{TS_{II}}$ (Figure 28.9). Additional favorable electrostatic or electronic interactions may exist between the negative oxygen of the developing *endo*-perepoxide I and C_{60}, which is strongly electron deficient.



SCHEME 28 Proposed mechanism for the irradiation of C_{60} and Danishefsky's diene **63**.



SCHEME 29 Self-sensitized ene photooxygenation of fullerene adduct **66** leading to allylic alcohols.

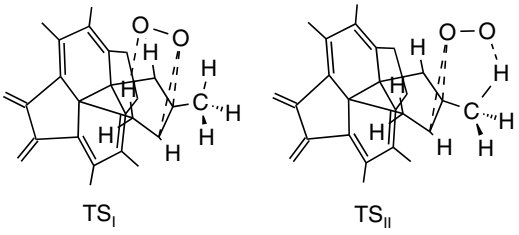


FIGURE 28.9 Transition states in the photooxygenation of C_{60}-fused cyclohexenes.

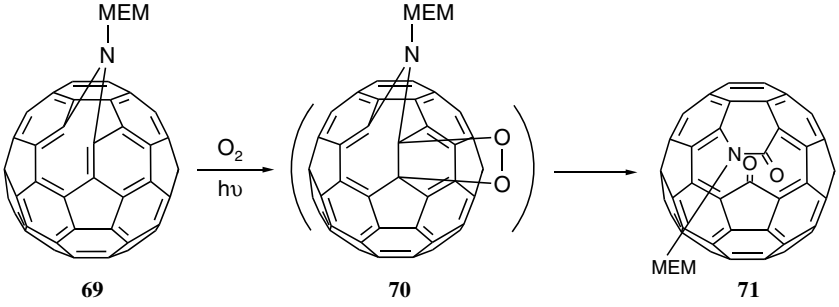
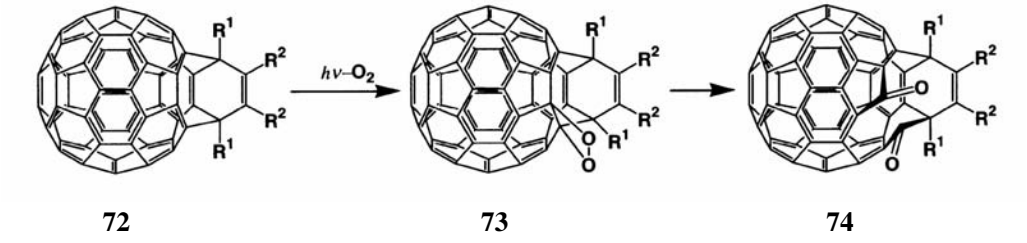


SCHEME 30 Self-sensitized photooxygenation of *N*-(MEM)-substituted [5,6]-azafulleroid **69**.

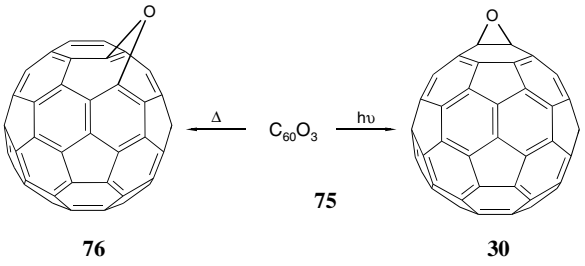


SCHEME 31 Self-sensitized photooxygenation of tetrasubstituted bis(fulleride) derivatives **72**.[146]

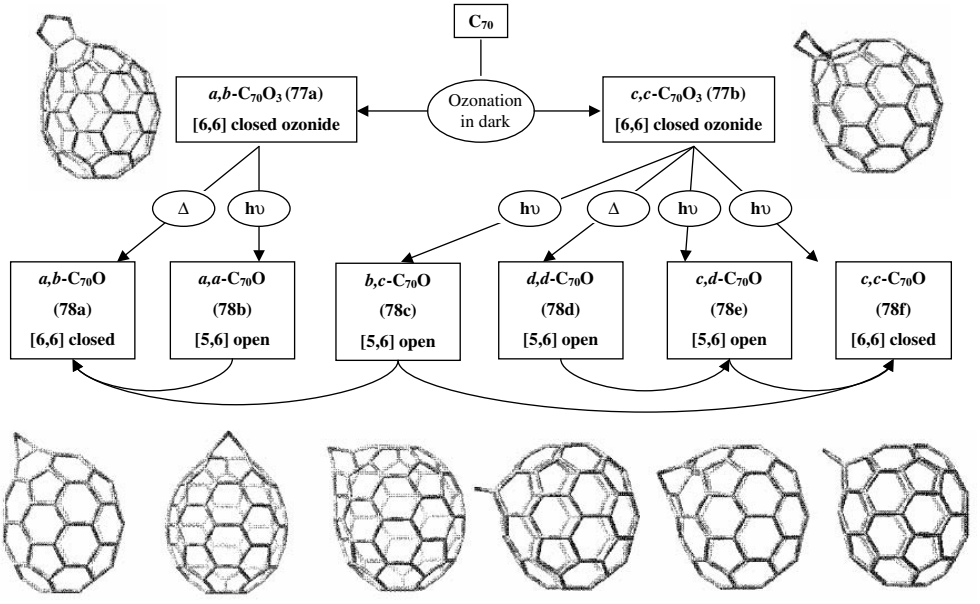
Self-sensitized photooxygenation of C_{60}-fused cyclobutanes containing an oxidizable alkene moiety[115] or alkenyl-substituted fullerene adducts[139] followed by reduction also results in the formation of allylic alcohols. Whereas in the former case formation of both the *threo* and *erythro* forms of the allylic alocohols is observed, in the latter case the reaction occurs regioselectively by the preferential abstraction of an allylic hydrogen next to the fullerene group. The hydrogen atom linked to the fullerene skeleton is unreactive under the reaction conditions.

Wudl et al. obtained the ring-opened *N*-MEM-ketolactam **71** by self-sensitized photo-oxygenation of *N*-methoxyethoxymethyl (MEM)-substituted [5,6]azafulleroid **69** (Scheme 30).[140] The reaction is highly regioselective, most likely because the anti-Bredt CC double bonds in **69** are more strained.

Similarly, irradiation of tetrasubstituted bis(fulleroid) derivatives **72** in the presence of oxygen affords a 12-membered ring diketone on the surface of the fullerene.[141] In spite of the same 60 π electronic structure as C_{60}, whose photooxygenation leads to the formation of the fullerene epoxide, [2 + 2]-cycloaddition of **72** with $^1O_2$ followed by symmetrical ring opening of the dioxetane **73** predominantly occured to give **74** (Scheme 31).[140,142] On the contrary, oxidation and Diels–Alder reaction of the mother compound ($R^1 = R^2 = H$) were reported to occur not at the fullerene skeleton but on the outside part.[143,144]



SCHEME 32 Photolysis of $C_{60}O_3$ leading to the [5,6] open fullerene oxide **76** (oxidoannulene).

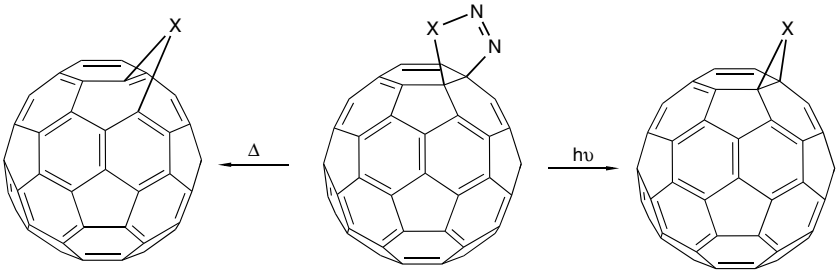


SCHEME 33 Thermolysis and photolysis of C_{70} ozonides **77a,b**.[146]

Photochemical Reactions Leading to Epoxides or Oxidoannulenes of C_{60}/C_{70}

The synthesis of fullerene epoxides via [2 + 1]-photocycloaddition of singlet oxygen has already been discussed (in the section "[2 + 1]-Photocycloaddition"). Alternatively, fullerene oxides can also be obtained by thermolysis or photolysis of the [6,6]-closed ozone adduct of C_{60} and C_{70}, namely $C_{60}O_3$ **75** and $C_{70}O_3$ **77**.[145,146] Thermolysis of $C_{60}O_3$ yields the fullerene epoxide with a [6,6]-closed structure. In contrast, photolysis resulted in the formation of the [5,6]-open oxidoannulene **76** with an ether structure (Scheme 32).[145]

In the case of the 1,3-diplar cycloaddition of ozone to C_{70}, formation of two isomeric forms of the [6,6]-closed C_{70} ozonide, *a,b*-$C_{70}O_3$ **77a** (C_1-symmetry) and *c,c*-$C_{70}O_3$ **77b** (C_s-symmetry), due to addition at the *a,b* or *c,c* bonds is observed (Scheme 33).[146] Upon thermolysis or photolysis of these ozonides, oxygen is released giving rise to the formation of different isomers of $C_{70}O$ by each route. The *a,b*-isomer of $C_{70}O_3$ resembles $C_{60}O_3$ in its unimolecular reactions, forming the epoxide **78a** through thermolysis and the oxidoannulene **78b** through photolysis. Extrusion of oxygen from the *c,c*-isomer **77b** leads to three isomeric oxidoannulenes, namely **78c**, **78d**, and **78e**, the latter arising from thermolysis, whereas the former are obtained by photolysis, showing that the dissociation pathways of *c,c*-$C_{70}O_3$ differ greatly from those of the *a,b*-isomer. In addition, epoxide **78f** is formed as a minor photoproduct. Photoisomerization of all the $C_{70}O$ oxidoannulenes to one of the C_{70} epoxides can be observed. Isomer *b,c*-$C_{70}O$



SCHEME 34 Thermolysis and photolysis of pyrazolino- (X = C) and triazolinofullerenes (X = N).

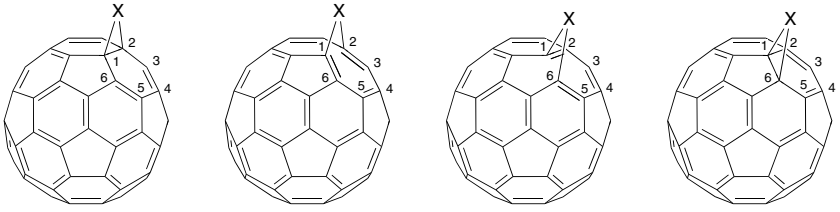


FIGURE 28.10 Possible and hypothetical structures of methano- and imino[60]fullerenes.

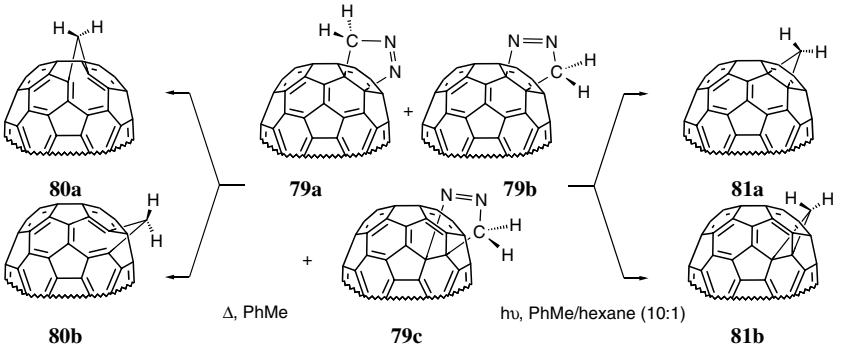
appears unique, as the photoisomerization leads directly to a mixture of both isomeric epoxides in similar amounts. Thus, in the presence of light, the two epoxides are the only stable monoadducts formed after ozonation of C_{70}.

Photochemical Reactions Leading to Methanofullerenes/Fulleroids and Aziridinofullerenes/Azafulleroids

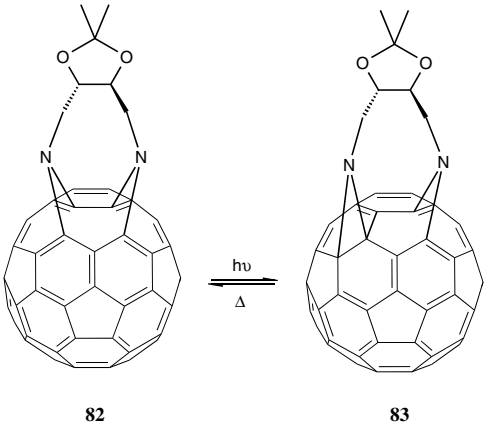
Among various exohedral fullerene derivatives, fulleroid, a C_1 homologue with the [5,6]-open structure on C_{60}, has attracted much attention since the pioneering work of Wudl, Diederich and others[147] because of the ability to reform the original 60 π electron system and its mechanistically unique rearrangement to the methanofullerene (*vide infra*). Synthesis of fulleroids and their corresponding nitrogen analogues, the azafulleroids, can be achieved as the kinetic products by thermolysis of pyrazolino- or triazolinofullerenes obtained via thermal [3 + 2]-cycloaddition of diazo compounds or azides (Scheme 34). In contrast, the photochemical extrusion of N_2 leads preferably to the thermodynamically more stable [6,6]-closed isomers, namely, the methano- or aziridinofullerenes. The exclusive formation of cluster open [5,6]-bridged and closed [6,6]-bridged isomers is a consequence of the principle of the minimization of [5,6]-double bonds. Hypothetically open [6,6]- and closed [5,6]-bridged isomers would require the formation of three and two unfavorable [5,6]-bonds, respectively (Figure 28.10). No monoadduct with such a structure has yet been observed.

For example, irradiation of the C_{60} diazomethane adduct resulted in the formation of the [6,6]-closed cyclopropane $C_{61}H_2$, accompanied by the [5,6]-open fulleroid. The two isomers cannot be converted neither photochemically or thermally.[148] Upon photolysis and thermolysis of C_{70} pyrazolino derivatives **79a–c** synthesized by addition of diazomethane to C_{70}, four isomeric methylene derivatives of C_{70} are obtained. Irradiation of the pyrazolines leads to a mixture of the two isomeric [6,6]-bridged methanofullerenes **81a** and **81b**, while the thermal reaction gives rise to the formation of the [5,6]-bridged isomers **80a** and **80b** (Scheme 35).[147d]

Recent reports from Mattay's group have shown a fundamental equivalence in reactivity between pyrazolino- and triazolinofullerenes. Thermal extrusion of N_2 predominantly leads to the formation of the opened [5,6]-bridged azafulleroids, whereas the major products formed by photolysis of triazolinofullerenes are the closed [6,6]-bridged aziridinofullerenes.[149,150] In addition, upon photolysis, conversion



SCHEME 35 Thermolysis and photolysis of C_{70} pyrazolino derivatives **79**.



SCHEME 36 Conversion of bisazafulleroid **82** to the aza-aziridinofulleroid **83** upon irradiation.

of the azafulleroid to the aziridinofullerene was observed. Analogously, bistriazolinofullerenes can be converted to the corresponding aziridinofullerene and/or azafulleroid by thermal extrusion of nitrogen.[150,151] As the bisazafulleroids are thermally stable, no interconversion between the aziridinofullerene and the azafulleroid has been observed in general.[152] In contrast, a quantitative conversion of bisazafulleroid **82**, when exposed to light, leads to the aza-aziridinofulleroid **83**, in which the two imino groups add at both the [5,6]- and [6,6]-ring junctions (Scheme 36). Thermolysis of **83** resulted in conversion to **82**. These observations provided the first example of an interconversion between an aza- and an aziridinofulleroid.[153]

Similar rearrangements have been observed in the corresponding carbon analogues. For example, conversion of the fulleroids to the methanofullerenes upon thermolysis or photolysis was reported by Wudl et al. Irradiation of fulleroid **84** in deoxygenated *p*-xylene gives rise to a quantitative conversion to the methanofullerene **85** (Scheme 37).[102] Conversion of the methanofullerene to the fulleroid is not observed. Wudl proposed a di-π-methane rearrangement in the photochemical conversion of fulleroid **84** to the [6,6]-closed isomer **85** (Scheme 38).[102a] This was supported by the observations of Shevlin,[154] who demonstrated a photochemical step in the thermal rearrangement of a cyclopentylidene fulleroid to a methanofullerene. The photochemically induced azafulleroid–aziridinofullerene rearrangement also might be rationalized in terms of a di-π-methane rearrangement rather than a cleavage–cycloaddition process of a nitrene unit.[155]

Cheng et al. studied the nickel-promoted cycloaddition of bisalkynes to C_{60} in order to obtain cyclohexadiene derivatives of C_{60}.[143] Reports on the preparation of a cyclohexadiene ring via metal-catalyzed

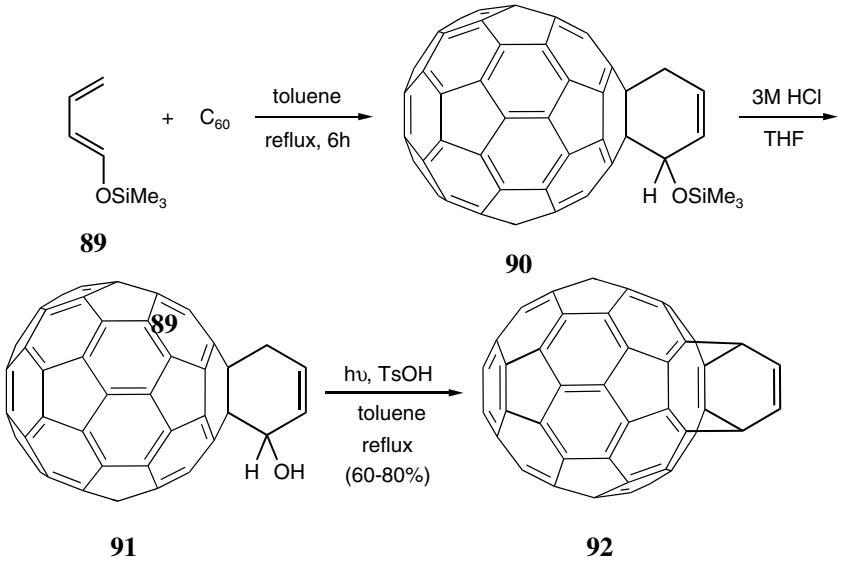
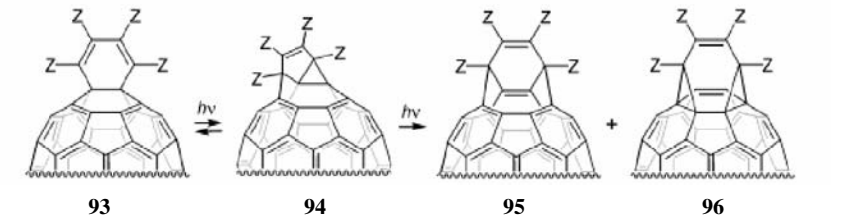
cyclotrimerization of two alkynes with an alkene have appeared in the literature. Indeed, treatment of C_{60} with terminal 1,6-diynes **86a–e** afforded [2 + 2 + 2] bicyclohexadiene derivatives **87a–e**, which readily underwent photoinduced [4 + 4]-cycloaddition upon irradiation (350 nm) to give the corresponding bisfulleroids **88a–e** in excellent yields (Scheme 39). The formation of **88** is likely to proceed via an intramolecular photoinduced [4 + 4]-cycloaddition reaction of **87** to give an intermediate bismethanofullerene. This, upon subsequent CC bond cleavage and rearrangement, yielded the bisfulleroid product. It should be noted that the methano groups in the intermediate are across [5,6]-ring junctions of the C_{60} moiety. The rearrangement of the intermediate to **88** is expected in view of the fact that a bisfulleroid is generally more stable than the corresponding methanofullerene. Examples of such rearrangement are known.[147c]

Prior to the work of Cheng et al., Rubin et al. reported a similar [4 + 4]-photocyclization reaction.[156] Rubin has shown that a cyclohexadiene derivative underwent a very facile photochemically promoted rearrangement to the stable bridged bisfulleroid **92**. This process occurs via the initial [4 + 4]-photoadduct (not observed), which undergoes a thermally allowed [2 + 2 + 2]-cycloreversion to afford a bis-methano[12]annulene (Structure **92**). Alternatively, compound **92** can be obtained by photolysis of the allylic



SCHEME 40 Double scission of a six-membered ring on the surface of C_{60} via [4+4]/[2+2+2] cycloaddition reactions.[156]



SCHEME 41 Photorearrangement of tetraakoxycarbonyl-substituted C_{60} cyclohexadiene derivatives **93** to bisfulleroids **95** and bismethanofullerenes **96**.[157]

alcohol **91** under reflux and acidic conditions in good yields (Scheme 40). The allylic alcohol is obtained by acidic work-up of the cycloadduct **90** formed by addition of a twofold excess of 1-((trimethylsilyl)oxy)-1,3-butadiene **89** to C_{60}. The structure of **92** was deduced from the high symmetry displayed by the ^{1}H and ^{13}C NMR spectra and the characteristic UV-vis spectrum. The x-ray structure of a cobalt complex formed by addition of $CpCo(CO)_2$ confirmed the suggested structure for compound **92**.[156]

Recently, Murata et al. described the photorearrangement of tetraalkoxycarbonyl-substituted cyclohexadiene derivatives of C_{60} **93**, yielding not only the well-known bisfulleroid **95** but also bismethanofullerene **96** (Scheme 41).[157] The existence of a labile and structurally new intermediate **94a** was observed in the reaction mixture. Although there still remained three possible structures as shown in Figure 28.11, only structure **94a** could be located as a local minimum. Furthermore, B3LYP chemical shifts of **94a** are in good agreement with the experimental values supporting this structure.

Formation of the unsymmetrical intermediate suggests that the rearrangement occurs *via* a different pathway than the previously described [4+4]/[2+2+2] mechanism. A possible mechanism includes the formation of an allylic biradical species bearing one [6,5]-closed structure. Then, isomerization from [6,5]-close to the [6,5]-open structure together with [6,6]-closed ring formation affords **94a**. Rearrangement of either the methanofullerene or fulleroid unit in **94a** into the other gives **95** and **96**.

Rubin et al.[158] also described the synthesis of C_{62}, a four-membered ring isomer of C_{60}. The dicarbonyl bridged bisfulleroid **100** seems to be a key precursor to C_{62}. Compound **100** was prepared by a stepwise

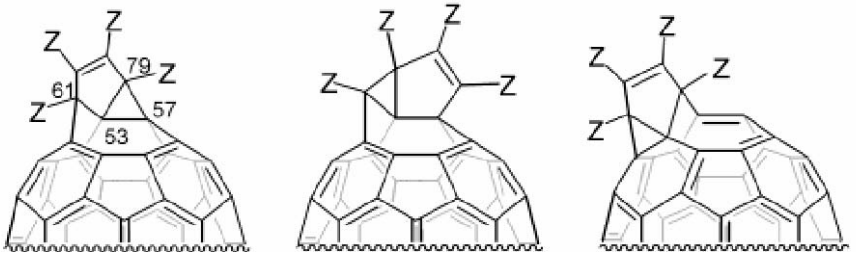


FIGURE 28.11 Possible structures for the intermediate **94** (Z = CO_2Me, $CO_2{}^tBu$).[157]

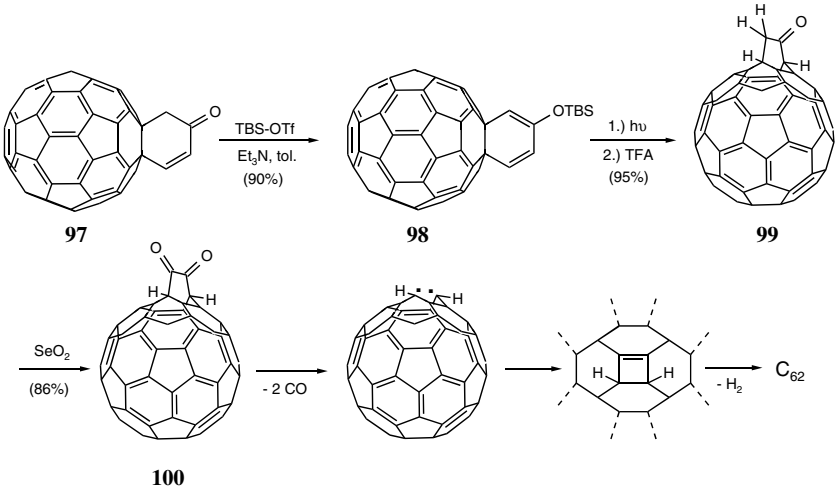
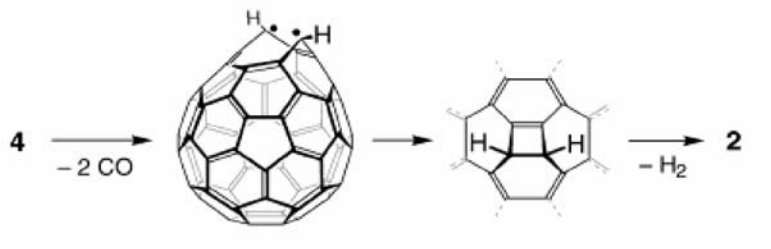


SCHEME 42 Formation of C_{62}.[158]



SCHEME 43

strategy (Scheme 42). Compound **97**[144] was converted to the corresponding silyl enol ether **98**. Visible light irradiation initiated its sequential [4 + 4]/[2 + 2 + 2] rearrangement to the bisfulleroid, which was deprotected with TFA to give the α-methylene ketone **99**. Oxidation of **99** results in the formation of the dicarbonyl compound **100**. Examples of photolytic α-fragmentation of 1,2-dicarbonyl compounds

with loss of two CO units have been described.[159] In the case of C_{62}, removal of both carbonyl groups under photochemical or thermal excitation should result in two adjacent radicals combining to the four-membered ring. Subsequently, facile dehydrogenation, which is characteristic for hydrofullerenes,[160] would give C_{62}.

28.5 Summary

In this review, we have given a brief summary of the photophysical behavior of C_{60} and C_{70}, followed by a detailed discussion of the photochemistry of these fullerenes and their derivatives. As shown in the last part of this review, photochemical reactions of C_{60}/C_{70} are very useful to obtain fullerene derivatives. In general, the photoinduced functionalization methods of C_{60}/C_{70} are based on electron transfer activation leading to radical ions or energy transfer processes either by direct excitation of the fullerenes or the reaction partner. In the latter case, both singlet and triplet species are involved, whereas most of the reactions of electronically excited fullerenes proceed via the triplet states due to their efficient intersystem crossing.

Acknowledgements

Financial support of our own research was provided by the Federal Department of Science, Research and Technology (BMBF) and the Deutsche Forschungsgemeinschaft (DFG). We also gratefully acknowledge the valuable contributions of Johannes Averdung, Christina Siedschlag, and Ingo Schlachter during their Ph.D. work and of Gregorio Torres-Garcia (Malaga University, Spain) and Waldemar Iwanek (University of Kielce, Poland) during their postdoctoral visits, as well as the helpful cooperation of the groups of Lothar Dunsch (IWF Dresden), Osamu Ito (Tohoku University, Sendai), Peter Luger (FU Berlin), Werner Abraham (HU Berlin), and Dirk M. Guldi (University of Notre Dame). Special thanks go to Heinrich Luftmann (University of Muenster), Matthias Letzel (University of Bielefeld), and Christian Wolff (University of Kiel) for their important contributions to mass spectrometry and NMR spectrometry, respectively. The support of Hoechst AG (now Aventis) during the early stages of our research is also gratefully acknowledged.

29.1 Introduction

In 1986, a natural product was isolated from the soil bacterium *Micromonospora echinospora* ssp. *calichensis* and assigned the name calicheamicin.[1] Investigation of its biological profile revealed very high activity in a primary screen (prophage induction assay), and calicheamicin turned out to be one of the most potent antitumor agents (both *in vitro* and *in vivo*) ever evaluated.[2] This initial research, followed by subsequent structural identification, led to the realization of an apparently new and unprecedented class of antitumor agents collectively known as the "enediyne antibiotics."

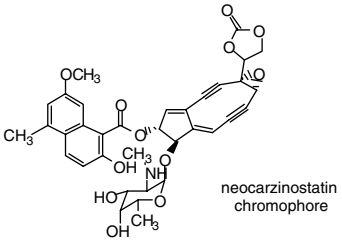
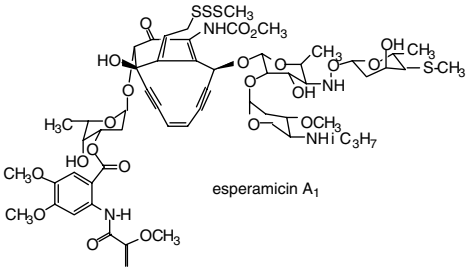
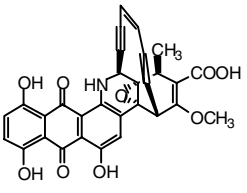
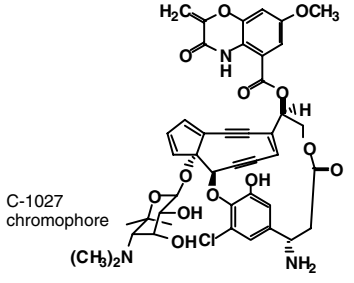
SCHEME 1 Thermal enediyne rearrangements that give rise to cytotoxic biradicals.

The history of the enediynes in fact dates back to 1965, with the discovery of neocarzinostatin.[3] Isolated as a chromoprotein complex, the structure of its enediyne-containing chromophore was finally determined in 1985,[4] and when the connection between it and the newly discovered calicheamicins and esperamicins was made, it sparked intense interest from research groups around the world. Over 20 discrete enediynes are now known, which fall into two distinct subcategories: those containing a 10-membered 3-hexene-1,5-diyne subunit [the calicheamicins, esperamicins and dynemicins] and those containing a nine membered enediyne, which are typically isolated as complexes with an associated apoprotein (neocarzinostatin, kedarcidin, C-1027, maduropeptin).[5]



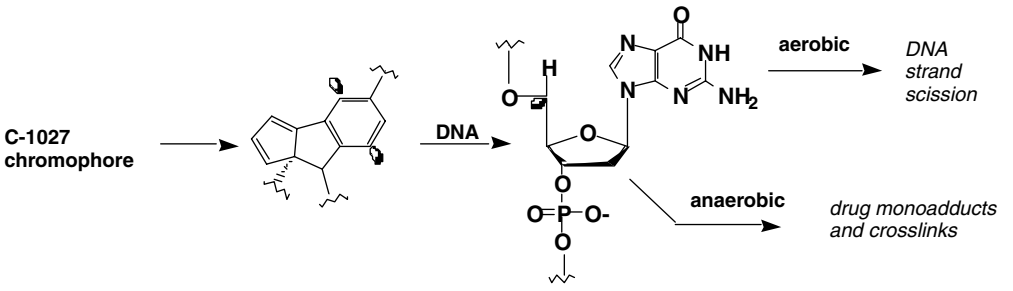






Clinical trials of neocarzinostatin derivatives continue in Japan, U.S. trials of a monoclonal antibody (MoAb) conjugate of calicheamicin have entered Phase III, and esperamicin has entered Phase II trials (Scheme 1).[6] Clinical interest in enediynes was heightened when it was found that a calicheamicin MoAb conjugate induced remission in up to 40% of patients with acute myeloid leukemia [AML] who had previously relapsed following other chemotherapies. It was demonstrated that calicheamicin, as well as other enediynes, are capable of causing single- and double-stranded DNA breaks at very low concentrations, and that the enediynes probably derive their biological activity from these events.[7] Enediynes *per se* are biologically inactive, but they undergo cycloaromatization reactions that give rise to cytotoxic diyl radicals, by either a Bergman-type cycloaromatization reaction[8] or, as in the case of neocarzinostatin, the Myers process (Scheme 1).[9]

In either case, the resulting biradicals [**2**/**4**] are highly reactive and undergo atom transfer chemistry in a bid to form stable arenes. Most typically, this involves hydrogen atom abstraction which, in the presence of biological targets, can inflict cellular damage, including DNA scission and, in specific cases,

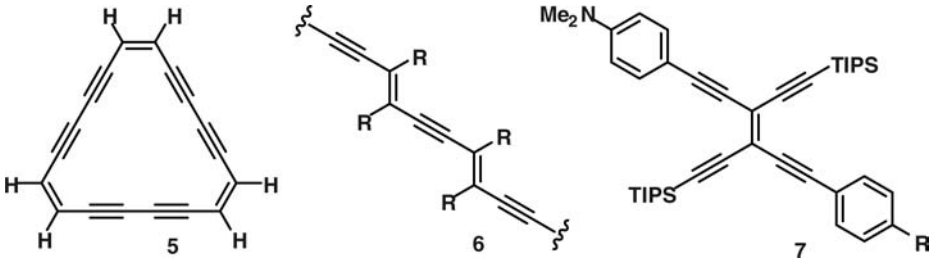


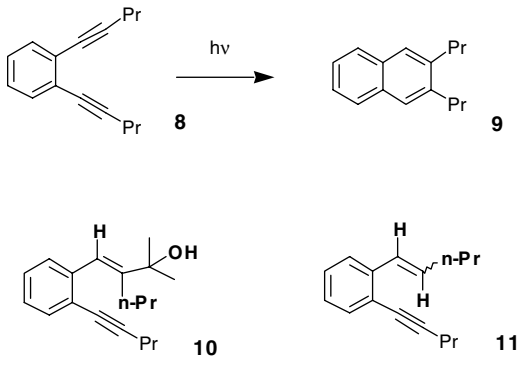
SCHEME 2 Fate of biradical-DNA interactions depends on environment.

other lesions.[10] The pathways by which the enediyne-derived biradicals inflict DNA damage and their sequence specificity has been extensively studied, and hydrogen abstractions from the C(5′), C(4′), and C(1′) positions have been proposed.[11] The resulting ribosyl radical is then typically intercepted by molecular oxygen, and the peroxide formed undergoes fragmentation resulting in cleavage. Specific enediynes are capable of inducing double-stranded lesions, whereas the more typical outcome is a single-stranded cut with limited sequence specificity. In the case of C-1027, Goldberg[5] demonstrated that adduction can occur under anaerobic conditions (Scheme 2), which may have ramifications for enediynes, which become activated in hypoxic regions, prevalent in solid tumors.[12]

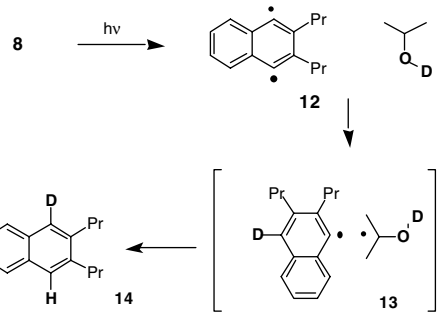
While the *in vitro* and *in vivo* effectiveness of enediynes against certain cancers is firmly appreciated, the exact contribution of DNA cleavage to such biological activity remains to be resolved. Studies involving calicheamicin suggest that specific DNA strand scission is not directly related to cytotoxicity, but that subsequent promotion of the DNA suicide repair enzyme poly(ADP-ribose)polymerase results in cellular death by means of depleting cellular NAD^+ and ATP levels.[13] Additionally, compelling evidence now suggests that proteins may be the target of certain enediynes (*vide infra*). Nonetheless, it is the DNA-cleaving activity of enediynes that has guided the development of most analogs.

The typical half-lives of most unstrained 10-membered enediynes (for Bergman cyclization) are approximately 3 to 18 h at physiological temperature, making them ideal for *in vitro* and *in vivo* studies, and this in turn has fueled the quest for designed (synthetic) enediynes.[14] Nearly all of the natural enediynes possess chemical triggering units which, when activated, promote either Bergman or Myers type cycloaromatization of the core unit. Though chemical synthesis of triggered enediynes, which mimic the natural systems, can be accomplished, preparation of the parent enediyne core structures requires special care due to thermal instability. For this reason researchers have recently begun to investigate the possibility of using photochemical methods of activating otherwise thermally stable enediyne prodrugs (*vide infra*). Additional interest in enediynes has recently surfaced in materials chemistry. Examples include synthetic polymers and designed nanostructures.[15] Representative examples of enediyne materials include the (explosive) dehydroannulenes 5,[16] carbon-rod polydiacetylenes 6,[17] and the molecular switching device **7** (R = dihydroazulene).[18]





SCHEME 3 The prototypical Photo-Bergman rearrangement.



SCHEME 4 Mechanistic examination of Photo-Bergman.

29.2 Basic Overview of Photo-Bergman

Interest in a photochemical variant of the Bergman cyclization was stimulated by a report from the groups of Turro and Nicolaou in 1994.[19] They revealed that *n*-propylenediyne **8** underwent photochemical conversion to arene products following irradiation using a medium pressure Hg lamp, with cutoff at 313 nm. The choice of solvent plays a key role in both the efficiency of the process and the product distribution, as it plays a dual role as an atom transfer agent. Isopropanol, benzene, and hexane all gave variable yields of expected product **9**, but when benzene/1,4-cyclohexadiene mixture was employed, cyclohexadiene adducts were recovered. Of these combinations, isopropanol was most effective, at 50% conversion giving products **9:10:11** in ratios of 2:4:3 (2:1 *cis:trans* for **11**).[20] This corresponds to a 25% yield of **9**. Subsequent labeling studies, in which **8** was irradiated in the presence of deuteroisopropanol, suggested the intermediacy of diyl **12**, with isolation of arene **14** implying combination of radical pair **13** (Scheme 4).[19] Control experiments supported this pathway, since neither **14** irradiated with the labeled solvent nor the presence of sensitizers gave rise to additional D incorporation. Alternative outcomes are possible, however, depending on reaction conditions. Photolysis of substrate **15** in the presence of isopropanol gives arene **16**, implying the intermediate diyl **17** (Scheme 5).[20] Repeat irradiation in the presence of tetranitromethane, however, results in isolation of indene **18**, presumably via trapping of the radical cation **19**.[21] This implies the reversibility of the photoreaction, and competing ionic/radical pathways dictate product distribution, in stark contrast to the thermal process.

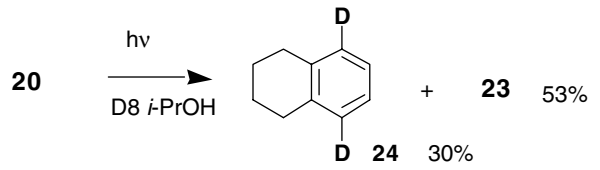
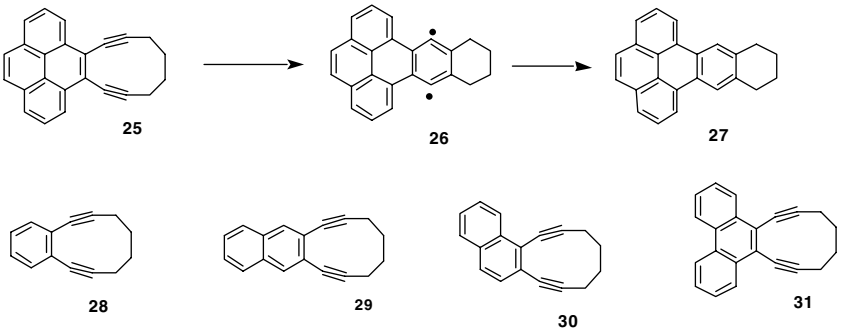
29.3 Cyclic Enediyne Substrates

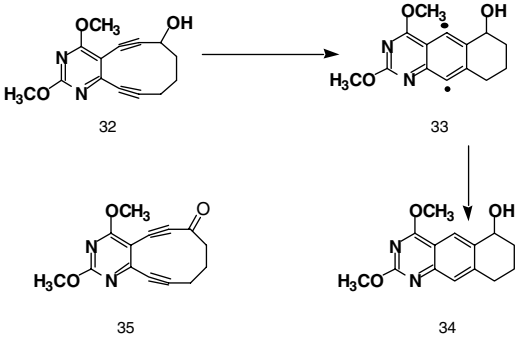
With these results in hand, interest in the photo-Bergman cyclization increased, and a number of studies on the basic atom transfer chemistry and reversibility of cycloaromatization emerged. Hirama demonstrated that the C10 pharmacophore **20**, present in many of the naturally occurring enediyne antitumor agents, was capable of undergoing photo-Bergman cyclization, giving arene **22** and product **23**, which is derived from the reversed reaction of diyl **21** (Scheme 6).[22] The process was heavily influenced by solvent, with nonpolar solvents giving appreciable yields (Table 29.1).



SCHEME 7 Reversed Bergman: Labeling Studies.



SCHEME 8 Pyrene enediyne Photo-Bergman cyclization.



SCHEME 9 Heteroaryl substrates.

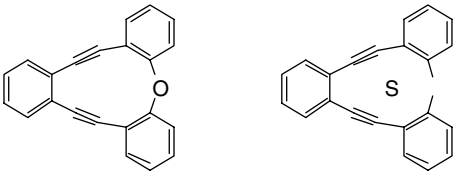
Subsequent labeling studies supported the reversed Bergman pathway, with isolation of the doubly labeled arene **24** in addition to enediyne **23** (Scheme 7).[22] It is interesting to note that the reversed pathway (isolation of enediyne **23**) has not been observed under thermal conditions.

Benzofused Systems

Following on from the initial reports of Turro,[19,20] a series of efficient substrates for photo-Bergman was reported by Funk and Williams (Scheme 8).[23] The most spectacular of these was pyrene enediyne **25**, which underwent smooth conversion to arene **27**, presumably via diyl **26**.[23] The template was later derivatized to allow DNA recognition, in part a consequence of the ability of the pyrene to intercalate (*vide infra*). The authors conducted systematic analysis of the prerequisites for efficient conversion, revealing that compounds **28**, **30**, and **31** (but not **29**) were good substrates.[23] An interesting heterocyclic variant was introduced by Russell and co-workers, involving fused systems e.g., **32** (Scheme 9).[24] The pyrimidine-fused enediyne **32** underwent highly efficient conversion to arene **34**, assuming the intermediacy

of diyl **33**. However, by contrast, ketone **35** gave only minimal conversion to the corresponding arene. It is interesting that compounds **32** and **35** showed a reversal in thermal and photochemical rates of reactivity. When cyclized thermally in toluene at 40°C, ketone **35** had a half-life of 5 h, while alcohol **35** had a half-life of 58 h. When treated photochemically in isopropanol for 2 h, again at 40°C, alcohol **32** underwent 83% conversion to arene **34**, with 4% **32** remaining. When ketone **34** was treated under identical conditions, only 10% of the corresponding Bergman cyclization product was produced, along with 34% starting material. The remaining mass resulted from other photochemical products of **34**. These results potentially point to subtle stereoelectronic effects in the transition state.[24] Compound **32** also demonstrated photochemically initiated DNA cleavage (*vide infra*).

Based partly on the success of benzofused enediynes such as **28**, **30**, **31**, and **34**, Wiest prepared highly strained enediynes **36** and **37** and subjected them to conditions suitable for photochemical Bergman cyclization.[25] These molecules proved stable to prolonged high-intensity irradiation. Based on calculations, it was suggested that the unexpected photochemical (and thermal) stability of **36** and **37** is the result of diyl intermediates that are unusually high in energy.

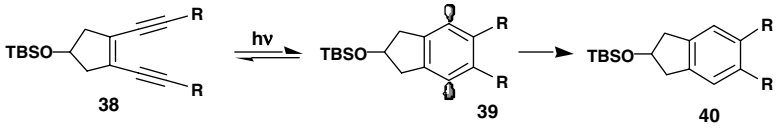


36 37

Carbocyclic Systems

Drawing analogy with the cyclopentane fused enediynes present in the naturally occurring chromoprotein enediyne antibiotic, Hirama has investigated the propensity for enediynes **38** to undergo photo-Bergman rearrangement (Scheme 10).[22] Surprisingly, the dialkyl enediyne was the most efficient (Table 29.2), and again the process had a strong solvent effect.[22] A labeling study was conducted, irradiating **38** (R = Me) in the presence of D_8 THF, which gave a 14% yield of labeled adduct with D_2:D_1:D_0 in ratios of 88:12:0.[22]

Based on the intriguing behavior of the alicyclic enediynes **38**, we sought to investigate the electronics and sterics of the photo-Bergman cyclization pathway. However, in order to be systematic, this would necessitate an entirely synthetic approach.



38 39 40

SCHEME 10 Photochemical Bergman cycloaromatization.

A *De Novo* Class of Photo-Enediynes

Based on **38** and the results from other laboratories involving diaryl enediynes, we wished to design enediyne systems where alkyne termini could be derivatized with variable functionality, and the photoactivity of the Bergman cycloaromatization could be tuned both in terms of electronics and strain energy. Specifically, since most photoactivated enediynes studied to date have the vinyl moiety embedded in an arene, we wished to design a family of differentially capped *alicyclic enediynes* **41** and investigate their photochemical activation to diyls **42** as a function of these effects (Scheme 11).

Commencing from commercially available acyl chlorides **43**, the corresponding diketones **44** were produced via the intermediate Weinreb amides (Scheme 12). Low valent Ti-mediated coupling gave **46** directly, but the yields were variable, in part due to problems recovering product from complex mixtures.

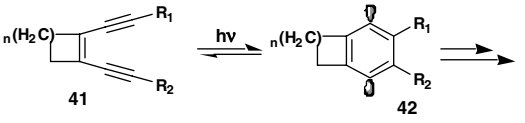
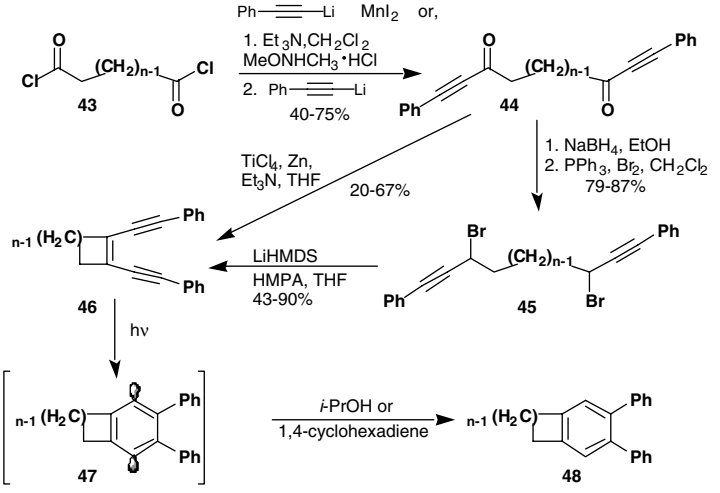


SCHEME 11 Photochemical Bergman cycloaromatization.



SCHEME 12 Synthesis of alicyclic Photo-Bergman candidates.

Alternatively, conversion to bromides **45** followed by carbenoid coupling gave **46** (n = 1–5) in good yield on a preparative scale.[26] Though stable at room temperature, photochemical Bergman cycloaromatization gave adducts **48** in moderate yield, presumably via diyls **48** (Table 29.3).[26]

As had been found previously, the nature of the hydrogen donor plays an important role in the conversion to arene adduct.[27] Thus, although consumption of enediyne was often rapid using 1,4-cyclohexadiene, optimal yields of cycloaromatization products were obtained using isopropanol, the balance of material typically composed of uncharacterized polymeric byproducts. Evidently, ring strain

effects play a role in the cycloaromatization, with lower conversion efficiency observed with the C7 and C8 analogs despite the appreciable reduction in intramolecular "c-d" distances relative to the 6-membered analog (Table 29.3).[28] Though photo-Bergman cycloaromatization yields are modest, the synthesis of this class of enediynes (4- through 8-membered) is noteworthy and may lead to many new applications in materials and polymer chemistry.

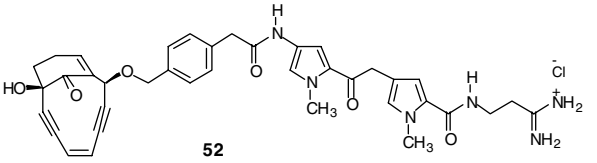
29.4 Biological Applications

DNA Targeted

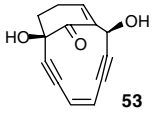
Since DNA is the predominant target of the natural enediynes, a natural extension of the photo-Bergman lies in the development of efficient enediyne-based photonucleases. Based on their model studies, Funk and Williams designed both a phenanthrene and pyrene enediyne **49**, which by virtue of the aminoalkyl side-chains had affinity for DNA (Scheme 13).[23]

Irradiation of these agents in the presence of supercoiled plasmid DNA (pUC19) resulted in single-stranded cleavage, with the pyrene-based substrate somewhat more efficient. Control studies supported the requirement of the enediyne structure for efficient cleavage, and it is implied that arene **51** is the terminal product, and the reactive species is diyl **50**.[23] This constituted the first example of an enediyne-based photochemical

nuclease, and the possibility for sequence specific variants clearly exists. It is not clear that compound **32** should possess significant DNA affinity, unlike **49** with its inherent ability to intercalate. Nonetheless, **32** did exhibit photochemically initiated DNA cleavage properties similar to those of **49**.[24] In this case, single-stranded cleavage was observed on the ΦX174 plasmid.



52



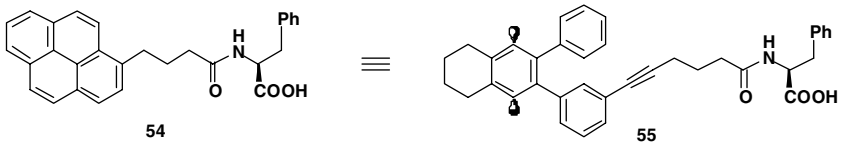
53

Protein Targets

While ongoing research will clarify their precise relevance, it is possible that DNA binding and/or DNA cleavage are not critical for antitumor activity of enediynes. Protein agglomeration induced by the enediyne *chromophores* of both C-1027[29] and kedarcidin[30] have been reported, but due to their unique architectures (which recognize DNA effectively), it is unlikely that this contributes to their biological effects. However, during development of the enediyne–netropsin conjugate **52**, researchers at Bristol-Myers Squibb noted the protein modulating ability of the enediyne core **53**[31] (related to the natural enediyne esperamicin), and this likely contributes to the observed *in vitro* and *in vivo* antitumor activity of the agent, whose affinity for DNA is low.[31] At physiological temperature, this agent induced damage to membrane extracts, tubulins, and histones, presumably via its derived diyl radicals. Spurred by these findings, we elected to study the viability of designing enediynes that (a) are targeted towards specific proteins[32] and (b) are substrates for the photo-Bergman reaction. Such a strategy could have far-reaching consequences. Excepting water, proteins are the most abundant constituents of cells and extracellular fluids by weight. Proteins govern the majority of events in a cell, and the ability to selectively inactivate or disrupt protein function in a tumor cell could be a valuable tool.

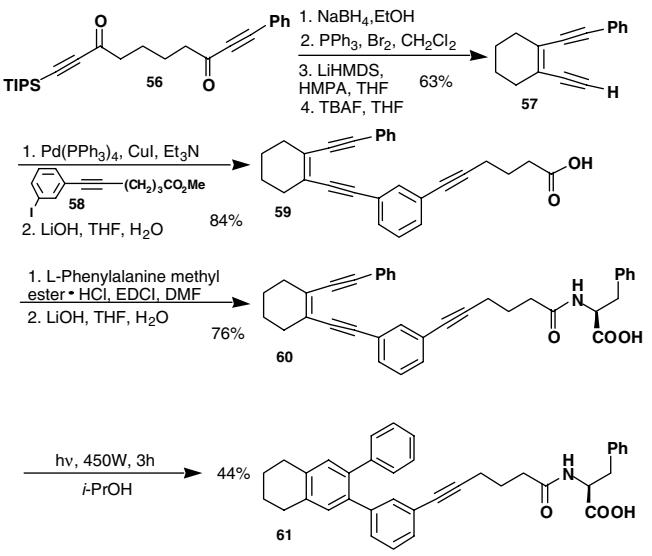
Bovine Serum Albumin

With a route to photoactivated enediynes **46** secure, we wished to investigate interaction of the intermediate diyl radicals **47** with protein targets and accordingly sought to prepare a hydrophilic variant, which was capable of recognizing protein architecture. Our design was influenced by the work of Kumar,[33] who reported that an alkyl pyrenyl derivative of phenylalanine (**54**) recognizes the proteins bovine serum albumin (BSA) and lysozyme, inducing photocleavage following irradiation in the presence an electron acceptor.[34] Molecular modeling studies indicated that diyl **55** would be a close mimic of this agent and could presumably be generated via irradiation of an enediyne precursor.



54 ≡ **55**

Accordingly, enediyne **60** became a logical candidate for proof-of-principle studies. First, diketone **56** was prepared from adipoyl chloride using a mixed coupling procedure. Subsequent functional group interconversion and carbenoid coupling gave the differentially functionalized C6-enediyne, which was unmasked to give **57**.[26] Photo-Bergman cycloaromatization of this enediyne (or the TIPS-protected precursor) gave <10% of the corresponding arene product, suggesting that the aryl groups play a key role in the (reversible) cyclization process. The alkyne was then coupled with methyl-3-(3-iododphenyl)hexynoate **58**, followed by hydrolysis to give carboxylate **59**, which was then coupled with L-phenylalanine methyl ester and subjected to saponification to give conjugate **60** in good yield. In contrast to the model series,



SCHEME 14 Preparation and Photo-Bergman cyclization of phe-enediyne hybrid.

FIGURE 29.1 10% SDS polyacrylamide gel of the reaction of bovine serum albumin (BSA) with **58** and **59**. All reactions were conducted in 50 mM Tris-HC1, pH 7.0 at 37°C. From right to left: lane 1, molecular weight markers (KDa); lane 2, BSA control (1.5 μM); lane 3, BSA (1.5 μM), **58** (150 μM), no irradiation; lane 4, BSA (1.5 μM), **59** (150 μM), 3h irradiation; lane 5, BSA (1.5 μM). **58** (7.5 μM), 3h irradiation.

photochemical activation (450 W, 3 h) of this enediyne gave arene product **61** in appreciable yield, together with unreacted starting material, underscoring the influence of the conjugated arene unit.[26]

Photochemically induced modification of BSA and lysozyme was examined by photolysing **60** in aqueous buffer, using **61** and enediynes **59, 57** as controls.[26] In the case of 66 kD protein BSA, subsequent analysis (SDS-PAGE) showed evidence of enediyne-induced degradation, with one principal fragment (~ 40 kDa) visible (Figure 29.1). Subsequent analysis by MALDI-TOF revealed the presence of fragments at 44.76 kDa, 11.28 kDa, and 10.22 kDa, suggesting the possibility of two sites of cleavage.[26,35] In the case of the 14 kDa protein lysozyme, dimerization to form a species with m/z 28.63 kDa was observed following irradiation (Figure 29.2), suggesting the possibility of intermolecular diyl-mediated cross coupling.[36] These initial findings led us to search for more specific photoproteases, and we were encouraged to use carboxylate **59** as a building block.

Histone H1

In the case of the naturally occurring chromoproteins kedarcidin, C-1027, and neocarzinostatin, the apoprotein component has proteolytic capacity. In the case of kedarcidin, studies have shown that the highly acidic apoprotein is capable of inducing selective degradation of histone H1.[37] As this is the most basic histone, a natural conclusion is that affinity plays a role. Following proteolysis of the histone, it has been suggested that the reactive enediyne chromophore is then more efficiently delivered to exposed DNA, contributing to the high efficiency of strand scission by kedarcidin. Based on our findings, we

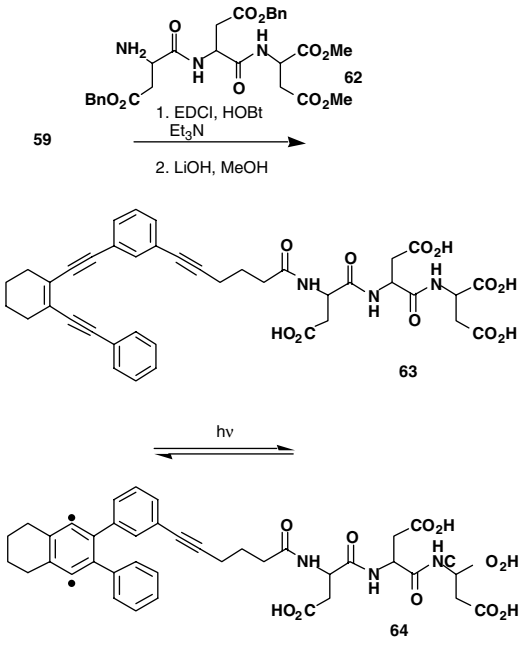
became interested in preparing an acidic enediyne–peptide conjugate to determine whether enediyne-mediated histone degradation could be achieved and if so, with what specificity. To investigate this, enediyne **59** was coupled with the triaspartic acid derivative **62.** Deprotection of the conjugate with LiOH gave the enediyne-tri-Asp conjugate **63** in good yield. As expected, this conjugate has appreciable solubility in aqueous buffer.[37] Binding of this agent to a variety of histones revealed that affinity, as expected, was greater for H1 versus others, and Scatchard analysis suggested that only one binding site is involved (Figure 29.3). More significantly, irradiation of **63** in the presence of histone H1 led to formation of **64** and degradation of the protein (Figure 29.4).[38]

Application of this concept towards other protein targets and subregional motifs within proteins would appear possible. Examples might include the SH2 and SH3 domains, which are important homology



SCHEME 15 Synthesis of tri (asp) conjugate.

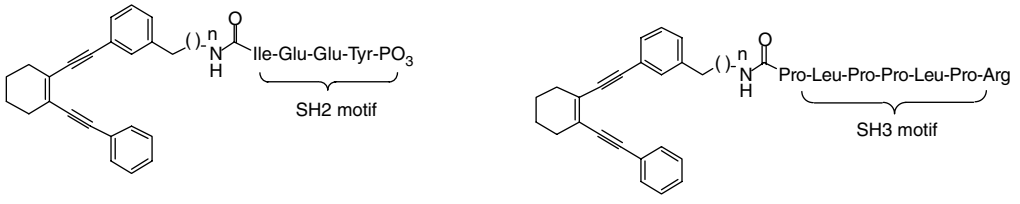


FIGURE 29.5 Possible protein targeted photoactivated enediyne candidates.

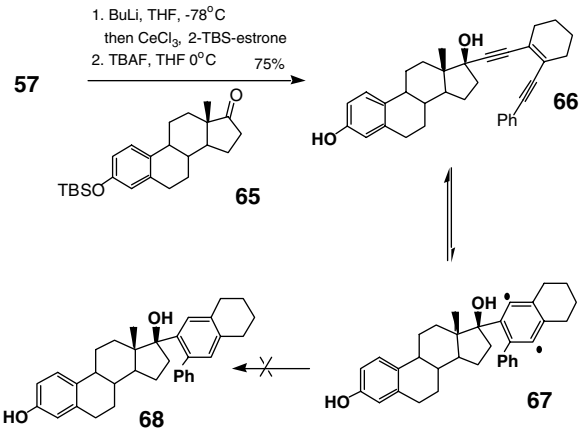
regions found in a diverse collection of proteins including signal transduction proteins, protein kinases, lipid kinases, protein phosphatases, phospholipases, and transcription factors.[39] Group I SH2 binders typically have a phosphorylated tyrosine flanked by hydrophilic–hydrophilic–hydrophobic amino acids; thus, the structure shown in Figure 29.5 would be predicted to have affinity.[40] In the case of SH3 binding peptides, a common motif is a proline-rich region P-X-X-P, present in class I ligands (consensus RXLP-PXP), e.g., the wild-type Src SH3 motif shown (Figure 29.5).[41]

Human Estrogen Receptor α

As a final example of application, we elected to study agents with the capability of degrading the human estrogen receptor (hER).[42] Though a multitude of substituted steroid templates are available via direct synthesis, we were particularly interested in commencing from a commercially available building block. Surveying numerous options, it was decided to utilize estrone, introducing the enediyne functionality at the 17α position. Through QSAR analysis it has been shown that 17α *alkynyl* derivatives of estradiol show comparable hER affinity to its endogenous ligand (estradiol), and we decided to construct a hybrid with an alkynyl linker between the enediyne and the steroidal template.[43] Accordingly, enediyne **57** was coupled to a protected (TBDMS) ether of estrone **65** via its organocerium derivative, then unmasked to give **66** (Scheme 16).

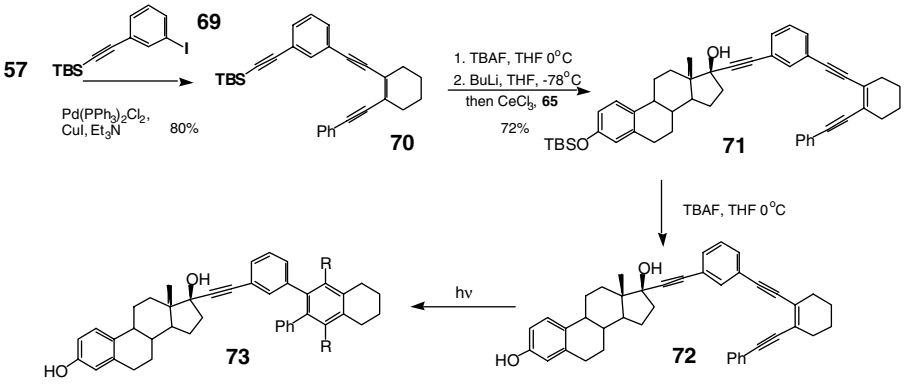


SCHEME 16 First generation photoenediyne-estrogens.

TABLE 29.4 Relative Binding Affinity of Steroid-Enediynes for hER[a]

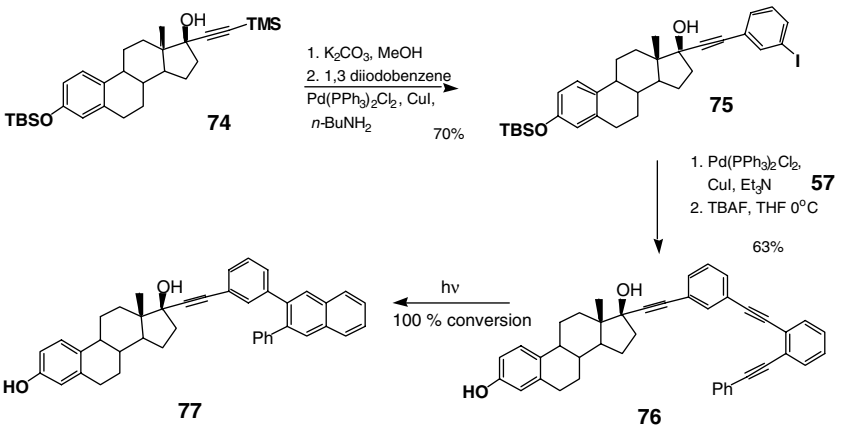
Entry	Substrate	RBA (nmol)
1	**66**	103
2	**72**	14
3	**76**	12

[a] Candidate + ^{3}H β–estradiol incubated with cytosol at 4°C. Unbound agents removed (DCC) and bound ^{3}H β–estradiol measured by scintillation counter. RBA corresponds to concentration required to reduce hER bound ^{3}H β-estradiol by 50%.[47]



SCHEME 17 Spaced photoenediyne-estrogens.

Unfortunately, this compound, which had an RBA of >100 nmol (Table 29.4), proved stable at physiological temperature and did not undergo the expected photo-Bergman cycloaromatization to give **68** even on prolonged irradiation.[44] Following a strategy adopted previously, we elected to insert a spacer unit in the system between the enediyne and ligand and pursued *m*-disubstituted ligand **72** (Scheme 17). Coupling of **57** with iodoalkyne **69** gave **70**, which was unmasked and subjected to 1,2 addition to **65**, followed by phenolic deprotection to give **72**. To our surprise, the affinity of **72** was greatly superior to that of **66**, supporting the notion that the LBD of hERα has considerable tolerance for lipophilic



SCHEME 18 High affinity photoactivated enediyne-estrogens.

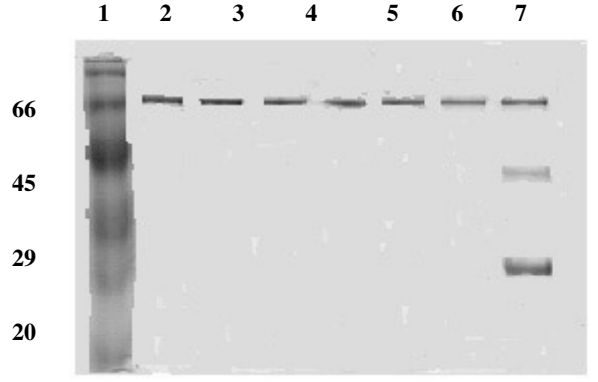


FIGURE 29.6 ER degradation. 10% SDS polyacrylamide gel of the reaction estrogen receptor (ER) (1.5 mg/ml) with the drug (550 μM). All reactions were conducted in 20 mM Tris-HCl buffer pH 8. From left to right: lane 1, molecular weight markers (KDa); lane 2, ER no irradiation; lane 3, ER after 6h irradiation; lane 4, ER after 12h irradiation, lane 5, ER + **72** no irradiation; lane 6, ER with control; lane 7, ER + **72** after 6h irradiation; and lane 8, ER + **72** after 12h irradiation.

functionality at the steroidal 17α position.[45] Though the binding affinity of **72** was spectacular, to our disappointment its photo-Bergman cycloaromatization profile was poor, giving only trace amounts of the expected cycloaromatization product **73** even after prolonged irradiation.[46] We elected to improve the efficiency of the critical process by extending the conjugation of the ligand and pursued **76** as a refined target. Though this required complete resynthesis, an efficient process was developed via pre-assembly of enediyne template **57** (Scheme 18).

This was coupled in turn to iodoarene **75**, produced by arylation of the unmasked alkyne derived from **74**, which could be produced either from **65** or the commercially available 17α-ethynyl estradiol. Though the binding affinity of **76** did not differ markedly from that of **72**, this ligand underwent smooth photocycloaromatization to give complete conversion to cycloaromatized product **77** within 3 h.[44] Irradiation in the presence of recombinant hER resulted in marked degradation, and control reactions confirmed the influence of the various constituents (Figure 29.6).[46]

Application of this strategy to other members of the hormone receptor superfamily would appear possible. The homology of the hormone receptor superfamily has been well studied, and endogenous small molecule ligands have been identified for most.[48] Examples include the progesterone and vitamin

D receptors and their associated coactivators[49] heat shock proteins.[50] Additional possibilities include the glucocortocoid and mineralcorticoid receptors and a number of orphan receptors, e.g., the aryl hydrocarbon receptor.[51] In the latter case, it has already been demonstrated that degradation can be effected by a thermally activated enediyne;[52] thus, a photochemical variant could be forthcoming.

In addition to the possibility of tethering enediynes to biological substrates for specific targeting is the concept of generating more intimate enediyne chimera, where the enediyne is fused with a biological substrate. One can envision photochemical activation of appropriate derivatives of uracil-enediyne **78**.[53] This compound already bears the hydrogen bonding pattern necessary for DNA duplex (AT) or triplex (TAT) formation. Such molecules could be incorporated into oligonulceotides for greater sequence specificity prior to photoactivation. Likewise, flavin–enediyne **79** might also be adapted for photochemical studies targeting selected flavoenzymes.[54] Studies have shown that many flavoenzymes can tolerate a number of different substituents at the flavin C7 and C8 positions.[55]

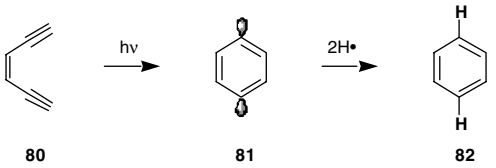
29.5 Theoretical Treatment of the Photochemical Bergman Cycloaromatization

Davidson and Zaleski have examined the photochemical Bergman cyclization computationally using spin-unrestricted density functional theory (UDFT) and multiconfigurational self-consistent field theory (MCSCF).[56] The ground states calculated using UB3LYP and CASSCF accurately reproduced the experimental geometry of *Z*-3-hexen-1,5-diyne (**80**). Other methods (UPBW91) overestimated some bond lengths. All of the methods used predicted a C_{2v} geometry strongly resembling a diradical for the transition state structure and a distorted benzene structure of D_{2h} symmetry when the intermediate (**81**) is completely formed. This is consistent with theoretical treatment of the thermal cyclization, where diyl formation has a late transition state.[57]

The excited states of the enediyne moiety were approximated by a weakly interacting ethylene acetylene model where the various states are expressed as linear combinations of the configurations for one ethylene and two acetylenes. The authors examined the first six excited states of **80**, three triplets and three singlets. All methods examined predicted that the spectroscopically forbidden triplet states (1^3B_2, 1^3B_1, and 1^3A_1, respectively) lie between the singlet ground state (S_0) and the first singlet excited state (1^1B_2).

The weakly interacting ethylene acetylene model indicates that the lowest energy triplet and singlet states of **80** are most closely related to the singlet and triplet states of ethylene. The model therefore predicts that symmetrical substitution at the enediyne alkyne termini will not affect the singlet–triplet energy gap (ΔE_{ST}), while substitution at the double bond will affect ΔE_{ST}. Indeed, enediynes with *n*-propyl or phenyl substituents at the triple bond termini have the same observed energy difference between fluorescent and phosphorescent states.[20] Other spectroscopic evidence supports this point of view when examining substituents on the carbon–carbon double bond.



SCHEME 19 Theoretical examination of Photo-Bergman cyclization.

Bergman cyclization along the C_{2v} lowest energy triplet potential energy surface (PES) is not possible, as the symmetry constraints do not allow the necessary mixing of in-plane and out-of-plane orbitals (Woodward–Hoffmann forbidden). Cyclization along the symmetry-relaxed (C_2) lowest energy triplet PES is Woodward–Hoffmann allowed; however, two other possible mechanisms (isomerization or hydrogen abstraction from the alkyne termini) compete with the Bergman cyclization pathway.

When the lowest energy excited singlet state residing primarily on the triple bonds (1^1B_1) is examined, it is Woodward–Hoffman spin forbidden due to the C_{2v} symmetry of **80**. However, this excited state of **80** was found to relax through a second order Jahn–Teller distortion to a 2^1A state of C_1 symmetry. This state has two major reaction paths, deactivation to the S_0 state or Bergman cyclization, either of which result in Bergman cyclization products.

Even though the 1^3B path may seem preferable thermodynamically, the multiple non-Bergman pathways along the potential energy surface make it an unlikely source of photochemically generated Bergman cyclization reactions. The less exothermic 2^1A PES, while higher in energy, reduces in-plane repulsion between the approaching triple bonds, which is thought to facilitate cyclization. Interestingly, these calculations also indicated that the *p*-benzyne intermediate has unusual characteristics, combining singlet carbene and open-shell diradical features.

29.6 Summary and Outlook

Several research groups have successfully demonstrated the viability of the photo-Bergman cyclization. The efficiency of the process is influenced by several factors, but near-quantitative yields can be obtained under ideal circumstances, rivaling the thermal version of this pathway. The application of this process in molecular biology and molecular medicine would seem particularly attractive. Photoactivated enediynes have been successfully employed as chemical nucleases and as protein degrading agents, in both cases showing good correlation between affinity and cleavage activity. Based on these findings, coupled with expeditious synthetic routes to the core warheads of great diversity, enediyne reagents capable of inducing specific nucleic acid/protein modulation can now be designed. Such affinity cleavage systems may offer advantages over conventional methods since they do not function via metal ion redox chemistry.[58] It is anticipated that the scope and limitations of this field will be the focus of future reports.

The Photochemical Reactivity of the Allenyl–Vinyl Methane System

Takashi Tsuno

Kunio Sugiyama
Nihon University

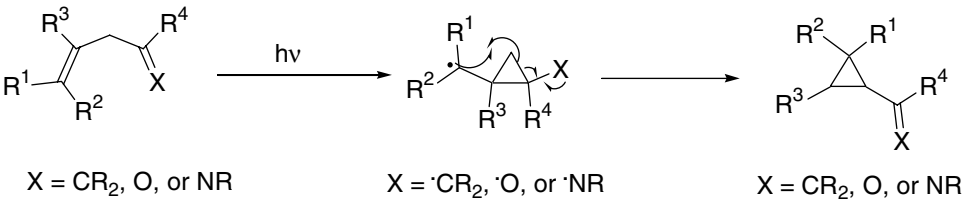
30.1 Introduction

The photochemistry of divinyl methane systems has been extensively examined on the base of energetic research by Zimmerman et al., and excellent published reports exist involving the reaction mechanism, multiplicities, and substituent effects.[1,2] These compounds mainly undergo a di-π-methane rearrangement (Scheme 1).[1,2] The divinyl methane systems in which one vinyl is an imine or carbonyl also undergo a di-π-methane rearrangement; the former is called an aza-di-π-methane rearrangement,[1a,3,4] and the latter is called an oxa-di-π-methane rearrangement[1a,5,6] (Scheme 1). Such structural photochemical rearrangements of the divinyl methane systems are important methods in organic syntheses.[1,3,5]

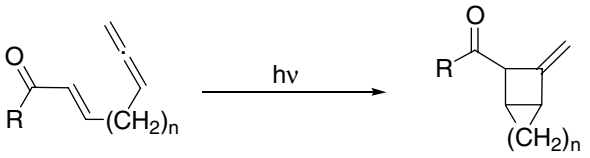
On the other hand, allenes are good alkenes and undergo intermolecular[7,8] and intramolecular [2 + 2]-cycloaddition[7–10] with enones to give *exo*-methylene–substituted fused cyclobutanes (Scheme 2). Because novel fused cyclic compounds or precursors of natural products can be formed from the resulting *exo*-methylene–substituted fused cyclobutanes, these reactions are also key reactions in organic syntheses.[8,9] Since 1,2-propadiene or alkyl-substituted allenes exhibit absorption maxima in the far-UV range and also show a shoulder absorption in the range of 200–250 nm, the enone moiety in the bichromophoric compounds is initially excited (>280 nm), and intramolecular [2 + 2]-cycloaddition then takes place. On the other hand, it has been found that excited allenes can undergo several intramolecular photochemical migrations and cleavage processes.[11,12] Thus, the photochemistry occurring from interaction between an excited state of the allene and the other chromophore in the ground state is also of considerable interest.

The allenyl and vinyl chromophores in allenyl–vinyl methanes are separated by a very short carbon chain: i.e., methylene; hence these compounds are expected to undergo interesting photoreactions within each of the excited states of the chromophores, multiplicities, substituent effects, etc. In 1973, Lankin et al.[13] communicated results dealing with the photochemistry of the allenyl–styryl methanes, and the

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1



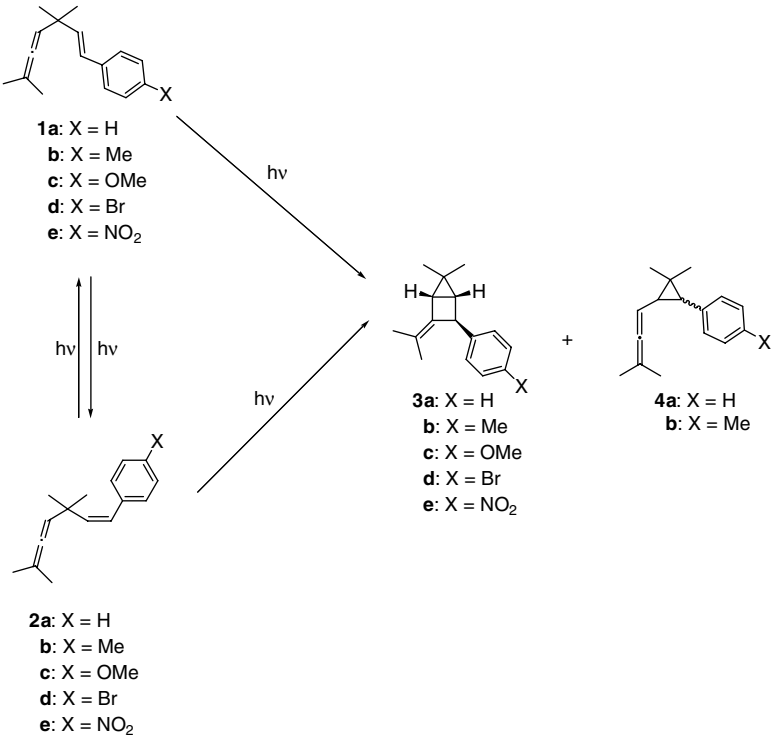
SCHEME 2

full report was published in 1975.[14] Although Jeger et al.[15] also reported the photochemistry of an allenyl–alkenoyl methane, the report is a mere note. Furthermore, several reports on the photochemistry of the allenyl–vinyl methanes substituted with an electron-withdrawing group(s) on the vinyl moiety have been published in the last decade by Tsuno et al.[16–27] In the following sections, we will discuss the observed photochemistry of the allenyl–vinyl methane systems.

30.2 Intramolecular [2 + 2]-Cycloaddition

Most of the divinyl methanes undergo mainly the di-π-methane rearrangement to give vinylcyclopropanes.[1,28] In contrast, there are quite a few examples of intramolecular [2 + 2]-cycloadditions during the direct and/or sensitized photolyses in spite of the substituents on the allenyl–vinyl methanes.[13–27]

Lankin et al. reported that allenyl–styryl methanes underwent an intramolecular [2 + 2]-cycloaddition upon both direct and acetone-sensitized photolyses (Scheme 3).[14] In the reinvestigation[16] of the allenyl–styryl methane systems, results similar to those in Lankin's report were obtained during the direct photolysis; however, the intramolecular [2 + 2]-cycloaddition by acetone-sensitization was not found, and *E,Z*-geometric isomerization proceeded to give an *E,Z*-equilibrium mixture. Sensitized photolyses of **1a** gave equilibrium ratios of **1a** to **2a** dependent upon the triplet energies of the sensitizers used (Figure 30.1).[29] Such a result is analogous to the photochemistry of 1-phenylpropene.[30] The photochemistry of allenyl *p*-substituent styryl methanes **1b–e** and **2b–e** has also been investigated, and Table 30.1 shows the quantum yields for the isomerization of these compounds. The values obtained from the quantum yield measurements show that the *E*-form **1a** prefers the intramolecular cycloaddition path rather than *E,Z*-geometric isomerization, whereas the *Z*-form **2a** reacts in the reverse manner. In the direct photolyses, **1c–e** and **2c–e**, which have an electron-withdrawing or electron-donating aromatic substituent, mainly undergo the *E,Z*-geometric isomerization.[16] Such tendencies indicate participation in barriers for twisting about the double bond on the singlet potential energy surface. In the photochemistry of 1-arylpropenes, the geometric isomerization of (*E*)-1-arylpropenes[31] occurs predominantly from the triplet excited state via intersystem crossing, whereas that of (*Z*)-1-arylpropenes occurs from the singlet state. Moreover, both the electron-donating and electron-withdrawing aromatic substituents of the (*E*)- and (*Z*)-1-arylpropenes have been found to have a low barrier for singlet state isomerization.[31] Hence, the singlet states of the allenyl–styryl methanes, except for **1a** and **1b**, can relax to a perpendicular singlet ($^1P^*$) to give either an *E*- or *Z*-form. The *E*-forms **1a** and **1b** undergo predominantly the intramolecular [2 + 2]-cycloaddition by the singlet state rather than undergoing the triplet geometric isomerization via intersystem crossing. In addition, within the triplet-sensitized reactions there can be relaxation



SCHEME 3

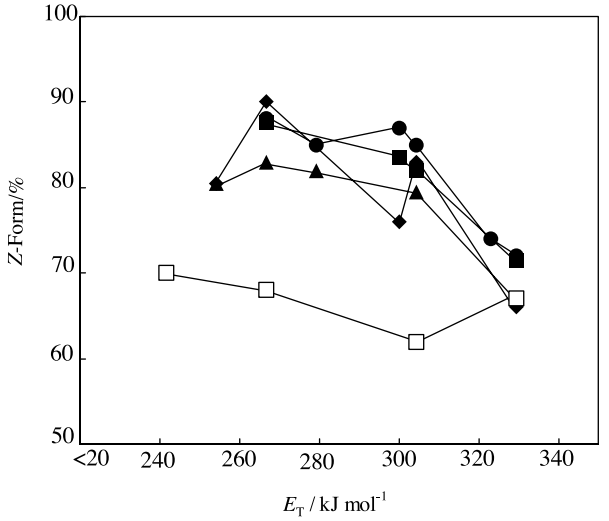


FIGURE 30.1 Compositions of the *Z*-forms in photostationary state by triplet sensitized isomerization of *p*-substituted styryl-allenyl methanes: (**2a**: ●), (**1b**: ■), (**2c**: ♦), **2d**: ▲), and **2e**: □).

to a perpendicular triplet ($^3P^*$) by a zero barrier energy surface. The decay to the ground state by intersystem crossing yields mixtures of the *E*- and *Z*-forms.

It has been reported that the divinyl methanes, in which one vinyl group is an electron-deficient alkene, undergo specific photochemistry: e.g., regioselective di-π-methane rearrangement[32] and an unusual diversion of the di-π-methane rearrangement.[2a] However, the allenyl–vinyl methanes **5–9**,

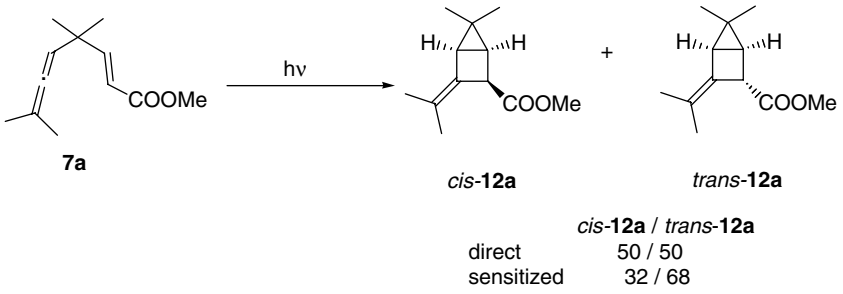
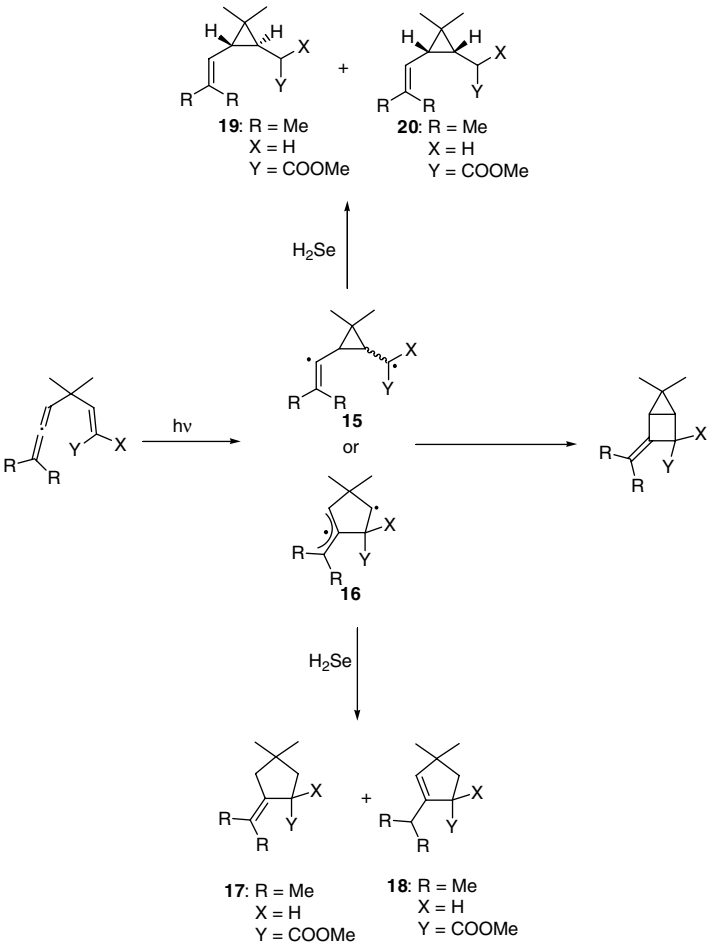


SCHEME 5

which have electron-withdrawing group(s) on the vinyl group, undergo predominantly the intramolecular [2 + 2]-cycloaddition by triplet sensitization (Scheme 4).[17–23] The triplet energies of these compounds were estimated from the energies of the sensitizers used, and the estimated values are shown in Table 30.2. The estimated energies reported are triplet energies of the vinyl moieties[32c,33,34] of the allenyl–vinyl methanes. Therefore, the intramolecular [2 + 2]-cycloaddition of **5–9** takes place, obviously, via the triplet-excited state of the vinyl chromophore.

These allenyl–vinyl methanes **5–9** also gave the housanes **10–14** as a main products or byproducts during direct photolyses.[17–23] From a consideration of triplet energies involved, it was expected that 2-methyl-1,3-butadiene could act as a quencher for intramolecular [2 + 2]-cycloaddition that occurs during direct photolyses. However, this effect was not observed. Thus, if intramolecular [2 + 2]-cycloaddition during the direct photolyses takes place via a triplet pathway only, the rate of its reaction is greater than that of diffusion control. Fortunately, the ratios of the resulting *cis*- and *trans*-housanes *cis*-**12a** and *trans*-**12a** from the direct and sensitized photolyses of **7a** were different (Scheme 5).[19] Therefore, the intramolecular [2 + 2]-cycloaddition of the allenyl–vinyl methanes **5–9** with electron-withdrawing substituents generally involves a singlet excited state pathway except where a triplet state has been definitely proven. Furthermore, because the formation of the *cis*- and *trans*-housane mixture indicates a biradical mechanism, the intramolecular [2 + 2]-cycloaddition involves either a pathway through the 1,4-biradical **15** or the cyclopentane-1,3-diyl radical **16** (Scheme 6). Hydrogen selenide is known to be a good radical hydrogenating reagent.[35–37] Weedon et al.[35–37] have reported the chemistry of trapping of a biradical intermediate for several ene–enone photocycloadditions. Their reports describe an experiment involving an intermolecular allene–cyclopentenone photocycloaddition. In this it has been found that the terminal carbon, rather than the central carbon of the allene, initially bonds to the α-carbon of the cyclopentenone.[35] If these allenyl–vinyl methanes undergo the intramolecular [2 + 2]-cycloaddition according to the mechanism proposed by them, the resulting intermediate would be the 1,4-biradical **15** (Scheme 6). However, we have observed that the path involving the "rule of five" for intramolecular [2 + 2]-cycloaddition of a cycloalkenone with a terminal alkene is involved, and the cyclopentane-1,3-diyl radical biradical intermediate was trapped with hydrogen selenide.[36] The intermediate of the intramolecular [2 + 2]-cycloaddition of the allenyl–vinyl methanes is the cyclopentane-1,3-diyl radical **16** on the basis of the "rule of five" (Scheme 6). If the bulk of the biradical intermediates was trapped with hydrogen selenide, each of the possible hydrogenated compounds **17–20** would be formed. From both the direct and sensitized photolyses of **7a** in the presence of hydrogen selenide, the formation of **17** and **18** by GCMS and GLC analyses was observed, but not that of **19** and **20**.[19] This result proves that the intermediate in the intramolecular [2 + 2]-cycloaddition is the cyclopentane-1,3-diyl radical **16**.

The photoreactivities for the intramolecular [2 + 2]-cycloaddition of the allenyl–vinyl methane systems increase with an increase in the number of methyl donating groups linked to the allene.[17–21,23,24] The results of PM3 MO calculations of the model chromophores **21–25** in the allenyl–vinyl methane systems are shown in Figure 30.2. The HOMOs of **22** and **23** lie at the C1-C2 position, whose coefficients have the same values. On the other hand, the HOMO of **21** lies at the C2-C3 position, and the MO coefficient of C3 has a larger value than that of C2. In addition, the MO coefficient of the β-carbon of **24** or **25** is



SCHEME 6

lower than that of the α-carbon. These coefficients also support the fact that the intramolecular [2 + 2]-cycloaddition apparently proceeds via the cyclopentane-1,3-diyl radical mechanism.

30.3 Formation of the Alkenylidenecyclopropanes

Because methylene Meldrum's acid is a very electron-deficient alkene,[38] the compounds **5a–c** form an intramolecular charge transfer (CT) complex and show CT bands in a range of 250 to 320 nm.[17,18] Each of the CTs (> 280 nm) and the local excitation (254 nm) of **5a–c** gave the alkenylidenecyclopropanes **26a–c** as main products (Scheme 7).[17,18] Triplet sensitization of these compounds brings about the intramolecular [2 + 2]-cycloaddition as mentioned above. Hence, these compounds are produced via a CT singlet excited state. This reaction mechanism is shown in Scheme 8. The 5-methine protons of a 5-alkyl-substituted Meldrum's acid act as a Brønsted acid.[26,38] These can possibly be exchanged with deuterium, and therefore deuteration under irradiation in methanol-O-*d* cannot fully prove the presence of the enol intermediate **27**.[17] However, when a solution of the monoester **7b** in methanol-O-*d* was irradiated, GCMS analysis showed the vinylidenecyclopropane with deuterium incorporated at the α-position (Scheme 9).[19] This strongly supports a reaction mechanism involving enol intermediates such as **27** or **28**.

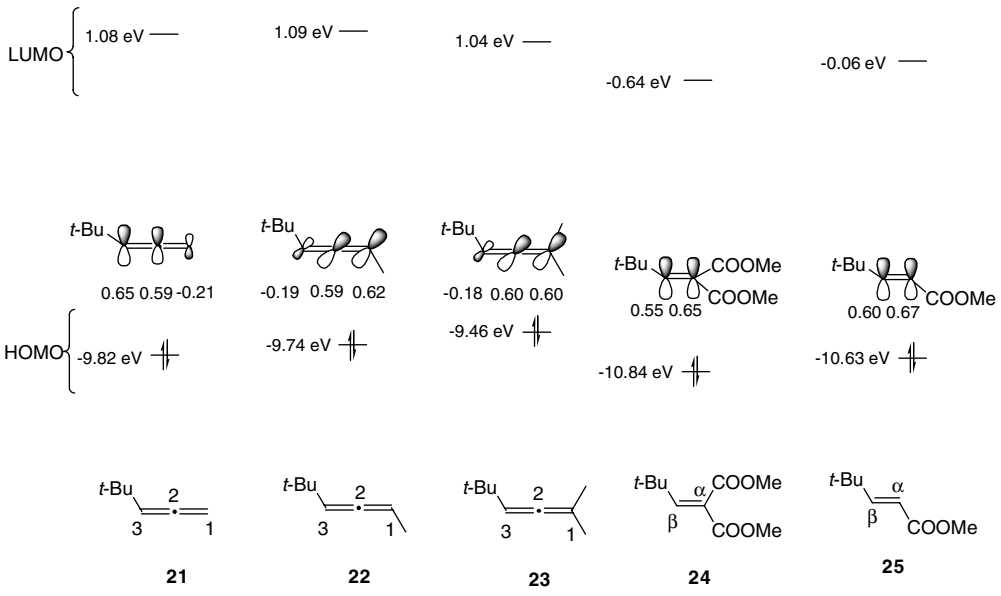


FIGURE 30.2 Molecular orbital correlation diagrams of **21–25**.

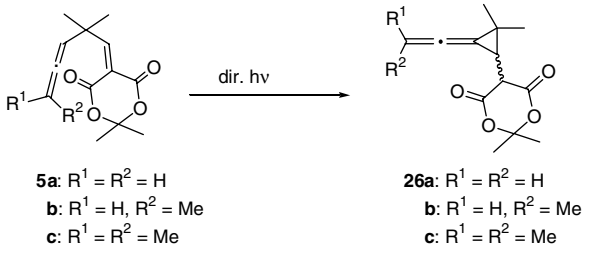
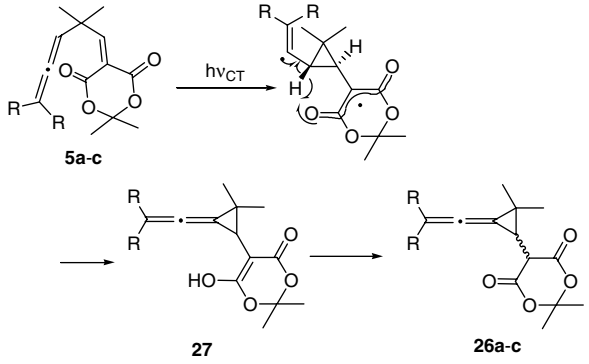
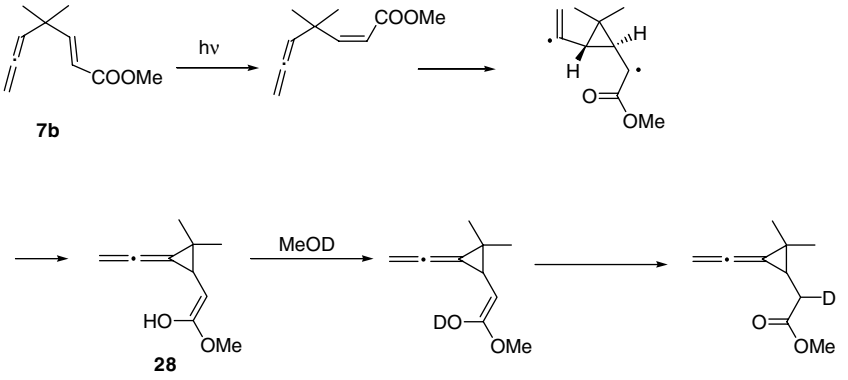


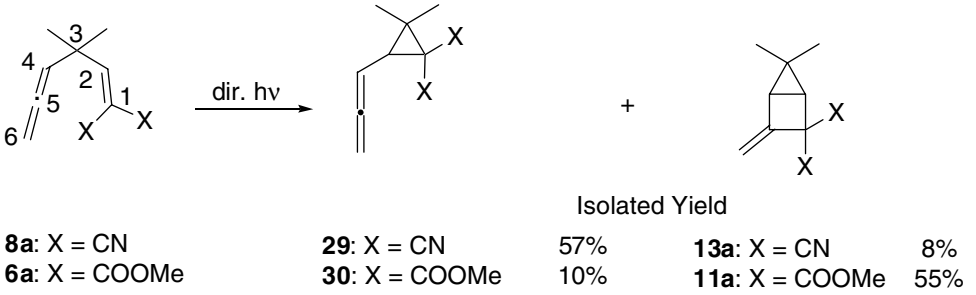
SCHEME 7



SCHEME 8



SCHEME 9



SCHEME 10

30.4 Di-π-Methane Rearrangement

Several allenyl–vinyl methanes undergo the di-π-methane rearrangement. All of the di-π-methane rearrangements observed take place regioselectively and lead to allenylcyclopropanes.[13,14,16,19–22] The allenyl-vinyl methanes, in which the allenyl is 1,2-propadiene, are apt to undergo the di-π-methane rearrangement. As shown in Figure 30.2, the MO coefficient of the C3 of allene **21** has a larger value than that of the C2; hence MO interaction between the C2 and C4 of the allenyl–vinyl methane brings about the di-π-methane rearrangement. Interestingly, the γ-1,2-propadienyl-substituted alkylidenemalononitrile **8a** gave the allenylcyclopropane **29** as the principal product,[21] while the γ-1,2-propadienyl-substituted alkylidenemalonate **6a** does not react by the di-π-methane pathway but prefers the intramolecular [2 + 2]-cycloaddition to give **11a** as a main product (Scheme 10).[19] The MO coefficient for the α-carbon of 2,2-dimethylpropylidenemalonate is larger than that of the β-carbon (Figure 30.2). Therefore, the principal MO interaction of the γ-1,2-propadienyl-substituted alkylidenemalonate **6a** is between C1 and C5, thus undergoing the intramolecular [2 + 2]-cycloaddition. On the other hand, the β-carbon of 2,2-dimethylpropylidenemalonitrile has a somewhat larger value: hence, the MO interaction between the C2 and C4 of the γ-1,2-propadienyl-substituted alkylidenemalononitrile **8a** is predominant, and this system undergoes the di-π-methane rearrangement.

30.5 Phenyl Migration

Phenyl migration and intramolecular [2 + 2]-cycloaddition occur in competition on direct and sensitized photolyses of phenyl-substituted allenyl–vinyl methanes.[21,22] The quantum yields for the isomerization of **31** and **32** upon the sensitized photolyses are shown in Table 30.3. Although the acetone, acetophenone, and benzophenone-sensitization of **31** yielded both **33** and, sensitizers with triplet energies < 280 kJ

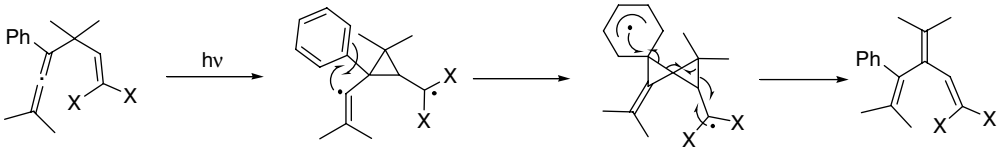

SCHEME 11

mol^{-1} did not affect the intramolecular [2 + 2]-cycloaddition. On the other hand, in the sensitized photolyses of **32**, acetone, acetophenone, benzophenone, and thioxanthen-9-one with triplet energies >270 kJ mol^{-1} show the formation of **35** and **36** from the triplet state, while Michler's ketone or 4-phenylbenzophenone gave only traces of **35**. The chemoselectivity of these compounds can be controlled by the correct choice of triplet sensitizer: e.g., the anthraquinone-sensitization of **31** gave **33**, while sensitization by Michler's ketone of **32** led to **36**.[21] These results indicate that there are two reaction pathways involving the triplet states of different chromophores. As mentioned above, the lowest triplet energies of the α,β-unsaturated ester and α,β-unsaturated nitrile have been estimated to be ca. 280 and 250 kJ mol^{-1}, respectively. The triplet energy of the phenyl-substituted allene has been estimated to lie in the range of 250–270 kJ mol^{-1}.[21,22] Hence, the triplet energies of the chromophores in **31** and **32** are in the order of $C = C(COOMe)_2 > PhC = C = CMe_2 > C = C(CN)_2$. The intramolecular [2 + 2]-cycloaddition of these compounds takes place above the estimated triplet energy level of the vinyl chromophore and further, when the triplet sensitizers over 260 kJ mol^{-1} were used, cross-conjugated trienes were produced. For the formation of the trienes **33** and **35**, it has been considered that the excited state of the allenyl chromophore bonds between the C3 and C5 yields a biradical, which undergoes a 1,2-phenyl migration to yield the trienes (Scheme 11).

30.6 Intramolecular Oxa–Diels–Alder Reaction

The (*E*)-exo-methylenecycloalkanones **37a**, **b** and **38a**, **b** mainly undergo *E,Z*-geometric isomerization during direct photolysis to give the (*Z*)-isomers **39a**, **b** and **40a**, **b**, respectively (Scheme 12).[23,24] In the photolyses of **37a**, **b** and **38a**, pyrans **41a**, **b** and **42** formed slowly on prolonged irradiation.[23,24] It is obvious that the pyrans are derived from the photochemical intramolecular oxa-Diels–Alder reaction of the (*Z*)-*exo*-methylenecycloalkanones, and this is supported by GLC analyses of the reaction mixtures and by quantum yield measurements. Such intramolecular oxa-Diels–Alder reactions have also been found in the photochemistry of several other allenyl–vinyl methanes;[17,21–24,27] in particular, the photolyses of the γ-allenyl-substituted 2-alkylideneindan-1,3-diones **43a, b** gave the pyrans **44a, b** as a sole or main product (Scheme 13).[27] For the intramolecular oxa–Diels–Alder reaction, both the torsion angle and the *s-cis* conformation in the C=C-C=O are important factors: e.g., the intramolecular oxa–Diels–Alder reaction readily takes place with a small torsion angle. The initial pathway in the intramolecular oxa–Diels–Alder reaction parallels the Paternó–Büchi reaction of ketones with allenes,[15,39] although the resulting biradical **45** (Scheme 12) prefers the pathway for the formation of **41a, b** or **42** to that of oxetane formation.[40]

Photochemistry of Vinylidenecyclopropanes

Kazuhiko Mizuno
Osaka Prefecture University

Hajime Maeda
Osaka Prefecture University

31.1 Introduction

The photochemical and photophysical properties of small ring compounds such as cyclopropanes and cyclobutanes have been well investigated from the mechanistic and synthetic viewpoints.[1–11] The main reaction pathways of conjugated or activated cyclopropanes such as alkenyl- or aryl-substituted cyclopropanes, methylenecyclopropanes, and cyclopropyl ketones include *cis,trans*-photoisomerization, photorearrangement, photoaddition, and photocycloaddition. The photocycloaddition of allenes to carbonyl compounds[12–17] and the photoaddition of alcohols to aryl-substituted allenes[18–19] have also been reported by several groups. However, little has been reported about the photochemistry of vinylidenecyclopropanes, which have not only allene and cyclopropane units, but also a methylenecyclopropane unit. We have previously reported a convenient method for the synthesis of vinylidenecyclopropanes in good to high yields.[20] In this chapter, we will discuss the *cis,trans*-photoisomerization, photorearrangements, and [3 + 2]-photocycloaddition of 1-diarylvinylidenecyclopropanes **1**. It should be noted here that the reactive site in the excited states of **1** is the cyclopropane ring, and the regioselective bond cleavage occurs at the a-bond of **1** in Scheme 1.

31.2 *cis,trans*-Photoisomerization

Direct Photolysis

Direct photolysis of *cis*- and *trans*-1-(2′,2′-diphenylvinylidene)-2,3-dimethylcyclopropane (***c*-2a** and ***t*-2a**) in benzene caused *cis,trans*-photoisomerization to give a 1:1 photostationary state (PSS) mixture.[21]

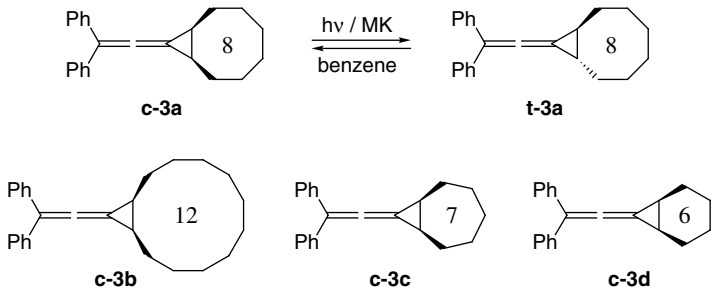
2c; Ar = *p*-ClC_6H_4 **2d**; Ar = *p*-$CH_3OC_6H_4$

SCHEME 2

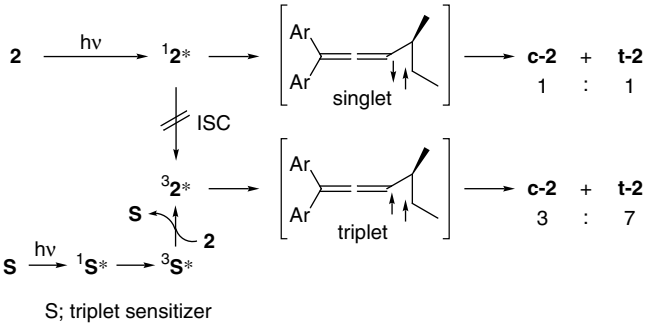
Similar photoisomerization of ***c*-2a** and ***t*-2a** occurs in other solvents such as acetonitrile and ethyl acetate to afford the same PSS mixture as that in benzene. Direct irradiation of *p*-substituted vinylidenecyclopropanes **2b-d** also afforded 1:1 PSS mixtures. The results are summarized in Table 31.1. These photoisomerizations were not quenched by typical triplet quenchers such as molecular dioxygen, 2-methyl-1,3-butadiene, and cyclohexa-1,3-diene. Therefore, this photoreaction proceeds through a singlet mechanism.

Triplet Sensitization

The photoreaction of ***c*-2a** and ***t*-2a** in the presence of triplet sensitizers such as acetophenone (E_T = 309 kJ mol^{-1}), benzophenone (E_T = 288 kJ mol^{-1}), thioxanthen-9-one (E_T = 265 kJ mol^{-1}), Michler's ketone (MK; E_T = 259 kJ mol^{-1}), and 1-acetonaphthone (E_T = 236 kJ mol^{-1}) gave a 3:7 PSS mixture of ***c*-2a** and ***t*-2a**.[21] However, pyrene (E_T = 203 kJ mol^{-1}) did not sensitize this reaction. The photoisomerization of ***c*-2a** to ***t*-2a** in the presence of 9-fluorenone (E_T = 211 kJ mol^{-1}) does occur but only slowly. These results clearly show that the excited triplet state of **2a** is a reactive species in this photoisomerization, and the triplet energy of **2a** is estimated as 220–230 kJ mol^{-1}.



SCHEME 3



SCHEME 4

The triplet-sensitized photoisomerization occurs more efficiently than does isomerization by direct irradiation. The quantum yield from ***c*-2a** to ***t*-2a** in the presence of MK at 366 nm is 0.62. The triplet-sensitized photoisomerization of **2b-d** also takes place to give approximately 3:7 (*cis:trans*) PSS mixtures. The PSS ratios in both direct and triplet-sensitized photoreactions do not depend on the *p*-substituents on the aryl rings, but depend on the multiplicity of the reaction.

Bicyclic diphenylvinylidenecyclopropanes ***c*-3a** and ***t*-3a** with eight-membered rings in the presence of MK photoisomerized to give a 1:1 PSS mixture with high efficiency.[22] Similar irradiation of ***c*-3b** with a 12-membered ring in the presence of MK afforded ***t*-3b**. However, *cis*-diphenylvinylidenebicyclo[4.1.0]heptane and *cis*-diphenylvinylidenebicyclo[5.1.0]octane ***c*-3c-d** did not isomerize to the *trans*-isomers ***t*-3c** and ***t*-3d**.

The simplified mechanism is shown in Scheme 4. Both the excited singlet and triplet states of **2** smoothly bring about C1-C2 bond cleavage followed by isomerization to the PSS mixture depending on the excited state. Probably, the intersystem crossing (ISC) from the excited singlet state of **2** to the triplet state is quite slow or inefficient. The singlet 1,3-biradical reforms the cyclopropane ring before ISC to the triplet 1,3-biradical occurs. The cleaved bond in both the singlet and the triplet photoisomerizations is postulated from the results of photocycloaddition and photorearrangement discussed in later sections of this chapter.

Electron Transfer Sensitization

The 9,10-dicyanoanthracene (DCA)-sensitized *cis,trans*-photoisomerization of highly electron-rich 1,2-diarylcyclopropanes and diarylmethylenecyclopropanes efficiently proceeds via a radical cation chain transfer mechanism.[1,3,4] The photoisomerization of electron-rich 1-diarylvinylidene-*cis*-2,3-dimethylcyclopropane (***c*-2d**) in acetonitrile was also sensitized by DCA via photoinduced electron transfer.[23] The photoisomerization efficiently takes place to give a 3:7 PSS mixture of ***c*-2d** and ***t*-2d**. However, the less electron-rich 1-diarylvinylidenecyclopropanes ***c*-2a-c** under the same reaction conditions slowly isomerized

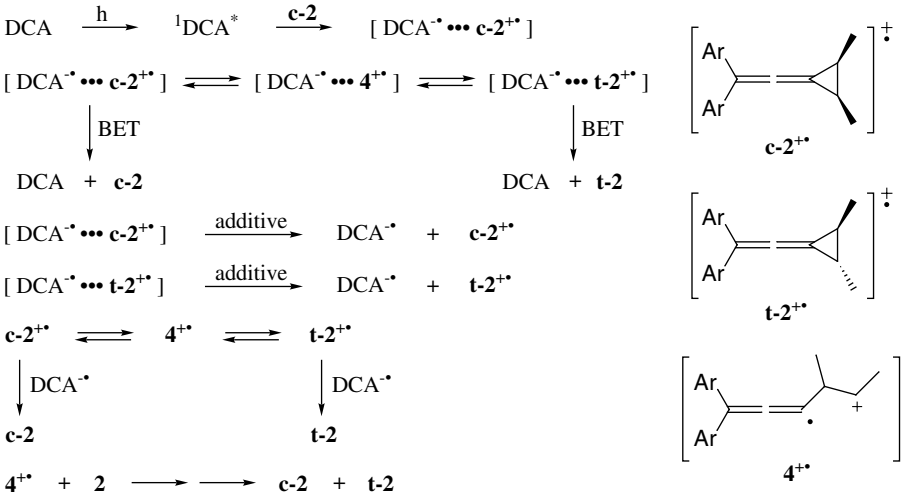
SCHEME 5

to ***t*-2a-c**, respectively. The efficiency for the photoisomerization depends remarkably on the additives and solvents (Table 31.2). The photoisomerization is accelerated by molecular dioxygen and by some additives such as $Mg(ClO_4)_2$ and phenanthrene in a manner similar to the photoinduced electron transfer reaction of the DCA-1,2-diarylcyclopropane system.[1,3,24–26] The simplified mechanism is shown in Scheme 6. The first step is a photoinduced one-electron transfer from ***c*-2** to the excited singlet state of DCA, $^1DCA^*$, to generate the free radical ions via the radical ion pair $[DCA^{-\cdot} \cdots \boldsymbol{c}\text{-}\mathbf{2}^{+\cdot}]$. The key step of this photoisomerization is the dissociation from the radical ion pair to the free radical ions assisted by additives such as $Mg(ClO_4)_2$. The ring opening of $\boldsymbol{c}\text{-}\mathbf{2}^{+\cdot}$ generates ring opened radical cation $\mathbf{4}^{+\cdot}$ by cleavage of the C1-C2 bond. The rotation of the C2-C3 bond of $\mathbf{4}^{+\cdot}$ followed by a back-electron transfer from $DCA^{-\cdot}$ to the opened 1,3-biradical and rebonding process brings about *cis,trans*-photoisomerization. It is notably here that a chain mechanism in which an electron transfer from neutral ***c*-2d** to $\mathbf{4}^{+\cdot}$ takes place is included in the reaction. The back electron transfer (BET) from $DCA^{-\cdot}$ to $\boldsymbol{c}\text{-}\mathbf{2}^{+\cdot}$ was effectively suppressed by the addition of molecular dioxygen and $Mg(ClO_4)_2$. The enhancement of the reaction can be interpreted by the rapid electron-transfer from $DCA^{-\cdot}$ to molecular dioxygen to afford DCA and $O_2^{-\cdot}$ and/or by the interaction of $DCA^{-\cdot}$ with Mg(II) ion.

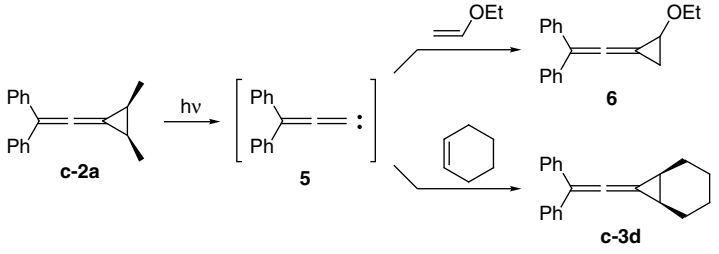
31.3 Generation of Vinylidenecarbenes

Photoirradiation of **2a** in methanol through a Pyrex filter did not give any methanol-incorporated product. On the other hand, irradiation of **2a** in the presence of a large excess of ethyl vinyl ether gave 2-ethoxy-1-(diphenylvinylidene)cyclopropane **6** in a 25% yield.[27] Similar irradiation of **2a** in the presence of cyclohexene gave the corresponding vinylidenecyclopropane, although in low yield. These results clearly demonstrate the formation of diphenylvinylidenecarbene, which is trapped by alkenes. The electrophilic character of this carbene was supported by the reactivity toward these alkenes. This carbene



BET; back electron transfer

SCHEME 6



SCHEME 7

was not generated by triplet sensitization. Therefore, the vinylidenecarbene is produced as a competitive process with the formation of 1,2,3-butatriene from the excited singlet state of **2a**, as discussed in next section.

31.4 Photorearrangements

1,2,3-Butatriene

Irradiation of a benzene solution containing 1-diarylvinylidene-2,2,3,3-tetramethylcyclopropanes (**7a–d**) efficiently afforded 1,1-diaryl-4,5,5-tetramethyl-1,2,3-hexatrienes (**8a–d**) in high yields. The quantum yields for the formation of **8a–d** were not high ($\Phi = 0.01 \sim 0.02$) as shown in Table 31.3.[27] The photorearrangement of 2,2,3-trimethyl and 2,2-and 2,3-dimethyl derivatives **7e–f**, **2a** also took place, but the rates for the formation of the 1,2,3-butatrienes were quite slow and products were not isolated. The bicyclic vinylidenecyclopropanes **7g–h** also rearranged to the 1,2,3-butatriene derivatives **8e–g**. The structure of **8b** is confirmed by x-ray crystallography.

This photorearrangement was not sensitized by triplet sensitizers such as benzophenone and MK and was not quenched by molecular dioxygen and 2-methyl-1,3-butadiene, and thus a singlet mechanism is proposed. The homolysis of the C1-C2 bond of **7** from the excited singlet state of **7** generates the 1,3-singlet

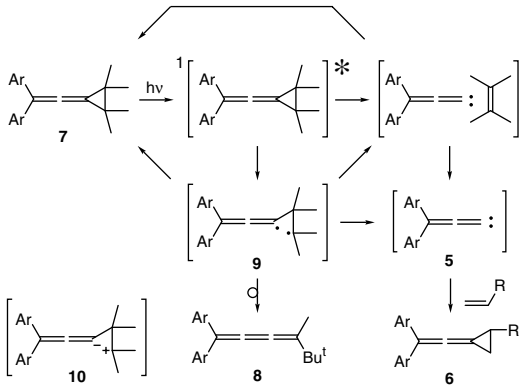
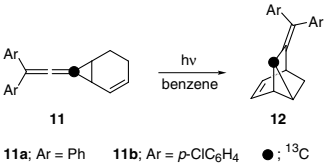
biradical intermediate, which rearranges to 1,2,3-butatriene by the migration of an alkyl group. A heterolytic cleavage seems unlikely, because the putative 1,3 dipolar intermediate **10** is not trapped by methanol under the reaction conditions.



SCHEME 11



SCHEME 12

Carbon Skeleton Rearrangements

Irradiation of a benzene solution of 7-(2′,2′-diarylvinylidene)bicyclo[4.1.0]hept-2-enes **11a-b** gave 8-(diarylmethylene)tricyclo[2.2.2.0^{6,7}]oct-2-enes **12a-b** in good yields.[28] The structures of **12a-b** were determined from their spectral properties and from x-ray structure analysis of **12a**. The IR spectra showed the disappearance of the stretching vibration of the allenyl bond at 1990 cm^{-1}. The photorearrangement was not sensitized by triplet sensitizers such as benzophenone and MK. These results strongly suggest that this photorearrangement occurs from the singlet excited state. The photoreaction of ^{13}C-labeled compound gave the ^{13}C-labeled rearranged product when the ^{13}C was introduced exclusively into the position shown in Scheme 12. However, the detailed mechanism of the rearrangement is not clear at this stage.

Irradiation of a benzene solution of *exo*-3-(diarylvinylidene)tricyclo[3.2.1.0^{2,4}]oct-6-enes (**13a-b**) gave 4-(diarylvinylidene)bicyclo[3.2.1]octa-2,6-dienes (**14a-b**) in good yields (Scheme 13).[28] Similar irradiation of the *endo*-isomer and *exo*-3-(diphenylvinylidene)tricyclo[3.2.1.0^{2,4}]octane did not give the corresponding rearranged product. Irradiation by a low pressure lamp through a quartz glass filter of *exo*-3-(dimethylvinylidene)tricyclo[3.2.1.0^{2,4}]oct-6-ene also gave a rearranged product in low yield.

In contrast to the above photorearrangement in Scheme 12, the photoreaction of **13a-b** was sensitized by benzophenone and MK, suggesting that this photoreaction occurs from the excited triplet state. The photoreaction of ^{13}C-labeled compound clarified the mechanism as shown in Scheme 13.

31.5 [3 + 2]-Photocycloaddition with Unsaturated Compounds

Triplet-Sensitized Regioselective Photocycloaddition with Electron-Deficient Alkenes

Photoinduced [3 + 2]-cycloaddition of cyclopropanes and methylenecyclopropanes as C3-units with alkenes is a useful method for the one-step synthesis of five-membered ring compounds.[1] However, there is no

example of the photocycloaddition of vinylidenecyclopropanes with alkenes to give vinylidenecyclopentanes and related five-membered ring compounds. In this section, [3 + 2]-photocycloaddition of vinylidenecyclopropane derivatives with electron-deficient alkenes and cyano-substituted compounds is described.

Photoirradiation of a benzene solution containing **7a**, acrylonitrile **15a**, and MK under argon atmosphere gives 2-cyano-1-diphenylvinylidene-4,4,5,5-tetramethylcyclopentane **16a** in an 85% isolated yield.[29] Similar photoreactions of **7a-b,f** with electron-deficient alkenes **15a-d** under similar conditions afforded the corresponding vinylidenecyclopentane derivatives. The photocycloaddition occurs in a highly regioselective manner (Table 31.4). However, **7a** reacts neither with β-substituted alkenes such as crotononitrile, 1,2-dicyanoethene, and cyclo-2-hexenone, nor with electron-rich alkenes such as ethyl vinyl ether. In the case of **7f**, cycloaddition occurs with alkenes with high selectivity, and the corresponding cycloadducts **16f,g** are produced. The photoreaction did not proceed in the absence of a triplet sensitizer such as MK. Therefore, a triplet 1,3-biradical mechanism is proposed for the [3 + 2]-photocycloaddition of electron-deficient alkenes to 1-diarylvinylidenecyclopropanes. The C1-C2 bond cleavage of **7** occurs regioselectively (Scheme 14). This result is quite interesting because methylenecyclopropanes usually cleave at the 2,3-bond to generate trimethylenemethane intermediates as reactive species. The regioselective photocycloaddition can be reasonably explained by the nucleophilic attack of electron-deficient alkenes at the tertiary alkyl radical to give 1,5-biradicals, which cyclize to diarylvinylidenecyclopentanes.

Ritter-Type Photocycloaddition via Electron Transfer

Ritter-type nucleophilic photocycloaddition of a cyano group to the cationic carbon of the 1,3-radical cation of vinylidenecyclopropane generated by photoinduced electron transfer has been reported by Mizuno et al. (Table 31.5).[30] Irradiation of an acetonitrile solution containing electron-rich 1-[2′,2′-bis(4-methoxyphenyl)vinylidene]-2,2,3,3-tetramethylcyclopropane (**7c**) with aliphatic nitriles and benzonitriles in

SCHEME 14

TABLE 31.5 (3+2) Photocycloaddition of Vinylidenecyclopropane **7c** with Organic Carbonitriles[a]

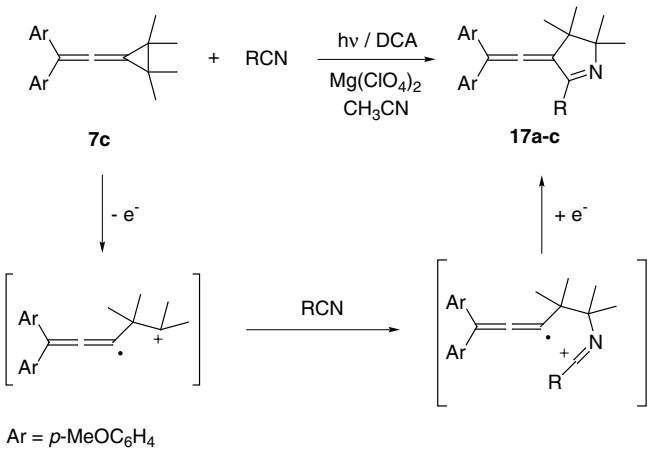
Entry	Cyclopropane	Ar	RCN	Product	Isolated yield / %
1	**7a**	Ph	MeCN	—	0
2	**7c**	*p*-$MeOC_6H_4$	MeCn	**17a**	86
3	**7c**	*p*-$MeOC_6H_4$	EtCN	**17b**	88
4	**7c**	*p*-$MeOC_6H_4$	PhCN	**17c**	90

[a] Photoirradiation was conducted by a 300 W high pressure mercury lamp through $CuSO_4$-NH_3 filter (> 400 nm). Conditions: [**7**] = 1×10^{-2} mol dm^{-3}, [$Mg(ClO_4)_2$] = 1×10^{-2} mol dm^{-3}, [DCA] = 5×10^{-4} mol dm^{-3} in acetonitrile.

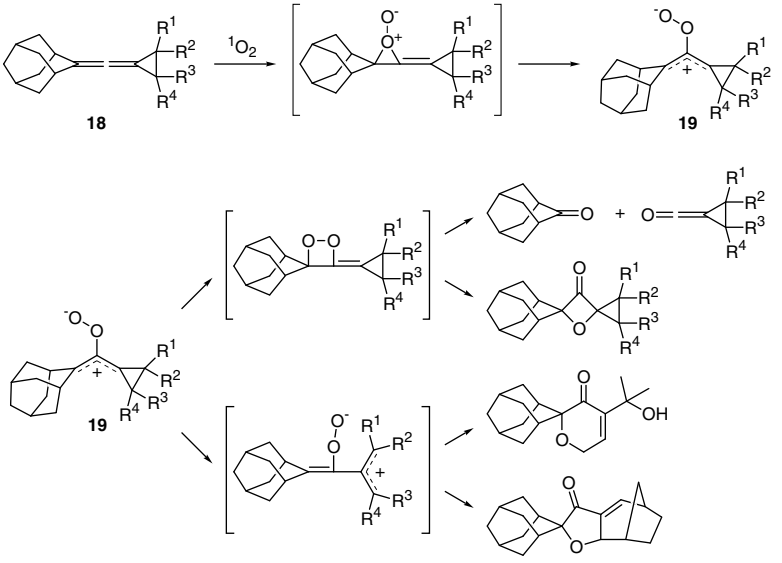
the presence of DCA and $Mg(ClO_4)_2$ gives 2-alkyl or 2-phenyl substituted 3-[2′,2′-bis(4-methoxyphenyl)vinylidene]-4,4,5,5-tetramethyl-1-pyrroline **17a-c**.[30] The [3 + 2]-photocycloaddition hardly occurs in the absence of $Mg(ClO_4)_2$. The less electron-rich vinylidenecyclopropanes **7a-b,d** did not give the corresponding [3 + 2]-photocycloadducts. The photoreaction can be reasonably explained by a photoinduced electron-transfer mechanism. Organic carbonitriles attack the cation site of the ring-opened radical cation of **7c** followed by cyclization to give [3 + 2]-cycloadducts. The addition of $Mg(ClO_4)_2$ to the reaction system probably suppresses a back-electron transfer from $DCA^{-\cdot}$ to the radical cation of **7c**.

31.6 Photooxygenation

Photooxygenation of small ring compounds has received considerable attention from synthetic and mechanistic viewpoints in the past two decades. Recent progress in photooxygenation via photoinduced electron transfer has provided a new aspect in this area. DCA-sensitized photooxygenation of electron-rich 1,2-diarylcyclopropanes and diarylmethylenecyclopropanes afforded 1,2-dioxolanes in high yields via their radical cations. [1,3,24–25] However, little has been published about the photooxygenation of vinylidenecyclopropane derivatives. Akasaka et al. reported the formation of oxygenated products in the dye-sensitized photooxygenation of vinylidenecyclopropane derivatives.[31] On the other hand, the DCA-sensitized photooxygenation of 1-diarylvinylidenecyclopropanes in acetonitrile afforded benzophenone derivatives as a main product.[32]



SCHEME 15



SCHEME 16

31.7 Photochemical Generation of Vinylidenecyclopropanes

Vinylidenecyclopropanes as photoproducts have been generated in some cases. Chapman et al. have reported the formation of unsubstituted vinylidenecyclopropane by the photolysis of 2,6-diazocyclohexanone in an argon matrix at 8 K.[33] The photolysis proceeds via several intermediates such as diazoketene, cyclopropenone, and cyclopentyne. The photolysis of allenyl(vinyl)methane derivatives produced the vinylidenecyclopropane derivatives as main products via intramolecular charge transfer complexes.[34–36] However, the photochemical behavior of these compounds has not been discussed.

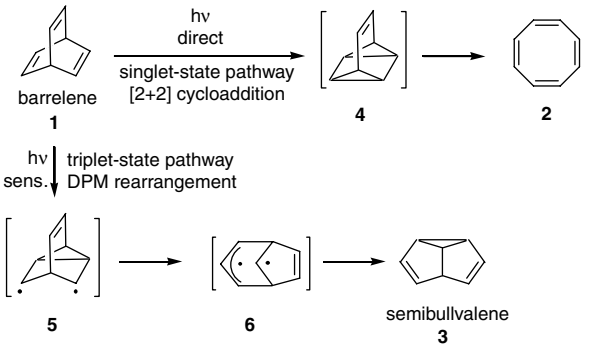
Rama Krishna Peddinti
National Tsing Hua University

32.1 Introduction

The photochemistry of barrelenes and arene-fused barrelenes has been extensively explored, and several reviews have been published in recent years.[1–6] Barrelenes undergo facile photoisomerizations to the corresponding cyclooctatetraenes or semibullvalenes based on the irradiation conditions employed. It has been established[7] that upon direct irradiation of barrelene (**1**), cyclooctatetraene (COT) (**2**) is formed through a singlet-state pathway involving [2 + 2]-cycloaddition to quadricyclane-like intermediate **4** followed by isomerization, whereas the formation of semibullvalene (SB) (**3**) involves biradical intermediates **5** and **6** under triplet sensitization; this is known as the di-π-methane (DPM) rearrangement (Zimmerman rearrangement) (Scheme 1).[8]

When an arene is fused to barrelene, competition exists between vinyl–vinyl and arene–vinyl bridgings in the photorearrangement of arene-fused barrelenes leading to the formation of regio-isomeric photoproducts in the case of unsymmetrical reactants. The competition between the modes of bridging increases when two different arenes are fused to barrelene (vinyl–aryl 1 bridging, vinyl–-aryl 2 bridging, or aryl 1–aryl 2 bridging) or when an arene and a heteroarene are fused to barrelene (vinyl–aryl bridging, vinyl–heteroaryl bridging, or aryl–heteroaryl bridging). Unlike arene-fused barrelenes, heteroarene-fused barrelenes have received very little attention, apparently due to the lack of their easy accessibility. Only one example of the photorearrangement of heteroarene-fused barrelenes had been reported in the literature[9] when we commenced our work in this area. During our studies on masked *o*-benzoquinone Diels–Alder strategy, numerous Diels–Alder adducts that are immediate precursors for α-diketones of

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1

the bicyclic[2.2.2]system have been accessed.[10] Thus, an opportunity had arisen to synthesize heteroarene-fused barrelenes from the Diels–Alder adducts derived from masked *o*-benzoquinones. This article will focus mainly on the photochemistry of heteroarene-fused barrelenes, and comparison will be made with that of arene-fused barrelenes wherever possible; the photochemistry of dihydrobarrelenes and barrelenes with heteroatoms in the skeleton is beyond the scope of this chapter.

32.2 Synthesis of Heteroarene-Fused Barrelenes

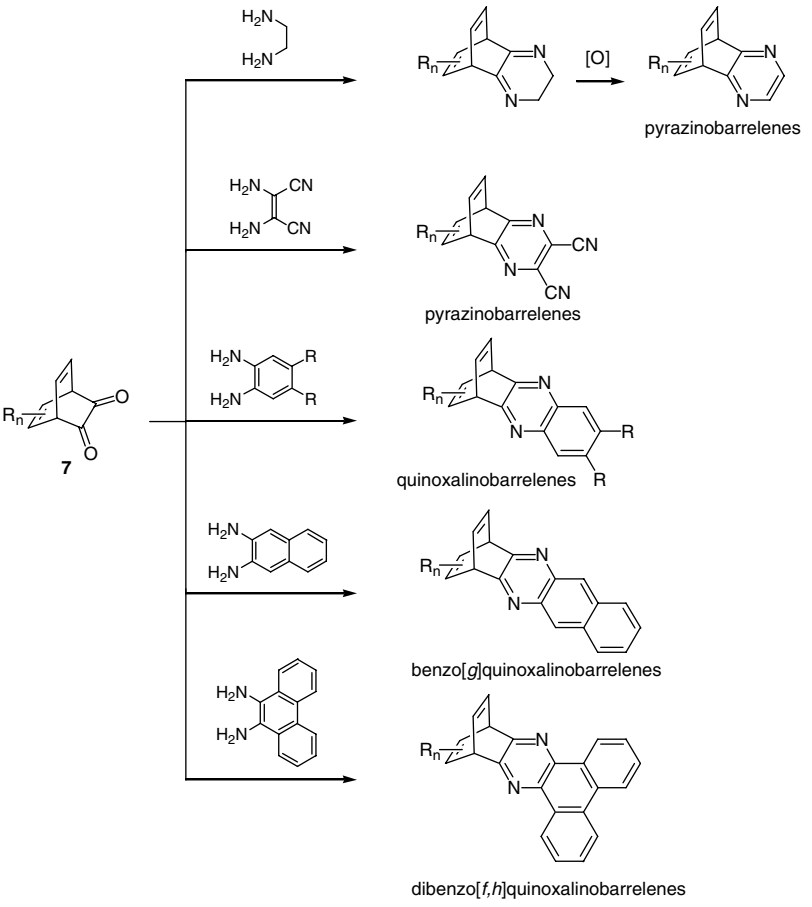
Heteroarene-fused barrelenes are generally synthesized from α-diketones **7** and 1,2-diamines. Pyrazinobarrelenes[11–13] could be prepared either by condensation of α-diketones **7** with ethylenediamine followed by oxidative generation of the pyrazine ring or by direct condensation of **7** with diaminomaleonitrile (Scheme 2). Quinoxalinobarrelenes,[9,13–16] benzo[*g*]quinoxalinobarrelenes,[13,15] and dibenzo[*f,h*]-quinoxalinobarrelenes[17,18] are easily obtained by simple condensation of **7** with *o*-phenylenediamines, 2,3-diaminonaphthalene, and 9,10-diaminophenanthrene, respectively.

32.3 Photochemistry of Pyrazinobarrelenes

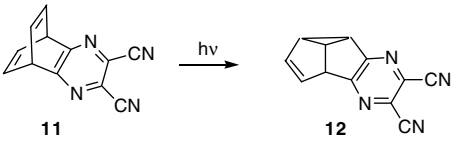
Pyrazinobarrelenes

The parent benzobarrelene upon direct irradiation produces benzocyclooctatetraene exclusively, whereas acetone-sensitized reaction affords the DPM rearrangement product benzosemibullvalene via a triplet-state pathway. Zimmerman's elegant studies on deuterated benzobarrelene (**8**) revealed that the benzo-vinyl bridging leading to **9a** is the predominant route on direct irradiation, and vinyl–vinyl bridging leading to **10a** is the predominant route in the sensitized reaction[19] (Scheme 3).

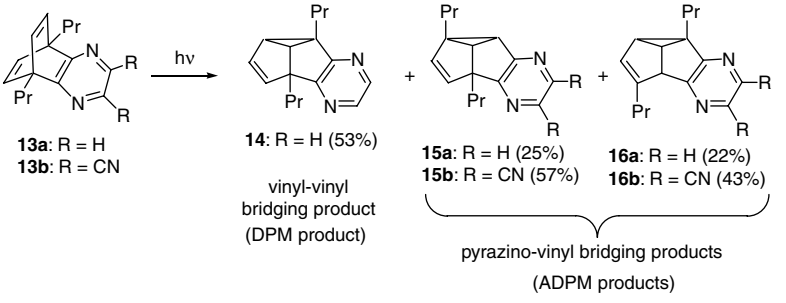
Our studies on the photochemistry of the pyrazinobarrelene **11** revealed that the pyrazinosemibullvalene **12** is the only product by either direct or acetone-sensitized reaction[20] (Equation 32.1). It is interesting to note that, in contrast to benzobarrelene, which upon direct irradiation undergoes [2 + 2]-cycloaddition followed by isomerization to furnish benzocyclooctatetraene, **11** affords no pyrazinocyclooctatetraene from the start of the irradiation. To distinguish the possible modes of rearrangement, *n*-propyl groups were substituted at bridgehead positions as shown in **13a,b**. Again, no pyrazinocyclooctatetraene is formed upon direct irradiation of **13a** in perdeuterated benzene; instead, almost equal amounts of the DPM product pyrazinosemibullvalene **14** (resulting from vinyl–vinyl bridging) and aza-di-π-methane (ADPM)[21] products **15a** and **16a** (resulting from pyrazino–vinyl bridging) are observed (Equation 32.2).[11] Nevertheless, in the case of pyrazinobarrelene **13b**, direct (in benzene or cyclohexane) irradiation results only in pyrazino–vinyl bridging products **15b** and **16b** in a 57:43 ratio, respectively. Even the acetone-sensitized reaction of **13b** affords **15b** and **16b** in a similar ratio.



SCHEME 2

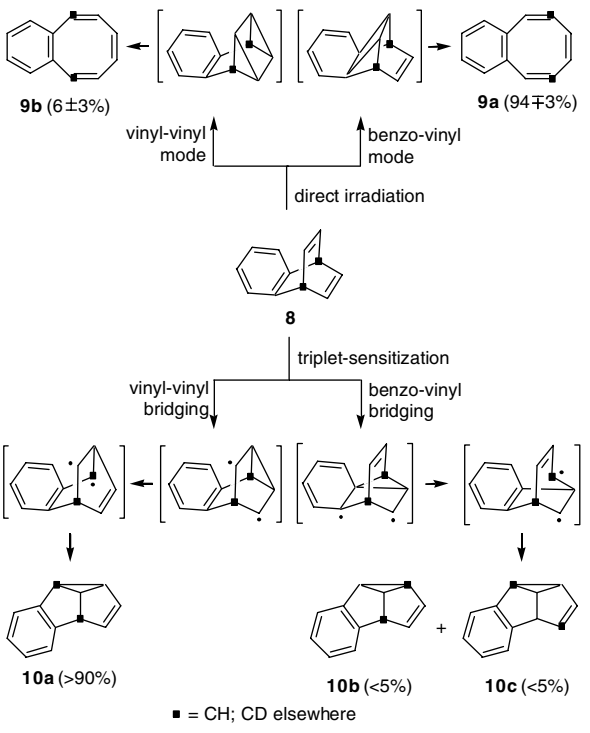


(32.1)



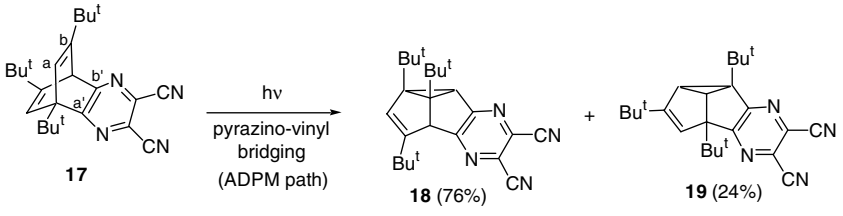
(32.2)

The pyrazinobarrelene **17** bearing three *t*-butyl groups (one on the bridgehead position and one on each vinylic double bond in a 1,3 and a 1,3′ manner) is a suitable substrate to ascertain the steric influence during the photorearrangement. Irradiation of a benzene solution of **17** gives pyrazinosemibullvalene **18**



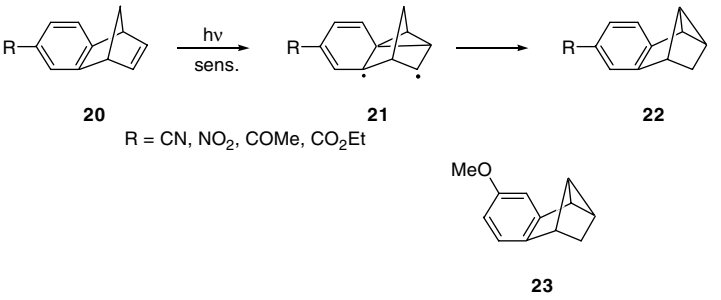
SCHEME 3

and **19** as a result of initial pyrazino-vinyl bridging in a 3:1 ratio[11] (Equation 32.3). The preferential formation of **18** (via a-a′ bridging) to **19** (via b-b′ bridging) may be attributed to the steric hindrance exerted by the *t*-butyl group at the b position.

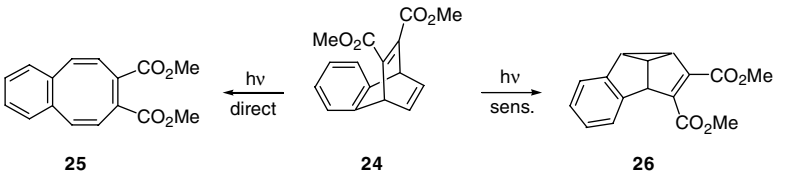


(32.3)

Obviously, owing to the presence of nπ* triplet-states in addition to ππ* triplet-states, the mechanisms of the photoisomerizations of **13** and **17** are even more complicated. It may be noted that the triplet energy of pyrazine[22a] [E_T(nπ*) = 74.3 kcal mol^{-1}; E_T(ππ*) = 75.3 kcal mol^{-1}] is lower than that of benzene[22b] (E_T = 84.3 kcal mol^{-1}), and the quantum yield of intersystem crossing of pyrazine[23a] (Φ_{isc} = 1.0) is greater than that of benzene[23b] (Φ_{isc} = 0.25) due to the presence of a nitrogen atom in the pyrazino moiety, which enhances the rate of intersystem crossing. The nitrogen atom in the pyrazine ring also stabilizes the radical-like intermediates, allowing **13a** to proceed at a higher percentage of pyrazino–vinyl bridging in contrast to benzo–vinyl bridging in the case of **8**. Furthermore, the cyano functionality greatly enhances the ADPM pathway in the reactions of **13b** and **17**.



(32.4)



SCHEME 4

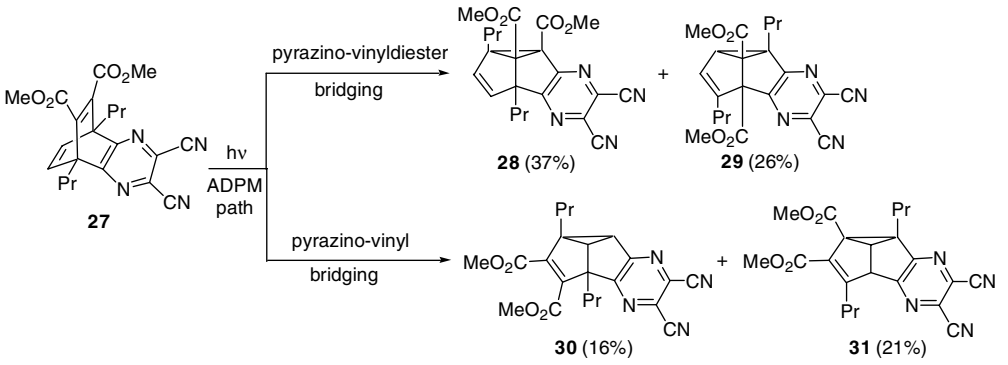
Paquette et al.[24] found that the acetophenone-sensitized photorearrangement of benzonorbornadienes **20** bearing electron-withdrawing groups proceeds with complete regiospecificity to afford tetracycloundecatrienes **22** as the sole products in each case (Equation 32.4). The reaction of methoxy compound **20** (R = OMe) produces the other regioisomer **23** as the major photoproduct. The formation of **22** occurs via the cyclopropyldicarbinyl biradical **21** as a result of exclusive benzo–vinyl bridging to the *para* position of the aryl ring. The excess negative charge of the carbinyl carbon of **21** is stabilized by the electron-withdrawing group.

The dimethyl dicarboxylate **24** upon direct excitation produces benzooctatetraene **25** via initial [2 + 2]-cycloaddition between vinyl and vinyldiester groups,[25a] whereas the acetone-sensitized reaction leads to the formation of the DPM rearrangement product **26** as the identified photoproduct. However, the mechanism of the process is not clear (Scheme 4).[25b]

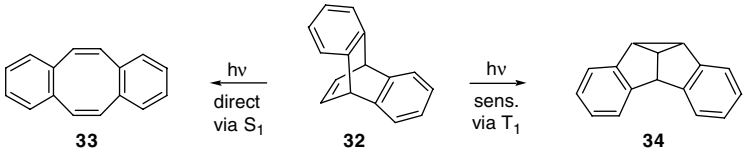
The pyrazinobarrelene **27** bearing two-ester groups, upon irradiation in benzene, yields the ADPM rearrangement products **28–31**[18] (Scheme 5). The pyrazino–vinyldiester mode leading to pyrazinobullvalenes **28** and **29** is preferred over the pyrazino–vinyl mode leading to **30** and **31**. No products involving vinyl–vinyldiester bridging are observed. The bridging of pyrazino–vinyl/vinyldiester and the absence of vinyl–vinyldiester bridging may be attributed to the fact that the presence of nitrogen atoms in the pyrazino moiety coupled with the cyano functionalities on the pyrazine ring enhances the ADPM pathway. The distribution of products (**28** + **30** = 53% and **29** + **31** = 47%) from the two ADPM modes indicates that there is no profound effect due to the presence of the ester moieties in **27**, in comparison with the reaction of **13b**, in which the products **15b** and **16b** are obtained in 57 and 43%, respectively, from two ADPM modes (Equation 32.2).

Benzopyrazinobarrelenes

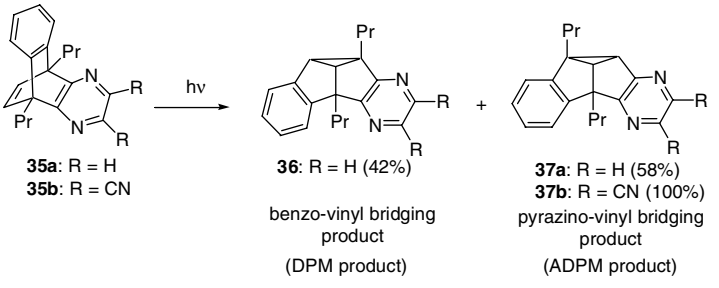
Within the barrelene system, the photochemistry of dibenzobarrelene and its derivatives have been extensively investigated, presumably due to their easy accessibility as well as the interesting mechanistic aspects. This material is covered in depth in other articles[3,5,26] and discussed here to the extent required for comparison with photochemical studies of heteroarene-fused barrelenes. Ciganek reported[27] that the acetone-sensitized reaction of dibenzobarrelene **32** results in the formation of dibenzosemibullvalene **34**.



SCHEME 5



SCHEME 6

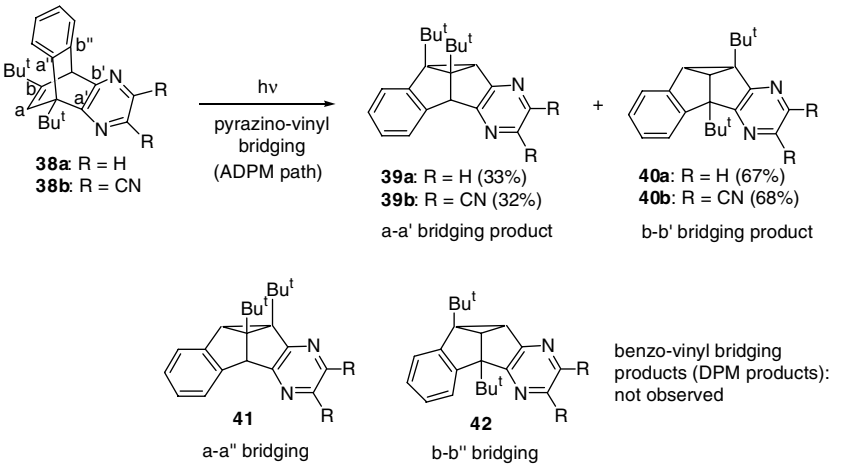


(32.5)

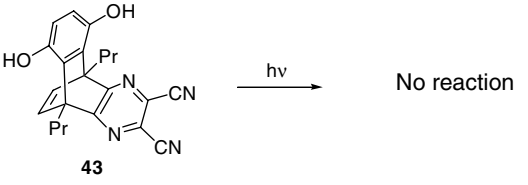
However, when a cyclohexane solution of **32** was irradiated, dibenzooctatetraene **33** was formed exclusively[19b] (Scheme 6).

Photoisomerization of several benzopyrazinobarrelenes was tested in this laboratory.[12] The irradiation of the parent benzopyrazinobarrelene (**35a**) in benzene produces the regioisomeric SBs **36** and **37a** via benzo–vinyl and pyrazino–vinyl bridgings, respectively; the latter is the major product. However, the reaction of the dicyano derivative **35b** undergoes ADPM rearrangement to furnish **37b** exclusively (Equation 32.5). Similarly, the *t*-butyl group substituted benzopyrazinobarrelenes **38a,b** afford SBs **39a,b** and **40a,b** via the ADPM process; the benzo-vinyl bridging products **41** and **42** are not observed (Scheme 7). Unlike **17**, the photolysis of **38** leads to the preferential formation of initial b-b′ bridging products **40**.

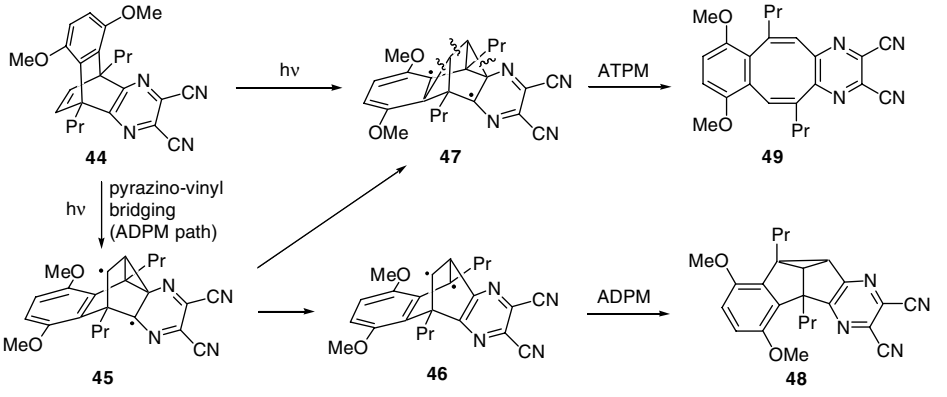
The hydroquinone-fused pyrazinobarrelene **43** did not undergo photoisomerization in methanol or benzene after prolonged irradiation (Equation 32.6).[28] Presumably, for the excited state of **43**, the proton transfer from a hydroxyl group of the hydroquinone moiety to a nitrogen atom of the pyrazine ring may be taking place to form an ammonium salt–like species, which may then go back to the ground state of **43** without undergoing any effective photochemical transformation. Subsequently, the free hydroxyl groups of **43** were protected as the dimethyl ether **44** and subjected to photolysis in benzene. The



SCHEME 7



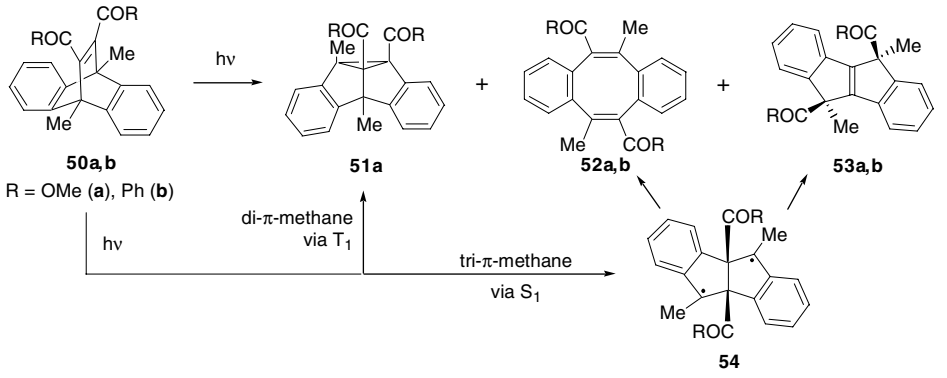
(32.6)



SCHEME 8

compound **44** undergoes photoisomerization and affords COT **49** and SB **48** in a ratio of 8:92 (Scheme 8). A plausible mechanism for the formation of **48** and **49** is outlined in Scheme 8. The compound **48** may be expected from the triplet state–mediated ADPM path via **45** and **46**. Interestingly, the product **49** might have arisen from **47** via an aza-tri-π-methane (ATPM) rearrangement directly from **44** or by the rearrangement of **45** or from both.

Interesting photochemistry involving the tri-π-methane rearrangement of bridgehead-substituted dibenzobarrelenes **50a,b** was reported earlier (Scheme 9).[29] When **50a** was irradiated in benzene, compounds **51a** and **52a** were obtained, whereas **51a** was the only product from acetone-sensitization, and

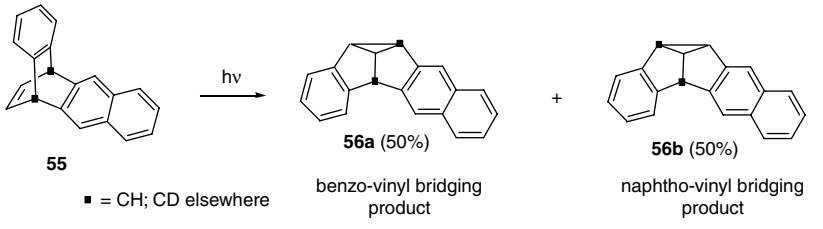


SCHEME 9

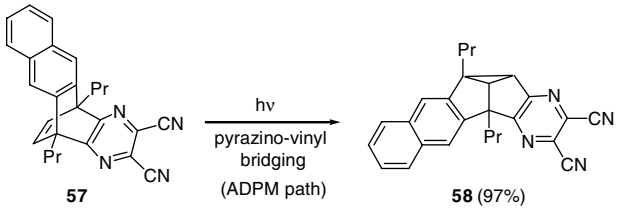
53a was observed in solid state reaction[29a]; the suggested mechanism is depicted in Scheme 9. The photoisomerization of **50b** in benzene yields **52b** and **53b**; the former is the major photoproduct.[29b]

Naphthopyrazinobarrelenes

The photoisomerization of benzo-2,3-naphthobarrelene **55** in cyclohexane was found to undergo the DPM rearrangement to provide SBs **56a** and **56b** in equal amounts via benzo-vinyl and 2,3-naphtho-vinyl bridgings, respectively (Equation 32.7).[30] However, in the case of pyrazino-2,3-naphthobarrelene **57**, the reaction affords SB **58** exclusively, resulting from the ADPM path[13] (Equation 32.8). Despite the fact that the triplet energy of pyrazine[22a] [E_T ($n\pi^*$) = 74.3 kcal mol^{-1}; E_T ($\pi\pi^*$) = 75.3 kcal mol^{-1}] is higher than that of naphthalene[31] [E_T = 60.9 kcal mol^{-1}], the reaction of **57** proceeds only via pyrazino–vinyl bridging. The stabilization effect of nitrogen atoms in the pyrazine moiety and the presence of cyano groups appear to be the driving forces for the enhancement of pyrazino–vinyl bridging.



(32.7)



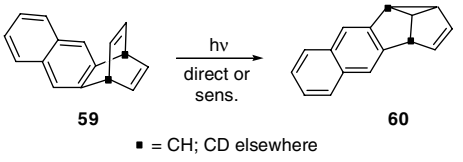
(32.8)

32.4 Photochemistry of Quinoxalinobarrelenes

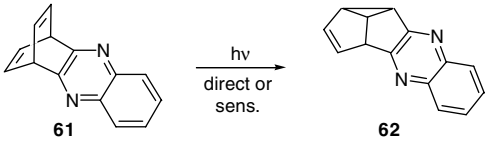
Quinoxalinobarrelenes

Irradiation of 2,3-naphthobarrelene (**59**) under direct or sensitized conditions affords SB **60** by a vinyl–vinyl bridging route (Equation 32.9).[32] With a view to comparing their photochemical behavior with that of naphthobarrelenes, in this laboratory, several quinoxalinobarrelenes have been synthesized,

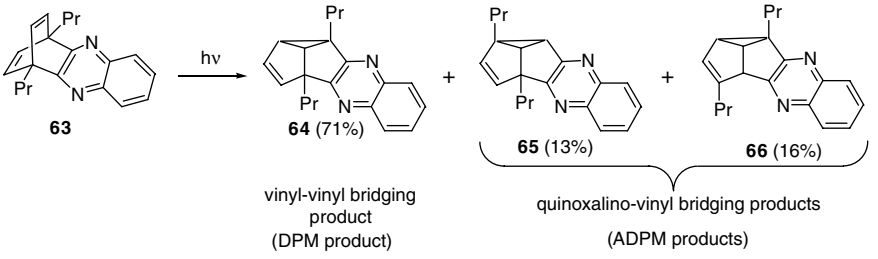
and their photoisomerization was carried out. The parent quinoxalinobarrelene (**61**) forms SB **62** exclusively upon direct or sensitized reaction[20] (Equation 32.10). To find out the possible modes of the rearrangement, bridgehead-substituted quinoxalinobarrelene **63** has been chosen as the starting material. Irradiation of **63** in benzene leads to the formation of DPM product **64** and ADPM products **65** and **66**. The major product **64** arises from initial vinyl–vinyl bridging, whereas the minor products **65** and **66** result from quinoxalino–vinyl bridging (Equation 32.11).[15]



(32.9)

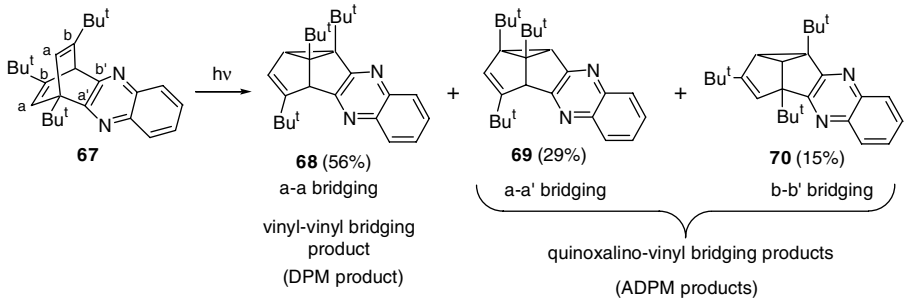


(32.10)

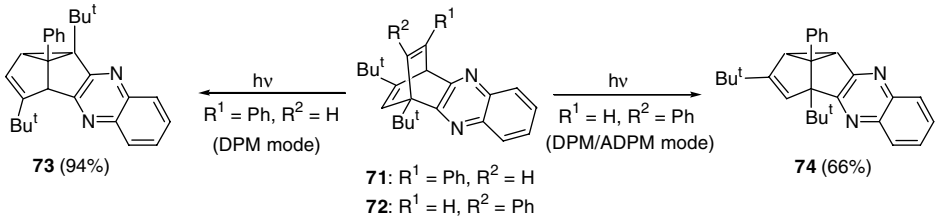


(32.11)

The phototransformation of the *t*-butyl group substituted quinoxalinobarrelene **67** in benzene gives **68** via the DPM mode and **69** and **70** as a result of the ADPM pathway[15] (Equation 32.12). The photoprocesses of **63** and **69** occur presumably via their triplet states, as the same reactions are sensitized by acetophenone. Furthermore, quinoxaline is known to undergo highly efficient intersystem crossing (ϕ_{isc} = 0.99).[33] Unlike naphthobarrelenes, where the vinyl–vinyl bridging is the only route, quinoxalinobarrelenes show enhancement in the quinoxalino–vinyl mode. As the triplet energies of naphthalene[31] and quinoxaline[34] are nearly the same (E_T = 60.9 and 60.6 kcal mol^{-1}, respectively), the increase in quinoxalino–vinyl bridging in **63** and **69** may be attributed to the stabilization effect of nitrogen atoms, which stabilize the biradical-like intermediate, as is evident in the case of the pyrazinobarrelenes. The enhanced quinoxalino–vinyl bridging for **69** over **63** and the preferential formation of the products derived from a-a and a-a′ bridging to b-b and b-b′ bridging in the case of **67** may be explained on steric grounds.



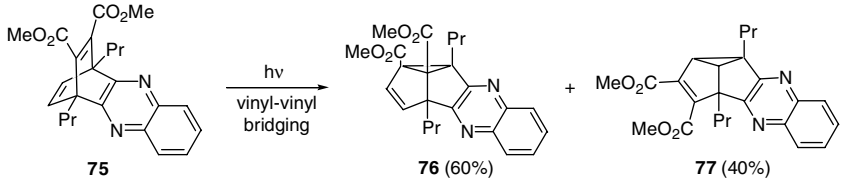
(32.12)



SCHEME 10

It is quite interesting to note that when a phenyl group replaces the *t*-butyl group at position b of **67**, the quinoxalinobarrelene **71** undergoes vinyl–vinyl bridging exclusively to furnish **73** as the sole product. The compound **72**, which is a regioisomer of **71**, photoisomerizes to SB **74** as a result of either a DPM or ADPM process (Scheme 10).[35]

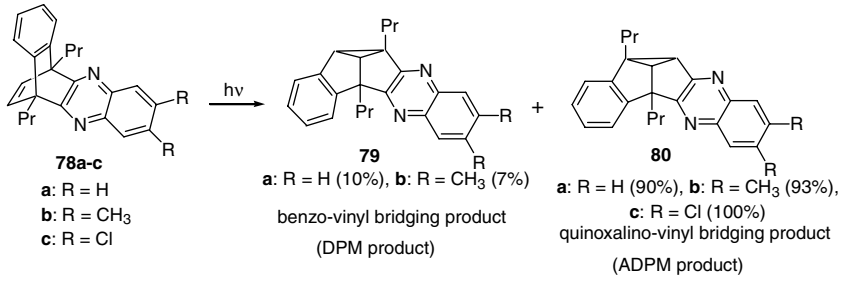
The quinoxalinobarrelene **75** bearing ester functionalities affords SBs **76** and **77** in a 3:2 ratio via vinyl–vinyl mode exclusively (Equation 32.13). The enhanced vinyl–vinyl bridging in this reaction, in comparison to that of **63**, is presumably due to the stabilization of biradical-like intermediate by the ester group.[18]



(32.13)

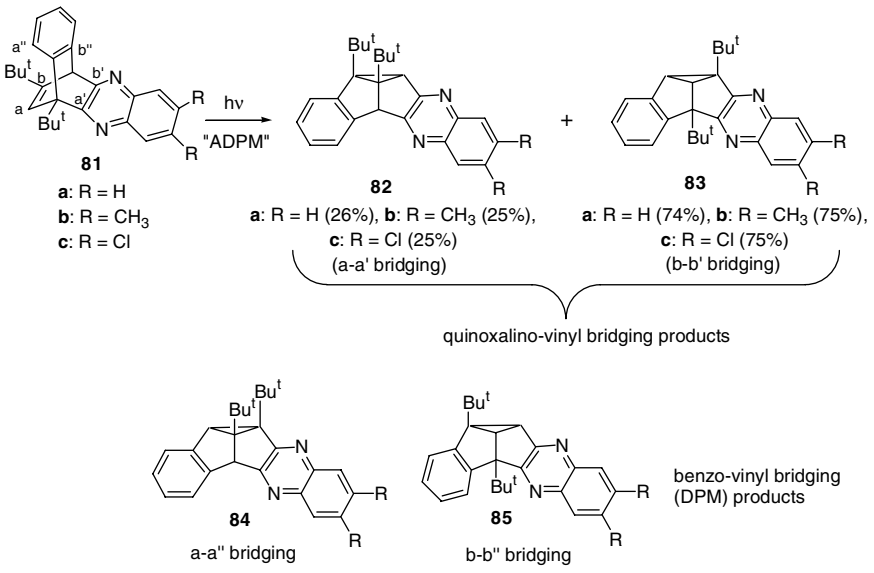
Benzoquinoxalinobarrelenes

Unlike benzo-2,3-naphthobarrelene, where the benzo–vinyl and the 2,3-naphtho–vinyl paths occur in equal proportions (Equation 32.7), the bridgehead substituted benzoquinoxalino-barrelenes **78a,b** predominantly undergo the ADPM process (Equation 32.14). In the case of chloro substituted **78c**, SB **80c** is formed as the sole product and occurs by the ADPM path.[14]



(32.14)

In the early seventies, it was reported[9] that irradiation of benzoquinoxalinobarrelene **81a** in furan affords SB **85a** via the DPM route. Contrarily, it was found upon re-examination of this reaction under similar conditions that ADPM products **82a** and **83a** arising from the initial quinoxalino–vinyl bridging are the only products.[14] The benzoquinoxalinobarrelenes **81b,c** also provide ADPM products **82b,c** and **83b,c** as the sole products in a similar ratio (Scheme 11). The enhanced quinoxalino–vinyl bridging observed in the reactions of **78a–c** and **81 a–c** in comparison with 2,3-naphtho-vinyl bridging in benzo-2,3-naphthobarrelene (**55**) may be a consequence of the lower triplet-state energy (60.6 kcal mol^{-1}) of



SCHEME 11

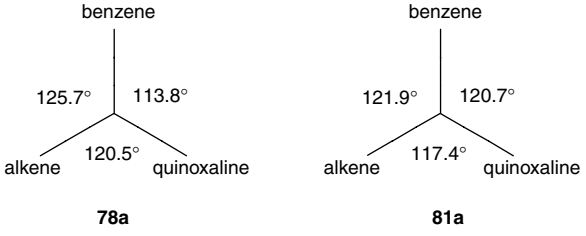


FIGURE 32.1

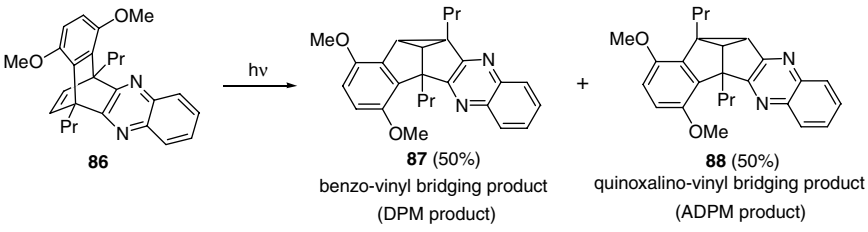
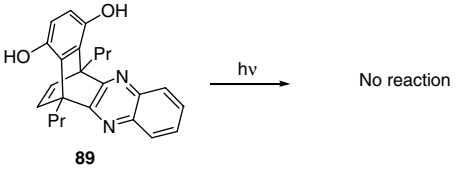
quinoxaline[34] than that of benzene[22b] (84.3 kcal mol^{-1}) coupled with the radical stabilizing effect of nitrogen atoms. The chlorine atoms also enhance the quinoxalino–vinyl bridging, as seen in the reactions of **78c** and **81c**.

As the barrelene is a rigid molecule, one can expect similar geometries in the ground state as well as the excited state. The crystal structures of heterobarrelenes **78a** and **81a** reveal that the dihedral angle between the quinoxaline and alkene moieties in **81a** is smaller than that in **78a** (Figure 32.1). The barrelene **81a** undergoes ADPM rearrangement exclusively owing to the relatively smaller distance between the quinoxaline and the alkene moieties, and the barrelene **78a** gives 10% benzo–vinyl bridging (DPM mode) product in addition to 90% ADPM product.

The benzoquinoxalinobarrelene **86** with methoxy functionalities at the 1,4-positions of the benzene moiety photorearranges to **87** and **88** in a 1:1 ratio, indicating that benzo and quinoxalino groups are in equal competition[28] (Equation 32.15). A fivefold enhancement of the DPM mode is observed in the reactions of **86** in comparison with those of **78** (see Equation 32.14). This enhancement arises from the introduction of methoxy groups in the benzene ring of **78**. As in the case of **43**, the hydroquinone-fused barrelene **89** did not undergo photoisomerization under direct or sensitized excitation (Equation 32.16).



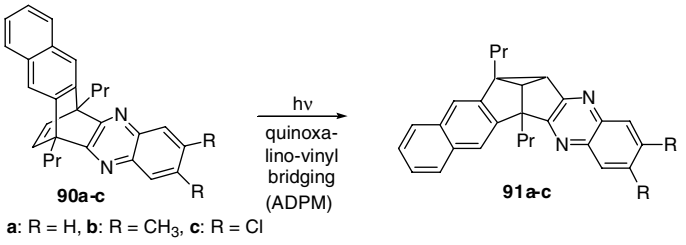
(32.15)



(32.16)

Naphthoquinoxalinobarrelenes

Recent research from this group revealed that the irradiation of 2,3-naphthoquinoxalinobarrelenes **90a–c** proceeds through an ADPM path to furnish SBs **91a–c** as the sole products as a result of quinoxalino–vinyl bridging (Equation 32.17).[13] The exclusive formation of ADPM products may be ascribed to the stabilization effect of nitrogen atoms of the quinoxaline ring, as evident in the phototransformation of 2,3-naphthopyrazinobarrelenes.

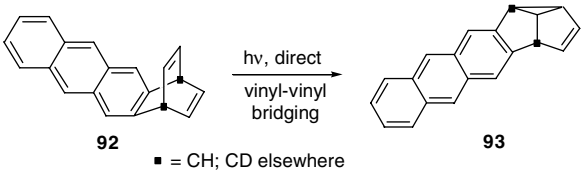


(32.17)

32.5 Photochemistry of Benzo[*g*]quinoxalinobarrelenes

Benzo[*g*]quinoxalinobarrelenes

2,3-Anthrabarrelene (**92**) undergoes the DPM rearrangement via initial vinyl–vinyl bridging under direct irradiation to form SB **93** (Equation 32.18). The reaction may proceed via the excited singlet-state (E_S = 76.3 kcal mol^{-1}) or the second excited triplet-state (E_{T2} = 74 kcal mol^{-1}), as the first excited triplet-state is unreactive owing to its low energy (E_{T1} = 43 kcal mol^{-1}).[36]



(32.18)

In contrast to **92**, the benzo[*g*]quinoxalinobarrelenes **94–97** failed to undergo photoisomerization under direct or sensitized excitation (Chart 1).[13,15,37] This may be attributed to the fact that the energy

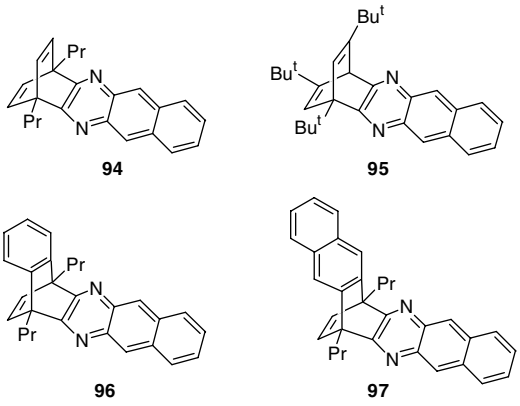


CHART 1

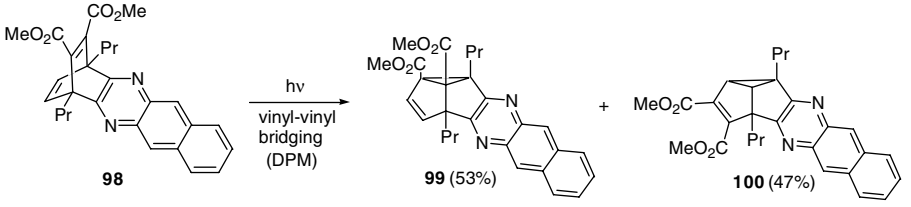
of the first excited triplet-state is too low to undergo photorearrangement and that the upper triplet-state is insufficiently long-lived for chemical reaction to occur. However, benzo[*g*]quinoxalinobarrelene **98** bearing ester groups gives the DPM products **99** and **100** almost in equal amounts via the vinyl–vinyl mode[18] (Equation 32.19). The success of this reaction is presumably due to the presence of the ester functionalities that lower the energy of the biradical-like intermediates.



(32.19)

32.6 Photochemistry of Dibenzo[*f,h*]quinoxalinobarrelenes

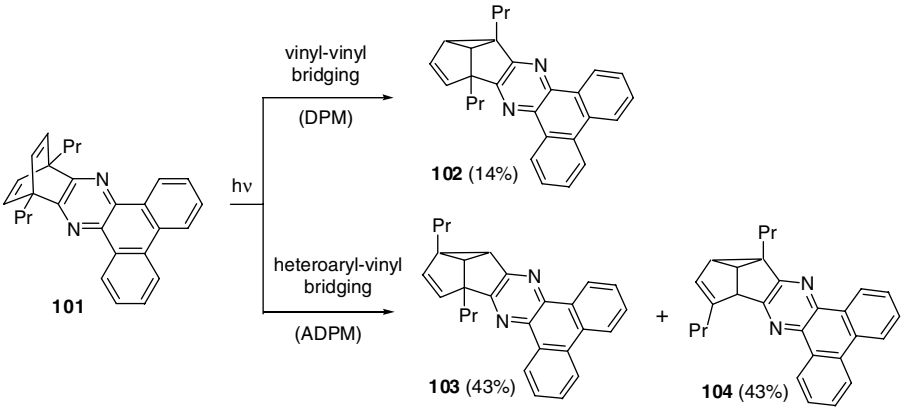
Dibenzo[*f,h*]quinoxalinobarrelenes

As a further extension of the photochemistry of heteroarene-fused barrelenes, dibenzo[*f,h*]-quinoxalinobarrelenes have been subjected to photoisomerization in this laboratory. Upon direct irradiation of **101** in cyclohexane, the DPM product **102** and the ADPM products **103** and **104** are obtained. The vinyl–vinyl bridged product **102** is minor (Scheme 12).[18] Similarly, the reaction of heterobarrelene **105** under direct irradiation proceeds through both the DPM and the ADPM modes and produces SBs **106–108**. Again, the DPM product **106** is formed as a minor photoproduct (Scheme 13).[17]

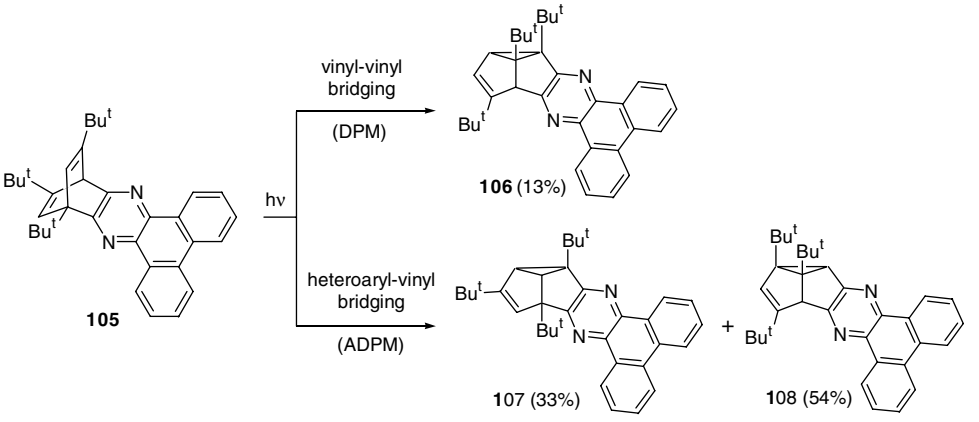
In contrast to the reactions of **101** and **105**, heterobarrelene **109**, which has ester functionalities, affords DPM products **110** and **111** predominantly and a minor product **112**, which arises from the ADPM process[18] (Scheme 14).

32.7 Conclusions

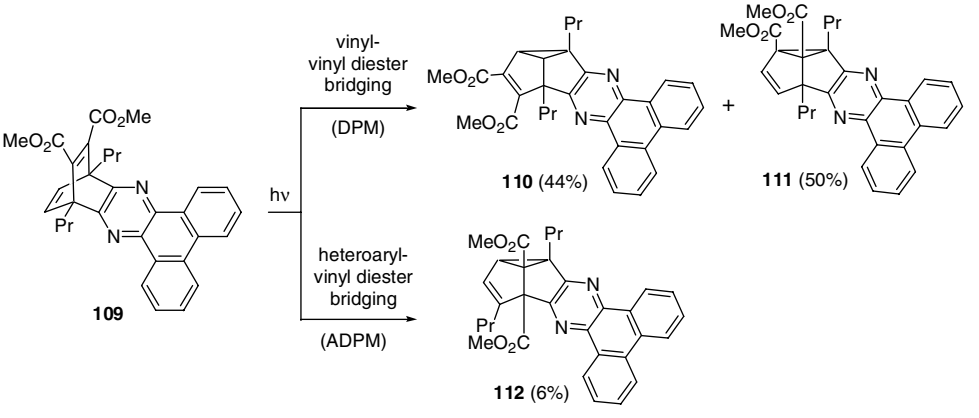
While arene-fused barrelenes generally produce COTs on direct irradiation and SBs via DPM rearrangement under sensitized conditions, the DPM and/or ADPM rearrangements leading to SBs are the major reaction pathways in both direct irradiation and sensitized reactions of heteroarene-fused barrelenes. The percentage of heteroaryl–vinyl bridging is increased due to the stabilizing effect of nitrogen atoms



SCHEME 12



SCHEME 13



SCHEME 14

present in the heteroaromatic ring. The cyano and chloro groups at pyrazine and quinoxalino moieties increase the percentage of pyrazino–vinyl and quinoxalino–vinyl bridging (ADPM mode). Pyrazino– and quinoxalino–barrelenes fused with a hydroquinone moiety do not undergo (A)DPM rearrangement. Contrarily, their methyl derivatives undergo photochemical transformations, and the percentage of benzo–vinyl bridging is increased due to the presence of methoxy groups at the benzene moiety. It is unusual that an ATPM rearrangement occurs in addition to an ADPM rearrangement in the case of dimethoxybenzene-fused dicyanopyrazinobarrelene. Benzo[*g*]quinoxalinobarrelenes and their benzo and naphtho derivatives do not undergo photochemical transformations, whereas benzo[*g*]quinoxalinobarrelene bearing ester groups provides DPM product. Based on the findings documented here, the relative order of preferential bridgings can be shown as: dicyanopyrazino > vinyl > pyrazino > quinoxalino = dimethoxybenzo > benzo > naphtho.

Cyclization of Stilbene and its Derivatives

Andrew Gilbert
The University of Reading

33.1 Introduction

The first report of the photoreactivity of stilbene appeared in 1934[1], but the product was not identified as phenanthrene until 1955.[2] It was, however, soon recognized that this type of process was common for many 1,2-diarylethenes and that the mechanism proceeded by photoinduced 6π-electrocyclization of the *cis*-isomer to give the *trans* 4a,4b-dihydrophenanthrene, which was readily oxidized by air or iodine to the arene (Figure 33.1).

The reaction was extensively reviewed in the 1980s,[3–6] and its potential as a convenient route to polynuclear aromatic compounds and as a reversible photochromic system continues to be exploited. In particular, the latter property for 1,2-dithienylethenes has attracted considerable interest in recent years in data storage and molecular switch applications.[7]

33.2 Substituted Stilbenes

The previous account of stilbene photocyclizations in this Handbook outlined the details of the mechanism of the process, including the factors that influence the arene positions between which the photocyclization may be expected to occur, as well as described the effects of substituents on the reaction.[8] This latter feature continues to attract attention and has been exploited in a number of synthetic applications. Examples to illustrate the variety of substituted stilbenes studied in recent years are given below. The amino *cis* stilbenes display differing photochemical reactivities.[9] The *meta* isomer undergoes photocyclization with the highest quantum yield of any reported monosubstituted *cis* stilbene and isomerizes with abnormally low efficiency, while the photochemistry of the *ortho* and *para* isomers is similar to that of many substituted stilbenes in being dominated by the *cis-trans* isomerization process. It is proposed that the marked differences in the photochemical behavior of the amino stilbenes results from perturbation of the excited state potential energy surface of the *meta* isomer. Not surprisingly, the acetamide **1** undergoes photocyclization to give the phenanthrene **2,** but it may be less expected that styryl-tetrahydroisoquinolines such as **3** can be converted by 6π-cyclization into the 1,2,3,4-dihydronaphtho[1,2-*f*]isoquinolines **4** in 60% yield.[10] Indeed, the photochemistry of the more flexible *trans* 2-(aminoalkyl)-stilbenes **5** reflects the propensity of stilbenes to undergo electron transfer and in this case yield the cyclized isomers **6** and **7** by a route involving intramolecular electron transfer followed by proton

0-8493-1348-1/04/$0.00+$1.50

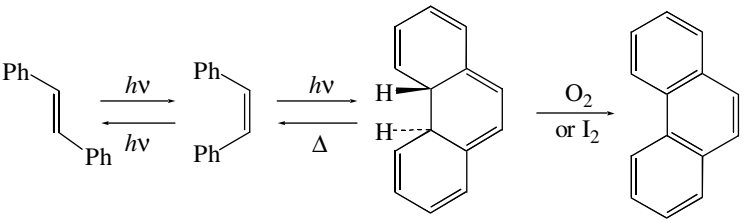

FIGURE 33.1 Stilbene photocyclization.

transfer and coupling of the biradical.[11] By a similar process, prolonged irradiation of the *N*-aminoalkyl-2-stilbenecarboxamides **8a–d** affords the 9- or 10-ring azalactams **9** in yields of 25–43%, while **10a–d** fluoresce with high quantum yields, and both series undergo *trans-cis* photoisomerization with similar efficiencies.[12] The radical cation of 1,2-distyrylbenzene, formed by intermolecular electron transfer to photoexcited *p*-dicyanobenzene, undergoes cyclization, and in the presence of ammonia yields 1-benzyl-3-phenyl-1,2,3,4-tetrahydroisoquinoline **11** and 1-amino-3-benzyl-2-phenylindan **12** (Figure 33.2).[13]

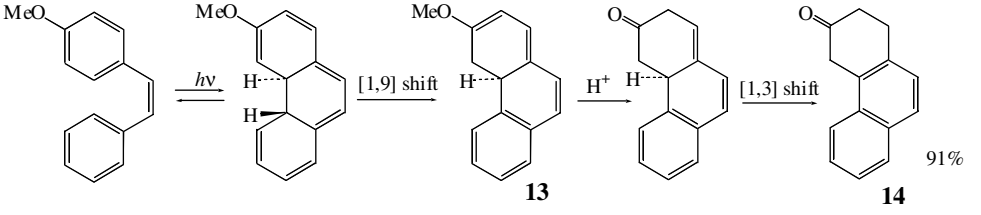

FIGURE 33.3 Photocyclization of 4-methoxystilbene in the presence of acid.

The 4a,4b-dihydrophenanthrene formed from the 6π-electrocyclization of 4-methoxy-stilbene undergoes a [1,9-H]-shift to give **13** which, in the presence of a protic acid, affords the ketone **14** in high yield (Figure 33.3).[14] The reaction has been extended to other methoxystyrylarenes, and evidently the ring closure is readily reversible since in a neutral degassed solution only geometrical isomerization is observed. The phenanthrenetetracarbonitriles **15** and **16**, required for use in phthalocyanine syntheses, can be obtained by irradiation of *cis*- or *trans*-1,2-bis(3,4-dicyanophenyl)ethene, but the more sterically crowded third possible isomer **17** is not formed.[15]

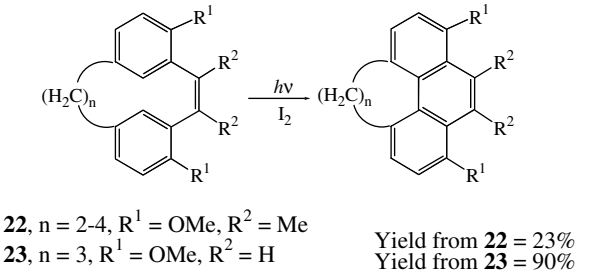
33.3 [n.2]Metacyclophanes

The influence on stilbene photochemistry of a bridge between the two aryl groups has been the subject of some interest. The ratio of *cis:trans* geometrical isomers of macrocyclic stilbenes **18** is, not surprisingly, dependent on the length of the bridge, but for n = 3 or 6, the sole product on irradiation in the presence of iodine is the 4,5-annulated phenanthrene **19**.[16] However, for **20**, which has a much longer bridge, the 6π-electrocyclic closure significantly favors the formation of the 2,5-bridged compound **21**. The photoreactivity of the stilbene unit in such [n.2]metacyclophanenes can be influenced by substituent interactions. In **22**, the steric repulsion between the methyl and methoxy groups forces the molecule into a *syn* conformation, whereas when the ethene bridge is unsubstituted, as in **23**, the *anti* conformation, typical of [3.2]cyclophanes, is preferred.[17] In the presence of iodine, both conformers undergo photocyclization, but the rate of reaction is appreciably greater for the *anti*-**23** than the *syn*-**22**. The *anti* isomer of 8-fluoro-16-methyl-[2.2]metacyclophane-1,9-diene **24** undergoes a 6π-electrocyclization-elimination process both thermally and photochemically to give pyrene and methyl pyrenes.[18] It is proposed that the reaction proceeds by the intermediate **25**, which yields the polynuclear arenes as outlined in Figure 33.4 by loss of fluoride ion and methyl shifts in the resulting carbocation **26**.



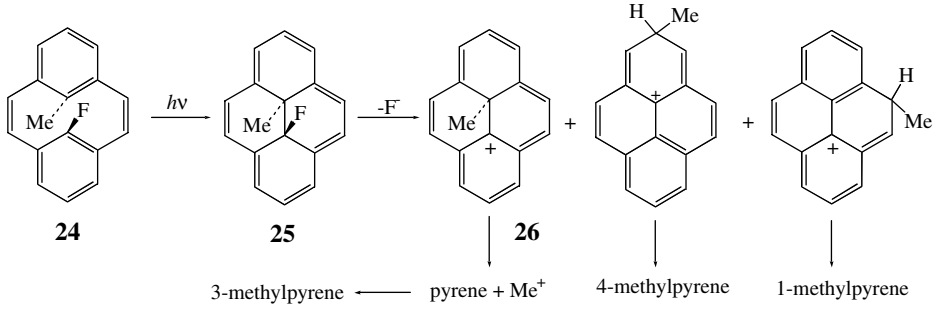


FIGURE 33.4 Formation of pyrenes from irradiation of **24**.

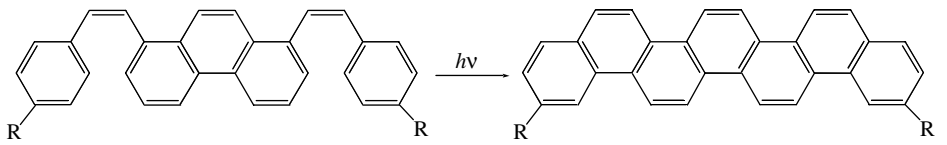
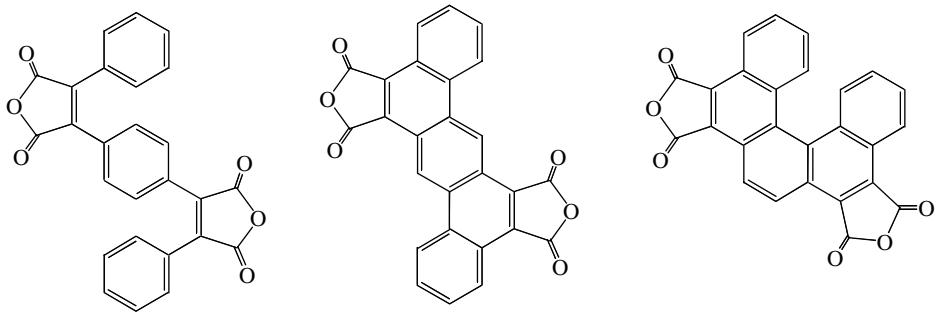
33.4 Formation of Polynuclear Arenes

In principle, the double photocyclization of 1,4-distyrylbenzenes offers a convenient route to dibenz[a,h]anthracenes and [5]helicenes dependent on the sites of reaction. In the first report of the photochemistry of 1,4-phenylene bis(phenylmaleic anhydride) **27**, the product was identified as the dibenz[a,h]anthracene **28**,[19] but more recently it has been shown that a mixture of isomers is formed (overall yield of 80%), in which **28** comprises less than 5%, with the [5]helicene **29** as the major product.[20] This approach towards the synthesis of polynuclear arenas, including helicenes, is complemented by the photocyclizations of styryl-naphthalenes, -phenanthrenes, etc. and of 1,2-dipolyarylethenes. Examples of these processes published during the review period are now considered.



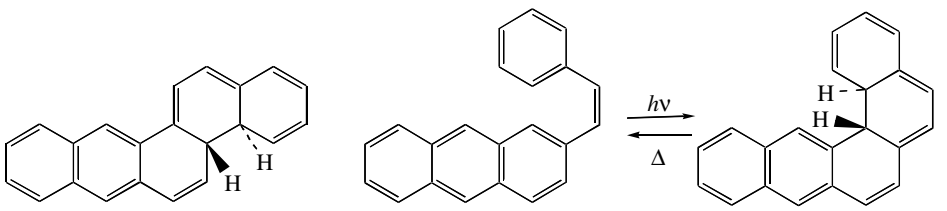
R = H, *n*-pentyl or *t*-butyl.

FIGURE 33.5 Formation of [7]phenacenes.



27 **28** **29**

1-Styrylanthracene undergoes photocyclization to yield 4a,4b-dihydrobenzo[b]chrysene **30**, which reverts to the starting material in deaerated solution and readily gives the fully aromatized compound under oxygen.[21] In contrast, although the *s-cis* rotomer **31** of 2-styrylanthracene does undergo 6π-electrocyclization, the 4a,4b-dihydroisomer undergoes ring opening appreciably faster than oxidation, and no 1,2-naphtho[a]anthracene is formed.[22] Phenacene is the name proposed for polynuclear arenes having an extended phenanthrene-like structure, and stilbene-type photocyclizations have been applied to the synthesis of both unsubstituted and 2,13-dialkyl[7]phenacenes, as outlined in Figure 33.5.[23] [6]Helicene **32** has a nonplanar structure due to overcrowding of the terminal rings, and hence there are two enantiomeric forms, designated P and M, of such compounds. Irradiation of 2-styryl-benzo[c]phenanthrene **33** provides an excellent access to these systems as yields are high (80–90%), and because of the very large optical rotation of P-**32** ($[\alpha]^{D}_{25}$ 3640°), even very small *ee* values can be determined accurately. The influence of circularly polarized light of the *ee* of **32** from **33** is of the order of 0.05%, but when the irradiations are carried out in chiral media, values on the order of 3% are achieved, which increase to around 6–7% on cooling the irradiated mixture to –26°C.[24] Iodine is frequently used as the oxidant in these photocycloaddition processes. From a study of the rate of formation of the polynuclear arenes produced on irradiation of di-2-naphthylethene, it has been shown that the yields of products are dependent on the concentration of I_2; it was concluded that complexation occurs between the *cis*-isomer and iodine.[25]



30 **31**

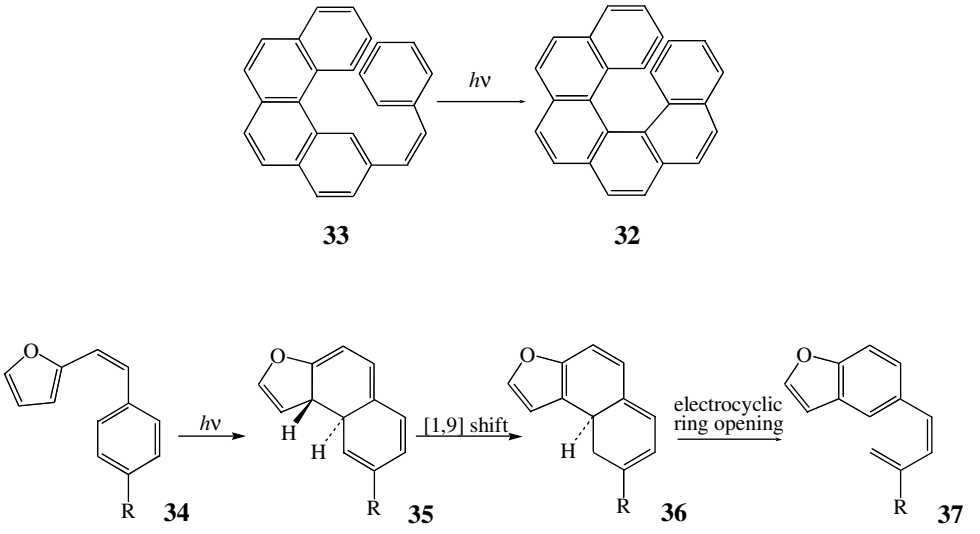


FIGURE 33.6 Photocyclization of 2-styrylfurans.

33.4 Heteroaryl Systems

It has long been known that the stilbene-type photocyclization occurs readily with styryl-heteroarenes and 1,2-diheteroaryl ethenes. Such processes not only provide a convenient access to novel as well as known polynuclear heteroarenes, but also in the latter series of these photoactive compounds, have been widely researched for a number of years as photochromic systems that have potential for development as the key element in data storage devices and as molecular switches.[7]

2-Styrylfurans **34** undergo photoinduced cyclization to the corresponding dihydroarenes **35** which yield **36** by a [1,9]-hydrogen shift.[26] This isomer undergoes thermal electrocyclic ring opening, initiated by aromatization, to give **37** in yields of 52–96% (Figure 33.6). In contrast, the dihydronaphtho[1,2-b]thiophene **38**, from photocyclization of 3-styrylthiophene, is readily converted into the heteroarene by air during the isolation procedure. However, when the photoreaction is carried out under oxygen, photo-oxidative cleavage and dimerization (in cyclohexane) also occur from a proposed complex of oxygen with the substrate (Figure 33.7).[27] The cyclization process of thienylethenes has been used by a number of research groups to synthesize novel sulfur-containing heteroarenes. For example, the double cyclization of tetra-substituted ethenes such as 1,1-bis(thiophen-2-yl)-2,2-diphenylethene **39** yields the sulfur heteroarene isoelectronic with dibenzo[g,p]chrysene.[28] In these systems, the intermediates isoelectronic with phenanthrene can be isolated, but the second ring closure is only efficient for those compounds with a thienyl group as one of the reacting arenes. A number of thiopyrone and pyrone derivatives have been synthesized using the photocyclization of 3-aryl-2-benzothienyl- and 2-naphthyl-3-thienyl-propenoic acids as the key step: for example, **40** is obtained in 73% yield from **41**.[29] In the absence of oxygen, 3-styrylpyridine and its 3′-amino derivative undergo highly regioselective photocyclization to give 2-azaphenanthrene products **42**.[30] As outlined in Figure 33.8, the reaction proceeds by a formal [1,7] hydrogen shift in the 4a,4b-dihydroazaphenanthrene intermediate to give the moderately stable 1,4-dihydropyridine **43**, which is converted into **42** in both the absence and presence of oxygen. However, when the reaction is carried out under oxygen, a mixture of **42** and the 4-azaphenanthrene **44** is formed. For some heteroarylethenes the photocyclization can be inefficient, but it has been reported that this limitation can be overcome by substitution of the ethene with a tosyl group, which promotes the formation of the cyclized product.[31]

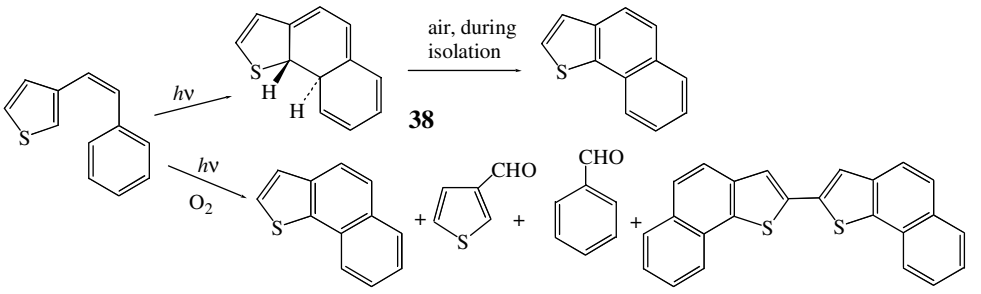

FIGURE 33.7 Photocyclization of 3-styrylthiophene.

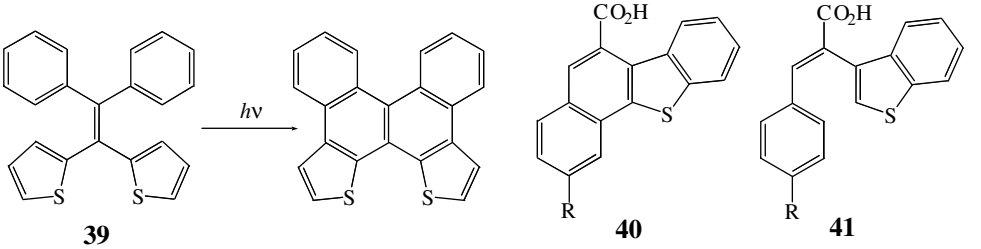

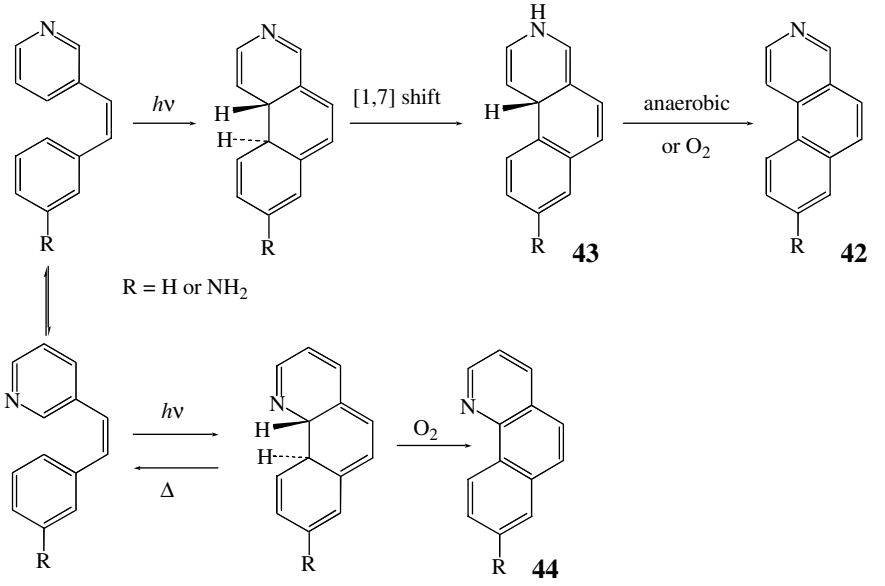

FIGURE 33.8 Photocyclization of 3-styrylpyridine and the 3′-amino derivative.

A huge variety of 1,2-diheteroarylethenes undergo photochemical 6π–electrocyclization, and much of this literature, particularly that of the photochromic reactions of 1,2-bis(methylthienyl)- and 1,2-bis(methylbenzothiophen-3-yl)-perfluorocyclopentenes, is reviewed elsewhere in this Handbook.[32] However, examples of these systems are presented here to illustrate the diversity of the molecular architectures that undergo this type of photochemical process. A variety of compounds derived from the basic 1,2-dithienylethene structure (e.g., **45**) undergo photochemical closure/ring opening in solution, films, and

the crystalline state. For derivatives such as **46**, the quantum yield of cyclization in aqueous solution can be increased appreciably by the presence of cyclodextrin, since the ratio of the photoreactive antiparallel conformer to the inactive parallel form is increased by its inclusion in the host cavity.[33] The open form of the derivative **47** uses the two crown ether moieties co-operatively like tweezers to capture large metal ions, which are then released from the photocyclized isomer[34]. The presence of an optically active substituent in the maleimide derivative **48** can lead to asymmetric photocyclization resulting in a diastereomeric excess as high as 86.6%.[35] Other photoactive systems in which the two heteroarenes are held in a *cis* geometry include 1,8a-dihydro-2,3-diarylazulenes such as **49**,[36] and the 2,3-bis(heteroaryl)quinones **50**.[37] As outlined in Figure 33.9, **49** undergoes both 6π-electrocyclization to **51** and conversion to the vinyl-heptafulvene **52** on irradiation, but when the 2,5-dimethyl-3-thienyl groups are replaced by phenyl, the photochromism only involves the latter process. Interestingly, the quinone derivatives **50** undergo cyclization both photochemically and by treatment with $AlCl_3$, $FeCl_3$, or CF_3SO_3H. The photocyclization of [2,3-a]quinolizinium salts (e.g., **53**) provides a convenient access to a series of novel hetero[5]helicenes having both thiophene and quinolizinium units.[38]

Synthesis of Heterocycles by Photocyclization of Arenes

Norbert Hoffmann
UMR CNRS et Université de Reims Champagne-Ardenne

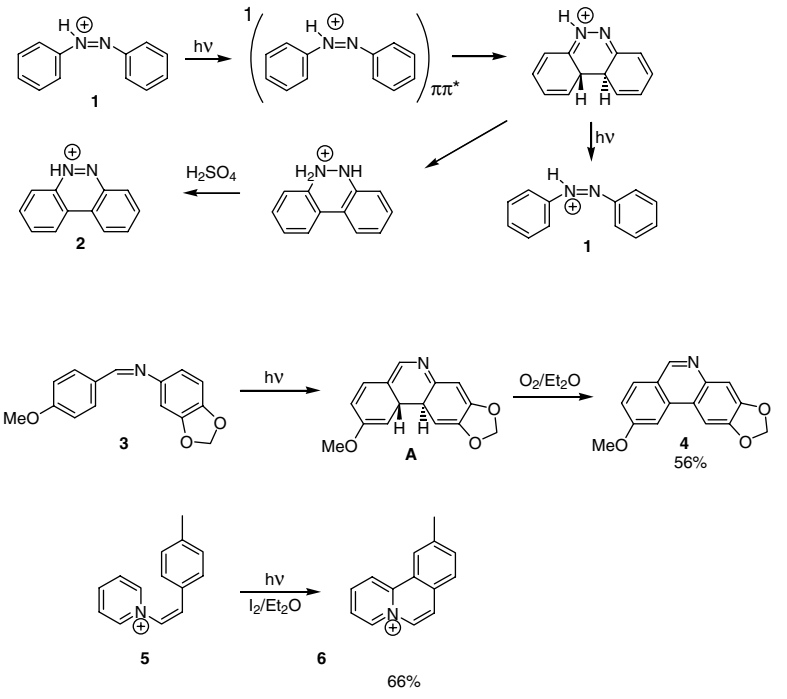
34.1 Introduction

Heterocyclic compounds are important targets in organic synthesis. They possess numerous biological activities and can be used as intermediates for further transformations. Starting from readily accessible starting materials, various photochemical cyclization reactions provide convenient methods to build up to a large variety of heterocycles; several reviews deal with them.[1] In this context, the cyclization of aromatic compounds plays an important role. In these reactions, as in many ground state reactions of aromatic compounds, the aromatic character is momentarily suppressed. In this chapter, some of these reactions are discussed.

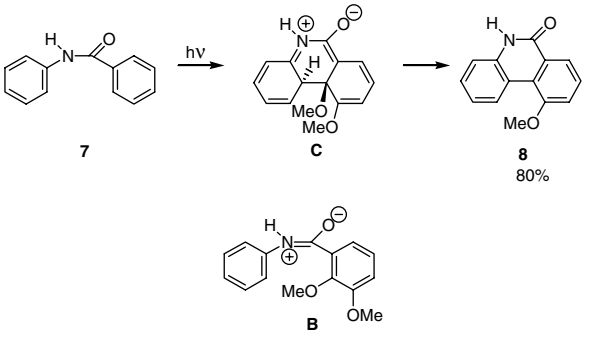
34.2 Electrocyclization

Electrocyclization provides an efficient way to synthesize a large variety of heterocyclic compounds. Among the many photocyclization reactions of aromatic compounds, electrocyclization is among the most frequently studied. An example of this is that illustrated in Scheme 1. This involves cyclization between the arene moieties of the protonated azobenzene **1**, which reacts from the $^1\pi\pi^*$ state reaction and is controlled by the Woodward–Hoffmann rules.[2] Six π-electrons are involved in the conrotatory cyclization. The reaction was not observed when unprotonated azobenzene was irradiated because in this case, the $^1n\pi^*$ state is populated. Since the photochemical electrocyclization is reversible, a consecutive trapping reaction is needed to obtain the final products in good yields. In the present case, as in many other reactions, a rearomatization step via oxidation took place to afford the final product **2**. In the same way, the imine **3** can be cyclized to the phenanthridine derivative **4**.[3] In this case, the oxidation of the

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1

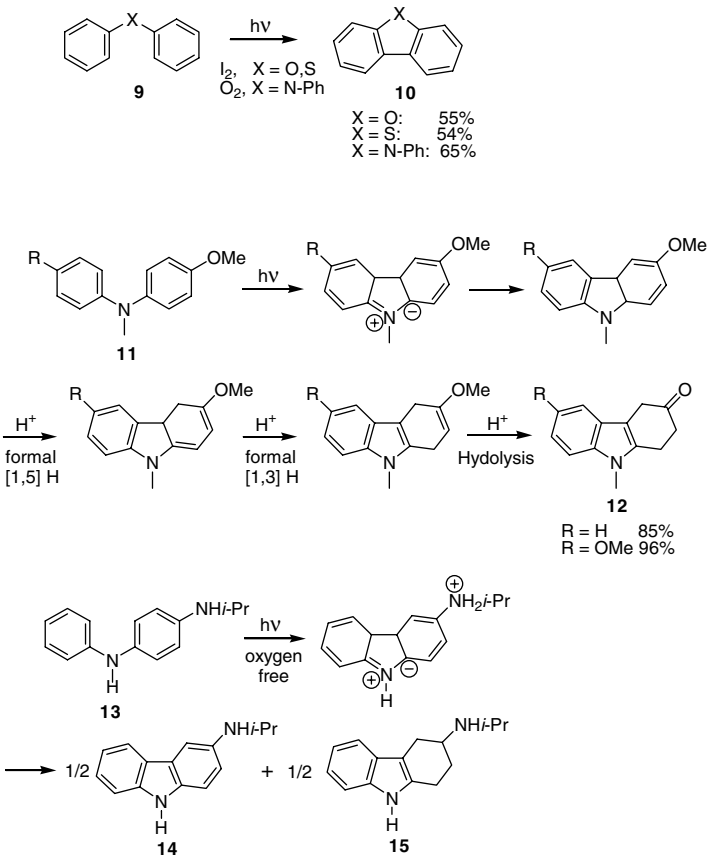


SCHEME 2

intermediate **A** was performed by oxygen. Phenanthridizinium derivatives **6** have been synthesized by photocyclization of styrylpyridinium **5** cations (Scheme 1) The rearomatization took place by oxidation with iodine.[4]

Cyclization of benzoanilide derivatives such as **7** is also possible (Scheme 2).[5] The 6π-electron system necessary for photochemical conrotatory cyclization is present due to the mesomeric structure **B**. In the present example, no oxidation was needed to regenerate the aromaticity in the final product **8**. In this case re-aromatization occurred via elimination of methanol from intermediate **C**.

Carbazoles,[6] dibenzofurans,[7] and dibenzothiophene[7] derivatives **10** have been obtained via photocyclization of the corresponding diphenylamine, diphenylether, or diphenylthioether precursors **9** (Scheme 3). In these reactions, the lone pair of heteroatoms contributes to the 6π–electrons engaged in the electrocyclization. The re-aromatization occurred under oxidative conditions in the presence of oxygen or iodine. When irradiated in acetonitrile solution containing aqueous HCl, compounds **11** were transformed into

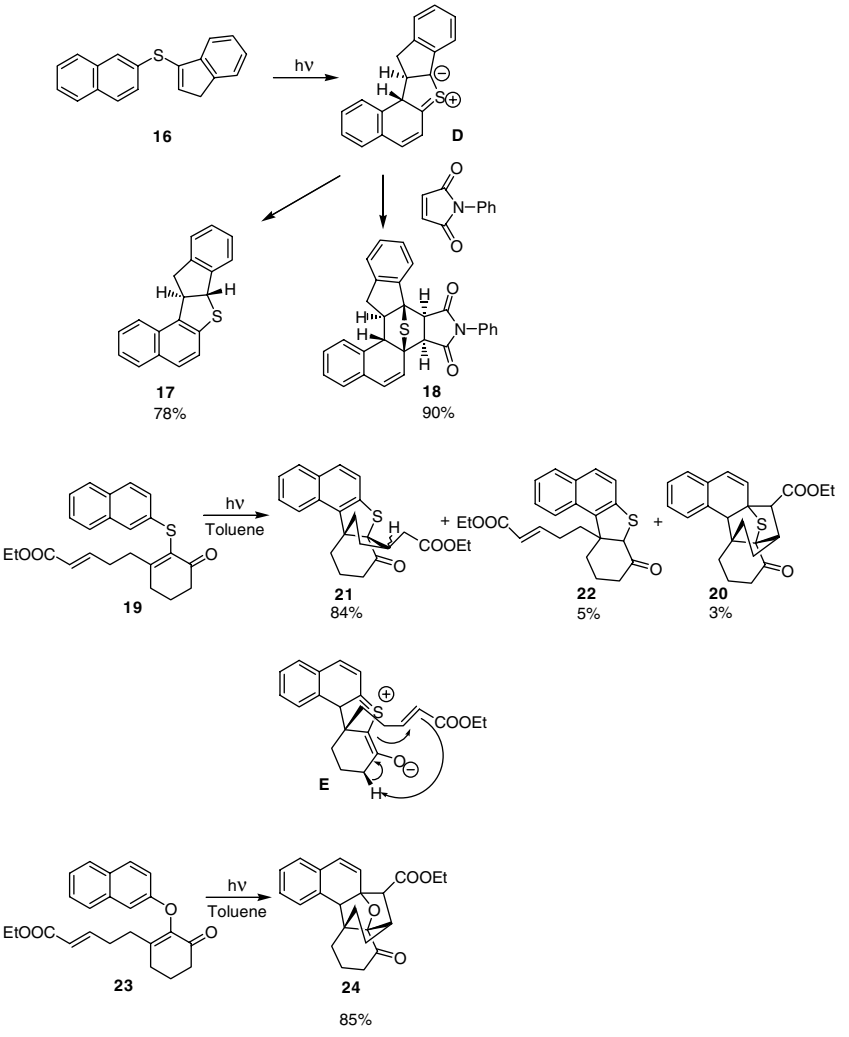


SCHEME 3

1,2,4-tetrahydro[4a*H*]carbazol-3-ones **12** with high yields.[8] Instead of aromatization through oxidation, acid-catalyzed rearrangements and hydrolysis took place. Under similar conditions and in the absence of oxygen the transformation of the corresponding amine derivative **13** yielded carbazole **14** and the tetrahydrocarbazole derivative **15**.[9]

Many photochemical electrocyclizations of compounds possessing an aromatic moiety and an olefinc substituent have been reported. Some examples are described here. Aromatic thioethers such as **16** afforded arenodihydrothiophene derivatives **17** (Scheme 4).[10] The presence of the ylide intermediate **D** was proven by its independent trapping in a 1,3-dipolar cycloaddition with *N*-phenylmaleimide. From this reaction, compound **18** was isolated in high yields. In the corresponding intramolecular reaction of **19**, product **20** was formed only in minor amounts.[11] However, the major product **21** resulted from an intramolecular trapping by a Michael reaction. A possible mechanism is indicated in structure **E**. Another minor product **22** resulted from simple cyclization. Under the same reaction conditions, the corresponding enol ether derivative **23** afforded product **24** resulting from an efficient intramolecular 1,3-dipolar addition of the alkene with the ylide intermediate of the photochemical cyclization.[12]

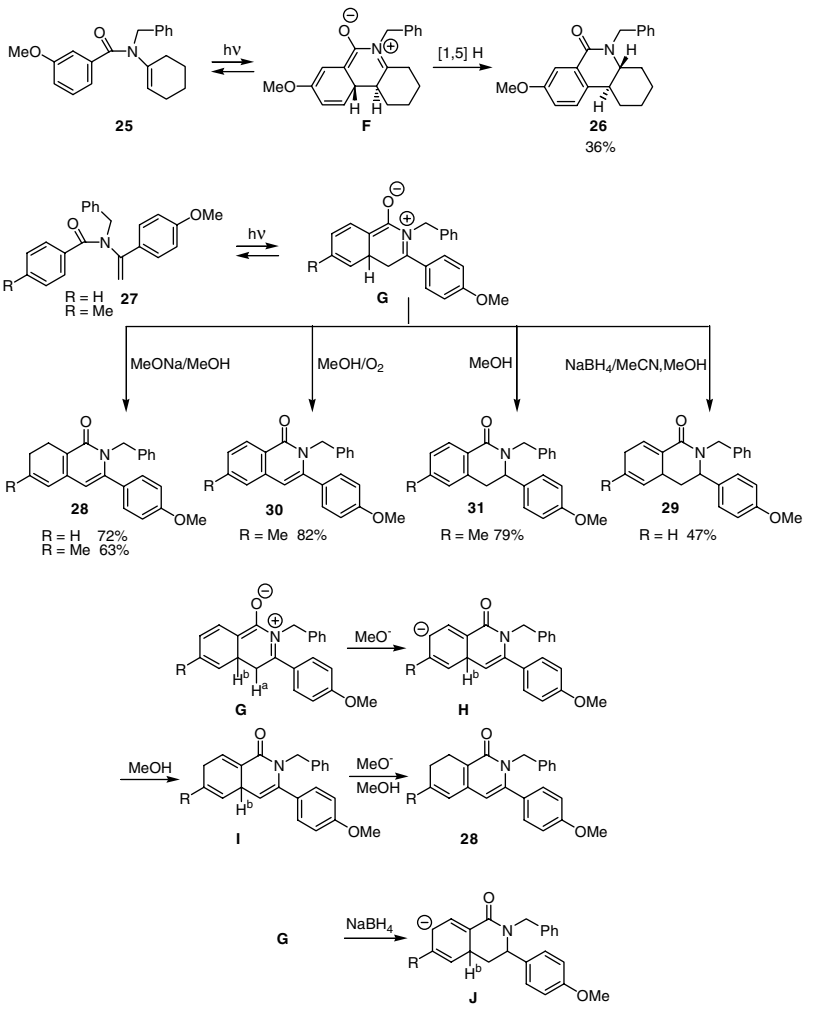
A large variety of *N*-benzoylenamines have been subjected to photochemical cyclization. Mostly *trans* fused ring systems were obtained from the cyclization of *N*-benzoylenamines such as **25** derived from cyclic amines, especially cyclohexylamines (Scheme 5).[13] The stereochemistry can be explained by a photochemical conrotatory cyclization leading to intermediate **F**. A thermal 1,5-suprafacial H shift leads then to the final product **26**. In this way, the aromaticity of the benzoyl moiety is reestablished. Frequently, the formation of a *cis*-isomer as a byproduct was observed. These products resulted from a consecutive photochemical or thermal isomerization of the *trans* product. When the reaction was carried out in the



SCHEME 4

presence of oxygen or iodine, the double bond of the enamine moiety was reformed in the final product. This aspect was recently studied with the reaction of **27**.[14] Depending on the reaction conditions, the transformation of the intermediate **G** can be controlled, and unsaturated, nonaromatic products, **28** and **29**, can also be isolated. Compound **28** resulted from base-catalyzed rearrangements via intermediates **H** and **I**. Intermediate **H** was formed by deprotonation at H^a, and the final product **28** resulted from a base catalyzed rearrangement involving H^b. Compounds **30** and **31** were formed *via* oxidation and the 1,5 H shift path, respectively. Under reductive reaction conditions, **G** was reduced at the iminium moiety leading to **J**. This latter intermediate yielded **29** after protonation. The sequence of acid/base reactions was proven by isotopic labeling with deuterium.

Interesting carbocyclic systems such the spiro cyclic compound **32** can be formed from benzoenamides **33** (Scheme 6).[15] The same class of spirocyclic compounds was available from heterocyclic carboxamides.[16] Starting from the furan and thiophene derivatives **34**, the corresponding spirocyclic products **35** were obtained when the reaction was carried out in dry actonitrile. The intermediate **K** is generated by photochemical cyclization. A 1,5-[H] shift regenerates the aromaticity of the furan or thiophene ring. When the reaction was carried out in methanol as solvent, the intermediate **K** was trapped by addition of a solvent molecule to the iminium bond, and products **36** were obtained in high yields. The reaction

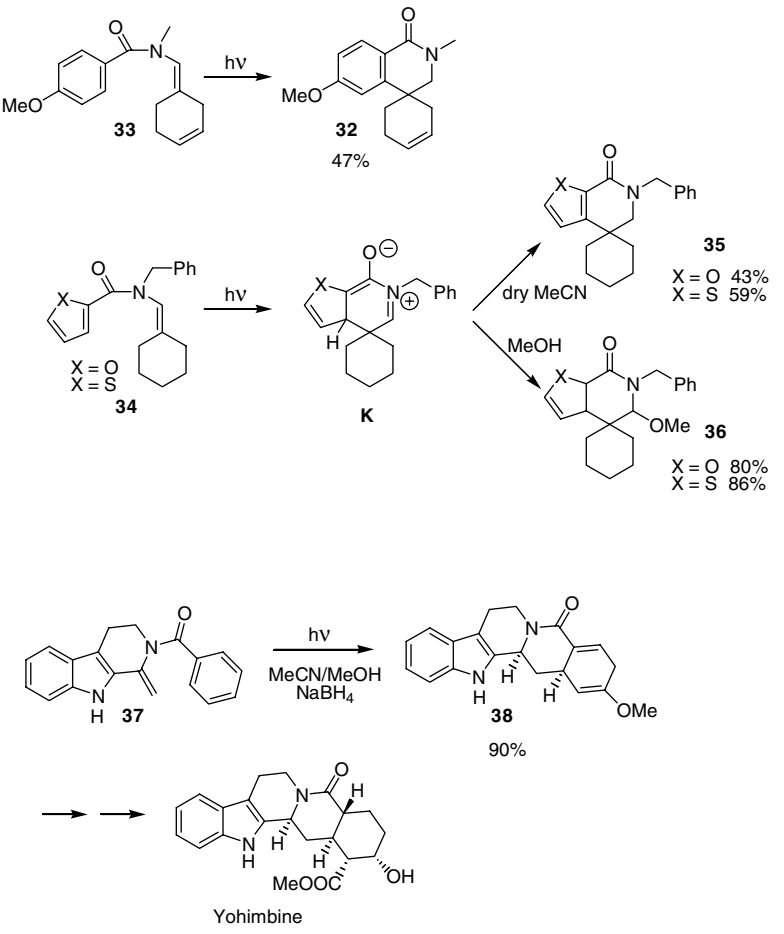


SCHEME 5

has been frequently applied to the synthesis of alkaloids. Thus, for example, irradiation of **37** in the presence of $NaBH_4$ yielded **38**, which was a convenient intermediate in the synthesis of the indole alkaloid, yohimbine.[17]

Aniline derivatives have been used to synthesize the indoline system. A large variety of indoline alkaloid substructures are available in a very efficient way. Enamine derivatives such as **39** bearing electron withdrawing substituents on the olefinic double bond were transformed in high yields (Scheme 7).[18] Two *syn/anti* isomers **41** and **42** were isolated. The isomeric ratio of the final products was influenced by a photostationary equilibrium between the substrates **39** and **40**. The reaction was applied to the synthesis of a variety of derivatives of the alkaloid aspidospermidine.[19] In this context, the cyclization products **43** were transformed into the polycyclic indole derivatives **44**, **45**, and **46**. Polycyclic indolone compounds **48** have been successfully produced by cyclization of enaminone derivatives **47** carrying a quinoline substituent.[20] In these cases and contrary to the examples **41**, **42,** and **43**, the products **48** resulted from an oxidation of the cyclization product (also compare the formation of **30** in Scheme 5).

The photochemical electrocyclization was also applied as key step in the synthesis of nitrogen-containing heterocycles possessing pharmaceutical activity such as, for example, the 5-$HT_{2C/2B}$ Receptor Antagonist **49**[21] or the nonsteroidal androgen receptor agonist **50** (Scheme 8).[22]

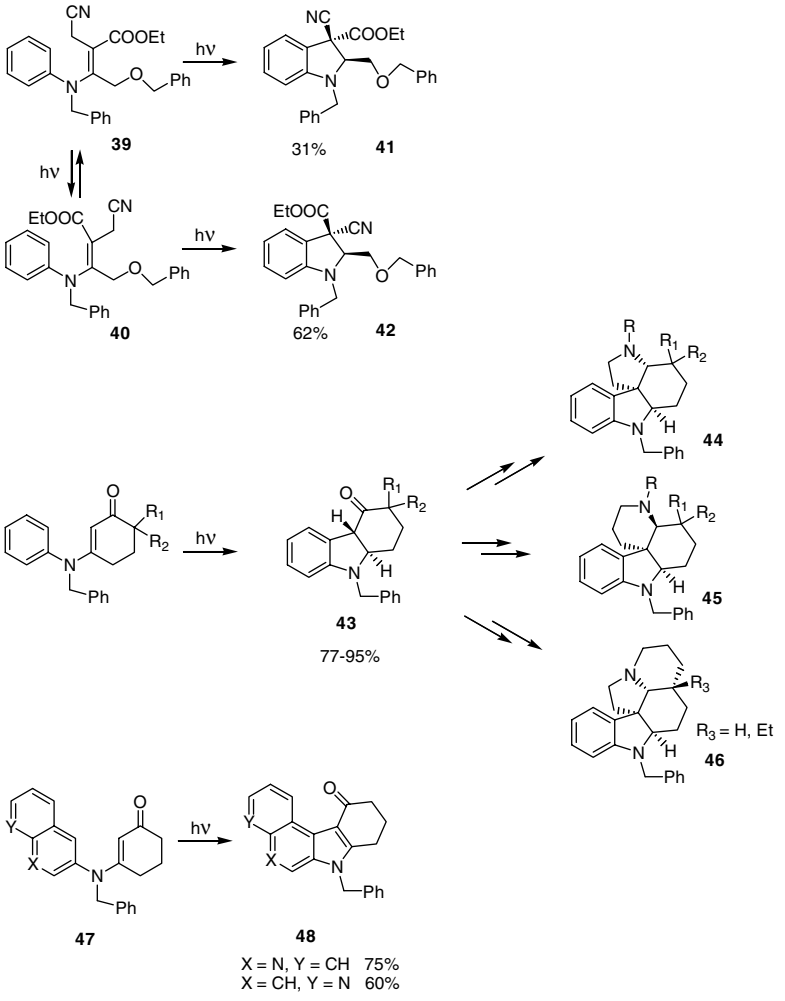


SCHEME 6

Higher functionalized aromatic compounds undergo photochemical electrocyclization as well. Two examples are presented in Scheme 9. When the benzoquinoxaline **51** was irradiated in an acidic medium, the indolo[1,2-a]quinoxaline **52** could be isolated in good yields.[23] The acid seems to have no significant influence on the photochemical cyclization, since the reaction can also be carried out in a neutral reaction medium. However, the acid might shift the equilibrium between the substrate **51** and the intermediate **L** towards the product side. The good yields resulted mainly from the fact that the protonated product **52** is more stable than the unprotonated form. The trifluoromethylated dihydroisoquinoline derivative **55** was obtained from the irradiation of benzamidine **53**.[24] Due to steric hindrance, the cyclization of the *Z*-isomer is unfavorable. However, the corresponding *E*-isomer **54** is formed in a photostationary equilibrium. After cylization hydrogen shifts lead to the final product **55**.

34.3 Chiral Induction in Electrocyclization Reactions

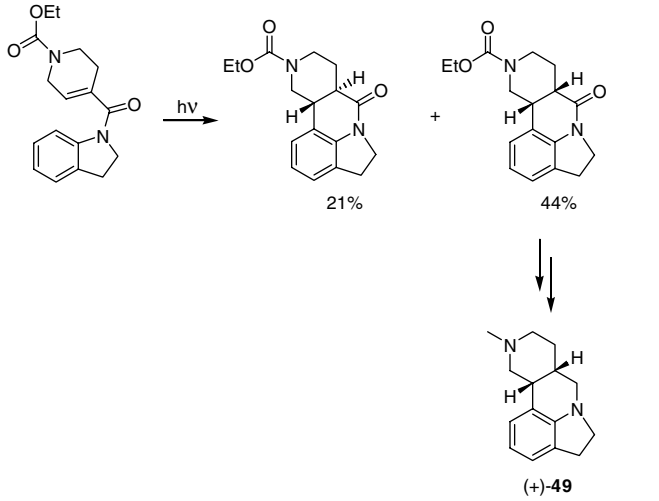
Few attempts have been made to induce chirality in these reactions. The cyclization of the homochiral enamide **56** was diastereoselective, and product **57** was obtained in good yield along with small amounts of the oxidation product **58** (Scheme 10).[25] Compound **57** was transformed into (–)-xylopinine. The exact mechanism of the chiral induction was not discussed. Most reasonably, the chirality was induced during the 6π-cyclization. The subsequent 1,5-[H] shift should be stereospecific. However, the diastereoselectivity was determined after several steps and revealed to be rather low. The stereoisomers **60a,b**

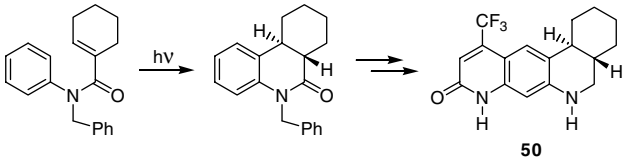


SCHEME 7

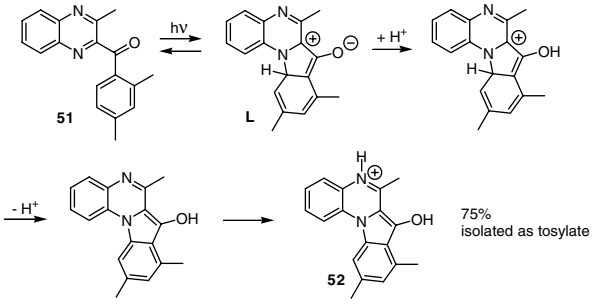
were isolated in a 3.7/1 ratio. It seems that during the transformations, partial epimerization occurred, especially when the lactam function was reduced to obtain **59**. For a similar derivative, the chiral induction in the photocyclization step was complete, but the products were obtained only in low yields.[26]

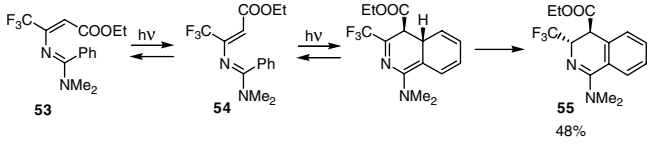
Absolute chiral induction was performed by irradiation with circularly polarized light with compound **61** (Scheme 11).[27] Using, for example, left-circularly-polarized light, the enantiomer of the cyclization product **62** possessing negative specific rotation was generated in a slight excess. Catalytical chiral induction in solution was carried out using the tartaric acid derivative **63** as inductor.[28] Complexation of intermediates of the substrate **64** with **63** led to the preferred formation of one enantiomer. The enantiomeric excess of the *trans*-isomer **65** was significantly higher than that of the *cis*-isomer **66**. Especially high chiral induction was observed when the substrate was co-crystallized with TADDOL derivatives.[29] TADDOLs are capable of forming crystal inclusion complexes with many organic compounds. The substrates are highly orientated and imobilized in the chiral environment, which favors one of the enantiotopic pathways. The sense of the chiral induction depends on the chiral cavity filled with the substrate molecule rather than on the configuration of the TADDOL derivative. Therefore, different enatiomers were favored when the cyclopentane- or the cyclohexane-derived TADDOL was used. When compound **64** was complexed with the cyclohexylidene TADDOL **67**, **ent-65** was isolated with almost complete enantioselectivity. However, when **64** was complexed with the corresponding cyclopentylidene TADDOL **68**, **65** was formed with only 70% enantiomeric excess.





SCHEME 8

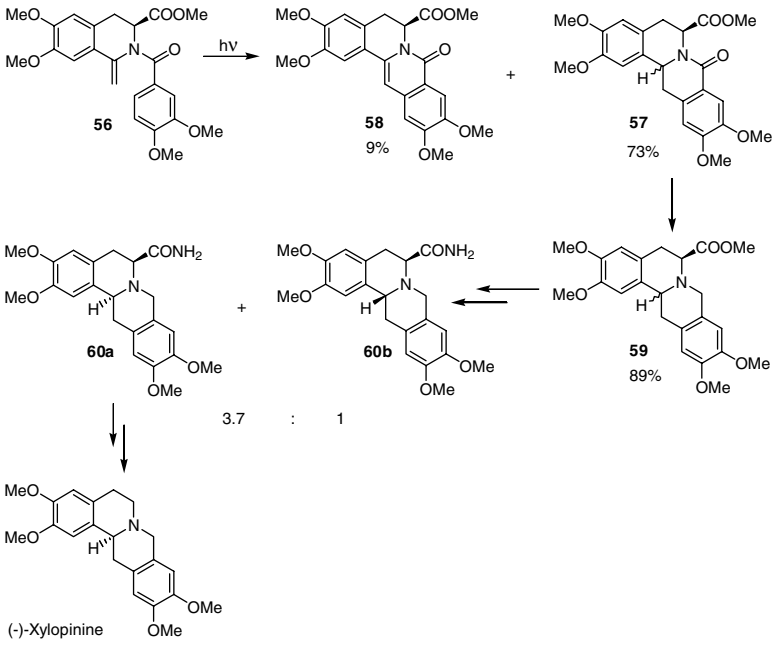




SCHEME 9

34.4 Photochemical Cyclization of Aromatic Compounds Involving Radical Species

Photochemically excited molecules often lose energy via production of radicals. Such intermediates are frequently involved in photochemical cyclizations. In this way, naphthylypyridylamine derivatives such

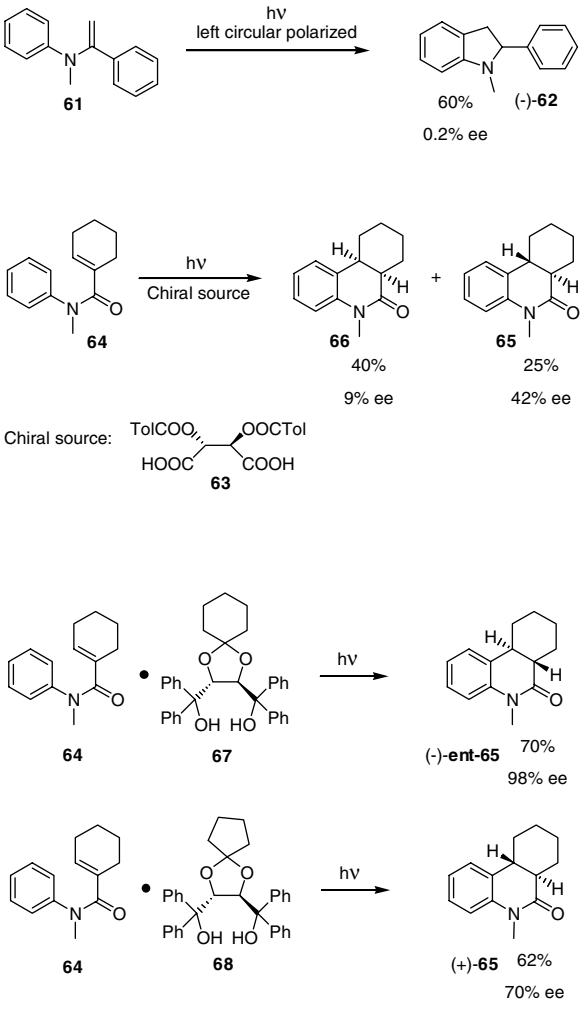


SCHEME 10

as **69** were successfully transformed into polycyclic compounds **70** and **71** (Scheme 12).[30] Cyclization was observed either at the ring nitrogen leading to **71** or at the 6-position of the pyridine ring leading to **70**. Benzo[*c*]naphthyridinones **73** were efficiently obtained by photocyclization of 2-halo-*N*-pyridinylbenzamides such as **72**.[31] Such photochemical cyclization of aromatic compounds carrying a halogen atom on the aromatic ring are frequently proposed to proceed via radical intermediates. However, in some cases, an electrocyclization followed by elimination of HX could explain the results as well. In the present case radical intermediates, especially n-complexes **M**, were identified by transient absorption spectra from laser flash photolysis of **72**. Polycyclic thiophene carbamides such as **74** yielded polycyclic lactams **75** in the same way.[32] This reaction was carried out with a large variety of such derivatives. Boron complexes of *N*-phenylbenzohydroxamic acids such as **76** were cyclized in high yields.[33] The complexation favorably orientates the two aromatic rings for cyclization. The presence of the bromine atom in the *ortho* position of the benzoyl moiety increased significantly the efficiency of the reaction. The corresponding bromine free boron complex, in the presence of iodine as oxidizing agent, needed 33 h for complete conversion instead of 2 h for the complex **76** (X = Br) to obtain the cyclization product **77**.

Mechanistic details were also discussed for the reaction of enamineones such as **78** (Scheme 13).[34] After photochemical excitation, single electron transfer took place. This transfer occurred in an intramolecular way leading to intermediate **N** or in an intermolecular way (in the presence of tertiary amines) leading to the radical ion pair **O**. After release of chloride, the latter intermediate yields the pyridyl radical **P**. Addition of the radical moiety to the enamineone double bond and loss of hydrogen led to the final product **79**. Hydrogen abstraction from a solvent molecule or addition with a solvent molecule (e.g., benzene) of **P** led to side products such as **80**. The same product could also result from the reaction of intermediate **N**. Under the described reaction conditions, **80** could not be isolated since under photochemical electrocyclization, it was transformed into **79** and **81**.

The enamine derivative **82** underwent photocyclization via intramolecular single electron transfer (Scheme14).[35] The favorable *E*-geometry **83** for the formation of the major product was generated by photochemical *cis/trans* isomerization. Electron transfer from the tertiary amine function on the side chain to the excited chromophore generated the radical ion pair **Q**. Consecutive hydrogen transfer from

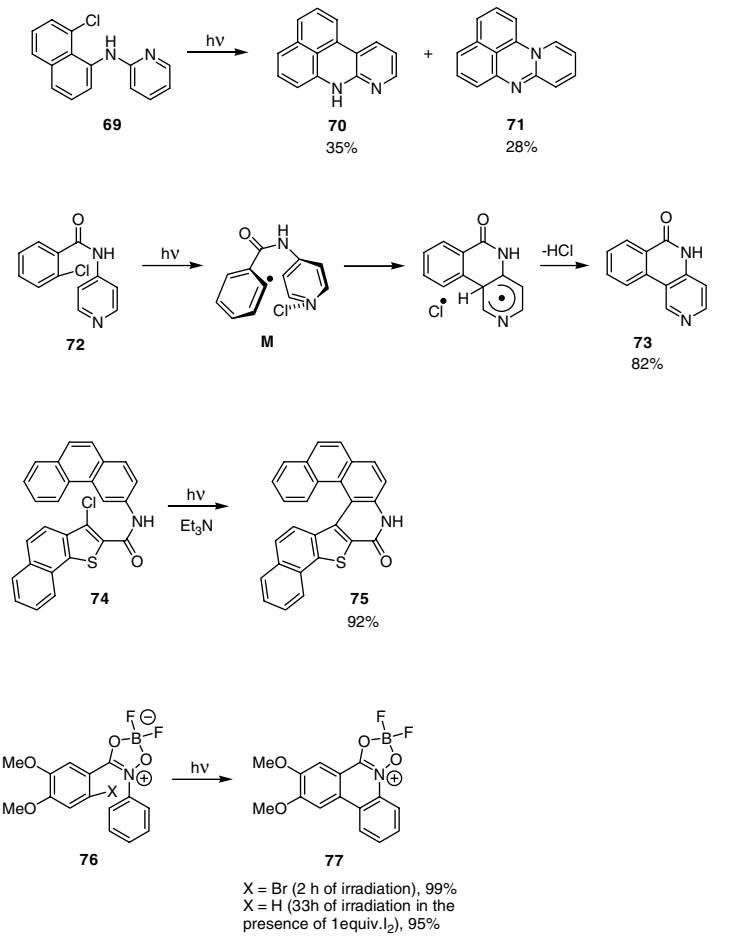


SCHEME 11

the amide nitrogen to the amide oxygen then led to the biradical **R**. Radical combination and tautomerization afforded the intermediate **S**. Finally, the main product **84** was formed via hydrogen shift. The side product **85** was formed by a cyclization/H shift/dehydration sequence of substrate **82**. A 4π–electrocyclization of the *trans*-isomer **83**, involving structure **T,** and followed by a H-shift and dehydration led to the didehydroazetidine derivative **86**.

A radical species can be generated on an aliphatic side chain. Intramolecular addition to the aromatic system then builds up a heterocycle. This strategy was applied to the synthesis of indanone derivatives (Scheme 15).[36] After photochemical excitation, intramolecular electron transfer in compound **87** took place leading to the intermediate **U**. Radical combination and deprotonation led to the final product **88**. In the present case, elimination of HBr occurred as a competing reaction and furnished the methacrylamide **89**. This compound underwent photochemical electrocyclization to yield **90**.

The photocyclization reactions of a large variety of aromatic chloroacetamide derivatives have been investigated. The cyclizations were applied to the synthesis of azepinoindol systems, which are not readily accessible by ground-state radical reactions.[37] The tricyclic azepine derivatives **92** were obtained from the cyclization of **91** (Scheme 16).[38] More complex azepine derivatives such as **93** could be synthesized in the same way.[39] The reaction of corresponding dichloroacetamides such as **94** is more efficient, especially

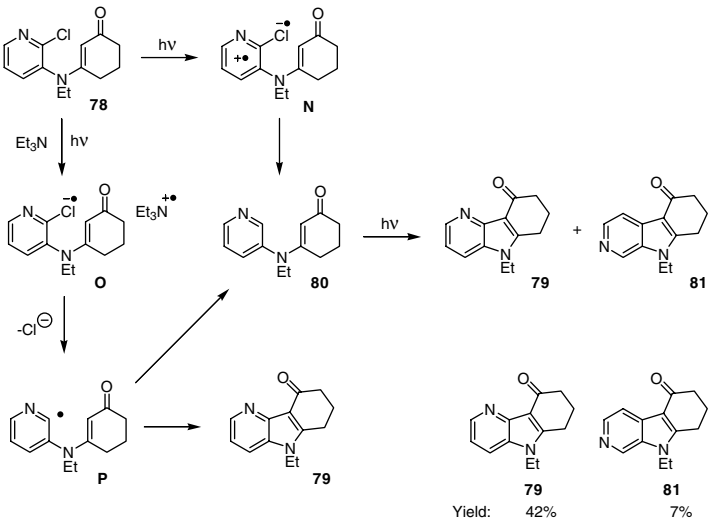


SCHEME 12

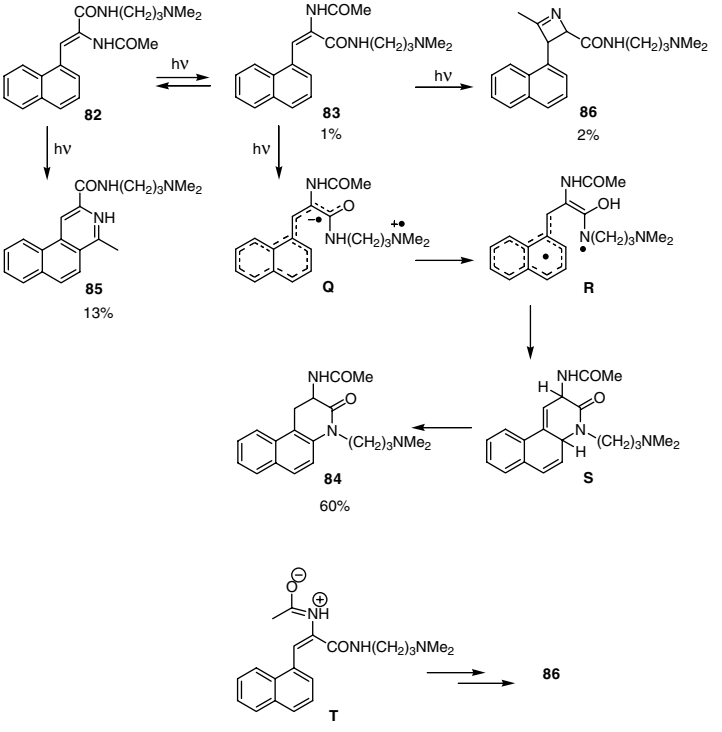
when the workup is carried out in the presence of nucleophiles such as methanol.[40] Eight-membered ring systems such as **95** were obtained in this way. The reaction of the indole derivatives **96** bearing a benzene ring in the *N*-sidechain was less selective.[41] Besides the eight-membered ring product **97**, a nine-membered lactam **98** and the pentacyclic product **99** were obtained from the cyclization.

Excited states of enones such as **100** can abstract hydrogen preferentially from the α position of alkyl ether or alkyl amines leading to the biradical intermediates **V**. Intramolecular addition to the benzene ring leads to dihydropyran or dihydropyridin derivatives **101** (Scheme 17).[42] Dibenzofuran derivatives **103** were obtained from polyfluorinated aryloxodihydronaphthalene compounds such as **102**.[43] Probably, in such cases, a photochemical electron transfer from the nonfluorinated aryl substituent to the fluorinated moiety takes place. When compound **104** was irradiated in the presence of $HClO_4$, the isoquinoline derivative **105** was isolated in good yields.[44]

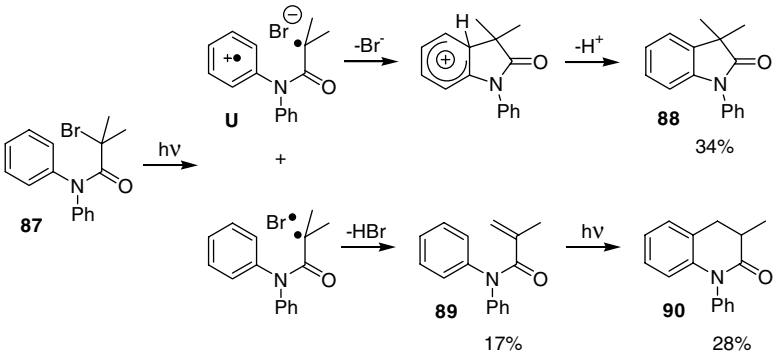
The cyclization was followed by hydrolysis and oxidation. The transformation is a photochemical analogue of the Mannich or the Pictet–Spengler reaction. A photochemically sensitized cyclization was applied to the synthesis of the tetrahydroisoquinoline derivative **107**.[45] The reaction starts with an electron transfer from **106** to the photochemical excited sensitizer dicyanonaphthalene (DCN). The resulting radical cation **W** undergoes cyclization followed by the release of a trialkylsilyl cation. Intermediate **X** then yields the final product **107** by hydrogen loss.



SCHEME 13



SCHEME 14



SCHEME 15

34.5 Photochemical Cyclization of Aromatic Compounds Involving Nitrenes and Other Reactive Intermediates

Electrocyclization of aromatic compounds involving temporary suppression of the aromatic character sometimes takes place in the context of photochemical rearrangements involving reactive centers other than radicals. The reaction of aromatic nitrenes has been particularly well studied. In addition to other methods, these intermediates were generated by photolysis of the corresponding azides. An example is depicted in Scheme 18. Under the indicated reaction conditions, the singlet nitrene **Y**, which was generated from the diphenylazide **108**, underwent cyclization to yield the carbazol **109**.[46] The concomitantly generated triplet nitrene (about 10%) yielded the side products, in particular the phenanthridine **110**. The yield of carbazole **109** was particularly high when the reaction was carried out at higher temperature. Control experiments have shown that thermolysis of the substrate **108** was negligible under these conditions. Singlet nitrenes obtained in the same way as described above could add to heterocyclic aromatic substitutents such as that illustrated in example **111**.[47] Upon irradiation, the azidophenylpyrazole **111** yielded the singlet nitrene **Z**, which cyclized to afford the pyrazolobenzotriazol **112**. The concomitantly generated triplet nitrene was at a minimum but still occurred to yield the pyrazolophenylamine **113** as a side product. 1,3-Dipolar intermediates **AA** were generated by irradiation of 2*H*-azirine derivatives **114**.[48] Cyclization followed by a 1,5-[H] shift afforded benzoazepine derivatives **155** in high yield. The corresponding naphthalene derivatives **116** and **117** were obtained in the same way and with the same efficiency.

34.6 Conclusion

Photochemical cyclization reactions provide an efficient route to a large variety of heterocyclic compounds starting from readily accessible substrates. Many of these heterocycles possess interesting biological activity. Aside from the halogen substrates, which are frequently used for cyclizations involving radical intermediates, no particular activation or derivatization or the use of metal reagents is necessary for C-C bond formation. This reflects the general advantage of photochemical reactions in the context of their application to organic synthesis.

Photochromism of Diarylethene Derivatives

Kingo Uchida
Ryukoku University

Masahiro Irie
Kyushu University

35.1 Introduction

Light-induced reversible transformation between two isomers having different absorption spectra is referred to as photochromism.[1,2]

$$A \underset{h\nu'}{\overset{h\nu}{\rightleftharpoons}} B$$

The two isomers differ from one another not only in the absorption spectra but also in refractive indices, dielectric constants, oxidation–reduction potentials, and geometrical structures. Therefore, upon irradiation with an appropriate wavelength of light, these properties can be reversibly switched.

Diarylethenes with heterocyclic aryl groups are newcomers to the photochromic field. They belong to the thermally irreversible (P-type) photochromic compounds. The most striking feature of the compounds is their fatigue resistance.[3] The coloration/decoloration cycle can be repeated more than 10^4 times while retaining the photochromic performance. Both properties, thermal stability of both isomers and fatigue resistance, are indispensable for application to optoelectronic devices, such as devices for memory and switches. In this chapter, recent research on diarylethene derivatives will be described.

35.2 Conformation of Diarylethenes

Diarylethenes with heterocyclic aryl groups have two conformations with the two rings in mirror (parallel) and C_2 (antiparallel) symmetries; the conrotatory photocyclization reaction can proceed only from

0-8493-1348-1/04/$0.00+$1.50

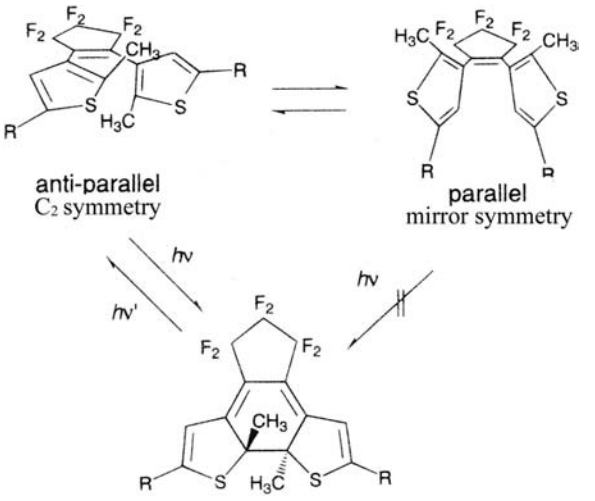

FIGURE 35.1 Anti-parallel and parallel conformations of diarylethene derivatives.

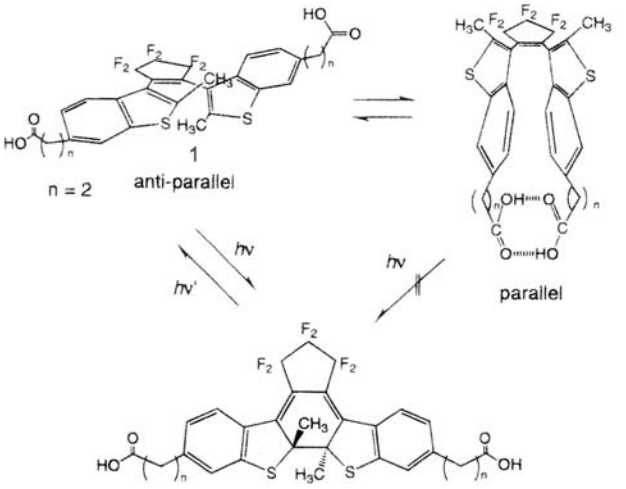

FIGURE 35.2 Locking of the conformations by intramolecular hydrogen bonds.

the C_2 symmetry,[4] as shown in Figure 35.1. The reactivity of the cyclization reaction can be controlled by controlling the conformations. A diarylethene **1** with terminal carboxylic acid moieties has no photoreactivity because the conformation is fixed in parallel by the intramolecular hydrogen bonds. The molecule becomes photoreactive by the addition of protic solvents or by elevating the temperature, which breaks the intramolecular hydrogen bonds. (Figure 35.2).[5]

The cyclization quantum yield can also be improved by controlling the conformations. When the ratio of the photoreactive antiparallel conformers is increased, the quantum yield is expected to increase. Introduction of bulky isopropyl groups at the 2 and 2′-positions of the benzothiophene rings enhanced the ratio of the conformers from 0.65 to 0.94 and increased the quantum yield of the cyclization reaction from 0.35 to 0.52. The increment of the population of photoreactive conformers accounts for the enhancement of the yield.[6]

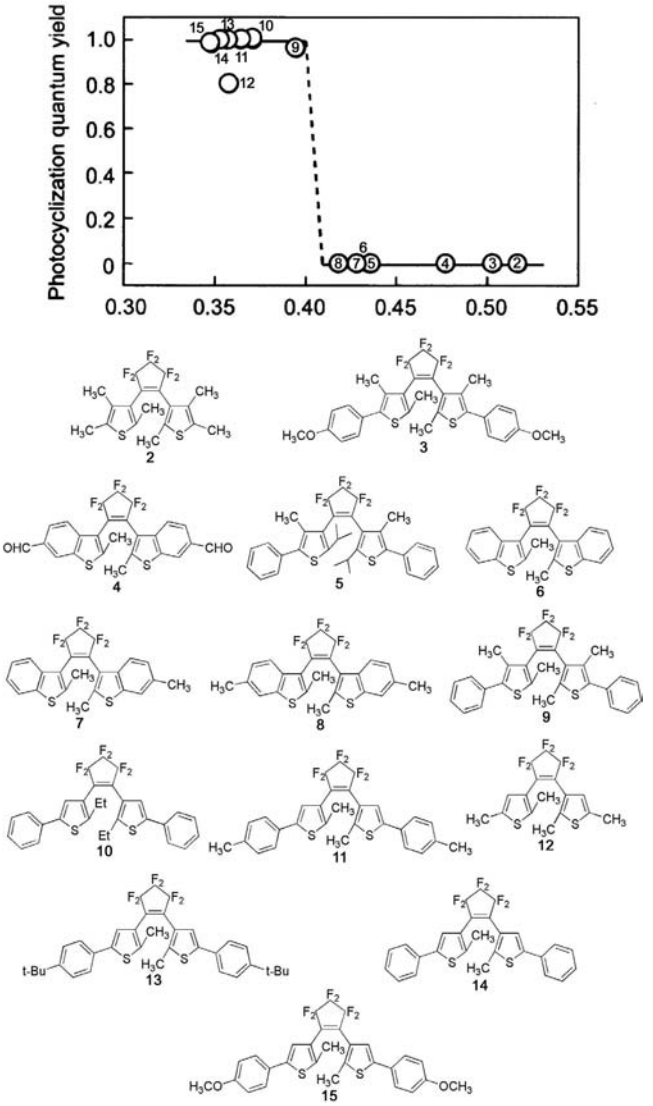

FIGURE 35.3 Relationship between the photocyclization quantum yields and the distances between the reacting carbons.

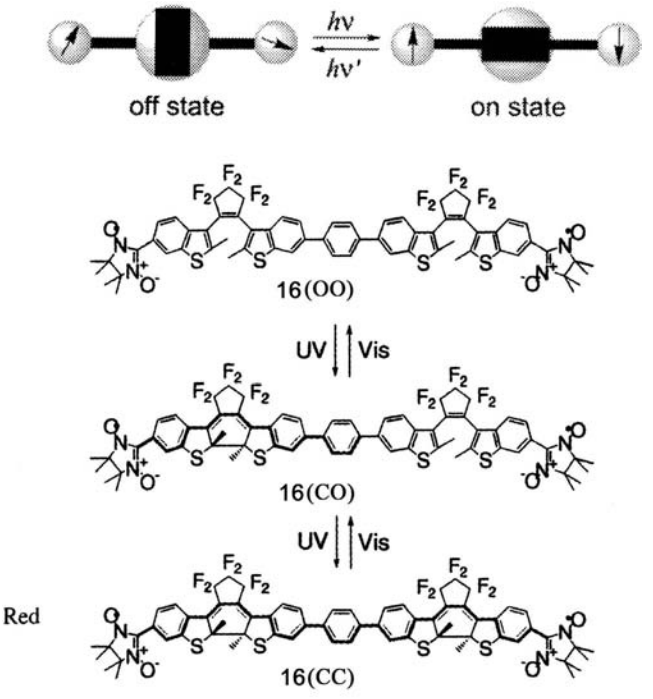
Another approach to increase the population of the photoreactive conformation is to include the compound into cyclodextrin cavities. α, β, and γ–Cyclodextrins were added to aqueous solutions containing 1,2-bis(2-methyl-1-benzothiophen-3-yl)perfluorocyclopentene having sulfonate groups, and the changes in the ratio of the two conformations were examined by NMR.[7–9] By the addition of 10 equivalents of β–cyclodextrin, the C_2 symmetry conformation ratio was increased from 0.64 to 0.94, and the cyclization quantum yield was increased from 0.32 to 0.49.

The most effective and ideal method to fix the compound into the appropriate photoreactive conformation is to use the crystal lattice. Some of the diarylethene derivatives exhibit photochromism even in the crystalline state.[10] X-ray crystallographic analysis revealed that the diarylethene molecules are packed in the crystal in the antiparallel photoreactive conformation. The reactivity in the crystals is dependent not only on the conformation but also on the distance between the reactive carbon atoms. Figure 35.3 shows the correlation of the cyclization quantum yields and the distance between the reactive carbon atoms in crystals. When the distance is shorter than 0.42 nm, the photocyclization quantum yield is unity (100%).[10,11]



[a]Bold line indicates the connection of the bond alternation.

FIGURE 35.4 Photoswitching of the spin interaction (top) and the photochromic reaction of **16**[a] (bottom).

35.3 Photoswitching

Spin Interaction

Diarylethene derivatives can be used as molecular-scale photoswitching units. In the open-ring isomer, the aryl groups can freely rotate along the single bonds connecting them to the ethene moiety, and the two aryl groups are electrically independent. On the other hand, in the closed-ring isomer the two aryl groups are linked by the π-conjugation, and π-electrons delocalize throughout the molecule. When two unpaired electrons are placed at the ends of the π–conjugated chain, the spins of the unpaired electrons are expected to be switched upon photoirradiation.[12]

The exchange interaction between two nitroxide radicals, which are located at both ends of the diarylethene system **16(OO)**, was photoswitched reversibly by alternate irradiation with ultraviolet and visible light (Figure 35.4). The ESR spectra of isolated **16(OO)**, **16(CO)**, and **16(CC)** were measured in benzene at room temperature (Figure 35.5). The spectra of **16(OO)** and **16(CO)** show five lines, suggesting that the exchange interaction between the two nitronyl nitroxide radicals was much smaller than the hyperfine coupling constant ($2J/k_B < 3 \times 10^{-4}$ K). However, the spectrum of **16(CC)** showed nine well-defined lines, indicating that the exchange interaction between the two spins was much larger than the hyperfine coupling constant ($2J/k_B > 0.04$ K). The result indicates that each diarylethene chromophore served as a switching unit to control the magnetic interaction. The magnetic interaction between the terminal nitronyl nitroxide radicals was controlled by the switching units in series.

Launay et al., showed that the intramolecular electric coupling between two redox sites can be controlled upon photoirradiation. A dithienylethene derivative **17** (Figure 35.6) with cyclometallated $Ru(bpy)_2(pp)$ units via ethynyl spacers was synthesized.[13] Open-ring isomer **17a** can be reversibly photoisomerized to the closed isomer **17b**. Upon oxidation, a new band in the 1000–1500 nm range due to

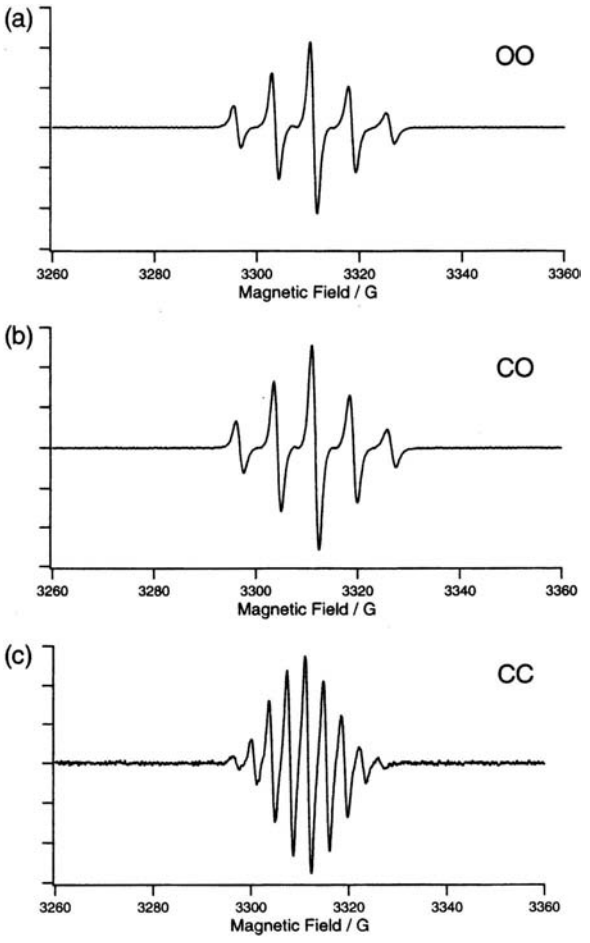


FIGURE 35.5 ESR spectra measured at room temperature in benzene (a) **16** (OO), (b) **16** (CO), and (C) **16** (CC).

the intervalence transition between ruthenium (II) and ruthenium (III) appeared in **17b** but was not observed in **17a**. The electric coupling parameter *V*ab was calculated to be 0.021 eV for closed-ring isomer **17b**, while it was 0.003 eV for **17a**. The former value is consistent with the observed coupling. *V*ab values in the 0.02 eV range have been observed for a π-conjugated system with four double bonds and a metal–metal distance of 20 Å. Compounds **17a** and **17b** allowed a fundamental study of switching in the electrical sense at the molecular level.

Fluorescence

Several methods to avoid destructive readout using fluorescence or infrared absorption as readout signals have been proposed. The fluorescence intensity change between the open- and closed-ring isomers makes it possible to use the change as the readout signal. When the fluorescence can be detected without influencing the ratio of the two isomers, the readout method becomes nondestructive.

Branda et al. reported the synthesis and optical characterization of a photochromic hybrid **18**, where porphyrin macrocycles are attached to the ends of the 1,2-bis(3-thienyl)cyclopentene backbone.[14] In the open ring isomer **18a**, the porphyrins exhibit significant fluorescence at 655 nm when excited at 430 nm. Upon irradiation with 313 nm light, **18a** converts to the nonfluorescent closed-ring isomer **18b**. The compound **18b** returns again to fluorescent **18a** upon irradiation with $\lambda > 480$ nm light. The intensity of the porphyrin fluorescence is conveniently regulated by alternate irradiation at 313 nm and >480 nm

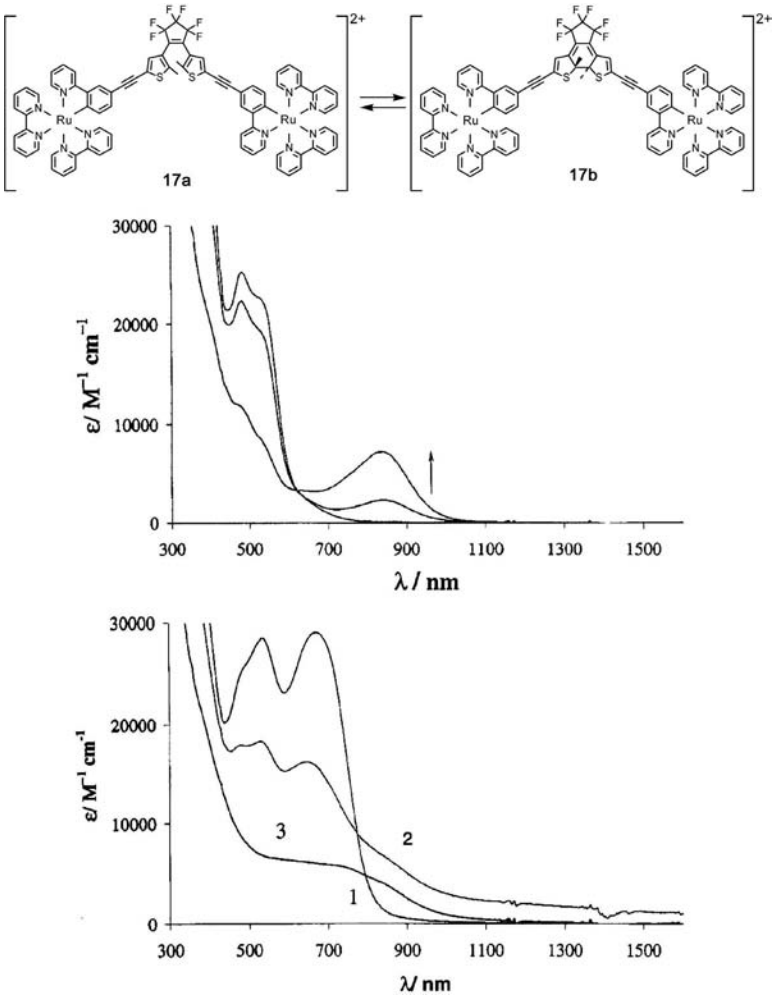

FIGURE 35.6 Spectra obtained during oxidation with bix(pyridyl)-phenyliodonium; top: open-ring isomer **17a**; bottom: closed-ring isomer **17b** exhibiting an intervalence absorption in the 1000–1500 range; 1: initial spectrum; 2: at half-oxidation; 3: spectrum of the fully oxidized solution.

(Figure 35.7). The molecule can be used as an optical memory medium with non-destructive readout capability.[14,15]

Branda et al. also reported the transition metal complexes coordinated to the ends of the pyridyl derivative of 1,2-dithienylethene **19**. The luminescence of the porphyrin macrocycle is dependent on whether the diarylethene moiety is in the open or closed state.[16] In this compound, ruthenium-based metalloporphyrins are axially coordinated to the Lewis-basic pyridyl ligands. Compound **20a** phosphoresces at 730 nm with varying intensities when excited throughout the UV region. The excitation wavelengths that yield the highest emission intensity exist in a narrow window of the visible spectrum between 400 and 480 nm. Irradiation with light at these wavelengths has little effect on the photochromic reaction of **20** in either direction. Therefore, the molecule can be used as a memory medium with nondestructive readout capability (Figure 35.8).

Another example of a metal complex of a diarylethene is shown in Figure 35.9.[17] In this case, the closed ring isomer **21b** shows the stronger fluorescence compared to the open-ring isomer **21a**. The emission quantum yield of **21b** was 0.15 (λ of excitation; 240 nm), while that of **21a** was 0.03 (240 nm). Excitation of this compound at 240 nm scarcely affects the photochemical reactivity. Therefore, the system can also be used potentially for nondestructive readout of optical memory.

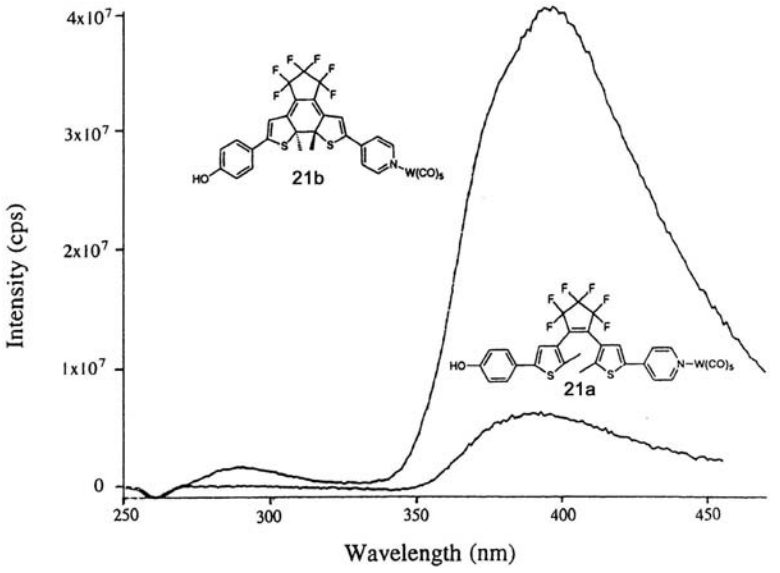

FIGURE 35.9 Fluorescence spectra of closed-ring isomer **21b** and open-ring isomer **21a** (excitation at 240 nm).

Another fluorescent diarylethene derivative is compound **22**, in which dithienylethene moieties are connected to fluorescent bis(phenylethynyl)anthracene. When the dithienylethene unit converted to the closed-ring isomer upon irradiation with 313 nm light, the fluorescence quantum yield decreased from 0.83 to 0.001.[18] The derivative exhibited a laser emission upon irradiation with 337.1 nm pulse laser, and the laser emission was controlled by the photochromic reaction of the dithienylethene units (Figure 35.10).

In diarylethenes with crown ether substituents, switching of the association with Ca^{2+} was observed.[19] The logarithm of the stability of the complex (log $K_{Ca}{}^{2+}$) of **23a** was 5.4 for Ca^{2+}, while that of **23b** was 1.7. These results indicate that the complexed cations can be released from **23a** by photocyclization. The open-ring isomer **23a** was fluorescent ($\Phi_f = 0.006$, $\lambda_{exe} = 390$ nm), while **23b** was nonfluorescent. The fluorescence intensity change suggests that photocyclization and binding-switch processes can be followed by fluorescence without perturbing the equilibrium (Figure 35.11).

35.4 IR Spectral Changes

Infrared (IR) spectral changes accompanied by photochromic reactions are useful for the nondestructive readout of the reactions. Zerbi et al. have demonstrated that the closed form **15b** shows the strongest band at 1495 cm^{-1} with an intensity of ~30,000 cm/mol. It turns out that this signal is highly selective for the closed-ring form as shown in Figure 35.12.[20]

35.5 Chiroptical Changes

Optical rotation changes accompanied by the photochromic reaction are a promising alternative for nondestructive readout. To enhance the readout signal intensity, two conditions must be satisfied:

1. The photochromic compounds should exhibit significantly contrasting optical rotating strengths between the two states.
2. The photochromic reactions should maximize the formation of only one stereoisomer.

Branda et al. reported self-assemblies of double-stranded copper (I) helicates with chiral ligands **24** and **25**.[21] When the chiral oxazoline auxiliaries on the periphery of the individual strands are brought into close proximity, chiral discrimination takes place. This orients the thiophene rings in a prochiral

conformation with respect to each other so that photocyclization yields a single diastereomer. The dramatic changes in optical rotation that accompany the stereoselective photochromic process can be used for nondestructive readout.

35.6 Control of the Liquid Crystalline Phases

The control of the structure and optical properties of liquid-crystalline (LC) phases by means of light is a major challenge in the development of molecular devices and optical data storage systems. Denekamp and Feringa[22] were first to report the induction of chirality by doping a diarylethene in nematic liquid crystals and effective photomodulation of LC phases. Doping of nematic LC materials ZLI-389 and K15 with (*S,S*)-**26a** resulted in stable cholesteric phases. When a mixture of **26a** in ZLI-389 was heated under a microscope slide and kept within the range of 51–54°C, the cholesteric phase was stable for many hours. When the mixture was irradiated with 300 nm light for 50 sec, the chiral nematic phase disappeared and

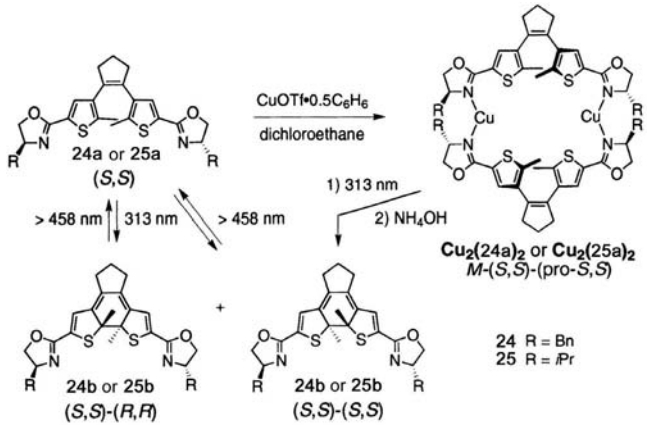

FIGURE 35.13 Formation of closed-ring products **24b** or **25b** from photochromes **24a** or **25a** and their complexes with copper.

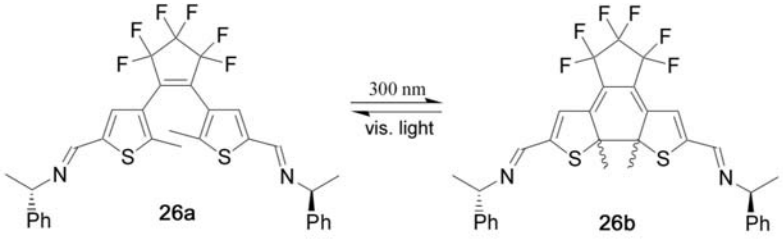
TABLE 35.1 Conversions and Diastereoselectivities in the Photochromic Processes[a]

Entry	Photochrome	Concentration [M]	Conversion [%][b]	de [%]
1	(*S,S*)-**24a** + Cu(l)	0.001	95	98
2		0.0001	94	86
3	(*R,R*)-**24a** + Cu(l)	0.0001	92	89

[a] In a typical reaction, the ligand and CuOTf · 0.5 C_6H_6 were mixed in deoxygenated dichloroethane and exposed to 313-nm light for 20 minutes. After washing with excess NH_4OH to remove the metal, the conversions and *de* values of the products were measured by ^1H NMR spectroscopy in CD_2Cl_2.

[b] Based on the disappearance of the open isomers.



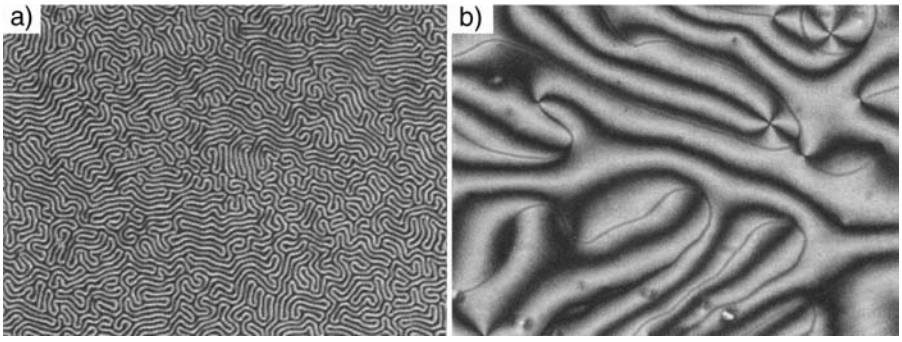


FIGURE 35.14 The texture of the nematic and twisted nematic liquid-crystalline phase; 1.4 wt.% of **26a** in ZLI-389 at 52°C. a)Cholesteric texture; b) nematic texture.

TABLE 35.2 Pitch Values, HTP, and Handedness of the Cholesteric Phases Formed by Doping Compound **26a** in K_{15} and ZLI-389, as Determined by the Cano-Grandjean Method

LC	wt.-% of **26**	Pitch [mm]	$\beta_m[\mu m^{-1}]$	Screw sense	Phase transition
ZLI-389	2.1	8.5	13	Negative[a]	N* 54 I
K_{15}	2.1	12	11	Negative	N* 33 I

[a] Doping with the cnantiomer of **26a** results in an opposite handedness.

changed to a nematic phase texture. Irradiation of the sample with visible light for 30 sec resulted in the reappearance of the cholesteric fingerprint texture (Figure 35.14).

Light-induced LC phase changes were also observed for a bisbenzothienylethene derivative with cholesterol units and a chiral binaphthyl derivative with two diarylethene moieties.[23,24]
