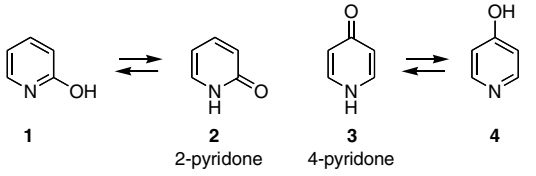
Photochemical Reactivity of Pyridones

Scott McN. Sieburth
Temple University

103.1 Introduction

Pyridone photochemistry has been extensively studied because of the important and interesting β-lactam and cyclooctadiene products (see Scheme 2), the dominance of a short-lived singlet excited state in most of the photochemistry, interesting substituent effects, and an absence of solvent effects. A number of reviews have included aspects of pyridone photochemistry[1–6] but no comprehensive discussion has been published. The breadth of 2-pyridone photoreactivity stands in contrast to its thermal stability, reluctant partners in Diels-Alder reactions, for example.[3,7] The 4-pyridones have provided less useful photochemical reactivity and, consequently, have been the subject of fewer studies.

Pyridones take two constitutional forms: 2-pyridones and 4-pyridones, **2** and **3** (Scheme 1). These two parent structures have tautomers, the corresponding hydroxypyridines **1** and **4**. These solvent-sensitive equilibria strongly favor the pyridone form.[8–10] Photochemically induced tautomerism has also been extensively studied.[11,12]



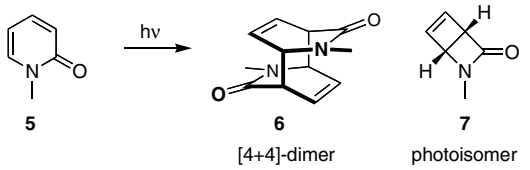
SCHEME 1 The two pyridone structures and their tautomers

103.2 2-Pyridone Photochemistry

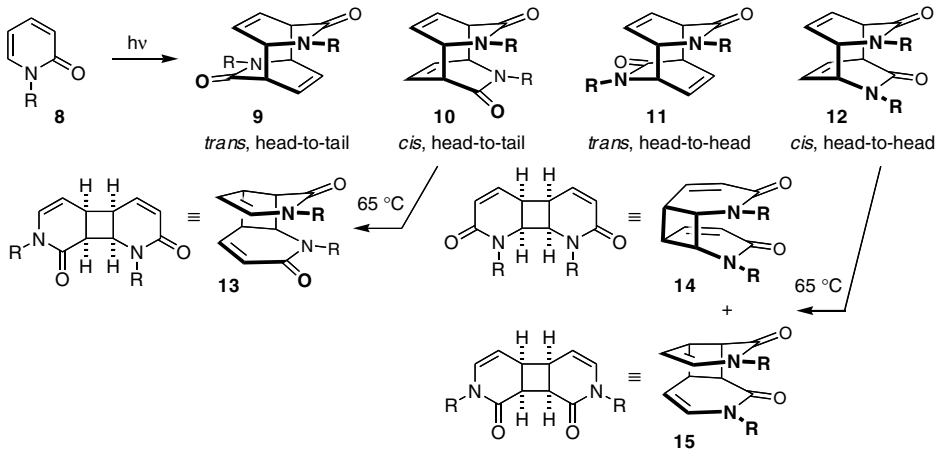
Overview

First described in 1960,[13] the most accessible photoproduct of 1-methyl-2-pyridone **5** is a dimer, with a *trans*-head-to-tail structure **6** (Scheme 2). Photoisomerization of 2-pyridone to give the 2-aza-bicyclo[2.2.0]hex-5-en-3-one **7** competes with dimerization. Both of these products are derived from a short-lived (ca. 0.2 ns) singlet excited state[14] generated by irradiation above 300 nm, typically using a Pyrex

0-8493-1348-1/04/$0.00+$1.50



SCHEME 2 Irradiation of 1-methyl-2-pyridone yields both dimer and isomerization products



SCHEME 3 Photodimerization can lead to four [4+4]-dimers but the head-to-head products are rare. *Cis*-isomers undergo a facile Cope rearrangement.[16]

filter. High-, medium-, and low-pressure mercury lamps have been employed, as well as a 300-nm fluorescent lamp setups such as the Rayonet photoreactor.[15] In general, triplet sensitization leads to other photoproducts (Schemes 8, 11, and 13). The competition between isomerization to give **7** and dimerization to give **6**, from the same transient intermediate, results in a concentration-dependent reaction. Studies in several laboratories have found that the dimerization dominates at concentrations above 0.1 *M* and isomerization is the major product at or below 0.01 *M*.[16] The quantum yield for the formation of **7** has been determined to be 0.6%.[14,17,18] It has been noted that [2+2]- and [4+2]-products are not formed during 2-pyridone photodimerizations.[16] Nevertheless, [2+2]-products can be produced with excellent regioselectivity by the proper choice of co-reactant and reaction conditions (Schemes 11, 12, and 13).

Both dimerization and isomerization reactions are essentially solvent insensitive, proceeding at similar rates and giving similar product ratios when run in water,[16] alcohols,[16] acetonitrile,[18] ethers,[18] or benzene[16] (see Figure 103.3). Moreover, a marked insensitivity of the photoreaction to oxygen has been noted.[17,19]

Photodimerization

Regio- and Stereochemistry

While the major reaction product is generally the *trans* head-to-tail dimer **6** (**9**, Scheme 3) and this can often be purified directly by crystallization, it was noted by several authors that additional dimeric structures were also formed.[14,19] Careful analysis of the mixture by Nakamura and co-workers led to the identification of all three of the other *cis/trans* and head-to-head [4+4]-isomers (**10**, **11**, and **12**).[16]

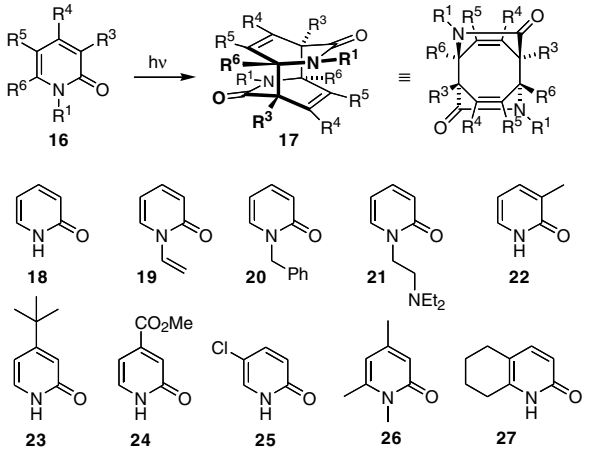


FIGURE 103.1 Examples of 2-pyridones that undergo [4+4]-photodimerization.

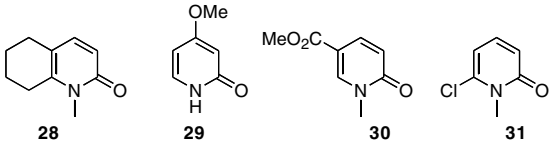

FIGURE 103.2 Examples of 2-pyridones that do not undergo [4+4]-photodimerization.

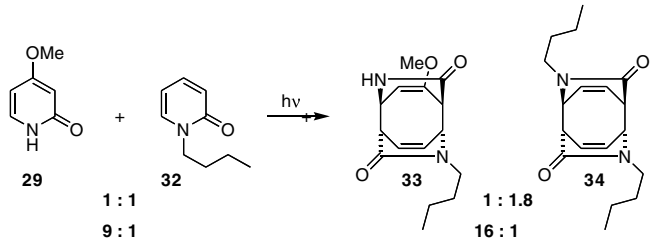
Nakamura also demonstrated a very simple method for differentiating the *cis*-isomers **10** and **12** from the *trans*-isomers **9** and **11**. Heating the dimers to 65°C results in a very facile [3,3]-rearrangement of the *cis*-1,5-cyclooctadienes to cyclobutanes. The C_2 symmetric **10** can form only one product **13**, whereas the *meso*-**12** leads to nearly equal quantities of two different Cope products **14** and **15**. *trans*-Isomers **9** and **11** are stable under these conditions.

Substituent Effects

The photodimerization reaction is highly tolerant of substitution (Figure 103.1). The dimer of the parent 2-pyridone **18** has been reported several times,[19–21] in isolated yields of up to 54%.[19] This *trans*-head-to-tail dimer is highly crystalline, precipitating during the photoreaction. An alkyl group on nitrogen, R^1 removes intermolecular hydrogen bonding and greatly enhances the solubility of the photodimer. Methyl substitution is tolerated at every ring position (e.g., **22** and **26**),[20,21] and even a 4-*t*-butyl group (**23**) does not prevent [4+4]-dimerization (35%[17]). Chlorine substitutions at R,[3] R^4, and R^5 (**25**) are individually compatible with [4+4]-photodimerization.[19] Photodimers from 2-pyridones with alkene substitution on nitrogen (**19**) have been reported,[18] and the presence of a proximal amino group (**21**) does not hinder dimer formation.[20] Multiple substitution is possible but steric limitations undoubtedly exist. Tetrahydroquinolone **27** readily yields a highly insoluble photodimer,[22,23] but the corresponding *N*-methyl congener **28** (Figure 103.2) does not photodimerize.[23,24]

Other notable incompatibilities with the [4+4]-dimerization reaction are 2-pyridones with 4-alkoxy (**29**),[25] 5-carboalkoxy (**30**),[26] and 6-chloro groups (**31**).[27] These incompatibilities are caused by alternative photochemical reaction paths (see Figure 103.6 and Scheme 14), although 4-alkoxy-2-pyridone **29** will undergo [4+4]-photocycloadditions with other pyridones (Scheme 4).[28,29]



SCHEME 4 Cross-[4+4]-cycloaddition of 4-methoxy-2-pyridone **29**[28,29]

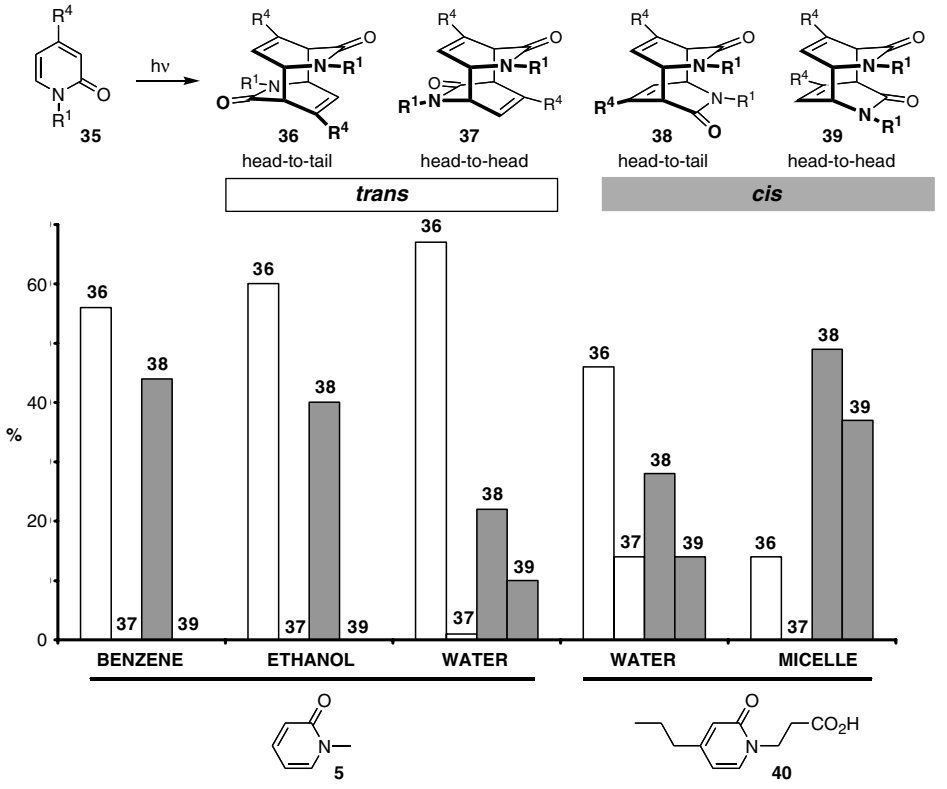


FIGURE 103.3 Solvent effects on the ratio of dimerization products **36**, **37**, **38**, and **39.**[30–32]

Alkoxy substitution at C4 leads to photoisomerization by eliminating the dimerization reaction (see Figure 103.6). It does not, however, prevent cross-[4+4]-cycloaddition with other pyridones (Scheme 4).[28,29] An equimolar mixture of **29** with 1-butyl-2-pyridone **32** led to a mixture of the cross product **33** and the known dimer **34**. Dimerization of **32** dominates, possibly because the UV light is largely absorbed by **32**. Systematic increases in the relative amount of **29** led to an increase in the amount of the cross product **33**. The excess **29** is recovered unchanged.

Solvent and Medium Effects

Solvent has little effect on pyridone dimerization, Figure 103.3. For 1-methyl-2-pyridone **5**, benzene and ethanol as solvent yield a nearly identical mixture of *trans*- and *cis*-head-to-tail isomers **36** and **38**, favoring the former. Only in water are head-to-head isomers **37** and **39** formed, favoring the *cis*-**39**. A similar result in water (and in alcohol) is observed for the 4-propyl-2-(2-pyridonyl) propionic acid **40**. Alignment of pyridone **40** in micelles can be used to give a high proportion of the *cis*-isomers **38** and **39**.[30–32]

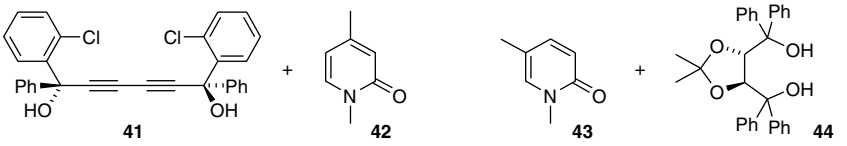

FIGURE 103.4 Pyridones crystallized with hosts **41** and **44** undergo *trans* head-to-tail photodimerization.[33]

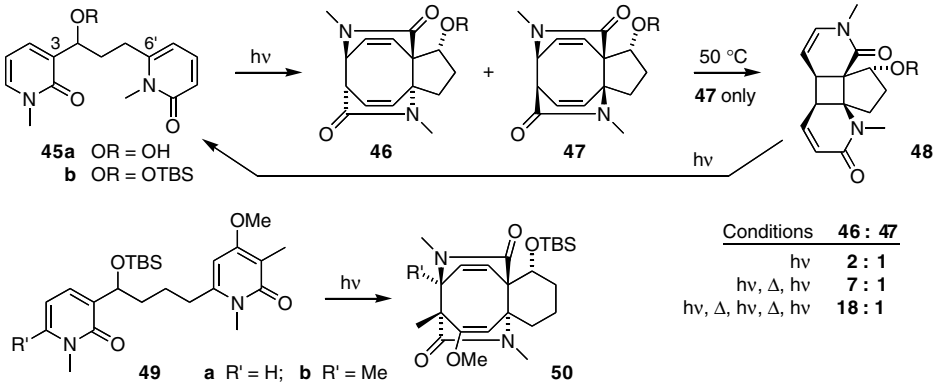


SCHEME 5 Intramolecular 2-pyridone cycloadditions.[35–37]

Photodimerization of 2-pyridones in the solid state has only been reported for pyridones co-crystallized with a chiral host, the 1:2 mixture of **41**/**42** and the 1:1 mixture of **43**/**44** (Figure 103.4). The resulting *trans*-head-to-tail dimers are formed in high yield but are centrosymmetric and achiral.[33]

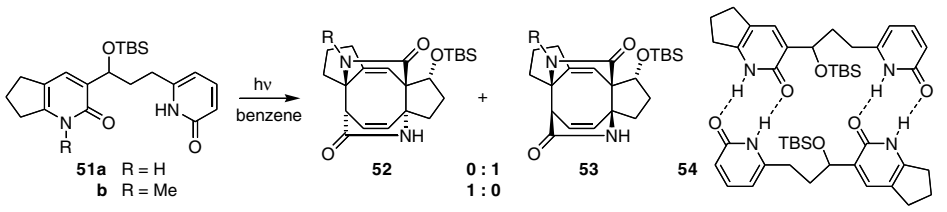
Intramolecular [4+4]-Cycloaddition

Intramolecular [4+4]-photocycloaddition of 2-pyridones is accommodated with appropriate tether length and points of attachment (Scheme 5). When the tether is linked at the 3- and 6′- positions (**45** and **49**), it reinforces the preferred head-to-tail cycloaddition. With a three-atom chain, the cycloaddition of **45** yields a 2:1 mixture of *trans*- and *cis*-isomers, similar to the intermolecular reaction.[34] A tether alcohol **45a** has little effect on the formation of stereogenic centers during the cycloaddition and yields two diastereomers for both **46** and **47**, epimeric at the alcohol carbon. Protection of the alcohol as the sterically demanding *t*-butyldimethylsilyl (TBS) ether (**45b**) leads to only **46** and **47**.

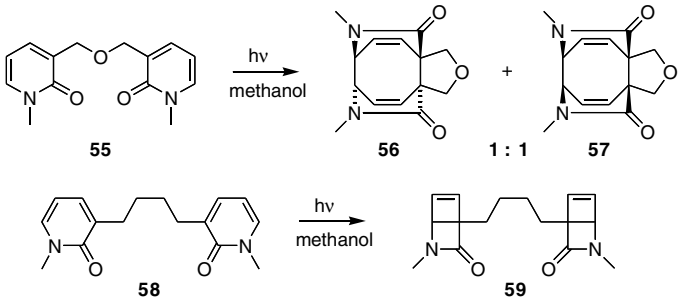
A highly *trans*-selective cycloaddition of **45** can be achieved utilizing the thermal instability of the *cis*-isomer (see Scheme 3). Heating the 2:1 mixture of **46** and **47** to 50°C results in Cope rearrangement of *cis*-**47** but does not alter **46**. This rearrangement of **47** generates an α,β-unsaturated carbonyl moiety. Irradiation of the resulting mixture cleaves **48**, regenerating **45,** and leads to a **46**:**47** mixture of 7:1. Another cycle of heat and light converts this mixture to an 18:1 ratio while maintaining a good isolated yield.[35]

A four-carbon tether (**49a**) yields only the *trans*-isomer. This is likely due to a high level of strain in the polycyclic product **50a**. The crystal structure of a dihydro derivative of **50a** found the tether-derived cyclohexane to be in a boat conformation, a substantial contribution to the strain of this adduct.[36] An analog carrying an additional methyl group at a carbon involved in bond formation, **49b**, does not undergo cycloaddition.[37]

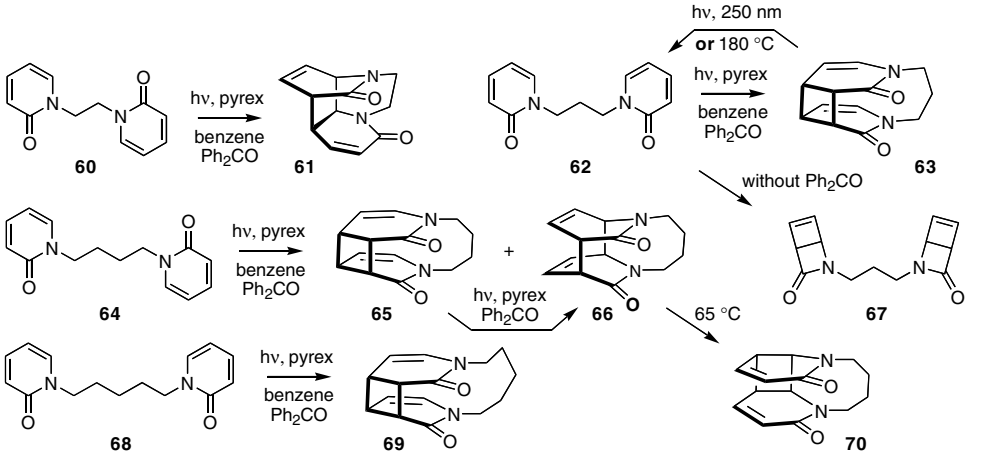
Highly selective formation of *cis*-cycloadduct **53** from three-carbon tethered pyridones can be achieved through intermolecular hydrogen bonding. Compound **51a**, lacking nitrogen substitution, yields exclusively the *cis*-**53a** when the photochemistry is conducted in benzene or toluene, but only the *trans*-isomer **52a** when the reaction is run in DMSO or methanol.[38] Solvent and concentration studies were consistent



SCHEME 6 *cis*-Selective cycloaddition with hydrogen-bonded pyridones.[38–40]



SCHEME 7 Tether-directed head-to-head photocycloaddition.[41–43]

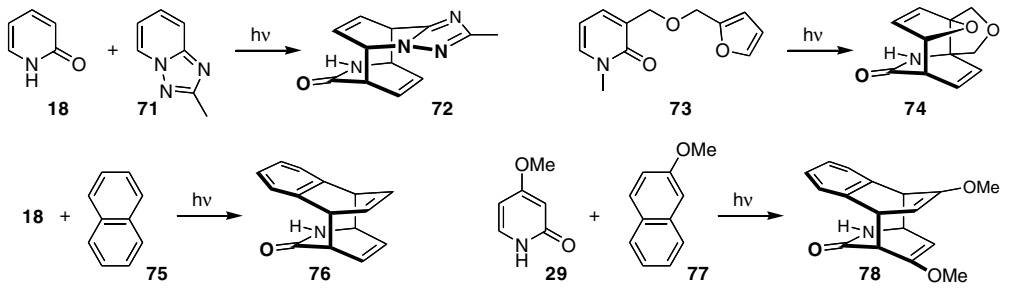


SCHEME 8 *N,N*-Tethered pyridones and triplet sensitized cycloadditions.[44]

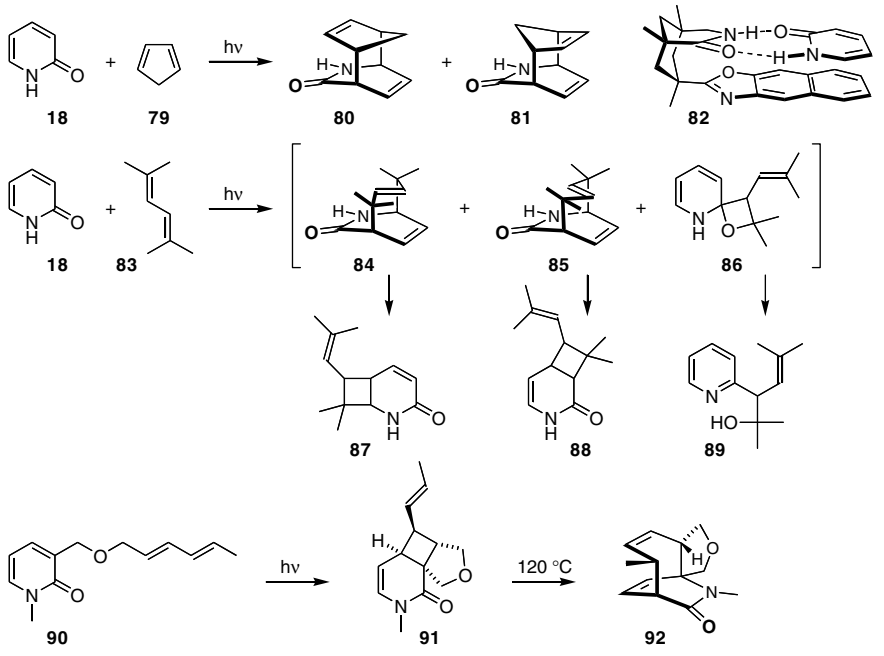
with involvement of a hydrogen bonded dimer **54**, aligning both molecules for *cis*-cycloaddition.[38,39] In keeping with this analysis, a single methyl substitution **51b** provides only the *trans*-isomer **52b**, regardless of the reaction solvent.[38,40]

Tethering of 2-pyridones can enforce the non-preferred head-to-head regiochemistry. For a three-atom tether, this cycloaddition is highly efficient but without stereoselectivity, for both the head-to-head tethered **55**[41] (Scheme 7) and the tail-to-tail tethered isomer.[42] The four-carbon tethered **58**, however, only undergoes isomerization.[43]

Tethering the pyridones at nitrogen has been explored with tether lengths of two through five carbons (Scheme 8).[44] Only the longest lengths are compatible with the [4+4]-cycloadduct and other products dominate. Benzophenone sensitization is utilized for most of these reactions. The two-carbon tethered



SCHEME 9 Photocycloadditions of 2-pyridones with other aromatics.[45–47]



SCHEME 10 Cycloaddition of 2-pyridones with *s-cis* and *s-trans* 1,3-dienes.[48–52]

structure **60** leads to the [4+2]-adduct **61**. Three carbons (**62**) give the [2+2]-adduct **63** involving only the C3,C4 alkenes. Without triplet sensitization, the Dewar pyridones **67** are formed from **62**. Adduct **63** reverts to starting pyridones **62** at 180°C or when irradiated with 250-nm light. The same type of [2+2]-adduct (**65**) is also formed from the four-carbon tethered pyridones **64**, accompanied by the *cis* head-to-head [4+4]-adduct **66**. Irradiation of the [2+2]-adduct **65** converts it to **66**. Heating the [4+4]-adduct **66** to 65°C leads to a Cope rearrangement and the new cyclobutane **70**. The [2+2]-adduct **69** is formed when the tether length is five atoms.

Other [4+4]-Cycloadditions

Pyridones and Other Aromatics

In addition to dimerizations, 2-pyridones undergo [4+4]-photocycloadditions with other aromatics and with 1,3-dienes (Schemes 9 and 10). Triazolopyridine **71** will photodimerize,[45] but when mixed with pyridone **18** yields significant amounts of cross product **72**.[46] Intermolecular reactions of pyridones with

furans has not been reported but intramolecular cycloaddition of **73** yields the *trans* [4+4]-cycloadduct **74** as well as the *cis*-isomer (10:3).[47] Naphthalene **75** and pyridone **18** yield the *cis*-adduct **76**, whereas the three-atom tethered intramolecular reaction gives a mixture of *cis*- and *trans*-isomers.[47] A mixture of 4-methoxy-2-pyridone **29** and 2-methoxynaphthalene **77** gives a single product **78**.[47]

Pyridones and 1,3-Dienes

2-Pyridones and 1,3-dienes also undergo [4+4]-cycloadditions. For *s-cis*-1,3-dienes like cyclopentadiene **79**, *trans*- and *cis*-adducts **80** and **81** are formed in good yield.[48,49] The hydrogen bonded complex of the pyridone to the enantiomerically pure scaffold **82** leads to enantiomerically enriched [4+4]-adducts with cyclopentadiene, in up to 87% *ee*.[50]

When the 1,3-dienes are largely or exclusively in the *s-trans*-conformation, such as with diene **83**, pyridone **18** leads to three products, **87**, **88**, and **89**.[48,49] The two cyclobutane products **87** and **88** derive from Cope rearrangement of the highly strained [4+4]-photocycloaddition adducts **84** and **85**, a mechanism precedented by photocycloadditions of 1,3-dienes with other aromatic species.[51] Pyridine **89** may be formed from oxetane **86**. When the 1,3-diene is delivered intramolecularly (**90**), the only photoproduct is **91**, presumably via an intermediate relating to **85**. In contrast with the chemistry of the *cis*-pyridone dimers (Scheme 3), cyclobutane **91** thermally rearranges to the cyclooctadiene **92**.[52]

Isomerization

Substituent Effects

When 2-pyridones are irradiated in dilute solution, generally below 0.01 *M*, they isomerize to 2-azabicyclo[2.2.0]hex-5-en-3-ones **93** in high chemical yields but low quantum yields.[14] A wide variety of substituents are compatible with this isomerization. The unsubstituted **18** and 1-alkenyl **94** have been isomerized (46%[25,53] and 60%[18] yields, respectively). Isomerization is reasonably efficient with pentamethyl **95** (45%) and tetrachloro **96** (70%). Electron-donating groups at C3 do not inhibit isomerization (**97**, 36%[25]; **98**, 62%[54]). For pyridones with chiral C3 and C5 substituents, isomerization yields diastereomeric mixtures from **99** (100%, 2:1[55]), **100** (59%[56]), and **101** (93%, 2.5:1[56]).

Two substitutions of 2-pyridones have been identified as preventing [4+4]-dimerization but compatible with isomerization, the 5-carboalkoxy group (**30**[26]) and the 4-alkoxy group (**102** and **103**) (Figure 103.6). The effect of the 4-alkoxy group was first observed with ricinine **102**, a naturally occurring toxin.[25] A broad set of 4-oxygen substitutions have been utilized, **103**.[53,55,57–60]

Enantioselective Isomerizations

The enantioselective preparation of pyridone photoisomers has been described by several laboratories, motivated in part by the importance of β-lactams as antibiotics. Lipase hydrolysis of racemic **104** and similar Dewar pyridones has led to resolutions with high enantiomeric purities.[53,60] Isomerization of pyridones when complexed to the chiral scaffold **106** gave the isomerized product with good to excellent levels of enantioselectivity.[50]

Two different approaches to control of the photoisomerization in the solid state have also been very successful. Complexes of 2-pyridones with a chiral host, such as the 1:1 complex of **41** and **107**, gave high *ee* levels even at significant conversion.[33] Pyridones with a 4-benzyloxy group, **108**, were found to crystallize in a chiral space group. Irradiation of these crystals gave excellent levels of asymmetric induction, but only at rather low levels of conversion.[61] This solid-state reaction has been analyzed computationally[62] (see Figure 103.7).

[2+2]-Cycloadditions

Intermolecular [2+2]-Cycloadditions

Irradiation of 2-pyridone in the presence of electron-poor alkenes leads to products of [2+2]-cycloaddition, both from direct and triplet-sensitized conditions (Scheme 11). Unsensitized irradiation of acrylonitrile

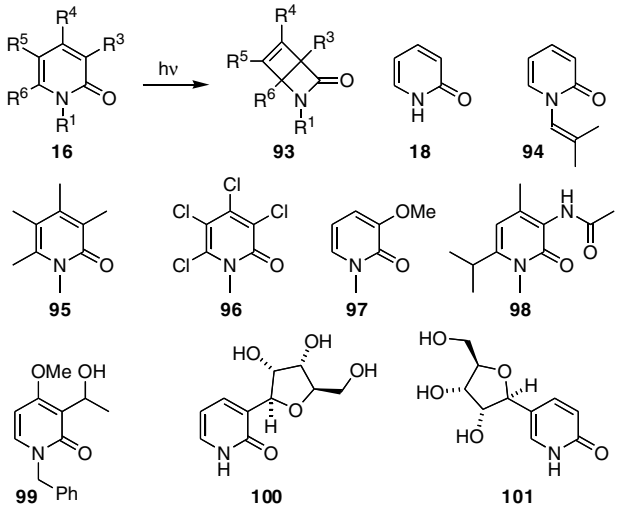


FIGURE 103.5 Examples of 2-pyridones that undergo photoisomerization to 2-aza-bicyclo[2.2.0]hex-5-en-3-ones **93**.

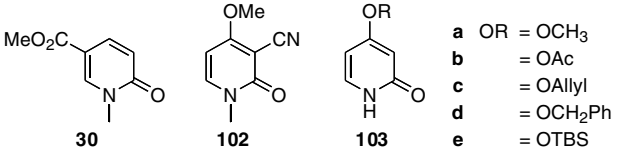

FIGURE 103.6 Pyridones that yield Dewar pyridones but do not dimerize.

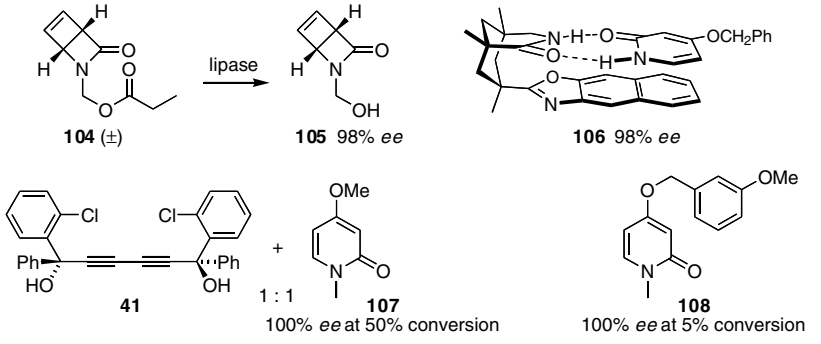

FIGURE 103.7 Preparation of enantiomerically pure Dewar pyridones has been accomplished by resolution (**105**),[53,60] use of a chiral host (**106**),[50] in the solid state by co-crystallization (**41** + **107**)[33] and with asymmetric crystals (**108**).[61]

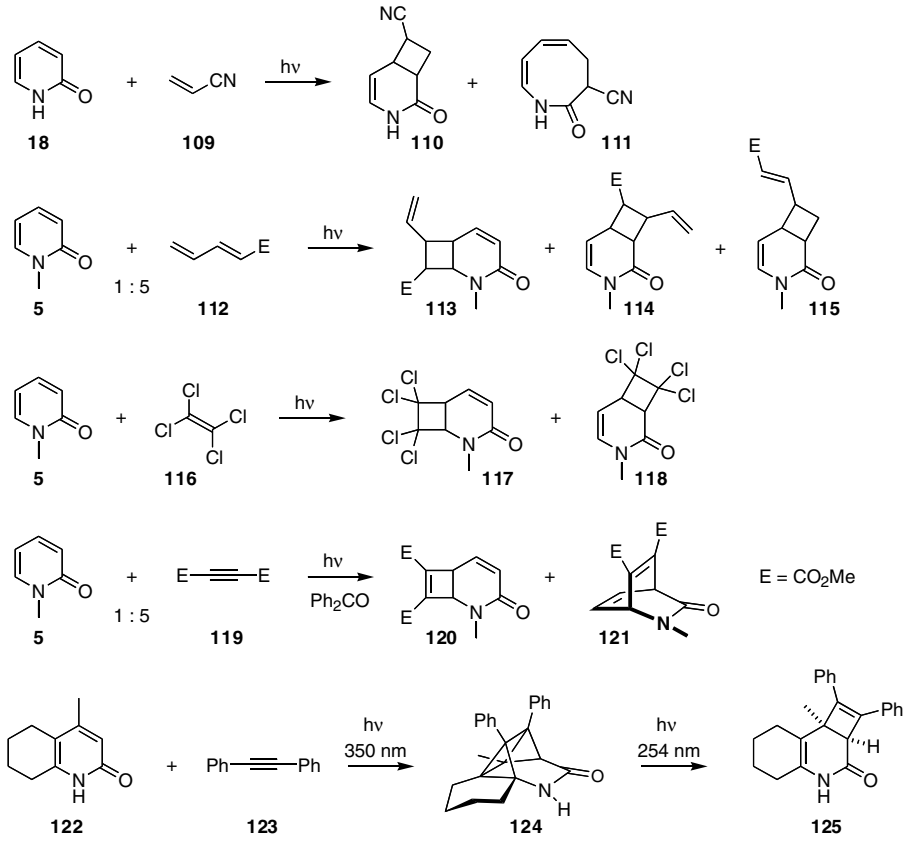
109 with 2-pyridone **18** leads to two products, cyclobutane **110** (41%) and the eight-membered lactam **111** (4%).[63] Substituting pentadienyl ester **112** yields a mixture of products **113**, **114**, and **115** with good regioselectivity, but derived from reaction at both alkenes of the ester and both alkenes of the pyridone.[64] Yields of up to 54% for isomers **113** have been realized. Di-, tri-, and tetrachloroethene **114** undergo [2+2]-cycloaddition with pyridone when the reactions are sensitized with benzophenone or xanthone,



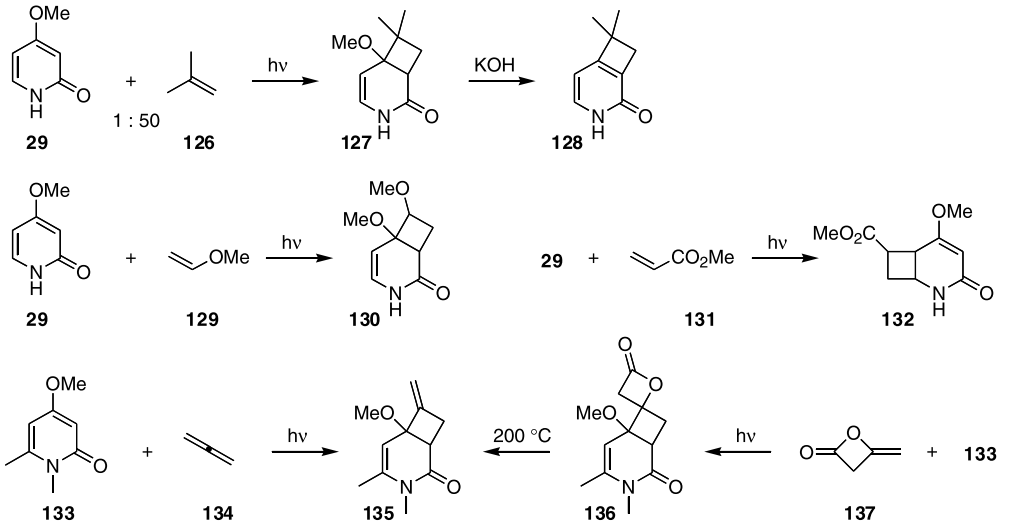
SCHEME 11 Cycloaddition reactions of 2-pyridone with alkenes and alkynes.[63–67]

giving product mixtures derived from reaction at both alkenes of the pyridone. Tetrachloroethene **116** and 1,1-dichloroethene both undergo cycloaddition without sensitization, but trichloroethene does not.[65] Intermolecular addition of dimethyl acetylenedicarboxylate **119** occurs with a triplet sensitizer, yielding a cyclobutene adjacent to the nitrogen, **120** and the [4+2]-adduct **121**, both in modest yield.[66] Combination of tetrahydroquinolones such as **122** with diphenylacetylene **123**, without triplet sensitization, yields the pentacyclic **124**.[23,24,67] Irradiation of **124** at shorter wavelengths leads to the cyclobutene adduct **125**.

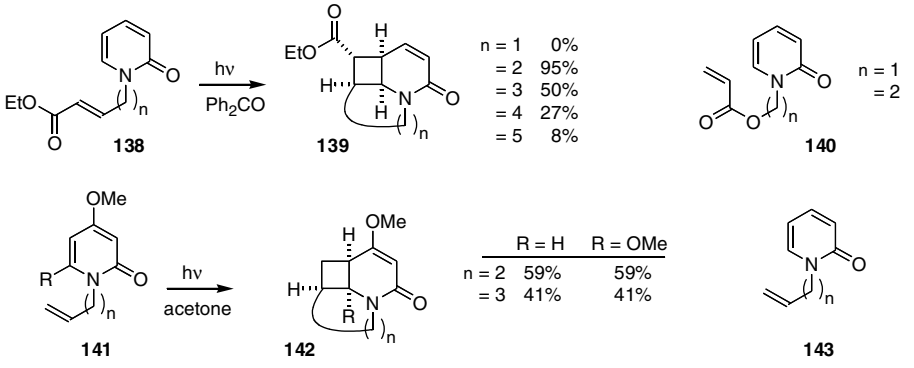
Pyridones with 4-alkoxy substitution do not dimerize, but they do photoisomerise (Figure 103.6) and they will undergo [2+2]-cycloaddition with a variety of alkenes, (Scheme 12).[68–72] Most alkenes react at the C3–C4 double bond of the pyridone, with the more substituted end of the alkene attached to C4 of the pyridone, **127** and **130**. Many of these products have been shown to eliminate methanol on treatment with base, regenerating the pyridone ring unsaturation (e.g., **128**). When the alkene has an electron-withdrawing group such as ester **131**, the major (but not exclusive) site of reaction is the C5–C6 bond, to give **132**. Allene **134** reacts in the standard way to give **135**,[71] but a more efficient route to **135** using diketene **137** has been reported.[72]

Intramolecular [2+2]-Cycloadditions

Alkenes have been tethered to pyridones at nitrogen (Scheme 13),[73] and at C3[74] and C4.[75] Triplet-sensitized reaction of unsaturated esters **138** leads to [2+2]-cycloaddition at the nearby pyridone double bond, for tether lengths of two to five carbons. When the ester attachment is reversed, **140**, no cycloaddition is observed. Alkoxy-substituted pyridones react with simple alkenes (compare with Scheme 12) tethered at



SCHEME 12 Cycloaddition of 4-alkoxy-2-pyridones with alkenes.[68–72]



SCHEME 13 Intramolecular [2+2]-cycloadditions of 2-pyridones.[73–75]

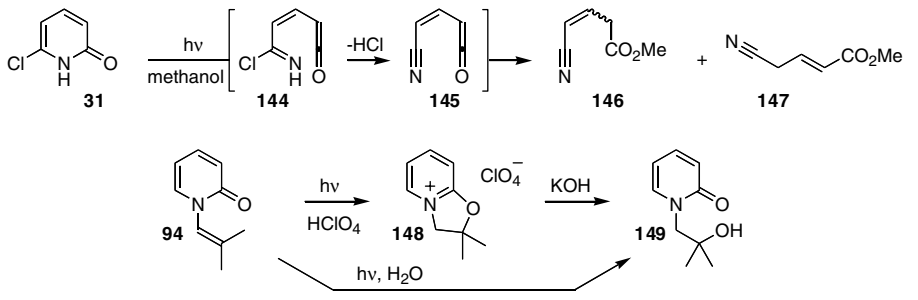
nitrogen, **141**.[73] Both 4-methoxy and 4,6-dimethoxy substitution are acceptable. Similar pyridones **143** lacking the alkoxy groups do not undergo cycloaddition.[73]

Other Reactions

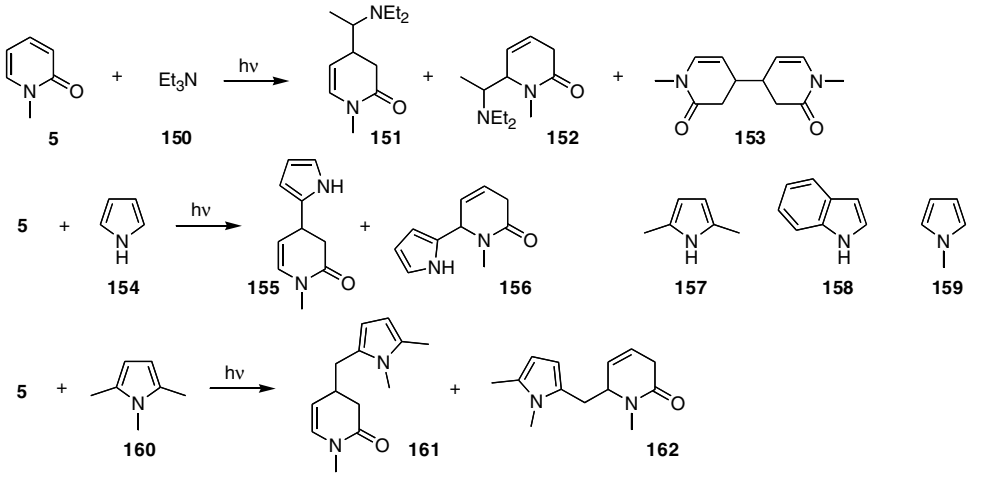
Substituent Effects

When 2-pyridone carries a chlorine or a bromine at C6 (**31**), irradiation leads to electrocyclic ring opening to give **144** (Scheme 14). The observed products are consistent with elimination of HCl and addition of methanol to a ketene. Both (*E*)-and (*Z*)-**146** as well as (*E*)-**147** are isolated.[27]

Pyridones carrying an *N*-alkenyl substituent such as **94** photodimerize (Figure 103.1) and photoisomerize (Figure 103.5),[18] but in water the alkene undergoes hydration to give **149**.[18,76] Performance of this reaction in the presence of perchloric acid leads to an isolable intermediate **148**. When the alkene is a styrene, (*E*),(*Z*)-isomerization and stilbene-like cyclization reactions are also observed.[77,78]



SCHEME 14 Photoisomerization of 6-chloro-2-pyridone[27] and photohydration of *N*-alkenyl pyridones.[18,76]



SCHEME 15 Photoreaction of 2-pyridone with aliphatic and heterocyclic amines.[79–81]

Pyridones with Aliphatic and Aromatic Amines

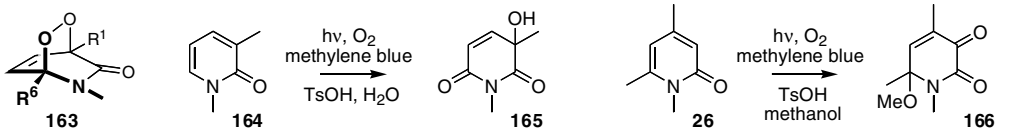
Photoreaction of 2-pyridone with aliphatic and aromatic amines leads to addition of the amines at C4 and C6 to give mixtures of dihydropyridone products (Scheme 15). All of these reactions appear to derive from a single electron transfer process. Tertiary aliphatic amines such as triethylamine **150** yield pyridones **151** and **152** (2:1) plus the reductively coupled pyridone dimer **153**.[79] Pyrrole **154** leads to a similar mixture of 4- and 6-substituted dihydropyridones **155** and **156** (1:1).[80] Dimethylpyrrole **157** and indole **158** lead to analogous products of 4- and 6-substition of the pyridone (at C3 of the pyrrole **157**). *N*-Methyl pyrrole **159**, however, does not yield photoproducts. When the *N*-methyl pyrrole is alkyl substituted at C2 (**160**), addition to the pyridone yields **161** and **162** (1:1).[81]

Pyridones with Singlet Oxygen

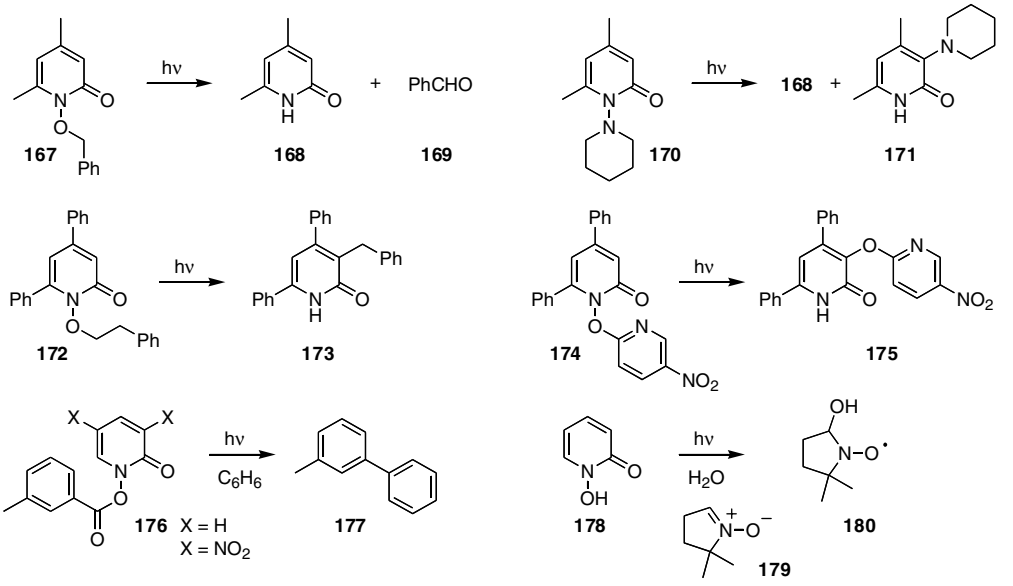
The addition of singlet oxygen to 2-pyridones leads to oxygenated products derived from intermediates **163** (Scheme 16). All reported examples carry alkyl substitution of the pyridone at C3 (**164**) or C6 (**26**). Acidic hydrolysis (methanolysis) of these intermediates yield dicarbonyl products **165** and **166**.[82]

N-Heteroatom Pyridones

When the pyridone carries an *N*-heteroatom group, homolytic cleavage occurs.[83,84] Irradiation of benzyloxy pyridone **167** leads to quantitative formation of **168** and benzaldehyde. The *N*-piperidinyl **170**



SCHEME 16 Singlet oxygen addition to 2-pyridones.[82]



SCHEME 17 Homolytic photocleavage of *n*-alkoxy-2-pyridones.[83–91]

also yields **168**, plus 3-piperidiyl pyridone **171**.[83] A broad survey of this reaction, employing 4,6-diphenylpyridones such as **172** and **174** found similar products.[85,86] A singlet excited state is the source of the N–O bond cleavage.[87] With benzene as solvent, the cleavage can be used to generate and trap aryl radicals, leading to biphenyl synthesis from **176** in good to moderate yields. The dinitropyridone gave somewhat higher yields.[88] Irradiation of *N*-hydroxy pyridone **178** generates hydroxyl radical cleanly and with solvent dependent quantum yields of 0.25 to 0.6.[89] The hydroxyl radical can be trapped with the spin trap **179** and has been shown to damage DNA.[90,91]

103.3 4-Pyridone Photochemistry

In contrast to 2-pyridones, 4-pyridones have little productive chemistry. Both **181a** and **181b** are reported to be unreactive.[92] Nicotinamide metabolite **182** has been found to interact photochemically with cellulose to yield a fluorescent product and in alcohol solution to give an aldehyde.[93,94] When two 4-pyridones are held in close proximity, **183**, a [2+2]-photocycloaddition occurs.[95] Product **184** is not photostable, with ambient light promoting photocleavage to return **183**.

The 4-pyridones can also isomerize to 2-pyridones. For the 1,2,6-trimethyl-3,5-diaryl-4-pyridones such as **185**, the isomerization to **186** and **187** occurs from the singlet excited state[96–98] (Scheme 18).

104

Reversible Photodimerization of Pyrimidine Bases

Yoshiaki Inaki
Osaka University

104.1 Photochemistry of DNA

UV irradiation of DNA is known to cause damage to the genetic information. DNA contains four nucleic acid bases where purine bases such as adenine and guanine are stable to UV light, but pyrimidine bases of thymine (uracil in RNA) and cytosine are unstable to UV light. Thymine bases in DNA undergo photodimerization via UVirradiation at 270 nm to form the photodimer. The photodimerization occurs at a thymidine sequence where the thymine bases stack with each other (Figure 104.1).[1–3] However, the photodimers in DNA are cleaved and regenerated by the action of an enzyme *in vivo*. There are four stereoisomeric dimers possible by linkage of two thymines to form a cyclobutane ring across the C5–C6 double bonds: *cis-syn*, *cis-anti*, *trans-syn*, and *trans-anti* (Figure 104.2).[4–7] The photodimerization in solution gives four kinds of isomers, but the photodimer from DNA is only the *cis-syn* isomer (Figure 104.1).

The reversible photoreaction was found to be controlled by the regulation of the UV wavelength. The thymine compound has a UV absorption with a high extinction coefficient at 270 nm. The absorbance

0-8493-1348-1/04/$0.00+$1.50

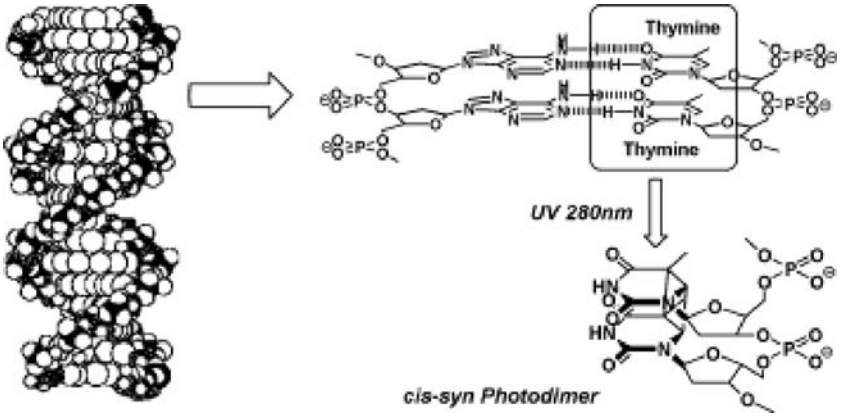

FIGURE 104.1 Photodimerization of thymine in DNA.

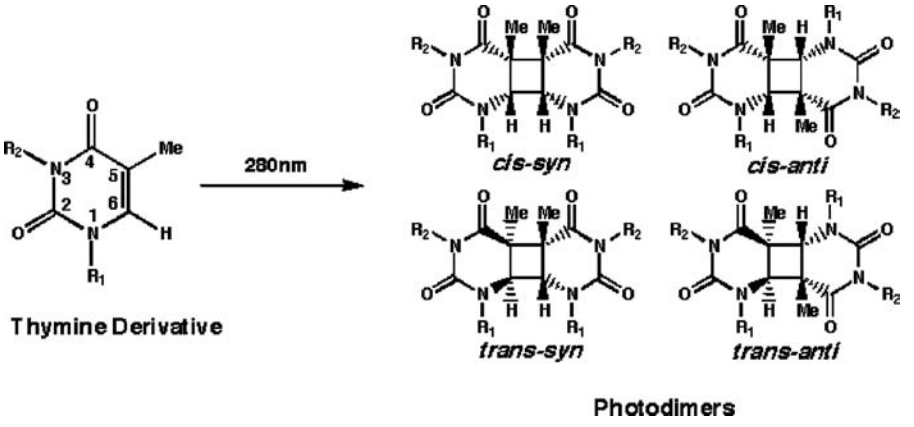

FIGURE 104.2 Isomers of thymine photodimers formed in solution.

of the thymine bases at 270 nm decreases on photodimerization, but increases again by the photosplitting of the photodimer on irradiation at short wavelength around 240 nm (Figure 104.3). Using white light, the photoreaction will be saturated below 100% conversion because the photodimerization is an equilibrium reaction and a photostationary state is achieved. If monochromatic UV light of 270 nm or UV light with wavelengths above 270 nm, using a cut-off filter, the photodimerization gives one photodimer. The driving force for the photosplitting reaction of the thymine photodimer is the steric repulsions of the methyl groups at C5 of the thymine. However, photosplitting is not observed for the photodimer of uracil, which has no methyl group at C5. The wavelength of 240 nm is the isosbestic point of the thymine and the thymine photodimer, and the quantum yield of the photosplitting reaction is very high (*ca.* 1). Therefore, UV irradiation at 240 nm of the photodimer causes complete photosplitting.

Thymine derivatives[8–11] are very resistant to UV irradiation in dilute solution because the triplet state is the precursor of the photodimer and intersystem crossing of thymine is very low.[12–18] The yield of the photodimer in solution is low, but a high yield of photodimer can be obtained with acetone as the sensitizer. In DNA polymers and solid state, however, the photodimerization reaction is fast and proceeds through the singlet state. The photodimerizations of thymine oligomers and polymers were studied in the presence of isoprene as a triplet quencher. The photodimerization of the thymine, monomeric and dimeric model, were quenched by isoprene, but the photodimerization of a polymer with thymine units was not quenched. This result appears to indicate that the photodimerization of aggregated thymine compounds occurs almost completely from the singlet state.[19–29]

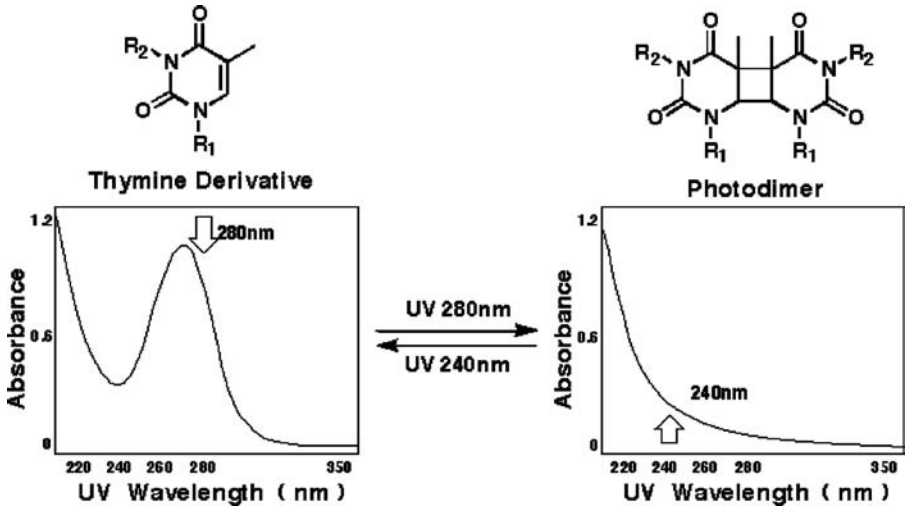

FIGURE 104.3 Reversible photodimerization and UV absorption of thymine derivatives.

The solubility of the thymine derivatives in alkaline solution or organic solvents can be changed by photodimerization or photodissociation. In addition, both the conversions of thymine units to the photodimer and the reverse photoreaction can be followed by monitoring the decrease and increase in absorbance at 270 nm, respectively. The reversible photodimerization of thymine derivatives therefore can be applied to negative or positive type photo-resist materials[30–47] and a photo-recording system by controlling the wavelength of UV light.[48–61] This system may satisfy the requirements for a high-resolution resist or for a high-density photorecording system due to the reversible photoreaction and monitoring in the far-UV. For applications of the thymine system, it is necessary to investigate the reactivity of thymine derivatives in thin solid films.

This chapter deals with the crystal structure and photodimerization reaction of thymine derivatives and the reversible photodimerization reactions in crystals and films.[48–61]

104.2 Photodimerization of 1-Alkylthymine in a Solid Film

Reversible Photodimerization

The photodimerization of thymine is reversible, depending on the wavelength of irradiating UV light. Polymer and monomer derivatives of thymine therefore can be used as reversible photosensitive materials such as reversible photo-resists and reversible photo-recording systems. For high sensitivity and completely reversible photoreactive materials, it is necessary to study the reversible photodimerizations and the conformation of the thymine derivatives in the solid film. There are troublesome problems for these studies. For the investigation of the photodimerization, the thymine compounds need to form a transparent film in an amorphous state. On the other hand, single crystals are necessary for the studies of conformation by x-ray structural analysis. For 1-*n*-alkylthymines and ester derivatives of thymine with long alkyl chains, transparent films and single crystals were obtained as discussed below.

Thymine compounds with long alkyl chains (Figure 104.4) gave the photodimer efficiently in a spin-coat film by irradiation at 280 nm. Figure 104.5 shows a typical repeatable reversible photodimerization of 1-*n*-hexadecylthymine (**C16**) in a solid film. The thin film was obtained by spin coating onto a quartz plate from chloroform solution, followed by drying overnight under reduced pressure. Irradiation with UV light was carried out by a spectro-irradiator (CRM-FA) at 280 nm for dimerization and 240 nm for splitting reactions. The energy irradiated was 8.0 (mJ/count) at 280 nm and 2.0 (mJ/count) at 240 nm. The photodimerization was followed by measuring the UV spectra at 270 nm. Photodimerization of

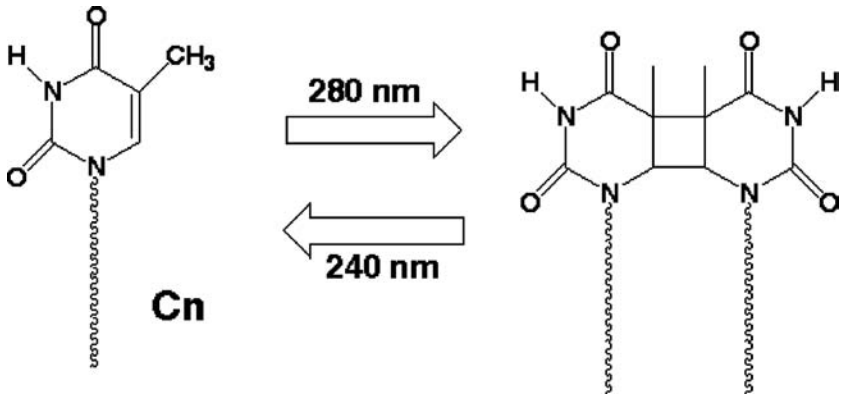

FIGURE 104.4 Reversible photodimerization of the 1-*n*-alkylthymine.

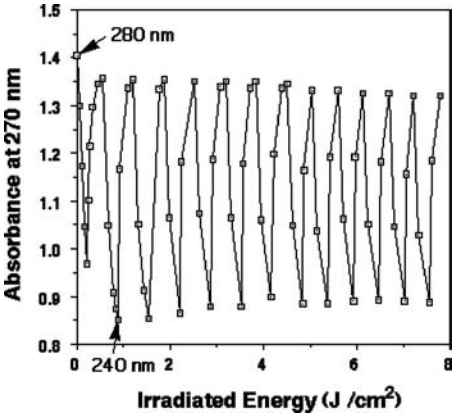

FIGURE 104.5 Typical repeated reversible photodimerization (1-*n*-hexadecylthymine in spin-coated film).

1-*n*-alkylthymine depends on the length of the alkyl chain. The results of the photodimerization are plotted in Figure 104.6. The reaction was fast at the beginning of the reaction but slowed in the later stages. In this case, the decyl (**C10**) compound had the fastest photodimerization reaction rate.

Annealing of the Thin Film

Annealing of the spin-coat film was found to affect the photodimerization of the 1-*n*-alkylthymine. Figure 104.7 is the result of photodimerisation of 1-*n*-tetradecylthymine (**C14**) in a thin film. Annealing for 1 min at 100°C below the melting temperature (123°C) caused an acceleration of the fast photodimerization reaction in the initial reaction stage, but the overall conversion decreased (Figure 104.7b). The photodimerization did not occur in the film after annealing for 4 min (Figure 104.7e). This finding suggests that annealing for 1 min enhanced the reactive site for the fast reaction in the film. However, annealing for 4 min changed the system to an inactive site.

Powder X-ray Diffraction

The powder x-ray diffraction (XRD) was measured for the spin-coat film of 1-*n*-tetradecylthymine (**C14**) and the annealed films (Figure 104.8). The spin-coat film had only a broad peak (a), suggesting an amorphous state. New peaks appeared on annealing the film for 1 min (b) the large peak at $2\theta = 4.360°$

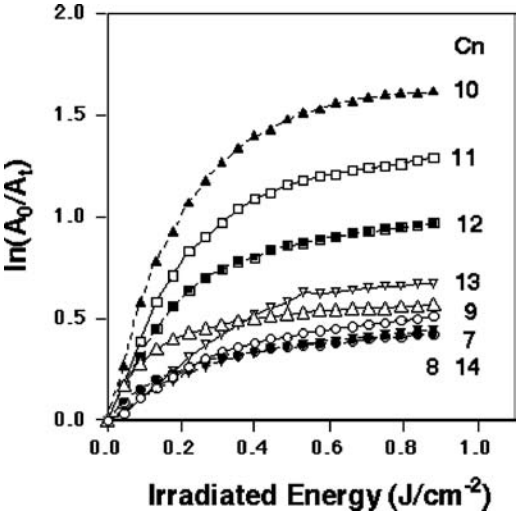

FIGURE 104.6 First rates of photodimerization for heptyl (**C7**) to tetradecyl (**C14**) derivatives of thymine.

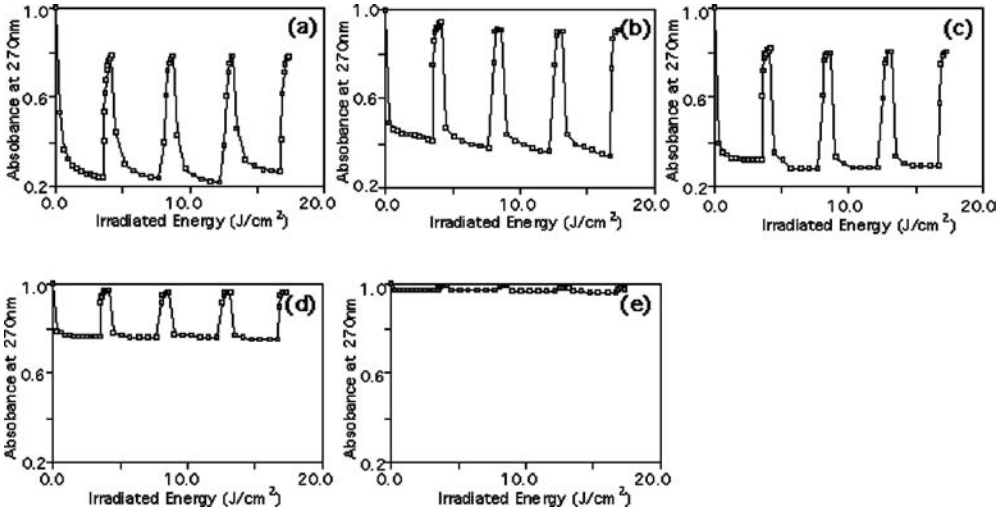

FIGURE 104.7 Reversible photodimerization on thin films in several annealing times for 1-*n*-tetradecylthymine. Annealing time (min): a: 0, b: 1, c: 2, d: 3, and e: 4.

on low angle and small peaks at 8.660°, 17.320°, 21.680°, and 26.080°. By additional annealing for 1 min, all peaks grew larger and the crystalline parts increased (c). Moreover, new peaks at $2\theta = 4.800$Åã and 9.620° appeared. These new peaks indicated that the thin film already had begun to shift to the next structure. After annealing for 3 min, the first five peaks derived from the first structure became smaller and the two new peaks grew bigger (d). For the 4-min annealed thin film, the peak at $2\theta = 4.360°$ was quite small and other four peaks on a higher angle disappeared gradually (e). Finally the first five peaks vanished completely and only the two peaks at $2\theta = 4.800°$ and 9.620° remained (f, annealing for 5 min). Annealing of the amorphous state of the spin-coat film caused crystallization of the thymine compound to give **Structure I**, which is very active toward photodimerization. Prolonged annealing, however, causes deformation of **Structure I** to **Structure II**, which is inactive for the photodimerization.

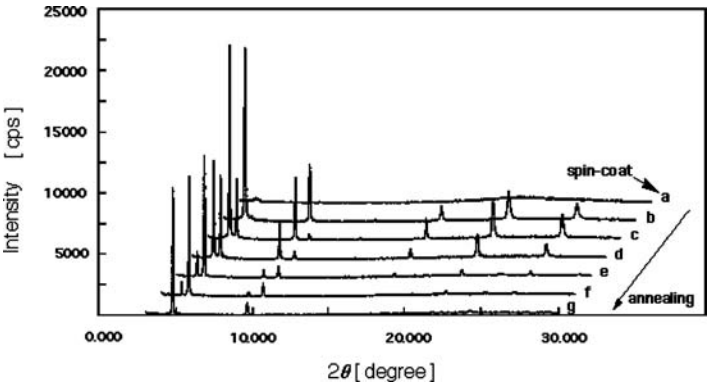

FIGURE 104.8 X-ray powder diffraction on thin films in several annealing times for 1-*n*-tetradecylthymine. Annealing time (min): a: 0, b: 1, c: 2, d: 3, e: 4, f: 5, and g: 10.

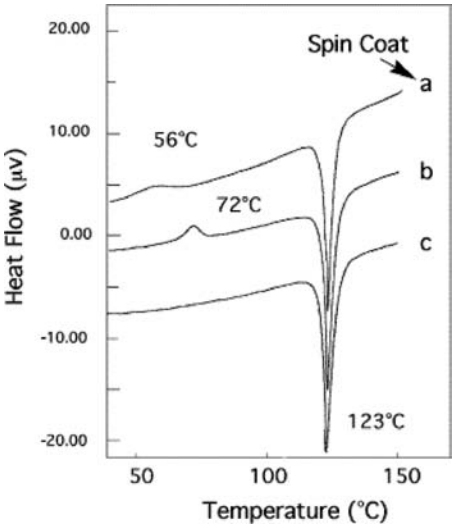

FIGURE 104.9 Differential thermal analysis of thin film for 1-*n*-tetradecylthymine in several annealing times. a: 0 min (spin-coated), b: 2 min, and c: 10 min's annealing.

Thermal Analysis of the Thin Films

Each transition point of the amorphous state to **Structure I** and **Structure I** to **Structure II** was obtained by a differential thermal analysis (DTA) study (Figure 104.9). Samples were prepared by removal from the quartz plate. The trace (a), without annealing, shows a broad exothermic peak at around 56°C and a large endothermic peak at 123°C (the melting point). The peak at 56°C should be the crystallization point of **Structure I**. The thin film, after annealing for 1 min (b), shows an exothermic peak at 72°C and the same endothermic peak at 123 °C as the spin-coat film (a). The exothermic peak at 72°C for (b) should be the deformation point from **Structure I** to **Structure II**. Only the endothermic peak at 123°C was observed for the thin film after annealing for 10 min (c). This indicates that **Structure II** is formed and this is confirmed from the powder x-ray analysis in Figure 104.8.

TABLE 104.1 Isomer Ratio of Photodimers for 1-*n*-Tetradecylthymine in Several States

	cis-syn	*cis-anti*	*trans-syn*	*trans-anti*
Solution	0.85	0.76	1.00	0.95
Spin-coated	0.14	0.32	0.98	1.00
2min annealed	0.06	0.16	0.23	1.00

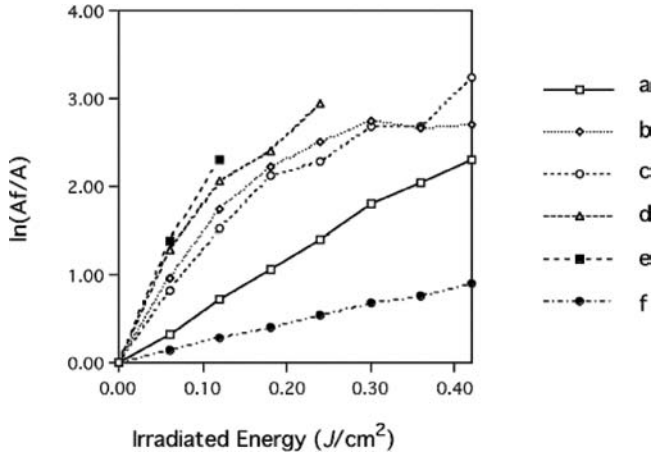

FIGURE 104.10 Splitting rate of photodimer on thin film in several annealing times. Annealing time (min): a: 0, b: 1, c: 2, d: 3, e: 4, and f: spin-coated thin film for *trans-anti* dimer

Isomers of the Photodimers

The photodimerization of thymine in solution gives four isomeric photodimers (Figure 104.2), but the spin-coat film of 1-*n*-alkylthymine from chloroform solution gave the *trans-syn* and *trans-anti* photodimers as the main products (Table 104.1, 1-*n*-tetradecylthymine). On the other hand, the photodimerization of the 2 min annealed film gave only the *trans-anti* photodimer. As mentioned below, the *trans-syn* and *trans-anti* photodimers were obtained by the photodimerization of needles obtained by crystallization from acetonitrile solution. Therefore, the spin-coated film may contain crystals that are the same as the needles from acetonitrile solution. The structure of the thymine in the annealed film may be the same as the plates obtained by crystallization from ethyl acetate solution because the crystals from ethyl acetate gave only the *trans-anti* photodimer.

Reverse Reaction in Spin-Coated Film

Splitting of the photodimer by irradiation at 240 nm also depends on the state of the films. Annealing of the spin-coat film (a to e) caused an acceleration of the reverse reaction as shown in Figure 104.10 for 1-*n*-octylthymine. In the same figure, the results of the reverse reaction for the film prepared from the solution of photodimer (f) obtained by photodimerization of crystal from ethyl acetate are also plotted. This film gave a slower reaction compared to the annealed film. As mentioned below, rotation of the thymines in the crystal during photodimerization may cause strain within the crystal. The strain in the crystal may be the driving force for the reverse reaction. However, the strain in the crystal disappears on dissolution and, therefore, the splitting reaction in solution is slow.

TABLE 104.2 Polymorphism and Properties of 1-*n*-Octylthymine

Crystal Structure	Solvent	Shape	Photo-reaction	Isomers	DSC
Form I	ethyl acetate	plate	Yes	*trans-anti*	108.0, 119.9
Form II	ethanol	plate	No	—	120.1
Form III	acetonitrile	needle	Yes	*trans-anti*, *trans-syn*	59.3, 120.1
Form IV	DMF	plate	No	—	122.6

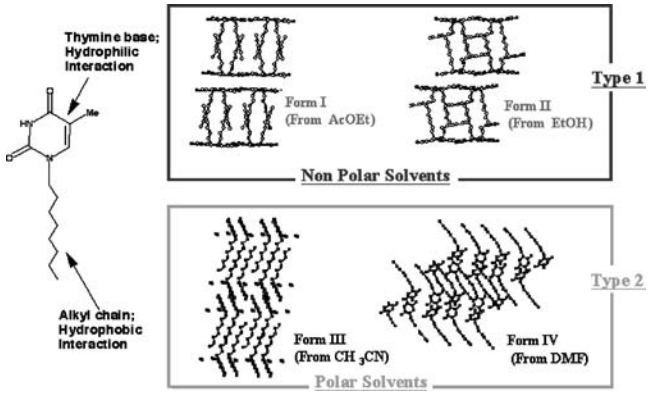

FIGURE 104.11 Formation of crystals in various solvents.

104.3 Crystal Structure and Photodimerisation of 1-Alkylthymine

Solvent Effect on Crystal Structure of 1-*n*-Octylthymine

The polymorphism found in crystals of 1-alkylthymines is related to the length of the alkyl chains and to the solvent used for crystallization. Alkylthymines have two sites for interaction: the thymine base for hydrogen bonding and stacking interactions and the alkyl group for hydrophobic interaction. The polarity of the solvents used for crystallization affects the structure of crystals. Four kinds of crystal structures were found for 1-*n*-octylthymine from x-ray crystal analysis as tabulated in Table 104.2. In less polar solvents (ethyl acetate and ethanol) compared with acetonitrile and DMF, 1-*n*-octylthymine forms **Type 1** crystals (**Form I** and **Form II**) (Figure 104.11).) In the **Type 1** crystals, hydrogen-bonded thymine bases form a plane and the alkyl chains form aggregates to give a bilayer. The bilayers form crystals by the stacking interaction of thymine bases. In the more polar solvents (acetonitrile and DMF), however, 1-*n*-octylthymine forms **Type 2** (**Form III** and **Form IV**) crystals (Figure 104.11). In the **Type 2** crystals, plates of thymine bases are not formed but alkyl chains aggregate regularly. Plates from an ethyl acetate solution (**Form I**) and needles from an acetonitrile solution (**Form III**) gave photodimers. The other crystals (**Forms II** and **IV**) did not give photodimers.

Crystal Obtained from Ethyl Acetate[54]

Photodimerization of 1-*n*-octylthymine in a single crystal obtained from ethyl acetate was very fast and gave only one photodimer. The crystal structure determined by the results of x-ray analysis suggested this to be the *trans-syn* photodimer. However, the photodimer was identified as the *trans-anti* isomer from the NMR spectrum.

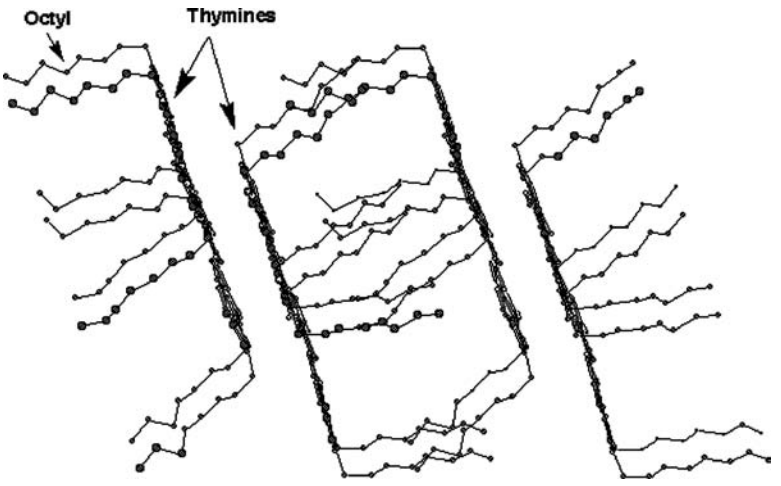

FIGURE 104.12 Lamella structure of 1-*n*-octylthymine (**Form I**).

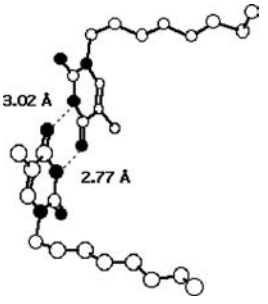

FIGURE 104.13 Two thymine derivatives associated with hydrogen bonding.

The crystal is a layer structure consisting of a hydrophilic layer of thymine bases and a hydrophobic layer of long alkyl groups (Figure 104.12, **Form I**). The distance between the two planes formed by the thymine bases was almost 3.3 Å. Moreover, the long alkyl chain groups aggregate and form a hydrophobic layer. The thymine bases are in the same plane and associated by hydrogen bonding in the plane (Figure 104.13). The thymine molecule faces another thymine in an opposite plane in a head-to-head arrangement (Figure 104.14). As shown in the Figure 104.14, two thymine bases on opposite planes are in the position of *trans-syn*. Therefore, the distance and the orientation of the two thymine bases in this crystal suggest that the *trans-syn* photodimer should be the dominant photodimer.

The plate crystals, obtained by recrystallization from ethyl acetate, were irradiated with UV light. The process of the photoreaction was confirmed from UV, IR, and NMR spectra. The conversion was calculated from the NMR spectra in $CDCl_3$ from the peaks of the 6-H of the photodimer and the original thymine. After UV irradiation of the plate crystal for 3 hours, a 98.3% yield of a single photodimer was obtained. The dimerization was rapid because the reaction proceeded through the singlet state. The isomer was identified as *trans-anti* from chemical shifts of the 5-CH and 6-H in the NMR spectra. This isomer is different from the *trans-syn* isomer predicted from the crystal structure.

If the photodimerization occurs face-to-face between the stacked thymines, the photodimer should be the *trans-syn* isomer. However, the photodimer obtained was the *trans-anti* isomer, suggesting another mechanism of photodimerization. The photocyclization of a diene compound is known to occur by disrotatory motion, although the thermal cyclization occurs by a conrotatory motion.[62] If the photodimerization of thymine bases in the crystal occurred by disrotatory motion, the product should be the

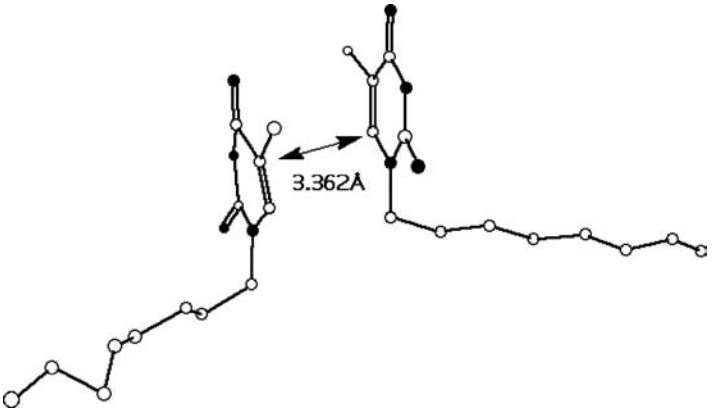

FIGURE 104.14 Two opposite thymine derivatives in the position of *trans-syn.*

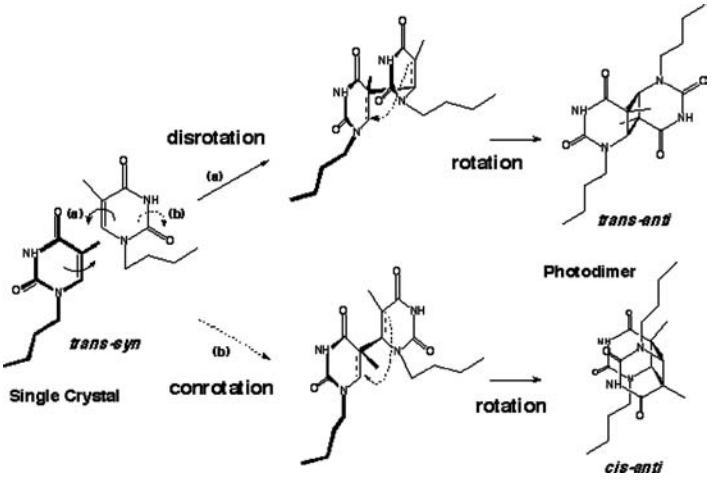

FIGURE 104.15 Probable mechanism of photodimerization of 1-*n*-octylthymine in crystal state from two opposite thymine derivatives in the position of *trans-syn.*

trans-anti isomer. This mechanism of disrotation may be possible because the motion of the molecule is fixed in the crystal by the interaction of the long alkyl chains.

The probable mechanism of the photodimerization is illustrated in Figure 104.15. When the thymine bases in the crystal rotate in the disrotatory manner (path a), the first bond is formed between C5 and C6′ in a *cis*-conformation. After rotation of the thymine in the plane, the second bond is formed between C6 and C5′, giving the *trans-anti* photodimer. By the conrotatory motion of thymine bases (path b), however, the *cis-anti* photodimer should be formed through the *trans*-type intermediate.

Crystal Obtained from Ethanol[55]

Figure 104.16 shows a molecular packing structure of 1-*n*-octylthymine crystallized from ethanol (**Form II**). The crystal is a double-layer structure consisting of a hydrophilic layer of thymine bases and a hydrophobic layer of long alkyl groups. The distance between the two planes formed by the thymine bases was about 3.3 Å. The long alkyl chain groups aggregate weakly and form a hydrophobic layer. Therefore, hydrogen bonding and van der Waals forces of the thymine bases are the main driving forces to form the crystal.

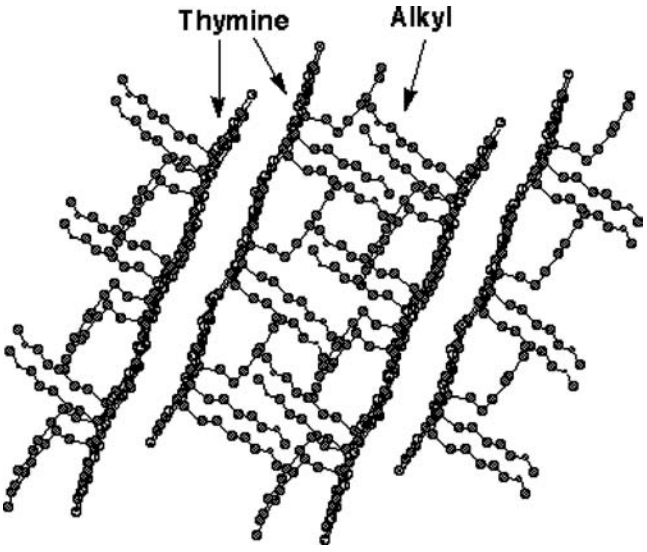

FIGURE 104.16 Lamella structure of 1-*n*-octylthymine crystallized from ethanol (**Form II**).

Irradiation with UV light (280 nm) of the crystal from ethyl acetate gave the photodimer with 98.7% conversion.[54] On the other hand, crystals from ethanol gave no photodimers under the same reaction conditions. These results of photodimerization in single crystals correspond with the results from the photoreaction in thin films. **Structure I** of the spin-coated film gave the photodimer, but the **Structure II** formed by annealing gave no photodimer. The differences between these photoreactivities will be clarified by the molecule orientation in the crystal structure obtained from x-ray structure analysis studies.

The transition points of the **Form I** to **Form II** were obtained by a differential thermal analysis (DTA) study. On the trace from **Form I** (ethyl acetate), a small endothermic peak was found at 106°C and an exothermic peak was found at 111°C. A large endothermic peak at 122°C should be the melting point. On the trace from **Form II** (ethanol), a broad endothermic peak is shown at 100°C and a large endothermic peak at 122°C. The small endothermic peaks at around 100°C can be assigned to the melting of the *n*-octyl chain. The differences of temperature between the two crystals forms may be caused by the difference of assembly for each long alkyl chain (Figure 104.17). Long alkyl chains cross each other in **Form II** but the chains are parallel in **Form I**. To make sure that the peaks at 106° and 111°C for **Form I** are the transition point, DTA was measured for the annealed crystal. **Form I** was heated to 110°C and cooled to 50°C. The DTA trace for the annealed crystal showed a similar DTA trace to **Form II**. This result indicated that **Form I** (ethyl acetate) transformed to **Form II** (ethanol).

Crystal Obtained from Acetonitrile[56]

Crystallization of 1-*n*-octylthymine from acetonitrile solution gave needles and plates. The plates of 1-*n*-octylthymine obtained by slow evaporation of acetonitrile were the same form as the plates from ethanol solution (**Form II**). Needles of 1-*n*-octylthymine were obtained by crystallization from acetonitrile solution. The form of the needles (**Form III**) was greatly different from those crystals obtained from ethyl acetate (**Form I**) and ethanol solutions (**Form II**). The needles contained acetonitrile in the cavity in a molar ratio of 1:1 (thymine: acetonitrile). As the *z* value was 2, one unit cell includes two thymine molecules and two acetonitrile molecules. Figure 104.18 shows the arrangement of the *ab* and *cb* planes. The thymine bases stacked on the *c* axis but did not completely overlap. The lamella structure consists of the hydrophilic and hydrophobic layers. The hydrophilic layer was composed of thymine bases and acetonitrile, and the hydrophobic layer of the long alkyl chains. The two layers were conjugated by hydrogen bonding and they contributed to the stability of the hydrophilic layer.

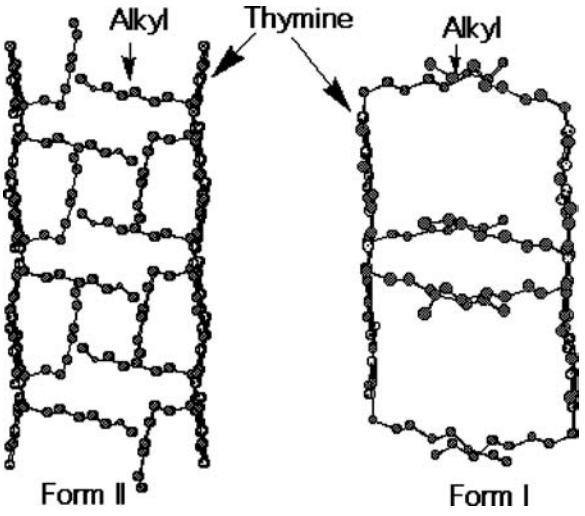

FIGURE 104.17 Packing of long alkyl chains in crystals: [a]; **Form II** (ethanol); and [b] **Form I** (ethyl acetate).

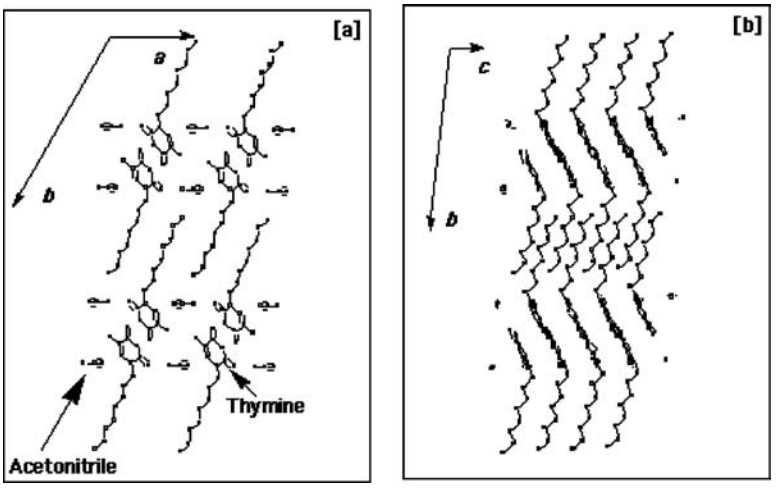

FIGURE 104.18 Molecular arrangement of 1-*n*-octylthymine in needles (**Form III**): [a] *ab* Plane and [b] *bc* Plane.

Irradiation with UV light around 280 nm of the needles obtained from the acetonitrile solution gave the photodimer. The NMR spectrum suggests the formation of two kinds of photodimers. The two isomers were identified as the *trans-anti* and *trans-syn* isomeric dimers by comparison of the NMR spectra of the isolated photodimers.[54]

The mechanism for the formation of the two photodimers was postulated from the form of the needles. There are two orientations of the thymine pairs that form photodimers in the needles from acetonitrile solution. One is in the *trans-anti* orientation. As shown in Figure 104.19, thymines in a *trans-anti* orientation (**a** in Figure 104.19) rotate for the reaction between C5 and C5′ and rotate again for the formation of the photodimer, giving the *trans-syn* isomer. The other orientation is *cis-syn* (**b** in Figure 104.19) and gives the *trans-anti* photodimer by rotation of thymines during the photodimerization reaction. As illustrated in Figure 104.20, the thymines rotate outside to give the *cis-syn* orientation of the intermediate that gives the *trans-anti* photodimer by reaction between C6 and C5′ with internal rotation. If the thymines rotate inside, the photodimer should be *cis-anti*. The rotation inside, however, may be inhibited by steric hindrance of the methyl groups of thymine. Therefore, only small amounts of the *cis-anti*

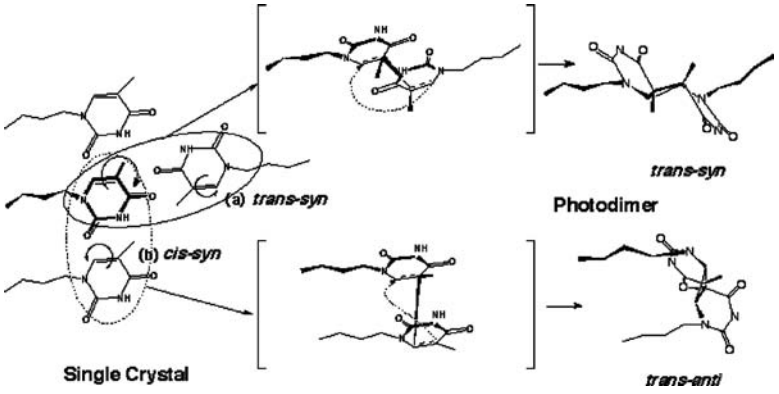

FIGURE 104.19 Mechanisms of photodimerization for 1-*n*-octylthymine in needles: [a] Orientation of *trans-anti* giving *trans-syn* photodimer; [b] orientation of *cis-syn* giving *trans-anti* photodimer.

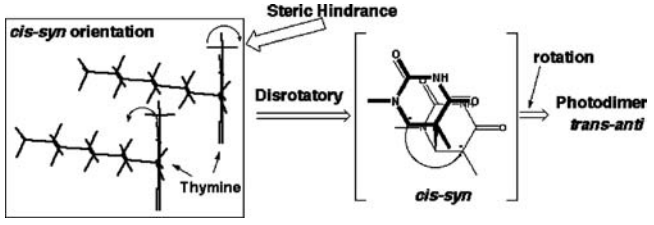

FIGURE 104.20 Illustration of disrotatory motion from *cis-syn* orientation to *cis-syn* intermediate.

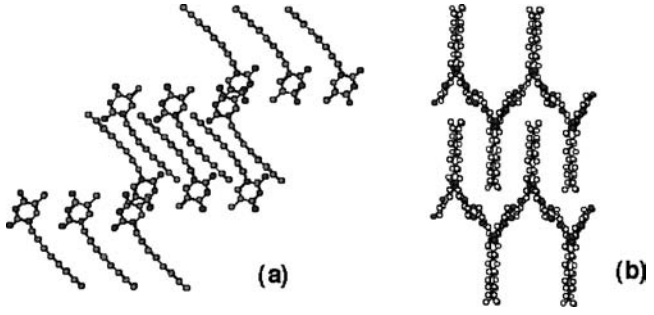

FIGURE 104.21 Molecular packing of 1-*n*-octylthymine (**Form IV** from DMF) along b axis (a) and a axis (b).

photodimer were obtained. In both pairs, the thymines gave the photodimers by disrotatory motion in the crystals during the photodimerization reaction. If conrotatory motion occurred during the photodimerization, another isomers would have been obtained.

Crystals Obtained from DMF[58]

Single-crystal of 1-*n*-octylthymine was obtained from DMF (*N*,*N*-dimethylformamide) solution. Figure 104.21 shows molecular packing of 1-*n*-octylthymine (**Form IV**) along *b* axis (a) and *a* axis (b). The thymine rings in crystal are not stacked but crossed at about 60° as shown in Figure 104.22. Moreover, the terminal methyl group of the molecule is closely located to the double bond of the thymine base in the molecule with the distance of 3.62 Å, and the terminal methyl group of the molecule is closely located to the thymine base of the molecule. Then two molecules in the crystal of 1-*n*-octylthymine form a pair instead of a helix.

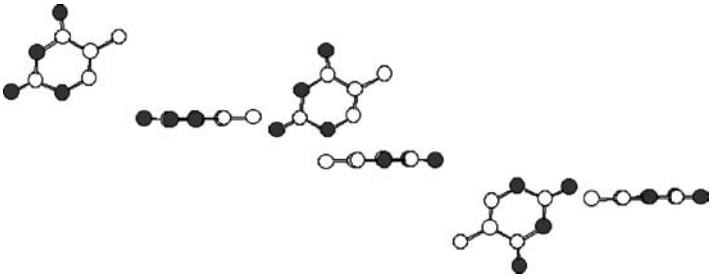

FIGURE 104.22 Thymine bases in **Form IV** crystal.

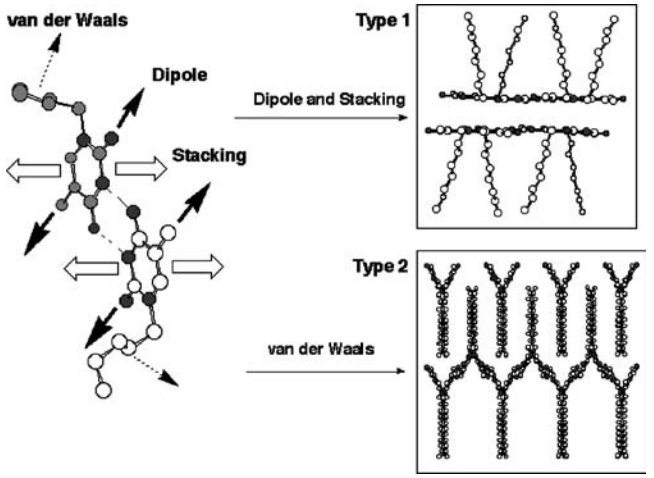

FIGURE 104.23 Interactions and crystallizations of 1-*n*-alkylthymine.

UV light was irradiated on the single crystal obtained from DMF for 1-*n*-octylthymine using an optical fiber with a cutoff filter (above 280 nm). The photodimerization of the thymine bases was followed by UV spectra at 270 nm in chloroform solution. A decrease in UV absorption at 270 nm, however, was not detected after irradiation for 2 days.

Crystal Structure and Photodimerization of 1-*n*-Octylthymine: Summary

Crystal Structure

Polymorphism of 1-*n*-octylthymine is related to polarity of solvent used for crystallization. Two types of crystals (**Type 1** and **Type 2**) are obtained, depending on solvent used. In both types, a hydrogen bonded-pair of thymine may be formed at first during crystallization from solution. For the formation of **Type 1** crystals, the hydrogen-bonded pairs associate to form stacked plates by dipole and stacking interaction, followed by association of the alkyl chains between two plates by van der Waals interaction to give **Type 1** crystals (Figure 104.23). In the case of **Type 2** crystals, alkyl chains of the hydrogen-bonded pairs crystallized by van der Waals interaction without stacking of thymine bases or formation of plates.

In **Form I** (**Type 1**), any interaction was found between the hydrogen-bonded pairs in the same plane (Figure 104.24). However, stacking interactions of thymine bases were found between the hydrogen-bonded base pairs on the opposite planes as shown in Figure 104.25.

Ethyl acetate (dielectric constant = 6.02 at 20°C, Dipole Moment = 1.88 D) and ethanol (dielectric constant = 23.8 at 20°C, Dipole Moment = 1.68 D) are aprotic and nonpolar solvents. The 1-*n*-octylthymine in these solvents forms hydrogen-bonded pairs, and then form double layers by the stacking interaction of thymine bases. Finally, the double layers aggregate by van der Waals interaction to form

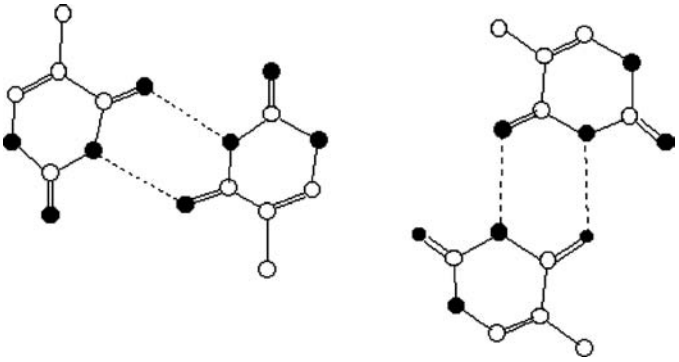

FIGURE 104.24 Hydrogen bonding of 1-*n*-octylthymine in a plane of **Form I**.

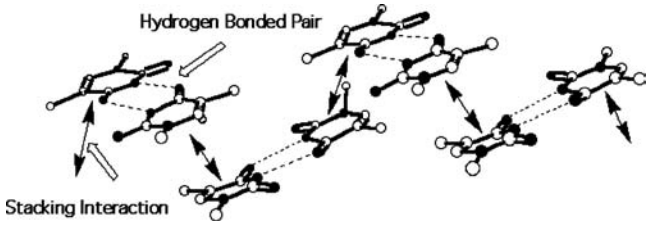

FIGURE 104.25 Stacking interaction between hydrogen-bonded pairs of thymine (**Form I**).

crystals. In these solvents, the stacking interaction of thymine bases take priority over the van der Waals interactions of the alkyl chain. In **Form I** from ethyl acetate, the interaction of the long alkyl chain is weak and rotation of the thymine base in crystal is possible; that is important for photodimerization. The structure of crystal obtained from ethanol (**Form II**) is similar to the crystal from ethyl acetate (**Form I**), but the interaction of the long alkyl chain is stronger than the crystal from ethyl acetate because the polarity of ethanol is higher than that of ethyl acetate. Therefore, the strong interaction of the long alkyl chain in **Form II** inhibits the rotation of the thymine base during photodimerization reaction.

In **Form III** from acetonitrile (**Type 2**), both stacking of the thymine bases and crystallization of the alkyl chains are found. Acetonitrile (dielectric constant = 37.5 at 20°C, Dipole Moment = 3.44 D) is an aprotic and polar solvent. Also, in acetonitrile, thymines form hydrogen-bonded pairs at first. For the association of the hydrogen-bonded pairs, the stacking interaction of thymine bases and the van der Waals interaction of the long alkyl chains occur at the same time. In this crystal, acetonitrile interacts with C2-O of thymine to give an inclusion crystal. Rotation of the thymine bases in crystal is possible because included acetonitrile is mobile. The formation of the inclusion crystal may be kinetic control, but slow evaporation of acetonitrile gives thermodynamically stable plates.

In the **Form IV** (**Type 2**) crystal, the hydrogen-bonded pairs are not parallel to each other (Figure 104.22). Therefore, the formation of the plane structure by stacking interaction of thymine bases is impossible. DMF (dielectric constant = 36.71 at 25°ãC, Dipole Moment = 3.86 D) is an aprotic and polar solvent as well as a good solvent for nucleic acid bases as DMSO. Therefore, the stacking interaction of the hydrogen-bonded pairs is weak because the thymine bases form the complex with DMF. Then, the long alkyl chains of the 1-*n*-octylthymine crystallize by van der Waals interaction. In DMF, the van der Waals interaction of the alkyl chain takes priority over the stacking interaction of thymine bases. In the crystal from DMF, inclusion of DMF molecules dose not occur because the DMF molecule is larger than acetonitrile. Rotation of the thymine bases in the crystal is impossible because molecules are packed closely by strong interaction of the long alkyl chains in the crystal.

TABLE 104.3 Factors Determining the Activity of 1-*n*-Octylthymine for the Photodimerization

Photodimerization

Intensive studies concerning topochemical reactions have been reported on the photodimerization of cinnamic acid and its derivatives. Schmidt and co-workers proposed a geometrical criterion for the photodimerization in the crystalline state: that the reacting double bonds should be situated within about 4.2 Å of each other and aligned parallel.[63] In the case of the photoactive single crystal of 1-*n*-octylthymine obtained from acetonitrile solution (**Form III**), however, the distance between the reacting double bonds of the thymine bases was 4.47 Å.[56] It is difficult to apply Schmidt's rule to the photodimerization of the 1-*n*-octylthymine crystals. Therefore, it is necessary to determine the feature within the crystal of 1-*n*-octylthymine for the photodimerization reaction in the crystalline state.

From the crystal structure of 1-*n*-octylthymine, we will study the factors determining the activity of the crystals for the photodimerization. The possible factors for the crystal structure are summarized in Table 104.3. An important feature of the thymine compounds is the hydrogen bonding between the thymine bases. The hydrogen bonding of the thymine bases does not directly influence the photoactivity, but is important for the stability of the crystal structure. The crystallization of 1-*n*-octylthymine from nonpolar solvents may begin from the hydrogen bonding of the thymine bases, followed by stacking of the thymine bases and aggregation of the long alkyl chains. Figure 104.26 shows the hydrogen-bonded pairs for four crystal forms of 1-*n*-octylthymine. In **Type 1** (**Form II** and **I**), the long alkyl chains extend in the same direction from the plane of the hydrogen-bonded thymine bases. On the other hand, in the case of **Type 2** (**Form III** and **Form IV**), the long alkyl chains extend in the opposite direction from the plane of the hydrogen-bonded thymine bases. The direction of the long alkyl chain may determine the aggregation of the long alkyl chains and, therefore, the crystal structure. The interaction of the solvent with the molecules may cause a change in the direction of the long alkyl chain during crystallization in solution.

The most important factor of the crystal structure for the photoactivity should be the distance between the C5–C6 double bonds of the thymine bases, as proposed by Schmidt and co-workers.[63] Two facing thymine bases in the crystals are shown in Figure 104.27 for four crystal forms of 1-*n*-octylthymine, and

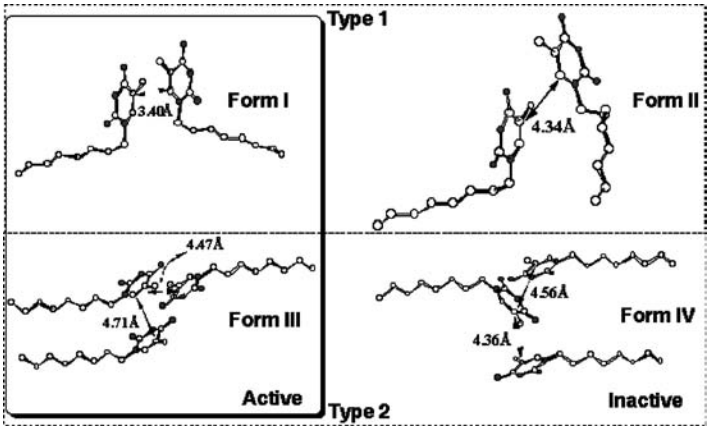

FIGURE 104.27 Facing thymine bases in **Form I**, **Form II**, **Form III**, and **Form IV**.

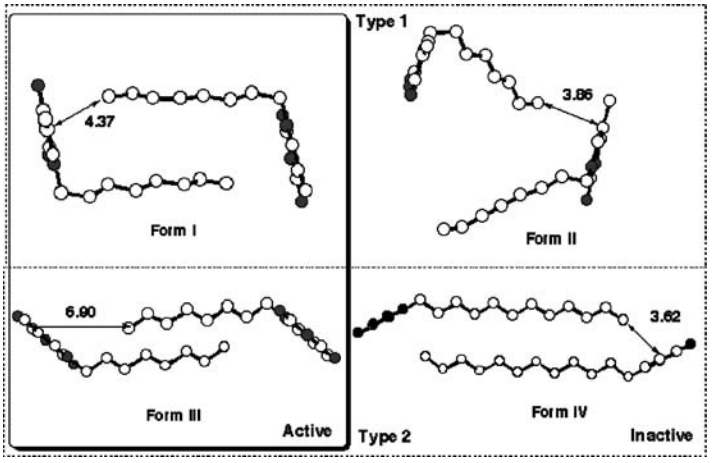

FIGURE 104.28 The nearest neighboring molecules of 1-*n*-octylthymine for **Form I**, **Form II**, **Form III**, and **Form IV**.

the distances between the adjacent double bonds of thymine bases are tabulated in Table 104.3. The distances between the thymine bases in **Form IV** are 4.36 Å and 4.56 Å, which are longer than the distance of the photoactive **Form I** (3.40 Å) but shorter than the distance of the photoactive **Form III** (4.47 and 4.71 Å). Therefore, the distance between the double bonds of the thymine bases is not the main factor for the photodimerization of thymine bases in crystal.

As mentioned, the characteristic of the crystal structure for **Form IV** is the presence of the terminal methyl group in the vicinity of the double bond in the thymine base. The nearest neighboring terminal methyl group and thymine bases are picked out from the crystal structure of 1-*n*-octylthymine for **Forms I**, **II**, **III**, and **IV** in Figure 104.28 and the distances are tabulated in Table 104.3. The distances between the methyl group and the thymine base (C5) are long for the photoactive **Form I** (4.26 Å) and **Form III** (7.34 Å), but are short for the inactive **Form II** (3.86 Å) and **Form IV** (3.64 Å). The terminal methyl group of the alkyl chain should be important for the photodimerization of the thymine bases, although the methyl group did not participate directly in the photodimerization.

The DSC curves of 1-*n*-octylthymine indicate the stability of the crystals (Figure 104.29). The inactive crystals of **Form II** and **Form IV** gave only one peak at high temperature (around 120°C). The photoactive crystals of **Form I** and **Form III**, however, had one more peak in the DSC. **Form III**, including acetonitrile molecules, released the acetonitrile at 59.3°C. This was followed by melting at 120.1°C. **Form III** underwent

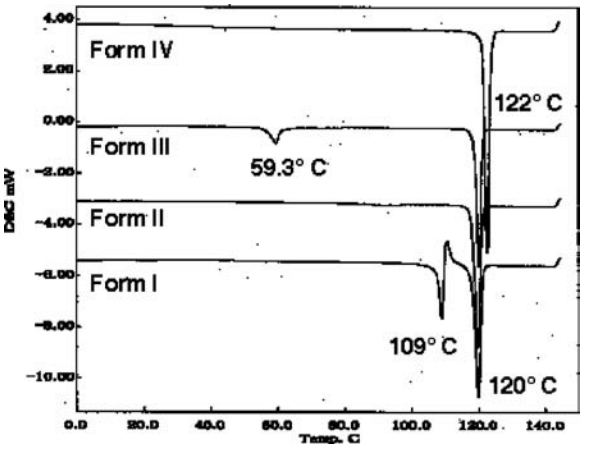

FIGURE 104.29 DSC of 1-*n*-octylthymine for **Form I**, **Form II**, **Form III,** and **Form IV**.

photodimerization but became inactive after annealing at 100°C. **Form I** was also active for the photodimerization but became inactive after annealing at 100°C. Then, the unstable crystals suggested by the DSC curves were active for the photodimerization.

Photodimerizations and crystal structures of 1-*n*-octylthymine are summarized as follows. In photoactive **Form I**, the distance between the double bonds of the thymine bases is short (3.40 Å) and the terminal methyl group of the alkyl chain is not near the thymine base (4.26 Å). The DSC data of **Form I** indicates that the crystals are unstable and change to the stable **Form II**. Consequently, the thymine bases in **Form I** can rotate in the crystal to give the photodimer. In photoactive **Form III** from acetonitrile, the distance between the photoactive double bonds of the thymine base was 4.36 Å, which was longer than the 4.2 Å of Schmidt's rule. However, the distance between the methyl group and the thymine base (C5) is long enough (7.34 Å) to permit the disrotatory motion of the thymine bases in the crystal. The DSC data also supports the instability of the crystal in **Form III**. Therefore, the crystal of **Form III** is active for photodimerization to give the photodimer.

When the terminal methyl group of the long alkyl chain is close to the double bond of the thymine bases, the terminal methyl group of the alkyl chain could block the rotation of the thymine bases during photodimerization. The DSC data indicated that the crystals of **Forms II** and **IV** were stable and could not transform to another crystal form. Therefore, the blocking of the disrotatory motion of the thymine base by the terminal methyl group of the alkyl chain was concluded to be the reason of the inactivity for the photodimerization of **Form II** and **Form IV**. The distance between the terminal methyl group and the C5–C6 double bond of the thymine bases is a measure of the blocking effect of the methyl group on the disrotatory motion of the thymine base.

Effects of Chain Length on Crystal Structure and Isomer Ratio of Photodimer[60]

Crystal Structure

The polarity of solvents determines the type of crystal for 1-alkylthymine: **Type 1** or **Type 2**. The chain length of the alkyl group is also an important factor for the determination of the crystal type (Figure 104.30). **Type 1** crystals were obtained for 1-alkylthymines with short alkyl chains such as **C5**. With the increase of chain length, both **Type 1** and **Type 2** crystals were obtained from **C8** to **C10**. For **C9** and **C10**, **Type 2** crystals were too unstable to isolate, but the DSC data indicated the presence of two crystal forms. For 1-alkylthymine with long alkyl chains above **C11**, only **Type 2** crystals were obtained. Crystallization of 1-alkylthymine is competitive crystallization of thymine bases with alkyl chains (Figure 104.23). For compounds with short alkyl chains, thymine bases crystallized in preference to alkyl chains to form **Type 1** crystals. For compounds with long alkyl chains, the alkyl chains crystallized in preference to thymine bases to form **Type 2** crystals.

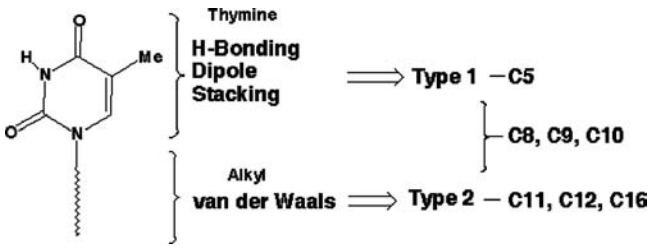

FIGURE 104.30 Interactions and crystallization of 1-*n*-alkylthymine.

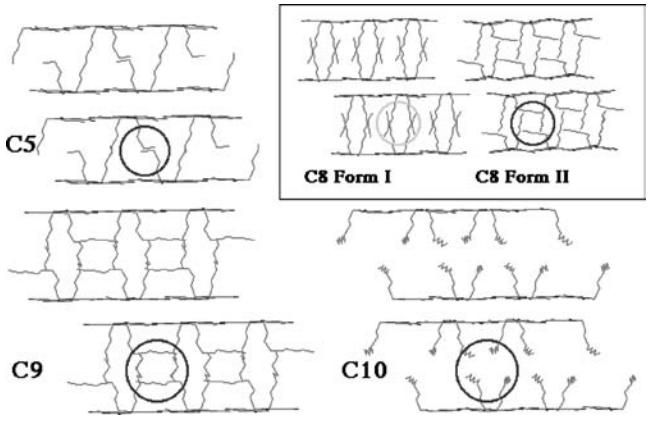

FIGURE 104.31 Molecular packing of **Type 1** crystals for **C5**, **C8**, **C9,** and **C10**.

Crystal structures of **Type 1** for **C5**, **C9**, and **C10** are shown in Figure104.31 along with the data for **C8**. In **Type 1** crystals, the hydrogen-bonded thymines form a parallel plane by stacking interactions and form sheets by van der Waals interactions of the alkyl chains. The style of aggregation of alkyl chains depends on the length of the alkyl chains (circles in Figure 104.31). This figure suggests that there is no significant interaction of the alkyl chains for **C10** between the bilayers of the thymine bases. This fact indicates that hydrogen-bonded pairs of thymines are first formed during crystallization from solution, followed by formation of two plates by dipole and stacking interactions (**Type 1** in Figure 104.31). Finally, the crystal was formed by van der Waals interaction of the alkyl chains between two plates. When the alkyl chains are long, the van der Waals interaction of the alkyl chains is strong enough to form a regular arrangement of the alkyl chain to give **Type 2** crystals.

Isomer Ratio of Photodimers

Photodimerization of 1-*n*-alkylthymine in solution gave four isomeric photodimers (Figure 104.2 and Table 104.1). **Type 1** crystals of 1-*n*-octylthymine (**C8**) (**Form I**), obtained from ethyl acetate, gave only the *trans-anti* isomer and **Form III** crystals, obtained from acetonitrile, gave two photodimers. In **Type 1** crystals, the length of the alkyl chain was found to affect the isomer ratio of photodimers (Table 104.4). In the case of 1-*n*-pentylthymine (**C5**) and 1-*n*-nonylthymine (**C9**), irradiation gave the *trans-syn* photodimer. **Type 1** crystals of 1-*n*-undecylthymine (**C10**) gave a mixture of photodimers, *trans-anti* and *trans-syn*. The photodimerization for **C8** was efficient (98%) but conversions of **C5**, **C9,** and **C10** were low, around 30%. The length of the alkyl chain should relate to aggregation of the alkyl chains in the **Type 1** crystals. Thus, types of aggregation may affect the isomer ratio of the photodimers formed. The conformation of facing thymines for photodimerization is *trans-syn.* This is the same for **C5**, **C8**, **C9**, and **C10**. The conformation of the thymines, therefore, cannot explain the differences of type and ratio of the photodimers obtained. The key factor must be the length of the alkyl chains.

TABLE 104.4 Conversion and Isomer Ratios of Photodimerization in Single Crystals

Compound	Solution	Penthyl(C5)	Octyl(C8)	Nonyl(C9)	Decyl(C10)
Conversion(%)	—	30	98	30	40
cis-syn	0.85	—	—	—	—
cis-anti	0.76	—	—	—	—
trans-syn	1.00	1.0	—	1.0	0.7
trans-anti	0.95	—	1.0	—	0.3

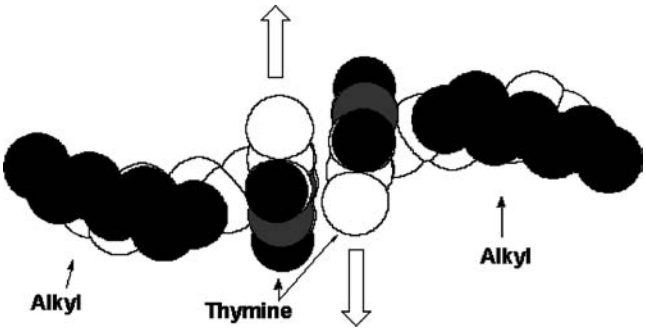

FIGURE 104.32 Restriction of rotation by terminal methyl groups for 1-*n*-octylthymine (**C8**).

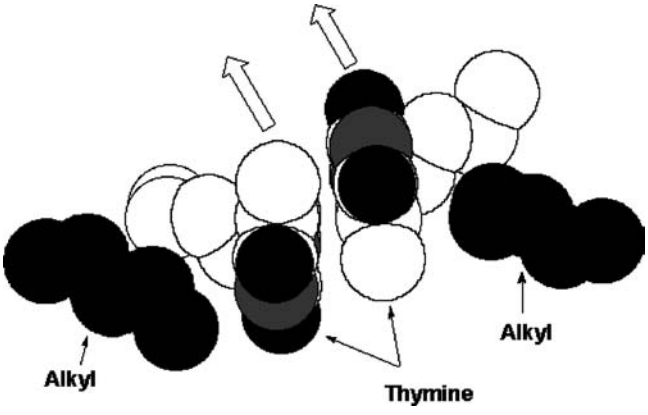

FIGURE 104.33 Restriction of rotation by terminal methyl groups for 1-*n*-pentylthymine (**C5**).

Figure 104.32 shows active thymine bases and surrounding alkyl groups in a space-filling model for **C8**. In this model, the terminal methyl group of the alkyl chain is closely located to the thymine base. The distance of the methyl group to N3 of the thymine was 3.6 Å and to C5 was 4.3 Å. The methyl groups inhibit rotation of the thymine bases and permit only one direction of rotation for two thymine bases, as in Figure 104.32. Permitted rotations of thymine bases during photodimerization may give the *trans-anti* photodimer.

In the case of **C5** (Figure 104.33), the blocking effect of the terminal methyl group permits rotation of the thymine bases in the same direction. The permitted directions of rotation for **C5** must be in a parallel sense, as shown in Figure 104.33. This is, however, opposite to the direction for **C8**. Different isomers of the photodimer (*trans-syn*) were obtained for **C5** than from **C8** as a result of the difference in rotation. The allowed direction of rotation for **C9** was the same as for **C5**.

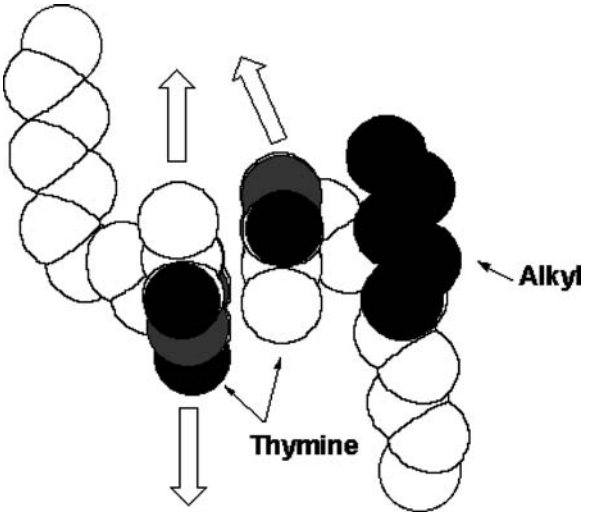

FIGURE 104.34 Restriction of rotation by terminal methyl groups for 1-*n*-pentylthymine (**C10**).

In the case of **C10**, there are no alkyl chains near the thymine base on the left and rotation of the thymine base can take place (Figure 104.34). However, rotation of the thymine base on the right is inhibited by the terminal methyl group of the alkyl chain that is in the same plane. The allowed rotation of the thymine on the right can only be in an upward direction. Then, two isomers of the photodimers, *trans-syn* and *trans-anti*, can be obtained for **C10** (Table 104.4).

Crystal structures of **Type 1** are similar for **C5**, **C8**, **C9**, and **C10**, except for the interactions of the alkyl chains. Alkyl chains play an important role in forming different isomers of the photodimers. Terminal methyl groups of the alkyl chains are close to the thymine bases and inhibit rotation of the bases during photodimerization within the crystals.

104.4 Ester Derivatives of Thymines Having Long Alkyl Chains

Photodimerization in Thin Solid Films[59]

The reversible photodimerizations of the ester derivatives of thymines (Figure 104.35) were studied in thin solid films that were prepared by spin coating from chloroform solution. Figure 104.36 shows typical repeated photodimerizations of tridecyl (**ES13**) ester derivatives of thymine in thin solid films. The absorbance of the UV spectra at 270 nm decreased on irradiation at 280 nm, indicating the formation of the photodimer and increased again by irradiation at 240 nm, suggesting the photosplitting of the photodimer (a in Figure 104.36). After annealing of the thin solid film at 100°C, the photodimerization was negligible, suggesting a structural change within the thin solid films (b in Figure 104.36).

Figure 104.37 shows the first and the second photodimerizations of the decyl ester (**ES10**) in the thin solid film (a, b, c) with the data in solution (e) and in polymer film (d). The rate of the photodimerization in chloroform solution was slow but proceeded completely (e). The photodimerization of thymine derivatives in solution is known to proceed by way of the triplet excited state. The short lifetime of the singlet state and the inefficient intersystem crossing are the reasons for the slow reaction rate for photodimerization of thymine in solution. The photodimerization was studied in the polymer film using poly(vinyl acetate) (PVAc) (d). The polymer film was obtained from a chloroform solution of the ester derivatives of thymine and poly(vinyl acetate) by spin coating on a quartz plate. The rate of photodimerization in poly(vinyl acetate) was faster than the rate in chloroform solution. In the polymer matrix, photodimerization occurs from associated thymine bases via the singlet state with a higher quantum yield than that from the triplet-state reaction.

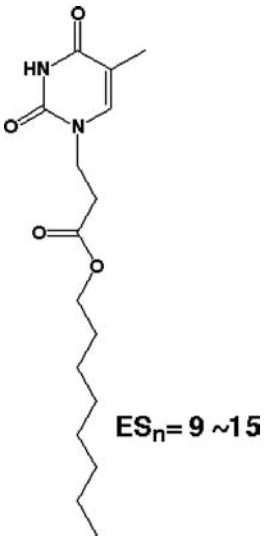

FIGURE 104.35 Ester derivatives of thymine.

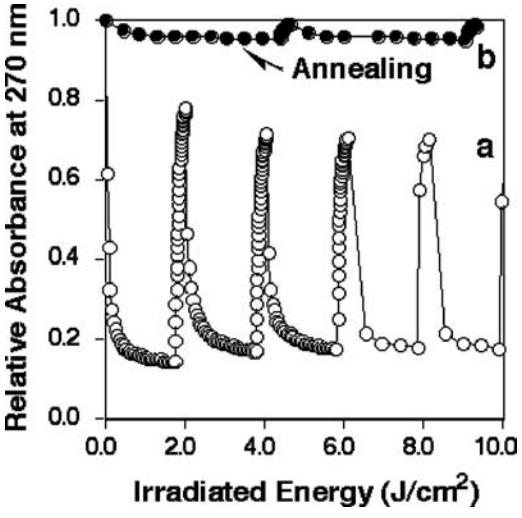

FIGURE 104.36 Typical repeated photodimerizations of tridecyl 2-(thymin-1-yl)-propionate (**ES13**) in thin solid film: (a) spin-coat film and (b) after annealing at 100°C

Repeated reversible photodimerizations in the spin-coated film were studied for nonyl (**ES9**), decyl (**ES10**), undecyl (**ES11**), dodecyl (**ES12**), tridecyl (**ES13**), tetradecyl (**ES14**), and pentadecyl (**ES15**) 2-(thymin-1-yl)-propionates. Decay of the photodimerization was observed for all except **ES12** and **ES13**. The conversions of the first photodimerization from **ES9** to **ES15** are plotted in Figure 104.38. Initially, the photodimerization was fast, up to about 0.5 J/cm^2 of irradiation energy; then the rate slows. The initial fast reactions of [**ES10**, **ES11**] were similar to the rate of [**ES9**]. Interestingly, the slower reactions above 0.5 J/cm^2 of [**ES10**, **ES11**] were faster than slower process for [**ES9**]. The initial rates of the first photodimerization of [**ES12**, **ES13**] were very fast and the conversion for **ES13** reached 90% within 0.5 J/cm^2. For [**ES14**, **ES15**], the initial rates were faster than the rates of [**ES10**, **ES11**], but the final conversions were lower than those of [**ES10**, **ES11**]. From these results, the rates of the first photodimerization in Figure 104.38 can be divided into four classes — [**ES9**], [**ES10**, **ES11**], [**ES12**, **ES13**], and [**ES14**, **ES15**] — according to the slopes of the curves shown in Figure 103.38.

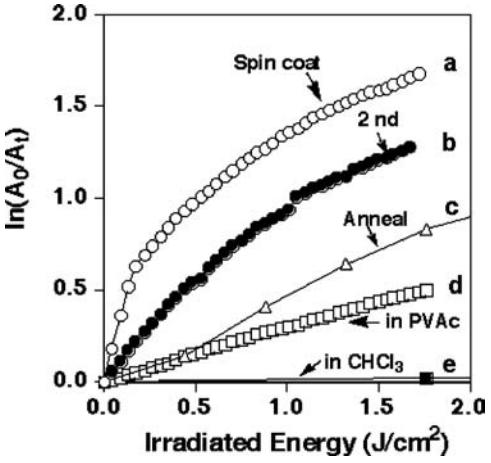

FIGURE 104.37 Conversions of the photodimerizations for decyl 2-(thymin-1-yl)-propionate (**ES10**) in various states under UV irradiation at 280 nm: (a) spin-coat film, (b) after photo splitting, (c) after annealing at 100°C, (d) in poly(vinyl acetate) film, and (e) in chloroform solution.

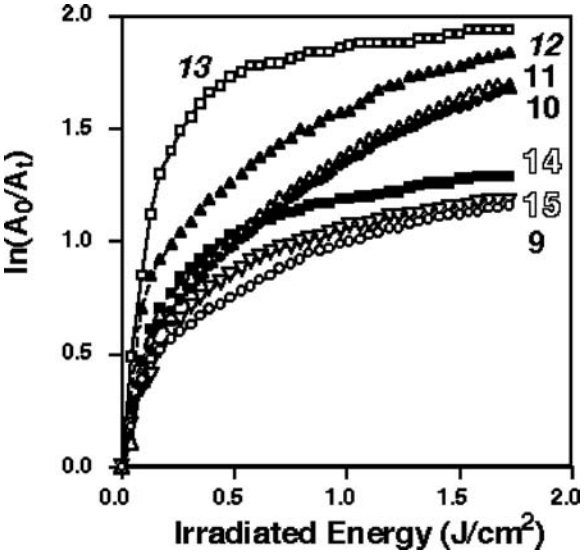

FIGURE 104.38 Conversions of the first photodimerization in the spin-coat film from **ES9** to **ES15**. UV irradiation: 280 nm. The numbers are the carbon number of the alkyl chain.

Photodimerization in Annealed Solid Films

Annealing is carried out at 100°C above the melting point for the spin-coated thin films. The first photodimerizations after annealing are shown in Figure 104.39. The reactivities of **ES10** and **ES11** were decreased by the annealing and become the same as shown by **ES9**. The curves in this figure can be classified into three groups; [**ES9**, **ES10**, **ES11**], [**ES12**, **ES13**], and [**ES14**, **ES15**]. The remarkable change observed for **ES12** and **ES13** after annealing was the absence of photodimerization. This result suggests that the structure of the thin film changes on annealing.

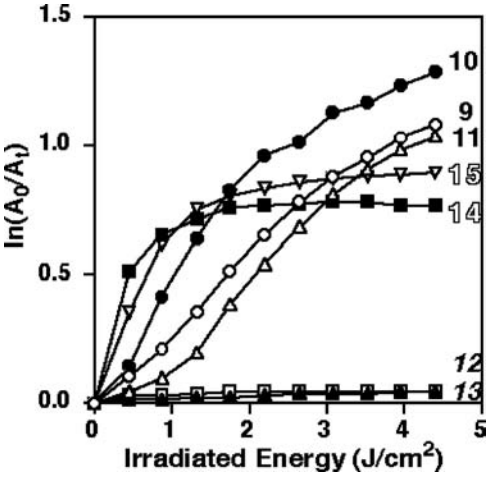

FIGURE 104.39 The first photodimerizations after annealing at 100°C. UV irradiation: 280 nm. The numbers are the carbon number of the alkyl chain.

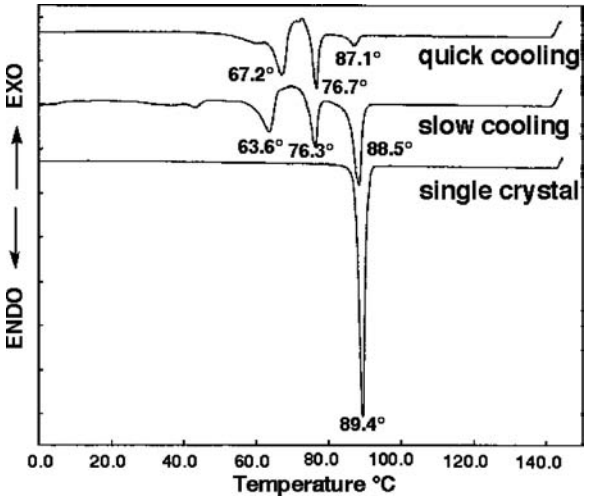

FIGURE 104.40 DSC curves for **ES10**. Heating: 5°/min. (a) Single crystal, (b) after slow cooling (3°/min) of the melt, and (c) after quick cooling (100°/min) of the melt.

DSC of the Ester Derivatives of Thymine

The results of the photodimerization for the ester derivatives of thymine in thin solid films suggested the presence of several crystal structures. Differential scanning calorimetry (DSC) measurements were carried out for the crystals obtained from benzene solution. The measurements were carried out for single crystals, for solids obtained after slow cooling (3°/min) of the melt and for the solid after rapid cooling (100°/min) of the melt.

The patterns of DSC curves for **ES10** and **ES11** were similar to that shown in Figure 104.40 for **ES10**. The peak at 89.4°C of the single crystal (a) was split into three peaks at 63.6°, 76.3°, and 88.5°C by slow cooling of the melt (b). Quick cooling of the sample (c) gave also three peaks (67.2°, 76.7°, and 87.1°C), but the ratios of these peaks were different from that of slow cooling. The results suggested that the single crystal became a mixture of crystals by melting. In the x-ray powder diffraction patterns of **ES10** (Figure 104.41), the cast film from chloroform solution (a) showed small peaks of crystal and strong

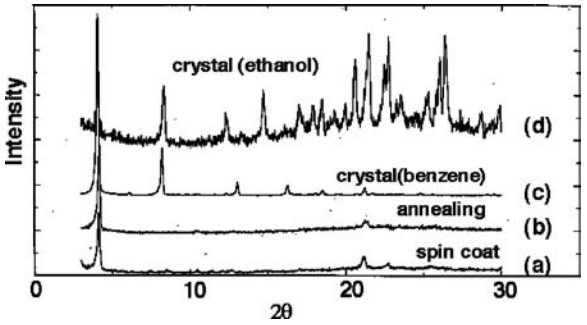

FIGURE 104.41 X-ray powder diffraction patterns for **ES10**. (a) The thin film cast from chloroform solution, (b) after annealing at 100°C (melting), (c) the single crystal from benzene, and (d) the single crystal from ethanol.

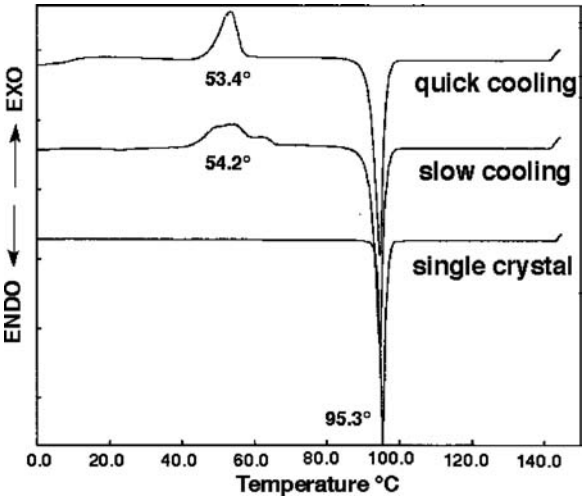

FIGURE 104.42 DSC curves for **ES12**. Heating: 5°/min. (a) The single crystal, (b) the solid after slow cooling (3°/min) of the melt, and (c) the solid after quick cooling (100°/min) of the melt.

peaks of interplanar spacing at 21.3 Å and 4.18 Å. However, the small peaks of crystal were different from the peaks of single crystals (c from benzene and d from ethanol). Melting of the single crystal gave no peaks of crystals but strong peaks of the interplanar spacing at 21.3 Å and 4.18 Å, suggesting the formation of a layered structure.

The DSC curves of the group [**ES12**, **ES13**] show similar curves as that shown in Figure 104.42 for **ES12.** A broad exothermic peak at 54.2°C in addition to a sharp endothermic peak at 94.7°C for the slow cooling sample of **ES12** (b) was observed. However, an additional endothermic peak was not shown for the peak of the single crystal (a). The exothermic peak around 54°C should be the melting of amorphous parts to form the crystal. The result indicated that the slow and the quick cooling gave the same hydrogen-bonded structure of thymines but also gave an amorphous part by aggregation of the alkyl chains. The melting point of the single crystals for **ES13** was 95.8°C. The compounds in this group gave similar patterns of x-ray powder diffraction. In the x-ray powder diffraction patterns, small peaks of the cast film from chloroform solution are the same as the peaks of single crystal from benzene. Melting of the film gave no peaks showing of crystals but gave strong peaks of interplanar spacing at 22.6 Å and 24.8 Å suggesting the formation of the bilayer structure. The DSC and the x-ray powder diffraction for the group [**ES14**, **ES15**] gave similar results as the data of the group [**ES12**, **ES13**]. The melting points of the single crystals for **ES14** and **ES15** were 97.2°C and 99.0°C, respectively.

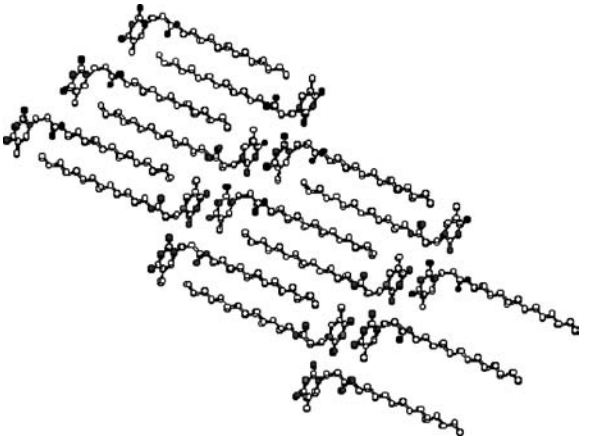

FIGURE 104.43 Crystal structures of decyl 2-(thymin-1-yl)-propionate (**ES10**) viewed along *a* axis.

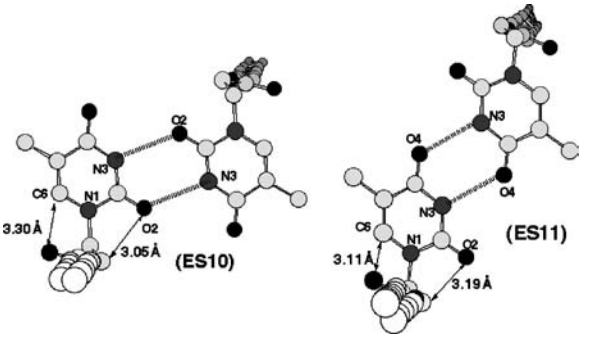

FIGURE 104.44 Racemic pairs connected by hydrogen bonds for (a) ES10 and (b) ES11.

Crystal Structure of the Ester Derivatives

Plates of decyl (**ES10**) and dodecyl (**ES12**) 2-(thymin-1-yl)-propionates and needles of nonyl (**ES9**), undecyl (**ES11**) and tridecyl (**ES13**) 2-(thymin-1-yl)-propionates were obtained from benzene solutions. Figure 104.43 shows the molecular packing of **ES10**. The crystal structure of **ES10** was the same as the structure of other ester derivatives with alkyl chains (**ES12**) containing even numbers of carbons. The only difference was the length of the *b* axis. The molecular packing of **ES11** was the same as the structures of the compounds having odd-numbered alkyl chains (**ES9**, **ES11**, and **ES13**) again apart from the length of the *b* axis. These structures show bilayer structures of the polar thymine bases and the nonpolar alkyl chains. For both structures, the thymine bases were hydrogen bonded.

The style of hydrogen bonding between thymines for the ester derivatives of the even-numbered alkyl chains (**ES10** and **ES12**) was different from the style for the compound with the odd-numbered alkyl chains (**ES9**, **ES11** and **ES13**). Figure 104.44 shows the hydrogen bonding pairs of the ester derivatives of thymine for **ES10** and **ES11**. In the crystals of **ES11** and of the odd-numbered alkyl chain derivatives, the hydrogen bonding formed between N3-H and O4 (Figure 104.44b), which was the usual hydrogen bonding observed in DNA (Watson-Crick type[64]). On the contrary, the hydrogen bonding for **ES10** and **ES12** was formed between N3-H and O2 (Figure 104.44a), which is the reversed Watson-Crick type.[65] The lengths of the hydrogen bonds, however, were 2.8 Å for both crystals. Watson-Crick type hydrogen bonding of thymine bases is more stable than the reversed Watson-Crick type because the basicity of O4 is higher than the basicity of O2[66] and the first protonation occurs at O4 of uracil.[67] The hydrogen bonding

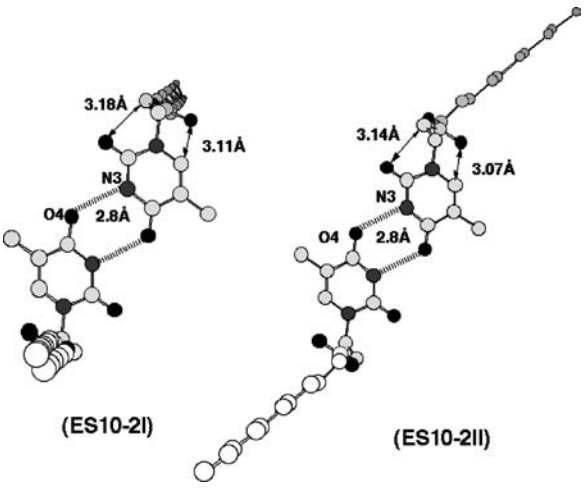

FIGURE 104.45 Two racemic pairs connected by hydrogen bonds for ES10–2. (a) ES10-2I and (b) ES10-2II.

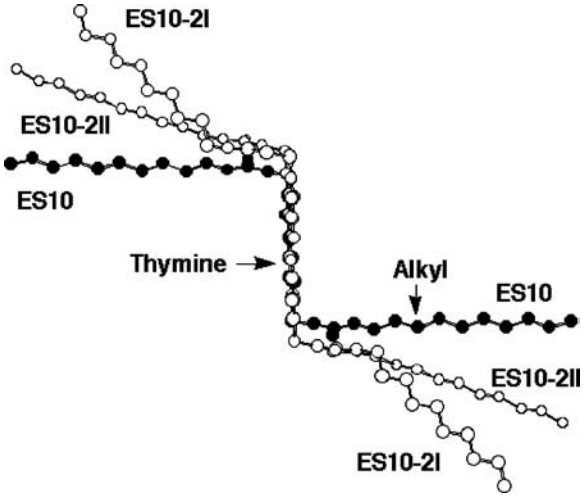

FIGURE 104.46 Three kinds of base pairs for **ES10**, **ES10-2I** and **ES10-2II.**

at O4, in preference to O2, was also shown for thymine monohydrate crystals[68] and 1-(2-hydroxyethyl)uracil[69] where water or the hydroxyl group formed the hydrogen bonds with O4 instead of O2. The unstable hydrogen bonds in **ES10** may be formed by blocking of O4 because of the absence of a hydroxyl group in **ES10**.

From ethanol solution, needles of decyl 2-(thymin-1-yl)propionate (**ES10–2**) were obtained. The crystal structure of **ES10–2** consists of two independent molecules forming a racemic pair. Figure 104.45 shows two kinds of conformations (**I** and **II**) in the crystal. The hydrogen bonds of the thymine bases in this crystal were formed between O4 and N3-H (Watson-Crick type) that is the same seen with derivatives with odd-numbered alkyl chain (Figure 104.44b). One base pair **I** (Figure 104.45a) shows a similar conformation to **ES11** where the alkyl chain is perpendicular to the thymine ring. The alkyl chains of the other base pair **II** (Figure 104.45b), however, were in an extended conformation.

In Figure 104.46, the angles of the alkyl chains from the thymine ring for three base pairs (**ES10**, **ES10-2I,** and **ES 10-2II**) were compared. The highest angle was **ES10-2I** (138°) and the lowest was **ES10** (93°).

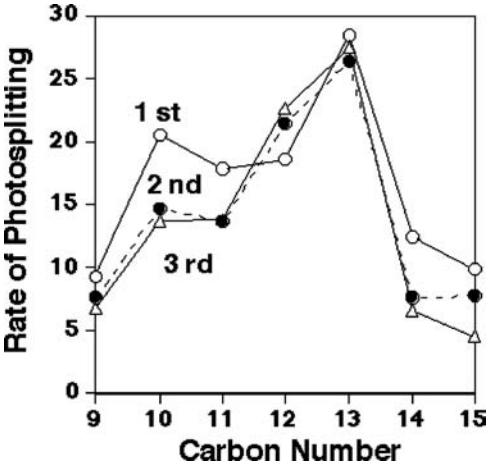

FIGURE 104.47 The initial rate of the photosplitting against the carbon number of the alkyl chains: (°) the first, (l) the second, and (Í) the third photosplitting. UV irradiation: 240 nm.

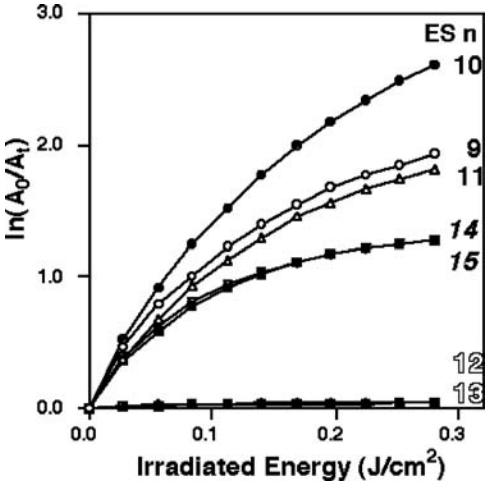

FIGURE 104.48 The conversions of the photosplitting of the photodimer in the annealed film from **ES9** to **ES15**. UV irradiation: 240 nm. The numbers are the carbon number of the alkyl chain.

However, the angles of the carboxyethyl group from the thymine were similar for the three pairs because of the interactions between the carbonyl group of the ester and C6 of the thymine base and between the carbonyl group at C2 of the thymine base and the α-methylene of the ester group (Figure 104.44). A higher dihedral angle of the alkyl chains from the thymine ring for **ES10-2** should result in a loose interaction of the molecules to form stable hydrogen bonds.

Photosplitting of the Photodimer

The thymine photodimers formed by UV irradiation at 280 nm in thin solid films were monomerised by UV irradiation at 240 nm. Figure 104.47 shows the results of photosplitting of **ES9** to **ES15**. The fastest reaction of photosplitting was observed for **ES13**. The dependence of the first photosplitting on the carbon number in Figure 104.47 was similar to that of the photodimerization in Figure 104.38, but the rates for **ES10** and **ES11** were fast compared with the case of the photodimerization. The photosplitting of the photodimer formed in the annealed film gave also irregularity for **ES12** and **ES13** (Figure 104.48).

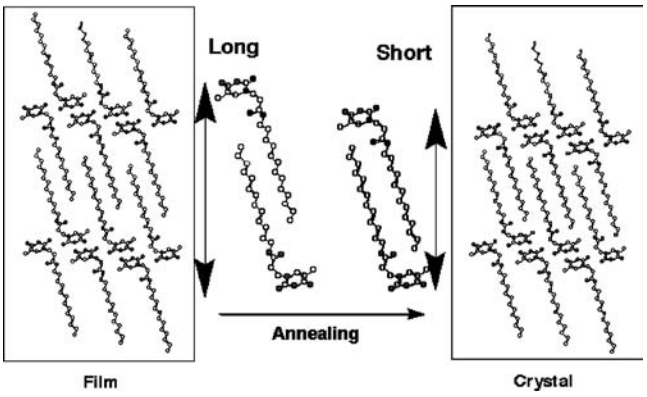

FIGURE 104.49 Illustration of the layered structure in the thin solid film and the crystal structure of **ES13**.

Summary of Photodimerization and Photosplitting of Ester Derivatives of Thymine

The results of the photodimerization and photosplitting reactions in thin solid films raises three questions: (1) classification of the first photodimerization reactions to four groups, (2) the fastest reaction for **ES13** and (3) absence of photodimerization by annealing of **ES12** and **ES13**. These questions will be made clear by crystal structure, DSC, and x-ray powder diffraction for the thin solid film as follows.

Photodimerization in Solid Film

For the photodimerization of the thymine derivatives in thin solid films, the essential factor is the rotation of the thymine bases during photodimerization. The data of the powder x-ray diffraction of the thin film indicated that the film has a layered structure. The layered structure should be formed by loose interaction of the alkyl chain of the hydrogen-bonded thymine pairs. The layered structure of the film is illustrated and compared with the crystal structure for **ES13** (Figure 104.49), where the distance between the layers in the thin solid film is longer than that of the crystals as supported by the powder x-ray diffraction. In the layered structure of the thin film, the rotation of the thymine bases should be possible, because the distance between the thymine and the terminal methyl group of alkyl chain is sufficiently long. With this arrangement the thymine compounds in the layered structure of the thin solid films are able to undergo photodimerization. The alkyl chain length may influence the arrangement of the layered structure and the photodimerizations are affected by the length of the alkyl chain (Figure 104.38). The thin solid films of the third group [**ES12**, **ES13**] had high activity for the first photodimerization. The photodimerization of the thymine bases should be fast in the layered structure of this group, where the thymine bases are arranged suitably for photodimerization and the rotation of the thymines is possible.

Annealing of the Film

The DSC data indicated that the thin solid films of **ES9** contain mixtures of two crystals, even if the crystals are formed after annealing. In the case of the second group [**ES10**, **ES11**], the thin solid films of this group contain three crystals when crystallization occurred in the film. Therefore, the photodimerization of these groups occurred after annealing of the film.

The third and fourth groups [**ES12**, **ES13**] and [**ES14**, **ES15**] are different from the former two groups. The single crystals melt at around 100°C and reform the same crystalline state on cooling. Recrystallization is accompanied by the formation of an amorphous part. The crystals formed by cooling should be inactive for photodimerization, although the amorphous part is active. The amorphous part of [**ES12**, **ES13**] may be small while that of [**ES14**, **ES15**] may be large.

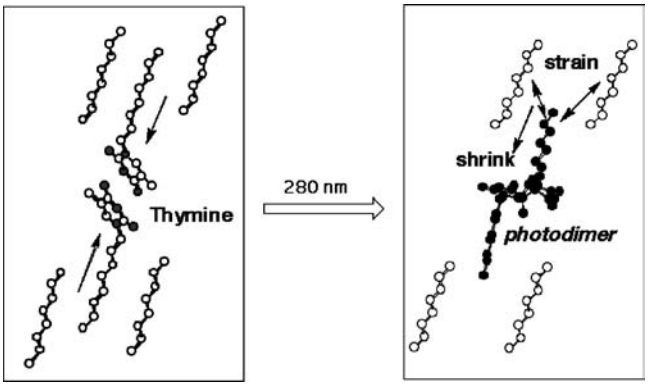

FIGURE 104.50 The induced strain during the photodimerization of thymine bases in the crystal (illustration).

Photosplitting

As shown in Figure 104.47, the rates of the first photosplitting increase with an increase in the length of the alkyl chains and decreases after **ES13**. Photosplitting of the thymine photodimer in solution is caused by steric repulsion of the C5-methyl groups of the thymine base. On the other hand, the photosplitting in the solid state is caused by the strain within the crystal lattice in addition to the strain of the C5-methyl groups. The reason is that the photodimerization of thymine bases with long alkyl chains in crystals induces the rotation of the thymine bases, thus involving strain in the crystal as illustrated in Figure 104.50. When the alkyl chains are long, the strain within the crystal lattice becomes strong because the interaction of the alkyl chains increases with the increase in the length of the chain. The rate of the photosplitting reaction should increase with lengthening alkyl chain. The reason for the slow reaction of [**ES 9**] and [**ES14**, **ES15**] is not clear, but low yields of photodimers may not cause high strain in the thin solid films.

104.5 Conclusion

Reversible photodimerizations of 1-*n*-alkylthymine in single crystals depend on the crystal structures. However, the orientation of the thymine bases in the single crystal does not correspond to the isomer of the photodimer formed because thymines undergo disrotatory motion during the photodimerization process in the single crystals. The most important factor of the crystal structure for the photodimerization is the distance between the thymine base and the terminal methyl group of alkyl chain because this can influence the rotation of the thymine bases.

The rate of photodimerization of thymine bases in thin solid films is fast in the amorphous areas. Annealing of the film cause crystallization to give inactive crystals. Alkylthymines with chains around C_{10} show polymorphism and the thin solid films contain many crystalline forms. Therefore, the films of thymine compound with C_{10} chains are very active for photodimerization.

Acknowledgments

The author would like to express his grateful acknowledgment to Dr. Norimitu Thonai and Dr. Eiko Mochizuk who obtained the results in this chapter. The author gratefully acknowledges the invaluable discussions with Prof. Mikiji Miyata and Prof. Yasusi Kai.

105.1 Introduction

The chemical modification of nucleic bases is recognized as one of the most promising approaches for developing bioactive substances such as anticancer and antiviral agents.[1]

The photochemistry of 5-bromouracil and its derivatives has been studied extensively in relation to radiation chemistry, radio-sensitization, and photobiology,[2] but little attention has been paid from a synthetic point of view.

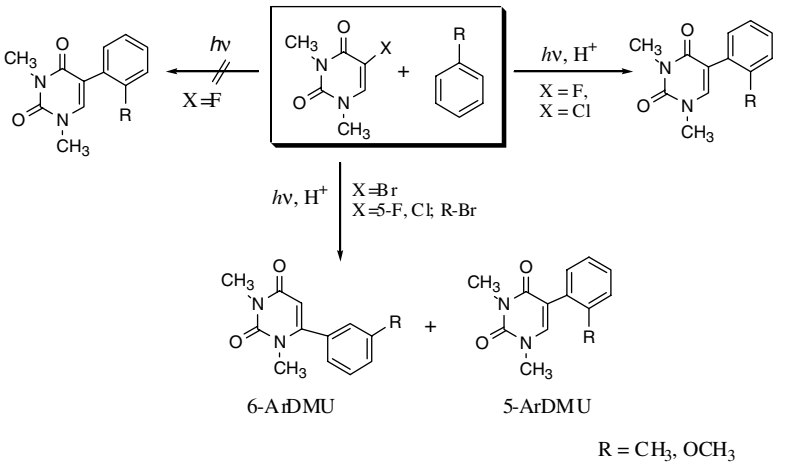
This chapter deals with the photoaddition reactions of halogenated pyrimidines with benzene derivatives.

105.2 Acid-Catalyzed Electrophilic Aromatic Photosubstitution Reactions with 5-Halo-1,3-dimethyluracils

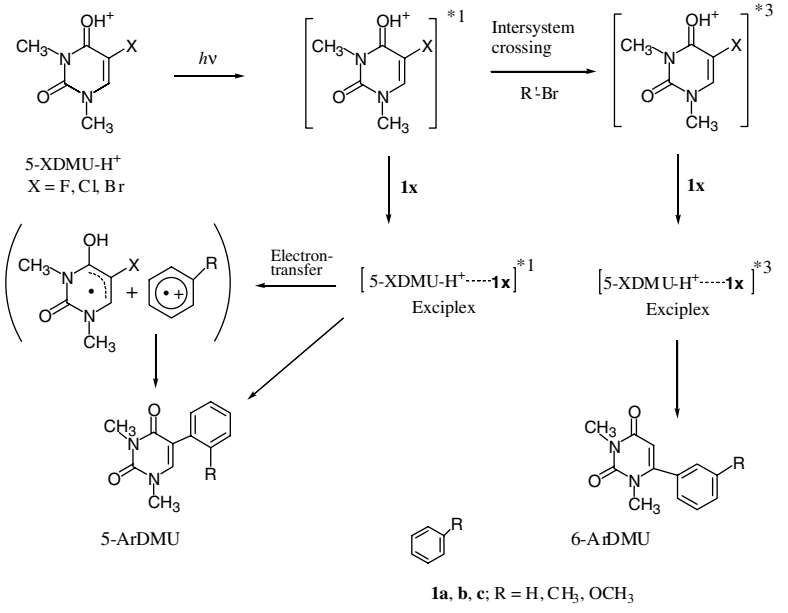
UV irradiation of 5-bromo-1,3-dimethyluracil (5-BrDMU) in benzene (**1a**) afforded 5-pheny-1,3-dimethyluracil (5-PhDMU), while prolonged irradiation of the solution afforded not only the corresponding 5-phenyl-1,3-dimethyluracils (5-PhDMU) but also the unexpected 6-phenyl isomer (6-PhDMU).[3] Similar results were obtained from the reaction of the uracil with substituted benzenes (Scheme 1). Detailed studies revealed that formation of the 6-aryl isomers (6-ArDMU) was effected by hydrogen bromide generated during the photoreaction.[4,5] It was suggested that the 5-isomers (5-ArDMU) are the products obtained through the excited singlet states, while 6-ArDMUs are produced via the excited triplet states. The anomalous 6-arylation was also effected by the addition of TFA. Noteworthy is the fact that 5-substitution occurred mainly at the *ortho*-position of the substituted benzenes while 6-arylation took place most favorably at the *meta*-position.

The isomer distribution for 5-ArDMU's was analogous to those typically observed in aromatic photosubstitution reactions.[6] On the other hand, few reports have appeared on the *meta*-oriented aromatic photosubstitution reaction, the primary example being the photoinduced proton exchange in benzenes[7] that proceeds via an electrophilic aromatic photosubstitution reaction.[8] In the case of either the 5-chloro- or 5-fluoro-1,3-dimethyluracil (5-ClDMU, 5-FDMU),[9,10] addition of TFA simply promoted 5-arylation (photo-Friedel-Crafts reaction), while the addition of a bromide (*p*-dibromobenzene, 1,2-dibromoethane, benzyl bromide, HBr) to the solution induced the *meta*-oriented 6-arylation (Scheme 2).[11]

It is proposed that 5-substitution is explicable by a mechanism involving an electron transfer from a benzene ring (**1x**) to **5-XDMU**-H$^+$ (X = Br, Cl, F), while 6-ArDMUs are derived from the direct coupling



SCHEME 2



SCHEME 3

between the excited **5-XDMU**-H^+ in the triplet state and **1x** in the ground state or through the triplet exciplex (Scheme 3).

105.3 Acid-Catalyzed Photoreaction of 6-ClDMU with Benzene and Its Derivatives: Synthesis of Cyclooctapyrimidine-2,4-diones

This acid-catalyzed photoreaction has successfully been applied to 6-chloro-1,3-dimethyluracil (6-ClDMU).

[a] Yields are reported on the basis of 6-ClDMU consumed.

UV irradiation of 6-ClDMU in a solution of benzene (**1a**) afforded 6-PhDMU through a substitution reaction. In sharp contrast, addition of TFA (2 molar equiv) to the reaction mixture induced [1,2]-photocycloaddition to give cyclooctapyrimidine (**2a**) in high yield (Scheme 4).[12] Among the various acids examined, trifluoroacetic acid (TFA) gave the best result for the formation of **2a** (Table 105.1).[13]

The photoreaction with monosubstituted benzenes (toluene **1b**, anisole **1c,** and fluorobenzene **1d**) in the presence of TFA at room temperature afforded the corresponding cyclooctapyrimidines (**2xn**: **x** = **b**, **c**, **d**; **n** = **i**, **ii**, **iii**, **iv**, **v**, and **vi** for substitution at 5, 6, 7, 8, 9, and 10) (Scheme 5, Table 105.2).

The photoreaction with *p*-xylene (**1e**) furnished predominantly the 5,8-dimethyl derivative (**2ei**) at low temperature (−58°C), while **2ei** and the 7,10-dimethyl derivative (**2eii**) were produced in the ratio of 1:3 at −25°C (Scheme 6).[14]

Similarly, UV irradiation of 6-ClDMU in mesitylene (**1f**) in the presence of TFA at −25°C for 5 h gave 5,7,9-trimethyl derivative (**2fi**) (20%) and 6,8,10-methyl isomer (**2fii**) (34%) in appreciable yields (Scheme 7).[15]

The UV spectrum of 6-ClDMU (λ_{max} 264 nm; 0.08 m*M*) shifted ca. 6 nm to the red in cyclohexane on the addition of TFA (9 molar equiv.) to the solution. This new spectrum was insensitive to added **1a**, whereas the fluorescence of this solution (emission λ_{max} at 330 nm with excitation at 285 nm) was quenched with **1a** (1.7 m*M*). Furthermore, addition of the triplet quencher piperylene to the reaction mixture of **1a** was ineffective in initiating the formation of **2a**, suggesting that the present cycloaddition may precede via the singlet excited state of protonated 6-ClDMU. This presumably occurs at either O-4 or the charge-transfer complex of 6-ClDMU and TFA.[13]

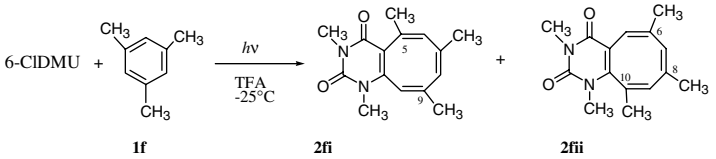
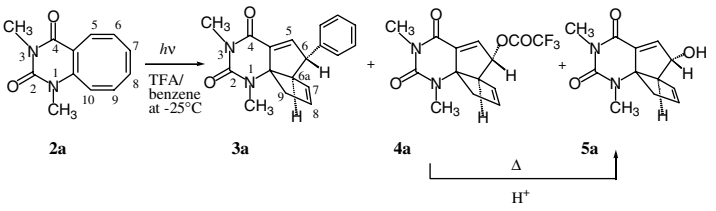


SCHEME 7

105.4 Acid-Catalyzed Photorearrangement of Cyclooctapyrimidines: Synthesis of (6a,1-d)Pentalenopyrimidine

Cyclooctatetraenes are one of the most interesting and well studied non-benzenoid $(CH)_n$ families that provide a considerable variety of isomeric strained compounds.[16,17] This section deals with the photochemical modification of cyclooctapyrimidines.



SCHEME 8

UV irradiation of a solution of cyclooctapyrimidine-2,4-dione (**2a**) in benzene with a 500 W high-pressure mercury lamp either at room temperature or at low temperature (−25°C) in the absence of TFA did not induce any reaction. Similarly, irradiation in the presence of 2 molar equivalents of TFA also gave no photoproduct.

However, it was found that at low temperature (−25°C) a photorearrangement product began to appear as the amount of TFA was increased. When a large excess of TFA (10 molar equiv) was used, tricyclic compounds 9*H*-6,6a-dihydro-1,3-dimethyl- 6-phenylpentaleno[6a,1-d]pyrimidine-2,4-dione (**3a**), 10,12-diaza-10,12-dimethyl-9,11- dioxotricyclo[6.4.0.0^{1,5}]dodeca-3,7-dien-6-yl 2,2,2-trifluoroacetate (**4a**), and 6-hydroxypentaleno[6a,1-d]pyrimidine (**5a**) were obtained in 55%, 5%, and 23% yields, respectively (Scheme 8).[18] When the reaction was performed in cyclohexane, the formation of **3a** could not be detected and the predominant product was trifluoroacetate (**4a**). Similarly, UV irradiation of the C-methyl derivatives (**2bii**, **iv**, **v**) in frozen benzene containing TFA gave varying yields of trifluoroacetoxypentaleno[6a,1-d]pyrimidines (**4b**) and/or phenyl derivative (**3b**) (Scheme 9).

The tri-C-methyl derivative (**2fii**) under similar conditions, furnished 7-methylene-1,3,6,9-tetramethylpentaleno[6a,1-*d*]pyrimidine-2,4-dione (**6fii**) in appreciable yield. Each of these structures contains a methyl group attached to the same carbon as the parent compound.

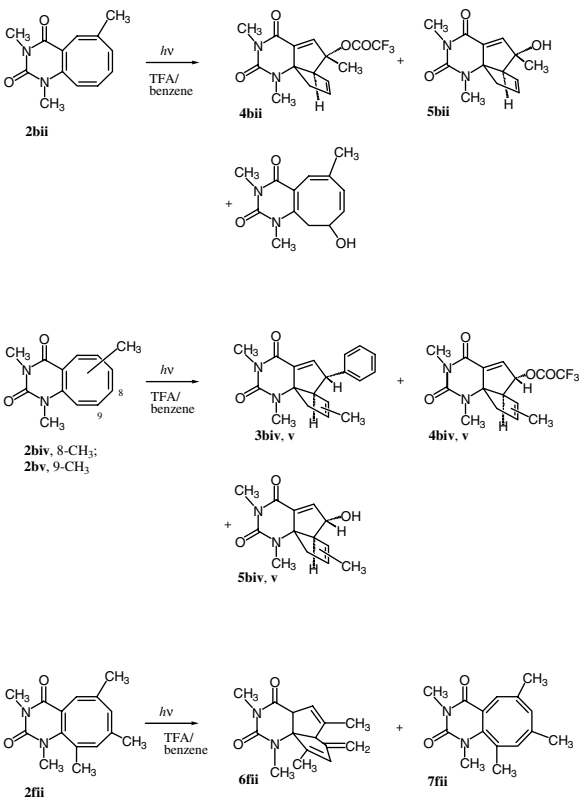
The participation of a di-π-methane process[19,20] through the benzocyclobutapyrimidine intermediate (**8bii**, **9bii**; R = CH_3) was ruled out (Scheme 10) by the fact that reaction with the 6-isomer (**2bii**) gave neither **3bii** nor **4bii**, but produced **3biii** and **4biii**.

The formation of these tricyclic compounds (**3**, **4**, and **5**) was explained in terms of a [π4s + π2a] type rearrangement[21] of the cyclooctatetraene moiety into the semibullvalene intermediate (**8**) or (**9**), followed by subsequent ring opening of the cyclopropane moiety through protonation. The MO of **2a,** on which the effect of TFA was neglected, showed that the LUMO (Figure 105.1A) has a large extension over C4a and C10a, and the next LUMO (NLUMO) (Figure 105.1B) extends largely over C7, C8, C9, and C10, supporting the [π4s + π2a] process.[22]

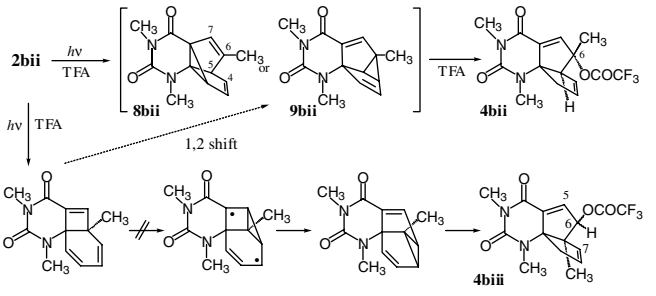
The role of acid in the photoreaction was studied using UV-spectroscopy. Sequential addition of TFA (0 to 10 molar equiv.) to a solution of **2a** in cyclohexane decreased the UV absorbance at λ_{max} 249 nm (ε = 10400) to ε = 9960 and increased the λ_{max} 307 nm (ε = 1640) to ε = 1820 with isosbestic points at 242 and 248 nm. Addition of aqueous potassium carbonate (2 molar equiv. to TFA added) returned the spectrum to its original form, suggesting that **2a** forms a charge-transfer complex with TFA. The other C-methylcyclooctapyrimidines (**2b**, **e**, **f**) that underwent the rearrangement showed similar spectroscopic behavior.

The effect of TFA on **2a** was investigated further using NMR spectroscopy. The signals due to C10a, C6, C9, and C4a were shifted downfield upon the addition of TFA, while the signals due to C5 and C10 were shifted upfield. The chemical shifts change drastically in the region of the plot where the amounts of TFA are increased from 0 to 3 molar equiv.. The changes, however, in the region where TFA is increased above 5 molar equiv. are minimal (Figure 105.2).

These results demonstrate that the presence of excess amounts of TFA is required for formation of the charge-transfer complex that is responsible for the photorearrangement into the semibullvalene intermediate (**8b** or **9b**). When **2a** was irradiated in the presence of TFA-*d*, significant amounts of deuterium



SCHEME 9



SCHEME 10

were incorporated into **3a**, and **4a** at C9 (50% for **3a**, and 94% for **4a**), suggesting that the resulting intermediate undergoes either a Friedel-Craft reaction or the addition of TFA to give the phenypentaleno[6a,1-*d*]pyrimidine (**3a**) or trifluoroacetoxy pentaleno[6a,1-*d*]pyrimidine (**4a**). Protonation of **8b** (or **9b**) would generate the carbocation center at C6 with the cleavage of the cyclopropane ring, which couples with benzene to form the ultimate product (**3a**), while the addition of TFA would lead to the formation of **4a**.

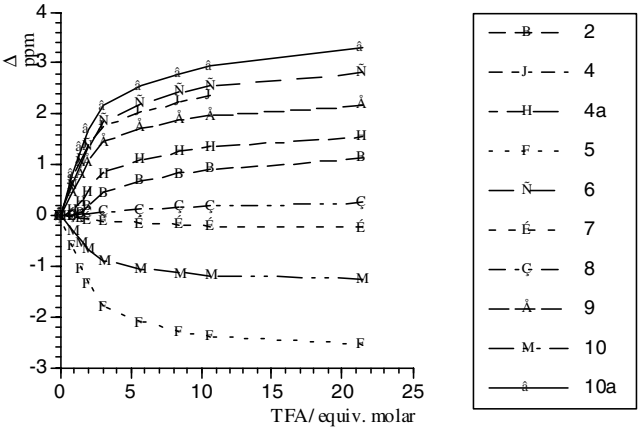

FIGURE 105.2 Changes in the ^{13}C-NMR chemical shifts of **2a** by the addition of TFA.

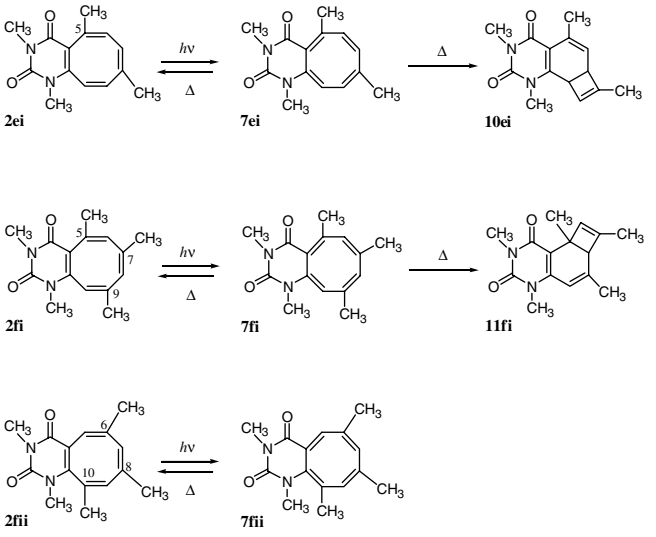
105.5 Synthesis of the Tautomeric Isomers of Cyclooctapyrimidines and their Photorearrangement

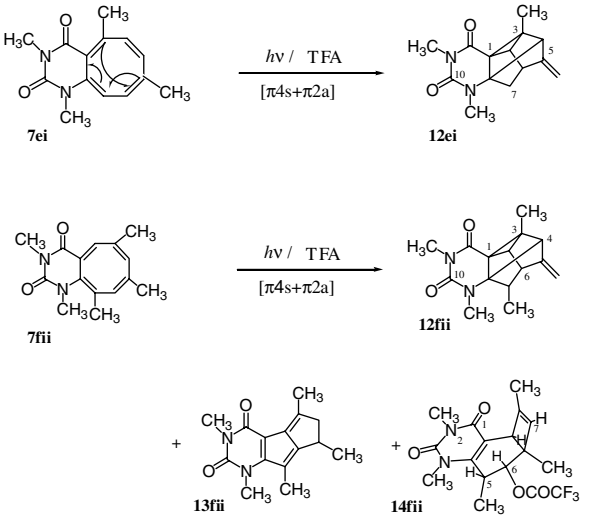
Photorearrangement of Cyclooctapyrimidine in the Absence of Acid: Synthesis of the Tautomer (*p*-Xylene)

UV irradiation of a solution of 1,3,5,8-tetramethylcyclooctapyrimidine (**2ei**) in benzene in the absence of an acid at room temperature for 1 h effected bond-switching to produce the tautomer (**7ei**)[23] as an equilibrium mixture with the starting material (1:10) (isolated by column chromatography on silica gel) (Scheme 11). Prolonged irradiation (4 h) of the solution was ineffective in altering the product ratio. No formation of other valence isomers was detected under the reaction conditions (Scheme 2).[16] Upon heating in the dark, transformation into cyclobutaquinazoline (**10ei**) occurred through an intramolecular Diels-Alder reaction.

Similar irradiation of 1,3,5,7,9- and 1,3,6,8,10-pentamethylcyclooctapyrimidine-2,4-diones (**2fi**, **2fii**) gave the corresponding tautomeric isomers (**7fi**, **7fii**).[24] Upon being kept in the dark at room temperature, the former (**7fi**) (half life, 30 min) was transformed into cyclobutaquinazoline (**11fi**) with competitive reversion into **7fi**, while the latter (**7fii**) reverted to **2fii** with half-life of 8 h.



SCHEME 11



SCHEME 12

Acid-Catalyzed Photorearrangement of Tautomer (7) in the Presence of TFA ([π4s + π2a] Reaction)

UV irradiation of **7ei** (6,8,10-methyl) in the presence of TFA gave rise to the formation of 9,11-diazapentacyclo[6.4.0.0.^{1,3}0.^{2,5}0^{4,8}]dodecane (**12ei**) as the major product.

Similar photolysis of **7fii** (6,8,10-trimethyl) in benzene in the presence of TFA for 18 h furnished 9,11-diazapentacyclo[6.4.0.0.^{1,3}0.^{2,5}0^{4,8}]dodecane (**12fii**) as the major product, together with pentaleno[2,1-*d*]pyrimidine (**13fii**) and a cyclobutaquinazoline derivative (**14fii**).[25,26]

The formation of these pentacyclic compounds (**12**) was explained by the analogous mechanism employed for the photorearrangement of cyclooctapyrimidines (**2**) involving a [π4s + π2a] process (Figure 105.3).[22] Through this process, **7** would be transformed into the semibullvalene intermediate

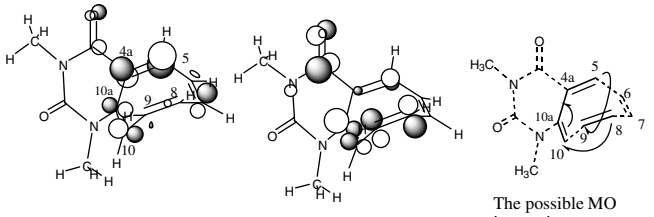


FIGURE 105.3 The molecular orbitals of **7a**.

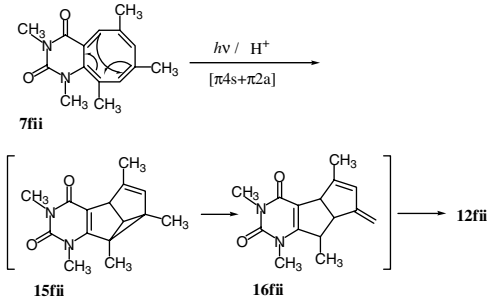
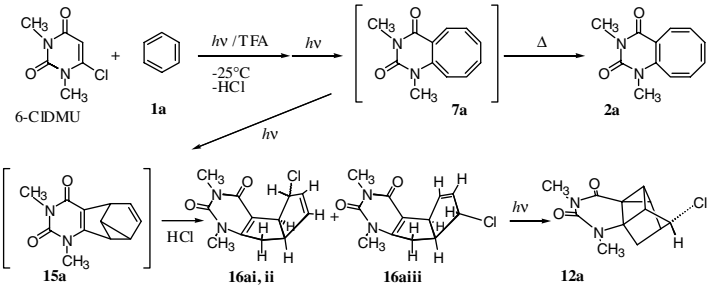


SCHEME 13



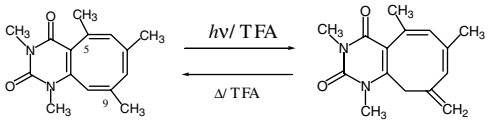
SCHEME 14

(**15fii**), followed by subsequent ring opening of the resulting cyclopropane moiety through protonation.[27] Subsequent intramolecular [2+2]-coupling of the resulting pentalenopyrimidine (**16fii**) would ultimately lead to its transformation into **12fii** (Scheme 13).

Although the synthesis or the detection of the tautomer of the simple cyclooctapyrimidine (**2a**) derived from **1a** was unsuccessful, photolysis of 6-ClDMU in frozen benzene (−25°C) in the presence of TFA resulted in the formation of pentalenopyrimidine derivatives (**16ai**, **ii, iii**) and a diazapentacyclo[6.4.0.0^{1,3}.0^{2,6}.0^{4,8}]dodecane derivative (**12a**) in moderate yields (Scheme 14).[28] These results indicate that the tautomer (**7a**) may be involved in the present reaction as the key intermediate.

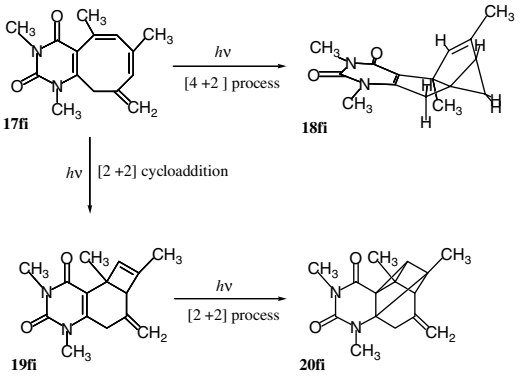
UV irradiation of the pentalenopyrimidine (**16aiii**) gave **12a**.[29]

These results substantiate the mechanism that pentacyclic compounds (**12x**) are derived from the tautomeric isomer (**7x**) by way of the semibullvalene intermediate (**15x**) followed by rearrangement to pentalenopyrimidine (**16x**). Thus, the present work demonstrates that pentacyclo[6.4.0.0.^{1,3}0.^{2,6}0^{4,8}]dodecanes (**3x**)



2fi **17fi**

SCHEME 15



17fi **18fi** **19fi** **20fi**

SCHEME 16

are products from the initial *ortho*-cycloaddition, but not from the *meta*-cycloaddition between 6-ClDMU and a benzene.[30]

105.6 Acid-Catalyzed Sigmatropic Rearrangements

Synthesis of 9-Methylenecyclooctapyrimidine

As described above, UV irradiation of cyclooctapyrimidines (**2x**) in the absence of an acid undergoes bond-switching to form the corresponding tautomers. In contrast, in the presence of TFA, photoisomerization of **2x** bearing a methyl group at C9 or C10 proceeds in a different manner.

Upon irradiation in the presence of TFA at room temperature for 1 h, **2fi** was quantitatiely transformed into the *exo*-methylene derivative (**17fi**) (Scheme 15).[15,26]

No deuterium uptake into **17fi** was observed when **2fi** was irradiated in the presence of TFA-*d*, suggesting that the present process can be regarded as an acid-catalyzed sigmatropic reaction.

In the presence of TFA, **17fi** was exclusively converted back to **2fi** in the dark.

Photorearrangement of *exo*-Methylenecyclooctapyrimidine

Irradiation of **17fi** at room temperature for 30 min effected the competitive synthesis of **18fi** (25%) through a [4+2]-process and cyclobutaquinazoline **19fi** (75%) via a [2+2]-process (at the stage when 35% of **2fi** had been consumed). Cyclobuta[*f*]quinazoline (**19fi**) was further converted to **20fi** *via t*he secondary [2+2]-process (Scheme 16).[15,26]

It is suggested that the NLUMO of **17fi** consists of 6π electrons developing over the carbon atoms C5–C9 and the *exo*-methylene carbon, which is responsible for the formation of **18fi** through the [π4s + π2a] orbital interaction (Figure 105.4). This process is regarded as analogous to that reported for the photo-transformation of vitamin D_3 into suprasterol I and II.[31,32]

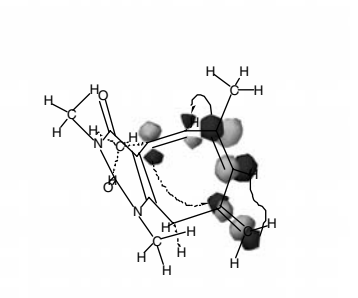


FIGURE 105.4

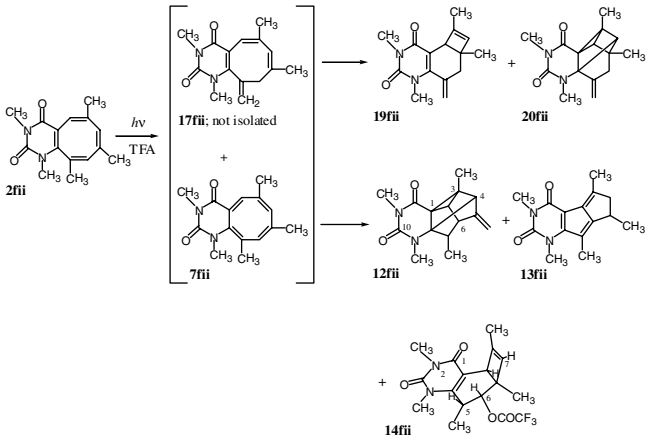


SCHEME 17

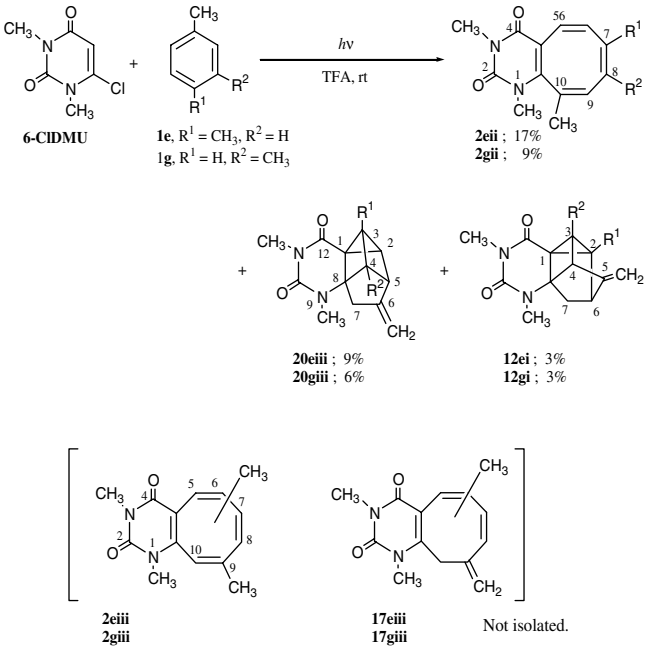
The 6,8,10-methylyclooctapyrimidine (**2fii**) is much less sensitive to UV irradiation than the 5,7,9-methyl isomer (**2fi**). Nonetheless, prolonged irradiation of **2fii** resulted in the competitive formation of its valence isomers (**19fii**, **20fii**), apparently through the *exo*-methylene intermediate (**17fii**) by way of a sigmatropic rearrangement, though not isolated, with pentalenopyrimidines (**12fii**, **13fii**) through the tautomer (**7fii**) (Scheme 17).[26]

Photoreaction of 6-ClDMU with *p*-xylene (**1e**) and *m*-xylene (**1g**) in the presence of TFA furnished the 6-methylenediazapentacyclo[6.4.0.0^{1,3}.0^{2,5}.0^{4,8}]dodecanes (**20eiii**, **20giii**)[33] together with 5-methylenediazapentacyclo[6.4.0.0^{1,3}.0^{2,6}.0^{4,8}]dodecane derivatives (**12ei**, **12fi**) (Scheme 18).[34] Due to the presence of the *exo*-methylene group at C6, these compounds (**20eiii**, **20giii**) can be regarded as originating from the 9-*exo*-methylene derivatives (**17eiii, 17giii**), although their isolation or detection has not yet been achieved (see Scheme 19).

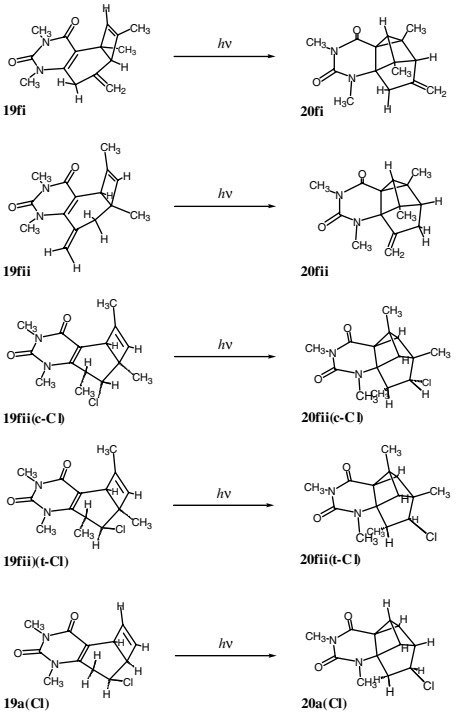
Photorearrangement of Cyclobutapyrimidines

As described above, each pentacyclo[6.4.0.0^{1,3}.0^{2,5}.0^{4,8}]dodecane (**2a**-**d**) includes a methylene group at C6 or C7 as a component, suggesting that the presence of a methylene group at C6 or C7 in the precursory cyclobutaquinazoline may be important for the construction of the ring system (Scheme 19).[35]

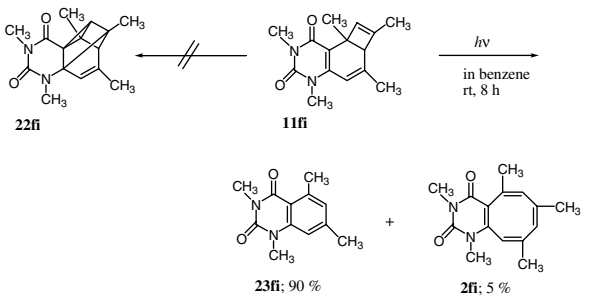
Recently, it was shown that the hydrochlorinated cyclobutaquinazolines (**19fii-cCl**,[35] **19fii-tCl**,[36] **19a-Cl**[30]), which have no *exo*-methylene group, underwent cycloaddition to give the corresponding pentacyclododecane derivatives (**20fii-cCl**, **20fii-tCl**, **20a-Cl**).



SCHEME 18



SCHEME 19



SCHEME 20

In contrast, UV irradiation of **11fi**, which retains the double bond between C5 and C6, resulted in the cleavage of the cyclobutene ring to produce propyne and quinazoline (**23fi**) in place of the anticipated pentacyclododecane (**22fi**) (Scheme 20). These findings indicate that the removal of the C5–C6 double bond may be essential for the formation of pentacyclo[6.4.0.0^{1,3}.0^{2,5}.0^{4,8}]dodecanes.

105.7 Summary

The present chapter describes various aspects of photoreaction with halouracils and benzenes, as listed below.

1. Aromatic photosubstitution, including acid-catalyzed photosubstitution reaction (photo-Friedel-Crafts reaction)
2. Anomalous aromatic photosubstitution regarded as related to an electrophilic aromatic photosubstitution reaction
3. Photocycloaddition of 6ClDMU to benzenes
4. Valence isomerization of the cycloadduct that could be explained in terms of (a) acid-catalyzed sigmatropic rearrangement, (b) [2 + 2] cycloaddition, (c) [π4s + π2a]-type cycloaddition, (d) [π4s + π2a] type electrocyclic reaction
5. Synthesis of various novel cycloadducts, including highly strained polycyclic compounds, through these various photochemical processes

Noteworthy is that a majority of these photoreactions take place only in the presence of acids (TFA). Thus, the present studies provide not only useful methods for modifying the pyrimidine ring, but also incorporate a novel photoreaction wherein the presence of acid can be employed to switch the photochemical behavior via a novel acid-catalyzed photoreaction.[37]

The Photochemistry of Thioamides and Thioimides

Masami Sakamoto
Chiba University

Takehiko Nishio
University of Tsukuba

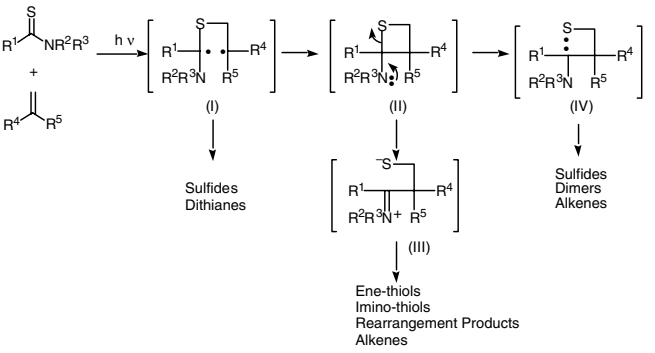
106.1 Introduction

The photochemistry of thiocarbonyl compounds has been extensively studied over the past three decades and many new photochemical reactions have been developed.[1–7] Thiocarbonyl compounds, such as thioketones and thioesters, show considerably high photochemical reactivity toward (2+2)-cycloaddition and hydrogen abstraction by thiocarbonyl sulfur. Simple thioamides are generally inert toward photolysis; however, in contrast, cyclic thioamides and arylthioamides show considerable reactivity in a variety of photochemical reactions such as photochemical (2+2)-cycloaddition with various alkenes, and which provides a method for the synthesis of a new C–C bond. The thioimides are more reactive than thioamides toward the photochemical cycloaddition to multiple bonds and hydrogen abstraction by thiocarbonyl sulfur atom. Most thioamides are conveniently prepared by sulfurization of the corresponding amides with thionation reagents such as Lawesson's reagent or phosphorous pentasulfide. Monothioimides or dithioimides are usually provided by thionation of the corresponding imides with the same thionation reagents or acylation of the corresponding thioamides. The photochemical reaction of thioamides and thioimides provides not only a new photochemical aspect in the area of organic photochemistry but also a useful synthesis of nitrogen-containing heterocycles. Some reviews for thione photochemistry, including thioamides and thioimides, have been reported; therefore, the photochemical reactions in this chapter are limited to those developed in the past ten years.[8–11]

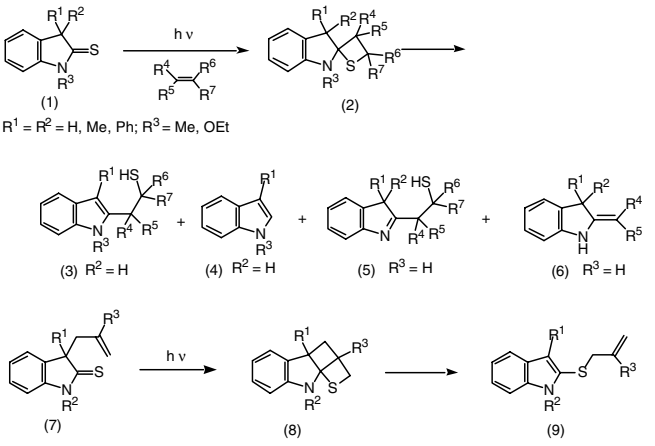
106.2 Photochemical (2+2)-Cycloaddition Reaction of Thioamides and Thioimides

Photochemical (2+2)-photocycloaddition of thiocarbonyl compounds with multiple bonds is a well-studied reaction. Thioamides undergo both inter- and intramolecular photocycloaddition reactions with alkenes to afford a variety of adducts (Scheme 1). The aminothietanes (II), formed as the primary

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1

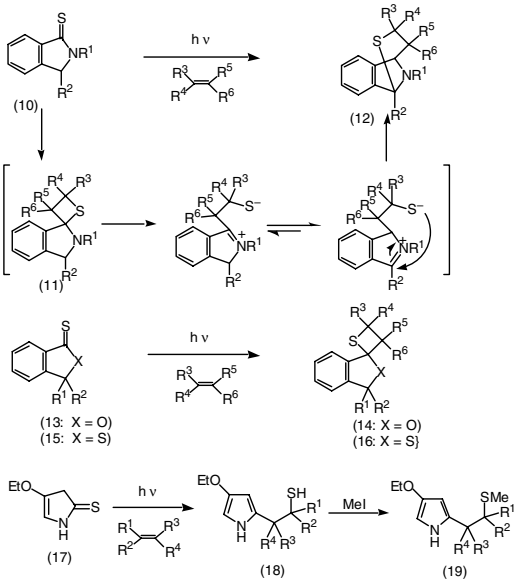


SCHEME 2

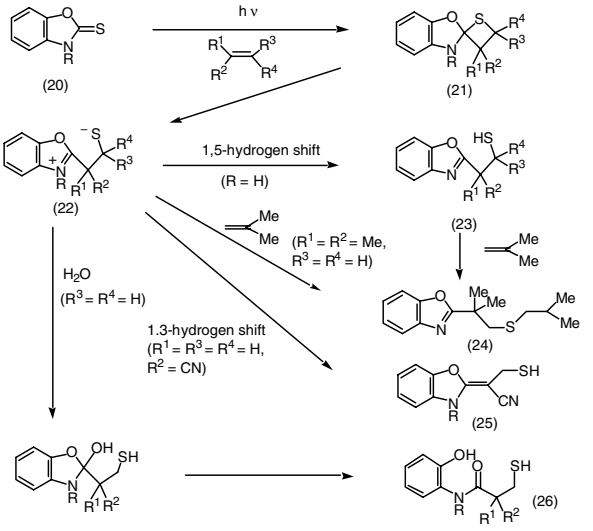
products via biradical (I), are generally unstable and undergo C–S bond cleavage of the thietane ring, leading to zwitterions (III) or diradicals (IV), followed by subsequent reactions. The instability of aminothietanes (II) may be due to the participation of lone-pair electrons on the nitrogen atom. Therefore, suppressing the participation will stabilize the aminothietanes. In fact, thietanes derived from thioimides (R^2 or R^3 = acyl group), in which the nitrogen atoms are cross-conjugated with a carbonyl or thiocarbonyl group, show considerable stability and many thietane derivatives are isolated. The photochemical cycloaddition of thioamides and thioimides with multiple bonds provides a facile route for the formation of new C–C bonds of nitrogen-containing heterocycles.

Irradiation of indoline-2-thiones (1) in the presence of alkenes gives 2-alkyl-3*H*-indoles and 2-alkylindoles (3–6) through the ring cleavage of the intermediates, spirocyclic aminothietanes (2), initially derived by (2+2)-cycloaddition of the C=S bond and alkenes (Scheme 2).[12] Intramolecular photoaddition has been also reported in the photoreaction of (7), in which allyl indole sulfide (9) is obtained.[13] The highly strained aminothietane intermediate (8) is proposed as the key intermediate in the reaction.

Photolysis of isoindoline-1-thiones (10), which are the structural isomer of indoline-2-thiones, brings about cycloaddition with various electron-rich and electron-deficient alkenes, yielding tricyclic isoindoline derivatives (12).[14] The plausible mechanism for this transformation is explained (Scheme 3) and involves amino-thietane intermediate (11), which undergoes ring opening to form zwitterions followed by further reaction. In contrast to the photoreaction of (10), stable thietanes (14, 16) are formed by the



SCHEME 3

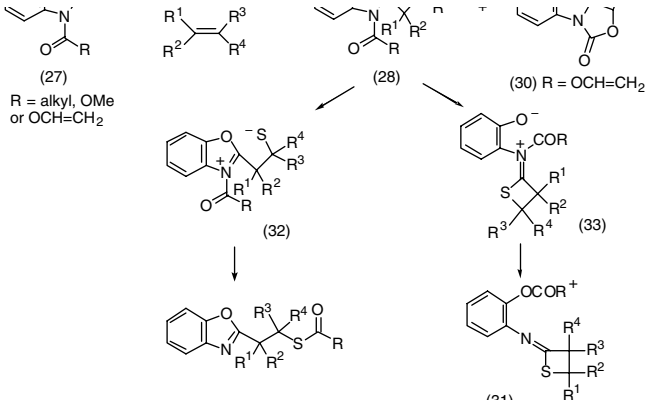


SCHEME 4

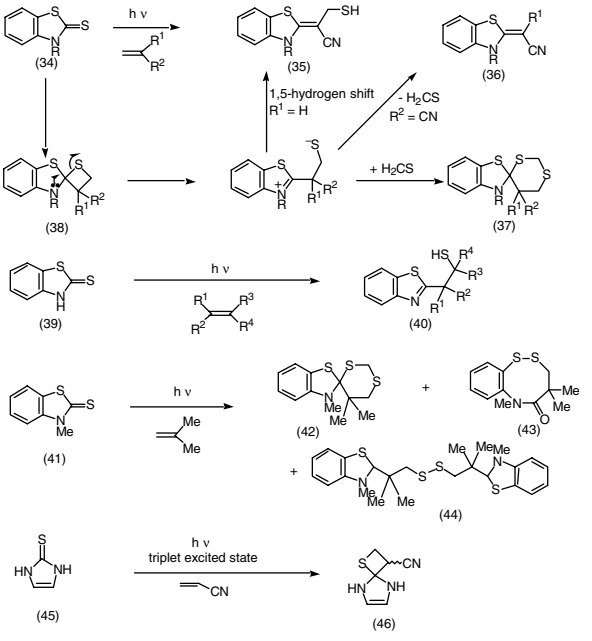
photoreaction of isobenzofuran-1-thione (13, X = O) and isobenzothiophene-1-thione (15, X = S) in the presence of alkenes.[15]

Irradiation of a benzene solution of 4-ethoxy-2,5-dihydro-1*H*-pyrrole-2-thione (17) and electron-rich alkenes gives 2-(mercaptoalkyl)pyrroles (18), which are alkylated with methyl iodide to give (19).[16]

Photochemical addition of benzoxazoline-2-thiones (20) to alkenes affords the 2-substituted benzooxazolines (23–25) or ring-opened products (26), depending on the substituent R and the alkenes used. The formation of these products may be rationalized in terms of zwitterionic intermediate (22), from ring-opening of an aminothietane (21), formed by regioselective (2+2)- photoaddition of the C=S bond of (20) to the C = C bond of the alkene (Scheme 4).[17,18]



SCHEME 5



SCHEME 6

On the other hand, *N*-acylbenzoxazoles-2-thiones (27, R = alkyl) also photocycloadd to alkenes regioselectively to give the 2-substituted benzoxazoles (29) and/or the iminothietanes (30) by intramolecular trapping of zwitterionic intermediate (32) and (33), respectively (Scheme 5).[18,19] Stable aminothietanes (28) have been isolated and characterized from the photoaddition of *N*-methoxycarbonylbenzoxazole-2-thiones (27, R = OMe) to alkenes. Furthermore, the *N*-vinyloxycarbonyl derivatives (27, R=O-CH=CH_2) undergoes intramolecular (2+2)-cycloaddition to give the analogous multi-fused aminothietane (31).[20]

Irradiation of benzothiazoline-2-thiones (34) and acrylonitrile affords 2-alkylidenethiazoles (35) (Scheme 6). On the other hand, two products (36, 37) are formed by the photoaddition of (34) with 1,1-disubstituted alkenes such as methacrylonitrile and methyl methacrylate.[21] Aminothietanes (38) is proposed as intermediates in these photoreactions. Thioformaldehyde formed by the decomposition of the intermediate has been detected by its trapping by a diene. Photocycloaddition reaction of *N*-unsubstituted

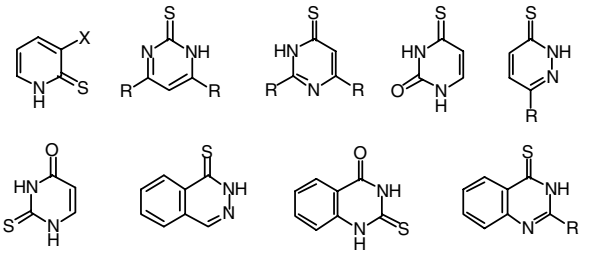


FIGURE 106.1

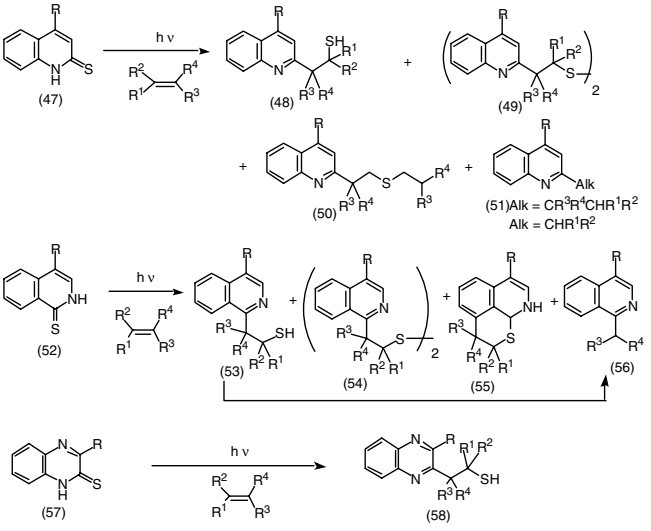


SCHEME 7

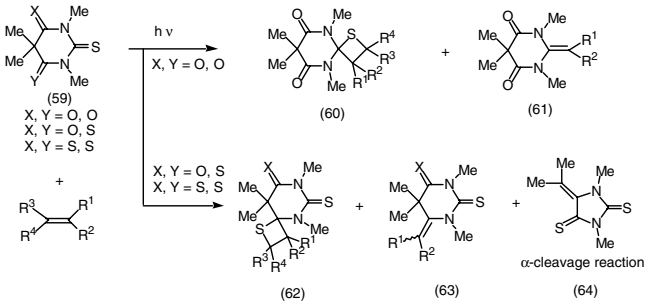
benzothioazole-2-thione (39) and electron-rich alkenes gives 2-substituted benzothiazole (40), whereas that of *N*-methyl derivatives (41) to isobutene gives three types of products (42–44) via aminothietanes.[22] Laser flash photolysis has been used to show that the triplet excited state of (45) is involved in the addition reaction which occurs to electron-deficient alkenes such as acrylonitrile, giving thietane (46).[23]

Photoreaction of six-membered thioamides, such as pyridinethiones, pyrimidinethiones, pyridazinethiones, thiouracils, thiouridines and their benzo-analogs (Figure 106.1), gives a variety of types of adducts in the presence of alkenes where thietanes are believed to be intermediates. Most of the reactions are already documented in previous reviews.[8–11]

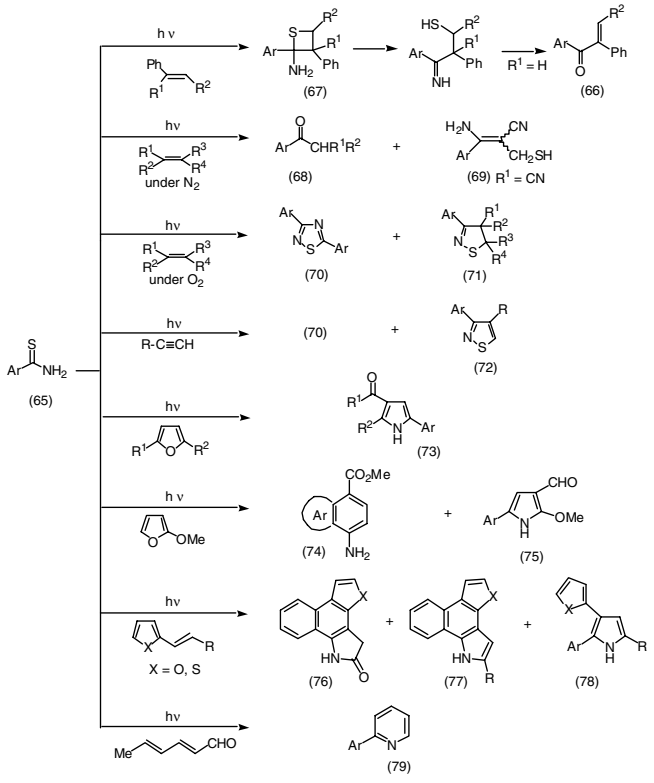
Photochemical reaction of benzo-analogs, quinoline-2-thiones (47), in the presence of a variety of alkenes gives 1:1 photoadducts via a thietane intermediate (Scheme 7). Irradiation of (47) in the presence of electron-deficient alkenes gives thiols (48) and affords 1:2 adducts (50) with alkyl vinyl ether. On the other hand, irradiation with other electron-rich alkenes, such as isobutene or tetramethylethylene, gives various products (48–51). The transpositional isomer, isoquinoline-2-thiones (52), also give many types of adducts (53–56) upon irradiation in the presence of electron-rich alkenes.[24–27]

Thietanes are also intermediates in the photoreaction of quinoxaline-2-thiones (57) with alkenes, leading to 2-substituted quinoxalines (58).[28] This behavior is strikingly different from the photoreaction of the oxo-analogs, quinoxalin-2-ones, which undergo photoaddition to carbon-nitrogen double bonds.

Thiobarbiturates (59) undergo (2+2)-cycloaddition with alkenes to give the thietanes (60) and the methylene derivatives (61) by secondary photolysis involving elimination of either thioacetone or thioformaldehyde (Scheme 8).[29,30] Dithiobarbiturate and trithiobarbiturate undergo analogous reactions.



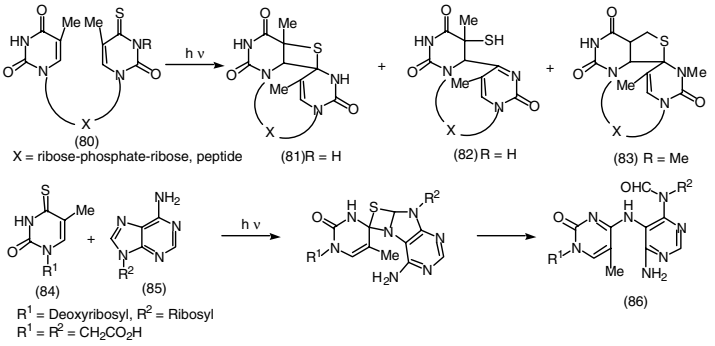
SCHEME 8



SCHEME 9

For trithiobarbiturate, a competing conversion to dithiohydantoin (64) occurs in all cases, accompanied by the formation of (62) and (63), possibly involving a α-cleavage reaction adjacent to the gem-dimethyl group, reclosure to form a sulfur heterocycle and subsequent carbon-carbon bond formation with exclusion of sulfur.

The formation of enones (66) by irradiation of the arylcarbothioamides (65) in the presence of styrene derivatives proceeds by initial formation of the thietane (67): this conversion provides a potentially valuable route for the arylation of simple alkenes as shown in (Scheme 9).[31] Several types of photoproducts are obtained by the irradiation of (65) in the presence of alkenes. The type of product obtained depends on the alkenes used and the reaction conditions.



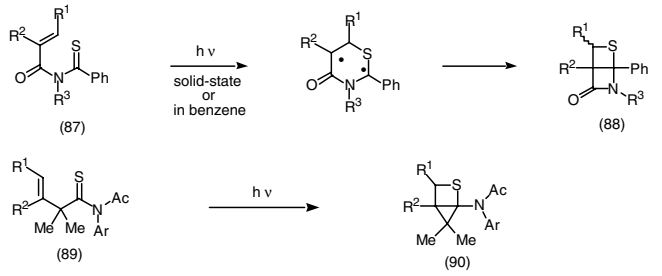
SCHEME 10

Irradiation of (65) with tetramethylethylene under nitrogen atmosphere gives arylketone (68) and thiol (69).[32] The reaction takes a different course in the presence of oxygen and yields 1,2,4-thiadiazoles (70) and isothiazolines (71, 72); a pathway via a nitrile sulfide has been proposed. Irradiation of (65) in the presence of five-membered heteroaromatics such as furan, thiophene, and pyrrole in benzene regioselectively gives the corresponding 3-aroyl derivatives (73). For the formation of aroylfurans, cycloaddition of the C–N bond with furan was proposed.[33–36] Photolysis with 2-methoxyfuran yields unstable thietanes, which rearrange to give moderate yields of benzo-fused arene derivatives (74) and pyrrole derivatives (75).[31,37,38] The intermediacy of the thietane is suggested from the formation of the fused furan derivatives (76–78) that are produced from irradiation of thiobenzamide with 2-vinylfurans or thiophenes.[39,40] Irradiation of (65) in the presence of aldehyde gives tetracyclic imidazole,[41] and pyridine derivatives (79) are obtained by the photolysis in the presence of a dienal (Scheme 9).[42]

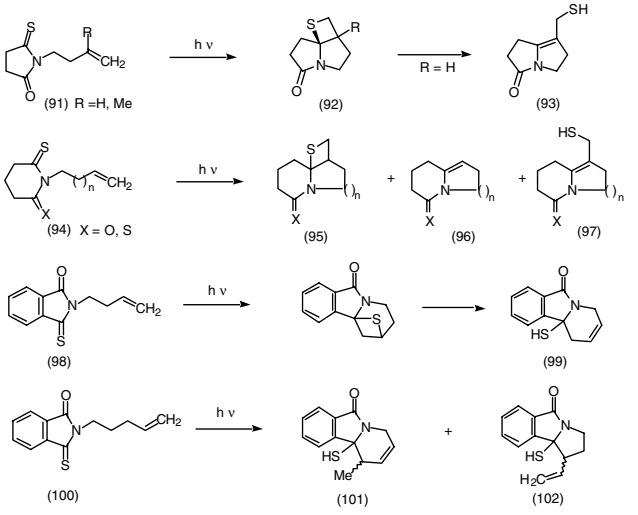
Intramolecular photocycloaddition is also reported to occur in the thiothymidine thymidinyl phosphates (80, R = H) and this gives the thietane (81) and the ring-opened thiol (82) (Scheme 10).[43,44] The importance of this process is related to lesion in DNA. Irradiation of (80, R = Me) gives a new type of photoproduct (83) in the nucleic acid series that involves attack of the thiocarbonyl across the propene moiety of the thymidine ring.[45] Irradiation at 366 nm in aqueous solution of the thiothymine (84) in the presence of adenine derivative (85) results in the formation of the adduct (86); this is formed presumably by way of the (2+2)-cycloaddition reaction between the C=S and the C=N bonds.[46] Intermolecular (2+2)-cycloaddition is also reported in the photoreaction of (84) with pyrimidinone derivative.[47] Intramolecular photocycloaddition also occurs between thymine and 6-thioinosine derivatives tethered with ribose-phosphate-ribose and thietanes are obtained.[48–50]

Many mono- and dithioimides show high reactivity toward intra- and intermolecular (2+2)-cycloaddition with alkenes. Introduction of an acyl group to the amide function shares the lone-pair electrons of the nitrogen atoms with carbonyl and thiocarbonyl groups; also, the acyl group of aminothietane decreases the activity for the ring-opening reaction. Therefore, stable thietanes are isolated in many cases. This reaction provides a powerful method to synthesize nitrogen-containing heterocycles by efficient modeling of the starting materials.

Irradiation of the acyclic imides (87) proceeds by (2+2)-cycloaddition to yield thietane-fused β-lactams (88) (Scheme 11).[51] Because the mechanism involves the 1,4-diradical intermediate, a more efficient reaction occurs when R^2 is not hydrogen. Furthermore, when the achiral imide (87, R^1 = H, R^2 = Me, and R^3 = Ph) crystallizes in a chiral fashion and the solid-state photoreaction gives an optically active product.[52] Irradiation of a benzene solution of *N*-[(*R*)-phenyl]-*N*-tigloylthiobenzamide, possessing an intramolecular chiral handle, does not show diastereoselectivity and gives four stereoisomeric β-lactams. On the contrary, high diastereoselectivity has been observed in the corresponding solid-state photoreaction.[53] The intramolecular (2+2)-cycloaddition is observed in β,γ-unsaturated thioimides (89) which have been converted photochemically into the 2-thiabicyclo[2.1.0]pentanes (90) in high yield.[54]



SCHEME 11

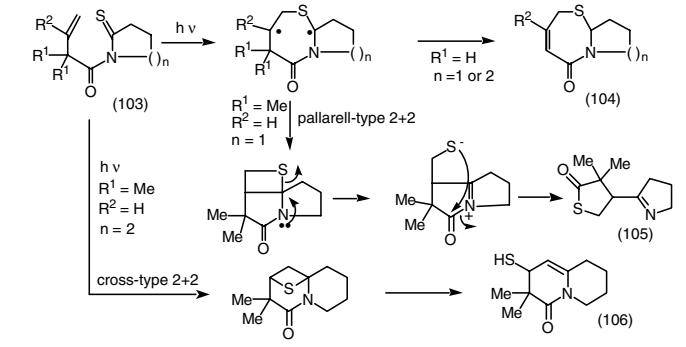


SCHEME 12

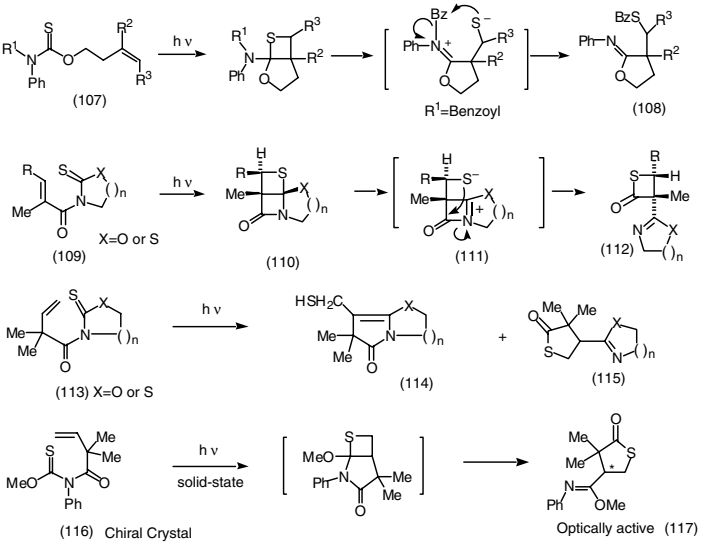
Cyclic thioimides (91) undergo intramolecular photocycloaddition in a regiospecific manner to afford spirocyclic amidothietanes (92) (Scheme 12).[55,56] These highly strained multicycles undergo a subsequent ring-opening reaction to furnish fused pyrrolidinones (93). Intramolecular photoreaction of *N*-(4-alkenyl)- or *N*-(4-alkenyl)-glutarimides (94) gives thietanes (95) and their fission products (96, 97).[57] Similarly, intramolecular thietane formation is observed in the photolysis of cyclic monothioimides (98) and the isoindole derivatives (99) were isolated through the photolabile thietanes. On the other hand, photolysis of (100) gives (101) and (102) via hydrogen abstraction by thiocarbonyl sulfur atom.[58]

Photoreaction of monocyclic monothioimides (103) gives lactams (104) and thioester (105), in which the products are dependent on the substituents on the alkenes and the ring size of thiolactam chromophore (Scheme 13).[59] Photoproducts (104) and (105) are formed via 7-membered biradical intermediate and another type of (2+2)-cycloaddition leads to bicyclic lactam (106).

Acyclic thiocarbamates (107) also give thietane formation on irradiation. This reaction is followed by ring opening, leading to oxylanes (108) (Scheme 14).[60] Irradiation of monocyclic thiocarbamates or dithiocarbamates (109) gives tricyclic β-lactams (110) and β-thiolactones (112).[61] The formation of (112) is reasonably explained via a zwitterionic intermediate (111). Irradiation of *N*-(β,γ-unsaturated carbonyl)-thiocarbamates and -dithiocarbamates (113) also promotes (2+2)-thietane formation and subsequently yields bicyclic lactams (114) and γ-thiolactone derivatives (115).[62] Similar reactivity is also shown in the solid state and absolute asymmetric synthesis is performed by the photoreaction of acyclic *N*-(β,γ-unsaturated carbonyl)thionocarbamate (116), leading to optically active thiolactones (117).[63]



SCHEME 13



SCHEME 14

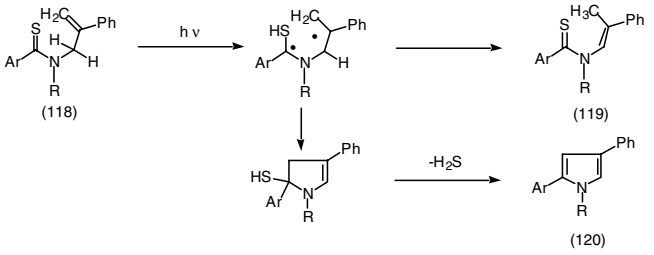
Irradiation of many other cyclic, semi-cyclic, and acyclic thioimides in the presence of variety alkenes, alkynes, allenes, or ketenes gives the corresponding thietanes by intermolecular reaction.[8–11]

106.3 Photochemical Hydrogen Abstraction of Thioamides and Thioimides

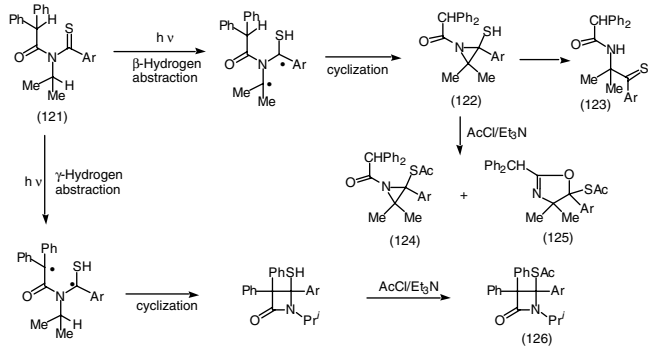
Photochemical hydrogen abstraction of a thiocarbonyl function is a common reaction. While thioamides generally do not show this photochemical reactivity, thioimides do undergo hydrogen abstraction by the thiocarbonyl sulfur of (C=S)-N chromophore from the β-, γ-, and δ-positions to yield various heterocycles.

A rare example has been reported for the hydrogen abstraction reaction of thioamides. Irradiation of amide (118) proceeds by β-hydrogen abstraction to generate a 1,3-diradical intermediate by a 1,3-hydrogen shift. Two reaction pathways are observed. One is the formation of thioenamides (119); the other is cyclization of a 1,5-diradical intermediate to yield pyrrole derivatives (120) (Scheme 15).[64]

In another case, β-hydrogen abstraction of acyclic monothioimides followed by cyclization leads to aziridine derivatives. When acyclic monothioimides (121) are irradiated at room temperature, thioketones



SCHEME 15



SCHEME 16

(123) are formed via ring-opening reaction of unstable mercaptoaziridines (122) (Scheme 16). Irradiation of (121) at low temperature, followed by acetylation, gives the stable aziridine (124) and rearranged oxazolidines (125). The β-lactams (126) are also obtained via γ-hydrogen abstraction, followed by cyclization.[65]

Furthermore, three achiral monothioimides (121) (Ar = Ph, 4-ClPh, and 4-MeOPh derivatives) crystallize in a chiral fashion and the solid-state photolysis followed by acylation gives optically active aziridines (124), oxazolidines (125), and β-lactams (126).

Hydrogen abstraction has been reported in *N*-acylthionocarbamates and dithiocarbamates (127) leading to cyclization products (128) and (129).[66] The formation of (129) is reasonably explained in terms of ring-opening reaction followed by an α-cleavage reaction of the C=S group. The resulting carbene is trapped intramolecularly to yield (129) (Scheme 17 and see also Scheme 21). Irradiation of 1-acylindoline-2-thiones (130) gives the deacylation products (131) via a γ-hydrogen abstraction. The ketene formed by this fission process is trapped by ethanol to yield the corresponding esters (132).[12] Similar deacylation involving a γ-hydrogen abstraction has been observed in the photolysis of *N*-acyl-2-thionothiazolidines.[67]

Photolysis of the monothioimides (133) gives γ-lactams (134) and disproportionation products (135, 136) via a 1,5-diradical intermediate generated by δ-hydrogen abstraction. Thioamides (137) are obtained via γ-H abstraction (Scheme 18).[68] Irradiation of *N*-(3-phenylpropionyl)-2-pyrrolidinethione, in which R^3 and R^4 substituents are tethered, gives isomers of pyrrolopyrrolidone.

Photolysis of 1-(ω-arylalkyl)cyclic thioimides (138) (X = O, S; m = 1, 2; Ar = Ph, 2-furyl) gives a pair of stereoisomers of 1-azabicycloalkanes (139, 140) in moderate yields (Scheme 19).[69] Similarly, phenylalkylcyclic dithioimides (141) (m = 1, 2; n = 2–4) give 2-azabicycloalkanes (142) and disproportionation products (143) on irradiation.

Irradiation of thiouracil tethered by peptide or ribose-phosphate (144) at 366 nm in water results in the formation of the products (145, 146) (Scheme 20).[45,49,70]

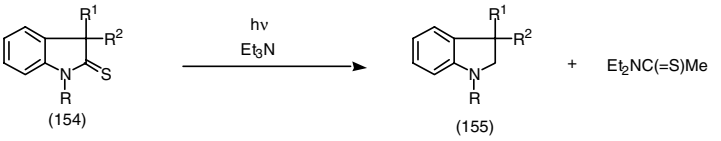
106.4 Miscellaneous Photoreactions of Thioamides and Thioimides

The Norrish Type I reaction (α-cleavage reaction) is a common process in carbonyl photochemistry. It is quite rare, however, in thiocarbonyl photochemistry. One of the reasons for this difference is that the C=S system has a lower triplet energy than that of the C=O analogs. Some strained thiocarbonyl compounds are known to undergo C-(C=S) bond cleavage in four-membered thioketone and thioesters.[7–9] Photolysis of four-membered thioimides (147) also promotes an α-cleavage reaction leading to thiacarbene (148) and this is trapped intramolecularly by thiol or alcohol to give bicyclic lactams (149) (Scheme 21).[66] Another example is reported for the six-membered trithiobarbiturate (150) leading to thiohydantoin (152) and a small amount of the imidazolinothiophene derivative (153). The reaction mechanism is explained in terms of initial formation of a 1,6-biradical intermediate, α-cleavage of the thiocarbonyl group, and this is followed by recyclization to (151). Ring contraction by loss of a sulfur atom leads to (152) and (153).[25]

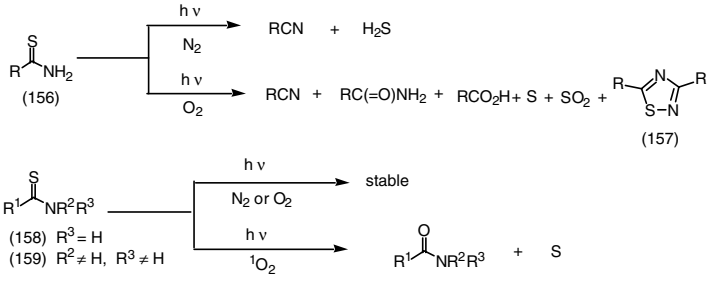
Irradiation of indoline-2-thiones (154) in the presence of Et_3N yields the desulfurization products, indolines (155), along with Et_2NCSMe (Scheme 22). The photodesulfurization reactions can be explained by a sequential electron/proton-transfer mechanism from amine to the excited indoline-2-thione (154).[71]

Primary thioamides (156) are photolyzed by UV light in nitrogen to the corresponding nitriles with evolution of H_2S (Scheme 23). Irradiation in the presence of oxygen gives nitriles, amides, carboxylic acids, and 3,5-disubstituted 1,2,4-thiadiazoles (157), together with S, SO_2 and SO_4^{2-} but no H_2S. Secondary thioamides (158) and tertiary thioamides (159) are stable under both conditions. Singlet oxygen reacts with secondary and tertiary thioamides to form the corresponding amides with expulsion of S.[72]

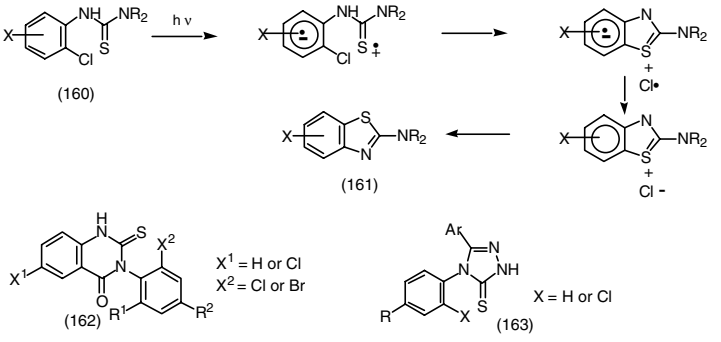
Examples of photocyclization involving the thiocarbonyl group have been reported. The 2-substituted benzothiazoles (161) are prepared in this way from *o*-halogenothiobenzanilides (160) via a



SCHEME 22



SCHEME 23



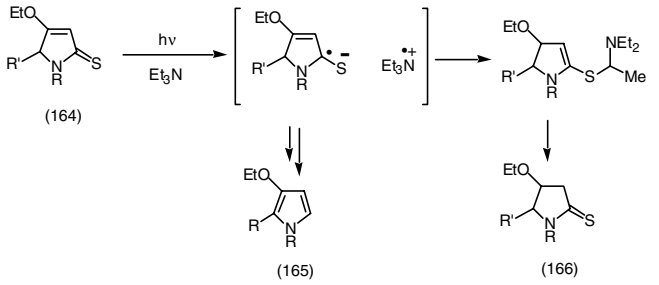
SCHEME 24

dehydrohalogenation initiated by electron transfer (Scheme 24).[73] Similarly, cyclization is observed in the photoreaction of 2-thiaquinazolinediones (162) and 4-(2-haloaryl)-5-aryl-1,2,4-triazol-3-thiones (163).[74,75]

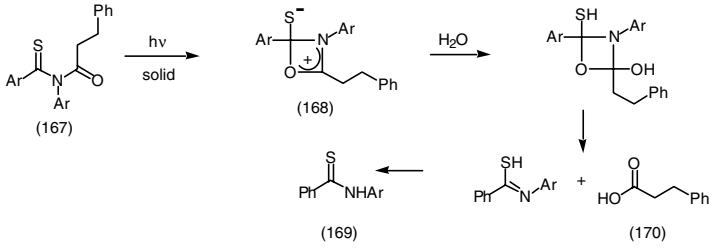
Irradiation of 2,5-dihydro-1*H*-pyrrole-2-thiones (164) in the presence of triethylamine gives desulfurization products, pyrroles (165), or reduction products, pyrrolidine-2-thiones (166), depending on the substituent on the nitrogen atom. This reaction can be explained by a sequential electron/proton-transfer mechanism from the amine to the excited pyrrole thione (Scheme 25).[16]

Photolysis of a benzene solution of acyclic monothioimides (167) proceeds via δ-hydrogen abstraction, leading to δ-lactams (Scheme 18).[68] However, irradiation of (167) in the solid state affords only thioamides (169) and the corresponding acid (170), where the mechanism via the 1,3-oxazetidinium ion (168) is proposed (Scheme 26).[76,77]

Irradiation of 2-methyl-4-phenyl-substituted benzaldehyde thiosemicarbazones (171) leads to the corresponding Δ^2-1,2,4-triazoline-5-thione derivatives (173) through the formation of stable 1,2,4-triazolidine-5-thione derivatives (172) (Scheme 27).[78] Irradiation of *N*-acylthiourea (174) in the presence of triethylamine gives thiourea (175) and benzothiazoles (176) via an electron-transfer mechanism.[79] A photochemically induced Dimroth rearrangement has been reported in the 1,2-thiazolino[5.4-*d*]-1,2-thiazoline-3,6-dithione (177) and yields the 3*H*,6*H*-1,2-dithiolo[4.3-*c*]-1,2-dithiole (178).[80]



SCHEME 25



SCHEME 26

106.5 Photoreactions of Conjugated Thioamides

The singlet $\pi\pi^*$ excited state of the *N,N*-disubstituted thioamides (179) is responsible for conversion to the thioazetidinones (180) accompanied by the fragmentation product (181) (Scheme 28). This product is presumed to be formed by a hydrogen abstraction path to afford the zwitterionic intermediate.[81] Furthermore, *N,N*-dibenzyl-1-cyclohexenecarbothioamide (179, R^1-R^2 = -$(CH_2)_4$-) crystallizes in a chiral fashion and the photolysis in the solid state leads to exclusive production of optically active thioazetidinone (180) in 94% enantiomeric yield.[82–84]

Unsymmetrically substituted *N*-benzyl-*N*-isopropyl-α,β-unsaturated thioamides (182) exist in an equilibrium between two rotamers owing to the rotation of the C(=S)–N bond. The free energy of activation lies in the range 18.4 to19.5 kcal mol^{-1}. Irradiation in benzene solution induces hydrogen abstraction by the alkenyl carbon from both the benzyl and isopropyl groups to give a β-thiolactam (183) and 1,3,5-dithiazinane products (185) as products, respectively. In the solid state, however, photolysis causes hydrogen abstraction from only the isopropyl group to give isomeric β-thiolactam (184).[85]

Photochemical isomerization of monosubstituted α,β-unsaturated thioamides (186) gives iminothietanes, *N*-(2-thietanylidene)amines (187), in good yields. The iminothietanes revert quantitatively to the starting materials on heating (Scheme 29).[86]

Photochemical (*E,Z*)-isomerization of *N,N*-disubstituted tigloylthioamide (179) occurs in solution and in the solid state.[81,82] Furthermore, photochemical (*E,Z*)-isomerizability of cinnamothioamide derivatives (188) in the solid state has been reported. Crystallographic analysis reveals that the isomerizability in the solid state partially depends on their molecular conformation in the crystal.[87] In addition, it is found that the packing coefficient has correlation with the isomerizability; a smaller value of the packing coefficient causes an increased formation of (*Z*)-isomers.

107.1 Introduction

Over a period of time we have learned to control thermal reactions. This control is often achieved by variation of temperature, pressure, and solvent and with the help of catalysts. Because the activation barrier for photochemical reactions is small, temperature is expected to have only a minor influence. Yet it can be a valuable tool. Solvents, by influencing the stability of products and/intermediates, play an important role in thermal reactions. In addition to such effects, solvents, by influencing the closeness and ordering of excited states, would have a profound effect on photochemical reactions. Solvents with special properties (e.g., with a heavy atom) may also control the spin configuration of the reactive state, a feature we rarely consider in ground-state reactions. Wavelength and the mode of excitation have a significant influence on photoreactions. They help to place molecules in various excited states of different energy and spin. Further, photoreactions are susceptible to control by addends such as cations and Lewis acids that would control the ordering of excited states by interacting with lone pairs present in a carbonyl chromophore. Because most photochemical reactions occur at room temperature, one could preorganize reacting molecules prior to excitation. Such a templating influence is much more difficult to achieve in thermal reactions because temperature has a significant negative effect on the pre-association of molecules. This chapter discusses how one can exploit these features to manipulate the known photochemical behavior of various chromophores. One or two examples are provided for each category to illustrate the concept.

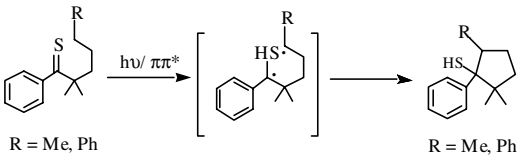


SCHEME 1

107.2 Wavelength Effect

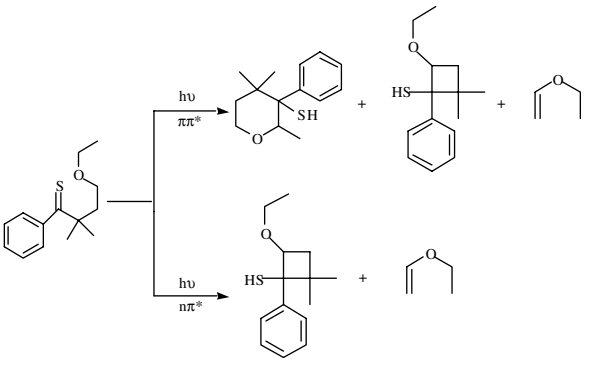
Wavelength effects in solution might arise due to two factors: (1) reactions from upper excited states (singlet and triplet) and (2) ground-state structural features.[1] The tri*vial* wavelength effect would be absorption by products, which is not considered here. One could visualize wavelength as a tool to expand the number and types of reactions a given molecule might undergo. Generally, most reactions occur from the lowest excited singlet and triplet states. Only if a molecule fulfills certain conditions will reaction from upper excited singlet and triplet states take place; however, this happens only with a few molecules. There are several methods that are adopted to acquire sufficient concentrations of molecules in the upper excited state.

Reactions from Upper Excited Singlet States

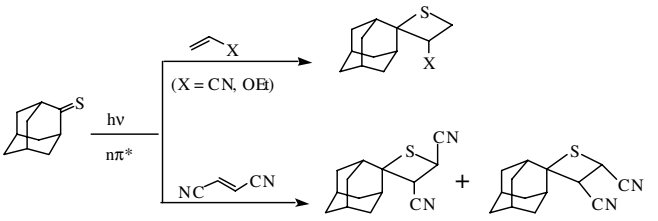
Thiocarbonyl compounds have a large energy gap between S_1 and S_2 (> 30 kcal mol^{-1}) and have lower and upper excited states with different electronic configuration ($n\pi^*$ and $\pi\pi^*$).[2] Because of these, the S_2 state of thiones has a long lifetime (10^{-11} sec in hydrocarbon solvents and 10^{-10} sec in perfluoro hydrocarbon solvents), allowing them to react from the upper singlet states. They undergo both intra- and intermolecular reactions from S_2.

Thiocarbonyls, their structure permitting, undergo distinct wavelength-dependent intramolecular hydrogen abstraction reactions. The course of hydrogen abstraction and subsequent product formation are related to the substituents on the thiocarbonyl function and the wavelength of excitation.[2,3] While in carbonyls γ-hydrogen is the most common one, in thiocarbonyls abstraction occurs from the β, γ, δ, and ε positions. Aryl alkyl thiones containing saturated hydrocarbon alkyl chains, upon excitation to the $S_2(\pi\pi^*)$ state, yield cyclopentane thiols via a δ-hydrogen abstraction from the alkyl chain (Scheme 1). This reaction does not occur upon irradiation into the $S_1(n\pi^*)$ band. Successful quenching of the reaction by singlet quenchers and unsuccessful triplet sensitization are taken to support $S_2(\pi\pi^*)$ as the reactive state. Aryl alkyl thiones lacking δ-hydrogens do not undergo any photoreaction. However, when an ethereal oxygen atom replaces the δ-carbon, photochemical hydrogen abstraction occurs from carbons adjacent (ε and/or γ) to the oxygen atom (Scheme 2) as a result of activation of the neighboring hydrogens by the heteroatom. ε-Hydrogen abstraction leads to six-membered ring thiols, while γ-hydrogen abstraction leads to cyclization (cyclobutanethiols) and cleavage (olefin) products. Whereas the γ-hydrogen abstraction can be initiated by light of short and long wavelength, ε-hydrogen abstraction is wavelength specific and occurs only upon excitation to the S_2 state.

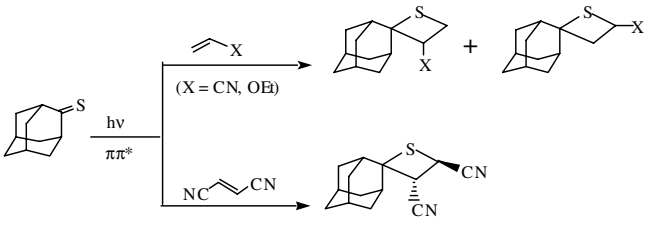
Adamantanethione adds to both electron-rich and -poor olefins upon excitation to the S_1 level.[2,3] The addition is nonstereospecific and regioselective (Scheme 3). Based on sensitization and quenching studies, the above addition has been established to occur via the triplet state (T_1). The quantum yield of the isolated adduct is low (10^{-4}). Upon excitation to S_2, adamantanethione adds to both electron-rich and -poor olefins to yield thietanes. These additions are stereospecific and regioselective (Scheme 4). Note that the characteristics of additions are different from the one occurring from the $n\pi^*$ triplet state. Based on sensitization and quenching studies and the nature of products formed, the reactive state has been identified to be the S_2 state.



SCHEME 2



SCHEME 3

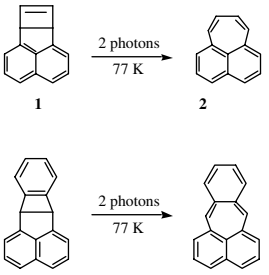


SCHEME 4

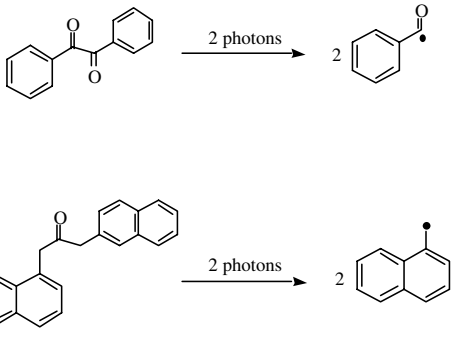
Reactions from Upper Excited Triplet States

An approach to produce upper triplets is via direct excitation into S_n followed by intersystem crossing. Except in cases where T_2 is below S_1, this approach is not successful. An alternative method for producing these higher triplet states involves direct excitation via $T_1 \rightarrow T_n$ absorption. In this method, a population of the lowest triplet state produced initially is converted to the higher triplet state using a second light source. Sufficient concentrations of molecules in the T_1 state are accumulated using either low-temperature matrices or high-intensity light sources.

An elegant illustration of the low-temperature matrix technique is provided by the photochemistry of pleiadene precursor **1** (Scheme 5).[4] Compound **1** rearranges to pleiadene (**2**) only after population of an upper triplet state by biphotonic excitation in rigid glasses at 77K. It is important to note that solution irradiation both at room and low temperatures leads to no reaction, and that triplet sensitization in solution is similarly ineffective. The reaction was achieved only in matrices at 77K using both UV and visible radiation sources simultaneously in a biphotonic process, or with a single UV source in a monophotonic



SCHEME 5



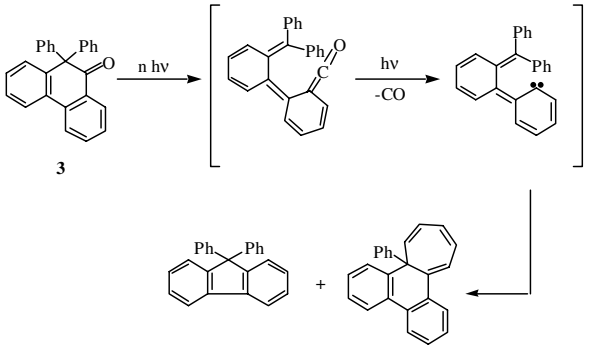
SCHEME 6

process, at wavelengths much shorter than that required to populate S_1. In the two-photon excitation experiments, the product yield has been maximized by tuning the visible source to wavelengths appropriate for known naphthalene $T_1 \rightarrow T_n$ absorption maxima (~400–415 nm). The proposed mechanism for the above two light source experiments involves UV absorption followed by relaxation to a long-lived T_1 state (3.3 sec for 1 at 77K), triplet-triplet absorption of the visible photon to populate a higher triplet state T_n, from which steps leading to the chemical reaction occur.

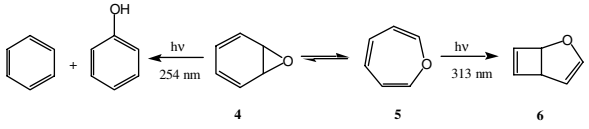
While matrix isolation spectroscopy is experimentally simple, it only allows unimolecular processes. Because diffusion is severely restricted, no bimolecular process can occur at low temperatures in a matrix. To allow such reactions, the upper excited-state chemistry needs to be conducted at room temperature in isotropic solution media. The high-intensity light sources required to produce high concentrations of excited states are achieved through the use of lasers.

In the two-laser (two-color) technique, two lasers of different wavelengths, firing sequentially, are employed to produce the upper states of molecules.[5] The first laser produces the lowest excited state of the molecule and the second laser selectively excites these molecules into an upper level. By this approach a variable delay can be introduced between the two photons to allow the lower excited state concentration to build up. Using a tunable laser, the wavelength of the second photon can be adjusted to correspond to the absorption maximum of the lower excited state. Because excited singlets (S_1) are too short-lived in comparison with the laser pulse duration to allow for efficient upper singlet production, the two-laser setup is better suited for populating upper triplets than upper singlets.

An illustration of the above technique is found in the cleavage reactions of several carbonyl and aromatic systems that do not cleave in solution when irradiated with conventional light sources (Scheme 6).[6] For example, benzil does not cleave when populated to the T_1 ($\pi\pi^*$) state by either direct excitation or triplet sensitization. However, generation of a higher triplet through excitation of T_1 results in α-cleavage.



SCHEME 7



SCHEME 8

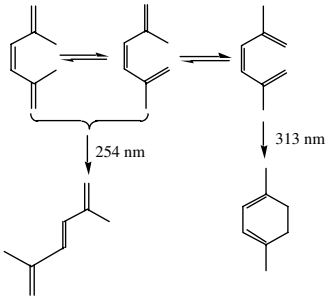
The two-laser (two-color) technique described above provides excellent spectroscopic information on the transients produced during the formation of products from upper excited states. However, isolation of the products of a photoreaction by this approach could be tedious. For product isolation, a "laser jet" apparatus is often used.[7] In this laser jet technique, a high-velocity microjet of a solution of material to be irradiated is injected into the focal region of an argon ion laser beam. The typical microjet flow rates can be controlled and the sample recycled as many times as necessary to bring the reaction to completion. Consequently, isolation of significant quantities of products is possible. Usually, a high-intensity CW argon ion laser is used to excite molecules. In this method, sufficient concentrations of molecules in their S_1 or T_1 states are trapped within a "microbubble" so that they can absorb a second photon. Reactions generally occur from the upper excited states. The ketone **3** shown in Scheme 7 is stable to low-intensity light (Rayonet reactor). However, when irradiated with an argon ion laser under laser jet conditions, it yields the product shown in Scheme 7, believed to be derived via T_n.[8]

Wavelength Effects due to Ground-State Structural Features

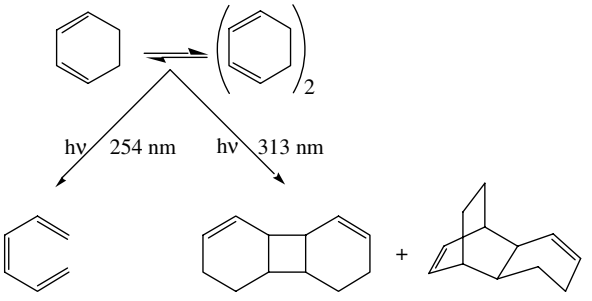
When there is more than one type of molecule in the medium with different absorption characteristics and photobehaviors, there is likely to be a wavelength effect. The two types of molecules need not be distinctly different molecules; they could be geometric isomers or conformational isomers in thermal equilibrium.

Irradiation of benzene oxide in ether solution with light of wavelength above 310 nm gave **6** as the only product (Scheme 8).[9] On the other hand, irradiation at 254 nm at −80°C gave benzene and phenol. This wavelength dependence has its origin in the equilibrium that exists between the open and closed forms of benzene oxide. The cyclic triene **5** absorbs at longer wavelength and results in product **6** when irradiated at >313 nm. At lower temperature, the benzene oxide exists in the closed form, which absorbs at shorter wavelength. Hence, 254-nm excitation gives a different set of products characteristic of the closed form.

The interconverting structures need not be structural isomers as in the above example, but could in fact be conformational isomers. As shown in Scheme 9, *cis*-1,3,5-hexatriene can exist in three conformations. In the ground state, equilibrium between the three conformers occurs. Upon excitation, equilibration is prevented in the excited state and each one gives its own product (Scheme 9).[10]



SCHEME 9



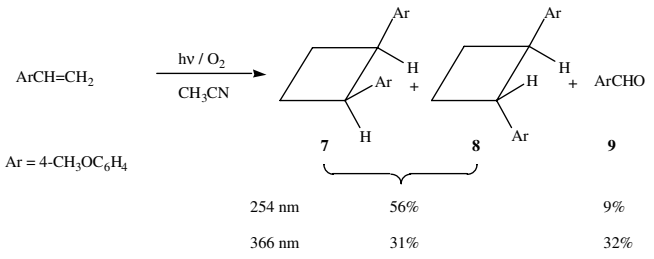
SCHEME 10

Equilibrium between monomer and aggregates with different absorption characteristics is likely to result in wavelength-dependent chemistry. For example, 1,3-cyclohexadiene upon irradiation with 254-nm light gives 1,3,5-hexatriene as the only product; but irradiation at 313 nm produces dimers (Scheme 10).[11] Upon irradiation at 254 nm, mainly the monomer is expected, while at 313 nm the dimer is excited with the two yielding different products.

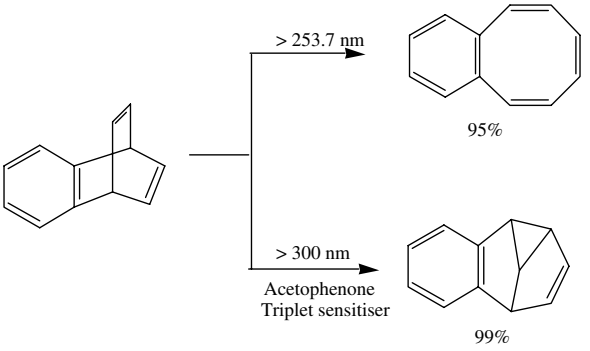
Yet another possibility is the presence of a charge-transfer (CT) complex in equilibrium with the reactant. If the CT complex and the uncomplexed reactant have different absorption characteristics as well as different photochemistries, wavelength-dependent chemistry is likely to result. The chemistry of styrenes aptly illustrates this point.[12] Styrenes form ground-state complexes with oxygen molecules, with the CT complex having a weak absorption shifted to the red of the absorption due to the olefin $\pi\pi^*$ transition. When an oxygen-saturated acetonitrile solution of the styrene derivative is irradiated with light of wavelength 254 nm (into the olefin absorption band), two dimers (via photocycloaddition) are obtained. However, when the excitation wavelength is shifted to 366 nm, the benzaldehyde is obtained as one of the major products (Scheme 11). The latter is believed to result from the excitation of the styrene–oxygen complex.

107.3 Mode of Excitation (Direct vs. Triplet Sensitization)

When a reactant is excited to the S_1 state, depending on the rate of intersystem crossing and reactivity of S_1 and T_1, products from both S_1 and T_1 or S_1 alone or T_1 alone may result. One could resort to triplet sensitization to obtain products only from T_1. If the intersystem crossing quantum yield from S_1 to T_1 is negligible one could obtain different products upon direct excitation and triplet sensitization (Scheme 12).[13]



SCHEME 11



SCHEME 12

107.4 Solvent Effects

Heavy-Atom Solvents

Solvents containing heavy atoms such as bromine and iodine can be used to promote singlet–triplet crossings in the excited state of the reactants. Most common solvents used in this context are alkyl halides such as propyl bromide and propyl iodide.

Heavy-atom solvents are often used to influence the product distributions when different products are obtained from S_1 and T_1. For example, acenaphthylene gives different dimers from S_1 and T_1 (Scheme 13).[14] The *trans*-isomer, the one arising from T_1, is formed in excess in solvents with the heavier atom. For example, the ratios of *cis*/*trans* in cyclohexane containing 10% n-butyl chloride, 10% n-butyl bromide, and 10% *n*-butyl iodide are 2.37, 0.73, and 0.25, respectively. Because the spin-orbit coupling parameter increases in the same order as the percentage of the *trans*-isomer (chloride < bromide < iodide), the heavy-atom solvent is believed to favor intersystem crossing from S_1 to T_1 of the reactant acenaphthylene.

Polar Solvents

Carbonyl compounds have close-lying $n\pi^*$ and $\pi\pi^*$ states with different photochemical properties. If the ordering of the two states can be controlled externally, then one could obtain, at will, products from the two states. One approach is to make use of a polar medium. If the ordering of the two states is different in polar and nonpolar solvents, different products would be obtained in these solvents. Even olefins have two states ($\pi\pi^*$ and doubly excited $\pi^*\pi^*$) of different polarizability. When these two states are nearby, the photochemistry could be solvent dependent.

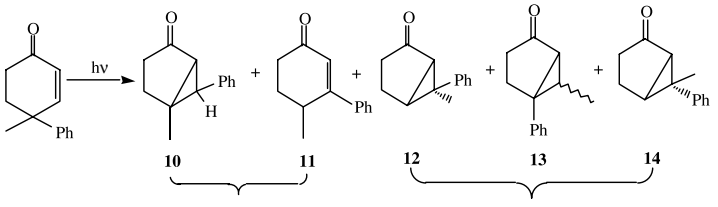
Ethyl iodide (10% mole %)	0.25

SCHEME 13



Benzene	100	0
Acetonitrile	58	42
Formamide	38	62

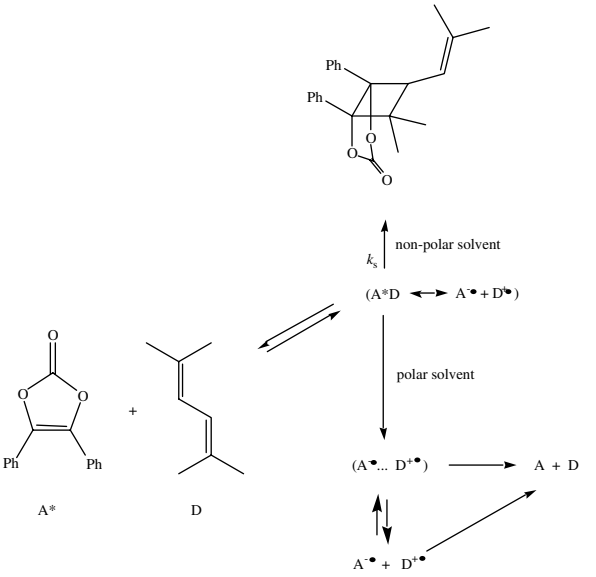
SCHEME 14

For example, 4-methyl-4-phenyl-2-cyclohexenone upon irradiation yields several products (Scheme 14).[15] Two of these products derive from a triplet of $n\pi^*$ character and three of them from a triplet of $\pi\pi^*$ character. As indicated in the scheme, in the nonpolar solvent benzene, only $n\pi^*$-derived products are formed; whereas in more polar acetonitrile and formamide, $\pi\pi^*$-derived products are also obtained.

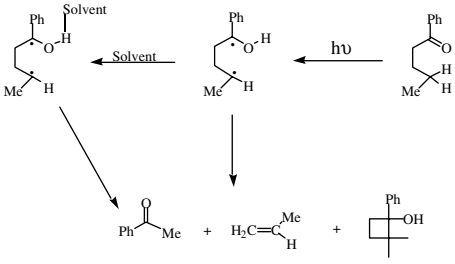
Solvents not only have an influence on the ordering of excited states but may also alter the reaction pathway taken by intermediates. For example, while the quantum yield of addition of diphenylvinylene carbonate to 2,5-dimethyl-2,4-hexadiene in hexane is 0.5, that in acetonitrile is <0.001 (Scheme 15); that is, adduct is formed in hexane but not in acetonitrile.[16] The reaction in both solvents proceeds via an exciplex. In nonpolar solvents, the exciplex yields the adduct while in polar solvents, electron transfer occurs, which leads to energy wastage.

Protic Solvents

The quantum yield of the Norrish-Yang reaction product from valerophenone (Scheme 16) is significantly enhanced in *t*-butanol (1.00) with respect to benzene (0.42).[17] In addition to the rate increase, the



SCHEME 15

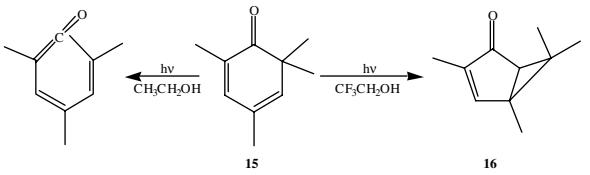


SCHEME 16

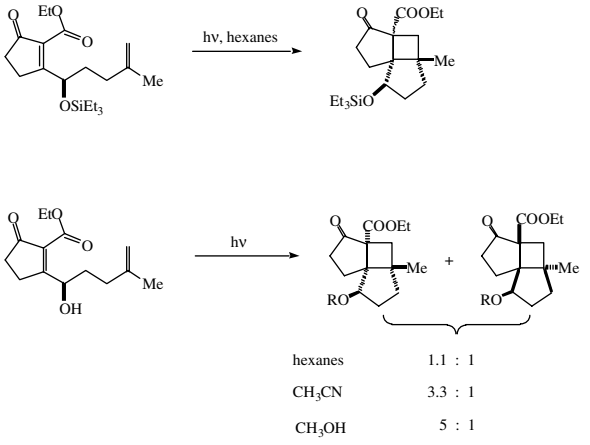
elimination (E) to cyclization (C) products ratio changed between the two solvents (C/E+C in benzene = 4 and *t*-butanol = 2; Scheme 16). These changes are consistent with hydrogen bonding between the solvent *t*-butanol and the intermediate in the 1,4-biradical. Hydrogen bonding shuts down the reverse hydrogen transfer and favors the elimination over cyclization.

Strong hydrogen bonding to the reactive carbonyl chromophore often alters the ordering of the $n\pi^*$ and $\pi\pi^*$ states. Similar to polar solvents, in a protic hydrogen-bonding medium, the $\pi\pi^*$ state becomes the reactive state. The hydrogen bonding could be even more powerful than a polar solvent in lowering the $\pi\pi^*$ state below the $n\pi^*$ state, which is illustrated by the photobehavior of the dienone **15** (Scheme 17).[18] While in ethanol α-cleavage characteristic of $n\pi^*$ state occurs (ketene product), in trifluoroethanol a product characteristic of the $\pi\pi^*$ state is obtained (bicyclic product). Apparently, polarity alone is not enough to bring out the $\pi\pi^*$ reactivity of the dienone; a strong hydrogen bonding or a proton donating solvent is needed.

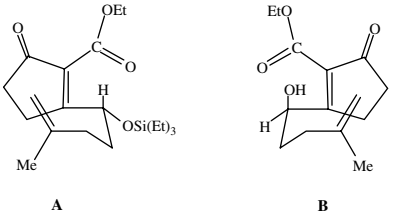
Consider the intramolecular cycloaddition of an enone to an alkene illustrated in Scheme 18.[19] The two adducts that are formed derive via the conformers A and B shown in Scheme 19. Of the two conformers, A is of lower energy in systems that do not form intramolecular hydrogen bonding. A single diastereomeric adduct is obtained when the proximal substituent is $OSiEt_3$. However, when the proximal substituent is OH, the selectivity is reversed, suggesting that intramolecular hydrogen bonding, favoring the conformer B controls the photoaddition. The extent of selectivity depends on the solvent. While in



SCHEME 17



SCHEME 18



SCHEME 19

non-hydrogen-bonding solvents (hexane and methylene chloride) the adduct formed from conformer B is favored, in the hydrogen-bonding solvent methanol, the selectivity is slightly favored toward the adduct from conformer A.

Fluorinated Solvents

Owing to the fact that the C–F compared to a C–H bond is stronger (the dissociation energy of a C–F bond is 129 kcal mol^{-1} while that for a C–H bond is 100 kcal mol^{-1}), perfluorinated solvents are generally inert. Fluorinated solvents are therefore the best medium when one wishes to avoid hydrogen abstraction reactions, which occur to some degree in almost any solvent. A remarkable influence of perfluoro solvents on the S_2 lifetime of thiones and on the T_1 lifetime of benzophenone at room temperature have been noted. Xanthione in hexane has an S_2 lifetime of 25 picoseconds while in perfluorohexane, the lifetime is 162 picosecond.[20] The triplet lifetime of benzophenone in cyclohexane is 5 microseconds while in perfluoromethylcyclohexane it is 0.7 milliseconds.[21] An increase of three orders is observed. The quantum

- 78	10	-	-	-	90

SCHEME 20

yield of phosphorescence of benzophenone in perfluoromethylcyclohexane at room temperature reaches as high as 0.1.

Singlet oxygen also has a significantly long lifetime in perfluorinated solvents, although the origin of this effect is different from the one observed in the case of thiones and carbonyls. While in benzene, singlet oxygen $^1\Delta_g$ has a lifetime of 32 microseconds, in perfluorobenzene the lifetime is 3900 microseconds!.[22] In hydrocarbon solvents, the singlet oxygen relaxes nonradiatively by a specific interaction with a C–H bond, which does not occur (or only very weakly) with the C–F bond.

107.5 Temperature Effects

Even excited-state reactions can have small activation energies. If this is the case, the photoreaction could be sensitive to the temperature at which the photolysis is conducted. The azoalkane **17**, when photolyzed at −78°C, yields a single product, diazacyclooctatetraene (Scheme 22).[23] On the other hand, when photolyzed at room temperature, benzene isomers are obtained. Diazacyclooctatetraene **22** is derived from the triplet state of azoalkane **17**. At low temperature (−78°C), when the cleavage from S_1 state is slow the intersystem crossing to T_1 occurs readily to yield the triplet product diazacyclooctatetraene. At room temperature, the S_1 gains enough activation energy to extrude nitrogen, resulting in highly strained benzene isomers. The energy of activation for nitrogen extrusion from S_1 is determined to be ~6 kcal mol^{-1}.

107.6 Use of Lewis Acids and Metal Ions

The $\pi\pi^*$ reactivity of a carbonyl chromophore could be induced and the $n\pi^*$ reactivity could be prevented provided the $n\pi^*$ state is pushed well above the energy of the $\pi\pi^*$ state. An approach to achieve this goal has been to protonate the carbonyl chromophore.[24] In an acidic medium, the $n\pi^*$ band of a neutral carbonyl is substantially blue-shifted as a result of one of the two pairs of n-electrons being bonded to the proton. On the other hand, the $\pi\pi^*$ band is red-shifted. As a result, the lowest excited energy state is $\pi\pi^*$ in character. The probability of intersystem crossing from the singlet to the triplet manifold is reduced in protonated carbonyl compounds owing to the energy of the $n\pi^*$ triplet being above that of the $\pi\pi^*$ singlet. Thus, the chemistry occurs essentially from an S_1 of $\pi\pi^*$ character. While acids are quite useful to effect protonation of a carbonyl compound and the photochemistry from the $\pi\pi^*$ state of the protonated carbonyl is clean, the isolation of primary products is troublesome. Due to this complication, instead of using strong Brønsted acids, most often Lewis acids are used to achieve the same goal.

	23	**24**	**25**
None	20	71	10
In presence of BF_3	0	10	90

SCHEME 21

Coumarins, upon direct excitation, yield a mixture of the syn-head-head (**23**), *anti*-head-head (**24**) and *syn*-head-tail (**25**) dimers (Scheme 21).[25] At moderate coumarin concentration (0.2 *M*) when the reaction occurs mainly from the triplet state, the major product (75%) in methylene chloride is *anti*-head-head dimer. This dimer is believed to arise from the $n\pi^*$ triplet of coumarin. Irradiation of coumarin–BF_3 complexes under similar concentration conditions gave the *syn*-head-tail dimer (**25**) as the major product (90%). There is a reversal in the geometry of the dimer formed in the absence and presence of the Lewis acid BF_3. This change is attributed to the lowering of the energy of the $\pi\pi^*$ state of coumarin by BF_3 complexation.

2-Naphthaldehyde has a non-fluorescent lowest $n\pi^*$ excited singlet.[26] However, in presence of Mg^{2+}, this becomes fluorescent. This change in the photophysics is attributed to the switching of the order of the $n\pi^*$ and $\pi\pi^*$ states. In acetonitrile, in the absence of $Mg(ClO_4)_2$, the S_1 is $n\pi^*$ in nature, which has a high rate of intersystem crossing to the triplet manifold. On the other hand, in the presence of $Mg(ClO_4)_2$, the S_1 state is $\pi\pi^*$ in character.

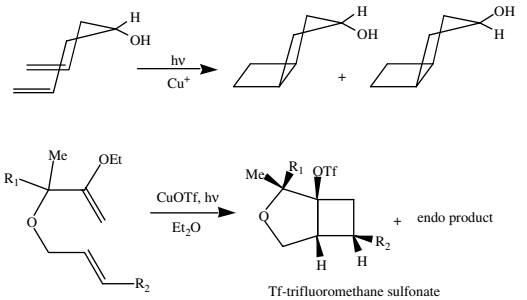
Intramolecular photocycloadditions of 1,n-dienes can be achieved by the use of Cu^+ ions. Cu^+ serves as a removable tether to preorganize the ene chromophores. Cu^+ triflate-catalyzed photoreactions of alkenes involve light absorption by preformed alkene–Cu^+ complexes. The Cu^+–alkene triflate complex generally shows two strong absorption bands (230–240 nm and 260–290 nm) while the uncomplexed alkenes are nearly transparent in this region. Because of this effect even if only a small percentage of alkene exists in the complexed state, only the complex will react. This cycloaddition reaction is run most often under catalytic conditions.

Irradiation of the diene in Scheme 22 as a Cu^+ triflate complex yields the intramolecular adducts. In the absence of the Cu^+ ,the intramolecular [2+2]-addition is very inefficient. The addition reaction in the presence of Cu^+ triflate is often *endo-exo* selective. One such example is also shown in Scheme 22.

107.7 Use of Chiral Sensitizers and Chiral Auxiliaries

Induction of chirality to obtain enantiomerically or diastereomerically enriched materials is achieved by several approaches:[27] (1) absorption of circularly polarized light by a racemate, causing different reaction rates for the enantiomers; (2) reactions in chiral medium such as chiral solvent; (3) the use of an enantiomerically pure sensitizer; and (4) the use of enantiomerically pure materials, that is, photochemically reactive components attached to an enantiomerically pure auxiliary. The first two methods have not yielded product with more than a few percent enantiomeric excess (*ee* < 5%). Chiral sensitization has yielded, in a few select examples, moderate *ee* (~15–65%), while the chiral auxiliary approach has yielded high diastereomeric excess (*de*). In this approach, because there is a chiral center in the reactant, the products are formed as diastereomers. Removal of the chiral auxiliary results in an enantiomerically enriched product.

cis-Diphenylcyclopropane is achiral while the *trans*-isomer is chiral. Energy- or electron-transfer sensitized irradiation of *cis*-diphenylcyclopropane in isotropic solvents provides the *trans*-isomer as a



R_1	R_2	exo : endo

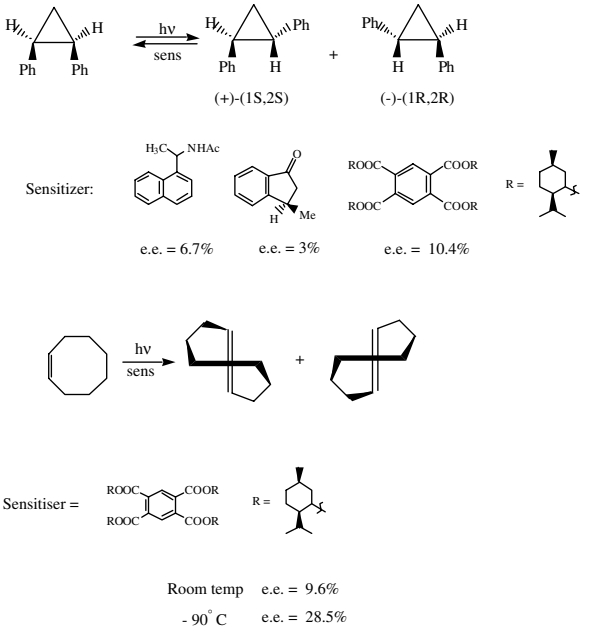
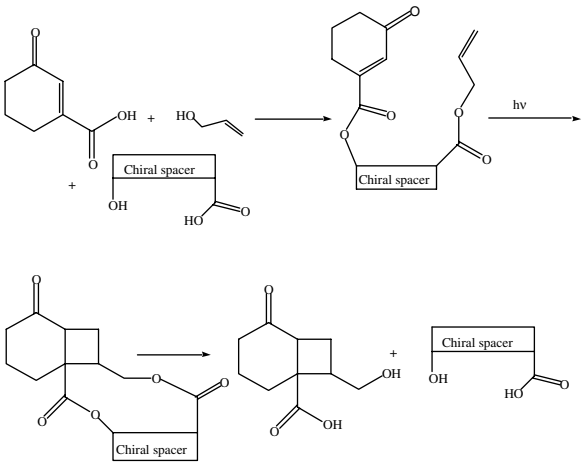
SCHEME 22



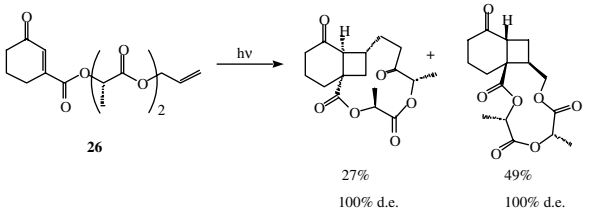
SCHEME 23

racemic mixture. However, the photoisomerization upon sensitization with a chiral sensitizer results in the *trans*-isomer with an *ee* of ~5 to 10% (Scheme 23).[29]

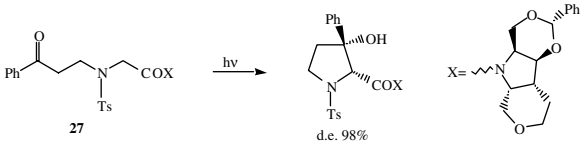
Achiral *cis*-cyclooctene upon singlet sensitization yields chiral *trans*-cyclooctene. While achiral sensitizers yield a racemic *trans*-cyclooctene, chiral sensitizers yield enantiomerically enriched *trans*-cyclooctene (Scheme 23).[30] The highest *ee* reported (73%) thus far is with optically active (−) tetramenthyl-1,2,4,5-benezene tetracarboxylate at −110°C in diethyl ether. The extent of *ee* depends on temperature, pressure, and solvent.



SCHEME 24



SCHEME 25

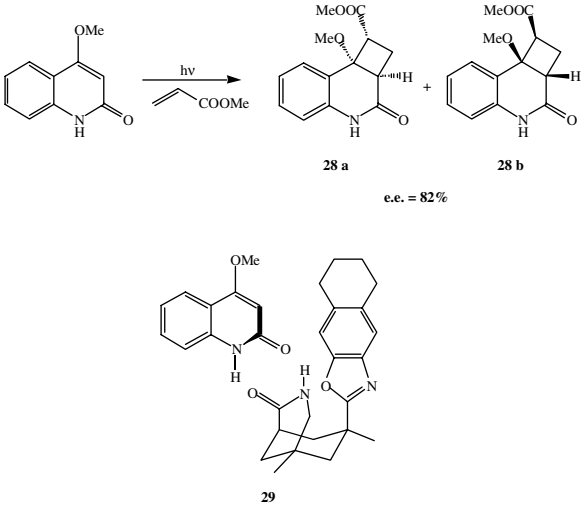


SCHEME 26

An alternate approach to chiral sensitization is to tie the chiral component and the reactant through a covalent bond.[31] This traditionally popular synthetic strategy is known as the chiral auxiliary approach. The best examples of this strategy are found in bimolecular photoaddition reactions. The chiral auxiliary could be either on the reactant to be excited or on the ground state molecule reacting with the excited-state species.

For this method to be a success, the chiral auxiliary should be an easily attachable and removable group (Scheme 24).[32] The dimalic ester substrate **26** gave head-head and head-tail adducts. What is remarkable is that both adducts are formed as single diastereomer (Scheme 25). Removal of the chiral auxiliary gave a single enantiomer in each case. This route is useful because the inexpensive chiral auxiliary is used as a temporary linker and can easily be removed after photocycloaddition.

The chiral auxiliary method yields exceptionally high *de* values even during intramolecular hydrogen abstraction reactions of carbonyl systems. A single isomer of highly substituted cyclopentanols was obtained when the chirally modified aryl alkyl ketones **27** shown in Scheme 26 were irradiated.[33]



SCHEME 27

107.8 Templating Effect

By a templating effect we mean that the reactants are prearranged for the reaction and the photoreaction becomes more selective or a reaction that would not occur otherwise takes place in the presence of the template. Best templating effects are achieved in organized/confined media, which is discussed in the next section. In this section we provide examples that illustrate a strategy that can be adopted to achieve selective chemistry.

Consider the addition of vinyl acetate to the quinolone shown in Scheme 27.[34] Addition to excited quinolone could take place from either prochiral face resulting in a diastereomeric mixture of **28**. Chiral amide **29** is able to hold the quinolone in a good orientation so that the addition occurs only to one of the two prochiral faces (Scheme 27). Hydrogen bonding between the amide and quinolone plays an important role in this operation. The *ee* obtained is fairly high with several olefins (>80%). The fact that the binding constants between the chiral amide and quinolone are high and the chiral amide is recoverable makes this a novel approach.

A modification of the above approach is one where one of the reactants is covalently linked to the chiral amide. Paterno-Buchi reaction of benzaldehyde under normal conditions would proceed equally from the two prochiral faces of the carbonyl chromophore.[35] If one wishes to control the addition, "somehow" one needs to distinguish between the two faces. This is done by the templating effect — that is, the olefin is steered to approach the carbonyl preferentially from one face by the use of external forces. The example shown in Scheme 28 illustrates this concept. The olefin dihydropyridone, when pre-associated to the carbonyl with the help of hydrogen bonding to the chiral amide, undergoes addition selectively from one face. A diastereomeric ratio of 95:5 is achieved in toluene while that in acetonitrile is 50:50. The importance of pre-organizing the dihydropyridone prior to exciting the carbonyl is evident from the fact that when the chiral amide is modified so that it cannot selectively form hydrogen bonds with the dihydropyridone, the diastereomeric ratio is 50:50.

Cinnamate esters in solution undergo geometric isomerization much more efficiently than dimerization. Consistent with this, the diaminotriazine-substituted cinnamate ester **30**, upon irradiation in solution, undergoes mainly geometric isomerization, with minor amounts of several dimers being formed upon prolonged irradiation. When the irradiation is conducted in the presence of the template, substituted barbituric acid **31**, three dimers were formed with much higher quantum yield (Scheme 29).[36] The hydrogen bonding complementary nature of the diaminotriazine unit and barbituric acid unit is exploited

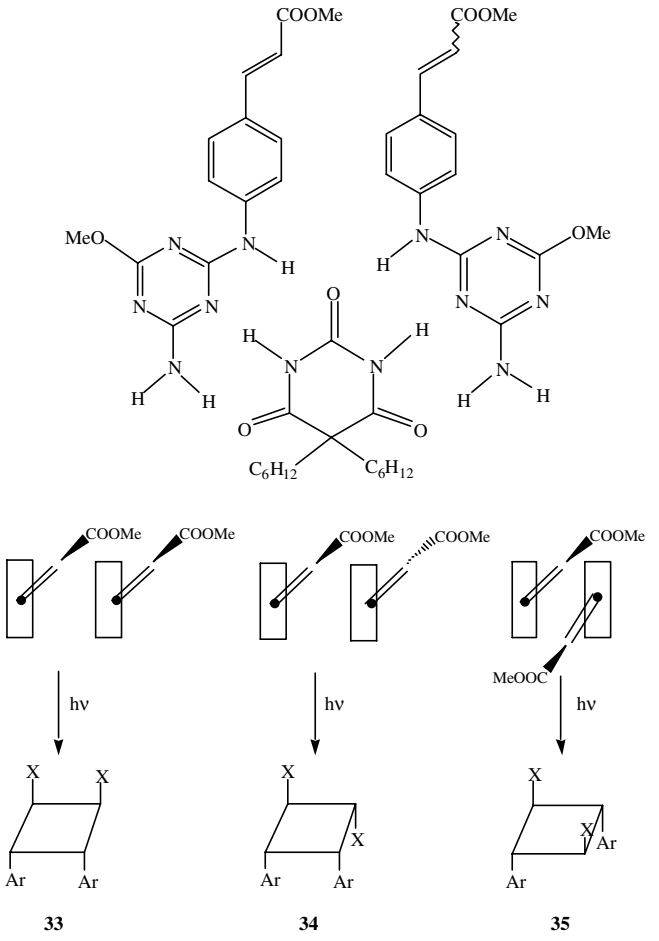
in this templating operation (Scheme 30). When the hydrogen-bonding ability of the barbituric acid unit was eliminated by alkylation of the amino groups (**32**), no enhancement in the dimerization occurred.

107.9 Influence of Organized Media

Chemists have long recognized the important role that the reaction medium plays in controlling the rates, product distributions, and stereochemistry of organic reactions. Recently, much effort has been directed toward the use of organized media to modify the photochemical reactivities achieved with isotropic liquids.[37] A principal goal of such studies is to utilize the order of the medium to increase the rate and selectivity of a chemical process in much the same way that enzymes modify the reactivity of the substrates to which they are bound. Notable among the many ordered or constrained systems are micelles, microemulsions, liquid crystals, inclusion complexes, monolayers, and solid phases such as porous solids (silica, alumina, clay, and zeolites) and crystals. The differences in chemical reactivities observed in ordered media, compared to isotropic solvent phases, are largely due to the physical restraints

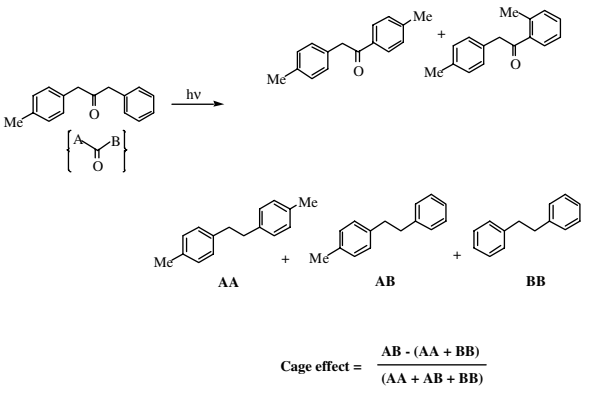


SCHEME 30

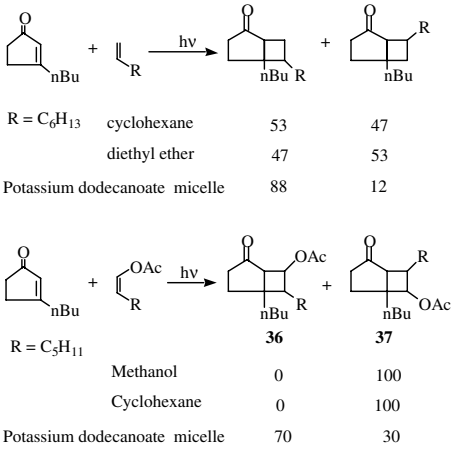
imposed by the environment. These include preventing large-amplitude conformational, configurational, and translational changes along the reaction coordinate, modifying diffusional characteristics of reactants, and facilitating alternate reaction pathways. The intrinsic reactivity of a molecule in an ordered medium is frequently of secondary importance in comparison to features such as site symmetry, nearest neighbor separation, and other geometric considerations. In organized media, the very familiar electronic and dipolar effects and hydrogen bonding of solution chemistry are replaced by structural and topological factors that frequently result in degrees of selectivity or stereospecificity of product formation that are not observed in solution. A few examples employing micelles, cyclodextrins, silica, and zeolite surfaces and liquid crystals as media are presented in this section.

Photochemistry of dibenzyl ketones has been examined in a number of organized media. Photolysis of 3-(4-methylphenyl)-1-phenylacetone (MeDBK) results in a 1:2:1 mixture of three products shown in Scheme 31.[38] Photolysis of the same molecule solubilized in a micelle (hexadecyltrimethylammonium chloride) gives a single product (AB). This remarkable change in product distribution is due to the cage effect brought forth by the micellar structure. The change in product distribution occurs at or above the critical micelle concentration.

Photocycloaddition of 3-*n*-butylcyclopentanone in the presence of 1-hexene in organic solvents gives two adducts **36** and **37** in a 1:1 ratio (Scheme 32).[39] However, irradiation in a potassium dodecanoate micelle yields the isomer **37** as the major product, consistent with the notion that a micellar interface



SCHEME 31

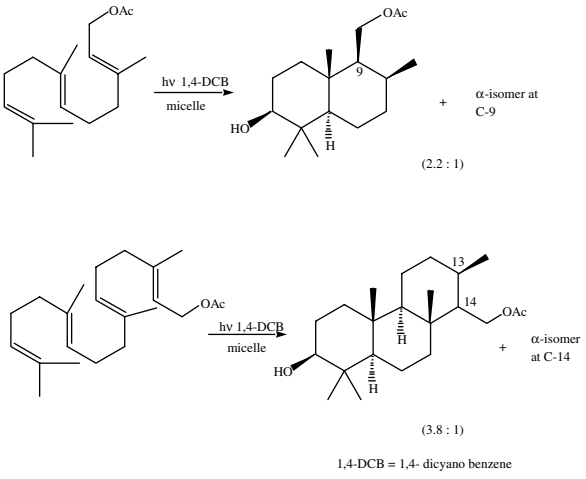


SCHEME 32

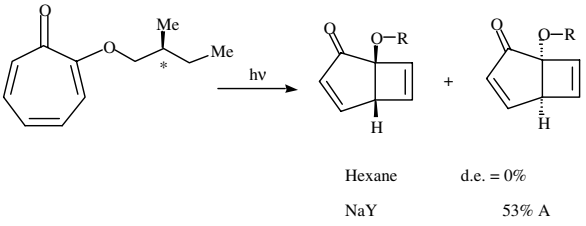
helps orient the reactant molecules. When the orientation of the reactive olefin is further fixed with a hydrophilic group, as when the olefin is heptenyl acetate instead of 1-heptene, a dramatic switch in the regiochemistry of the product is observed.

Upon irradiation, in acetonitrile/aqueous solution, of 1-cyanonapthalene in the presence of *all trans*-farnesyl acetate, the latter undergoes only *cis,trans*-isomerization via an electron-transfer process.[40] No products from any other reactions were isolated. However, when the same combination of molecules was irradiated in sodium dodecyl acetate micellar solution, the main product was the result of intramolecular cyclization (Scheme 33). The cyclization is stereo- and regioselective to yield a *trans*-fused product in which the water molecule has added stereoselectively. Such an amazing selective cyclization occurs only in a micellar medium.

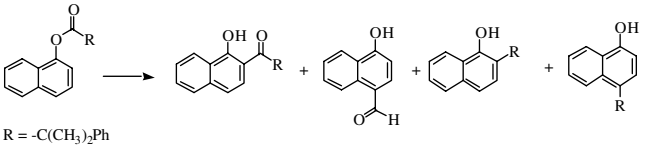
Irradiation of the (S)-tropolone 2-methyl butyl ether shown in Scheme 34 in solution yields a 1:1 diastereomeric mixture.[41] Clearly, in solution the presence of a chiral auxiliary in proximity to a reactive center has no influence on the product stereochemistry. When irradiated within NaY zeolite, the same molecule gave the cyclized product in ~53% diastereomeric excess. The smaller and controlled space of the zeolite supercage apparently has forced the establishment of communication between the chiral center and the reaction site.



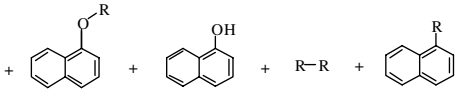
SCHEME 33



SCHEME 34

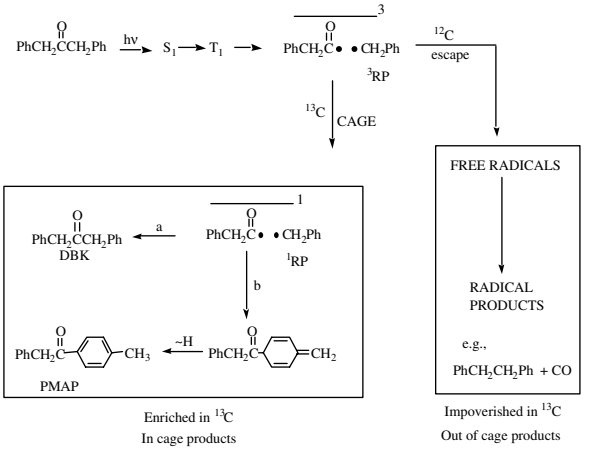


Hexane	28	15	9	14
NaY	99%	--	--	--



Hexane	0	13	15	6
NaY	99%	--	--	--

SCHEME 35



SCHEME 36

An impressive illustration of the influence of the medium on the photo-Fries reaction product distribution can be found in Scheme 35.[42] Remarkably, whereas in solution eight products are formed, within NaY zeolite a single product dominates the product mixture. Cations present within zeolites help to anchor the reactants, intermediates, and products to the surfaces of the zeolite and control the reactivity of the intermediates. In this case, the cation binding not only forced the phenyl acyl radical to react at the *ortho*-position preferentially but also prevented it from decarbonylation.

The difference in the nature of the reaction cavity provided by an isotropic solvent and a micelle is nicely demonstrated by the isotope enrichment observed during the photolysis of DBK. This process can be understood using the detailed mechanism for cleavage process presented in Scheme 36.[43] α-Cleavage of the triplet excited DBK results in a triplet geminate primary radical pair ($C_6H_5CH_2^{\bullet}$ and $C_6H_5CH_2CO^{\bullet}$, PRP^3). This initial radical pair loses CO to generate the secondary radical pair ($2C_6H_5CH_2^{\bullet}$, SRP). The two benzylic SRP combine to yield the final product, 1,2-diphenylethane. An option, unavailable in isotropic solution to the PRP^3, becomes available within a micellar reaction cavity. If the PRP^3 is constrained long enough to allow intersystem crossing to the singlet state PRP^1, it can recombine with rearrangement to yield 1-phenyl-4-methylacetophenone (PMAP) or without rearrangement to afford the parent DBK. In a micelle, the triplet-to-singlet intersystem crossing of PRP^3 competes with the decarbonylation process and the cage escape. The rate of decarbonylation of the phenylacetyl radical has been established to be 6.4×10^6 s^{-1} at room temperature and the rate of cage escape from the micelle has been estimated to be around 10^6 s^{-1}. Intersystem crossing facilitated by the hyperfine interaction between ^{13}C nuclei at the carbonyl carbon (or the benzylic position) and the unpaired electron spin could occur on the microsecond timescale. Because ^{12}C nuclei do not enhance intersystem crossing, the competition between decarbonylation and intersystem crossing of PRP^3 to PRP^1 can only occur in molecules containing ^{13}C nuclei. Based on the established mechanism for the nuclear hyperfine-induced intersystem crossing, one would expect a higher yield of PRP^1 from molecules containing ^{13}C nuclei and decarbonylation from those with ^{12}C nuclei. This selective process would be expected to yield ^{13}C-enriched DBK and PMAP. This has been demonstrated by photolysis of DBK that is 48% enriched in ^{13}C at the carbonyl carbon. After 90% photolysis, the CO carbon of the remaining DBK has 62% ^{13}C as compared to 48% at the start. Similar enrichment in PMAP was also noted. The absence of such effects in homogeneous solutions is due to the short lifetime of the solvent cage, which is much shorter ($<10^{-10}$ s) than that of a micelle ($\sim 10^{-6}$ s). Within the short time of the solvent cage, nuclear hyperfine coupling will not be able to induce intersystem crossing of PRP^3 to form PRP.[1]

107.10 Summary

This chapter provides examples where the established excited-state behavior of organic molecules has been altered by various techniques. Singlet–triplet control via sensitization and the heavy-atom effect are well-established, common methods used routinely by photochemists. Wavelength effects, although specific to chromophores, can be useful. Reactions from upper excited states continue to be unique and novel. Among the various solvents used, perfluorinated ones have unusual properties and should be used as reaction media especially when the chromophore reacts with hydrogenated solvents. Control via the templating effect is truly novel and imaginative. This approach will gain strength in the coming years when better understanding is reached about "weak interactions." Controlling reactions via cation–organic interactions in organic solvents, unfortunately, is a technically difficult one. Given the potential of this method, more attention needs to be paid to this system. Of the various approaches, the ones employing organized media have received considerable attention. Even in these, organic crystals, micelles, and zeolites show more promise than others in terms of product selectivity.

Endoperoxides: Thermal and Photochemical Reactions and Spectroscopy

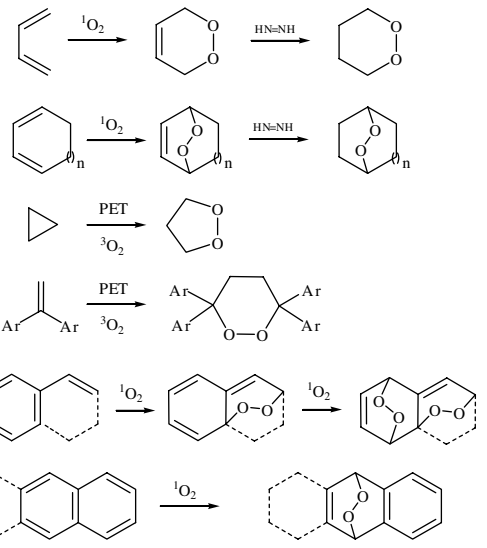
Axel G. Griesbeck
University of Cologne

Murthy S. Gudipati
University of Maryland

108.1 Introduction

Cyclic saturated or unsaturated dialkylperoxides are termed endoperoxides with 1,2-dioxetanes as exceptions that are normally not grouped in the endoperoxide family.[1] The prefix *endo* has only historical reasons[2] and by no means indicates stereochemical properties, thus the term "*exo*peroxides" should be avoided. Common useage also comprises monocyclic dialkylperoxides and bi- and polycyclic compounds. The central structural feature determining the thermal, the photochemical, and also the redox behavior of endoperoxides is the oxygen–oxygen single bond. In most thermal or photochemical processes, homolytic OO bond cleavage follows activation; redox processes are mostly initiated by one-electron reduction followed by mesolytic cleavage or a subsequent secondary electron transfer.[3] The bond dissociation energy of the OO bond in unstrained or moderately strained endoperoxides is approx. 37 kcal mol^{-1} and, thus, these compounds are prone to thermal decomposition.[4] It is commonly accepted that the peroxide chromophore is characterized by a broad $\pi^*\sigma_{oo}^*$ transition with a low extinction coefficient.[5] An increase in ring strain induces a blue shift of this absorption (1,2-dioxetanes — not counted as endoperoxides — are yellow compounds with λ_{max} around 450 nm). Unstrained endoperoxides exhibit absorption in the region of λ_{max} = 300–350 nm, higher strained or unsaturated endoperoxides absorb from 350 up to 400 nm with extinction coefficients of 10–15 M^{-1} cm^{-1}. From the reactivity point of view, it is appropriate to arrange endoperoxides into unsaturated and saturated compounds, that is, endoperoxides with the peroxy linkage in allylic position and saturated analogs. The additional double bond in unsaturated endoperoxides gives rise to secondary reactions preceding the primary cleavage of the oxygen–oxygen single bond. The thermal and photochemical behavior of different types of endoperoxides

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1

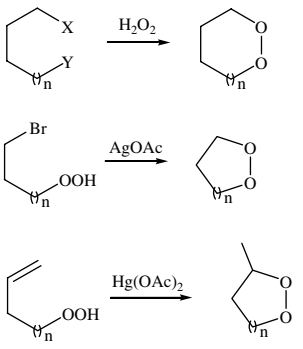
are outlined herein. Theoretical interpretation of the photochemistry of aromatic endoperoxides has been the subject of some controversy in the past few years few years and this is presented in detail in the last part of this review.

108.2 Synthesis

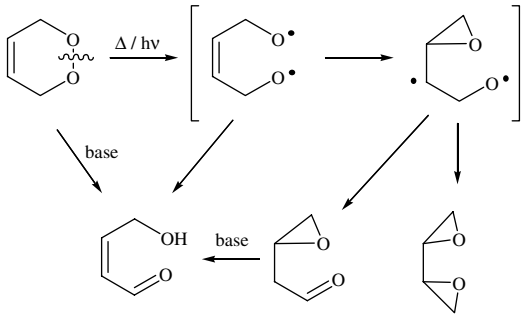
There are several synthetic approaches to endoperoxide structures. One of the most important routes is the singlet oxygen [4+2]-cycloaddition to acyclic or cyclic 1,3-dienes and hetero-analogs.[6] In some cases, also autoxidation ("type I process") can lead to endoperoxides but these processes often lack selectivity and have poor product stability.[7] For several applications, Lewis-acid-catalyzed peroxidations of 1,3-dienes results in high product yields.[8] Saturated endoperoxides are easily available from their unsaturated precursors by double-bond reduction with diimide.[9] 1,2-Dioxolanes (five-membered endoperoxides) are accessible by photoinduced electron-transfer reaction with cyclopropanes and trapping of the trimethylene radical cations by triplet oxygen.[10] A similar approach to saturated six-membered ring peroxides involves the photochemically induced one-electron oxidation of arylated alkenes and subsequent dimerization/triplet oxygen addition.[11] This reaction is superior for electron-donor substituted 1,1-diarylethylenes resulting in 3,3,6,6-tetraaryl-1,2-dioxanes.[12] The singlet oxygen route to monocyclic unsaturated endoperoxides (1,2-dioxenes) is possible from a large variety of substituted 1,3-butadienes.[13]

The solvent dependence of these [4+2]-cycloadditions has been intensively studied.[14] Cyclic 1,3-dienes and heteroanalogs are obviously more reactive and a multitude of endoperoxides have been generated by singlet oxygen addition to these substrates. Even vinylarenes (styrene, stilbene, vinylnaphthalene, vinylheteroarenes) can react with singlet oxygen to give monoadducts, which rapidly add another equivalent of singlet oxygen to give *bis*-endoperoxides.[15] Alkylated benzene or naphthalene derivatives are converted into doubly unsaturated endoperoxides by singlet oxygenation.[16] Naphthalene and higher arenes give monoadducts with singlet oxygen that can be applied in retro [4+2]-cycloadditions and thus store electronically excited oxygen.[17] In addition to photochemical reactions thermal pathways to endoperoxides also exist: hydrogen peroxide can be used as a *bis*-nucleophile and substitute two appropriate leaving groups (halogen, hydroxy, and activated hydroxy groups, respectively).[1]

By reaction with silver acetate, 1,n-bromohydroperoxides are converted into endoperoxides with (n+2) ring atoms.[18] Similar to the classical oxymercuration, intramolecular peroxymercuration of unsaturated (homoallylic or higher homologs) hydroperoxides can also serve as an efficient path to endoperoxides.[19]



SCHEME 2



SCHEME 3

108.3 Thermal and Photochemical Reactions

Aliphatic Unsaturated Endoperoxides

Due to the presence of an additional double bond in the starting material, alkoxy radicals generated by thermal or photochemical reactions can react in an intramolecular fashion to give *bis*-epoxides.[20] This symmetric path can be accompanied by a hydrogen transfer process, which leads to hydroxyenones, equivalent to the base-catalyzed Kornblum-DeLaMare process.[21] Alternatively, initiated by cleavage of two CO single bonds (either stepwise via a peroxy radical or concertedly) singlet oxygen is produced in a cycloreversion process and the diene substrate is regenerated.[22] A third (dissymmetric) path leads to the formation of epoxycarbonyl compounds involving the formation of the OO-biradical and subsequent ring formation and 1,2-hydrogen transfer reaction (see Scheme 3).[23]

A series of experimental and theoretical studies indicate that the two symmetric pathways, *bis*-epoxide and singlet oxygen formation, respectively, are initiated by two different excited states.[24,25,]

The OO cleavage path seems to originate from the dissociative $\pi^*\sigma_{oo}^*$ transition at relatively long wavelength, whereas the retrocleavage path results from a $\pi\pi^*$ transition of the unsaturated part of the molecule in a shorter wavelength region. In the absence of an additional CC double bond, no cycloreversion can be observed, whereas photoinduced isomerization processes were observed from saturated as well as from saturated endoperoxides. Dufraisse and co-workers published the first report on the photoisomerization of an unsaturated endoperoxide.[26] They investigated the endoperoxide from 2,3,4,5-tetraphenylfulvene and a series of substituted 2,3,4,5tetraphenyl-cyclopenta-2,4-dienes **1**. From these substrates the syn *bis*-epoxides **2** were formed efficiently and with high chemoselectivity (Scheme 4).

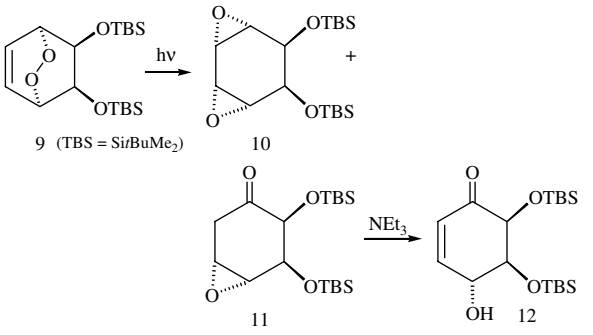
SCHEME 6

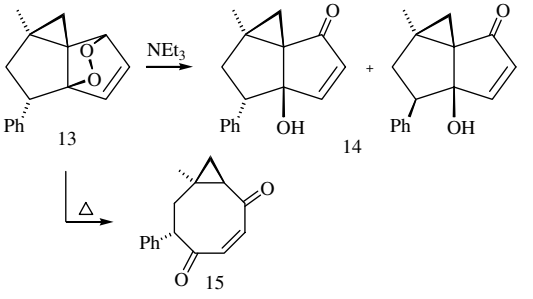
In contrast to the commonly observed, highly selective photochemical reactions, thermal rearrangements of endoperoxides often lead to more complex mixturex of products.[27] A naturally occurring compound, the terpene endoperoxide ascaridole (**3a**) rearranges into isoascaridole (**4a**) upon irradiation (long-wavelength excitation at 366 nm) while similar cyclohexadiene endoperoxides **3** result in mixtures of bis-epoxides **4** and epoxyketones **5** upon thermolysis (Scheme 5).[28]

A systematic study was performed by Carless and co-workers on the photochemical behavior of endoperoxides derived from cyclohexadiene, cycloheptadiene, and cyclooctadiene.[29] They found that epoxyketones are preferentially formed over *bis*-epoxides and that this trend is more pronounced in the photolysis than in the thermal isomerization of these compounds. The mechanism of these reactions is state dependent. After direct excitation as well as thermal activation, a singlet excited state is generated that can proceed by a concerted $[\sigma^2+\pi^2]$-cycloaddition to give the *bis*-epoxide.[30] Alternatively, a dioxyl biradical can be formed as a short-lived singlet intermediate. The latter species is a more likely intermediate for the corresponding triplet process, which has been also described in several examples.[28] Actually, triplet-triplet energy transfer can increase the efficiency of the photoisomerization in comparison with direct excitation. In the triplet path, an intermediate triplet dioxyl radical might constitute a longer-lived intermediate enabling a stronger competition of hydrogen migration (leading to epoxyketones) with the formation of the *bis*-epoxides. An increase in the endoperoxide ring strain often facilitates the ring opening, as seen in the *bis*-endoperoxide **6** where the more strained peroxy bridge opens more efficiently upon photolysis and results in a 1:2 mixture of *bis*-epoxide **7** and epoxyketone **8** (Scheme 6).[31]

Various applications of the endoperoxide-epoxide rearrangements in the multistep total synthesis of natural products are reported in the literature,[32] for example, the synthesis of stemolide, a natural *syn*-diepoxide with antileukemic activity.[33] A photochemical route from arenes to inositol intermediates was



SCHEME 7



SCHEME 8

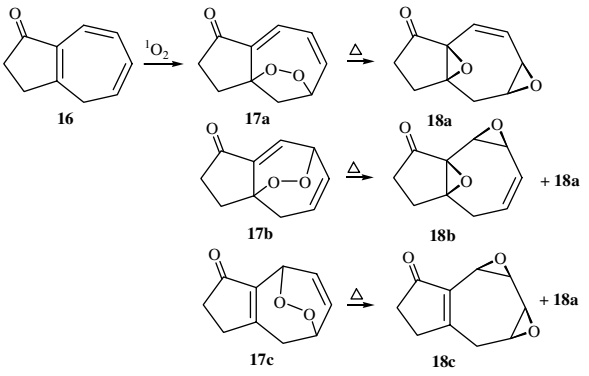
described using the photooxidation of substituted *cis*-cyclohexa-3,5-diene-1,2-diols and subsequent photolytic isomerization of the endoperoxide **9** to the *bis*-epoxide **10** and two diastereoisomeric β,γ-epoxyketones **11** (only one shown). The latter compounds can rearrange by base catalysis to give γ-hydroxyenones **12** (Scheme 7).[34]

In addition to photolytic or thermolytic conditions, the endoperoxide rearrangement to *bis*-epoxides can also be conducted in a catalytic version in the presence of metaloporphyrins (e.g., cobalt(II) tetraphenylporphyrin).[35] An illustrative difference between base-catalyzed (Kornblum-DeLaMare reaction)[21] and thermal rearrangement of a cyclopentadiene-derived endoperoxide **13** was described recently.[36] When **13** was treated with a base at low temperature, two diastereoisomeric hydroxyenones **14** resulted, whereas the eight-membered (ring-enlarged) enedione **15** was formed as the major rearrangement product from **13** when kept at room temperature for a longer time (Scheme 8).

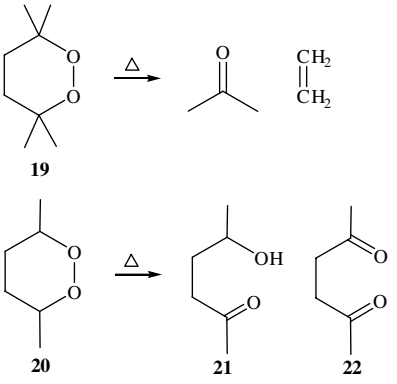
The synthesis and chemistry of endoperoxides **17** derived from 3,4-dihydroazulene-1-one **16** was studied by Balci and co-workers.[37] Three regioisomeric products **17a**,**b**,**c** derived from the singlet oxygen photoooxygenation of **16**, which were subjected to solution thermolysis as well as to CoTPP-catalyzed ring opening. All endoperoxides resulted in the same *bis*-epoxide **18a** as the major product, indicating a thermal endoperoxide–endoperoxide isomerization. This isomerization was not detected for the corresponding 1-methoxy-1,2,3,4-tetrahydroazulene, indicating the special role of the carbonyl group in **17** for isomerization processes (Scheme 9).[38]

Aliphatic Saturated Endoperoxides

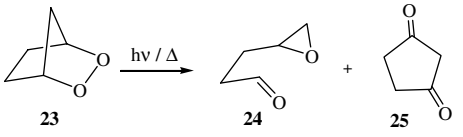
The thermolysis of the 3,3,6,6-tetramethyl-1,2-dioxane **19** results in the formation of ethylene and acetone.[39] Studies on the stereoselectivity of the alkene formation using deuterium labels at C4 and C5



SCHEME 9



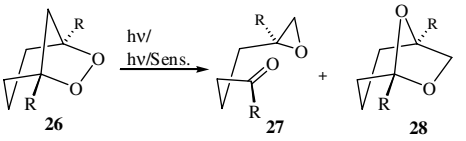
SCHEME 10



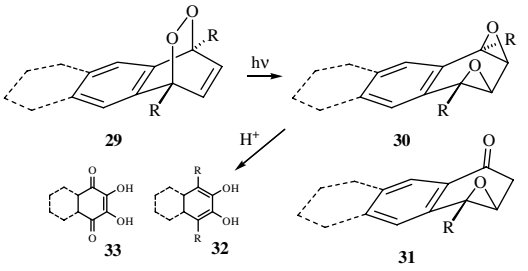
SCHEME 11

revealed that the β-scission occurs from two different conformers, leading to *cis*- and *trans*-alkenes. Permethylation of the C_α-positions is crucial for this process; for example, 3,6-dimethyl-1,2-dioxane **20** results in a hydrogen shift and a dehydrogenation product **21** and **22**, respectively, upon thermolysis (Scheme 10).[40]

The bicyclic endoperoxide **23** (from cyclopentadiene and subsequent diimide reduction)[9] thermally rearranged to two products (**24**, **25**) by hydrogen migration or dehydrogenation without β-scission.[41] The major photoproduct from 2,3-dioxa[2.2.1]heptane **23** is the 4,5-epoxypentanal **24** as also observed from gas- or solution-phase thermolysis (Scheme 11). An extended study on homologous bicyclic endoperoxides revealed comparable behavior under gas-phase thermolysis conditions.[42] Studies on the photolysis of saturated bicyclic endoperoxides showed similarities to the thermolytic behavior, which are interpreted via intermediate dioxyl radicals resulting from the homolysis of the OO bond. Saturated



SCHEME 12



SCHEME 13

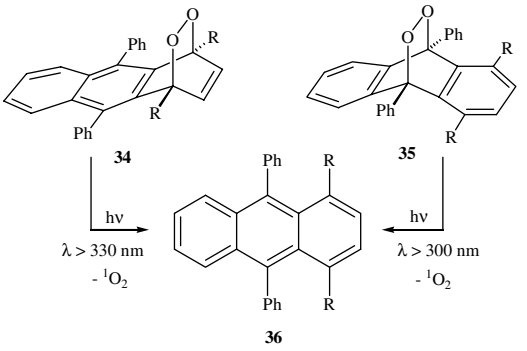
bicyclic peroxides have been investigated by Bloodworth and Eggelte.[43] Thermal and photochemical activation in several cases results in divergent processes due to different thermal or electronic states (singlet/triplet) of the initial generated dioxyl biradicals.

Under identical photochemical conditions, [n.2.1]peroxides (n = 3, 4, 5) afforded mainly the corresponding epoxyaldehydes, whereas gas-phase thermolysis resulted in ketoaldehydes in high yields. Concerning the multiplicity of the intermediary generated dioxyl biradical, the photolysis of the 6,7-dioxa[3.2.1]heptane **26** (R = H) is most illustrative. Upon triplet-sensitized photolysis in the presence of benzophenone, a rearranged product 6,8-dioxabicyclo[3.2.1]octane **28** is formed as the major product. Due to the spin multiplicity of the initially formed triplet 1,5-O,O-biradical, the formation of the carbonyl group with concerted CO bond cleavage generates a triplet 1,3-C,O-biradical that cannot directly form a new single bond and alternatively reacts with the carbonyl group in a [2+2]-cycloaddition. In contrast, the direct photolysis at lower wavelengths gives preferentially the epoxyaldehyde **27**. In this case, the singlet 1,3-C,O-biradical can directly combine without spin-barrier. An analogous effect was reported for the dimethyl analog, 1,5-dimethyl-6,7-dioxabicyclo[3.2.1]octane **26b** (R = Me), whose benzophenone-sensitized irradiation provided an elegant photochemical synthesis of the pheromone frontalin (Scheme 12).[44]

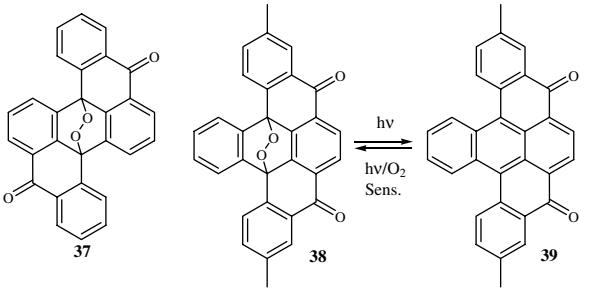
Aromatic Endoperoxides

The benzoannulated endoperoxides **29** derived from naphthalene and anthracene derivatives (endoperoxides of the 1,4-type termed *benzo*-endoperoxides) exclusively give *syn-bis*-epoxides **30** when irradiated at long wavelength ($\lambda > 366$ nm) (see Scheme 13).[45,46,] Formation of the corresponding epoxyketone **31** was solely observed from the tetramethyl-substituted **29** when the reaction was triplet sensitized.[47] The acid-catalyzed isomerization of *bis*-epoxides to give phenol derivatives **32**[45b,46b] and 2,3-dihydroxynaphtho- and anthraquinones **33** via the bridgehead methoxy-substituted endoperoxides **29**, respectively, is synthetically useful.[45a,46a]

Reactive *syn-bis*-epoxides available from the anthracene-endoperoxides by low-temperature irradiation at long wavelength could be thermally isomerized to benzocyclobutenic diethers and other products.[48] A new kind of isomerization of aromatic endoperoxides, which is initiated by a Grob-fragmentation step, was described recently for anthracene and naphthalene *bis*-epoxides.[49] The photochemistry of aromatic



SCHEME 14



SCHEME 15

endoperoxides (or, more pre*cis*ely, endoperoxides with annulated aromatic rings) is striking because not only do several reaction modes compete but also higher excited singlet states seem to be involved. The photoinduced cleavage of endoperoxides into singlet oxygen and the deoxygenated arene occurs upon irradiation at short wavelength. Thus, the high-energy excitation of the endoperoxide of 9,10-diphenylanthracene ($\lambda < 300$ nm) leads to photodissociation, whereas low-energy excitation ($\lambda > 300$ nm) leads to photoisomerization. Similar effects were observed with endoperoxides from anthracene and 9,10-dimethylanthracene.[50] For another substrate, the *benzo*-endoperoxide **34** (R = Me), cycloreversion from even higher excited singlet states S_3 and S_4 was postulated (Scheme 14).[51]

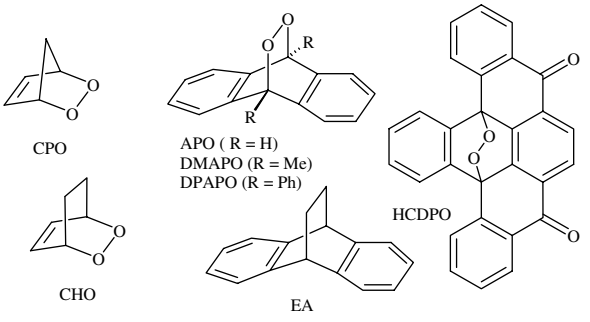
With the endoperoxide of heterocoerdianthrone **37**, the quantum yield of the (irreversible) photolytic decomposition becomes extremely small and the (reversible) photoinitiated cleavage to singlet oxygen and the arene establishes an efficient photochromic system.[52] A further improvement of this concept was achieved with the blue dimethylhomeocoerdianthrone **38**. This compound gave the colorless endoperoxide **39** by sensitized photooxygenation that reverts back quantitatively to the starting material **38** on irradiation at 313 nm (Scheme 15).[53]

The mechanism of the photochemical cycloreversion of endoperoxides has been a matter of debate. It was originally proposed that the CO bonds break simultaneously in a concerted fashion after electronic excitation of the endoperoxide.[54] From the relatively "slow" evolution of hydrocarbon ($\tau_2 = 1.6$ to 95 ps) compared to the very short lifetime of excited states ($\tau_1 \sim 3$ ps), it was concluded later that the photocycloreversion occurs in two steps (for a detailed discussion of the state-selectivity question, see Section 108.4). The first step is thus an ultrafast CO bond cleavage followed by the slow decay of the resulting 1,6-OC-singlet biradical to the ground state of the arene and singlet oxygen.[55] Laser-induced fluorescence[56] and transient absorption studies[57] have been used to measure the lifetimes of the intermediates; the shortest ones were detected for **39** ($\tau_1 < 0.35$ ps; $\tau_2 = 1.6 \pm 0.5$ ps). Photolysis at 275 nm of the anthracene endoperoxide in argon matrices at 15K resulted in cycloreversion exclusively.[58]

108.4 Spectroscopic and Theoretical Studies

Historical Perspective

Kearns and Khan predicted in 1969, using state and orbital correlation diagrams, that excitation of 1,3-cyclopentadiene endoperoxide (CPO) into S_1 or T_1 states leads to a barrierless rearrangement through OO homolytic bond cleavage and that the cycloreversion from these states has to circumvent a barrier.[54,59] However, a barrierless cycloreversion to generate cyclopentadiene and singlet molecular oxygen (O_2, $a^1\Delta_g$) was predicted by Kearns and Khan when CPO is excited into the higher singlet. These authors also generalized their predictions to aromatic endoperoxides and forecast that the family of endoperoxides should undergo wavelength-dependent dual photochemistry. Ironically, to date, dual photochemistry of CPO has not been experimentally proven. Nine years later, Rigaudy et al. reported wavelength-dependent photochemistry of 9,10-diphenylanthracene-9,10-endoperoxide (DPAPO).[60] They found that irradiation at 253.7 nm results in cycloreversion as the major channel and irradiation at longer wavelengths ($\lambda >$ 280 nm) leads to OO homolysis and rearrangement products. Around the same time, Brauer and co-workers had shown that photocycloreversion of dibenzo[*aj*]perylene-8,16-dione endoperoxide (HCDPO) occurs from the S_2 state and not from the S_1 or T_1 states.[61] Thus, three publications on three different molecules, consistent with each other on the dual photochemistry, lead to the general belief and acceptance that aromatic or aliphatic endoperoxides undergo photochemistry from higher excited electronic states,[62] consequently not in line with the photochemical interpretation of Kasha's rule: "the emitting electronic level of a given multiplicity is the lowest excited level of that multiplicity, (regardless of which state of a given multiplicity is excited)".[63]



Later on, more insight into the mechanistic aspects of endoperoxides photochemistry was obtained from time-resolved picosecond and femtosecond studies.[64] Unusually long risetimes of 40 to 95 ps, unexpected for a concerted and barrierless S_n ($n \geq 2$) photocycloreversion (should have been <3 ps), have been interpreted in terms of a biradical intermediate through a non-concerted cleavage of one of the CO bonds and due to a barrier which slows down the cycloreversion during the second CO bond cleavage. Thus, until recently, all the experimental findings sought their interpretation based on cycloreversion from higher excited states and OO homolytic rearrangement from the first excited singlet state of aliphatic and aromatic endoperoxides. If, on the other hand, the photocycloreversion occurs from the S_1 state, then the risetime of 40 to 95 ps is not very surprising. Two important underlying assumptions for the unusual photochemistry of endoperoxides were: the S_1 state has $\pi^*_{OO} \rightarrow \sigma^*_{OO}$ character and the S_2 state has $\pi^*_{OO} \rightarrow \sigma^*_{CO}$ character.

Recent Developments

Recent spectroscopic and theoretical studies[58,65] on anthracene-9,10-endoperoxide (APO) and 9,10-dimethylanthracene-9,10-endoperoxides (DMAPO) have shown that the well-accepted assignment of the electronic states based on the one and only empirical theoretical work carried out by Kearns and Khan[59,54]

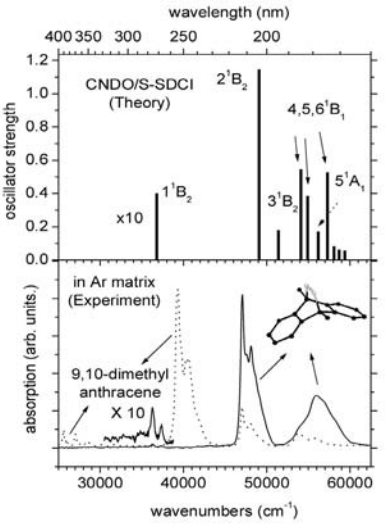


FIGURE 108.1 Bottom: Absorption spectra of DMAPO (solid line) and the cycloreversion product DMA obtained after photolysis at 275 nm, measured from the same sample using VUV synchrotron radiation. Top: Semiempirical predictions using CNDO/S (singly and doubly excited configurations included — SDCI) method.[58]

in 1969 and experimental observations of Brauer et al.[61] are not consistent with the spectroscopic data and semiempirical predictions.[64] Although it is convenient to think that the OO homolysis occurs through the $\pi^*_{OO} \rightarrow \sigma^*_{OO}$ character of the lowest excited singlet state (S_1), as accepted and believed earlier, this has been shown to be wrong in the case of the aromatic anthracene-endoperoxides APO and DMAPO.[58] Their assignment that the S_1 of APO and DMAPO should be the 1^1B_2 state with $\pi\pi^*$ (aromatic) character located around 275 nm in DMAPO is based on the semiempirical predictions that are in excellent agreement with the experimental data (Figure 108.1). Several consistency checks were carried out: (1) the nearly one-to-one correspondence between the predicted and observed energies of the singlet states of APO and DMAPO (Figure 108.1), (2) excellent agreement between the predicted and experimentally derived oscillator strength of the band at 210 nm due to the 2^1B_2 state of APO, (3) experimental observation of the theoretically predicted triplet states around 450 nm, (4) excellent agreement between the electronic states of APO and its isoelectronic molecule 9,10-dihydro-9,10-ethanoanthracene, and (5) successful application of exciton model to interpret the electronic states (singlet and triplet) of APO and EA.

Thus, the absorption due to triplet states detected at ~450 nm was attributed to the OO bond homolysis and subsequent rearrangement for the long-wavelength photochemistry and the normal $\pi\pi^*$ excitation into the first singlet (S_1) state for the cycloreversion reaction. These results lead to some controversy.[65,66] As discussed in these articles, it was proposed that to understand the photochemistry of endoperoxides, correlating the electronic states of the reactants and products alone (adiabatic approximation) may not be sufficient; rather, a non-adiabatic curve crossing needs to be considered seriously. That is, instead of a static picture of excited stationary states and their energies, a dynamic treatment including the evolution of the electronic excited states needs to be taken into account.

The spectroscopy and photochemistry of aliphatic endoperoxides should be clearly differentiated from the aromatic endoperoxides. The MOs containing significant coefficients on the non-dioxygen bridge and the dioxygen chromophore lie energetically very close to each other in aliphatic endoperoxides as, for example, in the case of CPO. They can even mix strongly. In such a case, the electronic states with MOs localized on the dioxygen bridge can become the lowest excited singlet states in accordance with the predictions of Kearns and Khan. However, for aromatic endoperoxides like APO, the MOs localized on the OO moiety are much further separated in energy compared to the MOs localized on the aromatic

units. Further, due to exciton-like interactions, the electronic states resulting from MOs localized on the aromatic units will be further stabilized to lower energies.[67] Due to the fact that the σ^* and π^* orbitals of the dioxygen bridge have very small overlap with the rest of the molecule, the OO bridge behaves like a sub-chromophore. This fact further supports the above-mentioned analysis.

Recently, Sevin and McKee carried out an extensive reaction pathway study using *ab initio* and DFT methods on reactions of 1,3-cyclohexadiene with singlet oxygen.[68] They located several transition states for the reaction pathways and computed the electronically excited states of 1,3-cyclopentadiene endoperoxides (CPO) and 1,3-cyclohexadiene endoperoxides (CHO), respectively. Their results for CPO disagree with the results of Klein and Gudipati, obtained using semiempirical (CNDO/S) methods.[58] On the other hand, the analysis of the electronic states of CPO by Sevin and McKee does not agree with the empirical predictions of Kearns and Khan either. Sevin and McKee conclude that their TD-DFT results for CPO and CHO indicate that photorearrangement should take place from $S_0 \rightarrow S_1$ excitation and photocycloreversion should take place from $S_0 \rightarrow S_2$ excitation, in accordance with earlier results.[54,59] In their analysis of the electronically excited states using the TD-B3LYP/6-31+G(d) method, they show that for CPO the $S_0 \rightarrow S_1$ transition at 290 nm has predominantly $\pi^*_{OO} \rightarrow \pi^*_{CC}$ character; hence, the OO bond would not be weakened and consequently may lead to cycloreversion. In Kearns and Khan's work, cycloreversion of CPO is predicted to occur from S_2. Further, Sevin and McKee analyze that the $S_0 \rightarrow S_2$ transition in CPO at 248 nm leads to a much weaker OO bond, which would favor rearrangement,[68] Kearns and Khan predicted rearrangement from S_1.[54,59]

Aromatic endoperoxides, on the other hand, are expected to show less discrepancy between semiempirical and *ab initio* theoretical predictions. The main reason is the grouping of the MOs that are localized primarily on the aromatic rings near the Fermi level, resulting in the MOs containing contributions from the dioxygen bridge to lie far above the unoccupied MOs and far below in the occupied MOs. Further, semiempirical methods have been tested on innumerable aromatic molecules and found to be very reliable.[69] Due to the importance of the theoretical work to interpret the mechanism of endoperoxide photochemistry, high-level *ab initio* quantum chemical treatment of the aliphatic and aromatic endoperoxides, including the evolution of the excited states, is needed. Ideally, thorough CASSCF-level computations on CPO and anthracene-9,10-endoperoxide (APO), the smallest aliphatic and aromatic endoperoxides, respectively, would end the present controversy.

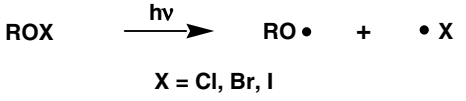
Reaction and Synthetic Application of Oxygen-Centered Radicals Photochemically Generated from Alkyl Hypohalites

Hiroshi Suginome
Hokkaido University

109.1 Brief Historical Background

Alkyl hypohalites (ROX; X = Cl, Br, I), a class of molecules that can be prepared from the corresponding alcohols by a variety of methods,[1] dissociate to alkoxyl and halogen radicals with high efficiency upon irradiation with light of wavelength longer than 300 nm (Scheme 1).



SCHEME 1

Methyl and ethyl hypochlorites, the first alkyl hypohalites known, were prepared by Sandmeyer in 1885.[2] Chattaway and Backeberg of Oxford subsequently reported the preparation of alkyl hypochlorites such as propyl, isopropyl, and *t*-butyl hypochlorites in 1923[3] and observed that although the primary and secondary hypochlorites are very unstable and decompose rapidly at room temperature, the tertiary hypochlorites, such as *t*-butyl hypochlorite, prepared by the reaction of chlorine, sodium hydroxide, and

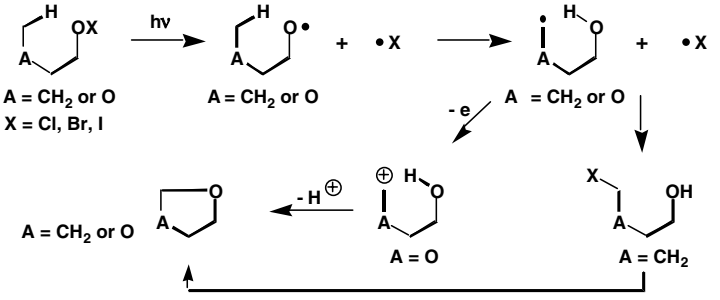
0-8493-1348-1/04/$0.00+$1.50

t-butyl alcohol, are moderately stable pale-yellow liquids that can be distilled without decomposition.[3] Moreover, they found that *t*-butyl hypochlorite decomposed upon exposure to bright sunlight to give methyl chloride and acetone (Scheme 2). During the following years, simple alkyl hypochlorites received attention, principally as free-radical chlorinating reagents and oxidants (as summarized in review articles by Anbar and Ginsburg[1a] and by Walling[4]). *t*-Butyl hypochlorite converts toluene into benzyl chloride and the allylic position of olefins is chlorinated.[5]

SCHEME 2

Since this early work, studies from the late 1950s until the 1960s by Walling,[6–8] Green,[9] Kochi[10] and their collaborators using *t*-alkyl hypohalites disclosed some fundamental characteristics of the principal radical chain reactions, such as intermolecular hydrogen abstraction and β-scission of intermediate alkoxyl radicals in hypohalite photolysis. This work was summarized in a review article by Kochi.[11]

The photochemistry of alkyl hypohalites, however, has attracted considerable attention from organic chemists since the 1960s when Barton and colleagues,[12] a group of Swiss chemists,[13,14] as well as Mills and Petrow[15] demonstrated that alkyl hypochlorites and hypoiodites can be utilized in a manner parallel to the organic nitrites for the functionalization of an unactivated carbon atom based on a concept delineated by Barton.[16,17] The photolysis of steroidal hypohalites with appropriate constitution provoked an intramolecular exchange of the halogen of the ROX group with a hydrogen atom attached to a carbon atom in the δ-position (Scheme 3). An analogous intramolecular δ-hydrogen abstraction of long-chain hypochlorites (Walling and Padwa,[18] Green,[9] and Jenner[19]) and hypobromites (Mihailovic[20]) were also reported. Both the mechanistic and synthetic aspects of remote functionalization via the photolysis of hypohalites have been the subjects of comprehensive review articles by Akhtar[21] as well as by Heusler and Kalvoda.[1b,14]



SCHEME 3

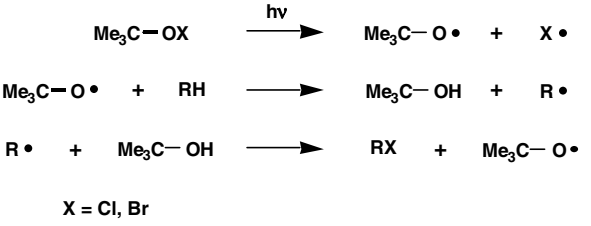
A more recent investigation by Suginome and collaborators has demonstrated that the selective fragmentation of alkoxyl radicals, one of the principal reactions of these species, can be utilized as the key step in the synthesis of a variety of molecules, including several natural products.[22] Subsequently, Suarez and colleagues have also demonstrated the utility of the (diacetoxyiodo)benzene/iodine procedure[23] in the hypoiodite photolysis in a series of articles.

109.2 Photochemistry of *t*-Alkyl Hypohalites

Alkyl hypochlorites, as prototype alkyl hypohalites, in carbon tetrachloride exhibit two absorption peaks in the ultraviolet region: one at about 260 nm and the other at about 310–320 nm.[12,24] Specifically, 3β-acetoxy-20-methylallopregnan-20-ol hypochlorite in carbon tetrachloride exhibits two absorption maxima

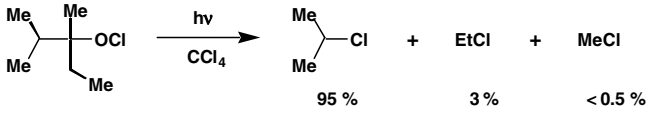
at 258 nm (ε = 107) and 318 nm (ε = 9.5). Although the corresponding hypobromites reveal similar absorptions, the peaks are displaced to longer wavelengths; *t*-butyl hypobromite exhibits an absorption maximum at 280 nm (ε = 120) and a long-tail absorption extending into the visible region.[7c] The UV spectra of alkyl hypoiodites, which are non-isolated species, have not been reported. Their absorption maxima, however, should appear at even longer wavelengths. Homolysis of the RO–X bond takes place when alkyl hypohalites in an inert solvent are irradiated with light of wavelength >300 nm.[25]

Homolysis is also initiated by azoisobutyronitrile or by thermolysis.[4,6] This characteristic of alkyl hypohalites differs from those of the corresponding nitrites in solution;[17] homolysis of the ON bond in solution can only be achieved by photolysis.

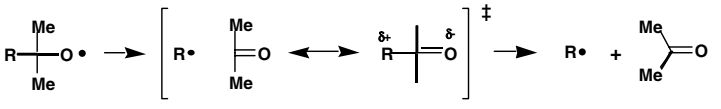


SCHEME 4

The competitive nature of the principal reactions of the alkyl hypohalites was investigated using *t*-butyl hypochlorite[26] and hypobromite as the prototypes.[7c] Walling and collaborators found that *t*-butyl hypochlorite and hypobromite are efficient free-radical chlorinating agents for saturated aliphatic hydrocarbons (Scheme 4).[6,7] They also investigated the photoinduced allylic chlorination of olefins with *t*-butyl hypochlorite, for which there have been sporadic reports from the 1940s until the 1950s, in great detail.[7] They found that a variety of olefins react with *t*-butyl hypochlorite via a photoinduced radical chain process to give a good yield of allylic chlorides in preference to an addition to give β-chloroalkyl *t*-butyl ethers.

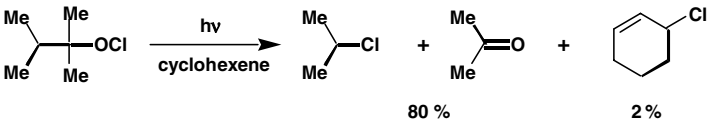


SCHEME 5

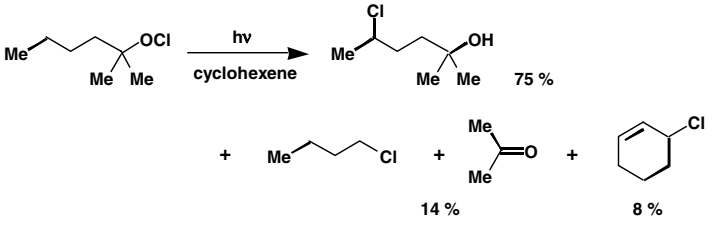


SCHEME 6

Another principal competing reaction of *t*-alkyl hypohalites in a photoinduced reaction is a β-fragmentation of the alkoxyl radicals to give alkyl halides and ketones. The factors that affect the relative rates of ejection of the alkyl radical in the β-fragmentation of alkoxyl radicals has been extensively investigated by Walling, Green, Kochi, and their collaborators[8–10] by carrying out the photodecomposition of a variety of *t*-alkyl hypochlorites. The results indicated increasing β-fragmentation in the order methyl < ethy l< isopropyl < benzyl < *t*-butyl (Scheme 5). The high degree of selectivity found in the β-fragmentation of alkoxyl radicals can be attributed to polar effects in the transition state[10,11] (Scheme 6). Studies with some aliphatic alcohol hypochlorites by Green and collaborators[9] indicated that intermolecular hydrogen abstraction from cyclohexene as the solvent competes poorly with β-fragmentation



SCHEME 7



SCHEME 8

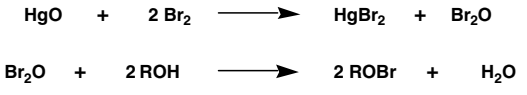
(Scheme 7). The results outlined in Scheme 8 also clearly indicate that intramolecular hydrogen abstraction by the alkoxyl radical via a six-membered transition state predominates over fragmentation and intermolecular allylic hydrogen abstraction. For more details concerning this subject, readers should refer to the original literature and also to a review article.[11]

109.3 Synthetic Applications of Oxygen-Centered Radicals Photochemically Generated from Hypohalites

Among the competing principal reactions of alkoxyl radicals, intramolecular hydrogen abstraction and β-fragmentation have been extensively and successfully used in organic synthesis. This situation is in contrast to the case of carbon-centered radicals in which intramolecular radical addition has been most successfully exploited in synthesis.[27] Some representative examples of the synthetic application are described below. The literature covers up to the beginning of 2002.

Preparation of Alkyl Hypobromites

Alkyl hypobromites can be prepared by the reaction of alcohols with either aqueous hypobromous acid[7c] or silver oxide-bromine or mercuric oxide-bromine[28] in an appropriate solvent. The proposed reaction sequence for hypobromite formation is shown in Scheme 9. Bromine oxide as the intermediate has been isolated and characterized.[29,30]



SCHEME 9

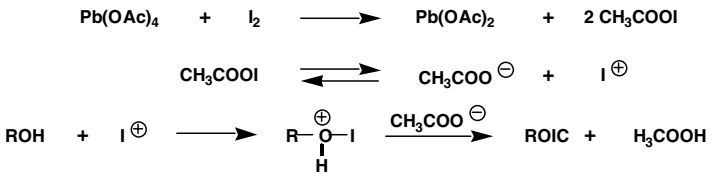
In situ Preparation of Alkyl Hypoiodites

Although alkyl hypochlorites and hypobromites are isolable species, alkyl hypoiodites are not isolable. They can only be prepared *in situ,* either by the reaction of alcohols with metal acetates or oxide and iodine in solution, or by the reaction of alcohols with a hypervalent iodine compound and iodine in

solution. Irradiation of the solution generates oxygen-centered radicals at room temperature. Active species in the formation of hypoiodites from metal acetate–iodine and hypervalent iodine-iodine reagents are considered to be acetyl hypoiodite, CH_3COOI, while active species in hypoiodite generation from mercuric oxide–iodine reagent should be iodine oxide, I_2O. The method for generating hypoiodites is thus occasionally reflected in the reaction products.

Metal Acetate–Iodine Reagents

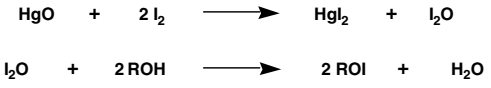
The hypoiodites can be generated from alcohols with iodine and metal acetates, such as silver, mercuric,[31] or lead acetate.[13] Among them, an iodine and lead tetraacetate combination, proposed by Meystre and collaborators in 1961,[13] was most extensively used to generate the hypoiodites *in situ* in the 1960s and 1970s.[14] The combination of mercuric or lead acetate and iodine initially generates acetyl hypoiodite,[31] analogous to the formation of acetyl hypochlorite,[32,33] which reacts with steroidal alcohols to give hypoiodites,[13] as outlined in Scheme 10.



SCHEME 10

Mercury (II) Oxide–Iodine Reagent

The reaction of alcohols with this reagent in solvents, such as carbon tetrachloride or benzene, generates alkyl hypoiodites at room temperature. The reactive species, which reacts with alcohol, should be non-isolable I_2O, since isolable Br_2O is formed by an analogous reaction of HgO and Br_2 (Scheme 11).[29,30] The products that arose from a dark reaction of alkenes with this reagent, reported by Goosen[31] and our numerous results concerning β-fragmentation reactions described in this chapter are indeed best rationalized in terms of the intermediacy of iodine oxide. An excess of iodine oxide occasionally gives products from reactions with carbon-centered radical intermediates. This powerful reagent was initially used by Barton and collaborators[12] in the 1960s and then extensively by us from the 1970s.



SCHEME 11

Hypervalent Iodine–Iodine Reagents

The combination of organic hypervalent iodine compounds, such as (diacetoxyiodo)benzene (DIB) or iodosylbenzene, PhI = O, with iodine, proposed by Suarez in the mid 1980s, was extensively used by his group for the hypoiodite reaction.[23] As in the case of lead tetraacetate–iodine, the alkyl hypoiodites were assumed to be formed by the reaction of alcohols with acetyl hypoiodite produced *in situ* by the reaction of DIB with iodine at room temperature. The reaction of the alcohols with acetyl hypoiodite generates the alkyl hypoiodite (Scheme 12). The acetoxy ion is occasionally incorporated into the reaction products.

SCHEME 12

Diphenylselenium Hydroxyacetate–Iodine Reagent

This selenium reagent, $Ph_2Se(OH)OAc$, was also proposed by Suarez in 1988.[34] The reaction is carried out in cyclohexane at the reflux temperature (80°C). The active species in the formation of alkyl hypoiodites could again be acetyl hypoiodite.

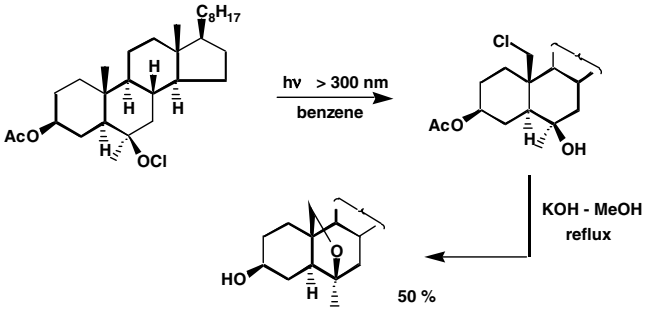
Other Reagents

The hypoiodites can also be prepared *in situ* from alcohols with *t*-butyl hypochlorite and iodine, with *t*-butyl hypoiodite, with N-bromosuccinimide and iodine, and with N-iodosuccinimide, etc.

Remote Functionalization by Hypohalites

Remote Functionalization by Hypochlorites and Hypobromites

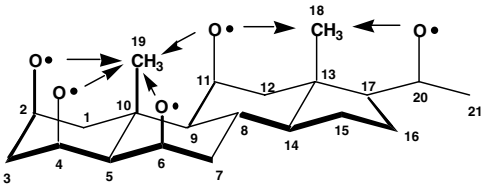
Akhtar and Barton[12] demonstrated a successful remote functionalization in the photolysis of a steroidal hypochlorite in 1960 (outlined in Scheme 13). The photolysis with Pyrex-filtered light of 3β-acetoxy-6α-methylcholestan-6β-ol hypochlorite, prepared from the parent 6β-ol and chlorine monoxide in dry benzene, gave a chlorohydrin, which was treated with a base to give the 6,19-oxide in 50% yield,[12] through a radical chain process.[6] Thus, functional groups can be introduced into the unactivated angular 10β- or 13β-methyl groups of steroids by the photolysis of hypohalites, as in the photolysis of nitrites.[16,17] An analogous photoinduced reaction of hypobromites of cedrol and the related bicyclo[3.2.1]octanes generated with mercury(II) oxide and bromine was reported.[35]



SCHEME 13

Remote Functionalization by Hypoiodites

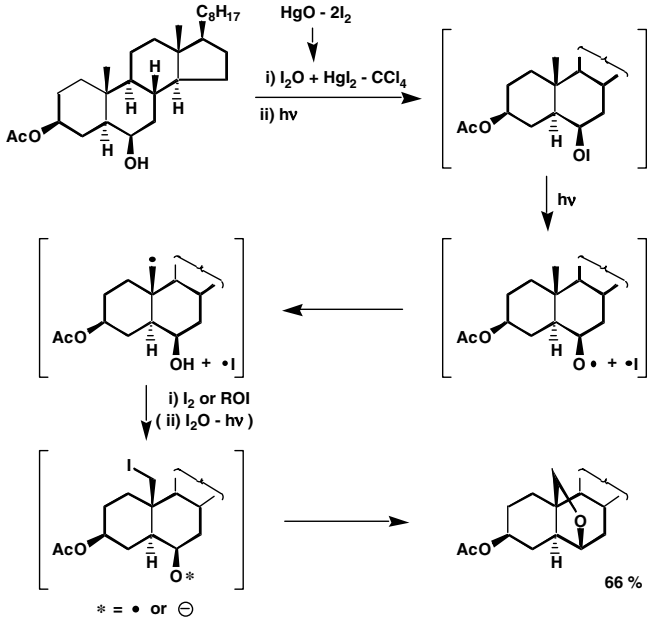
Although alkyl hypoiodites cannot be isolated, they are even more convenient and powerful for generating alkoxyl radicals for remote functionalisation.[12,14,16] They are prepared *in situ* from alcohols and lactols. The stability for the base-catalyzed heterolytic decomposition of secondary hypohalites is in the order hypoiodites > hypobromites > hypochlorites. Moreover, the reactivity of hypoiodites (and iodine) with ketones or carbon-carbon double bonds under neutral conditions decreases in comparison with that of hypochlorites or hypobromites.[14] Remote functionalization can be achieved by irradiating a solution of a hypoiodite prepared *in situ* by one of the methods mentioned above. Remote functionalization via photolysis of an alkyl hypoiodite was designated a "hypoiodite reaction" by Heusler and Kalvada.[14] It is not clear whether the hypoiodite reaction involved a chain process similar to the one postulated for hypochlorite photolysis. Scheme 14 illustrates the positions of the alkoxyl radicals by which the hydrogen in 10β- and 13β-methyl groups can be abstracted to give the carbon radical. The most favorable O–C separation for the intramolecular abstraction of hydrogen was estimated to be 2.5 to 2.7 Å by a Swiss group on the basis of the results concerning the remote functionalization of a number of hypoiodites of rigid systems, such as steroids (*vide infra*) and an inspection of Dreiding models.[14] In the following, some representative examples among the numerous applications of the hypoiodite reaction to remote functionalization are outlined.



SCHEME 14

Functionalization of 10β-Me of a Steroid from the 6β-ol Hypoiodite Generated with Mercury(II) Oxide and Iodine[12] (Scheme 15)

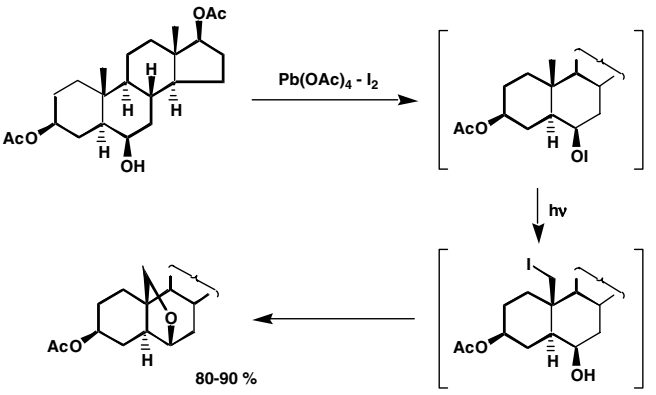
A light-induced reaction of steroidal hypoiodites prepared by the reaction of a steroidal alcohol with iodine oxide generated from mercury(II) oxide–iodine generally gives a five-membered oxide, which should be formed by an intramolecular S_N2 or S_H2 reaction of intermediate 19-iodide, as outlined in Scheme 15.



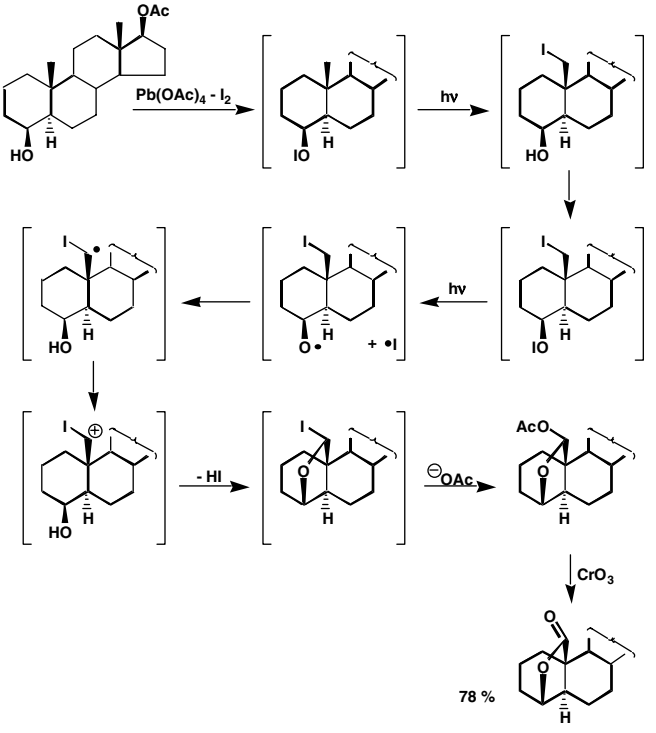
SCHEME 15

Functionalization of 10β-Me of a Steroid from the 6β-ol Hypoiodite Generated by Lead Tetraacetate and Iodine (Schemes 16 and 17)

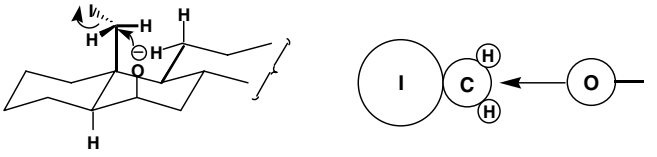
Among the numerous results reported by the Swiss group, two typical examples of remote functionalization with this reagent are outlined in Schemes 16 and 17. The products of the remote functionalization of steroids by the hypoiodite reaction are either the five-membered oxide (Scheme 16) or the α-lactol acetate (Scheme 17), depending on the relative disposition between the relevant alkoxyl radical and the iodine attached to C18 or C19 of a conformer of the first-formed intermediate monoiodide. Thus, the five-membered oxide is an exclusive product[14] in the example outlined in Scheme 16, because the iodomethyl group can adopt an orientation that is appropriate for an S_H2 or S_N2 displacement of the iodine by the 6β-alkoxyl radical or ion, to give the observed oxide, as shown in Scheme 18. On the other hand, the α-lactol acetate is an exclusive product in the example[36] outlined in Scheme 17, because the preferred orientation of the iodomethyl group with respect to the 4β-hydroxyl in the first-formed intermediate



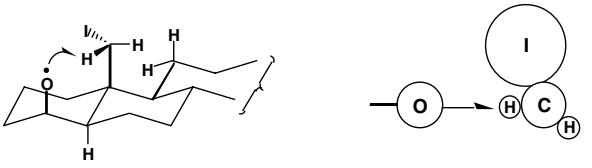
SCHEME 16



SCHEME 17



SCHEME 18



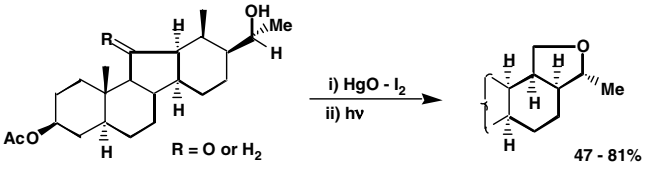
SCHEME 19

monoiodide does not allow any displacement of the iodine by the 4β-hydroxyl; however, it is appropriate for the second intramolecular hydrogen abstraction by the 4β-alkoxyl radical to give the iodo-oxide (Scheme 19), the iodine on which is displaced by an acetoxy ion to give a lactol acetate. Its oxidation with chromium trioxide then readily results in a transformation into the corresponding lactone. Analogously, the product of the hypoiodite reaction of the 20β-hydroxysteroid was the corresponding 18,20β-α-lactol acetate, which was isolated as the corresponding lactone by oxidation with chromium trioxide in 72% yield.[37]

For a thorough discussion concerning this subject, including more examples and accompanying reactions, the readers should consult the comprehensive review articles.[1b,14,21]

Functionalization of 18β-Me of* D-*homo*-C-*norsteroids from the 20β-ol Hypoiodite Generated with Mercury(II) Oxide and Iodine[38]

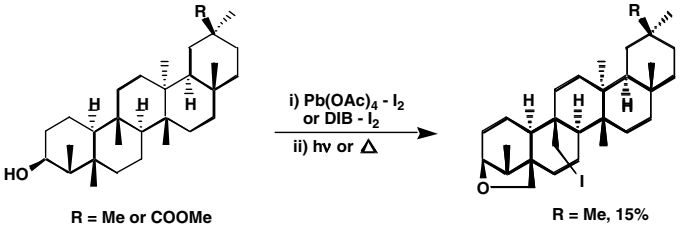
The photolysis of *D*-homo-*C*-norsteroid 20β-ol hypoiodites gives the corresponding cyclic ethers, which are formed via an intramolecular hydrogen abstraction from their 18β-methyl group by the 20β-alkoxyl radical, as outlined in Scheme 20.



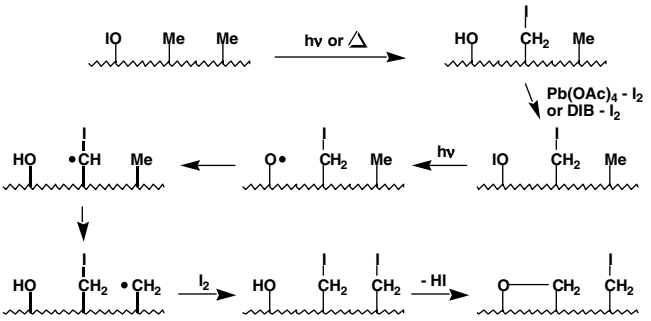
SCHEME 20

"Billiard Reaction" in the Hypoiodite Photolysis[39]

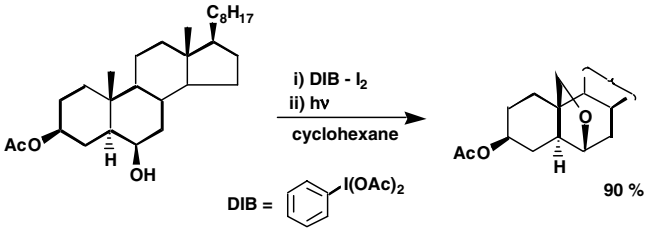
The "billiard reaction," a second intramolecular hydrogen abstraction from a 1,3-diaxially located methyl group by a carbon-centered radical, initially generated by an alkoxyl radical was observed in the remote functionalization of certain triterpenoids and diterpenoids by a thermal hypoiodite reaction with lead tetraacetate–iodine by Wenkert and Milari in 1967.[39a,b] Recent work by Suarez indicates that similar results can be achieved by the photolysis of hypoiodites in the presence of (diacetoxyiodo)benzene–iodine[39c] (Scheme 21). Scheme 22 outlines the reaction path.



SCHEME 21



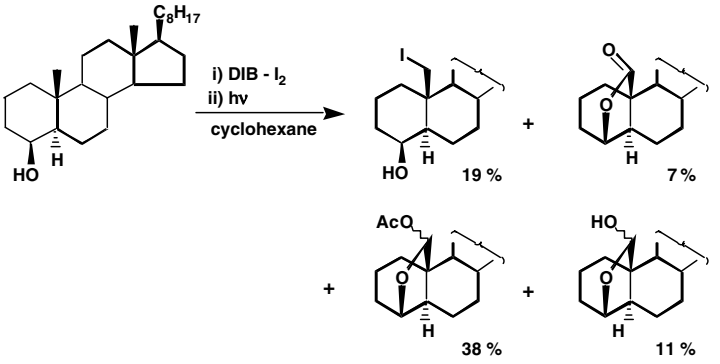
SCHEME 22



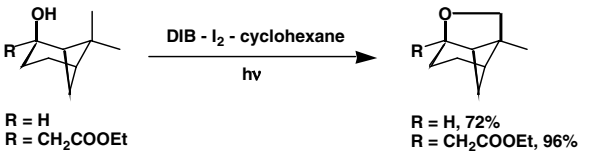
SCHEME 23

Functionalization of 10β-Me of Steroids by (Diacetoxyiodo)benzene (DIB) and Iodine[23]

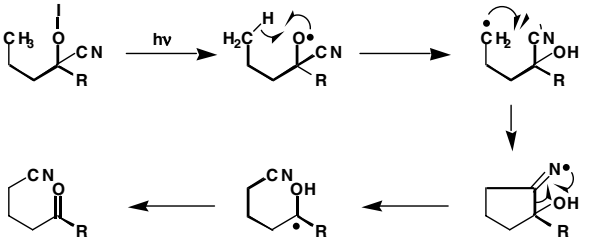
Suarez and colleagues[23] have shown that each one equivalent of DIB and iodine in cyclohexane reacts with steroidal alcohols to produce the corresponding hypoiodites, and that irradiation of the solution with visible light gives cyclic ethers and monoiodo-alcohol derivatives as the major products arising from intramolecular hydrogen abstraction. Two examples[23] concerning the functionalization of the 10β-methyl group of a steroid from the 6β-ol and 4β-ol hypoiodites and an example[39c] of the remote functionalization of (−)-*cis*–nopiol reported by Suarez are outlined in Schemes 23, 24, and 25. These results should be compared with the products from the lead tetraacetate–iodine procedure outlined in Schemes 16 and 17. The products are more complicated as a result of the double intramolecular hydrogen abstraction processes.



SCHEME 24



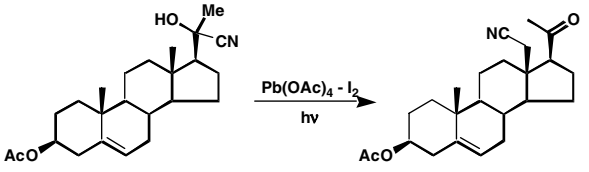
SCHEME 25



SCHEME 26

The Oxidative Cyanohydrin–Cyanoketone Rearrangement

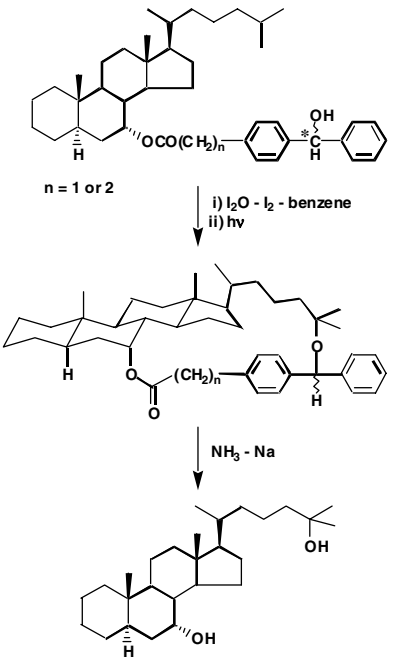
An especially interesting example of the hypoiodite reaction is the oxidative cyanohydrin–cyanoketone rearrangement,[14,40] which is represented by the general pathway outlined in Scheme 26. The hypoiodite reaction of 20-hydroxy-20-cyanosteroids gives the 18-cyanoketones arising from a 1,4 shift of the cyano group accompanied by the loss of two atoms of hydrogen[14] (Scheme 27).



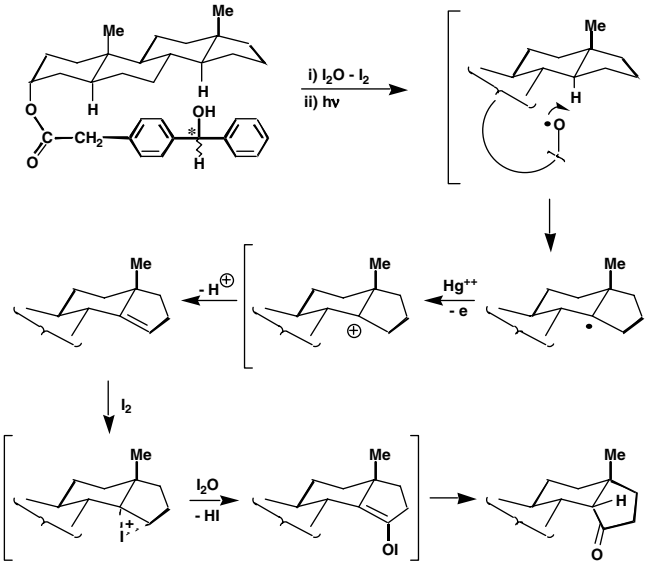
SCHEME 27

Intramolecular Functionalization via a Many-Membered Cyclic Transition State

Successful intramolecular hydrogen abstraction via a many-membered cyclic transition state by alkoxyl radicals generated by the photolysis of hypohalites has recently been reported; alkoxyl radicals generated by the irradiation of hypoiodites of 5α-cholestan-7α-yl-(hydroxymethyl)-phenyl acetates and propionates, respectively, abstracted a hydrogen from the remote C25 of the cholestane side chain to give novel macrocyclic ether lactones, which gave 5α-cholestane-7α,25-diol by reduction with Na and liquid ammonia (as outlined in Scheme 28[41]). A similar one-step introduction of a carbonyl group to C15 of the 5α-androstane skeleton, based on a long-range intramolecular hydrogen abstraction by alkoxyl radicals, generated by the irradiation of 5α-androstane esters carrying a benzhydryl group in carbon tetrachloride containing mercury(II) oxide and iodine, is outlined in Scheme 29. The proposed reaction path is also illustrated here.[42] Suginome and collaborators also reported a one-step double introduction of a carbon-carbon double bond and oxygen functions to ring C of 5α-steroid skeletons, based on a long-range intramolecular hydrogen abstraction by alkoxyl radicals generated from the esters of 5α-cholestan-3α-ol carrying a benzhydryl group.[42]

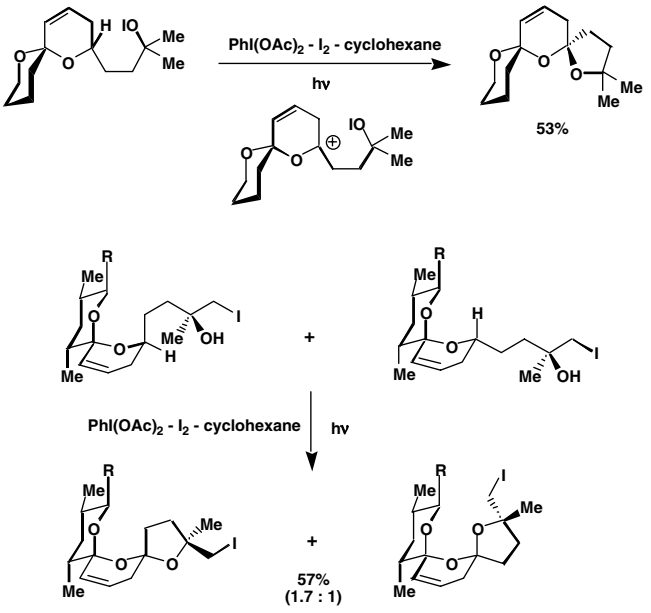


SCHEME 28



SCHEME 29

These results indicate that hypoiodite photolysis with mercury (II) oxide and iodine reagent is a powerful method that is applicable to even remote functionalization involving a many-membered transition state, because alkoxyl radicals are considered to be repeatedly generated from the regenerated hypoiodites in a solution containing an excess of the reagent.

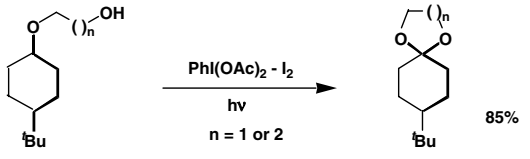


SCHEME 30

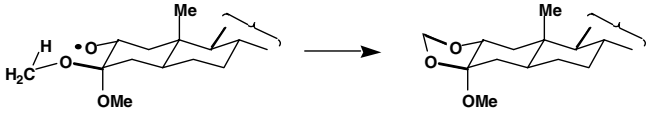
Formations of Cyclic and Spiro Acetals by a Tandem Intramolecular Hydrogen Abstraction-Cyclization Process (Schemes 30 through 36)

The application of hypoiodite photolysis for remote functionalization has been mostly in the steroid field. There has been, however, a resurgence of applications in the field of spiroacetal-type compounds. The reaction was originally found in 1966 by Mihailovic and collaborators, who described remote functionalization by a thermal reaction of alcohols with lead tetraacetate.[43]

Thus, two groups of investigators reported that the irradiation of certain oxygen heterocycles having a hydroxyalkyl side chain in cyclohexane in the presence of (diacetoxyiodo)benzene and iodine at room temperature gave bis-spiroacetals in good yields[23b,44] (Scheme 30). Subsequent work showed that similar reaction conditions could be applied to the synthesis of a number of five- and six-membered cyclic acetals from γ- and ε-hydroxyethers[45] (Scheme 31). The formation of a cyclic acetal was also found in the hypoiodite reaction of hydroxysteroid with mercury(II) oxide and iodine[46] (Scheme 32).

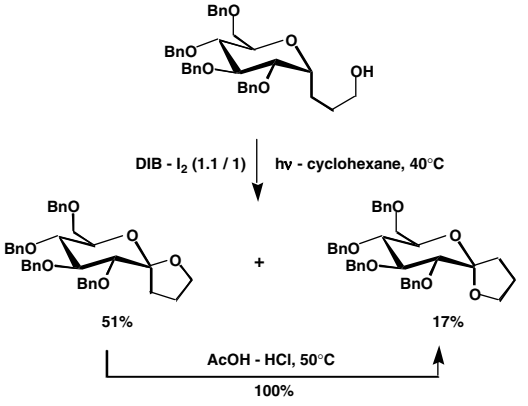


SCHEME 31

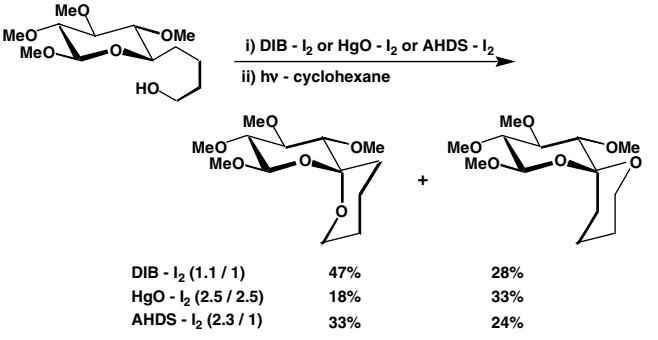


SCHEME 32

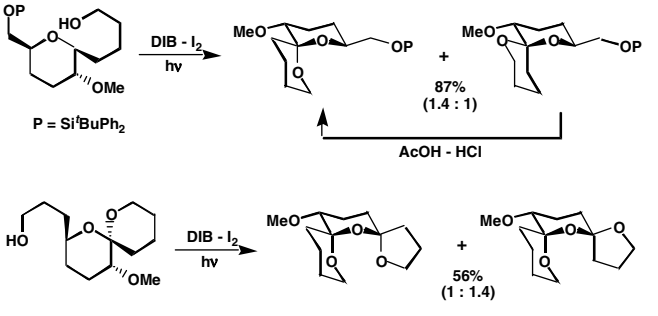
More recently, spiroacetal formation has been successfully exploited by Suarez and collaborators in the synthesis of a number of chiral spiroacetals and dispiroacetals from carbohydrates[47] (Schemes 33, 34, and 35). The approach was also used to synthesize anomeric spironucleosides[48] (Scheme 36). The best yields were achieved with the DIB-iodine reagent. Some typical examples are shown in Schemes 30 through 36.



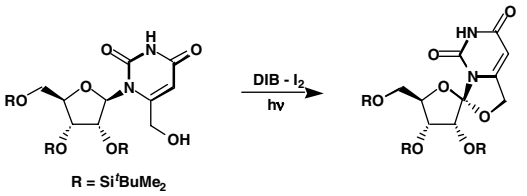
SCHEME 33



SCHEME 34



SCHEME 35



SCHEME 36

A notable feature of the remote functionalization of γ-hydroxyethers is that six-membered rings can be formed by intramolecular hydrogen abstractions through a seven-membered cyclic transition state. This exceptional regioselectivity in intramolecular hydrogen abstraction by oxygen-centered radicals can be attributed to the effect of the ethereal oxygen; one-electron oxidation of carbon radicals, generated by intramolecular hydrogen abstraction involving seven-membered cyclic transition state, to the corresponding carbocation is influenced by the ethereal oxygen atom, as suggested by Mihailovic.[43]

The acceleration of carbocation formation implies that spiroacetal formation may take place by the cyclization of a carbocation intermediate, but not by cyclization through an iodohydrin intermediate.

β-Fragmentation and Its Synthetic Application

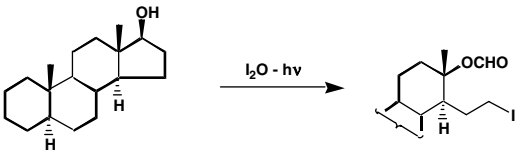
In contrast to the intramolecular hydrogen abstraction mentioned above, fragmentation, another principal reaction of alkoxyl radicals, was seldom used in organic synthesis until the 1970s. An analysis of the numerous examples reported in the past and our own results concerning the photochemistry of alkyl nitrites[17] and hypohalites indicated that the direction of β-fragmentation in unsymmetrical substrates is the outcome of an interplay of multiple factors, such as the relative thermodynamic stability of the resultant radicals, ring strain, and stereoelectronic factors.

This situation is in contrast to the heterocyclic cleavage of bonds, such as the ring-fusion bond in bicyclic compounds, in which the cleavage requires a bifunctional substrate with strict stereoelectronic constraints.[49] Nevertheless, β-scission is frequently not only the predominant reaction, but also takes place in a highly selective manner and comprises an exclusive reaction when the alkoxyl radical and the hydrogen to be abstracted are not ideally disposed for intramolecular hydrogen abstraction. The β-scission is especially enhanced in the hypoiodite reaction when alkoxyl radicals appear to be repeatedly generated from the regenerated parent alcohol by excess reagent. Since the 1980s, Suginome and colleagues have shown that a variety of molecules, including natural products, can be synthesized using the β-scission of alkoxyl radicals generated by the photolysis of hypoiodites as the key step.

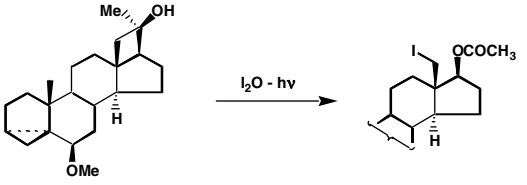
In the following, the type of the reaction and the formation paths, together with some representative examples of the synthesis, when they are necessary, are outlined. These selected examples may indicate that the β-scission of alkoxyl radicals takes place in a very selective manner and has become an integral part of synthetic strategies. For more details, readers should consult the original papers.

Cascade Radical Rearrangement Triggered by a Selective β-Fragmentation of Alkoxyl Radicals Generated by the Photolysis of Cyclic Alcohol Hypoiodites

The irradiation of hypoiodites generated *in situ* from cyclic alcohols with an excess of mercury(II) oxide and iodine with Pyrex-filtered light results in the formation of novel iodo-esters, arising from cascade radical rearrangements triggered by a selective β-fragmentation of the corresponding alkoxyl radicals, as shown by two examples outlined in Schemes 37 and 38.[51] The photolysis of cyclopentanol as a prototype cyclic alcohol under similar conditions gave rise to 5-iodopentyl formate corresponding to the steroidal formates.[51,52b]



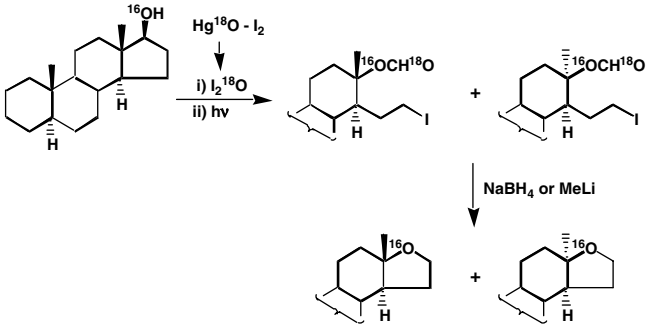
SCHEME 37



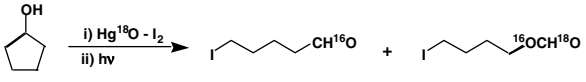
SCHEME 38

Mechanism of the Formation of the Iodo-Formates

Labeling studies using ^{18}O applied to the hypoiodites derived from androstan-17β-ol[51a] and cyclopentanol[51b] (Schemes 39 and 40) in which ^{18}O-labeled mercury (II) oxide as the source of $I_2{}^{18}O$ was used, proved that the ^{18}O was specifically incorporated in the formyl group of the formates, and that no ^{18}O was incorporated in the oxasteroid derived from it.

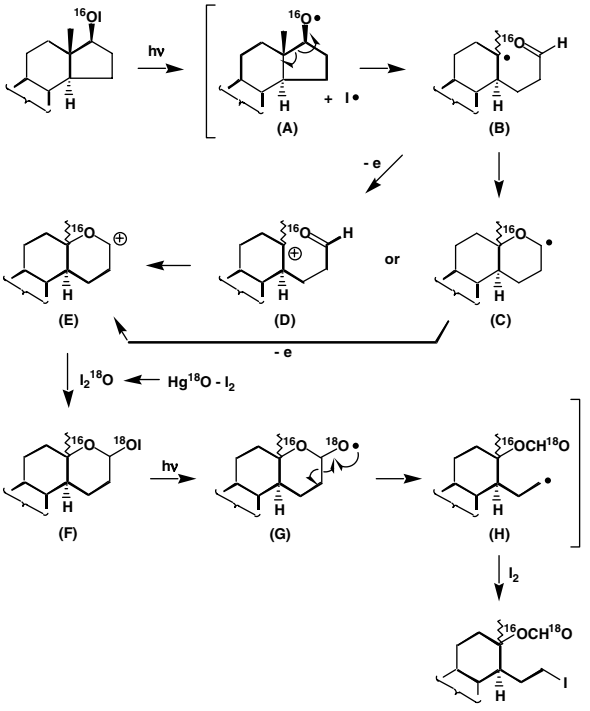


SCHEME 39



SCHEME 40

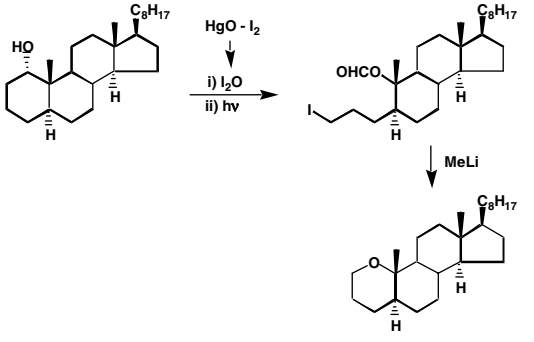
The pathway of the formation of the iodo-formates based on the ^{18}O labeling results thus involves the following sequence: (a) a selective β-fragmentation of the alkoxyl radical (A) to give a carbon-centred radical (B) bearing a carbonyl; (b) its cyclization to give a tetrahydropyranyl radical (c) followed by the one-electron oxidation to a tetrahydropyranyl cation (E) or one-electron oxidation of (B) to a tertiary carbocation (D), followed by the cyclization to (E); (c) its reaction with iodine oxide to form the second hypoiodite (F) and (d) a regioselective β-fragmentation of the secondary alkoxyl radical (G) generated from (F) to give the formate through (H), as outlined in Scheme 41.



SCHEME 41

A Two-Step Transformation of Hydroxysteroids into Oxasteroids

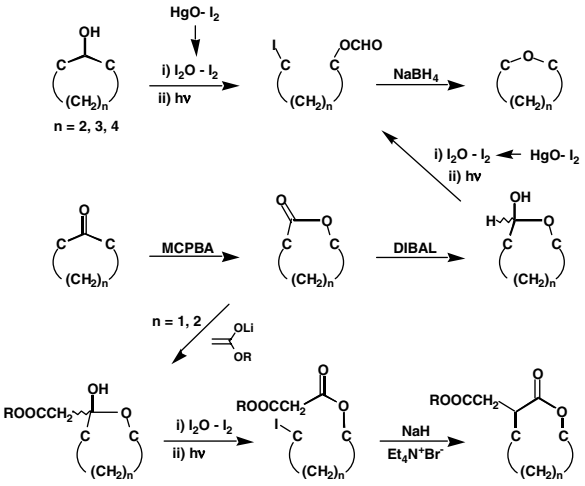
This cascade radical rearrangement to the esters, followed by cyclization to cyclic ethers, comprises a new method of transforming hydroxy steroids into oxasteroids under essentially neutral conditions. A number of hydroxysteroids have been converted into oxasteroids. Another example is outlined in Scheme 42.[50a,52]



SCHEME 42

The Selective β-Fragmentation of Alkoxyl Radicals Generated by the Photolysis of Lactol Hypoiodites

The above-mentioned pathway for the formation of formates involves β-fragmentation of the second alkoxyl radicals generated from the hypoiodites cyclic alcohols. In fact, the irradiation of hypoiodites generated *in situ* from lactols prepared from appropriate ketones by the standard method in the presence of an excess amount of mercury(II) oxide-iodine and pyridine in benzene resulted in selective β-fragmentation to yield iodo-formates.[53] This fragmentation, which was found to be general in the alkoxyl radicals generated from the lactols, is of considerable value for organic synthesis, as shown below.



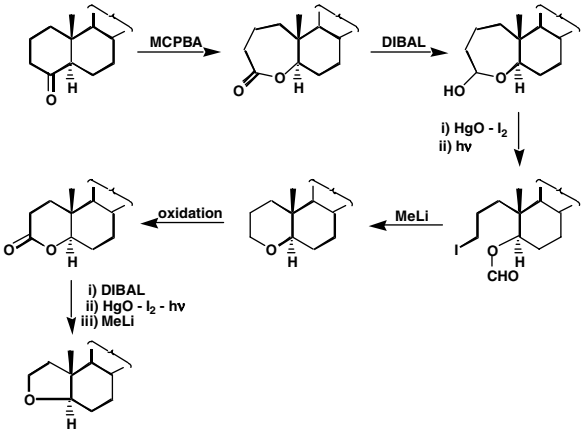
SCHEME 43

A New Four-Step Transformation of Cyclic Ketones into Cyclic Ethers[53]

Scheme 43 outlines a versatile method for transforming cyclic ketones as starting materials into cyclic ethers with the same ring size via four steps. The method is applicable not only to synthesize oxasteroids, but also to synthesize cyclic ethers in general. Among examples of the transformation of a number of cyclic ketones, such as steroidal ketones, adamantanone,[54] and camphor,[55] etc. into the corresponding cyclic ethers. Three are outlined in Schemes 44, 45, and 46.

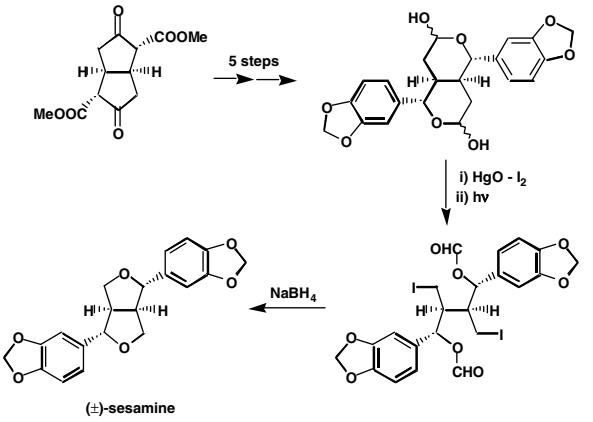
An interesting application of the method, in which 5α,6β-dihydroxypregnane was transformed into 6-oxa-5β–pregnane-3,20-dione, has recently been reported.[56]

1. The transformation of a steroidal ketone into an oxasteroid and the ring contraction[52] (Scheme 44)



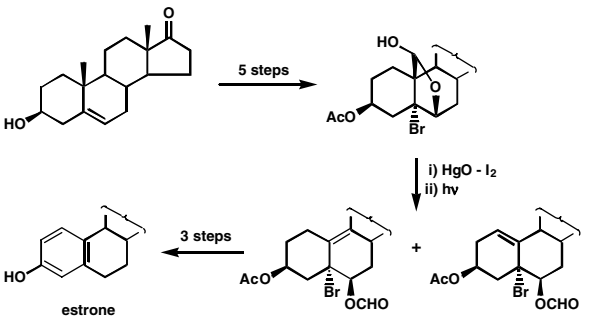
SCHEME 44

2. New stereo- and regioselective synthesis of (±) sesamin[57] (Scheme 45)



SCHEME 45

3. The transformation of steroids into 18- and 19-norsteroids[58] (Scheme 46)



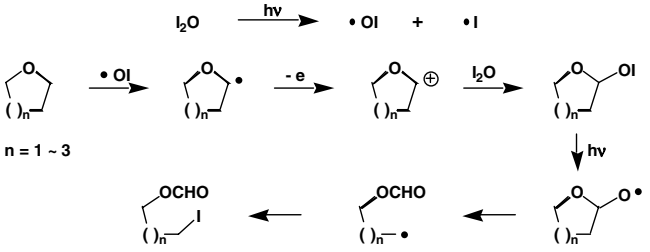
SCHEME 46

One-Carbon Intercalation of γ- and δ-Lactones

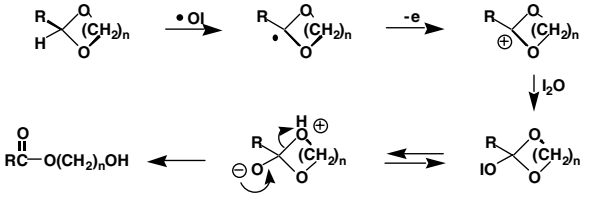
The reaction of γ- and δ-lactones with lithioalkyl acetate gave alkyl-(2-hydroxytetrahydrofuran-2-yl) acetates or their pyranyl homologs. The photolysis of the hypoiodites results in a selective endocyclic β-fragmentation of the corresponding alkyl radicals to give alkyl iodoalkylpropanedioates. Treatment of the iodo esters with tetraethyl ammonium bromide and sodium hydride gives the corresponding δ- or γ-lactones (Scheme 43).[59]

Transformation of Cyclic Ethers into ω-Iodoalkyl Formates and of Aldehyde Cyclic Acetals into α,ω-Alkanediol Esters by Hypothetical Iodoxyl Radical[60]

The photolysis of cyclic ethers with an excess of $HgO\text{-}I_2$ reagent in benzene gives the corresponding iodoalkyl formates in one step; tetrahydrofuran can be transformed into ω-iodoalkyl formate in 31% yield (Scheme 47). Aldehyde cyclic acetals lead to monoesters of α,ω-alkanediols in one step (Scheme 48). The formation of the products can be rationalized by postulating iodoxyl radical participation, as outlined in the schemes.



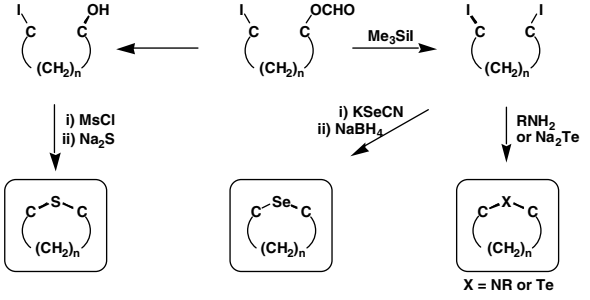
SCHEME 47



SCHEME 48

Substitution of a Carbonyl Group of Cyclic Ketones by a Heteroatom; Synthesis of Aza-, Oxa, Thia-, Selena-, and Tellurasteroids[53,61]

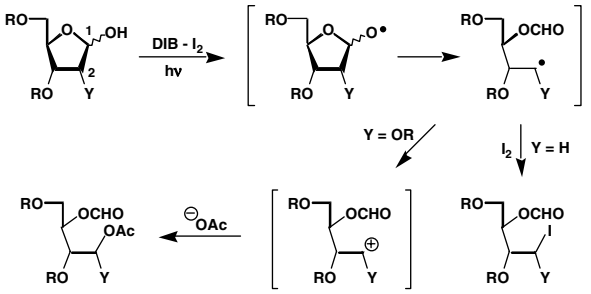
The iodo-formates obtained as described above are useful intermediates, which can be further transformed into cyclic amines, cyclic sulfides, cyclic tellurides, and cyclic selenides by the sequences outlined in Scheme 49.[61] A variety of heterosteroids have been synthesized from the corresponding steroidal ketones by these methods.[61]



SCHEME 49

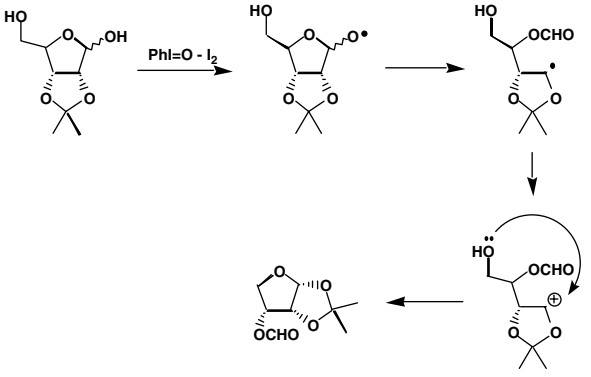
The Transformations of Carbohydrates by Selective β-Fragmentation

During the past decade, Suarez and collaborators have made use of the above-mentioned selective fragmentation of alkoxyl radicals generated from lactols. They reported on the preparation of four-carbon chiral building blocks of the D- and L-erythrose types by β-fragmentation of the anomeric alkoxyl radicals generated from the protected D- and L-arabinose, D-ribose and 2-deoxy-D-ribose in the presence of DIB-iodine or iodosylbenzene-iodine reagent, as outlined in Scheme 50.[62] When the starting carbohydrates bear an alkoxyl group, the fragmentation reaction in the presence of DIB-iodine terminates at the acetate stage, because the oxidation of the generated carbon radical to the carbocation, which traps acetoxy group, is facilitated.

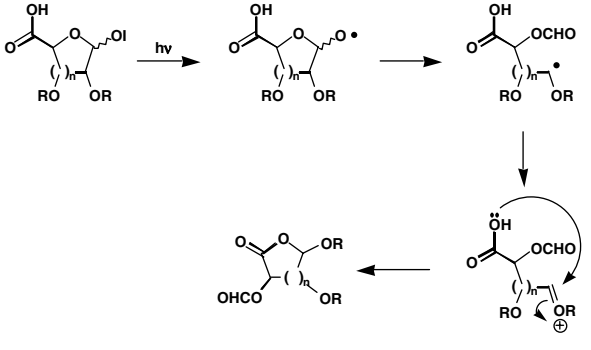


SCHEME 50

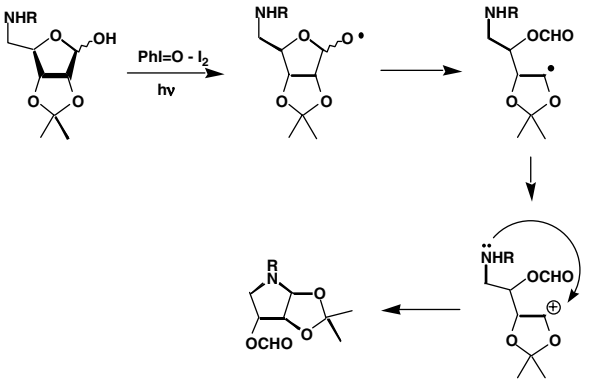
Schemes 51, 52, and 53 outline an extension of the method by the tandem β–fragmentation-cyclization sequence to modify the carbohydrates by the iodosylbenzene-iodine reagent instead of DIB-iodine. Thus, the transformations of D-ribofuranose to 3-O-formyl-α-D-erythrofuranose (Scheme 51),[63,64] furanose to cyclic ketoses, such as alduronic acid lactones (Scheme 52),[65] and carbohydrates to five- and-six-membered azasugars (Scheme 53) can be achieved.[66] β-Fragmentation of carbohydrate suitably substituted by azide group resulted in the formation of chiral nitriles (Scheme 54).[67]



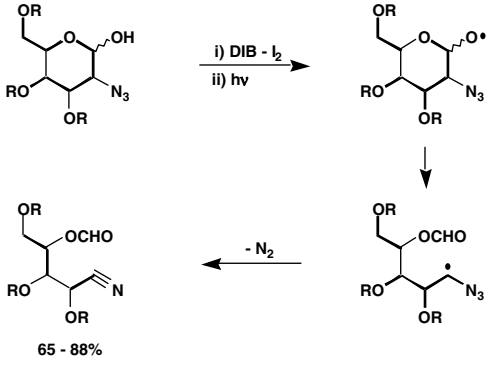
SCHEME 51



SCHEME 52



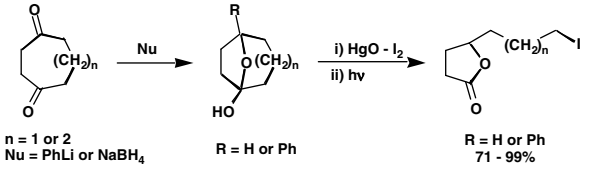
SCHEME 53



SCHEME 54

The Synthesis of 3-Substituted γ-Lactones

3-Substituted γ-lactones including some pheromones can be synthesized in three steps from cyclic 1,4-diketones. The key step is a selective β-fragmentation of lactols, as outlined in Scheme 55.[68]

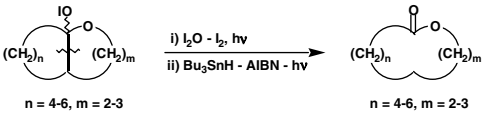


SCHEME 55

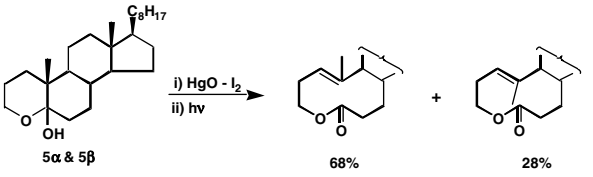
New General Synthesis of medium-ring lactones via a Regioselective β-Fragmentation of Alkoxyl Radicals Generated from Catacondensed Lactols

Suginome and collaborators further extended the above-mentioned regioselective β-fragmentation to the synthesis of medium-ring lactones in 1985. The irradiation of the hypoiodites of catacondensed lactols gives lactones arising from a regioselective cleavage of the inner bond of the systems.[69] The reduction of iodo-lactones with tributyltin hydride gives medium-ring lactones in high yields, as outlined in Scheme 56. A number of nine- to eleven-membered lactones were synthesized from 6/5, 6/6, 7/5, 7/6, and 8/5 fused lactols by this method. Scheme 57 outlines a ring expansion of steroidal substrate and Scheme 58

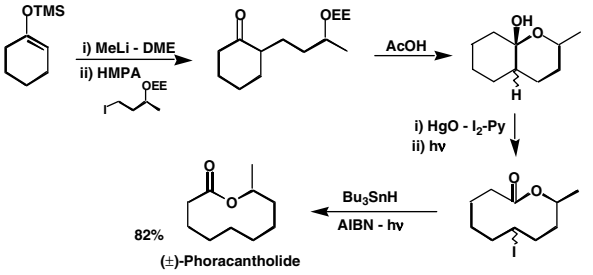
outlines a new four-step synthesis of a racemic phoracantholide from cyclohexanone trimethylsilyl enol ether by this method.



SCHEME 56

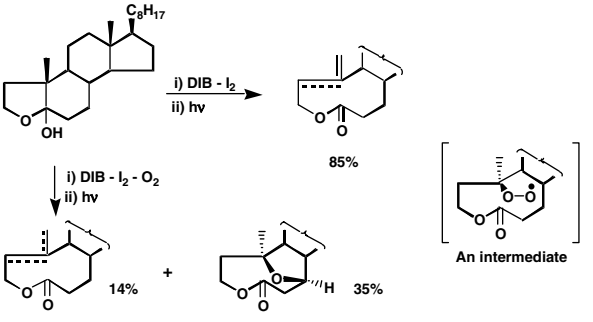


SCHEME 57



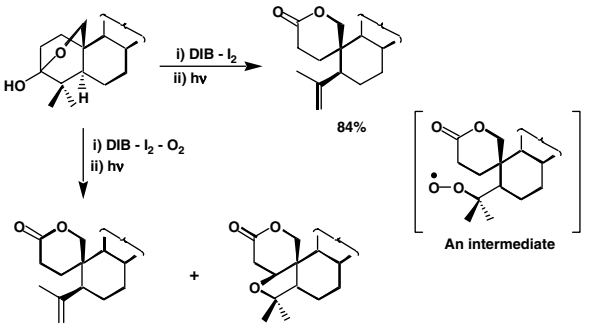
SCHEME 58

Subsequently, a similar ring expansion of steroidal substrates with (diacetoxyiodo)benzene-iodine reagent was reported by Suarez and collaborators,[70] and the method was applied to natural product synthesis.[70] Meanwhile, Suarez has studied products formed in a ring-expansion reaction in the presence of oxygen. Thus, while the photolysis of lactol in the presence of DIB-iodine gave a mixture of lactones in 85% yield, molecular oxygen scavenged the intermediary carbon-centered radical to give an epoxy product in 35% yield, together with the ring-expansion products in 14% yield, as outlined in Scheme 59.[70]



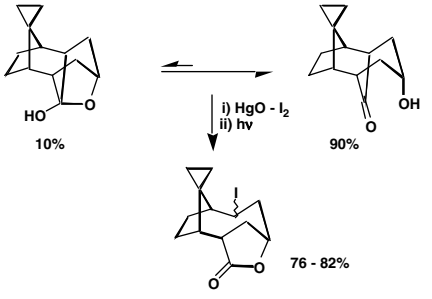
SCHEME 59

Similarly, the photolysis of a lactol in the presence of molecular oxygen afforded a lactone incorporated by oxygen, as outlined in Scheme 60.[71]



SCHEME 60

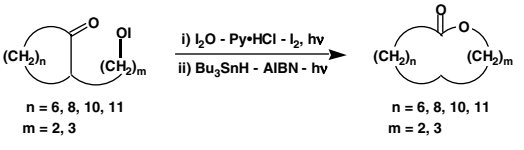
It has been reported that the treatment of a hydroxytricycloundecenone derivative, which exists largely in the form of a hydroxyketone in solution (90%), with DIB-iodine in cyclohexane, followed by the photolysis resulted in the formation of a iodolactone arising from a β-fragmentation in 76 to 82% yield[72] (Scheme 61).



SCHEME 61

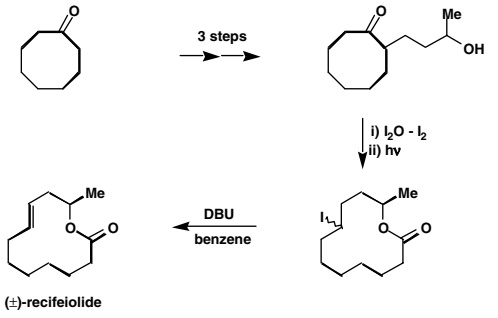
New General Synthesis of Macrolides via β-Fragmentation of Alkoxyl Radicals Generated from Lactol–Hydroxyketone Equilibrium

11- to 17-Membered macrolides can analogously be synthesized by photolysis of the hypoiodites of open-hydroxy ketones, as outlined in Scheme 62.[73] The iodo-lactones mentioned here are believed to be formed either via a regioselective β-fragmentation of alkoxyl radicals generated from the lactol, which is in equilibrium with the hydroxy ketone form or, although less likely, via a consecutive homolytic process — an intramolecular homolytic addition of the alkoxyl radicals to the carbonyl carbon followed by a fragmentation of the bridged bond of the generated alkoxyl radicals. It then traps an iodine atom to give iodo-macrolides.



SCHEME 62

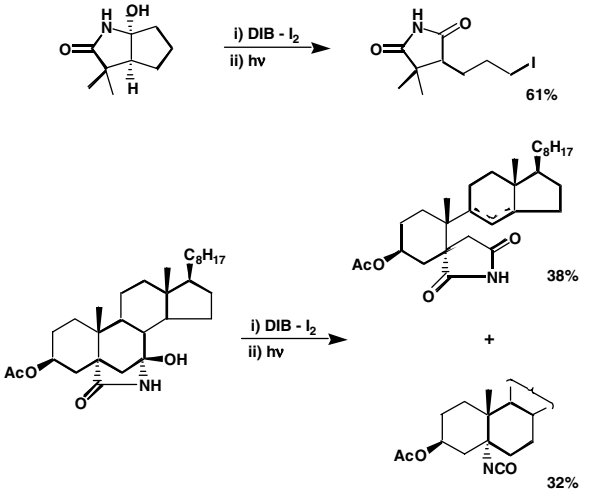
(±)-Recifeiolide, a natural 12-membered macrolide, was synthesized from cyclooctanone based on this process, as outlined in Scheme 63.[74]



SCHEME 63

The Formation of Cyclic Imides by β-Fragmentation of Bicyclic Carbinolamides

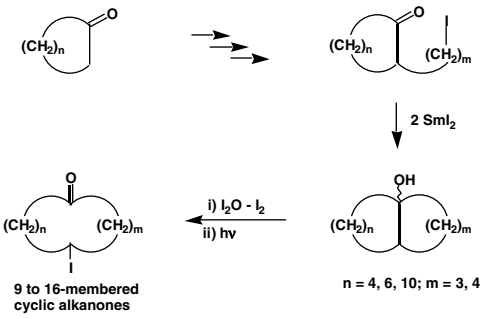
According to Suarez and collaborators, the photolysis of the hypoiodites of certain bicyclic carbinolamids in the presence of DIB-iodine leads to fragmentation to give cyclic imides, as outlined in Scheme 64.[34b,75] The cleavage, however, appears not to be as selective as the cleavage of lactols.



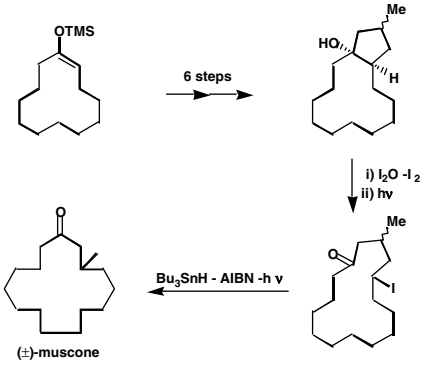
SCHEME 64

The General Synthesis of Medium and Macrocyclic Ketones Based on Ring Expansion by the Photolysis of the Hypoiodites of Bicyclic Alcohols

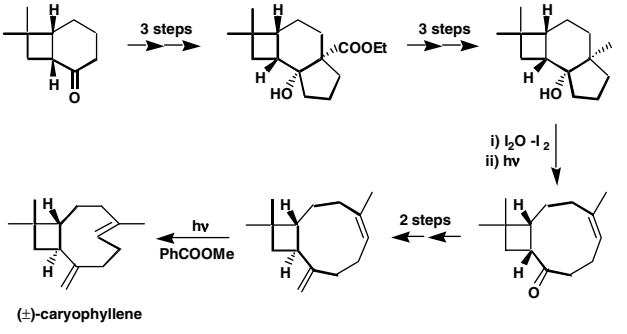
A medium or macrocyclic ketone can generally be synthesized by selective β-fragmentation of alkoxyl radicals generated from the hypoiodites prepared from catacondensed bicyclic alcohols, analogous to the synthesis of the macrolides mentioned above. The products of the ring expansion are either iodo ketone and/or olefinic ketones (as outlined in general Scheme 65).[76] In contrast to the established ring expansion involving an ionic cleavage, such as retro-Aldolization, the synthesis can be carried out under virtually neutral conditions, and no extra functional group is necessary for the cleavage. Schemes 66 and 67 outline the new synthesis of (±)-muscone[76] and (±)-caryophyllene[77] based on this method as the key step.



SCHEME 65

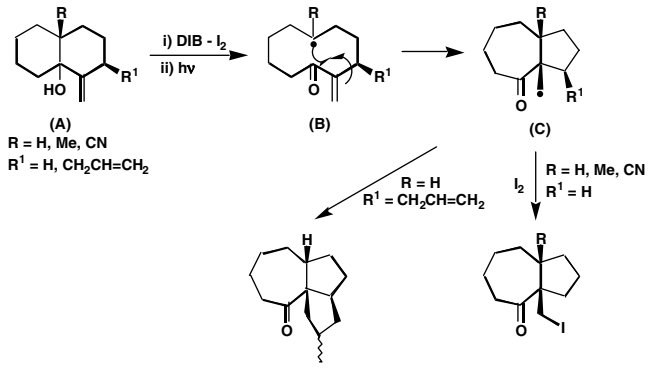


SCHEME 66



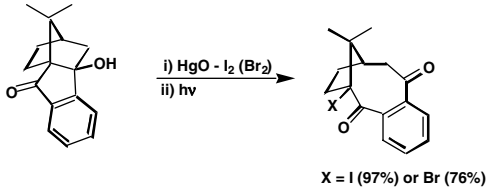
SCHEME 67

An interaction of the intermediate carbon-centered radical (A) with a neighboring carbon-carbon bond in this ring expansion leads to a transannular radical cyclization; the treatment of the unsaturated decanols with (diacetoxyiodo) benzene-iodine followed by irradiation underwent fragmentation of intermediate allyloxy radicals (A) to give the bicyclo[5.3.0]decanones (40–78%) and to give the 7,5,5-tricyclic compound (81%) by way of a "Billiard reaction," as outlined in Scheme 68.[78]



SCHEME 68

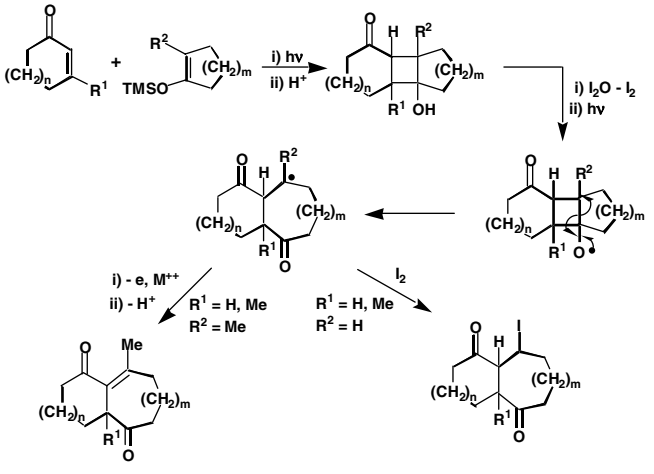
It has been reported that, while ring expansion by ionic fragmentation of a bicyclo[3.3.0]octanol could not be achieved, an alkoxyl radical generated from the octanol resulted in a selective β-cleavage of the fused bond to give a functionalized bridged cyclooctane derivative[79] (Scheme 69).



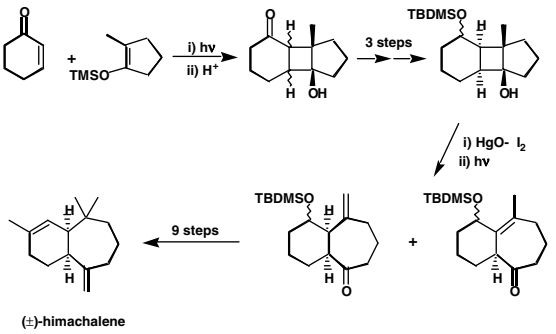
SCHEME 69

The Construction of 5/7, 5/8, 6/7, and 6/8 Bicyclic Systems Based on [2+2]-Photoaddition of Cyclic Enones with Enol Ethers of Cyclic Ketones Followed by a β-Fragmentation of Alkoxyl Radicals Generated from the Resulting Cyclobutanols

Functionalized bicyclo [x.y.0]alkanes (x = 5 or 6; y = 7 or 8) can be synthesized by the irradiation of hypoiodites prepared by [2+2]-photoaddition of cyclic enones with the trimethylsilyl enol ethers of cyclic ketones (as outlined in general in Scheme 70).[80] Scheme 71 outlines the new total synthesis of (±)-α-himachalene based on this method as the key step.[81]



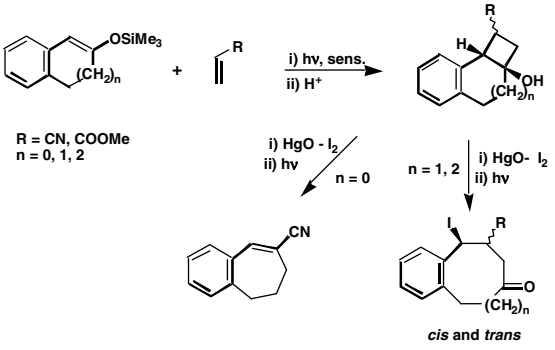
SCHEME 70



SCHEME 71

Two-Carbon Ring Expansion of Cyclic Ketones through [2+2]-Photoaddition-β-Fragmentation Sequence[82]

Two-carbon ring expansions of the five-, six,- and seven-membered rings of β-indanone, β-tetralone, and β-suberone can be achieved via a sensitized [2+2]-photoaddition of the trimethylsilyl enol ethers of the cyclic ketones with acrylonitrile or methyl acrylate followed by β-fragmentation of the alkoxyl radicals generated from the hypoiodites of the resulting cyclobutanols and mercury(II) oxide-iodine, as outlined in Scheme 72. The ring expansion of the cyclobutanol derived from β-indanone enol ether and acrylonitrile gave an α,β-unsaturated nitrile.



SCHEME 72

Analogous ring expansion via β-fragmentation of cyclobutanoxyl radicals derived from the photoadducts between α- or β-naphthyl trimethylsilyl ether and acrylonitrile or methyl acrylate resulted in the formation of a benzohomotropone after treatment with a base.

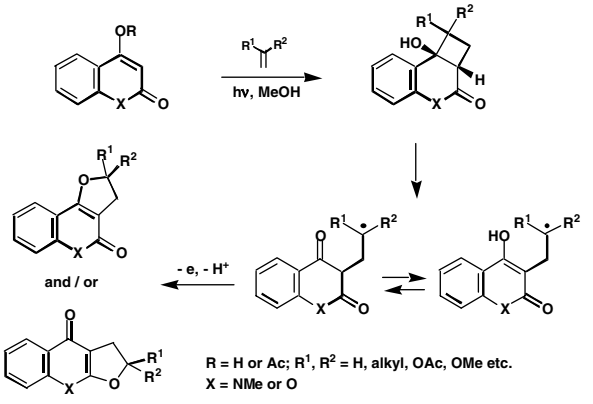
Thus, these ring-expansion experiments have confirmed that the β-fragmentation of the cyclobutanoxyl radicals generated from the [2+2]-photoadducts takes place selectively at their ring-fused bonds.

Insertion of Oxygen Atom of Alkoxyl Radical Generated from Fused Cyclic Alcohols by Tandem β-Fragmentation-Cyclization

Suginome and collaborators have found that heterocyclic compounds can be formed by insertion of the oxygen atom of alkoxyl radicals into alicyclic compounds; the insertion takes place through a tandem β-fragmentation-cyclization sequence.

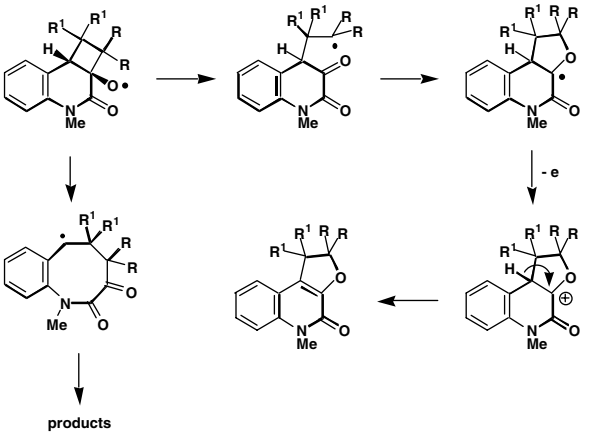
The Formation of Fused Furan Rings via Tandem β-Fragmentation-Cyclization of Cyclobutanoxyl Radicals Generated from [2+2]-Photoadducts Derived from 4-Hydroxycoumarin, 3-(or 4-)-Hydroxyquinolinone or 2-Hydroxynaphthoquinone withA alkenes

The [2+2]-photoaddition of aromatic lactones and lactams with an enolized 1,3-dicarbonyl group with alkenes, followed by photolysis of the hypoiodites generated from the resulting cyclobutanols, induced regioselective β-fragmentation of the corresponding cyclobutanoxyl radicals. This results in a transformation of the cyclobutane rings into furan rings via the incorporation of the alkoxyl oxygen. For example, photolysis of the hypoiodites derived from the [2+2]-photoadducts of 4-hydroxycoumarin (R = H; X = O)[83] or 4-hyroxyquinolin-2(2*H*)-one (R = H; X = NMe)[84a] with alkenes underwent a regioselective β-fragmentation of their non ring-fusion bond to give furocoumarins (X = O), furochromones (X = O), furo[3,2-*e*]quinolin-4-(5H)-ones (X = NMe), and furo [2,3-*b*]quinolin-4(9*H*)-ones (X = NMe), as outlined in Scheme 73.[83,84a] The analogous furanoheterocycles were formed from the [2+2]-photoadduct of 4-hydroxy-1-phenyl- [1,8]-naphthyridin-2(1*H*)-one with alkenes.[84b] The intermediate carbon-centered radical arising from the fragmentation may well be in equilibrium with a resonance-stabilized heteroaromatic radical A. This explains why the observed fragmentation is preferred over ring expansion.



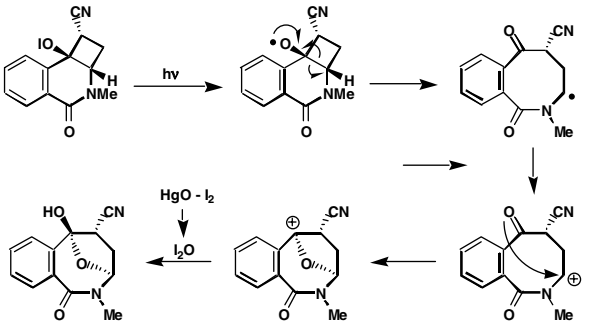
SCHEME 73

The photolysis of the hypoiodites of cyclobutanols derived from the [2+2]-photoadducts of 3-hydroxyquinolin-2(1*H*)-one with alkenes induced β-fragmentation at the outer bonds of the corresponding cyclobutanoxyl radicals to give furo[2,3-*c*]quinolin-4(5*H*)-ones in 5 to 50% yields with an accompanying formation of products arising from a ring expansion, as outlined in Scheme 74.[85]



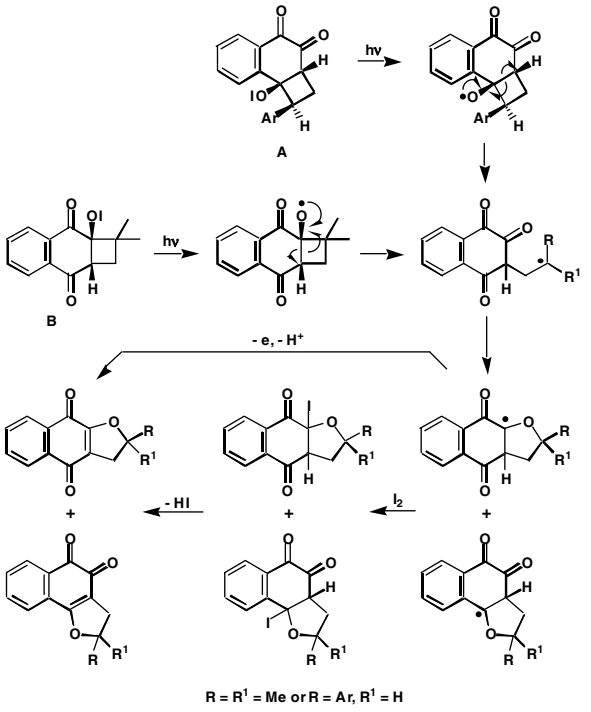
SCHEME 74

The photolysis of the hypoiodite generated from a cyclobutanol derived from the [2+2]-photoaddition of 4-hydroxy-1(2*H*)-isoquinolinone with an electron-deficient alkene in the presence of mercury(II) oxide and iodine resulted in a β-scission at the ring-fusion bond of the cyclobutanoxyl radical to give a 3,6-epoxybenzazocinone derivative in 76% yield (Scheme 75).[86] A weaker aromatic stabilization and destabilization by the cyano substituent in the carbon-centered radical arising from a fragmentation at the non-fusion bond led to ring expansion.



SCHEME 75

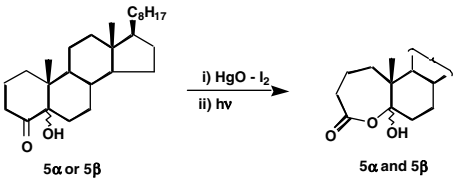
The photolysis of the hypoiodites generated from the cyclobutanols, derived from the [2+2]-photoaddition of 2-hydroxynaphthoquinone with alkenes (A) and of 2-aminonaphthoquinone with vinyl arenes (B) in the presence of mercury(II) oxide and iodine induced regioselective β-fragmentations of the cyclobutanoxyl radicals to give a 2,3-dihydronaphtho[2,3-*b*]furan-4,9-dione and its [1,2-*b*]furan-4,5-dione isomer[87](Scheme 76).



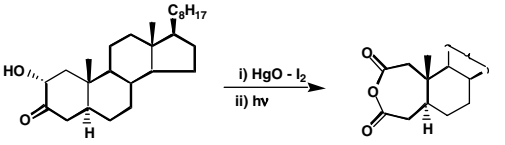
SCHEME 76

The Formation of Cyclic Anhydrides via β-Fragmenation of Steroidal α-Axoalkoxyl Radicals

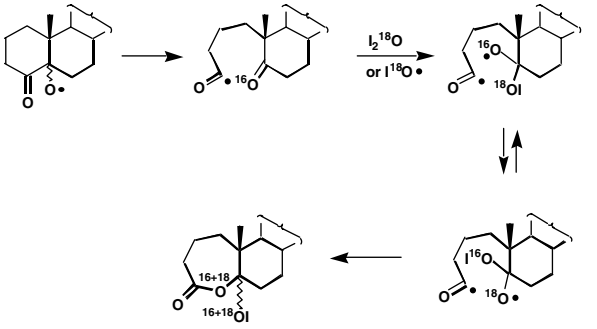
Irradiation of the hypoiodites of five- or six-membered cyclic α-ketols in the presence of mercury(II) oxide and iodine resulted in the formation of the corresponding cyclic anhydrides or α-hydroxy ε–lactones arising from regioselective β-fragmentation of the bond between the carbonyl and the carbon carrying an alkoxyl radical[88] (Schemes 77 and 78). An ^{18}O labeling study indicated that an oxygen atom in mercury(II) oxide is incorporated in the hydroxy group and the ring oxygen of the hydroxy ε-lactones. A rationalization for the observed incorporation of ^{18}O to the ring in all of the products is outlined in Scheme 79.



SCHEME 77



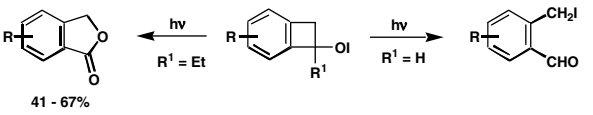
SCHEME 78



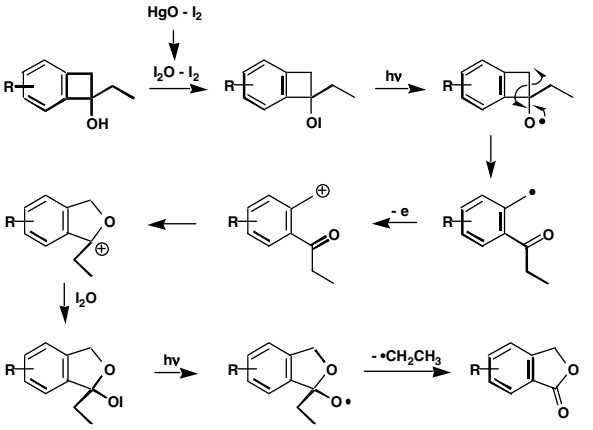
SCHEME 79

New Synthesis of Isobenzofuran-1(3H)-ones (Phthalides) via a Cascade Radical Process Involving Double β-Fragmentation of Alkoxyl Radicals[89]

The photolysis of the hypoiodites of 1-ethylbenzocyclobuten-1-ols, prepared by a treatment of the 1-ols with mercury(II) oxide and iodine gives the corresponding phthalides in good yields (Scheme 80). The pathway is outlined in Scheme 81.[89a] The principal feature of this process is an intramolecular combination of a carbocation or, less likely, a carbon-centered radical with a carbonyl oxygen generated by a regioselective β-fragmentation of the alkoxyl radicals. The photolysis of the hypoiodite of benzocyclobuten-1-ol gives simply a cleaved product; the alkyl group attached to C1 of cyclobutenol is necessary in order to keep the conformation appropriate for cyclization to give the furan ring. The reaction can also be achieved by lead tetraacetate oxidation.[89b] This lactone formation by an expulsion of the alkyl radical was applied to a two-step general synthesis of 3-substituted dihydroisocoumarins from the lactols.[89c]

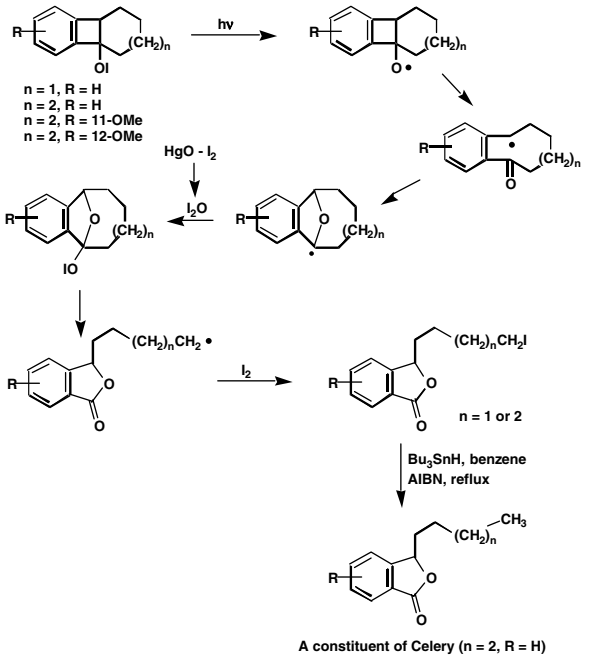


SCHEME 80



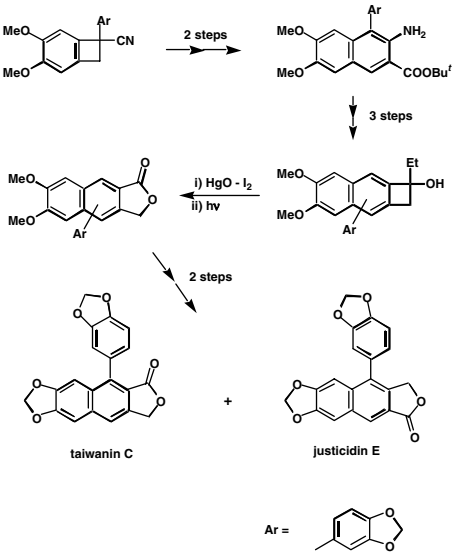
SCHEME 81

1. Synthesis of 3-(ω-iodoalkyl)phthalides.[89a,89b] Scheme 82 outlines the synthesis of phthalides bearing a four- or five-carbon chain at C3 from catacondensed 1,2-dihydrocyclobuten-1-ol hypoiodites.



SCHEME 82

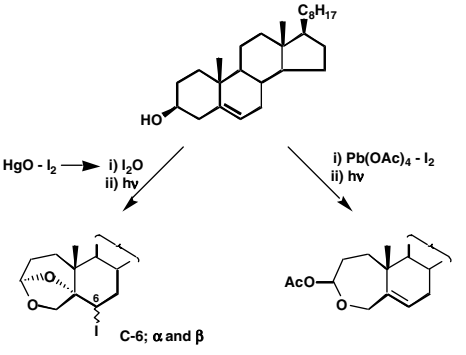
2. New synthesis of naphthalide lignans, taiwanin C and justicidin E.[90] Scheme 83 outlines a new synthesis of taiwanin C and justicidin E based on the cascade β-fragmentation strategy.



SCHEME 83

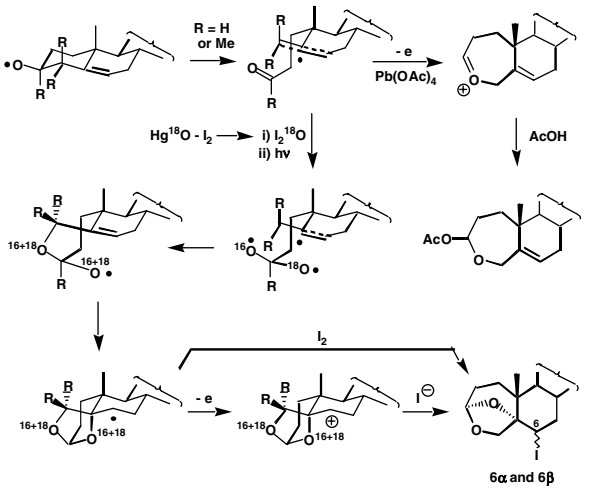
Oxygen Insertion by Tandem β-Fragmentation-Cyclization of Alkoxyl Radicals

Oxasteroids arising from tandem β-fragmentation and cyclization are products in the photolysis of the hypoiodites generated from 3-hydroxy-Δ^5-steroids and lead tetraacetate-iodine, as outlined in Scheme 84. The path of the formation of the oxasteroids is outlined in Scheme 85; one-electron oxidation of the intermediate radicals arising from the cyclization of allylic radicals generates the oxonium ions, which trap acetic acid to give the products.[91]



SCHEME 84

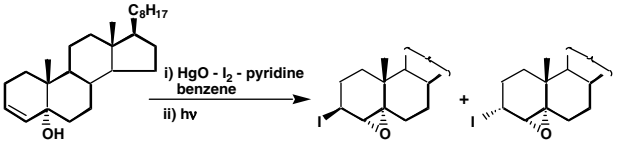
On the other hand, when mercury (II) oxide instead of lead tetraacetate is used to generate the hypoiodites, 3a,5-epoxy-4-oxa-A-homo-5a-steroids are the products, as outlined in Scheme 84. An ^{18}O labeling study using $Hg^{18}O$ and iodine and an analysis of the extent of ^{18}O incorporation by mass spectrometry showed that the oxygen of mercury (II) oxide is incorporated into the epoxy oxygen of the products (31–61%).[92] Based on these labeling results, the pathway of the formation is rationalized as outlined in Scheme 85.



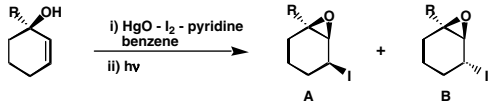
SCHEME 85

Intramolecular Additions of Alkoxyl Radicals to Carbon–Carbon Double Bonds

The intramolecular additions of alkoxyl groups to carbon–carbon double bonds to give β-iodo-alkyl ethers from alkyl hypoiodites under photolytic conditions have been reported. Suginome and collaborators found that the formation of α-iodoepoxides arising from an intramolecular α, β-addition of an allylic alkoxyl radical is a major general process in the photolysis of tertiary and some secondary allylic alcohol hypoiodites in the presence of mercury (II) oxide and iodine in benzene.[93] Thus, 5-hydroxy-5β-cholest-3-ene gave epimeric α-iodoepoxides in a ratio of 10:1 in 86% yield as outlined in Scheme 86. Similar reaction of 1-alkylcyclohex-2-en-1-ols gave a mixture of *cis*- and *trans*-α-iodoepoxides (Scheme 87). The addition of pyridine dramatically enhanced the yield of the addition product. The yields of the α-iodoepoxides obtained from the photolysis of 1-alkylcyclohex-2-en-1-ols and the ratios of *cis*- to *trans*-isomers are summarized in Table 109.1.



SCHEME 86



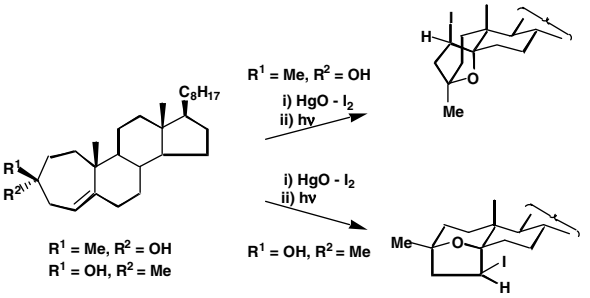
SCHEME 87

It has been reported that epoxides arising from an intramolecular γ,δ–*trans*-additions of homoallylic alkoxyl group are the major products in the photolysis of the hypoiodites of several seven-membered cyclic steroidal homoallylic alcohols, such as *A*-homocholest-4a-ene-3-ols,[94] *A*-homo-5α–cholest-1-en-4-ols,[95] and *B*-homocholest-5-en-7a-ols[93] in the presence of mercury (II) oxide and iodine in benzene;

TABLE 109.1 Ratio of A:B Combined Yield(%)

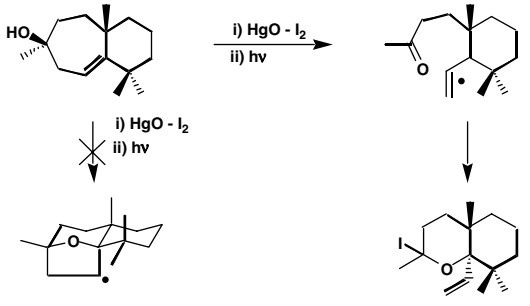
Me	1:0	61
Bu	5:1	99
Bu^t	7:1	46
Ph	4:1	84

the irradiation of the hypoiodites of 3α- and 3β-methyl-*A*-homo-4a-cholesten-3-ols in the presence of mercury(II) oxide-iodine gave 3α,5-epoxy-3β-methyl-4aβ-iodo-*A*-homo-5β-cholestane and its 3β,5-epoxy isomer in high yields, as outlined in Scheme 88.[96]



SCHEME 88

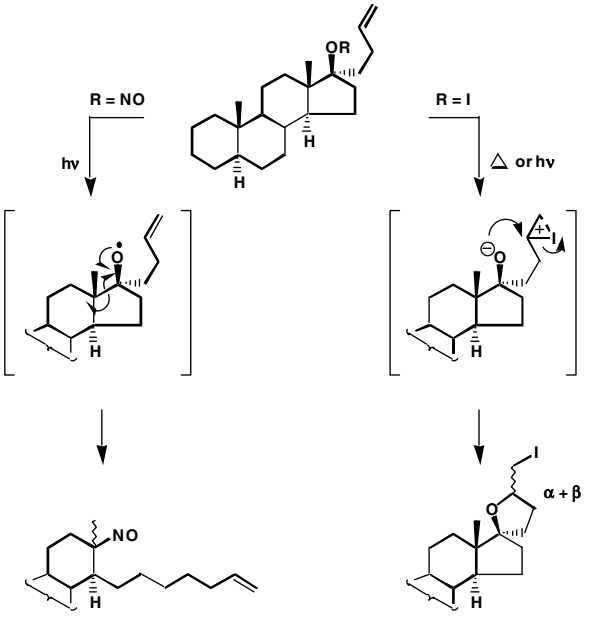
The steric effects for the addition *vs* the β-fragmentation pathway seems to be of importance. Thus, irradiation of the hypoiodites of a sesqiterpene, widdrol, which has a structural unit corresponding to the A- and B-rings of 3 methyl-*A*-homo-4a-cholesten-3β-ol, except that it has *gem*-dimethyl groups on the carbon corresponding to C6 of the steroids, resulted in exclusive β-fragmentation of the corresponding 3β-alkoxyl radical and gave a cyclic ether having iodine, but no products from intramolecular addition were formed[97] (Scheme 89). The sharp contrast in the results obtained for the steroids can be rationalized in terms of steric effects. Thus, a transition state leading to the rigid intermediate radical involves a 1,3-diaxial interaction between the angular methyl and one of the *gem*-dimethyl groups; therefore, the addition would be slower and result in the observed β-fragmentation.



SCHEME 89

It has been reported that *t*-butyl hypoiodite adds to alkenes via a bridged iodonium ion intermediate in a *trans* manner in benzene to give β-iodo-ethers in the dark.[98] Unlike the addition in nitrite photolysis,[17] thermal ionic additions may take place in hypoiodite photolysis. The additions in the steroids, even under photolytic conditions, can be rationalized in terms of an ionic *trans*-addition of alkyl hypoiodites via bridged iodonium ions, although a homolytic mechanism cannot be excluded.

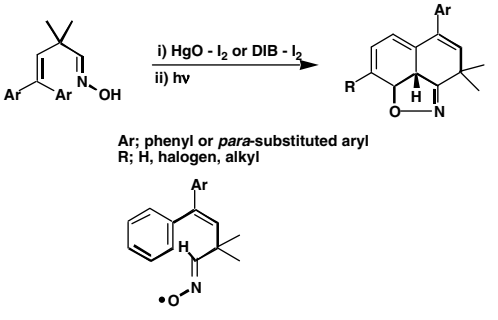
Intramolecular heterolytic additions of the hypoiodites of bishomoallyl alcohols *under photolytic conditions* have been proved:[99] while alkoxyl radicals generated from the photolysis of steroidal bishomoallyl alcohol nitrite resulted in products arising from a β-fragmentation, the corresponding hypoiodite in the presence of mercury (II) oxide and iodine in benzene at room temperature in the dark and in the photolysis gave a spirotetrahydrofuran derivative that arose from addition via bridged iodonium ions in high yield, as outlined in Scheme 90. Thus, if the double bonds are appropriately located, the ionic intramolecular addition is preferred to the β-fragmentation, even in the photolysis of hypoiodites of alcohols, such as steroidal 17β-ols,[50] which form alkoxyl radicals very susceptible to β–fragmentation.



SCHEME 90

Reaction of Iminoxyl Radicals

Horspool and collaborators recently found that the irradiation of β, γ–unsaturated oximes in benzene in the presence of either HgO-I_2 or DIB-I_2 resulted in the formation of a *peri*-naphthisoxazoles in 55 to 77% yields, as outlined in Scheme 91.[100] The path of the formation involves the generation of an iminoxyl radical formed from a homolytic fission of the OI bond of the oxime hypoiodites, followed by its intramolecular cycloaddition to the aryl group to afford the product.[100]



SCHEME 91

109.4 Conclusions

The past half a century has witnessed that alkoxyl radicals are highly reactive, unique chemical species and are as important and useful as carbon-centered radicals in organic synthesis. The usefulness of intramolecular hydrogen abstraction and β-fragmentation of alkoxyl radicals in synthesis is believed to be comparable to the intramolecular addition of carbon-centered radicals. This chapter is an attempt to bring together the diverse photochemical reactions of hypohalites, which are the most powerful and convenient precursors of alkoxyl radicals.

Photochemistry of Hypervalent Iodine Compounds

Tsugio Kitamura
Saga University

110.1 Introduction

This chapter deals with the photochemical reactions of hypervalent iodine compounds, especially organoiodine(III) species. Although there has been an increasing interest in the synthetic use of hypervalent iodine compounds,[1–12] the photochemical study is very limited. Recently, remarkable progress has been made in the use of diaryliodonium salts as photoinitiators for cationic polymerization and as photoacid generators for imaging systems. On the other hand, the photochemical applications of hypervalent iodine compounds to organic synthesis have been found in the reactions accompanying generation of alkyl and alkoxy radicals, carbene formation, halogenation, and arylation.

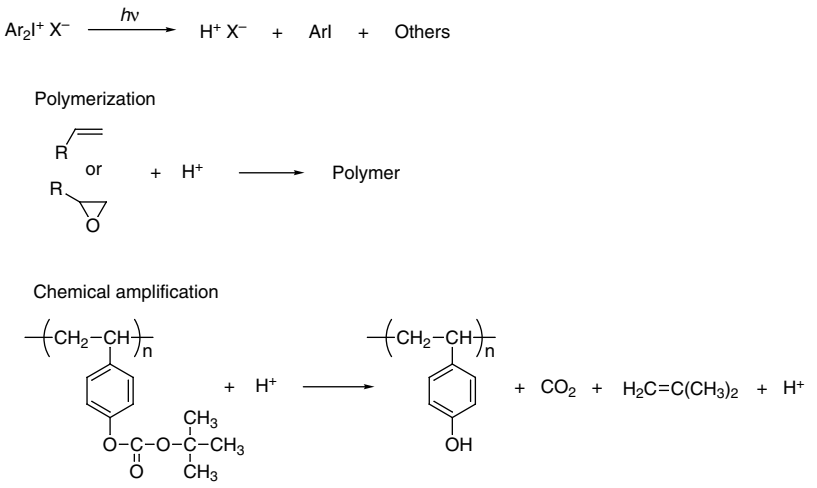
110.2 Photochemistry of Diaryliodonium Salts and Related Iodonium Salts

The photochemistry of diaryliodonium salts has been investigated extensively for use in cationic polymerization and microlithographic applications (chemical amplification).[13–20] In principle, these applications are based on the generation of a strong acid by the photolysis as shown in Scheme 1.

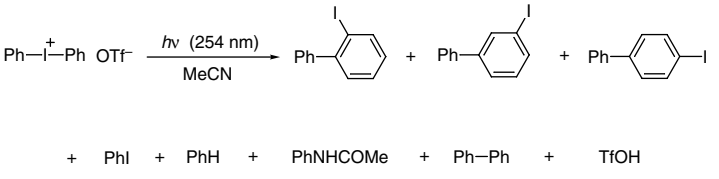
Typically, diaryliodonium salts exhibit an intense absorption band in the 230- to 260-nm region ($\varepsilon \sim 17{,}000\ M^{-1}\cdot cm^{-1}$) as shown in Table 110.1.[21] Electron-donating substituents on the aromatic rings induce a bathochromic shift while electron-withdrawing substituents shift the UV absorption to shorter wavelengths.

Direct photolysis of diphenyliodonium triflate in acetonitrile, as shown in Equation 110.1, gives iodobenzene, 2-, 3-, and 4-iodobiphenyls, benzene, acetanilide, and biphenyl. In addition to these products, triflic acid is also formed.

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1 Application of diaryliodonium salts photochemistry.



(110.1)

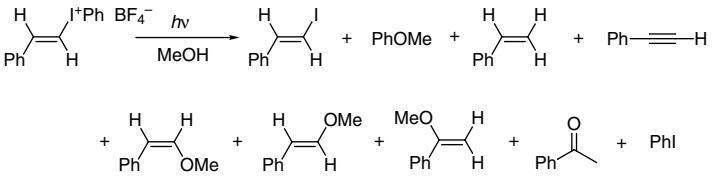
The mechanistic studies have been demonstrated by product analysis, analysis of the polymer formed, and by the detection of the intermediates.[22–47]

The photolysis of diphenyliodonium salts has been proposed to occur by both heterolytic and a homolytic cleavage of the carbon–iodine bonds (Scheme 2). Excitation by irradiation produces the excited singlet diphenyliodonium salt. This species can undergo a heterolytic cleavage, leading to a caged pair of phenyl cation and iodobenzene. Intersystem crossing from the excited singlet state leads to the excited triplet state, which can undergo homolysis to a caged pair of iodobenzene radical cation and phenyl radical. Each of the corresponding caged pairs of reactive intermediates undergoes further reactions leading to products. Detection of the reactive intermediates was made using flash photolysis.

When diphenyliodonium salts are photolyzed, acids species are generated by several reaction paths as shown in Scheme 3. These acids are the predominant species responsible for cationic polymerization and photodepolymerization.

Photosensitized decomposition of diphenyliodonium salts occurs mostly through electron transfer, as shown in Scheme 4. Another mechanism via triplet energy transfer is possible for specific photosensitizers

The photochemistry of alkenyl(phenyl)iodonium tetrafluoroborates in methanol as well as 2,2,2-trifluoroethanol, dichloromethane, and toluene has been investigated (Equation 110.2).[48–50] Homolysis as well as heterolysis of both bonds, the vinylic C–I bond and the aromatic C–I bond, occur. The predominant formation of styryl cation accounts for the product derived from nucleophilic substitution, elimination, and rearrangement, as shown in Scheme 5.



(110.2)

TABLE 110.1 UV Spectra of Diaryliodonium Salts

Structure	Anion	λ_{max}, nm (ε_{max})[a]
	BF_4^-	227 (17,800)
	BF_4^-	246 (15,400
	AsF_6^-	215 (35,000) 245 (17,000)
	BF_4^-	236 (18,000)
	PF_6^-	237 (18,200)
	AsF_6^-	237 (17,500)
	BF_4^-	238 (20,800)
	AsF_6^-	240 (23,000)
	AsF_6^-	275 (30,000)
	AsF_6^-	264 (17,300)

[a] In MeOH.

Photolysis of alkynyl(phenyl)iodonium salts results in the major formation of products derived from homolysis of the carbon–iodine bonds, such as iodoalkynes, iodobenzene, and phenylalkynes as the major reaction paths (Equation 110.3).[51]

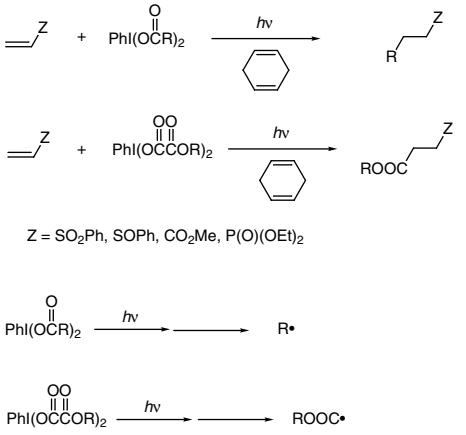


SCHEME 6

110.3 Application to Organic Synthesis

Generation of Alkyl Radicals[52–63]

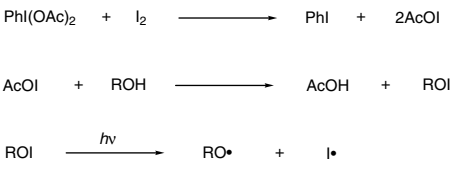
(Diacetoxyiodo)benzene and [bis(trifluoroacetoxy)iodo]benzene generate radicals under photochemical conditions. These [bis(acyloxy)iodo]benzenes are efficient radical initiators for the polymerization of 2-[2-((dimethylamino)ethyl)methacrylate, methyl methacrylate, and styrene. Under photochemical conditions, [bis(acyloxy)iodo]benzenes readily produce free radicals that, in the presence of a hydrogen donor such as 1,4-cyclohexadiene, react with electron-deficient alkenes to give reductive addition products, as shown in Scheme 6.

Further applications of this procedure are found in the radical alkylation of nitrogen heterocycles, *C*-nucleosides, and disulfides, and in the cyclization of the radicals to yield heterocycles.

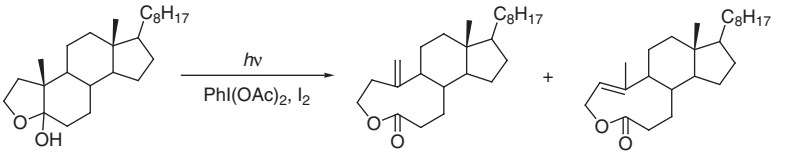
Generation of Alkoxy Radicals[64–73]

Photolysis of (diacetoxyiodo)benzene with alcohols in the presence of iodine leads to the generation of alkoxy radicals that can undergo fragmentation, rearrangement, or cyclization. The generation of an alkoxy radical is accomplished in the following way (Scheme 7). The acetyl hypoiodite initially forms and converts alcohols to alkyl hypoiodites. Under photochemical conditions with visible light, the alkyl hypoiodites generate the alkoxy radicals by I–O bond homolysis.

For example, photolysis of steroidal hemiacetals with (diacetoxyiodo)benzene and iodine in the absence of oxygen affords medium-sized lactones as a result of alkoxy radical fragmentation (Equation 110.4).[65]



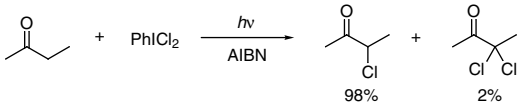
SCHEME 7



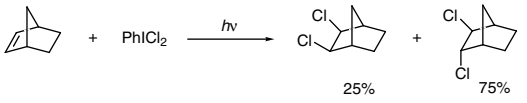
(110.4)

Halogenation[74–80]

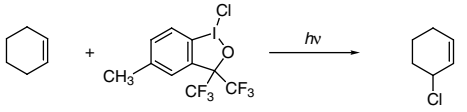
Dichloroiodobenzene and 1-chlorobenziodoxoles were used as reagents for chlorination under photochemical conditions. The chlorination of alkanes or alkenes using this method proceeds via a radical mechanism (Equations 110.5 through 110.7). Special interest is given to the selective chlorination of a steroid derivative bearing dichloroiodo group at an appropriate position (Equation 110.8).[75]



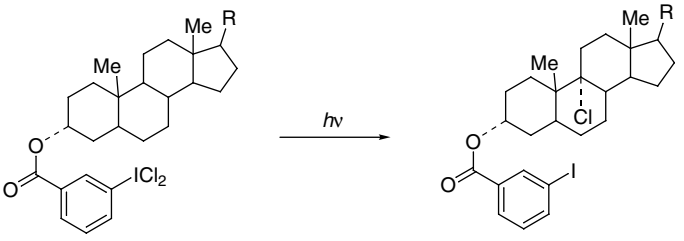
(110.5)



(110.6)



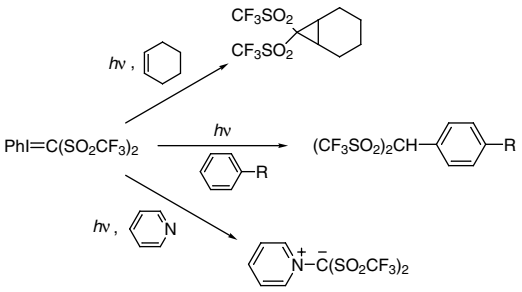
(110.7)



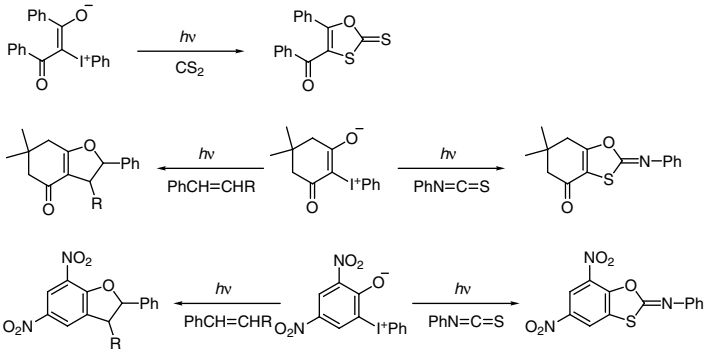
(110.8)

Carbene Precursors[81–84]

Iodonium ylides can serve as precursors of carbenes under photochemical, thermal, or catalytic conditions. For example, phenyliodonium bis(trifluoromethylsulfonyl)methide under photochemical conditions affords the cycloaddition product with cyclohexene, the CH insertion products with aromatic substrates, and the ylide transfer product from pyridine, as shown in Scheme 8.[82–84]



SCHEME 8



SCHEME 9

Synthesis of Heterocyclic Compounds[81,85,86]

Another use of iodonium ylides is as a synthetic route to heterocyclic compounds (Scheme 9). Iod**o**nium ylides can be photochemically converted to oxathiole-2-thiones in the presence of CS_2. In the presence of phenyl isothiocyanate or styrenes, the iodonium ylides undergo photochemical conversion to 2-phenyliminooxathioles, dihydrofurans, and dihydrobenzofurans, respectively. Many other interesting reactions of iodonium ylides based on the photochemical approach are also reported in the literature.

Phenylation[87]

Diphenyliodonium chloride and tetrafluoroborate undergo light-catalyzed reaction with triphenylphosphine to give tetraphenylphosphonium salts (Equation 110.9).

Photolysis of Short-Lived Transient Species in Solutions: Product Analysis Studies

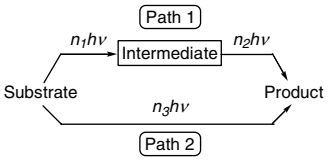
Akihiko Ouchi
Research Institute for Green Technology
National Institute of Advanced Industrial Science and Technology

111.1 Introduction

Lasers are ideal light sources for studying organic photochemical reactions, so much so that they are widely used in spectroscopic studies. However, product analysis studies of organic laser-induced reactions have not been carried out as much as spectroscopic studies. For product analysis studies, it is necessary to conduct reactions with high efficiency, compared with spectroscopic studies, in order to determine the yields of photochemical products by GC and/or HPLC analyses. This can be accomplished by applying precise control of the irradiation of light using four major characteristics of lasers that differ from conventional light sources; that is, light intensity, monochromaticity, coherency, and intermittence (for pulse lasers).

Using these characteristics of lasers, photochemical reactions that cannot be conducted with conventional light sources can be brought about,[1,2] and a multiphoton reaction is one of these processes. Multiphoton reactions can be classified in two categories: (1) stepwise reactions through short-lived transient species (Path 1 in Scheme 1) and (2) reactions by concerted multiphoton absorptions (Path 2 in Scheme 1). In many cases, Path 1 predominates when the substrates are complex organic compounds. The transient species can be either long-lived excited states, such as triplet states, or chemical species, such as radicals, carbenes, nitrenes, and thermally unstable molecules.

0-8493-1348-1/04/$0.00+$1.50



SCHEME 1

Product analysis studies of the photochemical reactions of such transient species have been conducted using various lasers and techniques. Such studies not only complement spectroscopic studies to give a better understanding of multiphoton reactions, but also give new methods for the study of short-lived transient species.

111.2 Photolysis Techniques

Laser Photolysis

This method comprises simple irradiations of substrate solutions in reaction vessels by continuous or pulsed lasers. For the continuous irradiation of high-intensity pulse lasers, the laser-drop photolysis technique[3] and a flow system with a short optical path length have been used.

In general, the high-intensity character of lasers is considered the most important factor for efficient multiphoton reactions. However, matching the wavelength of the lasers to both starting materials and intermediate species is also necessary to obtain high efficiency in the reactions. When pulse lasers are used, laser pulse width and the timing of the generation of the intermediates must be considered, in addition to wavelength matching; the intermediates must be generated within the same laser pulse for successive photon absorptions.

Laser-Jet Photolysis

This method was developed to conduct high-intensity, continuous laser photolysis.[4] However, this technique can be used also for the optimization of laser wavelength to both starting materials and intermediates and for the matching of the timing of the intermediate generation and laser irradiation. Figure 111.1 shows an experimental setup of a laser-jet apparatus. The solution of sample is pumped through a glass capillary with an internal diameter of 50 to 100 μm and the focus of a focused continuous laser is set on the liquid stream just below the outlet of the capillary. In general, 333-, 351-, and 364-nm emissions of argon ion lasers are used at the same time. However, when only one wavelength of the laser is needed, a prism can easily separate the three distinct emissions. The matching of the laser wavelength to both starting materials and intermediates can be often accomplished by using all the three laser emissions. By changing the internal diameter of the capillary and the flow rate, irradiation times can be varied between 10 and 100 μs. Multiple irradiations of the solution is also possible by recycling of the solution. However, the laser intensity of this method is much less than that of pulse lasers.

Time-Delayed, Two-Color Pulse Laser Photolysis

This technique has been used often in flash photolysis experiments but has not been used much in product analysis studies. Figure 111.2 shows a diagrammatic experimental setup of the method. The concept of this method is to generate intermediates with the first laser pulse and photolyze the intermediates with the second laser pulse. The wavelength of the first laser pulse can be adjusted to the absorption of starting materials and that of the second laser pulse to the absorption of the intermediates. The maximum yield of the photochemical products of the intermediates should be obtained if the second laser pulse irradiates when the concentration of the intermediate becomes maximum.

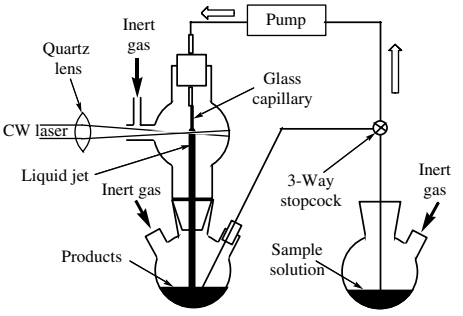


FIGURE 111.1

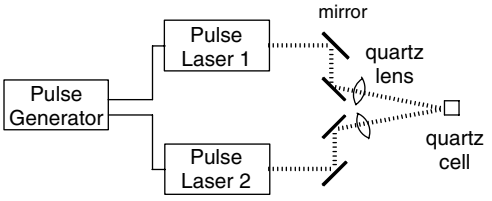

FIGURE 111.2

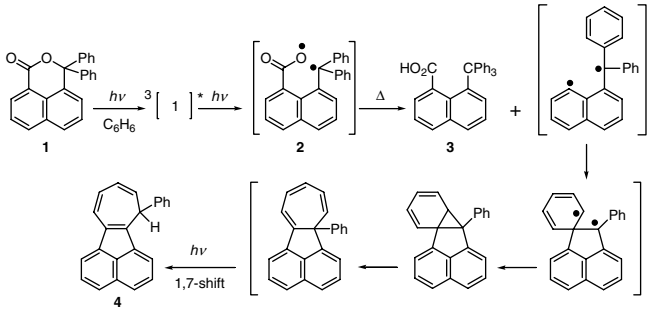
111.3 Selected Examples

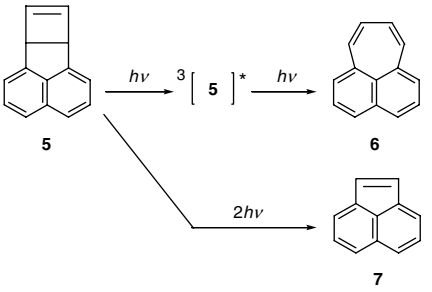
Photolysis of Triplet Species

Scheme 2 shows an example of the photolysis of a triplet state.[5] The reaction was conducted under high-intensity, laser-jet conditions. The triplet state of **1** is further excited to a higher state, which gave products **3** and **4** via biradical **2**. Compound **3** is formed by the reaction of **2** with solvent benzene and **4** is formed by a decarboxylation followed by a series of reactions shown in the scheme.



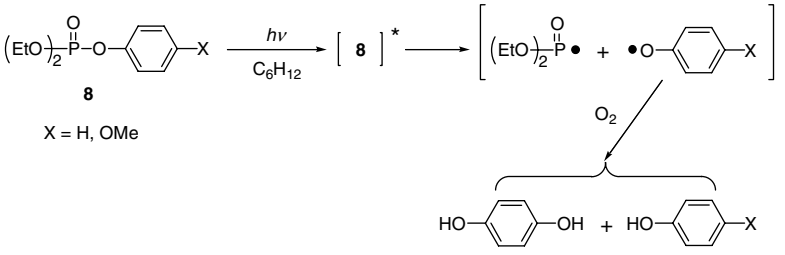
SCHEME 2

When cyclobutene **5** is irradiated with an XeCl excimer laser (308 nm), compounds **6** and **7** are formed (Scheme 3).[6] It was revealed that **6** is formed by the excitation of the triplet state of **5** whereas **7** was formed from higher singlet states. The transient spectrum of **5** shows a triplet absorption maximum at 440 nm with its maximum intensity appearing 3.9 μs after the laser pulse. The time-delayed, two-color pulse laser photolysis technique using an XeCl and 440-nm laser pulses showed the increase in the ratio of the yields **6**:**7**.



SCHEME 3

Scheme 4 shows the cleavage of the P–OAr bond in **8** from higher excited states, in contrast to the PO–Ar bond cleavage that occurs by a one-photon process.[7] The excited state that is populated by the second photon absorption is still not clear at the moment. However, participation of a triplet state is most likely because the heavy-atom effect of phosphorus is expected and the photolysis in alkane solution reduces the possibility of charge-transfer processes.

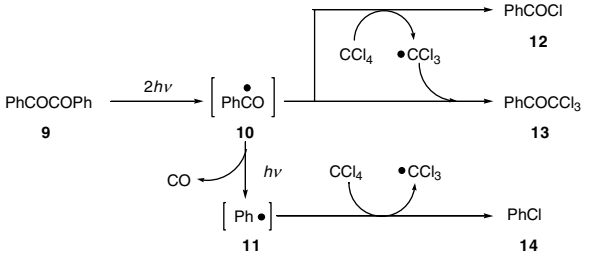


SCHEME 4

Further examples of the reactions from higher triplet states are shown in a review.[8]

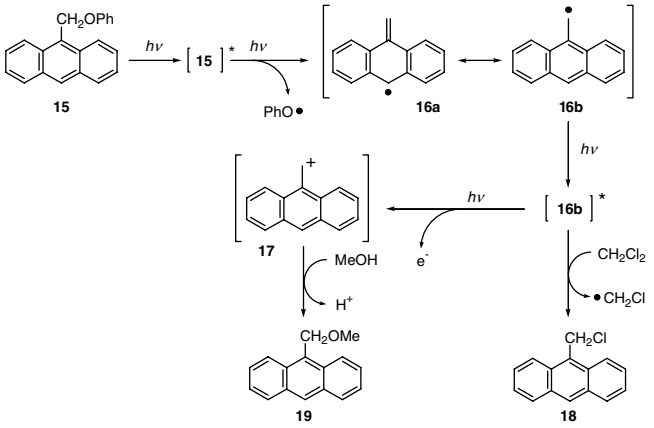
Photolysis of Radicals

Radicals are also further photolyzed to give products. Scheme 5 shows the photolysis of benzil **9** that is conducted by the laser-jet technique in CCl_4, giving **12**, **13**, and **14** as photoproducts.[9] Compound **14** is a photochemical product of the benzyl radical **10**, which is generated by a two-photon process from **9**. The laser-jet reactions of diphenylmethyl radicals in CCl_4 and alcoholic solvents are also reported.[10]



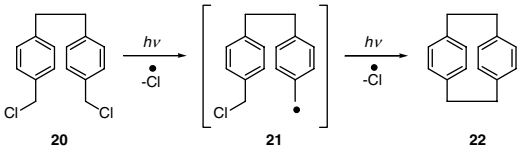
SCHEME 5

Scheme 6 is an interesting example of radical photolysis conducted by the laser-jet technique.[11] Radical **16** is generated by a two-photon reaction of **15**. When radical **16** absorbs another photon in CH_2Cl_2, it gives **18**, similar to the reaction shown in Scheme 5. However, when **16** is photolyzed in MeOH, the excited radical **16b** ionizes to cation **17**, which reacts with MeOH to give **19**. Similar reactions are also observed with 1-naphthyl[12] and 4-biphenylmethyl radicals.[13]



SCHEME 6

Scheme 7 shows another example of radical photolysis, in which radical **21** is the intermediate that undergoes the second photolysis.[14] Laser-drop photolysis of **20** shows the formation of **22**, which is confirmed by GC-MS analysis. The presence of radical **21** is observed by flash photolysis experiments using a 266-nm pulse laser. Similar reactions of 1,*n*-dihaloalkanes have been the subject of a review.[15]



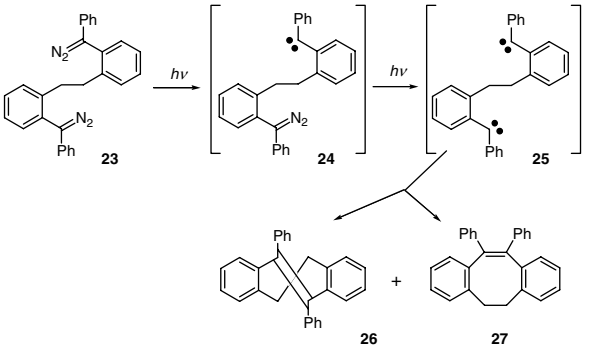
SCHEME 7

Further examples of such reactions brought about on the photolysis of radicals have also been reviewed.[8]

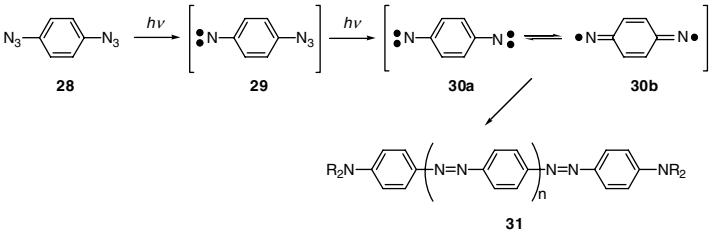
Photolysis of Carbenes and Nitrenes

Scheme 8 shows a two-photon reaction of bis(diazo) compound **23** conducted with a 248-nm pulse laser. Monocarbene **24** is generated as an intermediate and further photolyzed to biscarbene **25** within the same laser pulse, which undergoes intramolecular coupling to **26** and **27**.[16] Compounds **26** and **27** are not observed in conventional light photolysis.

Scheme 9 is the result of an experiment using a KrF excimer laser (248 nm) to bring about photolysis of diazide **28**. Diazide **28** is photolyzed to the mononitrene **29** and then to dinitrene **30a**, which tautomerizes into biradical **30b**. Intermediates **30a** and **30b** undergo polymerization and form a violet solid **31**.[17]



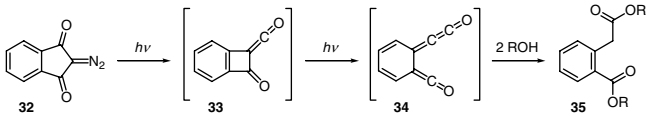
SCHEME 8



SCHEME 9

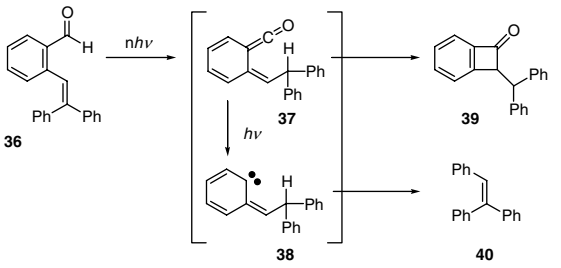
Photolysis of Unstable Molecules

Most of the photolyses of unstable compounds is directed toward the behavior of ketenes. Scheme 10 shows a laser-drop photolysis of diazo compound **32**. Ketene **33** is formed and further photolyzed to **34**, to which two alcohol molecules add to give the stable diester **35**.[18]



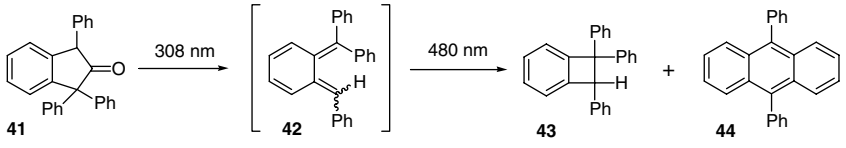
SCHEME 10

Scheme 11 is a laser-jet photolysis of the intermediate ketene **37** generated from **36** by a multiphoton process.[19] In addition to the formation of **39**, photochemical decarbonylation of **37** also occurs under photolysis conditions to give carbene **38**, which forms **40**. Similar examples on the photolysis[20] and photochemical decarbonylation[21] of ketenes have been reported.



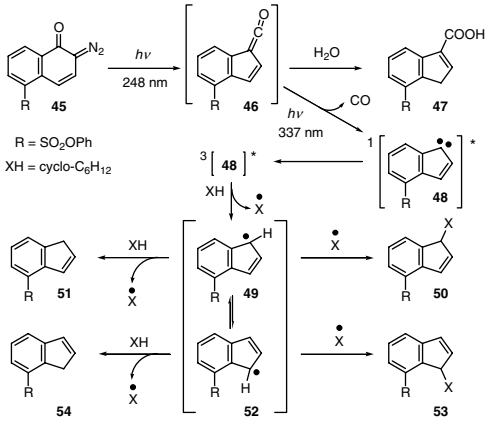
SCHEME 11

The reaction shown in Scheme 12 was studied using the time-delayed, two-color pulse laser photolysis technique.[22] An unstable *o*-quinodimethane derivative **42** is photochemically generated from substituted indanone **41**. The *o*-quinodimethane derivative **42** is further photolyzed to **43** and **44**. In the case of simple 308-nm laser photolysis, the ratio of the yields **44**:**43** is 2.54, whereas the ratio changes to 3.93 when the time-delayed, two-color photolysis technique is used. In the two-color photolysis, the first laser used is a 308-nm laser pulse and the second is a 480-nm laser pulse that is irradiated 2 μs after the first laser pulse. The wavelength of the second laser is adjusted to the absorption maximum of **42**.



SCHEME 12

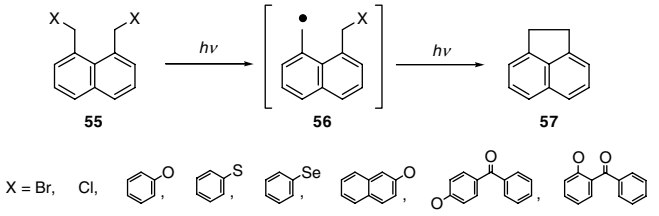
Scheme 13 is another example of a time-delayed, two-color pulse laser photolysis.[23] The unstable ketene **46** was generated by the first KrF laser pulse irradiation, which gave **47** by the addition of H_2O. However, with successive 337-nm laser pulse irradiations, **50**, **51**, **53**, and **54** are formed through the sequence of reactions shown in the scheme. The yields of **47**, **50**, **51**, **53**, and **54** were very dependent on the delay time of the two laser pulses.



SCHEME 13

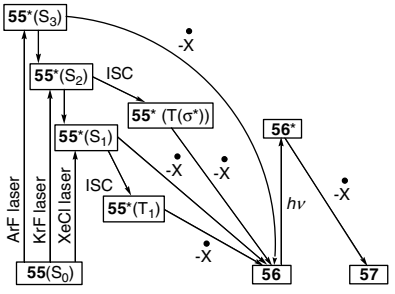
111.4 Improving the Efficiency of the Photochemical Reactions of Short-Lived Transient Species

A systematic study of the increase of the efficiency in the photochemical reactions of transient species has been reported using 1,8-bis(substituted-methyl)naphthalenes **55** (Scheme 14).



SCHEME 14

A simple laser photolysis of **55** (X = Br, Cl) using XeCl (308 nm), KrF (248 nm), and ArF (193 nm) excimer lasers shows that the yield of the two-photon product acenaphthene **57** decreases in the order KrF > XeCl > ArF.[24,25] By analogy with the photolysis of 1-halomethylnaphthalenes,[26] **55** is excited to its S_1, S_2, and S_3 states by the irradiation of XeCl, KrF, and ArF excimer lasers, respectively, and the energy dissipation from each excited state is shown in Scheme 15.[25] The presence of the intermediate monoradical **56** is confirmed by nanosecond flash photolysis experiments.[27]



SCHEME 15

When **55** is excited to the S_1 state by the XeCl laser pulse, it undergoes intersystem crossing (ISC) to the T_1 state. The lifetime of the T_1 state is expected to be 0.5 to 0.7 μs, so that the monoradical **56** is generated at least 0.5 to 0.7 μs after the irradiation by the first laser pulse. However, this time range is larger than the pulse width of the XeCl laser (17 ns); thus, **56** has a very small chance of absorbing the second photon. This explains the low yield of the two-photon product **57** by the XeCl laser photolysis (*cf.* Scheme 15: **55***(S_1) → **55***(T_1) → 56).

KrF laser photolysis of **55** gives a very fast generation of **56** through its S_2 state and successive ISC to the T(σ*) state. The high yield of **57** by the excitation of **55** to its S_2 state is explained by the efficient generation and succeeding second photon absorption of **56** within the same laser pulse (30 ns) (*cf.* Scheme 15: **55***(S_2)→**55***(T(σ*))→**56**).

The use of halogen atoms for leaving groups X decreases the yield of **57** due to the high reactivity of the eliminated halogen atoms.[24a,25]

The above results indicate several problems in the photolysis of short-lived intermediates, including:

1. Wavelength matching. Starting materials and intermediates have different absorptions so that when the wavelength of lasers is optimized for the photolysis of the starting compounds, it is not the ideal wavelength for the intermediates and vice versa.

2. Photolysis timing. When pulse lasers are used, the generation of intermediates and successive photolyses have to be conducted within the same laser pulse.
3. Energy transfer. In the case of **55**, photons are absorbed by the naphthalene moiety and the energy is transferred to the cleaving C-X bond that is not directly connected to the naphthalene ring. For efficient energy transfer, cleaving bonds should be directly connected to the chromophores.
4. Secondary reactions. Suppression of the reactivity of the cleaved leaving groups is necessary to minimize secondary reactions.

These problems can be improved by two means: (1) improving the photolysis technique and (2) by chemical modification of the substrates.

Increasing the Photochemical Efficiency by Improvement of Photolysis Technique

Laser-jet and time-delayed, two-color pulse laser photolysis techniques can be used to overcome problems 1 and 2 above. In the case of the laser-jet technique, the three emissions (333, 351, and 364 nm) of an argon ion laser can be used at the same time for the wavelength matching of the starting materials and the intermediates; in general, the shorter wavelength is suitable for the photolysis of starting materials and the longer wavelength for the intermediates. The irradiation time is generally 10 to 100 μs, which is sufficient for the generation of intermediates and for conducting successive photolysis. In the case of the time-delayed, two-color pulse laser photolysis technique, the wavelength of the first and the second laser pulses can be matched with the starting material and the intermediate, respectively, and the second laser pulse can be fired at the time when the concentration of the intermediate is at its maximum.

Laser-Jet Photolysis

In the reaction shown in Scheme 14, the low yield of **57** by the excitation to the S_1 state is explained by the difference of the timing between the laser pulse irradiation (17 ns) and the generation of **56** (> 0.5–0.7 μs). By the laser-jet photolysis technique using an argon ion laser (using all 333-, 351-, and 364-nm emissions), the irradiation time of the laser to **55** can be prolonged to *ca.* 100 μs so that the timing problem can be solved. Furthermore, the 333-nm emission is suitable for the photolysis of **55,** and the 351- and 364-nm lines are good for the photolysis of **56**.

There are no standards for the comparison of the efficiency between pulse laser photolysis and laser-jet photolysis. However, when the efficiency is compared with parameters — yield of **57**/photon and yield of **57**/fluence (photons·m^{-2}·s^{-1}) — the laser-jet photolysis technique showed an increase of both parameters by three orders of magnitude compared with that in the simple XeCl laser photolysis.[25,28] A similar trend was also observed when the leaving group X is changed to OPh, SPh, and SePh.[29]

Time-Delayed, Two-Color Pulse Laser Photolysis

Time-delayed, two-color pulse laser photolysis is applied to the reaction of **55** (Scheme 14). An XeCl (308 nm) (first laser pulse) and an XeF (351 nm) (second laser pulse) excimer laser pulse are irradiated successively to **55** (X = Cl) with varying delay times.[25,30] The result is shown in Figure 111.3. The horizontal

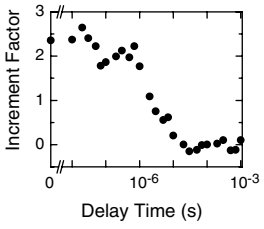


FIGURE 111.3 Increment factor of **57** as a function of the delay time of the two laser pulses.

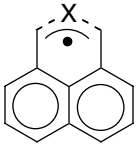
axis of the figure shows the delay time of the two lasers and the vertical axis shows the Increment Factor (IF), which is defined as (A − B)/B, where A is the yield of **57** obtained by the time-delayed, two-color pulse laser photolysis and B is the yield of **57** obtained by the simple XeCl laser photolysis. An interesting feature in Figure 111.3 is that the IF, which reflects the concentration of **56**, shows two maxima: at 0 to 30 ns and and at 0.2 to 0.5 μs. The maximum at 0.2 to 0.5 μs is explained by the formation of **56** via the T_1 state and that at 0 to 30 ns is rationalized in terms of direct formation of **56** from the S_1 state (*cf.* Scheme 15: **55***(S_1) → **56**). A similar trend is also observed when the leaving group X is OPh, SPh, and SePh.[31] In the case of SPh, the IF increases to 8.

Improving the Photochemical Efficiency by Chemical Modification of Substrates

By using OPh, SPh, and SePh groups as the leaving group X in the reaction of **55**, the two leaving groups can be directly excited by the same wavelength because they have identical absorptions. This solves problems 1 and 2. Problem 3 is also solved because the chromophore of these leaving groups is directly connected to the cleaving bonds. The stability of the OPh, SPh, and SePh radicals is expected to be greater, especially for SPh and SePh, so that problem 4 can be also overcome. The photolysis of **55** (X = OPh, SPh, SePh) shows considerable improvement in the yield of **57**, which shows the maximum yield of 72% by simple KrF excimer laser photolysis using PhS leaving groups.[32] The presence of intermediate **56** was confirmed by nanosecond flash photolysis experiments.[33] However, when X is Se, the monoradical **56** prefers to exist as the bridged structure **58**, which is supported by semi-empirical MO calculations.[29] The photolysis can be conducted at longer wavelengths using an XeF (351 nm) excimer laser when 4-benzoyloxyphenoxy and 2-benzoyloxyphenoxy groups are used for the leaving groups.[32]



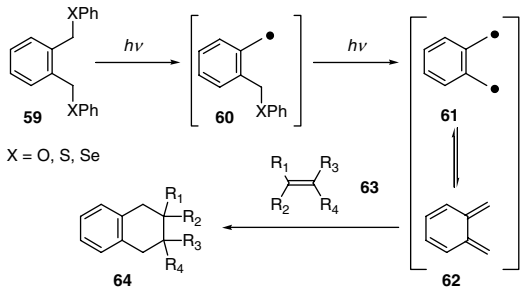
58

111.5 Applications

Synthetic Applications

o-Quinodimethane **62** can be generated from 1,2-bis(substituted-methyl)benzenes **59** (X = O, S, Se) via monoradical **60** by a two-photon process using excimer laser photolysis (Scheme 16). The conventional precursors of **62** often used in organic synthesis generally need several steps for preparation, whereas **59** can be synthesized in one step in good yield from commercially available 1,2-bis(bromomethyl)benzene.

The effects of laser fluence, substrate concentration, and optical path were investigated by simple laser photolysis of KrF, XeCl, and XeF excimer lasers.[34] The yield of **64** increased with the decrease of the concentration of **59**, with the decrease of the length of the optical path, and with the increase of the fluence of the laser. The maximum yield of **64** obtained by irradiation of the KrF excimer laser was 48% at room temperature and 60% at 60°C. The decrease in length of the optical path for increasing product yields has considerable synthetic importance because the increase in laser intensity often results in the destruction of the reaction vessel.

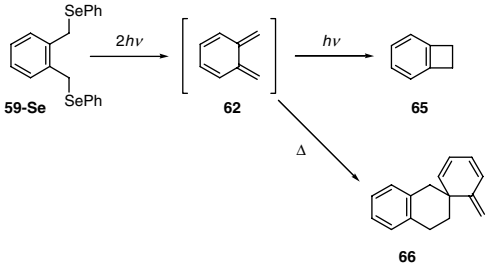


SCHEME 16

Mechanistic Studies

Photochemical Efficiency of the Photolysis of *o*-Quinodimethane in Solution at Room Temperature

As shown in Scheme 17, the KrF laser photolysis of **59-Se** in the absence of olefins yielded benzocyclobutene **65** and *o*-quinodimethane spiro dimer **66**. The formation of **65** is explained by the initial generation of **62** from **59-Se** via a two-photon process and the successive one-photon reaction of **62**, within the same pulse of the KrF laser.[35] The thermal dimerization of **62** to **66** is known to occur even at −150°C in an organic solid matrix.[36a,b] This photochemical reaction of **62** was never conducted in solution at room temperature; thus, its photochemical efficiency remains unknown.



SCHEME 17

A time-delayed, two-color pulse laser photolysis of **59-Se** was conducted using KrF and XeCl (or XeF) excimer lasers. The result of this is shown in Figure111.4.[35,37] This figure shows that the yield of **65** is maximum at *ca.* 20 ms, whereas that of **66** achieves its minimum at the same delay time. The yield of **65** at each delay time reflects the concentration of **62** so that the result indicates that the concentration of **62** becomes a maximum at 20 ms. Figure 111.4c shows that **62** decreases with second-order kinetics, which is consistent with the flash photolysis experiment of which **62** is generated from different precursors.[38]

The photochemical efficiency of the formation of **65** from **62** is obtained by analysis of the delay-time dependence of the yield of **65**. An interesting result in this experiment is that a wavelength effect on the formation of **65** was observed when XeCl (308 nm) (Figure 111.4a) and XeF (351 nm) (Figure 111.4b) excimer lasers were used as the second laser. Although the molar absorption coefficient of **62** at 351 nm is threefold larger than that at 308 nm,[36b,c] the yield of **65** was 2.5-fold higher when the 308-nm laser was used instead of the 351-nm laser. Participation of the higher excited state S_2 [36a,b,d] for the photochemical conversion of **62** to **65** is postulated but the $S_0 \rightarrow S_2$ transition is still not explicitly observed by spectroscopic means. It is probably buried under the more intense $S_0 \rightarrow S_1$ band. The wavelength effect of the second laser in the time-delayed, two-color pulse laser photolysis supports this theoretical prediction.

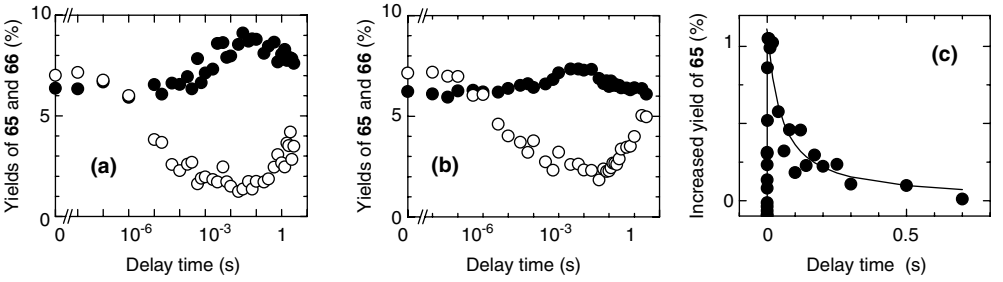


FIGURE 111.4 Yields of **65** and **66** (a,b) and increased yield of **65** (c) as a function of the delay time of the two laser pulses. Combination of the two lasers: KrF – XeCl (a), KrF – XeF (b). **65**: closed circle; **66**: open circle.

Determination of Kinetic Constants of Fast Reactions

Although the cycloaddition of **62** with alkenes (**63**) and alkynes is one of the well-investigated reactions, the rate constant for cycloaddition in solution at room temperature has not been reported thus far. This may be due to the difficulty in conducting the experiments spectroscopically. The rate constant for the cycloaddition of **62** and maleic anhydride **67** in solution at room temperature is determined by product analyses using the time-delayed, two-color pulse laser photolysis technique (Scheme 18).[39] Compound **62** is generated via irradiation of a KrF laser pulse to **59-Se** in the presence of **67**. The cycloaddition of **62** to **67** yields the adduct **68** (Path 1), together with the thermal products of **62**[38c] (Path 2). The cycloaddition is quenched by the decomposition of the remaining **62** by the second XeCl laser pulse, which is irradiated after varied delay times between 0 and 0.1 s. The rate constant for the cycloaddition of **62** and **67** is obtained by analyzing the delay-time dependence of the yield of **68**, which is found to be $2.1 \times 10^5\ M^{-1}\cdot s^{-1}$.

112

Action Spectroscopy: General Problems

Edward D. Lipson
Syracuse University

112.1 Introduction

Action spectroscopy is a general approach toward identifying the receptor pigment for a particular photobiological response or effect. The early identification of major chromophores, such as rhodopsin and chlorophyll, depended on comparison of the action spectra for vision and photosynthesis, respectively, with the absorption spectra of candidate pigments.

It is remarkable how few chromophore types with intrinsic photochemistry are employed in photobiological systems.[1,2] A basic list consists of the following:

1. Retinal pigments (in rhodopsins)
2. Tetrapyrroles (including chlorophylls, and phycobiliproteins including phytochromes)
3. Flavin and pterin accessory chromophores (in cryptochrome and phototropin pigments; these are blue-light receptors in plants and microorganisms and, in the case of cryptochromes, in animals too)
4. Hypericin pigments[2]
5. The *p*-coumaric acid chromophore of the photoactive yellow protein (PYP) of *Ectothiorhodospira halophila*[3,4] (now reclassified *Holorhodospira halophila,* see Chapter 123)

This focus in this chapter is on analytical methods for measuring action spectra, with emphasis on those derived from fluence-response data. For a set of examples, the reader can consult studies of *Phycomyces,* not only studies of its phototropism[5–7] but also of the light–growth response,[8,9] carotene synthesis,[10] and differentiation,[11] as well as studies of other blue-light systems.[12–16] The later studies on *Phycomyces* employed formal data analysis methods — including error analysis (and error propagation[17])

0-8493-1348-1/04/$0.00+$1.50

in the curve fitting and parameter estimation — as summarized elsewhere,[18] so that error bars could be assigned to the points in the action spectra derived from the fluence-response raw data points and their error bars.

For other representative action spectra, the reader is referred to the following chapters in this volume and to the major photobiology journals: *Photochemistry and Photobiology, Journal of Photochemistry and Photobiology, B: Biology,* and *Photochemical and Photobiological Sciences*. There are also a number of review articles that give various perspectives on action spectroscopy.[18–27] For practical advice on light sources and radiometry, the reader should consult standard photobiology texts.[28–30]

112.2 Alternative Types of Action Spectra

The most elementary type of action spectrum consists of a graph of some response or effect as a function of wavelength, under conditions where the photon fluence is maintained constant at all wavelengths. This convenient approach, however, can be confounded by the frequent circumstance that the response may depend nonlinearly on the fluence (or fluence rate). For example, if at some wavelengths the response is in a saturation region, then the action spectrum will be "clipped" (*viz.* peaks flattened) at those wavelengths; similarly, other types of nonlinearities will produce other distortions. Accordingly, a preferred way of obtaining an action spectrum — provided that the experimenter is willing and able to apply the additional effort needed — is to derive it from fluence-response curves (sometimes called dose-response curves, by analogy with pharmacology). In this way, one essentially obtains a graph of sensitivity, rather than response, as a function of wavelength. Operationally, for each wavelength, the photon fluence required to achieve a standard response level is determined and then the reciprocal of that photon fluence is plotted as a measure of sensitivity. The graph so obtained is sometimes called an "equal-response action spectrum," which is not subject to the nonlinear distortions above and is, therefore, more likely to represent the absorption spectrum of the responsible chromophore (subject to various considerations specified below).

112.3 Photophysics

After a chromophore absorbs a photon, a number of alternative photophysical events may ensue. These can be represented graphically by a "Jablonski diagram" depicting transitions among the electronic, vibrational, and rotational states of the pigment molecule.[31] Upon absorption of a photon, the molecule is promoted from the ground state (usually of singlet character, and designated, therefore, as S_0) to an excited electronic state (also singlet, and designated S_1, S_2, etc.); the molecule generally becomes excited with respect to vibrational and rotational motions, as well (the corresponding energy spacings among these states are progressively lower than those between electronic states). The molecule then de-excites rapidly by internal conversion and vibrational relaxation to the lowest excited singlet level S_1, before there is time for photochemistry to take place. Consequently, regardless of the wavelength of the incident photon that excited the molecule, the molecular excitation relaxes rapidly to the bottom vibrational levels based on S_1. Then, the relevant photochemistry proceeds directly from S_1 or — following intersystem crossing from the singlet to the triplet manifold — from the lowest triplet state T_1, provided that the excitation energy has not been dissipated in the meantime by internal conversion or fluorescence.

112.4 Illumination Units

Fluence-response curves are sometimes measured using broadband rather than monochromatic light, because higher fluence rates are achievable with broadband filters, and unless one is trying to study the wavelength dependence of a particular response or effect, it may be more representative of natural illumination conditions to use broadband light covering the range of sensitivity. For example, in studies of photogravitropism "threshold curves" of *Phycomyces* wild-type and mutant strains,[6,32] it is customary

to employ broadband blue illumination at fluence rates extending over a 10-decade range. With broadband illumination, the units pertain to energy fluence rather than photon fluence. The energy units are J m^{-2} for fluence and J m^{-2} s^{-1} (or, equivalently, W m^{-2}) for fluence rate. In action spectroscopy, however, one must use monochromatic light (occasionally in combination with polychromatic background light; see Chapter 113). It is then preferable to use photon units: photons m^{-2} for fluence, and photons m^{-2} s^{-1} for fluence rate.

112.5 Conditions for Measurement and Interpretation of Action Spectra

The shape of an action spectrum may be distorted significantly from the absorption spectrum of the responsible pigment. To obviate such distortions, the experimenter should strive to satisfy the following conditions insofar as possible:[24,27]

1. The quantum efficiency (or quantum yield) — defined as the probability that a particular type of event of photobiological or photochemical interest occurs as the result of absorption of a photon — should be independent of wavelength.
2. The absorption spectrum of the receptor pigment should be the same whether measured *in vivo* or *in vitro*.
3. Screening or shading pigments, as well as scattering effects, should not cause significant wavelength-dependent distortion. Scattering is generally stronger at shorter wavelengths, but the trend is a gradual one and normally would not obscure the key features of an action spectrum; instead, scattering tends to superpose a sloping baseline, which can be largely eliminated, if desired, by using a suitable scattering reference.
4. When an action spectrum is derived from fluence-response curves, the condition of reciprocity should be valid over the range of fluence rates and exposure times used. In other words, the response should depend on the product of fluence rate and exposure time but should not otherwise depend on either factor.
5. Light should not be totally absorbed by the sample for any wavelength under study. More specifically, an ample fraction of the incident light (a practical guideline is 50%) should reach the receptor pigment region under all conditions.

112.6 Reciprocity

For measurements employing continuous illumination, the stimulus strength is given by the fluence rate. With pulse illumination, however, the fluence can be adjusted by varying the exposure time (pulse width) and the fluence rate. Considering the kinetics of photochemical and subsequent dark reactions, it is preferable in most circumstances to maintain the exposure time constant and vary the fluence rate. In general, though, one should establish the range of validity of reciprocity between exposure time and fluence rate (see above).

112.7 Fundamental Derivations

For action spectroscopy with pulse illumination, assume that the response R can be expressed as a function of the product of four variables:

$$R = R\left(\phi \sigma_1 I_1 \Delta t\right) \tag{1}$$

where ϕ is the quantum efficiency (or quantum yield), σ_1 is the cross section (see below) at wavelength λ_1, I_1 is the fluence rate (note that the traditional symbol I stands for "intensity," which is sometimes used

informally in place of fluence rate; however, according to strict radiometric terminology, intensity is defined as the power per unit solid angle), and Δt is the exposure time (pulse duration). The fluence is given by $F_l = I_l \Delta t$.

To derive an equal-response action spectrum from fluence-response curves, the first step is to specify a "criterion" response level. Then, for each wavelength, the fluence (or fluence rate) needed to produce that standard response should be determined. Choices for the criterion response include the following:

1. Some fixed absolute level
2. A percentage (typically 50%) of the maximum response level, which may depend on wavelength
3. The maximum response (peak) level, for those instances where the response descends at high fluence after reaching a peak
4. The absolute threshold fluence rate (often extrapolated downward to the baseline from the linearly rising part of the fluence-response curve; note that an alternative approach that should be avoided would be to try to find the limiting fluence at which there just begins to be a perceptible response; the difficulty is that this measure is highly susceptible to experimental noise and subjective judgment; see below for a further discussion of threshold measurements)

If fluences $F_{\lambda 1}$ and $F_{\lambda 2}$ elicit the same response level — the criterion response — and if one assumes that Δt is the same in both experiments (or, if reciprocity applies, one can correct for the different values of Δt), then the argument of the function in Equation 1 is the same for both experiments at these two wavelengths, λ_1 and λ_2. If the quantum efficiency ϕ is assumed to be the same at both wavelengths, then

$$\frac{\sigma_{\lambda_1}}{\sigma_{\lambda_2}} = \frac{F_{\lambda_2}}{F_{\lambda_1}} \tag{2}$$

It is assumed implicitly that the fluence response curves are monotonic, or at least that the corresponding criterion response points on the curves are chosen (otherwise, if the fluence-response curve were, for example, bell-shaped, there would be two values of fluence with the same response value, and one could conceivably err by choosing noncorresponding points on curves for different wavelengths). From Equation 2, it is evident that the cross section at any wavelength λ is inversely proportional to the applied fluence that produces the criterion response at that wavelength, or $\sigma_\lambda \propto F_\lambda^{-1}$.

If, instead, the response is measured as a function of fluence rate rather than fluence, then a derivation similar to that above, starting from the equation

$$R = R\left(\phi \sigma_1 I_1\right) \tag{3}$$

leads to the relation

$$\frac{\sigma_{\lambda_1}}{\sigma_{\lambda_2}} = \frac{I_{\lambda_2}}{I_{\lambda_1}} \tag{4}$$

or

$$\sigma_\lambda \propto I_\lambda^{-1}$$

112.8 Relationship between Extinction Coefficient and Cross Section

The extinction coefficient ε is used in conventional spectrophotometry and measured in the traditional units of L mol^{-1}cm^{-1}. It can be related by a conversion factor to a quantity from physics, the absorption

cross section (introduced in the previous section), in traditional units of cm^2. The ratio between the fluence rate I transmitted through a spectrophotometric sample and the incident intensity I_0 can be derived from the following relations:

$$\frac{I}{I_0} = 10^{-\varepsilon c \ell} = e^{-\sigma n \ell} \tag{5}$$

where c is the molar concentration of the pigment, ℓ is the internal path length through the cuvette (usually 1 cm), σ is the absorption cross section, and n is the pigment concentration in units of molecules per cm^3. The expression in the first exponent, $\varepsilon c \ell$, represents the absorbance, A.

The extinction coefficient and the cross section are, therefore, interrelated by the following conversion formula:

$$\varepsilon = 2.62 \times 10^{20}\ \sigma \tag{6}$$

where ε is in units of L mol^{-1} cm^{-1}, and σ is in cm^2. As an example of applying this conversion formula, consider riboflavin (or other flavin), which has an extinction coefficient of 1.25×10^4 L mol^{-1} cm^{-1} (at ~450 nm); then $\sigma = 4.8 \times 10^{-17}$ cm^2. This represents the effective target area the chromophore presents for absorption of light. As another example, rhodopsin, with an extinction of 4×10^4 L mol^{-1} cm^{-1} (at ~500 nm) has $\sigma = 1.5 \times 10^{-16}$ cm^2.

112.9 Derivation of Action Spectrum from Fluence-Response Curves

Shown in Figure 112.1 is a set of five idealized fluence-response curves. In the following discussion, it will be demonstrated how action spectra can be derived from such curves. The hypothetical response is presumed to be measured as a function of the photon fluence; alternatively, fluence rate could have been chosen as the independent variable. The fitting function of the form $ax/(x+b)$, where x stands for the fluence (or fluence rate), is plotted for the five wavelengths on both logarithmic (a) and linear (b) scales for x. In this example, wavelength λ_3 is the most effective, because the least amount of light is required to achieve the criterion response level, chosen here to be half of the maximum response. Conversely, λ_5 is the least effective. So, when this set of "data" is converted into an action spectrum, the ordinate representing the sensitivity, or effectiveness, will be high for λ_3 and low for λ_5.

In the semilogarithmic plot (Figure 112.1a), the curves have the same sigmoidal shape and differ only by lateral displacement. The symmetrical sigmoidal shape is a property of the hyperbolic saturation function, which is frequently used to fit fluence-response curves and other types of stimulus-response relationships in sensory physiology,[33,34] in photochemical kinetics,[35] and in other areas of biophysics and biology, including the well-known Michaelis–Menten enzyme kinetics (see below).

The procedure for deriving the action spectrum (Figure 112.2) from these curves is straightforward. The action spectrum ordinate, often labeled as "relative quantum effectiveness," or just "effectiveness," is simply the reciprocal of the fluence required to produce a criterion response (see Equation 2 and Equation 4) as a function of wavelength. Some authors choose instead to label the ordinate in "relative units," for example, by normalizing several action spectra to the wavelength of maximal effectiveness of one of them. However, it is preferable to retain the proper physical units of m^2 mol^{-1}. If fluence rate-response curves are used instead as the basis for the action spectra, then the corresponding reciprocal units for the "effectiveness" are m^2 s mol^{-1}. In the former case — based on fluence rather than fluence rate — the units of the action spectrum ordinate are reciprocal to the fluence units, which are essentially m^{-2} (apart from dimensionless entities such as photons or moles of photons). Consequently, the action spectrum physical units are m^2, indicating that some kind of area quantity is involved. This dimensionality corresponds specifically to that of a cross section (see relationship, above, between extinction coefficient and cross section).

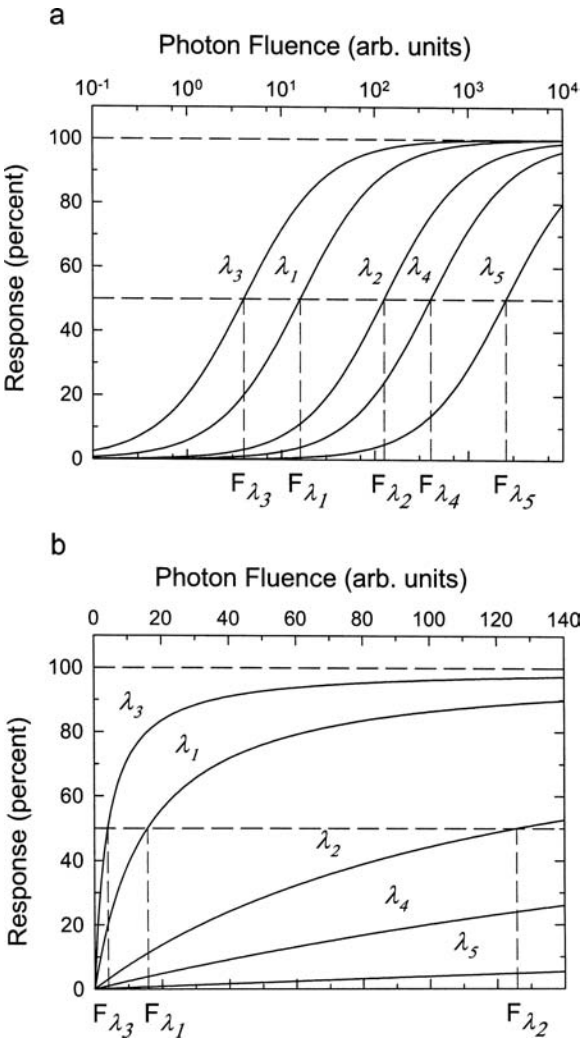

FIGURE 112.1 Generic fluence-response curves for five wavelengths (λ_1 through λ_5) shown on logarithmic (a) and linear (b) scales for photon fluence. The curves represent the hyperbolic saturation function of the form $ax/(x+b)$, where x is the fluence (also denoted in this chapter by the symbol F) (see top row of Table 1). On a semilogarithmic scale (a), the curves have the same sigmoidal shape (see functions in Rows 4 and 5 of Table 112.1). The fluence F needed to produce the standard criterion response (here chosen to be 50%) at each wavelength is shown by the vertical dashed lines. The designation of "arbitrary units" on the abscissa scales above each graph means that no importance should be given to the absolute numbers used in this example, and, implicitly, that fluence rate could be used instead of fluence if continuous rather than pulse illumination were employed; the actual units of photon fluence would be mol m^{-2}. If photon fluence rate were used instead, the units would be mol m^{-2} s^{-1}.

For a given application, one has to decide between plotting the action spectrum on a logarithmic or linear ordinate. In *Phycomyces*, with a sensitivity range exceeding 10 decades, it is particularly appropriate to plot such action spectra on a logarithmic ordinate.[6,32] This choice is advantageous for comparing action spectra to one another or to absorption spectra of putative receptor pigments. Spectra that differ only by a scale factor will have identical shapes on a logarithmic scale (and will be displaced by the logarithm of the scale factor). Now, if such spectra were identical, apart from a scale factor, they could be forced to have the same shape on a linear scale too, simply by normalizing them at any wavelength of choice (thereby, superposing the spectra completely). The practical problem, however, is that in the usual case,

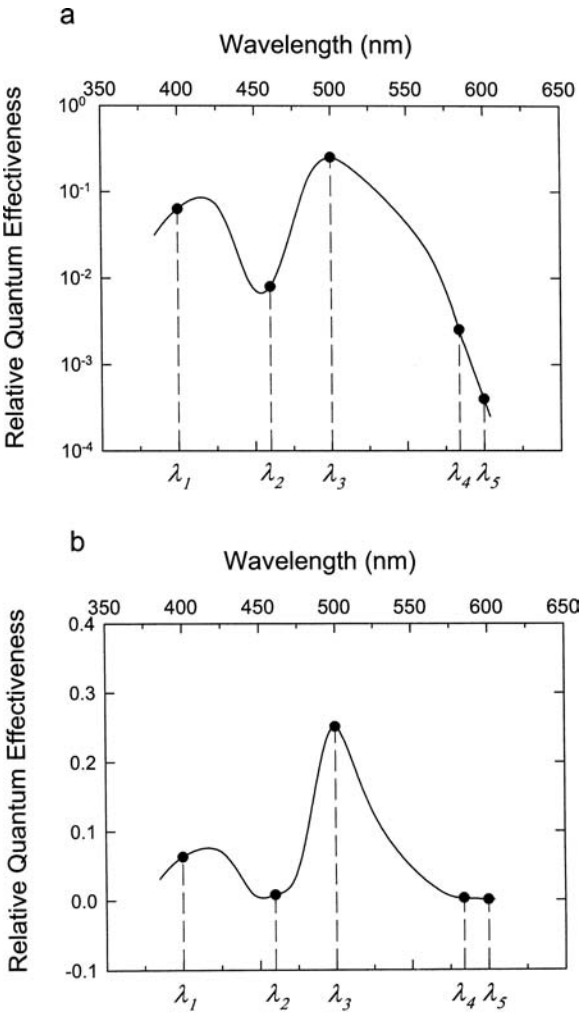

FIGURE 112.2 Five-point action spectrum derived from the fictitious fluence-response curves shown in Figure 112.1. The relative quantum effectiveness, shown on logarithmic (a) and linear (b) scales, is simply the reciprocal of the photon fluence F required at each wavelength to achieve the criterion response, as indicated in Figure 112.1.

when spectra are similar but not identical, choosing one wavelength or another for normalization will lead to different relative shapes. Such ambiguity and subjectivity are avoided by doing the comparison on a logarithmic scale. On the other hand, using a linear ordinate scale has the advantage that it is the more familiar way of viewing absorption spectra, for example, the chart records from commercial spectrophotometers.

The abscissa of an action spectrum is usually presented as a wavelength scale. On the basis of quantum mechanical principles, it would be preferable to use an energy rather than a wavelength scale; the two are related reciprocally according to the relation $E = hc/\lambda$, where E is the energy of a photon of wavelength λ, h is Planck's constant, and c is the speed of light. When an action or absorption spectrum is plotted as a function of energy, the positions of peaks are linearly related to transitions between the energy levels corresponding to molecular states (as on a Jablonski diagram; see above)). This is particularly worthwhile in the case of rhodopsin-type pigments in animals — as well as in halophilic bacteria and algae — because such pigments have spectra of standard shape, except for lateral shifts in the energy of maximum

TABLE 112.1 Representative Functions for Fluence-Response Curve Fits

Description	Function	References
Hyperbola	$\frac{ax}{x+b}$	11
Two hyperbolas plus a constant[a]	$\frac{ax}{x+b}+\frac{cx}{x+d}+h$	11, 36
Hill function	$\frac{ax^n}{x^n+b^n}$	7
Sigmoid[b]	$\frac{a}{1+\exp\left[n(k-u)\ln 10\right]}$	7
Sigmoid[b]	$\frac{a}{2}\left[1+\tanh\left\{n(u-k)\frac{\ln 10}{2}\right\}\right]$	7
Hill plus hyperbola[c]	$\frac{ax^n}{x^n+b^n}+c\log\left(\frac{x}{d}\right)+\sqrt{c^2\log^2\left(\frac{x}{d}\right)+k^2}$	10, 37

[a] This function consists of a sum of two hyperbolas plus an optional constant, h. The coefficients *a* and *c* may be positive or negative for saturation components that rise or fall, respectively.

[b] These two equivalent functions are derivable from the Hill function (familiar in the context of ligand binding for hemoglobin, for example) in the third row, with the substitutions $u = \log x$ and $k = \log b$. They represent the sigmoidal shape taken on by the Hill function when plotted on a semilogarithmic scale, i.e., plotted against log *x* instead of *x*. In the special case with $n = 1$, these sigmoidal functions are equivalent to the hyperbola function in the top row (see Figure 112.1). In general, the Hill exponent does not need to be an integer.

[c] The last two terms together comprise a hyperbola when plotted on a *logarithmic* scale for x. Note that this usage of hyperbola is different from that in the top row function. The hyperbola here has a horizontal asymptote for small *x* and a slant asymptote with slope 2*c* for large *x*.

absorption and vertical shifts in the absolute extinction or effectiveness. Nevertheless, most action and absorption spectra are plotted customarily on a wavelength scale for the abscissa, in keeping with the usual display from spectrophotometers.

112.10 Additional Fitting Functions

The hyperbolic saturation function of the form $ax/(x+b)$ often arises in biophysical and biochemical applications. It is more obvious that this represents a hyperbola, if it is written in a double-reciprocal form, as in a Lineweaver–Burk transformation of the Michaelis–Menten enzyme kinetics that employs this type of function. Other contexts where this function appears are monomolecular photochemical kinetics[35] and visual physiology.[33,34] In the present context of action spectroscopy, *x* would stand for the fluence or, in some cases, the fluence rate. When $x = b$, the function is at the half-maximum level that is often chosen to be the criterion response. So, when one performs least-squares fits using such a function, the parameter *b* is the estimate of the fluence needed for the criterion response, and the effectiveness (action spectrum ordinate) is just b^{-1}.

Given in Table 112.1 are several functional forms that are useful for fitting fluence-response curves. These are all based on the hyperbolic saturation function given above and shown in the top row of the

table. In certain cases, fluence-response curves have a two-component (biphasic) structure. The first component reaches a plateau, as shown in Figure 112.1, and then, at high fluence, a second component appears that may or may not approach saturation at the maximum available fluence. For such a two-component curve, if saturation is reached for the second component, then the function in the second row of Table 112.1 may apply, perhaps with the addition of exponents n (often attributable to cooperativity) for each component, as in the Hill function in the third row. Otherwise, if saturation is not reached at some or all wavelengths, then the function in the last row of Table 112.1 may be useful. The second and third terms of that function together have the shape of a hyperbola when plotted on a semilogarithmic scale (i.e., with abscissa log x). Note that this hyperbola, with a (rising) slant asymptote at high fluence, is unrelated to the hyperbola functions (for linear axes) in the first and second rows.

The functions in Table 112.2 depend nonlinearly upon their parameters (unlike the case of a polynomial, for example, where the coefficients are linear parameters). Therefore, it is appropriate to use nonlinear least-squares data-analysis methods. These are widely available and are specifically incorporated in graphical packages such as SigmaPlot® (SPSS Science) and Origin® (OriginLab Corporation). For applications, like the present one of deriving action spectrum values from fluence-response curves, that require error propagation methods, it is important to have the *variance-covariance matrix* of the parameter estimates obtained by least-squares methods. This matrix is made available in Origin® but not yet in SigmaPlot® (Version 8). For those preferring to develop their own data analysis programs, a valuable resource is the *Numerical Recipes* series of books and software (http://www.nr.com), which includes source code in Fortran, Pascal, C, and C++ programming languages for various numerical analysis problems including nonlinear regression (nonlinear least squares), applicable here.

112.11 Null and Threshold Action Spectra

Another way to measure action spectra is to employ a balance or null method, in which the criterion response is zero, but there is no need to work at absolute threshold levels. For example, two lights, one a fixed "reference" light and the other a variable "test" light, could be applied, as appropriate, from opposite directions or in temporal alternation, in such a way that no net response occurs. Examples for action spectroscopy on *Phycomyces* are balance experiments on phototropism[6] and null experiments on the light–growth response.[8,9]

In general, when sigmoidal and other functions are fit to fluence-response curves for the purpose of action spectroscopy, there is another clear choice for criterion response besides the half-maximum (50%) level, namely, a "threshold" response level. However, as mentioned above, thresholds (defined as the highest fluence at which there is no apparent response) per se are difficult to measure because of signal-to-noise considerations at low response levels. A more practical measure of the threshold can be defined operationally as the fluence at which the tangent line at the inflection point (or midpoint) intersects the baseline. This level is generally somewhat higher than the actual threshold, but it has the advantages of being much better defined and easier to measure. For a fluence-response curve, or component thereof, described by the Hill function (third row of Table 112.1), the operational threshold fluence is smaller than the midpoint fluence by a factor of $e^{-2/n}$. In the special case when $n = 1$ (top two rows of Table 112.1), the factor is just e^{-2}. On a $\log_{10}$ scale, this threshold fluence is displaced to the left of the midpoint fluence by 0.869/n "log units".

112.12 Conclusions

This brief chapter on action spectroscopy has given some practical methodology for obtaining action spectra from fluence-response data. Special mention was made of applications in the field of blue-light effects, in which action spectroscopy remains particularly active, mainly because, in most organisms with blue-light response, the responsible pigments remain to be isolated and identified.

In this chapter, we did not delve into action spectroscopy for photochromic receptors, such as phytochrome, a complex topic dealt with in many of the references on action spectroscopy cited in the introduction. Photochromic systems, and others with significant kinetic complexity, call for a mathematical approach termed "analytical action spectroscopy" by Hartmann.[23]

Beyond the key recommendation of basing action spectra on fluence-response curves, readers are encouraged to apply formal data analysis techniques, including error analysis, for analyzing experimental results in action spectroscopy research. Details on such methods are available elsewhere.[18]

Action Spectroscopy: Ultraviolet Radiation

Thomas P. Coohill
Siena College

113.1 Introduction to Ultraviolet Radiation

Ultraviolet (UV) radiation is that portion of the electromagnetic spectrum that extends from the lower wavelength limit of human vision (usually defined as 380 to 400 nm) to wavelengths as short as about 10 nm, where it overlaps the x-ray region. In the natural environment, the shortest wavelength of sunlight that can be routinely measured at the earth's surface is about 290 nm, largely due to the absorption properties of ozone and other atmospheric gases. So, the only environmentally relevant UV region is from 290 to 380 nm. However, artificial UV sources, such as certain fluorescent lamps, mercury and xenon arcs, and lasers, are readily available and extend the possibility of exposure of biological specimens to UV down to wavelengths of about 190 nm. Below 190 nm, air (oxygen) and water begin to absorb UV heavily, making it difficult to expose biological samples except under extreme conditions (e.g., in a vacuum). Hence, the focus of UV photobiology is mainly on the effects on biological processes due to exposure to photons in the wavelength range of 190 to 380 nm.[1]

113.2 Division of the Ultraviolet Region for Photobiological Studies

Vacuum UV (10 to 190 nm)

Photons in the "vacuum" UV (VUV) are heavily absorbed by water and oxygen (in air), both of which become essentially transparent (more than 50% transmission, for a 1 cm path length) to UV at wavelengths above 190 nm. Because of this limited penetration, VUV damage to cells is usually confined to

0-8493-1348-1/04/$0.00+$1.50

a narrow region (a few micrometers) near the cell surface. The energies of single photons in this region are above 6.5 eV, sufficient to ionize many biomolecules. Because the biological effects due to ionizing photons are different from those due to nonionizing photons, the VUV often causes different types of cellular and molecular damage. Thus, VUV effects can be qualitatively different from those of other UV regions.

UV-C (190 to 290 nm)

The shorter-wavelength end of the UV-C (190 nm) is the wavelength region where air and water become transparent. The longer-wavelength limit (290 nm) is the shortest solar UV wavelength easily measured at the earth's surface. Thus, all of the UV-C is environmentally irrelevant. However, research in the UV-C range was central in elucidating many important features of cell functioning. DNA, the genetic material, has peak absorption near 260 nm that falls by a factor of six by 290 nm. This fact, combined with the readily available 254 nm "germicidal" UV fluorescent source, allowed for simple experimental molecular manipulation of DNA, and UV-C photobiology was central in establishing the then-new field of molecular biology.

UV-B (290 to 320 nm)

The shorter-wavelength limit (290 nm) of the UV-B region can be defined as the shortest UV wavelength routinely measurable at the earth's surface, where it is about 1 million-fold less prevalent than 320 nm radiation. The longer-wavelength limit (320 nm) is where ozone and other atmospheric components begin to (more than 50%) attenuate sunlight appreciably. This absorption prevents much of the significant DNA damage that would result if no ozone layer existed. DNA absorption rapidly decreases by more than four orders of magnitude from 290 nm to 320 nm.[2] Nevertheless, absorption of UV-B photons by DNA contributes to a wide variety of bioeffects. The UV-B, which constitutes less than 0.3% of the total sunlight spectrum, is responsible for most of the damage inflicted on organisms by sunlight.

UV-A (320 to 380 nm)

The shorter-wavelength limit of the UV-A (320 nm) can be defined as that wavelength at which ozone becomes transparent. The longer-wavelength limit (380 nm) is where human vision begins, and the UV ends. The UV-A region is also biologically effective and causes cellular death, mutation, and DNA damage, although the primary chromophores for these effects may be non-DNA sensitizers that are chemically matched to the photon energy and act as intermediates in relaying the absorbed energy to DNA.[3] UV-A exposures from sunlight are considerable, constituting about 8% of the total sunlight spectrum.

Terrestrial Solar UV (290 to 380 nm)

This region is easily defined as the wavelength bracket that is the limit of human vision (380 nm) at the long-wavelength end and the effective limit of the solar UV reaching the earth's surface at the short-wavelength (290 nm) end. This is the environmentally relevant UV region and is, of course, the UV-B plus the UV-A regions.

113.3 Absorption of UV by Cells

The responses of biological samples to UV can be greatly affected by their absorption properties. Beginning at the cellular level, it can be seen in Table 113.1 that 200 nm UV-C, for example, is absorbed only slightly by viruses (about 30%), more so by bacterial cells (about 70%), and entirely by mammalian cells (more than 90%). This absorption is due mainly to the presence of endogenous molecules that absorb heavily in the UV-C. At longer wavelengths, cell absorption decreases. The absorption of two important biomolecules, the genetic material DNA and protein, are compared in Figure 113.1. Both molecules begin

TABLE 113.1 Percent Transmission to the Center of Selected Cells and Viruses in the Ultraviolet

Biological sample	Diameter (μm)	Wavelength (nm) 200	250	300	350
Bacteriophage (T_2)	0.1	74	86	100	100
Herpes simplex virus	0.15	66	80	100	100
Bacterial cell	1	33	78	98	100
Yeast cell	5	1.6	69	97	100
Mammalian cell (spherical)	20	10[a]	20	91	96
Mammalian tissue (100 μm thick)	—	—	10[b]	39	66

[a] See also Coohill, T.P., in *Topics in Photomedicine*, Plenum, New York, 1984, p. 1.
[b] See also Coohill, T.P., *Photochem. Photobiol.,* 54, 859, 1990.

Note: All values are approximate. Values at λ above 300 nm can vary widely due to the presence of endogenous chromphores (see also Coohill, T.P., in *Topics in Photomedicine*, Plenum, New York, 1984, p. 1).

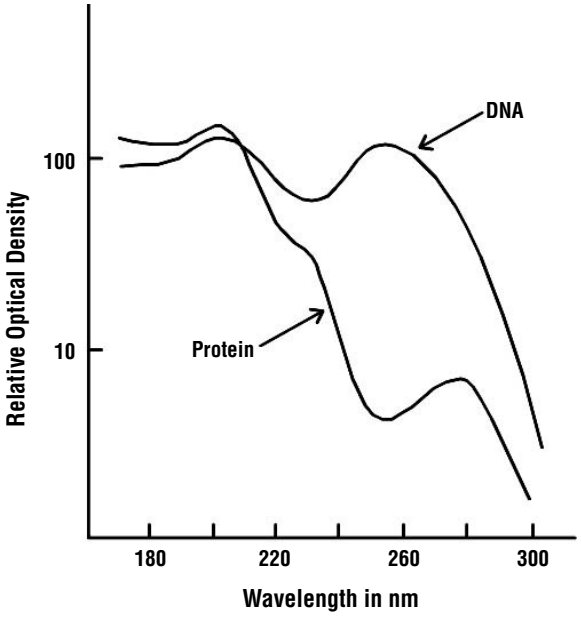

FIGURE 113.1 The absorption spectra of DNA and protein (bovine serum albumin). Both curves are for a 1% solution and 1 cm pathlength.

to absorb appreciably in the UV-B region and substantially in the UV-C region. In a weight-by-weight comparison, DNA absorbs about 20-fold as much 260 nm radiation as does protein. Therefore, the absorption of even homogenates of mammalian cells is similar in the wavelength range 220 to 290 nm to that of DNA. The absorbance (a logarithmic function) of such homogenates is seven times higher at 240 nm compared to 300 nm. As the UV wavelength decreases below 220 nm, proteins and nucleic acids contribute greatly to the total cellular absorption. At wavelengths below 190 nm, water and oxygen absorption prevails. In addition to these macromolecules, some cells contain certain pigments that can alter cellular absorption significantly, even at the longest UV wavelengths. Also, cellular particles and organelles can absorb and scatter UV radiation and, at some wavelengths, shield the center of the cell from a significant portion of the incident beam. Such cytoplasmic screening can alter measured bioeffects to a large degree, especially in the UV-C region, and must be considered when cellular exposure is

attempted.[4] Such concerns are important, because biological cells and tissues will absorb radiation in a wavelength-dependent manner and alter the exposure of the target accordingly. Therefore, the absorption properties of cells are not merely a summation of the individual absorptions of their component molecules.

113.4 Absorption by Tissue

Much of the direct absorption of UV by tissues such as the human skin can be accounted for by the presence of endogenous pigments, especially melanin, hemoglobin, carotenes, and keratin, and exogenous pigments and drugs. Because skin is such a heterogeneous material, UV can be reflected, absorbed, scattered, and rescattered. This means that the direct component of the UV beam is augmented by additions from photons scattered and reflected back into the beam pathway. Hence, at any tissue depth, the sum of the total UV exposure is the direct plus the diffuse. At wavelengths below 300 nm, absorption by tissue rapidly increases, making all but the first few cell layers of the skin essentially opaque to radiation below about 290 nm.

113.5 Action Spectroscopy

Differences in Effects with Wavelength

An action spectrum (AS) is simply defined as the measurement of a biological effect as a function of wavelength. Crude AS was first used in the 19th century to help identify chlorophyll as the chromophore most responsible for the growth of plants. In this century, more sophisticated methods refined the analysis of AS so that it is now possible, in some instances, to make a reasonable determination of the molecule that is likely to contain the chromophore responsible for the response being studied (see Chapter 112). It is this latter usage that was among the first methods that pointed to DNA as the genetic material. This was possible, because small unicellular organisms, such as bacteria, had relatively high transmission rates for UV and, thus, met the rather stringent criteria[5] for a reliable analysis called an analytical action spectrum (AAS). An AAS can only be claimed if the AS corresponds closely to the absorption spectrum of the suspected molecule.

UV-C (190 to 290 nm) Action Spectra

Because some molecules absorb heavily in the UV, certain bioresponses are highly dependent on the wavelengths to which the cell is exposed. In 1930, Gates (Figure 113.2) reported[6] that the AS for bacterial cell death closely followed the absorption of nucleic acid, not protein, which was then widely believed to be the genetic material. In retrospect, this was the first clear evidence that DNA was the genetic material. It should be remembered that an AS could not distinguish between DNA and RNA as the target molecules, because both have similar absorption spectra. However, an AS for a photoproduct exclusive to DNA, such as the thymine dimer, can. Although conducting AS analysis utilizing small cells is somewhat simple, it is difficult to extend these studies to larger (e.g., mammalian) cells because of the substantial absorption of UV by large cells and tissues (Table 113.1). Two other AS in the UV-C region for cell death, one for mammalian tissue and one for individual mammalian cells, are shown in Figure 113.2.[5] Experiments utilizing hanging-drop mammalian tissue samples failed to produce an AS with the fine structure of those studies that utilized bacteria, because the tissue was essentially opaque to radiation near the peak of DNA absorption (260 nm). Thus, the target molecule (DNA) was shielded to an extent such that the shape of the AS did not parallel the absorption spectrum of the target. The advent of single-cell mammalian culture techniques and the unique flattened geometry that mammalian cells assume when in monolayer culture allowed for these studies to begin. Thus, AS for killing of cultured mammalian cells reported data similar to those with bacteria, but the peak was shifted to about 270 nm. This discrepancy can be accounted for by looking at the absorption properties of single mammalian cells and considering, as is the case in bacteria, that the likely target molecule for cell killing is also DNA that resides in the

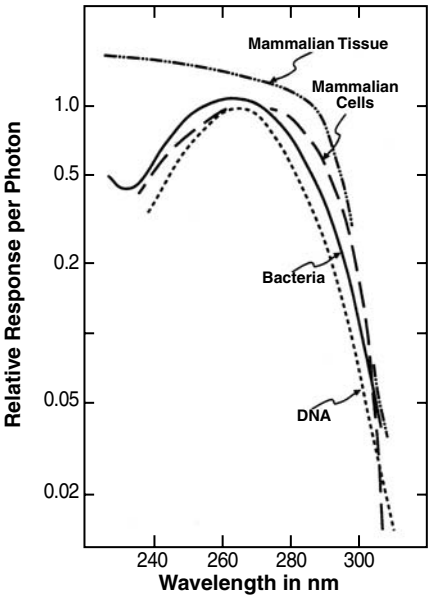

FIGURE 113.2 UV action spectra for the killing of bacteria, mammalian cells, and mammalian tissue. Also represented is the absorption spectrum for DNA. Note that the fine structure inherent in the analytical action spectra for bacteria and mammalian cells is absent in the case of the essentially opaque mammalian cell.

nucleus. This means that the UV beam had to traverse half of the cell, on average, to strike its target. In bacteria, this distance is small enough to allow one to neglect absorption effects; in mammalian cells, the absorption is substantial. An AS for the production of pyrimidine dimers caused by UV exposure to the DNA in mammalian cells matched the action spectrum for cell death. Therefore, DNA was considered responsible for mammalian cell lethality in the 220 to 290 nm region.[7] However, if detailed knowledge of scattering and absorption events before the beam reaches the target is not known, or if the identification of the target is unsure, then any attempt to "correct" or interpret the data generated is suspect. In some cases, it may be useful to modify the incident beam such that the center of the cell, rather than the cell surface, always receives the same exposure.

Not all UV-C AS follow DNA absorption. For example, the loss of saxitoxin binding to sodium channels in rodent cells, or sodium conduction loss in frog cells or lobster axons, or the UV-induced termination of beating by embryonic chick heart aggregates, all follow an AS similar to the absorption spectra of protein moieties.[7] In addition, UV-C AS for highly pigmented tissue (such as plants) shows little correspondence to the absorption of any chromophore. The latter is due to the high degree of absorption of UV-C, which essentially rules out useful AAS in this region for cells and tissues that absorb most of the incident radiation before it can reach the target molecule. Thus, UV-C AS is useful for small or relatively transparent cell studies, but is of limited use for multicellular or highly pigmented samples. Even if a chromophore cannot be identified, an AS still shows the effect of separate wavelengths on a biological response and, as such, is of some use in predicting results due to exposure. Studies of human skin exposure to UV-C (e.g., skin cancer or erythema) show, on average, an essentially flat response in the UV-C region, or in some cases a lessening of effect at shorter wavelengths, that is probably due to limited penetration of the UV beam.

UV-B and UV-A (290 to 380 nm) Action Spectra

It was widely thought that experimental work in the UV-C and UV-B (wavelength range 190 to 320 nm) could be extrapolated to predict photobiological responses in the UV-A (320 to 380 nm). This is not the

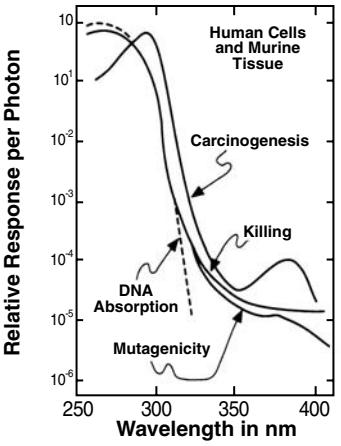

FIGURE 113.3 UV action spectra for human cell killing and mutagenesis and carcinogenic AS for mouse skin.

case, and UV-A AS are more complex than predicted.[3] Here, even events such as cell mutation, which surely involve the genetic material, can be affected at fluences that appear to be below those necessary to affect DNA in these wavelength regions. Details of the divergence of several AS for human cell photoresponses from the DNA absorption spectrum as the curves shift to longer wavelengths in the UV-A are given in Figure 113.3. In the UV-C, cell killing and mutagenesis follow the absorption spectrum of DNA, and carcinogenesis shows a decrease in effect at shorter wavelengths. The UV-B is a transition region from the highly damaging UV-C to the less damaging UV-A region. In the UV-A region, all of the biological parameters are affected at levels that are not fully explainable by the absorption properties of DNA. The absolute absorption of moieties in the DNA molecule is difficult to measure at wavelengths above 320 nm because of scattering and contamination by extraneous chromophores.[2] It is thought that if the absorption is not intrinsic to DNA, then an intermediate molecule may be involved that absorbs the incident UV-A photon and transfers the effect to DNA.

The motivation for focusing on studies of the effects of UV-A and UV-B, the solar UV wavelength region, is provided by three observations. First, many cells and tissues are more transparent to terrestrial solar UV than to UV-C, especially in the UV-A region; thus, this region should be more amenable to AS analysis. Second, research suggested that the nature of the primary and secondary chromophore, photoproducts, and mechanisms for cellular response to solar UV appears, in some cases, to be different from those elucidated for wavelengths shorter than about 300 nm. For example, in contrast to their marked sensitivity to UV-C, certain photosensitive human cell lines, such as xeroderma pigmentosum cells (XP), exhibit the same sensitivity to UV-A as normal cells.[8] Third, solar UV impacts a large number of important bioresponses, such as skin cancer, plant growth, cellular survival and mutagenesis, etc. Research in this area should ultimately reveal the nature of biological responses to a portion of the radiation present in a normal environmental setting.[9,10]

113.6 Carcinogenesis

The role of solar UV in human skin cancer has long been established. Squamous and basal cell carcinomas are believed to be the result of chronic UV exposure. The expression of these cancers is highly dependent on skin type and individual predisposition. The carcinogenic data in Figure 113.3 is mainly a composite drawn from the analysis of De Gruijl and van der Leun[11] and incorporates 12 separate studies utilizing mice. This AS shows major effects in the UV-C and UV-B regions, and falls off rapidly in the UV-A compared to the UV-B in solar radiation (about a factor of 35) — the contribution of UV-A to carcinogenesis is significant. As shown, however, the major cause of UV-induced cancer is the UV-B component of sunlight.

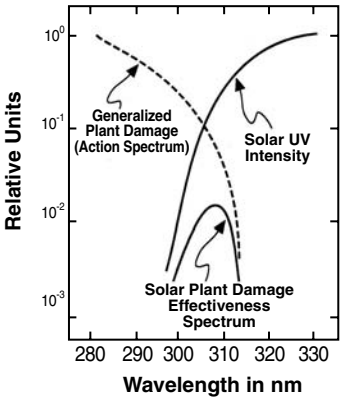

FIGURE 113.4 An AS for generalized plant damage, the terrestrial solar UV intensity spectrum, and a solar plant damage effectiveness spectrum obtained by combining the previous two spectra.

113.7 Polychromatic Action Spectra (PAS)

Some scientists, perhaps realizing the futility of attempting to construct monochromatic AAS using multicellular organisms, reported AS that employs polychromatic sources.[12] These studies vary from irradiating the affected system with additional single wavelengths added to an ambient background, to generating a set of data using polychromatic sources that employ cut-off filters at successively shorter wavelengths. The polychromatic system is complex and tends to obscure individual chromophores, but it is the experimental setup closest to natural field conditions. A major advantage of using polychromatic radiation in the development of PAS is that interactions of biological responses to different wavelengths (usually unknown) are empirically incorporated into the composite spectrum. In addition, highly pigmented tissues, such as plants, have a large variety of chromophores that interacts to give a total effect. Here, PAS can give a composite view of the organism's response, even for such complex parameters as "generalized plant response,"[12] and many other field measurements.

In a recent paper, Sutherland[13] described mathematical procedures for calculating the biological effects from exposing samples to polychromatic (especially ultraviolet) radiation. His analysis included a variety of fluence-response functions and presented an approach for predicting total effect and analyzing subtle differences between classical action spectrum analysis and biological weighting functions.

113.8 Effectiveness Spectra (ES)

It is also possible to estimate the damage to a biological system by exposure to UV by combining AS for a given effect with a known ambient exposure.[14] These are called effectiveness spectra (ES), and they give at least a first approximation to the effects of UV on the studied system. One such ES spectrum is shown in Figure 113.4, which charts the AS for generalized plant damage[12] and the ambient solar UV. The product of these two curves is the solar plant damage ES. From this chart, one can see that the UV-B region is the most damaging, with a peak at about 308 nm. Although solar intensity increases by a factor of 10 from 310 to 330 nm, the biological response decreases more rapidly over the same wavelength range so that the overall effect is less.

Cullen[15] and his coworkers, using spectrally resolved model calculations of water-column photosynthesis (and its inhibition by UV), were able to generate simple mathematical functions that allowed researchers to add environmentally relevant variables and generate results that predict total yield that matches field measurements.

113.9 Constraints

Finally, it should be pointed out that even if all of the constraints necessary to produce a detailed AS are adhered to, experimental variables usually limit the reliability of any AS. These variables include but are not limited to the following:

1. Spectral purity of the radiation source (including the bandwidth of any "monochromate radiation")
2. Accuracy of the dosimetry measurements
3. Presence of endogenous or exogenous "nonparticipating" chromophores
4. Presence of ambient (even microenvironmental) condition
5. Time in the life cycle (cellular) or growth cycle (developmental) of the exposed organism
6. Geometry of the cell or tissue when irradiated
7. Availability of proper nutrients
8. Presence of water stress in plant studies
9. Occurrence of numerous extraneous conditions

114.1 Introduction

In the last two decades of the past century, the presence in the atmosphere of ozone-depleting substances (CFCs, HCFCs, halons, carbon tetrachloride, etc.) has been reducing the ozone concentration in the stratosphere over high and mid-latitudes of both hemispheres. Ozone concentration in the atmosphere is very low (about 3 parts in 10 millions), and that of the total ozone column is equivalent to that of 3 mm at standard temperature and pressure. Nevertheless, its optical density is about 45 at the absorption maximum around 255 nm, about 13 at 280 nm, and goes to 0 at 320 nm. Therefore, the stratospheric layer, which contains approximately 90% of the total ozone, has the function of a protective filter for the Earth's surface, fully cutting off solar radiation under 280 nm and greatly reducing UV-B radiation (280 to 315 nm).

The reduction of stratospheric ozone was recognized as the main cause of the increase in UV-B irradiance at the Earth's surface. From meteorological measurements at several sites distributed over mid- and high latitudes of both hemispheres, this increase was estimated to be in the range of 6 to 14% in the last 20 years. Also, spectral measurements performed at various sites in Europe, North and South America, Antarctica, and New Zealand correlated an UV-B radiation increase with ozone decline.[1]

UV-B has various direct adverse effects on human health (skin cancer, immunosuppression, eye disorders), terrestrial plants and aquatic organisms [DNA alterations, photosynthesis inhibition, reduced growth, photoresponsiveness suppression (see Chapter 116)]. Moreover, due to the differences in UV-B sensitivity and adaptation among the various species, shifts in species composition may occur as a consequence of increased UV-B radiation, thus leading indirectly to alterations in ecosystems.[2–4]

Being clear that the above-mentioned ozone-depleting compounds are almost exclusively of industrial source, nations have agreed (Montreal Protocol, 1987) on the gradual elimination of these substances. Since the first half of the 1990s, their abundance in the atmosphere is slowly declining. However, even models based on the most optimistic scenarios predict that the return to normal ozone levels will take several decades.[5] Moreover, the observation that other atmospheric gases, with an abundance that depends on anthropic activities, may affect stratospheric ozone concentration, and the uncertainties due to the ongoing climate change make it difficult to reliably predict future UV trends.[1] The reader is also referred

to Kondratyev and Varotsos[6] for a complete discussion of the basic aspects of ozone variability in the atmosphere.

114.2 Radiation Amplification Factors

As the enhancement of solar UV-B is highly wavelength specific and increases when the wavelength decreases, action spectroscopy plays a central role in assessing the effects of ozone depletion on the biosphere. The effectiveness spectrum (ES) obtained by determining the convolution product of an action spectrum for a biological effect with a given solar irradiance spectrum, originated by a particular ozone-depletion scenario, indicates the biological significance of the change in solar UV-B (see Chapter 113). A useful measure of the overall effect of a particular irradiation condition (E) is the biologically active irradiance (E_{BA}) defined as the area under the ES curve:

$$E_{BA} = \int AS(\lambda)E(\lambda)d\lambda$$

The radiation amplification factor (RAF) is a convenient indicator for correlating the sensitivity of a biological effect to different UV exposures caused by various levels of ozone depletion.[5,6] For small variations (about 1 to 10%) of ozone concentration (OC), the RAF can be defined as follows:

$$RAF = - (\Delta E/E)/(\Delta OC/OC)$$

i.e., the ratio between the relative increase in active irradiance and the corresponding relative decrease in ozone concentration. For larger ozone changes, a more accurate relation is as follows:

$$RAF = - \ln(E_2/E_1)/\ln(OC_2/OC_1)$$

where the index denotes a particular situation of ozone concentration and the corresponding biologically active irradiance. As a decrease in ozone is accompanied by an increase in E, in both formulas, the minus sign is used to give positive values of the RAF. RAFs are useful for comparing, at a glance, the UV sensitivity of various biological processes, but they must be used with some caution, because they constitute an oversimplified representation both of the complex radiative transfer in the atmosphere and the biological action of UV radiation.[5]

114.3 Polychromatic Exposures

Ecologically relevant studies aimed to determine action spectra require the careful consideration of various experimental features, such as treatment duration (short exposures may not allow for the observance of overall response of the organism), use of suitable samples (*in vitro* studies can have limitations for extrapolation to the performance of the whole organism), presence of reciprocity effects, and irradiation patterns. For a comprehensive discussion on the correct methodology with which to determine ecologically significant action spectra, the reader is referred to Holmes.[7]

We only want to focus here on the importance of using irradiation conditions not too far from the present levels of natural radiation or those under predictable ozone depletion scenarios. Using extraterrestrial or such high irradiances that the organisms are irreversibly damaged certainly produces a clear effect, but this is not meaningful for a realistic assessment of ozone depletion consequences. Not only radiation intensity but also spectral composition are crucial. Monochromatic action spectra can provide indications on the effects of UV-B without interference due to processes induced by other radiation bands. And, they are useful in demonstrating a direct photochemical effect on a specific target. For example, the action spectrum for DNA cyclobutyl pyrimidine dimer formation in alfalfa seedlings shows that the damage extends well into UV-A up to about 370 nm.[8] However, studies conducted using

monochromatic irradiation do not allow for photoregulated compensatory mechanisms that occur in nature, such as photorepair[9] and the induction of protective UV-absorbing compounds.[10,11] A complementary approach, which takes into account information from monochromatic and polychromatic irradiation conditions, seems to be more appropriate to describe the complex biological responses to UV of whole, intact organisms.

Sun simulators (also known as phytotron), which allow irradiation conditions and climatic factors to be reproduced at any time and disturbing agents to be excluded, are promising tools for overcoming the difficulties of outdoor studies.[12–14] The employment of a wide range of modern lamp types and different filter combinations allow for the spectral quality and the intensity of natural global radiation to be obtained and for the appropriate shaping of the short-wave cutoff.[15,16]

Notwithstanding the complexity of experiments under natural radiation, various spectral studies have been performed by removing increasingly larger portions of the solar UV spectrum by means of different combinations of long-pass filters,[17–19] or by supplementing UV radiation by means of appropriate fluorescent lamps.[20,21] Recently, a sophisticated irradiation system was described, which uses filters and supplementary UV lamps and can provide computer-controlled modulated changes in any radiation band between about 250 and 730 nm.[22–24]

114.4 Determination of Action Spectra from Polychromatic Exposures

Two different approaches were proposed for extracting an action spectrum from experimental data obtained with polychromatic exposures in which UV irradiance is varied by means of filter combinations with progressively decreasing cutoff wavelength. Differential action spectroscopy (DAS) takes into account the spectral bands given by the difference in irradiance of two filter combinations with successive cutoff wavelength. Assuming that different spectral bands supplement one another in producing the observed effect, it is possible to estimate the weighted contribution of each band by dividing the differences in response to the treatment by the corresponding differential irradiances. Finally, the action spectrum is derived by plotting the weighted effects as a function of the average wavelength of the corresponding band. As UV action spectra tend to exponentially increase with decreasing wavelength, the main limit of this method is given by the potentially large variability of the response in the range of each differential band, which could significantly alter the shape of the resulting action spectrum.[25] This limit, however, is also present for monochromatic action spectroscopy, when using currently available interference filters. The differential method can be improved by using several irradiance levels for each differential band, thus reducing statistical errors and allowing correct shaping of the action spectrum.[7]

If DAS reduces the problem to the monochromatic situation, the other approach proposed by Rundel[25] is a deconvolution technique in which it is assumed that the action spectrum [which, in this case, can be defined as the "biological weighting function" (BWF)[26]] is an analytical continuous function $\varepsilon(\lambda)$, and the predicted system response R_i to the ith irradiation regime $E_i(\lambda, t)$ can be expressed as a function, F, of the biologically active irradiance integrated over the irradiation time:

$$R_i = F\left[\iint_{t,\lambda} \varepsilon(\lambda) E_i(\lambda, t)\, d\lambda\, dt\right]$$

Once a functional form for $\varepsilon(\lambda)$ has been chosen depending on a given number of parameters, the latter can be determined by means of iterative calculations to minimize the differences between each R_i and the corresponding measured response. The limit of this method is that the *a priori* choice of the form of $\varepsilon(\lambda)$ and the functional relationship F between response and exposure is critical for the correct determination of the action spectrum. However, the use of multivariate statistical analysis (such as, for example, principal component analysis) allows more detailed BWFs to be obtained.[26,27]

National Institute for Basic Biology

115.1 Introduction

Action spectroscopy (Chapter 112) is primarily a crucial methodology for experimentally estimating the absorption spectra and, thus, the chemical nature, of the (sometimes unidentified) photoreceptor molecules[1] involved in various light-dependent chemical and biological reactions. Technically, the development and extensive collaborative use (Table 115.1) of the Okazaki Large Spectrograph (OLS),[2] at the National Institute for Basic Biology (NIBB), Okazaki, Japan, and of computerized video image analysis methods[3,4] are especially noteworthy.

For a definition of and comprehensive information about the major categories of plant and microbial photosensory processes, i.e., photomovement and photomorphogenesis, the reader is referred to the chapters in this volume (e.g., Chapters 120 to 124) and also to other textbooks.[5,6]

The aim in this chapter is to provide the reader with a selected set of representative action spectral documentation in a way that enables the reader to easily grasp the overview of the present status of our knowledge. For this aim, after showing some typical action spectra, most of the materials are presented in tabular form, closely coupled with a figure that shows the distribution of spectral sensitivities with respect to phylogenetically arranged taxonomic groups.

115.2 Action Spectra for Photosensory Processes

Major Types of Photosensory Action Spectra

Five major types of photosensory action spectra and examples of them are shown in Figure 115.1:

1. *UV-B~C type*,[1] for which the putative UV-B receptor is not yet chemically identified
2. (*UV-B~C), UV-A, blue type*,[7] for which several flavoprotein photoreceptors (cryptochromes, phototropins, photoactivated adenyl cyclase, AppA, and WC-1)[8–13] were successfully identified and characterized in the last decade

TABLE 115.1 List of Action Spectral Data for Photosensory Processes

Entry Number	Organism	Response Type	Sign[a]	Wavelength Range[b]	Peaks and Shoulders (nm)	Ref.
		Photomovement				
	Eubacteria					
1	*Beggiatoa*	Phobic	-	B	430	16
	Archaebacteria					
2	*Halobacterium*	Phobic	-	UV-A, B	380, 480	17
3	*Halobacterium*	Phobic	+	G	592	18
	Cyanobacteria					
4	*Anabaena*	Taxis	+	B, O, R	440, 600, 620–650, 670	19
5	*Phormidium*	Taxis	+	Y, R	560, 670	20
6	*Phormidium*	Phobic	+	UV-A, B, G, R	390, 490, 560, 610	20
7	*Synechococcus*	Taxis	+	G, Y, R, FR	530, 570, 640, 680, 720, 740	126[f]
8	*Synechocystis*	Taxis	+	Y, R, FR	560, 660, 730	123[f]
	Red Algae					
9	*Porphyridium*	Taxis		V, B	416, 443, 467–477	21
	Slime Molds					
10	*Dictyostelium*	Taxis in amoebae	+	V, B, G, Y, R	405, 450, 520, 580, 640	22
11	*Physarum*	Taxis; O_2- generation	-; +	UV-B~C, UV-A, B	260, 370, 460	23[f]
12	*Physarum*	Taxis	-	UV-B~C, UV-A, B, FR	270, 350, 460, 750	116[f]
	Zygomycetes					
13	*Phycomyces*	Tropic balance with reference (450; 507 nm)	+	UV-A, B	383, 394, 455, 477; 383, 455	24
14	*Phycomyces*	Tropism in sporangiophores	+	UV-A, B	370, 445, 470	25
	Diatoms					
15	*Pleurosira*	Chloroplast migration	-; +	G; B	540; 450	121[f]

	Xanthophyceae					
16	*Vaucheria*	Tropism	+	V, B	415, 430, 450, 480	26
17	*Vaucheria*	Chloroplast accumulation	+	B	470	27
	Brown Algae					
18	*Ectocarpus*	Taxis in gametes	+	UV-A, B	380, 430, 450, 460	28
19	*Pseudochorda*	Taxis in zoospores		B	420, 460	29[f]
	Cryptomonads					
20	*Cryptomonas*	Taxis	+	B, Y	490, 560	30
21	*Cryptomonas*	Taxis	+	UV-B~C, B, Y	280, 430, 480, 560	113[f]
	Protozoa					
22	*Blepharisma*	Phobic	-	B, G, Y	473, 491, 538, 580	31
23	*Blepharisma*	Phobic	-	B, G, Y	493, 538, 580	32
24	*Ophryoglena*	Taxis	+	B, G, O	420, 540, 590	129
25	*Paramecium*	Accumulation; membrane depolarization	+; +	B, G	420, 560	33
26	*Stentor*	Phobic; membrane depolarization	-; +	G, R	560, 610	34
27	*Stentor*	Taxis	-	R	610–620	35
	Dinoflagellates					
28	*Alexandrium*	Taxis	+	UV-B~C, B, G	260, 420, 460, 500	122[f]
29	*Gymnodinium*	Phobic; taxis	-; +	UV-B~C, B	280, 450	36
30	*Peridinium*	Taxis	+	R	640	37
	Euglenoids					
31	*Euglena*	Phobic	+	UV-A, B	370, 440, 470	38
32	*Euglena*	Phobic	-	UV-B~C, UV-A, B	280, 370, 440, 480	120[f]
	Prasinophyceae					
33	*Platymonas*	Taxis	+; -	UV-B~C, UV-A, V, B	275, 333, 405, 450, 495	39
	Green Algae					
34	*Boergesenia*	Tropism	-	UV-A, B	380, 430, 443, 470	40
35	*Bryopsis*	Tropism	-	UV-B~C, UV-A	260, 310	112[f]
36	*Chlamydomonas*	Taxis	+	B, G	443, 503	41

TABLE 115.1 List of Action Spectral Data for Photosensory Processes (continued)

Entry Number	Organism	Response Type	Sign[a]	Wavelength Range[b]	Peaks and Shoulders (nm)	Ref.
37	*Chlamydomonas*	Photoreceptor current	+	B, G	475, 510; (470, 500)	131
38	*Cosmarium, Micrasterias*	Phobic; taxis		B, R	440, 670	42
39	*Dunaliella*	Phobic; taxis	+, -; +	B, G	510; 450–460	43[f]
40	*Mesotaenium*	Chloroplast rotation		UV-A, B, R(/FR)	366, 450, 650	44
41	*Mougeotia*	Chloroplast rotation	+/-	R/FR	679, 717	45
	Ferns					
42	*Adiantum*	Chloroplast redistribution	+	B, R(/FR)	420, 450, 480, 680	46[f]
43	*Adiantum*	Tropism; polarotropism	+	R(/FR)	662; 680	47[f]
	Angiospermeae					
44	*Arabidopsis*	Enhancement of phototropism	+	UV-A, R	378, 669	48
45	*Avena*	Tropism; growth	+; -	UV-A, B	360, 440, 470	49
46	*Hordeum*	Streaming in root hair	+	UV-A, B, G	366, 433–465; 540	50
47	*Medicago*	Tropism	+	UV-B, UV-A, B	280, 380, 450	51[f]
48	*Phaseolus*	Membrane depolarization	+	UV-A, B	380, 420, 460	118[f]
49	*Zea*	Induction of geotropism	+	R	640	52
		Photomorphogenesis				
	Photosynthetic Bacteria					
50	*Rhodobacter, Erythrobacter*	Bchl and carotenoid synthesis	-	B	470	53
51	*Roseobacter*	Bchl and carotenoid synthesis	-	V, Y, FR	400, 575, 770	54
	Cyanobacteria					
52	*Anabaena*	Germination	+	R	620–630	55
53	*Anabaena*	Intracellular cAMP	+; -	FR; R, B, UV-A	720; 660	128[f]
54	*Chlorogloeopsis*	MAA synthesis	+	UV-B	310	131
55	*Tolypothrix*	Phycoerythrin synthesis	+	B, G	480, 540	56[f]
	Red Algae					
56	*Chondrus*	MAA (shinorine) synthesis	+	UV-A	345	132

	Ascomycetes					
57	*Gelasinospora*	Sexual induction	+	UV-B~C, B	280, 350, 370, 420, 440, 460, 480	57[f]
58	*Leptosphaerulina*	Sexual induction	+	UV-B~C, UV-A	265, 287, 300	58
59	*Neurospora*	Conidiation rhythm	-	UV-A, V, B	375, 415, 465, 485	59
60	*Rhodotorula*	Carotenoid synthesis	+	UV-B~C, UV-A, V	280, 340, 370, 400	60[f]
	Bacidiomycetes					
61	*Coprinus*	Sexual induction	+	UV-B~C, UV-A, B	260, 280, 370, 440	61[f]
62	*Polyporus*	Styrylpyrone synthesis	+	UV-A, B	380, 440	62
	Fungi imperfectiae					
63	*Alternaria*	Conidiation	+; -	UV-B; UV-A, B	300, 320; 385, 420, 447, 478	63
64	*Fusarium*	Catotenoid synthesis	+	UV-A, B	380, 430, 455, 475	64
65	*Mycobacterium*	Carotenoid synthesis	+	UV-B~C, UV-A,B	280, 370, 410, 445, 470	65
66	*Verticillium*	Absorbance change and carotenoid synthesis	+	UV-A, B	384	66
	Slime Molds					
67	*Physarum*	Acid from glucose	-	UV-A, B	390, 465, 485	67
68	*Physarum*	Sporulation	+	UV-B~C, UV-A, B, FR	(270, 350, 460), 750	116[f]
69	*Physarum*	Fragmentation	+	UV-A, B, FR(/R)	350, 450, 750	127[f]
	Zygomycetes					
70	*Phycomyces*	Macrophore formation	+	UV-A, B, G	383, 431, 477, 514	68
71	*Phycomyces*	Beta-carotene synthesis	+	UV-A, V, B, G	394, 416, 450, 491, 530	69
72	*Phycomyces*	Sexual fusion	-	UV-A, V	370, 410	114[f]
	Diatoms					
73	*Thalassioiosira*	Gene expression of FCP	+	UV-A, B, G, Y, R, FR	380, 430, 520, 560, 660, 760	124[f]
	Dinoflagellates					
74	*Gyrodinium*	MAA synthesis	+	UV-B	310	133
	Brown Algae					
75	*Laminaria*	Egg production		UV-A, V, B	380, 412, 435, 480	70
76	*Scytosiphon*	Night break of erect thallus formation	-	V, B	414, 442, 480	71
77	*Dictyota*	Egg release	+	UV-A, B	366, 464, 491	72

TABLE 115.1 List of Action Spectral Data for Photosensory Processes (continued)

Entry Number	Organism	Response Type	Sign[a]	Wavelength Range[b]	Peaks and Shoulders (nm)	Ref.
	Euglenoids					
78	*Euglena*	Synthesis of Chl; alkaline DNase, etc.	+	B, R	433, 631	73
	Green Algae					
79	*Acetabularia*	Hair whorl formation	+	UV-A, B	370, 425, 470	74
80	*Chlamydomonas*	Gametogenesis	+	UV-A, B	370, 450	75
81	*Chlamydomonas*	Division	-	V, G	400, 500	76
82	*Chlamydomonas*	Carbonic anhydrase synthesis	+	B	460	77[f]

96	*Onoclea*	Germination	+/-	R/FR	660/730	90
97	*Dryopteris*	Germination	+/-	R/FR	660/730	91
	Angiospermeae					
98	*Arabidopsis*	Hypocotyl growth (HIR[e]) in WT; *hy-2*	-	UV-A, B, R, FR; UV-A, B	375, 450, 625, 725; 375, 450	92[f]

99	*Arabidopsis*	Germination	+/-	R/FR	660/720–740	93
100	*Arabidopsis*	Hypocotyl growth (HIR[e]) in *phyB*; *phyAphyB*	-	B, FR; B	400, 460,750; 400, 460	125[f]
101	*Arabidopsis*	Germination in *phyB*; *phyA*	+/-	V, B, R; R/FR	400, 460, 660/730	115[f]
102	*Arabidopsis*	Hypocotyls grow CRY-1 overexpressor	-	B	440, 450, 470, 485	134
103	*Armoracia*	Adventitious shoots from hairy roots	+	UV-A, B, R	380, 460, 680	94[f]
104	*Cuscuta*	Haustoria formation	+	FR (/R)	740 (/660)	117[f]
105	*Daucus*	Anthocyanin synthesis in cultured cells	+	UV-B~C	280	95[f]
106	*Daucus*	Expression of PAL; CHS	+	UV-B~C; UV-B~C, UV-A	280; 280, 330	111[f]
107	*Daucus*	Promoter activity of PAL gene	+	UV-B~C	280	119[f]
108	*Egeria*	Membrane hyperpolarization	+	B, R	400, 450, 650, 700	96[f]
109	*Haplopappus*	Anthocyanin synthesis in cultured tissue	+	UV-A, B	372, 438	97
110	*Lactuca*	Germination	+/-	R/FR	660/730	98
111	*Lactuca*	Germination (HIR[e])	-	B, FR	470, 720	99
112	*Lactuca*	Hypocotyl growth (HIR[e])	-	UV-A, B, FR	363, 441, 716	100
113	*Lemna*	Flowering	-	R, FR	640, 730	101[f]
114	*Pharbitis*	Flowering in etiolated seedlings	-	R	660	102[f]
115	*Phaseolus*	Gene expression (Cab, etc.)	+	V, G, R	400, 510, 660	103[f]
116	*Raphanus*	Hypocotyl growth	-	B, R, FR	455, 515, 630–660, 705–735	104
117	*Sinapis*	Hypocotyl growth (HIR[e])	-	B, R, FR	448, 655, 716	105
118	*Sorghum*	Anthocyanin synthesis	+	UV-B, UV-A, B, R	290, 385, 480, 650	106
119	*Triticum*	Flowering in light-grown plants	+	R, FR	660, 716	107
120	*Triticum*	Chl a,b synthesis	+	R	650	108

[a] + = positive (phototaxis), step-down or photoattractant (photophobic reaction), induction or stimulation (of photomophogenetic reactions); - = negative (phototaxis), step-up or photorepellent (photophobic reaction), suppression or inhibition (of photomorphogenetic reactions).

[b] B = blue; G = green; R = red; FR = far-red.

[c] LIR = low irradiance reaction.

[d] VLIR = very low irradiance reaction.

[e] HIR = high irradiance reaction.

[f] Work done at the Okazaki Large Spectrograph (OLS), National Institute for Basic Biology (NIBB), Okazaki, Japan; these and other works done there are listed at http://www.nibb.ac.jp/%7Elspectro/papers.htm and http://www.nibb.ac.jp/%7Elspectro/reviews.htm.

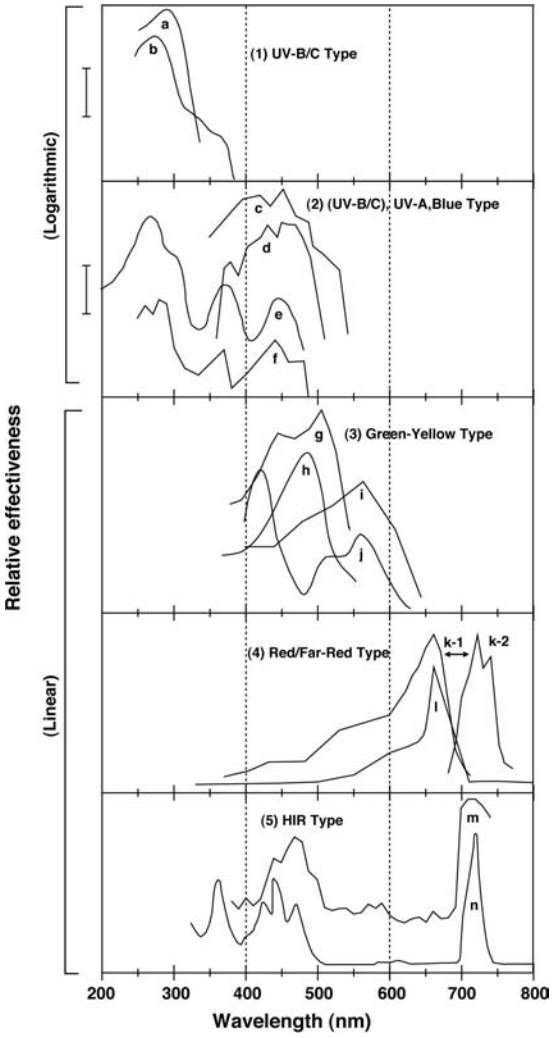

FIGURE 115.1 Major types of photosensory action spectra and examples. (1) *UV-B C type*: (a) induction of anthocyanin synthesis in *Sorghum* (Angiospermae) [entry number (EN), 118 in Table 115.1] (Curve was replotted after Yatsuhashi, H. and Hashimoto, T., *Photochem. Photobiol.*, 41, 673, 1985); (b) induction of carotenoid synthesis in *Rhodotorula* (Ascomycetes) (EN 60) (Curve was replotted after Tada, M., Watanabe, M., and Tada, Y., *Plant Cell. Physiol.*, 31, 241, 1990.). (2) *(UV-B C), UV-A, blue type:* (c) phototaxis in *Ectocarpus* gametes (brown alga) (EN 18) (Curve was replotted after Kawai, H., Mueller, D.G., Foelster, E., and Haeder, D.-P., *Planta*, 182, 292, 1990.); (d) induction of carotenoid synthesis in *Phycomyces* (Zygomycetes) (EN 71) (Curve was replotted after Bejarano, E.R., Avalos, J., Lipson, E.D., and Cerda-Olmedo, E., *Planta*, 183, 1, 1991.); (e) photoavoidance in *Physarum* (slime mold) (EN 11) (Curve was replotted after Ueda, T., Mori, Y., Nakagaki, T., and Kobatake, Y., *Photochem. Photobiol.*, 48, 705, 1988.); (f) sexual induction in *Coprinus* (Basidiomycetes) (EN 61) (Curve was replotted after Durand, R. and Furuya, M., *Plant Cell. Physiol.*, 26, 1175, 1985.). (3) *Green yellow type*: (g) phototaxis in *Chlamydomonas* (green alga) (EN 36) (Curve was replotted after Nultsch, W., Throm, G., and Rimscha, I.V., *Arch. Mikrobiol.*, 80, 315, 1971.); (h) photoavoidance in *Halobacterium* (archaebacterium) (EN 2) (Curve was replotted after Takahashi, T. and Tsuda, M., *Protein Nucl. Acid Enz.*, 34, 452, 1989.); (i) phototaxis in *Cryptomonas* (cryptomonad) (EN 20) (Curve was replotted after Watanabe, M. and Furuya, M., *Plant Cell. Physiol.*, 15, 413, 1974.); (j) induction of membrane depolarization in *Paramecium* (protozoa) (EN 25) (Curve was replotted after Matsuoka, K. and Nakaoka, Y., *J. Exp. Biol.*, 137, 477, 1988.). (4) *Red/far-red type*: (k-1) induction and (k-2) its cancellation of germination in *Arabidopsis* (Angiospermae) (EN 99) (Curve was replotted after Shropshire, W., Klein, W.H., and Elstad, V.B., *Plant Cell. Physiol.*, 2, 63, 1961.); (l) suppresion of flowering in *Pharbitis* (Angiospermae) (EN 114) (Curve was replotted after Saji, H., Vince-Prue, D., and Furuya, M., *Plant Cell. Physiol.*, 24, 1183, 1983.). (5) *HIR type*: (m) suppression of germination in *Lactuca* (Angiospermae) (EN 111) (Curve was replotted after Gwynn, D. and Scheibe, J., *Planta*, 106, 247, 1972.); (n) suppression of hypocotyl growth in *Lactuca* (Angiospermae) (EN 112) (Curve was replotted after Hartmann, K.M., *Z. Naturforsch.*, 22b, 1172, 1967.). Vertical bars beside the ordinates of (1) and (2) indicate one $\log_{10}$ unit.

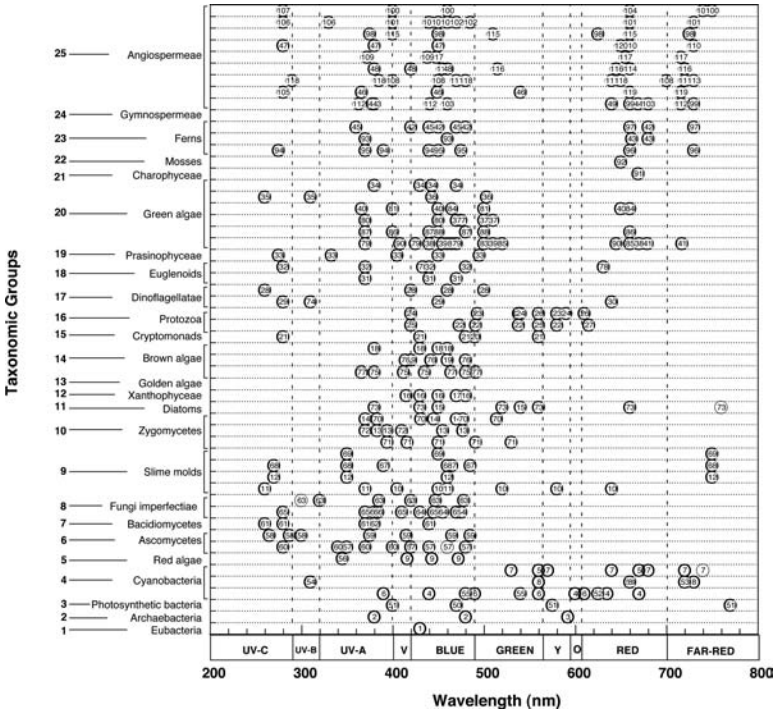

FIGURE 115.2 Distribution of action spectral peak wavelengths with respect to phylogenetically arranged taxonomic groups. The number in each datum point corresponds to the entry number in Table 115.1.

3. *Green yellow type*, for some cases (e.g., g and h in Figure 115.1), of which rhodopsins[14] are established as the photoreceptors
4. *Red/far-red type*,[1,15] in which "/" means a reversible mutually canceling effect between Red and Far-Red lights, and for which phytochrome, a photoisomerizable chromoprotein, is the established and well-characterized photoreceptor (Chapters 129 and 130)
5. *HIR type*,[1,15,92,100,125] often observed in the case of long-term irradiations of plant materials; HIR standing for "High Irradiance Reaction," because a strong dependency of the light effect on fluence rate ("irradiance") is generally observed

Distribution of Action Spectral Peak Wavelengths with Respect to Phylogenetically Arranged Taxonomic Groups

The distribution of action spectral peak wavelengths with respect to phylogenetically arranged taxonomic groups is shown in Figure 115.2.

Recent demonstrations of red/far-red-type responses in microorganisms such as cyanobacteria, slime mold, and diatom are especially clear. Hopefully, together with Table 115.1 below, the information presented in Figure 115.2 can help the reader to think about trends of evolution of photoreceptors, find out new problems to solve, and find suitable experimental materials for his or her own research.

List of Action Spectral Data for Photosensory Processes

A list of 120 selected sets of action spectral data for photosensory processes (photomovement and photomorphogenesis) in the same phylogenetical order of taxonomic groups as shown in Figure 115.2 is presented in Table 115.1.

115.3 Prospects

Future evolution of action spectroscopy research would include the following:

1. Extensive use of photosensitivity mutants, including gene-manipulated organisms,[92,109,110,115,125,130,134] as well as chemical manipulation of contents and characteristics of (sometimes putative) photoreceptors by means of inhibitors and analogs
2. Development and extensive collaborative use of even more efficient, innovative irradiation and observation systems than the ones now available[2]
3. Rapid exchange, retrieval, and analysis of action spectral data on the combined bases of a well-organized action spectral database to be constructed and the worldwide digital communication networks which are already available

Acknowledgments

The author cordially thanks M. Kubota for assistance in preparing Table 115.1; M. Iseki and S. Matsunaga for assistance in preparing Figure 115.1 and Figure 115.2; and H. Kawai for phylogenetical arrangement of the taxonomic groups in Figure 115.2 and Table 115.1.

A substantial part of the works cited here was supported by the National Institute for Basic Biology (NIBB) Cooperative Research Program for the Use of the Okazaki Large Spectrograph (OLS) (Table 115.1).

Photoecology and Environmental Photobiology

Donat-P. Häder
Friedrich-Alexander-Universität Erlangen-Nürnberg

116.1 Introduction

Light is used by photosynthetic organisms as an energy source to produce organic substances in the process of photosynthesis. Solar radiation is harvested by the photosynthetic pigments chlorophyll *a* and the accessory pigments, including phycobilins, carotenoids, and other chlorophylls (*b, c, d*). Completely independent from this process, plants and other photosynthetic (and also nonphotosynthetic) organisms utilize light as an environmental information source with which they select and optimize their positions in their habitats. This selection is governed by two aims. On the one hand, the organisms try to obtain sufficient solar energy for efficient photosynthesis that can be brought about by aquatic motile microorganisms, e.g., by moving toward the water surface.[1] On the other hand, unfiltered solar radiation at the surface may be detrimental for many photosynthetic organisms, and their delicate photosynthetic apparatuses may be damaged by excessive solar energy, particularly in the UV range.[2] Many photosynthetic organisms try to solve this dilemma by using antagonistic responses to light and other environmental clues to optimize their positions dynamically over time.

116.2 Orientation Mechanisms in Plants and Microorganisms

Motile microorganisms use active propulsion or passive movement mechanisms based on buoyancy[3] to select suitable habitats. But, sessile higher plants are also capable of adjusting their organs (roots, stems, leaves, flowers) with respect to light.[4]

Orientation Mechanisms in Higher Plants

The classical orientation mechanisms in higher plants with respect to light are photonasty and phototropism.[5] Plant shoots show positive phototropism (bending toward the light source) at low fluence rates,

0-8493-1348-1/04/$0.00+$1.50

and they show negative phototropism (bending away from the light source) at higher fluence rates. Roots perform negative or no phototropism, and leaves orient themselves perpendicular or at other angles to the impinging light beam (plagio- or diaphototropism) (see Chapter 133). In some higher plants, the leaves track the sun during its daily cycle so that the leaf area is mostly perpendicular to the impinging light rays.[6]

Photonastic movements are independent of the light direction and follow a built-in direction, e.g., flower opening or stomata movements follow predefined patterns and are elicited by changes in the light quality or quantity. The photoreceptor pigments involved in these responses are independent from the photosynthetic pigments and include phytochrome and flavoproteins (see Chapters 130, 132, and 133).

Photoorientation in Microorganisms

Motile microorganisms rely on external factors and endogenous rhythms[7,8] to control the movements in their habitats. Major sources of information are gravity,[9,10] chemical gradients (such as oxygen or carbon dioxide),[11,12] temperature (gradients),[13] magnetic field lines,[14–16] and electric currents.[17,18] Light is one of the major clues for microorganisms. Photophobic responses, phototaxis, and photokinesis are three responses of microorganisms with respect to steady state light quality, quantity, direction, or changes in these parameters[19] (for details, see Chapters 120, 121, and 122).

Photomorphogenetic Reactions

Microorganisms and higher plants show morphological changes in dependence of the impinging light quality and quantity,[20] e.g., germinating seedlings elongate in darkness or shaded conditions to reach a niche with sufficient irradiation for optimal growth conditions.[21] Likewise, leaf form, thickness, and area, as well as stomata and chloroplast density and position, can be controlled by ambient light.[22,23] The pigment concentration as well as the quantitative ratio between various light harvesting pigments employed in photosynthesis can be governed by the irradiance or wavelength distribution of solar radiation. In cyanobacteria, the ratio between the green-light-absorbing phycoerythrin and the red-light-absorbing phycocyanin is rapidly altered when the organisms are grown in red or green light (chromatic adaptation).[24,25]

116.3 Ecological Consequences of Photomovement

The movement responses of individual organisms may result in a mass movement of populations and accumulation of organisms in favorable light environments. Positive phototaxis guides a population toward the light source (water surface), and negative phototaxis guides away from detrimental excessive surface irradiation. Often, upward movement is supported by negative gravitaxis.[9] This response has the advantage in that it works in darkness or in murky waters so that the photosynthetic organisms get to the surface even without seeing the light. Often, several responses operate antagonistically, e.g., in the green flagellate *Euglena*, negative gravitaxis is countered by negative phototaxis. The result is an accumulation of the cells at a certain depth. In the case of this flagellate, the optimal depth is at a fluence rate of 30 W m^{-2}, which also corresponds with its requirements for optimal photosynthesis.[26]

Photophobic responses result in accumulations of organisms in light fields or in dark areas, depending on whether the response is elicited when the organisms experience a step-up or a step-down in irradiance. At low irradiances, filamentous gliding cyanobacteria cross dark–light boundaries without a response. In contrast, leaving a light field will result in a reversal of movement. This behavior causes the organisms to accumulate in light fields (light trap).[27] The same organism shows the opposite response at high irradiances, causing the filaments to leave the irradiated areas and accumulate in the shade. These fine-tuned antagonistic reactions allow the organisms to precisely select optimal light conditions. The ciliate *Stentor* is easily killed within minutes by exposure to unfiltered solar radiation.[28] The cells protect themselves by step-up photophobic responses.[29] Consequently, in nature, the organisms are found in the shade of leaves or other objects.

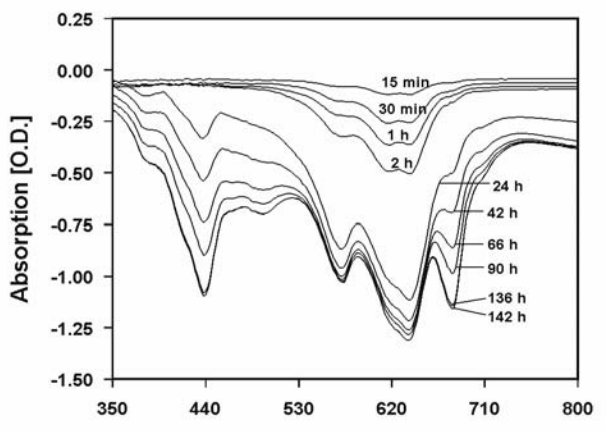

FIGURE 116.1 Absorption difference spectra of *Oscillatoria tenuis* after increasing times of exposure to UV radiation. Spectra are obtained by subtracting the initial absorption spectrum of the unirradiated sample from each spectrum of the irradiated samples. (From Donkor, V.A. and Häder, D.-P., *Aquatic Microbiol. Ecol.*, 11, 143, 1996. With permission.)

In photokinesis, the actinic steady state light intensity modulates the velocity of movement[30–32] and, thus, governs the time spent in dark or lit areas in the environment.[33] A higher swimming speed in light compared to in darkness causes the organisms to spend less time in irradiated areas and more time in darkness. This can be taken to its extreme: cells moving in light and stopping in darkness will result in the population eventually accumulating in dark areas of their habitats. The opposite behavior results in leaving dark areas and accumulating in bright areas. Some organisms settle on and stick to surfaces when irradiated and start moving again when in darkness. There are many deviations in the light-dependent movement patterns of microorganisms, and some do not even fit the definitions described above.

116.4 Excessive Light Stress

Obviously, photosynthetic biomass production is suboptimal under low light conditions. The break-even point between photosynthetic oxygen production and respiratory oxygen uptake (light compensation point) is different for different organisms: shade-adapted organisms need less light for a positive net production than do high-light-adapted ones.[34]

By several molecular mechanisms, excessive light exposure causes stress in many photosynthetic organisms. Excitation energy, which cannot be used by chlorophyll *a* in the photosynthetic reaction center, can be passed to oxygen that normally occurs in its triplet state. Upon uptake of the excitation energy from the excited chlorophyll, oxygen reaches its singlet state, which is fairly short-lived but aggressive, and can destroy proteins, lipids, and other biomolecules in its vicinity.

Solar energy can be absorbed by a number of cellular pigments and can then be used to form reactive oxygen species, including superoxide radicals ($O_2^{\bullet -}$), hydroxyl radicals ($OH^{\bullet}$), hydrogen peroxide (H_2O_2), and singlet oxygen ($^1O_2$) and other radicals, all of which can be destructive for cellular organelles and biomolecules.

Solar energy can also directly bleach cellular chromoproteins, such as the photosynthetic accessory pigments, including chlorophylls, carotenoids, and the algal phycobilins (Figure 116.1). The highly energetic, short-wavelength UV radiation (UV-A 315 to 400 nm and UV-B 280 to 315 nm) is effective in causing damage to cellular targets. Solar UV-B also breaks down proteins, especially those with high concentrations of aromatic amino acids, which strongly absorb around 280 nm. The even more detrimental UV-C does not play an ecological role because it is almost quantitatively absorbed in the atmosphere.

Another target of solar UV radiation is the nuclear and plastidic DNA. Mainly, UV-B causes the formation of cyclobutane dimers, such as thymine-thymine dimers. Shorter-wavelength UV-C mainly causes the formation of 6–4 photoproducts, pyrimidine hydrates, and DNA-protein cross-links.

116.5 Defense Systems against Excessive Solar Radiation

Higher plants and photosynthetic microorganisms developed a number of effective defense mechanisms to limit damage caused by excessive solar radiation. One strategy relies on habitat selection. Low-light-adapted plants select niches in their habitats in the shade. The distribution of macroalgae in the tidal zone is governed by the availability of solar radiation.[35] Many of the delicate and shade-adapted Rhodophytes are found in the understory of kelps in the subtidal zone, where they are never reached by unfiltered solar radiation. Vertical migration of motile phytoplankton organisms and protection in the shade of floating objects were mentioned above. The earliest organisms with oxygenic photosynthesis were the cyanobacteria, which are believed to have developed before a protective oxygen layer was present in the troposphere.[36] Also, the stratospheric ozone layer, which absorbs most of the detrimental solar UV-B radiation, was built up only later. These organisms are believed to have developed deep down in the water column or in endolithic habitats.

Most photosynthetic organisms developed protective pigments to absorb solar UV radiation before it can hit sensitive cellular targets. Scytonemins are yellow-brown lipid-soluble dimeric pigments located in the extracellular sheath of certain cyanobacteria growing in extreme habitats mostly exposed to high light intensities; these substances have been proposed to serve as UV-B sunscreens.[37,38] Other cyanobacteria and many eukaryotic phytoplankton organisms produce mycosporine-like amino acids (MAAs), which are water-soluble substances characterized by a cyclohexenone or cyclohexenimine chromophore conjugated with the nitrogen substituent of an amino acid or its imino alcohol, having absorption maxima ranging from 310 to 360 nm and an average molecular weight of around 300.[39]

Reactive oxygen species (ROS) and other radicals are effectively quenched by carotenoids, tocopherols, ascorbate, and reduced glutathione, supported by antioxidant enzymes, including superoxide dismutase (SOD), catalase, glutathione peroxidase (GSH-Px), and the enzymes involved in the ascorbate–glutathione cycle to detoxify ROS, such as ascorbate peroxidase (APX), monodehydroascorbate reductase (MDHAR), dehydroascorbate reductase (DHAR), and glutathione reductase (GR).[40]

The photosynthetic apparatus is protected by several mechanisms. Carotenoids absorb access excitation energy and dissipate it thermally (see above). Some photosynthetic organisms developed the xanthophyll cycle to improve this protective mechanism.[41] The photosynthetic electron transport is downregulated at the site of the D1 protein in Photosystem II. This mechanism, called photoinhibition, is found in algae and higher plants.[42,43] Many photosynthetic organisms show a typical midday decrease in the photosynthetic yield around noon. This pattern is believed to be mainly due to dynamic photoinhibition. In marine algae, this pattern is complicated by the tidal rhythm, so that the highest irradiance stress occurs when low tide coincides with high solar angles.[44,45] When exposed to excessive solar radiation, the quantum yield of PS II decreases. Upon short-term exposure, this process may be reversible within minutes or hours, while long-term exposure may cause irreversible damage. Regeneration is brought about by resynthesis of the damaged and cleaved D1 protein. Using pulse amplitude modulated (PAM) fluorescence, a number of fluorescence parameters can be determined, from which the photosynthetic quantum yield can be calculated (Figure 116.2).

If not repaired, UV-induced damage of the DNA can potentially result in mutations and death of the cells affected. Several mechanisms were developed to detect and repair damaged regions. In excision repair, the damaged site is cleaved, e.g., by an endonuclease, and excised by an exonuclease.[46] The gap is closed by a polymerase and a ligase. Photoreactivation is based on the photolyase enzyme, which utilizes the energy of UV-A/blue photons to split pyrimidine dimers.[47] If these systems fail to repair the damage, postreplication repair is another chance to regenerate the original state of the DNA.[48]

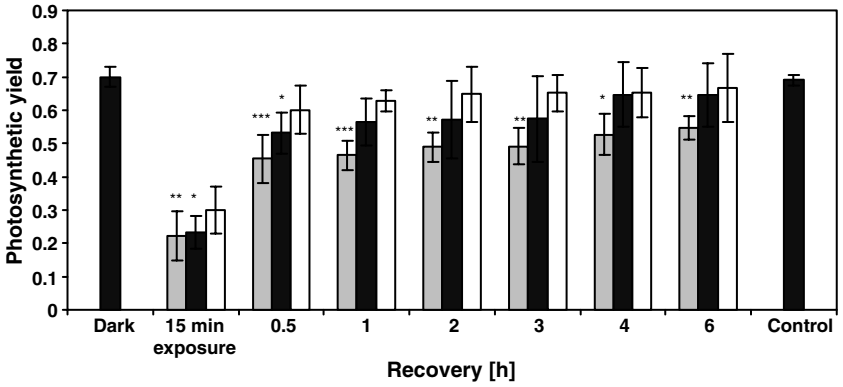

FIGURE 116.2 Effective photosynthetic quantum yield of *Enteromorpha linza* measured after 30 min dark adaptation, 15 min exposure, and after increasing recovery times in the shade, calculated as (*Fm*' - *Ft*)/*Fm*'. Gray bars denote the specimens exposed to unfiltered solar radiation. Black bars denote the specimens exposed to UV-A and PAR. White bars represent the specimens exposed to PAR only. The data are mean values of eight measurements and SE. The values for unfiltered solar radiation and under the 320 nm cutoff filter treatments are statistically significantly different from the PAR-only values (395 nm cutoff) in each set with $^{***}P < 0.001$, $^{**}P < 0.01$, or $^{*}P < 0.1$, respectively, as indicated by the student's *t*-test. Irradiances for the experiment were as follows: PAR 349 W m^{-2}, UV-A 44.15 W m^{-2}, and UV-B 1.34 W m^{-2}. (From Häder, D.-P., Lebert, M., and Helbling, E.W., *J. Photochem. Photobiol. B: Biol.* 62, 43, 2001. With permission.)

Chemistry and Spectroscopy of Chlorophylls

Hugo Scheer
Universität München

117.1 Introduction

The chlorophylls (Chl) and bacteriochlorophylls (BChl) comprise a group of more than 50 tetrapyrrolic pigments with common structural elements and functions.[1,2] Chemically, they are defined as Mg-complexes of cyclic tetrapyrroles of the porphyrin (Figure 117.1b), chlorin (Figure 117.1a), or bacteriochlorin (Figure 117.1b) oxidation state, all bearing a fifth, isocyclic ring, and most of them esterified at C-17[3] by the diterpenoid alcohol, phytol (Phy) (Figure 117.1a). However, an increasing number of structural variations have become obvious that do not strictly follow this definition (Section 117.2).

In a more biological definition, those of the above pigments and their derivatives are chlorophylls, which function in photosynthetic light harvesting or energy transfer. This excludes precursors or degradation products that conform to the chemical definition, and *vice versa*, it includes several pigments that deviate from the chemical definition but are functional in photosynthesis. Among them are the pheophytins (Phe) and bacteriopheophytins (BPhe) lacking the central Mg, a [Zn]-BChl *a* in which it is replaced by zinc, and the *c*-type chlorophylls [or more strictly speaking, chlorophyllides (Chlid), because they are generally are not esterified at C-17[3]]. There also exists a relatively small number of hydroporphyrins that are structurally related but functionally unrelated to chlorophylls, *viz*. the sex determinant(?) bonellin in *Bonellia* viridis,[3] a structurally yet uncertain component of the visual system of deep-sea fish,[4] and antioxidants(!) from several clams and diatoms.[5] Heavy-metal derivatives of chlorophylls were isolated from plants growing on media enriched in the respective metals.[6] Open-chain tetrapyrroles derived of chlorophylls were identified as breakdown products of chlorophylls[7] but also as bioluminescent pigments in krill.[8]

FIGURE 117.1 Structures of chlorophylls and their functions in photosynthesis. a) Chlorin-type chlorophylls derived of the *trans-17,18-dihydroporphyrin* macrocyle (left) and a selection of esterifying alcohols at C-17[3]; b) bacteriochlorin-type chlorophylls (left) and porphyrin-type chlorophylls (right) derived of the *trans-7,8,17,18-tetrahydroporphyrin* and the fully unsaturated porphyrin macrocyle, respectively. The [8-vinyl] pigments are often also termed "divinyl" chlorophylls. The bacteriochlorophylls c, d, and e, which are chlorins, comprise a complex mixture of pigments with varying R_8, R_{12}, and R_{17^3}, and of epimers at C-3[1]. *The* stereochemistry at C-13[2] of most c-type chlorophylls is uncertain. Chl c_3 is probably a mixture with $R_8 = C_2H_3$ and C_2H_5.

117.2 Chlorophyll Structures and Functions

Chlorophylls function in photosynthetic organisms as light-harvesting pigments in antenna complexes (LHC)[9] and as electron carriers in reaction centers (RC) that carry out the light-driven electron transfer across the photosynthetic membrane.[10] A Chl *a* molecule of unknown function is also present in the electrogenic cytochrome b_6/f complex located between the two photosystems, PSII and PSI, of oxygenic organisms.[11,12]

A wide variety of chlorophylls (Figure 117.1) were identified in the various types of LHC, which are probably polyphyletic.[13] This number is increasing with advances in microbiology and improved analytical techniques, and some of the more recently discovered pigments are, by no means, "exotic." The most striking examples are [8-vinyl]-Chl *a* and *b*, often referred to as "divinyl" Chl *a* and *b*, respectively. In marine prochlorophytes, they are responsible for a sizeable amount of the earth's photosynthetic CO_2 fixation.[14] BChl with Zn as central metal has recently been found in several acidophilic purple bacteria as the main LHC pigment.[15] While most of the recently identified heavy-metal chlorophylls (e.g., Cu, Ag) are deleterious to photosynthesis,[6] [La]-Chl *a* has been suggested to be beneficial.[16] In LHC of anoxygenic bacteria, alcohols other than phytol were frequently found at C-17[3] (Figure 117.1). A number of C-20 terpenoid alcohols other than phytol were identified in purple bacteria, C-15 terpenoid alcohols in heliobacteria, and these and other alcohols, including unbranched ones, in green bacteria. The *c*-type Chls generally do not carry a long-chain esterifying alcohol at C-17[3]. However, some do, and among them, an unusual lipid ester was recently identified[17] (Figure 117.1).

By contrast, there are only two types of RC, which are probably monophyletic.[10] In all RC, chlorophylls act as primary electron donors (generally designated Pxxx, with xxx giving the wavelength of the red-most absorption maximum) and also as primary electron acceptors. In the Type I RC, into which the core antenna is integrated, the secondary acceptors are chlorophylls as well, while in Type II RC, the secondary acceptors are pheophytins lacking the central Mg. One of the four BChl in purple bacterial RC (which are of Type II), is also implicated in triplet energy transfer to carotenoids, e.g., in the light protection.[18] Chl *a* is found in the RC of nearly all organisms capable of oxygenic photosynthesis, together with Phe *a* in PS II RC. They are replaced by [8-vinyl]-Chl *a* (and possibly [8-vinyl]-Phe *a*) in the oxygenic marine *Prochlorococcus* species, and by BChl *a*, *b*, or *g* in most anoxygenic bacteria. BPhe *a* and BPhe *b* replace Phe *a* in the Type II RC of purple bacteria containing BChl *a* and BChl *b*, respectively, as major pigments. Additional, more specialized chlorophylls were identified in RC.[19] Chl *a*′, *viz.* the 13[2]-epimer of Chl *a*, has long been known as a component of PSI RC and was recently identified as one pigment of the dimeric primary donor of PSI, P700.[20] BChl *g*′ was found in the RC of heliobacteria. Because they are of Type I, too, a BChl *g*/BChl *g*′ heterodimer was suggested, in analogy, as primary donor in these phototrophic prokaryotes. A Chl *a*-type pigment, [8[1]-OH]-Chl *a*, is discussed as the first electron acceptor (A_0) in PSI. In the oxygenic prokaryote, *Acaryochloris marina*, Chl *d* replaces at least part of the Chl *a*, and Chl *d*′ replaces Chl *a*′. Recently, an autotrophic mutant of a cyanobacterium was described, in which 50% of the Chl *a*/Phe *a* content of PSII RC was replaced by Chl *b*/Phe *b*.[21] In the RC and the LHC of several *Acidiphilium* species, [Zn]-BChl *a* replaces BChl *a*.[15] The BChl of the purple bacterium, *Rhodospirillum rubrum*, contains geranylgeraniol as the esterifying alcohol, while the BPhe *a* of RC is esterified with phytol.[22]

Exchange experiments showed that a surprising variety of modified chlorophylls can be incorporated into the various pigment-protein complexes, often with distinct specificities of the individual binding sites.[23–27] It remains a challenge to understand these binding specificities, as well as the functional significance of the various aforementioned "specialized" chlorophylls on a molecular level.

117.3 Spectroscopy

The absorption spectra of cyclic tetrapyrroles are generally described by the four-orbital model first proposed by Gouterman for cyclic tetrapyrroles, resulting in four possible electronic transitions[28,29] that are generally each split into two vibrational bands. In the fully unsaturated porphyrin-type pigments like

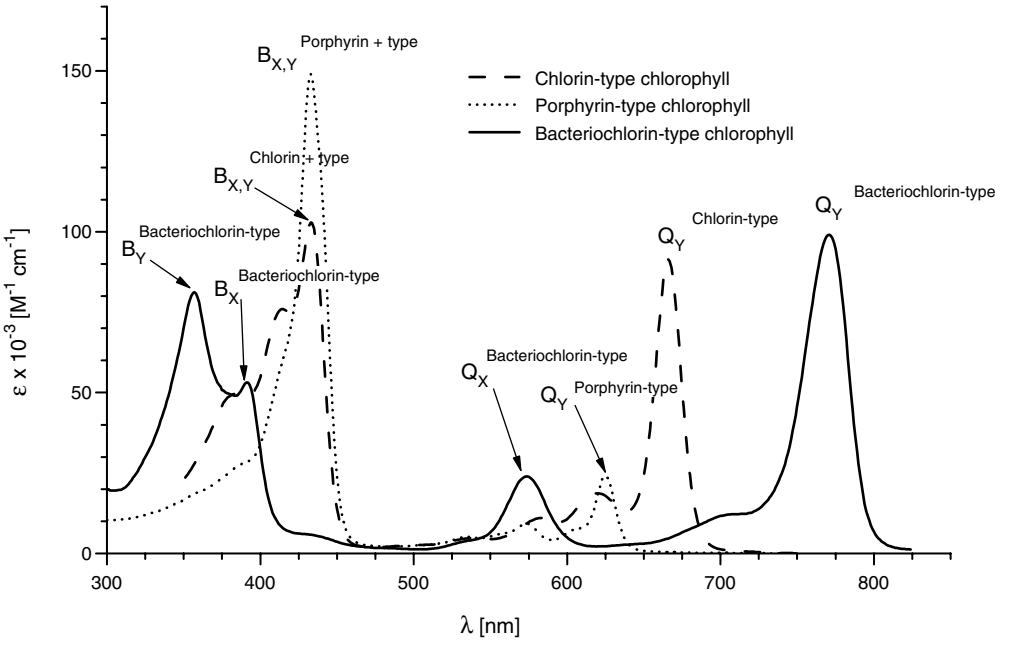

FIGURE 117.2 Type-spectra of chlorophylls.

Chl *c*, the two transitions in the visible (Q_y, Q_x) are only weakly allowed, while two in the blue or near-UV spectral region (B_y, B_x) are intense ($\varepsilon_{max} \approx 3 \times 10^5$). The Q_y-band is less forbidden ($\varepsilon_{max} \approx 10^5$) and progressively red-shifted in chlorin- and bacteriochlorin-type chlorophylls (Figure 117.2). These pigments have, therefore, two regions of intense absorptions in the red to near-IR (Q_y) and in the blue to near-UV spectral ranges (Soret or *B*-bands). The Q_x-band remains weak in the chlorins but is moderately intense in the bacteriochlorins. Because in the latter, the B_x- and B_y-bands are also well separated, all four canonical transitions are clearly discernible in the bacteriochlorophylls. The significance of this fact was first realized by Scherz et al., who used it, subsequently, as a sensitive environmental probe.[30,31]

Absorption spectroscopy after extraction is the most common method for (B)Chl quantitation.[32–34] The solution spectra of the more common chlorophylls are summarized in Table 117.1. Monomeric (B)Chls are highly fluorescent, and phosphorescence was observed for many pigments. Both are quenched *in situ*, and the degree and dynamics of fluorescence quenching are valuable indicators for photosynthetic processes.[35,36]

In (B)Chl proteins, the *Q*-bands are generally red-shifted and hyperchromic. Aggregation was recognized as a major factor of these changes, based on x-ray structures[20,37,38] and a large number of aggregation studies in various environments (see Section 117.4). It is generally accompanied by an induction of strong optical activity, with conservative as well as nonconservative excitonic bands.[39–41] While point charges (which are important in linear polyenes) seem to play only a minor role as "spectral modifiers," conformational changes can induce considerable red shifts[42,43] and optical activity.[44] Interactions with nearby aromatic amino acids were recognized as another important factor.[45]

The intense absorptions in the visible and NIR spectral regions are an important factor in photosynthetic light harvesting. However, the bands are narrow, and there is only moderate absorptivity in the green spectral region, where the light flux is often highest. In antennas, (B)Chls are, therefore, almost always supplemented by additional light-harvesting pigments, in particular, in microorganisms.[9] The lowest excited electronic state, ^{1}S, of (B)Chls absorbs in the red region close to the ground-state absorption.[46] Excited state dynamics were studied, in solution and in pigment-protein complexes, by high-resolution spectroscopy, in the time[47–48] and frequency domains,[49,50] by nonlinear absorption techniques[51] and, more recently, by single molecule spectroscopy.[52] The absorption spectra of triplets and anion and

cation radicals feature generally broader and less-structured absorptions.[53,54] The cation radical of the primary donor of purple bacterial RC has an intense and narrow near-infrared band characteristic of mixed-valence complexes, and a less-intense feature is also seen in Chl *a* containing oxygenic reaction centers.[55] There is, furthermore, an electronic absorption band at much longer wavelengths, assigned to charge-transfer absorptions in the cation radical.[56] Radical ions and triplets were studied widely in reaction centers by optical, magnetic resonance, and vibrational spectroscopy, in order to obtain selective information on the pigments involved in electron transfer (see Ref. 10 for a list of the leading references).

Many types of chlorophyll show, in solution, a fairly efficient intersystem crossing from the ^{1}S to the lowest triplet (^{1}T) state. Accordingly, they are good sensitizers for singlet oxygen. This potentially damaging effect is neutralized in photosynthetic organisms by an efficient triplet and $^1O_2$-quenching by carotenoids. Carotenoid-less mutants are, therefore, prone to photodynamic killing at high light intensities in the presence of oxygen. On the other hand, triplet formation and their intense red and NIR absorptions in the therapeutic window, render chlorophylls and, in particular, bacteriochlorophylls, good candidates for photodynamic therapy (and photodiagnosis) of certain types of cancer.[57,58]

117.4 Aggregates

Several modes of aggregation are known in chlorophylls. Because the process was implicated as an important factor in the stability, structure formation, and spectral properties of (B)Chls in their functional native environments, it was studied widely (for leading references, see Refs. 41, 59, 60). One type of aggregation can be induced by interactions of the central Mg of one pigment with a peripheral donor group of another. This mechanism is of particular importance in hydrophobic environments. It is also a factor in BChl *c*, *d*, and *e* aggregation in the chlorosome, the major antenna of green and brown bacteria, which contains only very little protein.[61] Dispersive and π,π interactions are probably more important in other aggregation types of (B)Chl, because aggregation here occurs equally well with the metal-free (bacterio)pheophytins. This process was studied, in particular, in aqueous-organic solvent mixtures,[41] in micelles, and in vesicles.[60] Large micellar aggregates are formed in aqueous systems, and aggregation is important on surfaces.

117.5 Reactivity

Chlorophyll chemistry before 1991 was treated in a comprehensive review article[62] (the recent advances were covered in a review of Senge[63]). Some of the early and more recent works are summarized in Figure 117.3. Only few details are given here, and the reader is referred to the cited references. While most of the early work was focused on the chemistry of chlorophylls as photosynthetic pigments, it has become of interest lately, with regard to their potentials in photodynamic therapy.[57,58]

Dark Reactions of the Aromatic Macrocyclic System

A large variety of redox reactions is known for the (B)Chls and related (hydro)porphyrins.[62,64] The reductions generally involve methine bridges but are often followed by rearrangements of the system. Reductions at the pyrrolenine-peripheral double-bonds are important in the dark biosynthesis of (B)Chls, which for the dark reaction, is carried out by enzymes related to nitrogenase.[65] Chemical equivalents of such reductions are only known for simple porphyrins, and the more gentle diimide reaction yields the *cis*-isomer. Alternatively, oxidation to *vic*-diols followed by pinacol rearrangement to ketones leads formally to hydroporphyrins.[66,67] Isomerization of endo- into exocyclic double-bonds would yield similar results but only the inverse process is experimentally known in the conversion of BChls *b* and *g* to the respective chlorins, [3-acetyl]-Chl *a* and Chl *a*.[68,69] The electrochemistry of (B)Chls shows several one-electron redox reactions of the macrocyclic π system. Pigments containing other central metals show redox reactivities of the metal, the macrocycle, or both.[70,71]

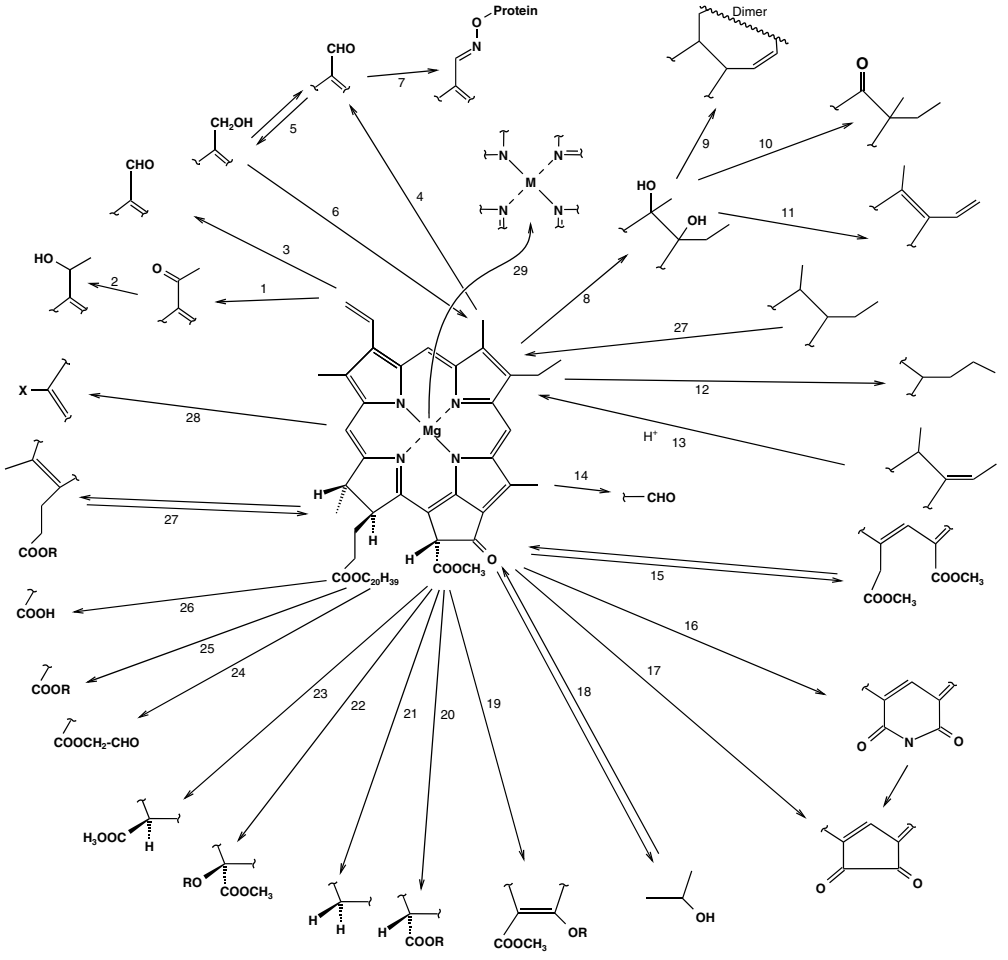

FIGURE 117.3 Schematic overview of chemical modifactions of the chlorophyll side chains and the central metal. For natural variations, see Figure 117.1. Substitution reactions are dependent on the relative electron densities, like in other aromatic systems. Electrophilic substitutions at methine bridges next to reduced rings are studied well.[72] The central Mg is easily lost in the presence of acid. Mg and a variety of other metals were (re)introduced into Phes of the chlorin and porphyrin type[73] and into BPhe.[74]

Ring opening to bile pigments, in particular at the C-5 position, was recognized as a critical step in chlorophyll degradative metabolism, because the linear tetrapyrroles are much less phototoxic than the cyclic ones. In contrast to the ring opening of the Fe porphyrins, the hemes, the bridging methine is retained in this process.[7,75] In green plants, Chl *b* is converted first to Chl *a*, while degradation products of both were identified in green algae. Another ring opening at C-20 gives rise to linear tetrapyrroles involved in the bioluminescence of *Euphausid* shrimps.[8]

Reactions of Peripheral Substituents

The peripheral groups of (B)Chls react as they would in similarly substituted simpler aromatic systems. There is a considerable long-range influence of other substituents that have an origin that is not fully understood. A variety of reactions are known at the isocyclic ring, and many are related to the presence of an enolizable β-ketoester system and to "peripheral crowding." The β-ketoester system can compete with the central N_4-cavity for chelation of metals. Conjugation reactions with amino acids, sugars, or other biological materials are of considerable interest for affinity labeling and the design of photo drugs. Useful handles are the 17^3-propionic acid groups *via* esterification or amide formation, C-13^2 via hydroxylation, C-3^1 and, in particular, C-7^1 (in Chl *b*), and C-8^1 (in BChl *b* and *g*) (see Figure 117.3).

Photochemistry

Light-induced redox reactions are important for the biological function of chlorophylls in RC and for the biosynthesis of Chl *a*; a photochemical ring opening may be involved in the breakdown of (B)Chls. Metalloporphyrins and chlorins are photoreduced in a two-electron reaction, e.g., by amines or thiols, at the methine bridges,[76] the former products rearrange to *cis*-chlorins.[64] The light-dependent protochlorophyllide reductase performs a *trans*-reduction at Ring *D* of the porphyrin precursor, protochlorophyllide, which structurally resembles the *c* chlorophylls. In spite of a large body of work, the structures of the intermediates are still unknown. With the recent development of reconstitution methods,[77] the photoreduction of chlide was characterized. A photoreaction of unknown mechanism has been reported for a rare water-soluble Chl protein from *Chenopodium*.[78]

One-electron redox reactions are most important in photosynthetic RC. BChls *a*, *b*, and *g*, and Chl *a*, and in certain bacteria, also [Zn]-BChl *a* or Chl *d*, act as electron donors. The same or similar (B)Chls act as primary and secondary acceptors in Type I RC, while in Type II RC, the secondary acceptors are the respective metal-free (B)Phe.[10] (B)Chl-sensitized reductions of redox partners, in particular, across membranes are of considerable interest as model reactions for photosynthesis. These reactions were also studied in solution in covalently linked systems like caroteno-chlorophyllo-quinones and more elaborate systems.[79]

Most photooxidative ring-opening reactions of Chls of the chlorin-type cleave the macrocycle at the C-20 methine bridge. But, cleavage at the C-5 bridge was reported for a Cd-pheophytin.[80] There is currently no evidence that the biodegradation involves light (see Section 117.6). The photosensitized oxidations of (B)Chl are of growing interest in photodynamic applications, e.g., in tumor therapy. However, little is known on the fate of the sensitizer, which in many cases, is irreversibly bleached.[81] Yet another type of photoreaction is demetalation ("photopheophytinization"), on what little is known.[82]

117.6 Metabolism

The starting point for the biosynthesis of chlorophylls is 5-amino-levuIinate (ALA), which in most photosynthetic organisms is formed from glutamate and in animals and purple bacteria from glycine and succinyl CoA. Dimerization leads to the monopyrrole, porphobilinogen, which then tetramerizes to protoporphyrin in a step involving the rotation of one of the pyrrole rings (for leading references, see Ref. 83). The specific part of Chl biosynthesis (Figure 117.4) starts with the insertion of Mg, followed by the formation of the isocyclic ring, reduction of the macrocycle (except for Chl *c*), and esterification. In angiosperms, the reduction *via* the so-called light protochlorophyllide reductase, is a photoreaction (see above). Several modified cyclic tetrapyrroles were identified during the biodegradation of chlorophylls. The subsequent crucial step in removing these phototoxic compounds is the ring opening to bile pigments, which in the currently studied cases in plants and green alga, is an enzymatic reaction that does not require light. These and the following reactions on the resulting open-chain tetrapyrroles were recently studied in some detail.[7,75]

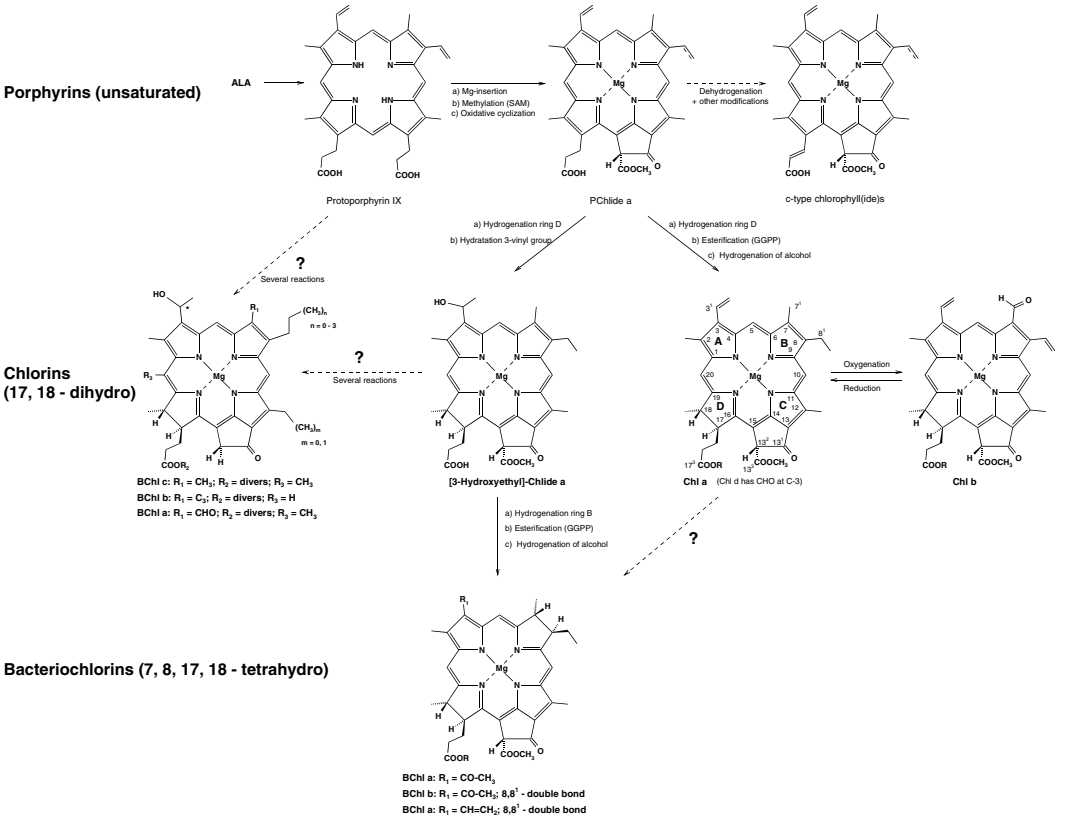

FIGURE 117.4 The biosynthesis of various chlorophylls from the common precursor, protoporphyrin IX**.**

117.7 Abbreviations

BChl	bacteriochlorophyll
BPhe	bacteriopheophytin
B_x, B_y	higher-energy absorption bands of tetrapyrroles in the Vis/UV spectral range
Chl	chlorophyll
ε	molar extinction coefficient [M^{-1} cm^{-1}]
Far	farnesol
GGPP	geranyl-geranyl pyrophosphate
IC	internal conversion
ISC	intersystem crossing
λ	wavelength (nm)
NIR	near-infrared spectral range (700 to 1200 nm)
nmr	nuclear magnetic resonance
Phe	pheophytin
Phy	phytol
Q_x, Q_y	low-energy absorption bands of tetrapyrroles in the Vis/NIR spectral region
RC	reaction center (Type I and Type II relate to the homologies with PSI and PSII, respectively)
UV	ultraviolet spectral range (200 to 400 nm)
Vis	visible spectral range (400 to 700 nm)

117.8 Nomenclature

IUPAC numbering is used throughout (see Figure 117.1a).

Photosynthetic Reaction Centers

Paul Mathis
CEA-Saclay

118.1 Presentation of Reaction Centers

General Properties, Composition, and Isolation

In plants, algae, and photosynthetic bacteria, the photosynthetic apparatus converts light energy into chemical energy. This machinery is an assembly of membrane proteins, in which the action of light starts in an "antenna," an ensemble of pigments (chlorines such as chlorophylls, polyenes such as carotenoids, and phycobilins) embedded in proteins. The antenna absorbs light and funnels excitation energy toward large specific proteins named reaction centers, where photoinduced charge separation takes place. Reaction centers (RC) can thus be considered as microscopic photocells that realize the first steps of energy conversion. In this system, all elementary processes take place rapidly (in less than 1 ps for pigment-to-pigment energy transfer, in less than 3 ps for primary electron transfer), so that the overall quantum yield is higher than 90%, with only a small fraction of excitation being lost by internal conversion, by fluorescence (less than 2%), or by conversion to the triplet state (less than 4%). For many years, RCs were simply hypothesized as specific sites in the photosynthetic membrane, but progress in membrane biochemistry has led to their effective isolation as large proteins made of several polypeptides (from two in the simplest case of nonsulfur green bacteria to at least 12 in Photosystem I and Photosystem II of oxygenic organisms) and of several pigment molecules (all RCs contain at least six chlorin-type molecules and one or more carotenoids). They contain several chemical groups implicated in electron transfer (these groups are called "redox centers": quinones, hemes, iron-sulfur centers, Mn atoms, amino acid residues of polypeptides, etc.).

Several classes of reaction centers (Table 118.1) are found among the various photosynthetic biological organisms.[1] Their basic mode of functioning is always the same: excitation energy arriving from the antenna is trapped by the primary electron donor P [which is most often, and perhaps always, a well-defined aggregate of two molecules of (bacterio)chlorophyll, often named "special pair"]; excitation of P is followed by several steps of electron transfer on the acceptor side, and P^+ is then re-reduced by an electron donor. Several classes of RCs will be briefly presented, starting with the best-known RC, that of purple bacteria.

Note: MQ, UQ, PQ: menaquinone, ubiquinone, plastoquinone, respectively; Pc: plastocyanin; (FeS): iron–sulfur center; I: intermediate electron acceptor; Other symbols: see text. The numbers are redox midpoint potentials Em (versus the normal hydrogen electrode), in mV.

Purple Bacteria

The reaction center of purple bacteria serves as a general model for all classes of RCs, because it was isolated as a pure protein a long time ago. Its structural and functional properties were studied in detail by biochemical and spectroscopic methods, and its structure was determined at atomic resolution by x-ray crystallography, providing a firm basis for site-specific mutations, for theoretical calculations of spectroscopic properties and of electron transfer kinetics, etc.[2–4]

The RC is made of three polypeptides: L, M, H (MW: 32, 34, and 28 kDa, respectively). L and M make up the core of the reaction center. They carry the cofactors: four bacteriochlorophylls, two bacteriopheophytins, two quinones of species-dependent chemical nature, and one nonheme Fe^{2+} atom. In many species of bacteria, the RC also includes a bound tetraheme *c*-type cytochrome of about 12 kDa MW (when it is absent, its function of electron donation to P^+ is fulfilled by a soluble *c*-type cytochrome). Proteins and cofactors are organized, as sketched in Figure 118.1. The RC is endowed with an approximate C_2 symmetry in structure that is not found in the function. The primary donor *P* is a dimer of bacteriochlorophylls, a so-called "special pair," in that the two molecules are held in close proximity by the *L* and *M* subunits; they are in electronic interaction without establishing any chemical link. Recent developments in the structural analysis of RCs dealt with refinements of the structure and with possible structural changes coupled to electron transfer.[5,6]

Excitation by energy transfer from the antenna brings *P* to its lowest excited state P^*, permitting the fast ($t_{1/2} = 2$ ps) transfer of an electron to the bacteriopheophytin located on the L branch (the involvement of bacteriochlorophyll B_L is still a matter of debate). The electron is then transferred to the quinone Q_A with $t_{1/2} \approx 200$ ps, and from there to the quinone Q_B ($t_{1/2}$ in the microsecond time domain). The quinone Q_A functions as a one-electron carrier, but Q_B functions as a two-electron, two-proton carrier. After its full reduction by two electrons and two protons, Q_B (in the form of an hydroquinone) leaves the reaction center and diffuses in the membrane to reduce another redox protein, the cytochrome *b/c* complex, while another oxidized quinone from the membrane binds at the Q_B site. P^+ is re-reduced by a *c*-type cytochrome. The *c*-type cytochrome is reduced by the *b/c* complex in a complicated mechanism involving transmembrane proton movement. Altogether, the RC functions as a proton pump, transferring protons against their concentration gradient across the membrane, while the electron flow is mainly cyclic.

Photosystem II

In oxygen-evolving organisms, such as plants, algae, and cyanobacteria, the photosynthetic membranes contain two types of RCs, called Photosystem I and Photosystem II. The latter presents strong analogies

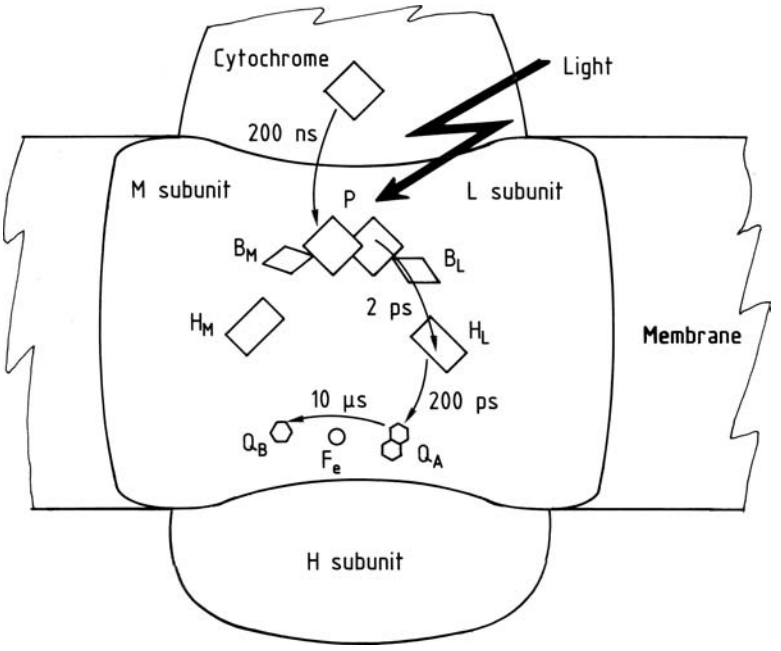

FIGURE 118.1 The *Rhodopseudomonas viridis* reaction center, with approximate half-times of the three major steps of electron transfer on the active acceptor branch, and of one step from the cytochrome moiety (only partly drawn). Membrane thickness: about 35 Å. (Inspired from Deisenhofer, J. and Michel, H., *EMBO J.*, 8, 2149, 1989.)

with the RC of purple bacteria.[1,7,8] The inner part of the reaction center is built from two polypeptides (named D1 and D2) of about 32 kDa, which are homologous to L and M. The sequence of electron acceptors is similar: pheophytin → quinone Q_A → quinone Q_B. Both quinones are plastoquinone A, and their functional properties are like their bacterial counterparts. Specific inhibitors block electron transfer by binding specifically at the Q_B site in competition with plastoquinone. Several of them are used as herbicides: dichlorophenyl-dimethylurea and other urea derivatives, triazines, etc. Many of them also bind at the Q_B site in purple bacteria.

The Photosystem II reaction center,[9] however, differs from the RC of purple bacteria in at least three important respects:

1. It performs water oxidation, resulting in O_2 evolution and in proton release. The redox equilibrium $2H_2O \rightarrow 4H^+ + 4e^- + O_2$ has an Em of +0.82 V at pH 7. The reaction is pulled by the oxidized primary donor P^+ (named P-680$^+$ in Photosystem II). P-680 is a "special pair" of chlorophyll *a* molecules, but these molecules are not as close as in purple bacteria, and they are surrounded by two other chlorophyll *a*, so that P-680 can also be described as a "special tetramer." The P-680/P-680$^+$ redox couple must have an Em (perhaps around +1.2 V) much more positive than +0.82 V, in order to oxidize water irreversibly. P-680$^+$ is directly reduced by a tyrosine residue named TyrZ; it is Tyr 161 of the polypeptide D1. Oxidized TyrZ then oxidizes a cluster of four manganese atoms, which is the catalytic site for water oxidation. A histidine residue is probably involved in the process, which also requires Ca^{2+} and Cl^- ions. The details of the structure and mechanism of this ensemble are still under intense investigation.[10,11]
2. The Photosystem II reaction center is highly complex because it contains at least 10 polypeptides. In addition to D1 and D2, there are the two subunits of cytochrome b_{559}, two chlorophyll-proteins named CP47 and CP43, several hydrophobic polypeptides of unknown function, and three peripheral proteins located at the water oxidizing site (MW: 33, 24, and 16 kDa).

3. The Photosystem II RC is susceptible to degradation by an excess of light in a process called photoinhibition. In the dark, the process is followed *in vivo* by a recovery that requires specific protein synthesis. Photoinhibition is usually thought to be an adaptive protective mechanism avoiding permanent photodamages.

For a long time, the Photosystem II RC could not be crystallized, perhaps because of its complexity or because of its inherent instability. Hypothetical structural models were proposed, based on its partial similarity with the RC of purple bacteria. Two-dimensional crystals were studied by electron crystallography, leading to a reasonable structure.[12] It is only recently that the Photosystem II RC from thermophilic cyanobacteria was crystallized in a three-dimensional manner. A structure was published at the resolution of 3.8 Å,[13] and data acquired at high resolution by the same laboratory are being analyzed.

Photosystem I

The other reaction center from oxygenic organisms, Photosystem I,[7,14–16] is organized according to the same basic principles as other RCs (see Figure 118.1) but with important differences. It was crystallized from the thermophilic bacterium *Synechococcus elongatus* (like Photosystem II), and its structure was determined at a resolution of 2.5 Å.[17,18] It includes 12 protein subunits and 123 cofactors: 96 molecules of chlorophyll *a*, two phylloquinones (also named vitamin K_1), 22 carotenoids, and three 4Fe-4S clusters. The core of the RC is made of two large polypeptides (PSI-A and PSI-B, of about 83 kDa each) that carry the pigment molecules which serve as undissociable antenna, and they carry most of the redox-active cofactors: the primary donor P-700 (a special pair of chlorophyll *a*), the primary acceptor A_0 (a specialized chlorophyll *a*), the secondary acceptor A_1 (phylloquinone), and a low-potential 4Fe-4S iron-sulfur center named F_X, which is held at the interface between the two large polypeptides. After absorption of a photon and subsequent steps of energy transfer, P-700 becomes excited; an electron then goes from P-700* to A_0, and then to A_1, and then to F_X, and from there to a small polypeptide (PSI-C) holding two 4Fe-4S centers (F_A and F_B), which serve as a relay toward the physiological electron acceptor, a soluble 2Fe-2S ferredoxin (replaced by flavodoxin in some cases). All the electron acceptors have a low Em (see Table 118.1). To complete the electron path, P-700$^+$ is re-reduced by a soluble acceptor (plastocyanin or cytochrome *c*-553) on the membrane side opposite that of ferredoxin action. The successive steps of electron transfer are rapid and difficult to analyze in detail. A cycle is completed in a few microseconds.

The structure of the Photosystem I RC is nearly symmetrical, with an approximate symmetry axis running from the center of P-700 to the center of F_X. The electron acceptors A_0 and A_1 have symmetrically located counterparts, also chlorophyll *a* and phylloquinone, which were first postulated to be inactive but might well play a role in electron transfer.[19] Two additional chlorophyll *a* molecules are located between P-700 and A_0 (and its symmetric counterpart). These molecules have not been identified as discrete intermediates in electron transfer, but they might be involved in facilitating electron transfer from P-700* to A_0. It should also be mentioned that the roles of most of the protein subunits are still not understood; several serve for the docking of ferredoxin or of plastocyanin, but many small hydrophobic polypeptides have no obvious functions.

Green Sulfur Bacteria and Heliobacteria

Like the purple bacteria, these classes of bacteria have only one type of reaction center, but it greatly resembles the Photosystem I RC of oxygenic organisms.[20] Their RCs are still poorly known, because their study is extremely difficult, but their sequence of electron carriers, as far as it is known, is similar to that of Photosystem I,[21,22] with small chemical differences in the structure of the chlorin pigments and a tendency to have lower redox potentials (see Table 118.1). They contain quinones of the menaquinone family, but all functional tests failed in showing a function for them; it is thus hypothesized that electron transfer goes directly from A_0 to F_X.[23] Like in Photosystem I, the RC core is made of two large polypeptides that carry about 30 molecules of antenna pigments, in addition to the redox centers involved in primary photochemistry. These polypeptides, however, have an identical sequence of amino acids,[24] and it is

usually assumed that the RC has a symmetrical structure, whereas other RCs have a pseudo-symmetry axis. It is also supposed, but not demonstrated, that the electron leaving P-840 has an equal probability of using two equivalent paths to reach the FeS center F_X. Although they are not well known, these classes of RCs play a key role in the speculations concerning the evolution of photosynthesis.

Altogether, it is possible to classify all of the types of photosynthetic RCs according to the structure of their protein matrix, to the nature and corresponding redox properties of their redox centers, to the size and chemistry of their antenna pigments.[1,8,20,25] Purple bacteria and Photosystem II RCs are named Type II or pheophytin-quinone-type RCs. Their RC core is made of small polypeptides holding a small antenna; they have two quinones (Q_A and Q_B) functioning in series, and they operate at a rather high redox potential (not mentioned yet, the RC of green nonsulfur bacteria has similar properties). Green sulfur bacteria, heliobacteria, and Photosystem I of oxygenic organisms are Type I or FeS-type RCs, characterized by a large protein core holding a large number of antenna pigments; they operate at a low redox potential, and their most characteristic electron acceptors are iron–sulfur clusters.

118.2 Methods for Studying Structural and Functional Properties

Biochemical Methods: Proteins

Reaction centers are complex membrane proteins, and their study requires appropriate biochemical methods that are only briefly mentioned here:

- The isolation of reaction centers requires treatment of the membranes by detergents, followed by classical purification methods such as centrifugation, chromatography, etc. (see, e.g., Reference 26). Their polypeptidic composition is determined by dissociation of pure RCs with sodium dodecyl sulfate, followed by gel electrophoresis under denaturing conditions.
- The sequencing of polypeptides is done directly for rather small polypeptides or, more generally, by sequencing the corresponding genes. Eventual processing of the preprotein can be checked by comparison with N- or C-terminal partial sequences of the polypeptide.
- The crystallization of RCs in view of structure determination by x-ray crystallography requires special methods that have worked successfully for two kinds of purple bacteria (*Rhodopseudomonas viridis* and *Rhodobacter sphaeroides*) and for Photosystems I and II of thermophilic cyanobacteria.

Successful methods for the biochemical manipulation of RCs have been developed progressively during the last 20 years: site-directed mutagenesis [for four purple bacteria (*R. capsulatus*, *R. sphaeroides*, *Rps. viridis* and *Rvx. gelatinosus*), for several species of cyanobacteria, and for the green alga (*Chlamydomonas reinhardtii* [27])], protein extraction (or denaturation) followed by reconstitution (this was especially successful for the iron–sulfur centers of Photosystem I and for the peripheral polypeptides of Photosystem II), etc. Selective pigment extraction, modification and reconstitution are also in progress.

Optical Spectroscopy

Methods of optical spectroscopy are especially important, because they provide plentiful information on RCs, in which pigments are involved directly in energy or electron transfer, and in which redox centers also have characteristic optical properties.[28]

Absorption Spectroscopy

All photosynthetic pigments have intense and distinctive absorption spectra, in relation to the ability of each of them to capture specific parts of the solar light spectrum.[29] The pigments chlorophylls and bacteriochlorophylls belong to the chemical group of chlorins. Their reduced symmetry compared to porphyrins results in a strong Q_Y band absorbing well into the red or IR, the position of which is highly sensitive to the local environment of the molecule.[30,31] From a single chemical molecular species, such as chlorophyll *a* (Figure 118.2) or bacteriochlorophyll *b* (Figure 118.3), complex spectra are thus obtained

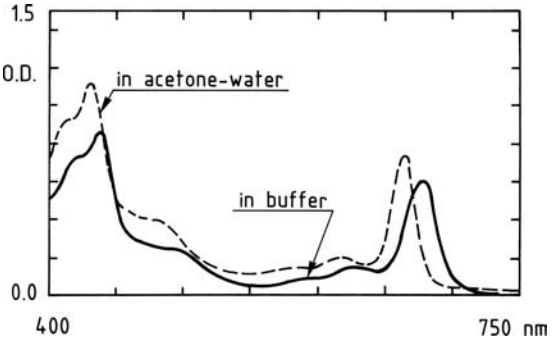

FIGURE 118.2 Absorption spectra of (a): Photosystem I reaction centers from the cyanobacterium *Synechocystis 6803*, isolated with the detergent dodecylmaltoside (kindly provided by Dr. H. Bottin); (b): the same material (same pigment concentration) extracted with an acetone–water (80:20) mixture.

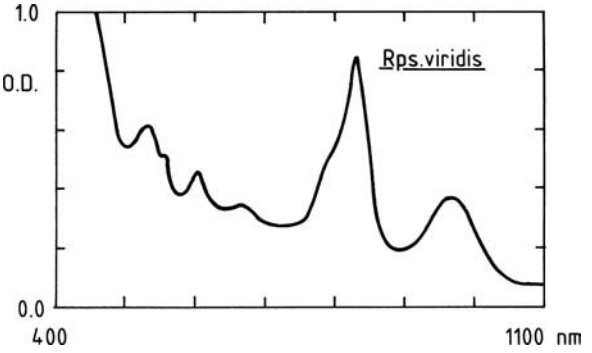

FIGURE 118.3 Absorption spectrum of a suspension of *Rhodopseudomonas viridis* reaction centers (plus 100 μM Na ascorbate) dispersed by a detergent (LDAO). The absorption band at 970 nm is due to the primary donor *P*, and the large massif around 820 nm is mainly due to the two bacteriochlorophylls other than *P*, and to the two bacteriopheophytins. (Reaction centers kindly provided by Dr. J. Breton.)

as a result of pigment–pigment or pigment–protein interactions. This effect is especially clear for the primary donor *P* in purple bacteria (Figure 118.3). Absorption spectroscopy thus remains a basic technique in separation procedures, to check for the good state and the purity of samples.

Difference Spectra and Kinetic Properties

Absorption of light results in the formation, in RCs, of excited states and, after charge separation, of reduced and oxidized species. The molecules involved experience a change in their absorption spectrum that can be detected with a high sensitivity by differential absorption spectroscopy.[28] This technique is often coupled to flash excitation and to time-resolved detection (as shown in Figure 118.4), permitting the identification of successive partners in energy or electron transfer (from the difference spectra), kinetics of the successive steps, and the factors that control the reactions. This methodology is in constant development, especially in terms of time resolution, because the pump–probe methods provide a resolution well below 1 ps.[32–34]

Fluorescence

Fluorescence spectroscopy has been used for a long time to investigate energy transfer in photosynthetic membranes.[35] Spectral and time-resolved properties can be studied. Fluorescence is still of interest in many cases (e.g., for the screening of photosynthetic mutants), but its impact is especially important in the study of Photosystem II, because the fluorescence yield of chlorophyll *a* in photosynthetic membranes

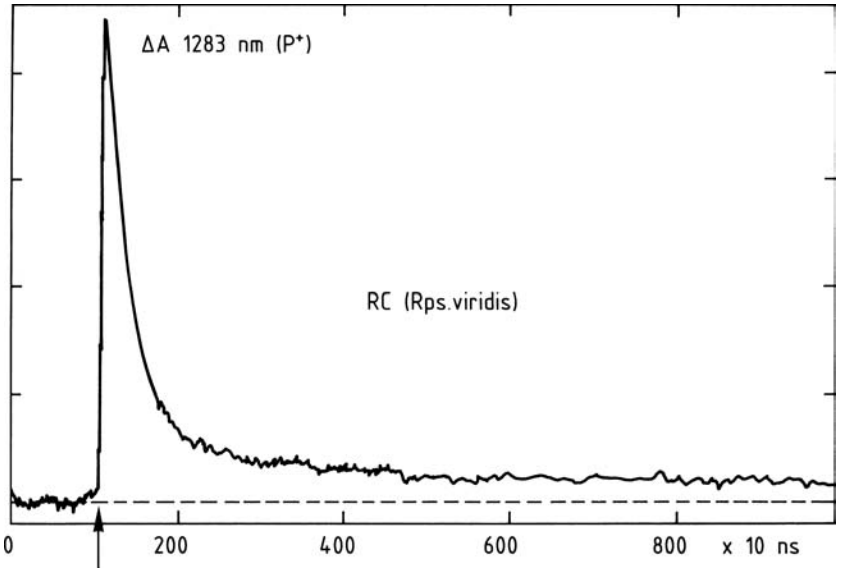

FIGURE 118.4 Absorption change at 1283 nm due to the oxidation of *P* by a flash, followed by its re-reduction by an electron coming from the high-potential heme of the tetraheme cytochrome in *Rhodopseudomonas viridis* reaction centers, at 287 K, at an ambient redox potential of about +200 mV (see Reference 48).

is dependent on several properties of the Photosystem II reaction center: (1) the redox state of Q_A and, by way of consequence, properties related to electron transfer from Q_A to Q_B (herbicide binding and resistance, photoinhibition, etc.); and (2) properties more related to the water-oxidizing enzyme and to the *in vivo* functioning of photosynthesis, such as the pH inside thylakoids or defects in the manganese cluster.[36,37] Also informative on the state of Photosystem II, thermoluminescence is a technique in development, because it can be used *in vivo* with cells or leaves, without isolating reaction centers or membranes.

Vibrational Spectroscopy

Molecular vibrations can be studied by infrared absorption or by Raman scattering spectroscopy. Both methods are fairly classical for the study of small molecules, but their utilization for the complex molecules involved in reaction centers was made possible only by recent developments in lasers and in detectors technology. Resonance Raman spectroscopy is mostly informative on the mode of binding of cofactors (pigments, redox centers) to polypeptides.[38] Fourier transform infrared (FTIR) spectroscopy is used mainly in a differential mode to investigate the structural changes that are coupled to electron transfer, involving polypeptides, cofactors, water molecules, etc. Most studies were conducted on RCs of purple bacteria, in which differential FTIR spectra were recorded for the oxidation of *P*, reduction of bacteriopheophytin, reduction of Q_A or Q_B, oxidation of cytochrome, etc. (see e.g., References 39, 40). These difference spectra have a rich content of information (as exemplified in Figure 118.5) that starts to be unraveled, often by comparisons with model molecules *in vitro* or by selective labeling with stable isotopes (^{13}C, ^{15}N, ^{18}O).

Other Optical Methods

The large number of questions raised by the structure–function relations in RCs, and the wealth of their optical properties, led to intensive use of many methods that cannot be examined here (see Reference 28). Let us briefly mention a few of them. Linear dichroism with oriented samples or coupled to photoselection gives access to the relative and absolute orientations of practically all the cofactors in RCs.[41] Circular dichroism allows for the probing of the interactions between pigments or between pigments and proteins. Several methods give access to properties of excited states: phosphorescence (for triplet states), hole burning (for singlet excited states), the Stark effect (in absorption or fluorescence)

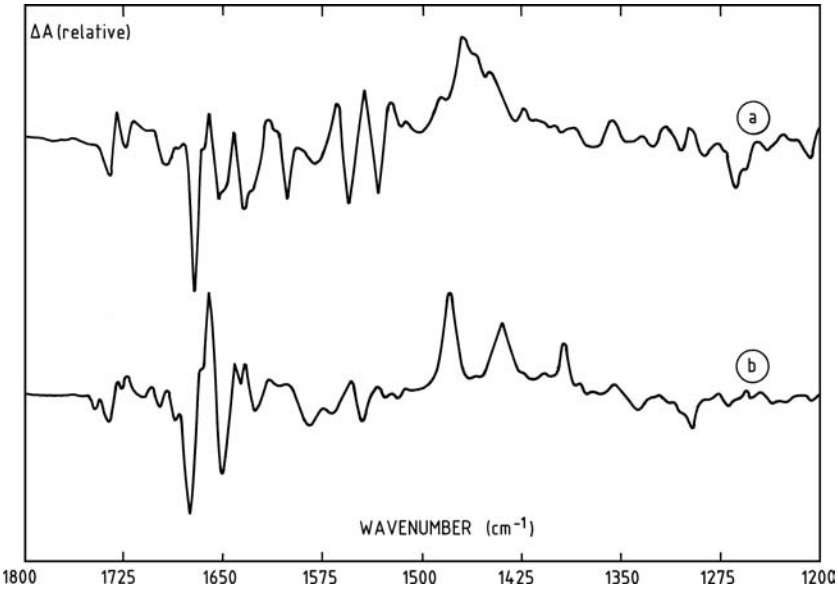

FIGURE 118.5 FTIR difference spectra ("light" minus "dark") of reaction centers of *Rhodobacter sphaeroides* (a) and *Rhodopseudomonas viridis* (b), at 10°C. The spectra are due to the reduction of Q_A (Q_A^- minus Q_A). Q_A is ubiquinone-10 in (a) and menaquinone in (b). The features between 1380 and 1500 cm^{-1} are attributable to the quinone anion, while the features around 1530 to 1570 cm^{-1} are due to an indirect effect of Q_A reduction on the protein. (Spectra kindly provided by Dr. E. Nabedryk.)

for evaluation of the charge–transfer character of singlet excited states, etc. Most of these methods are useful complements to x-ray crystallography, by the kind of information they provide, and by the fact that they can be used more simply on mutants, on intact membranes, or on noncrystallized RCs.

Electron Paramagnetic Resonance

Electron paramagnetic resonance (EPR) is a method that is extremely important for structural and functional studies of RCs. Detailed, authoritative presentations were published for the method and for its applications to RCs (see, e.g., References 42, 43). Briefly, it can be said that EPR detects three types of molecular states, all of which have a nonzero spin: triplet states, radical ions (cations or anions), and centers possessing transition metals. These states are relevant to the functioning of reaction centers.

The triplet state of *P*, designated ^3P, is populated as a result of charge recombination in the primary radical pair P^+I^-. Under conditions of normal functioning, this radical pair is extremely short-lived (under 1 ns) because of a rapid electron transfer from the primary acceptor to the secondary acceptor. When that transfer is made impossible, usually because the secondary acceptor is prereduced or absent, the radical pair may live between 10 and 100 ns, and decay primarily by charge recombination with high probability (10 to 100%) of populating the state ^3P. This artifactual reaction is extremely informative with regard to interactions between *P* and the primary electron acceptors and to the structural properties of *P*: orientation, degree of symmetry of the pair, etc. It is, thus, frequently studied, mainly by EPR spectroscopy.[44]

Radicals are formed in electron transfer reactions involving organic molecules such as chlorins [*P*, (bacterio)chlorophylls, (bacterio)pheophytins], quinones (Q_A, Q_B, A_1 of Type I RCs), tyrosine (TyrZ and TyrD in Photosystem II), carotenoids, etc. Classical EPR spectroscopy, now complemented by more elaborate techniques such as pulse EPR, ENDOR, or high-field EPR, is the most efficient way to study them (see examples of applications in References 3, 4, 14, 42–45).

EPR is the major tool for determining the redox state of metal centers and of some of their structural properties. Many of them participate in secondary steps of electron transfer in RCs: iron–sulfur-centers

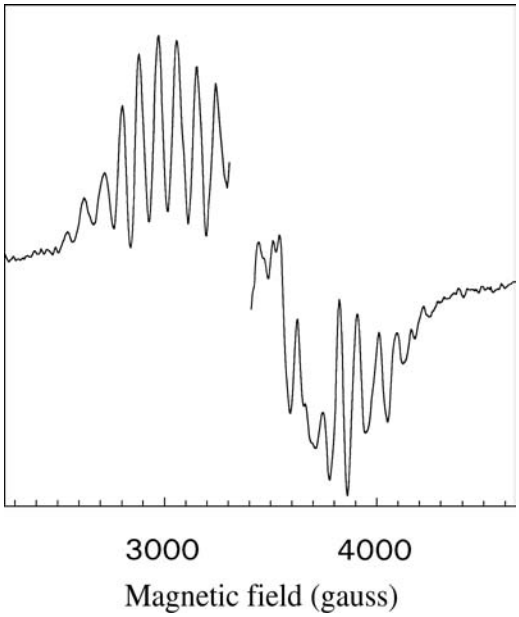

FIGURE 118.6 EPR spectrum measured in Photosystem II membranes at 10 K (X-band at 9.45 GHz; modulation amplitude: 25 G): difference between a sample illuminated at 200 K and a sample kept in darkness, before freezing to 10 K. The spectrum is attributed essentially to the S_2 state of the $(Mn)_4$ water-oxidizing enzyme. (Data kindly provided by Dr. A. Boussac.)

(in low-potential Type I RCs), cytochromes (in purple bacteria and in Photosystem II), Mn cluster in the water-oxidizing enzyme of Photosystem II, etc. Each is EPR-detectable at low temperature in one or several of its redox states: the reduced state for iron–sulfur centers, the oxidized state for cytochromes. The situation is more complex for the Mn cluster, which includes four Mn ions[10,11,46] (see Figure 118.6). X-ray absorption (near-edge structure and extended fine structure) is used in conjunction with EPR to derive a hypothetical structure in each of the redox states of the cluster.[10]

Electrochemical Properties

Midpoint redox potentials of the redox centers bound to the RCs polypeptides are essential properties that determine their functional behavior. They naturally define the possible directions of electron flow, but they are also implicated in controlling the rates of electron transfer steps and the energetic yield of photoconversion. Redox midpoint potentials are measured by classical methods, where a potential is imposed electrically or chemically, and the redox state of the studied couple is measured, usually by a spectroscopic technique such as EPR or UV-visible absorption spectroscopy. The approximate redox potentials of redox centers are given in Table 118.1, in a manner that emphasizes similarities between classes of reaction centers. Several values are not known precisely, mainly because they are too positive (donor side of Photosystem II) or too negative (first acceptors of Photosystem I and of other Type I RCs). Midpoint potentials depending on pH are given for pH = 7.0. The table clearly shows that electron-accepting and electron-donating sides can be classified into two separate classes that share common features. This has been recognized for a long time, and the more recent findings on green sulfur and on heliobacteria lead to valuable hypotheses on the phylogeny of photosynthetic organisms.[8,20,25]

Facts and Questions

The availability of detailed crystallographic three-dimensional structures for several classes of RCs makes these proteins interesting objects. They already served as models for membrane proteins, since they were

the first of them to provide a three-dimensional structure at nearly atomic level. They are also important for the study of electron transferring proteins in general because of the possibility to trigger charge separation precisely with a short pulse of light and for the study of electron transfer reactions with many spectroscopic methods.

It should be kept in mind, however, that the relationships between the structure and the function of RCs include a large number of unresolved basic problems that are the motivations of a strong research effort.

In the best-known purple bacteria, understanding of the primary electron transfer events is still rudimentary: why is a dimer needed as primary electron donor, what is the function of the monomeric bacteriochlorophyll located on the active branch, what makes possible a high yield of charge separation even at low temperature, why are there two branches in the RC structure and why is only one of them active?

How can a better knowledge of plant reaction center be arrived at? To what extent can the knowledge acquired on purple bacteria be used to better understand Photosystems I and II? What is the mechanism of water oxidation, a key biological process that proves difficult to unravel?

Electron transfer from Q_A to Q_B in purple bacteria and in Photosystem II is sensitive to many parameters, including the presence of a metal center (most often Fe^{2+}). How does this step work? How is it coupled to H^+ movements? Are there privileged paths for H^+ around Q_B? Are there well-defined structural changes of the protein during the process, as indicated in a seminal paper?[47]

Generally, the description of function in RCs is limited to the cofactors (pigments and redox centers). Apart from scaffolding, what are the roles of the protein? How are its structural changes coupled to electron transfer? In order to receive satisfying answers, all of these basic questions will require concerted multidisciplinary approaches in the future.

Biological Incorporation of Alternative Quinones into Photosystem I

119.1 Introduction

All well-characterized photosynthetic reaction centers contain quinone molecules. Type II reaction centers, such as Photosystem II (PS II), contain two quinones, one that functions as a bound one-electron acceptor, and the other that functions as a mobile two-electron (and two-proton) accumulator. In PS II, plastoquinone-9 (PQ-9) serves the role of the mobile quinone, which shuttles electrons to Photosystem I (PS I) via the cytochrome $b_6 f$ complex. Type I reaction centers, such as PS I of cyanobacteria and green plants, contain two bound phylloquinones (PhQ — vitamin K_1, 2-methyl-3-phytyl-1,4-naphthoquinone).[1–4] One or both PhQ molecules function as one-electron acceptor, shuttling electrons from the primary acceptor A_0 (a chlorophyll *a* monomer), to F_X (a [4Fe-4S] cluster).[5] PhQ neither becomes protonated as part of the electron transfer process nor diffuses from the PS I complex as part of its normal function. The drop in Gibbs free energy from A_0 to F_X is estimated to be ca. 250 mV[6] to 320 mV.[7,8] Thus, PhQ plays an important role as an intermediate in the early stages of electron transfer in PS I.[8]

Phylloquinone has become a focus of a variety of structure function relationships due to its central role in electron transfer. The PhQ molecules can be extracted from PS I using dry or water-saturated diethyl ether[9,10] or using hexane containing 0.3% methanol.[11,12] Water-saturated ether extraction also removes a significant number of antenna chlorophylls, and all of the carotenoids (and probably lipids), while leaving the iron–sulfur clusters unaffected. As might be expected, both extraction procedures block room-temperature electron transfer from A_0 to the iron–sulfur clusters.[4,9] Reconstitution of one PhQ fully restores electron transfer from A_0 to the iron–sulfur clusters.[13] Iwaki and coworkers reported that PhQ could be replaced by a variety of quinones with appropriate redox potentials.[14] Moreover, an assortment of non-native quinones can be inserted into the PhQ binding site *in vitro*.[15,16] In particular,

artificial quinones (benzo- naphtho-, anthraquinones) and quinoid compounds added *in vitro* to chemically extracted PS I bind to the PhQ site and are capable of forward electron transfer.[13,17,18] Biggins suggested that in addition to energetic considerations, a necessary structural constraint was the presence of an alkyl tail.[19] However, a recent review supported the assessment that a quinone head group of appropriate redox potential is alone capable of restoring electron transfer from A_0 to the iron–sulfur clusters.[16]

In this chapter, we focus on protocols that were developed for modifying or replacing PhQ *in vivo*. This method utilizes the biosynthetic machinery of the cell to replace PhQ with PQ-9, a molecule otherwise associated with PS II, and with a variety of naphthoquinone derivatives. We will first identify candidates for genes responsible for the biosynthetic pathway of PhQ. It will be shown that inactivation of these genes disallows PhQ production. We will then describe the physiological and bioenergetic changes that result from the insertion of PQ-9 and naphthoquinone derivatives into the PhQ binding site. These derivatives will be shown to result from a specific gene inactivation or from *in vivo* feeding of (naphtho- and anthra-) quinones to living cells.

119.2 Phylloquinone Biosynthetic Pathway

The only known function of PhQ in cyanobacteria and plants is to function as an electron transfer cofactor in PS I. In spite of its importance in cyanobacteria, the biosynthetic route of PhQ was not previously elucidated. Many prokaryotes contain the metabolic pathway for the biosynthesis of menaquinone (MQ), a PhQ-like molecule (Figure 119.1). In certain bacteria, MQ is used during fumarate reduction in anaerobic respiration.[20,21] In green sulfur bacteria and in heliobacteria, MQ may function as a loosely bound secondary electron acceptor in the photosynthetic reaction center.[22] The genes encoding enzymes involved in the conversion of chorismate to MQ were cloned in a variety of organisms. MQ differs from PhQ only in the tail portion of the molecule: an unsaturated C-40 side chain is present, rather than a mostly saturated C-20 phytyl side chain. Therefore, the synthesis of the naphthalene rings in PhQ and MQ involves similar steps in both pathways.

Given that PhQ biosynthesis is comparable to MQ biosynthesis, the starting molecule for the naphthoquinone nucleus is isochorismate (Figure 119.2), which is ultimately derived from shikimic acid. The first committed step involves the loss of pyruvate and carbon dioxide with the attachment of 2-oxoglutarate to the benzene ring.[23] The next two steps involve stripping the aromatic ring of the hydroxyl group and subsequently attaching a CoA to the aromatic carboxylate group. A succinyl moiety provides the C-2 through C-4 carbons in the formation of the second aromatic ring, which is catalyzed by DHNA

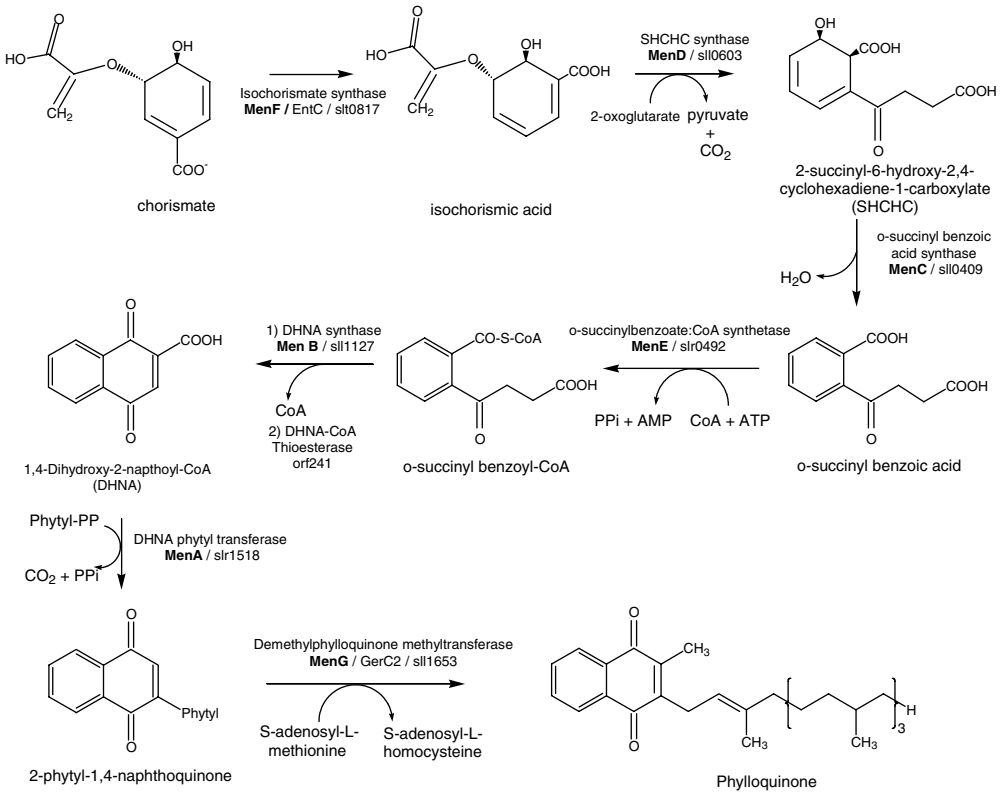

FIGURE 119.2 Proposed biosynthetic pathway of phylloquinone in *Synechocystis* sp. PCC 6803. The genes responsible for the biosynthesis of menaquinone were initially described in *E. coli*. The homologs of these genes were identified in the genome sequence of *Synechocystis* sp. PCC 6803, and *menA*, *menB*, *menD*, *menE*, and *menG* were confirmed by experiment.

synthase with subsequent removal of the CoA by a thioesterase. Both quinone oxygens are derived from water, not from molecular oxygen.[24] At this point, the naphthoquinone head group of PhQ is essentially formed. The biosynthesis of the phytyl tail is thought to be generated from acetyl-CoA through the mevalonate pathway to form geranylgeranyl pyrophosphate.[25] This molecule is then hydrogenated to phytyl pyrophosphate using NADPH as the contributing electron donor.[26] The synthesis of the PhQ phytyl tail and the MQ isoprenoid tail is treated in greater detail in the literature.[27] The remaining steps involve attaching a phytyl group in the C-3 position, with loss of pyrophosphate and carbon dioxide from the pyrophosphate-phytyl group and carboxylate, respectively. Finally, the demethyl-PhQ is methylated, with the methyl group derived from L-methionine, at the C-2 position.

The search for the proteins involved in the PhQ biosynthetic pathway in *Synechocystis* sp. PCC 6803 begins with a search for the genes involved in MQ biosynthesis in other organisms. The genes encoding enzymes involved in the conversion of chorismate to MQ were cloned in *Escherichia coli*[28–34] and *Bacillus subtilis*.[35–38] Specific genes involved in the pathway were identified in spinach[39] and *Bacillus stearothermophilus*.[40] MQ biosynthetic genes were also identified by homology in a variety of other genomes (Table 119.1), including *Haemophilus influenzae* and *Arabidopsis thaliana*.[41] The genome database for *Synechocystis* sp. PCC 6803[42] contains homologs for several genes that encode enzymes for MQ biosynthesis: *menF* (isochorismate synthase), *menD* (2-succinyl-6-hydroxy-2,4-cyclohexadiene-1-carboxylate synthase), *menE* (*O*-succinylbenzoic acid-CoA ligase), *menB* (DHNA synthase), and *menA* (identified as a MQ biosynthesis protein). Possible homologs of *menC* and ORF241 (the DHNA thioesterase) were also identified in database searches. The proposed pathway is illustrated in Figure 119.2. We will focus here

[a] No homologous proteins were identified.

on the dedicated steps to PhQ synthesis from isochorismate, involving products of the *menD*, *menC*, *menE*, *menB*, ORF241, *menA*, and *menG* genes. The product of the *menF* gene is involved as a dedicated step, even considering that isochorismate also participates in the synthesis of serine and enterochelin.[60] Each protein in the PhQ biosynthetic pathway was examined individually for domain/active site homologies between *Synechocystis* sp. PCC 6803 and organisms ranging from bacteria to higher plants. The phylogenetic tree was determined for each gene product, suggesting overall evolutionary ties among organisms.

In general, the phylogenetic tree comparisons for *menD*, *menC*, *menE*, *menB*, and *menA* indicate that *Synechocystis* sp. PCC 6803 (*Syn*) and *B. subtilis* (*BSU*) tend to be paired first. *E. coli* (*Eco*) and *H. influenza* (*HIN*) also tend to form an initial pair throughout the biosynthetic pathway. Those two first pairs (*Syn*/*BSU* and *Eco*/*HIN*) are usually joined before *A. thaliana* (*Art*) intersects. The *Syn* enzymes tend to be more closely conserved with other bacteria, with *Art* showing the greatest discrepancy in protein alignment.

The *menD* (SHCHC synthase) and *menC* (o-succinyl benzoic acid synthase) genes are the first two genes coding for enzymes that are likely to be involved exclusively in PhQ biosynthesis. Starting with isochorismic acid, SHCHC synthase produces 2-succinyl-6-hydroxy-2,4-cyclohexadiene-1-carboxylate (SHCHC), with the subsequent enzyme o-succinyl benzoic acid synthase producing o-succinyl benzoic acid. Both *menD* genes from *E. coli*[28] and *B. subtilis*[37] were cloned. The *menC* gene was also cloned in *E. coli*[30] and *B. subtilis*.[36,43] The protein alignment of SHCHC synthase from both organisms shows a 42 to 52% similarity. The similarity is 37 to 46% for o-succinyl benzoic acid synthase (Table 119.1). Protein alignments for SHCHC synthase show a highly conserved *N*-terminal domain. This domain may be part of the active site or a possible substrate-binding site for 2-oxoglutarate, which is consumed in the reaction with pyruvate and carbon dioxide released as side products. O-succinyl benzoic acid synthase (*menC*) has no well-defined domains that can be identified as active sites. However, there are several sets of residues that have complete identity in the direction of the *C*-terminal end. The reaction involves loss of an hydroxyl from the substrate without cofactor involvement, and this may suggest that a smaller less-conserved active site may be present.

The largest enzyme in the pathway is o-succinyl benzoate:CoA synthetase, which has ca. 450 residues and is encoded by the *menE* gene The homology comparison of the sequence of this protein in *Synechocystis* sp. PCC 6803 to other organisms is lower compared to the other protein similarities probed in this pathway. There is a *C*-terminal region of identity that could represent the active site domain. This generally basic domain has conserved hydrophobic, basic, and hydroxyl amino acids from residues 350 to 400 and also contains two conserved proline residues. The enzyme attaches a CoA while utilizing the energy of hydrolysis of ATP (to AMP). This suggests that there may be several domains that perform different aspects of the enzyme function.

The *menB* gene product (DHNA synthase) is the most conserved protein within the PhQ biosynthetic pathway among different organisms (Table 119.1). The *menB* gene in *A. thalina* has the lowest identity

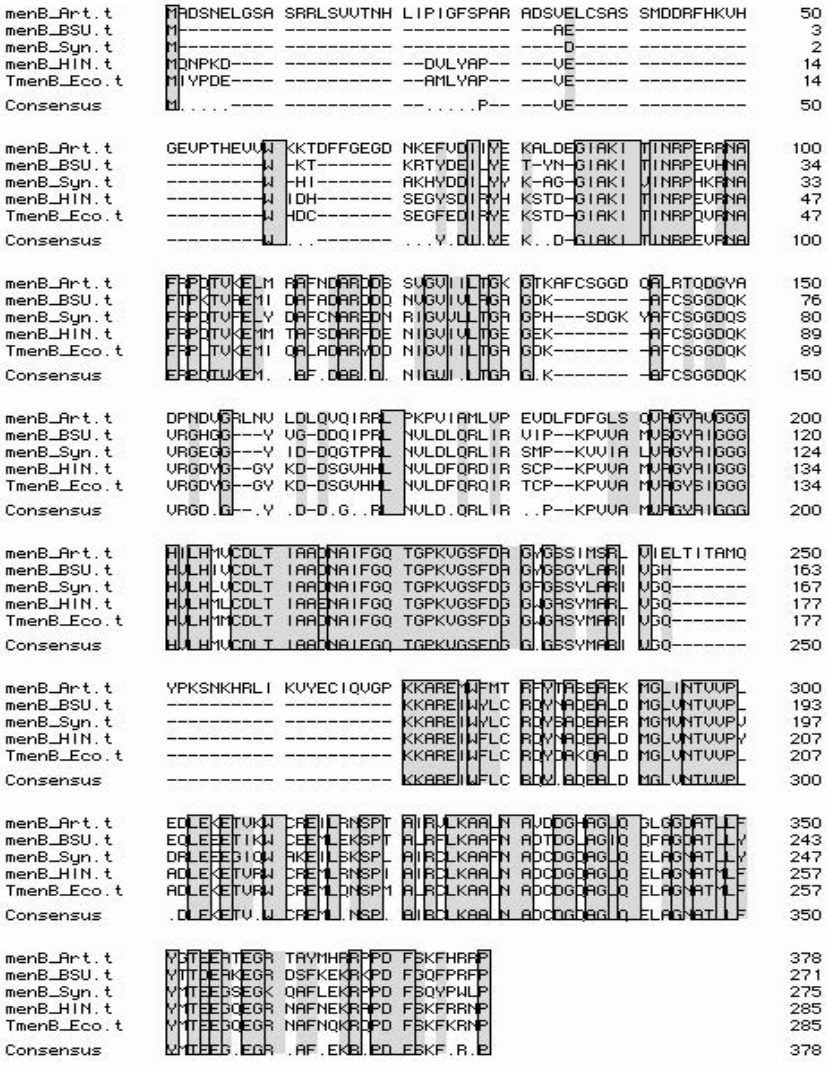

FIGURE 119.3 Homology comparison of the *menB* gene. Abbreviations for each organism: Art is *Arabidopsis thaliana*, BSU is *Bacillus subtilis*, Eco is *E. coli*, HIN is *Haemophilus influenza*, and Syn is *Synechocystis* sp. PCC 6803.

at 54%, which may be due to the presence of an intron in the *N*-terminal region (Figure 119.3). The overall homology of the bacterial proteins is about 80%. The *C*-terminal half is highly conserved. Given the high degree of similarity, the second ring closure can be considered a critical step, converting a substituted benzene ring into naphthoquinone. DHNA synthase is the only step that does not produce by-products or consume high-energy cofactors. This suggests that the enzyme mechanism is refined, hence imparting a high degree of functional and structural similarity between species.

Given the small amount of information on *orf241*, we will only acknowledge that it is a likely component of the MQ/PhQ biosynthetic pathway. The homology is relatively low among the organisms compared (Table 119.1). It is thought to be a thioesterase that releases CoA from DHNA-CoA.

The DHNA phytyl transferase encoded in the *menA* gene is clearly an important step, and it differentiates the production of PhQ from MQ in *Synechocystis* sp. PCC 6803. The homology comparisons among organisms are surprisingly similar, given that DHNA phytyl transferase in *Synechocystis* sp. PCC 6803 transfers to the naphthoquinone a C-20 mostly saturated phytyl tail, whereas in other bacterial organisms, it transfers an unsaturated C-40 group.

The *menG* gene codes for a demethyl-PhQ methyl transferase. The gene involved in the PhQ biosynthetic pathway has proven difficult to identify because methylation is a common cellular reaction and is performed by many enzymes on a variety of substrates.[44] Although the homology comparison among organisms is comparable to other enzymes in this pathway, the protein alignment fails to yield a consistent domain for the active site.

Genes involved in PhQ biosynthesis of *Synechocystis* sp. PCC 6803 were thus identified. The percent homology and identity among organisms vary significantly, leading to tentative identification. To prove that these proposed genes code for enzymes involved in the biosynthetic pathway of PhQ, several were selected for gene disruption studies.

119.3 Phylloquinone Biosynthetic Pathway Gene Disruption

Five of the seven identified genes (*menA, menB, menD, menE*, and *menG*) in the PhQ biosynthetic pathway were disrupted. With the pathway interrupted at specific points, our goals were to characterize the physiology of the mutant cells and to study the effect on PS I electron transfer.

The *menB* and *menA* genes were chosen for the first set of inactivation studies. The *menB* gene encodes DHNA synthetase, which is responsible for the biosynthesis of the naphthoquinone head group. By disrupting the *menB* gene, we hoped to prevent the synthesis of a molecule that would be capable of binding in the PhQ site. We expected that *menB* gene inactivation would lead to an empty PhQ binding site. The *menA* gene was chosen for disruption as a complement to the *menB* gene. The *menA* gene encodes phytyl transferase, which is responsible for displacing the carboxy group with a phytyl group. According to Itoh and coworkers, tail-less naphthoquinones are capable of binding to the PhQ site.[16] By disrupting the *menA* gene, synthesis halts at the production of DHNA, which we thought might be incorporated into the PhQ binding site. This could allow us to determine if phytylation is a necessary precondition for binding, and whether the naphthoquinone head group, with an appropriate redox potential, is the only requirement for function. The results of these mutations are discussed in the next section.

The *menD* and *menE* genes were chosen for the next set of inactivation studies. The *menD* gene was chosen because its product was thought to be the first dedicated step in the pathway. The *menE* gene was chosen to confirm the gene's assignment, given the relatively low sequence homology. Isochrosmate, the product from the previous step (coded by *menF*), is an intermediate found in many other pathways and yet has been recently determined necessary for PhQ biosynthesis.[60]

The identification of the *menG* gene was difficult, and after careful consideration of several potential methylases in a variety of genomes, disruption as the open reading frame *sll1653* in *Synechocystis* sp. PCC 6803 confirmed its involvement in the PhQ biosynthetic pathway.[45,55] This disruption is important, not only in identifying the proper methylase, but also for generating demethyl-PhQ, a potentially interesting substitute for PhQ in PS I.

119.4 Results of Phylloquinone Pathway Gene Disruption

The *menA* and *menB* genes were inactivated by disrupting and partially removing the targeted gene with an antibiotic resistance cassette, thereby preventing a fully functional enzyme from being translated.[46] High-performance liquid chromatography coupled with detection by UV-Vis (HPLC/UV-Vis) and mass spectroscopy (LC-MS) showed that pigments extracted from membranes and PS I trimers of the *menA* and *menB* deletion mutant strains lacked detectable levels of PhQ. Therefore, one immediate conclusion was that the *menA* and *menB* genes in the *Synechocystis* sp. PCC 6803 genome code for phytyl transferase and DHNA synthase, respectively, in the PhQ biosynthetic pathway. However, interesting observations were made regarding function. The *menA* and *menB* deletion mutant strains continued to grow photoautotrophically, albeit with increased doubling times, indicating that photosynthesis was still functional. Plastoquinone-9 (PQ-9) was found by HPLC/UV-Vis and LC-MS analysis in extracted pigments of PS I

trimers from the *menA* and *menB* deletion mutant strains but not from the wild type. Using low-temperature electron paramagnetic resonance (EPR) spectroscopy, it could be shown that an electron derived from P700 reduced the terminal iron–sulfur clusters, F_A/F_B. Additionally, steady state electron transfer rates of cytochrome c_6 to flavodoxin in PS I complexes from the *menA* and *menB* deletion mutant strains were about 80% that of the wild type. This led us to two possible conclusions: (1) that the PhQ-binding site is bypassed as the electron is transferred from A_0 to the iron–sulfur clusters or (2) that a foreign molecule is recruited into the PhQ binding site, and that it participates as a cofactor in forwarding the electron transfer.

A series of careful magnetic resonance experiments identified a foreign quinone as this intermediate cofactor in PS I.[47] Initially, a semiquinone anion radical (Q^-) was observed transiently by EPR spectroscopy at X-band (9 GHz) when living whole cells of the *menA* and *menB* deletion mutant strains were illuminated with white light. The molecule responsible for this radical was not only capable of accepting an electron from P700, but also, it was able to discharge electrons forward to the iron–sulfur clusters. When the radical was photoaccumulated at low temperatures and studied at higher microwave frequencies (34 GHz), the larger *g*-anisotropy hinted that the quinone contained a single benzoquinone ring rather than a naphthoquinone ring. Also, the prominent hyperfine splittings due to the 2-methyl group of PhQ[48] were missing. ENDOR spectroscopy showed that Q^- remained the same in the *menA* and *menB* deletion mutant strains, and there were two asymmetric methyl groups on the molecule. These structural features are consistent with the identity of the intermediate cofactor as PQ-9. Spin-polarized transient EPR at three microwave frequencies (X, Q, and W-bands) indicated that the vector connecting the quinone carbonyls is pointed toward P700, which is the same orientation as in native PhQ.[49] Pulsed EPR techniques indicated that the distance from P700 and Q^- is 25.3 Å, which is close to the $P700^+$ and A_1^- distance.[50,51] Hence, Q^- is the same orientation and distance from P700 as PhQ. The accumulated magnetic resonance data, therefore, prove that Q^- is PQ-9, and that it is likely bound to the same site as PhQ.

We next focused on the kinetics of electron transfer in PS I complexes from the *menA* and *menB* deletion mutant strains. Electron transfer rates are sensitive to distance, Gibbs free energy, and reorganization energies among donor and acceptor pairs. The replacement of PhQ with PQ-9 translated into changes in forward and backward electron transfer rates through the quinone. In particular, the forward electron donation from the PhQ^- to F_X slowed by about a factor of 10 relative to the wild type. In wild-type PS I, the charge recombination between $P700^+$ and $[F_A/F_B]^-$ is multiphasic after a saturating flash.[6] When measured in the absence of an external electron acceptor, the reduction of $P700^+$ is biphasic, with typical lifetimes of 10 to 30 ms and 80 to 100 ms. The reduction of $P700^+$ in *menA* and *menB* deletion mutant strains reduction are also biphasic, with lifetimes of ca. 3 and ca. 10 ms. The 30-fold increase in the $P700^+$ reduction kinetics in the *menA* and *menB* deletion mutant strains was confirmed using CW EPR spectroscopy. The 3 ms phase has proven to be a highly useful characteristic that allows one to determine whether PQ-9 or PhQ is in the binding site. The changes in the electron transfer kinetics are explained by a change in the redox potential of PQ-9. It is estimated to be ca. +95 mV more oxidizing than PhQ, resulting in a thermodynamically "uphill" electron transfer step from Q^- to F_X.[6]

The *menD* and *menE* genes code for enzymes that function and reside earlier in the PhQ biosynthetic pathway. These genes were targeted for gene inactivation due to the possibility that there may be an alternative pathway that circumvents the *menD* and *menE* gene inactivations. The *menD* and *menE* deletion mutant strains were similarly engineered by inserting an antibiotic-resistant cassette into the gene.[52] The physiological characteristics of the *menD* and *menE* deletion mutant strains were found to be similar to the *menA* and *menB* deletion mutant strains. The cells grew at a fraction of the wild-type rate, and all showed high light sensitivity, a lower chlorophyll content *a* per cell, and a lower ratio of PS I:PS II. All of the mutant strains had comparable rates of whole-chain and PS II oxygen evolution. Using LC-MS and HPLC-UV/Vis detection of extracted pigments we showed that the mutant strains did not contain PhQ in the thylakoid membrane or the purified PS I complexes. As with the *menB* deletion mutant strain, PQ-9 was identified in PS I complexes by Q-band EPR spectroscopy. A 3 ms lifetime was also observed for the kinetic back-reaction. Therefore, similar to the *menA* and *menB* deletion mutant strains, PQ-9 is recruited into the PhQ binding site of PS I in the *menD* and *menE* deletion mutant

strains. We therefore find the same general physiological and phenotypic responses when PQ-9 is in the PhQ binding site of PS I, regardless of which gene in the PhQ biosynthetic pathway is inactivated. A corollary of this conclusion is that no alternative pathways exist for the biosynthesis of PhQ in *Synechocystis* sp. PCC 6803.

119.5 High-Light-Tolerant Strains of *menB* and *menD* Mutant Strains

All of the original PhQ biosynthetic pathway mutant strains (including *menA*, *menB*, *menD* and *menE*) have a low content of PS I and a low chlorophyll content per cell, and they are sensitive to high-light intensities.[46, 52–54] Previously known as the *menB* mutant strain, the original *menB*18 deletion mutant strain is high-light sensitive and was used for the experiments described here. Two high-light-tolerant strains were isolated from the *menD* and *menB* deletion mutant strains. Colonies of the mutant strains were streaked onto BG11 agar plates containing antibiotics and were placed under high-light intensities (160 μM m^{-2} s^{-2}). The *menD*-R1 and *menB*26 mutant strains were two of several isolates that could grow under high-light intensities. The latter mutation also occurred spontaneously in liquid cultures grown under normal-light intensities (40 to 60 μM m^{-2} s^{-2}), in which the cells were recultured continually for many generations. Presumably, these high-light-tolerant, suppressor mutations can be generated in any of the PhQ biosynthetic pathway gene disruption mutations. To prevent the development of high-light tolerance, liquid cultures should only be grown for two to five generations under low-light intensities (5 μM m^{-2} s^{-2}). Cells stored on BG11 plates in low light have not been found to become high-light tolerant.

Approximately 20 *menB* deletion mutant strains were characterized for growth rate, PS I to PS II ratio, PhQ/PQ-9 content, and oxygen evolution.[54] Of the 20, 10 were high-light tolerant. The other strain, *menB*26, was selected for robustness, the ability to tolerate high-light intensities, and the ability to grow in the presence of supplemented (benzo-, naphtho-, and anthra-) quinones. This trait was necessary for the naphthoquinone feeding experiments described later. The other strains did not have the ability to thrive in liquid cultures containing low levels (10 μM) of supplemented quinone.

The doubling time of the *menD*-R1 mutant strain (30 h) was comparable to the wild type (26 h), which grows nearly three times faster than the *menD* mutant strain (80 h).[52,54] Both the *menB*18 and *menB*26 mutant strains had comparable doubling times (over 70 h). Additionally, *menB*26, unlike *menB*18, was more tolerant of quinones added to the liquid growth media. The *menB*18 strain tended to die or enter an early stationary phase upon addition of quinones.

The high-light tolerant *menD*-R1 and *menB*26 strains are otherwise similar to the original high-light sensitive *menD* and *menB*18 strains.[54] All mutant strains contain active PQ-9 in the PhQ binding site, and the chlorophyll content per cell is reduced to 67 to 85% that of the wild type. To determine if the quinone-binding pocket contained a secondary site mutation, the appropriate regions of the *psaA* and *psaB* genes were sequenced and found to be identical to the wild type, *menD*, and *menB*18 strains. The quinone-to-chlorophyll ratio for all mutant strains is similar to that of the wild type, 1:50.

The differences that arise between the original mutant strains (*menD* and *menB*18) and the high-light-tolerant strains (*menD*-R1 and *menB*26) relate to the PS I to PS II ratio.[54] Phenotypic differences are noted in several ways. Shown in Figure 119.4 is the 77 K fluorescence emission of whole cells on a equal cell number basis; the 720 nm emission is characteristic of PS I, while the 685/695 nm emission is characteristic of PS II. When compared to the wild type, the original *menD* strain and the original *menB*18 strains reduced ratios of PS I:PS II. This is also true of the *menA* and *menE* mutant strains (not shown). The high-light-tolerant *menD*-R1 and *menB*26 strains have PS I:PS II ratios comparable or greater than those of the wild type. Oxygen evolution rates provide a striking example in the differences in the high-light-tolerant strains relative to the wild-type strains and the *menD* and *menB*18 mutant strains. Under the growth conditions of these experiments, the wild type, and the *menD*, *menB*18, and *menE* mutant strains have approximately a 1:3 ratio of water-to-bicarbonate whole-chain oxygen evolution versus PS II oxygen evolution alone. In the high-light-tolerant strains, this ratio drops to ca. 1:1. Whole-chain

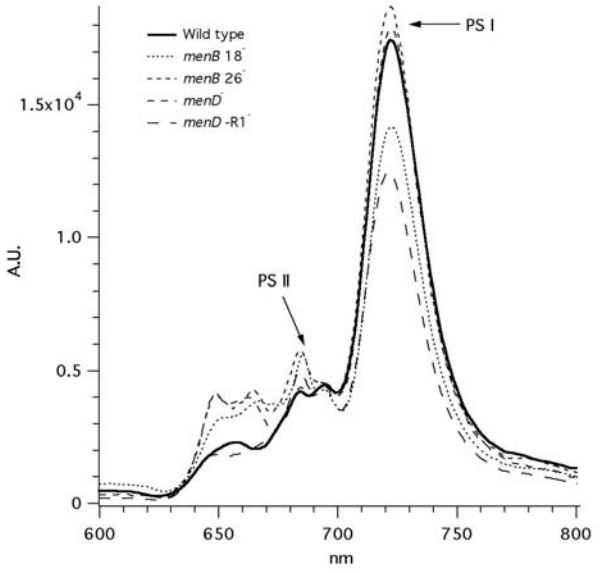

FIGURE 119.4 Fluorescence emission spectra at 77 K of whole cells from *Synechocystis* sp. PCC 6803 wild type, *menB* mutant strains, and *menD* mutant strains. Spectra were recorded at the same cell density and normalized relative to PS II. Each spectrum was the average of the four measurements performed in duplicate. The excitation wavelength was 435 nm, which excites mostly chlorophyll. PS II and its accessory pigments exhibit emission maxima at 685 and 695 nm; PS I has a maximum emission at 721 nm.

electron transfer rates decrease 86% and 58% in the *menD*-R1 and *menB*26 strains, compared to the original strains (*menD* and *menB*18), respectively. The PS II oxygen evolution levels of *menD*-R1 and *menB*26 decreased to 30% and 49% of the levels in the original *menD* and *menB*18 mutant strains, respectively. The change in oxygen evolution for *menD*-R1 and *menB*26, coupled with the 77 K fluorescent measurements, indicate that the cell has downregulated the amount of PS II. The lower level of PS II per cell generates less reductant under high-light conditions, an amount that can be adequately processed by the lower amount of PS I. This leads to a lower level of stress on the cells under high-light conditions, which, in turn, allows the cells to grow.

119.6 Modification of Phylloquinone through Gene Inactivation

A novel PhQ derivative was introduced biologically into the PhQ binding site by inactivating a specific methyltransferase coded by the *menG* gene, one that methylates the naphthoquinone ring ortho to the phytyl tail.[55] Mass spectrometric measurements show that pigments extracted from PS I complexes of the *menG* mutant strain lack the $m/z = 450$ peak characteristic of PhQ and instead reveal an $m/z = 436$ peak characteristic of 2-phytyl-1,4-naphthoquione. EPR spectroscopy of the photoaccumulated semiquinone Q^- signal in PS I complexes showed the presence of a hyperfine doublet that indicated the presence of an H in place of the CH_3 group ortho to the phytyl tail.

Unlike PQ-9 containing mutant strains, the phenotype of the demethyl-PhQ mutant strain is similar to the wild type.[55] The doubling times of the *menG* deletion mutant strain under photoautotrophic and mixotrophic conditions are the same as those of the wild type. The chlorophyll content is also comparable. The steady state rates of electron transport for PS I complexes of the *menG* deletion mutant strain were virtually identical to those of the wild type. Transient EPR shows that the lifetime for the forward electron transfer from Q^- to the iron–sulfur clusters slowed from a lifetime of 290 ns in the wild type to 600 ns

in the *menG* deletion strain. This would be expected if the redox potential of 2-phytyl-1,4-naphthoquinone were +50 to +60 mV more oxidizing than PhQ. The lifetime of the $P700^+[F_A/F_B]^-$ backreaction also decreased from 80 ms in the wild type to 20 ms in the *menG* deletion mutant strain.

119.7 *In Vivo* Recruitment of Media-Supplemented Naphthoquinones

Success at genetically disrupting the PhQ biosynthesis pathway allowed us to embark on a project aimed at the biological replacement of the native PhQ with alternative quinones. The initial gene disruptions resulted in a PQ-9 molecule occupying the PhQ site of PS I. These mutant strains allowed us to introduce a variety of phytylated benzyl- and naphthoquinone in order to probe the structural requirements for quinones to function in PS I. This method has proven to be a useful adjunct to PhQ removal by organic solvents[16,19,56,57] and has additional advantages because it allows physiological observations of living cells. We found that it is possible to introduce phytylated quinones into the PhQ site *in vivo* by utilizing the phytyltransferase in the *menB* mutant strain and the methyltransferase in the *menA* mutant strain and by selecting tolerant strains (Figure 119.2).[53] For example, the *menB*26 mutant strain prevents the naphthoquinone head group from forming, yet it allows phytylation of a quinone supplemented in the growth medium. Because the *menA* mutant strain is incapable of phytylation, it serves as a control to determine if the supplemented quinone head group alone is capable of displacing PQ-9 and functioning in forward electron transfer.[53]

To assess the stability of PhQ over time and to gauge the relative binding of PQ-9, an *in vivo* PhQ pulse experiment was conducted on the living *menB*26 cells. Within 15 min of the addition of PhQ to the growth media, PQ-9 was completely displaced by PhQ in PS I. Hence, PhQ must enter the PhQ binding site by diffusion, and it must displace the resident PQ-9. This rapid incorporation of PhQ suggests a significant difference in the affinity of the binding site for PhQ and PQ-9. This displacement of the loosely bound PQ-9 is the key for incorporating alternative phytylated quinones.

Reincorporation of PhQ was also achieved by supplementing the *menB*26 growth media with the enzymatic product of DHNA synthetase, 2-CO_2-1,4-naphthoquinone, which resulted in a 94% replacement of PQ-9 with PhQ.[53] The Chl:Q_{total} in the supplemented *menB*26 deletion mutant strain is comparable to that of the wild type. This proves that phytyltransferase (the *menA* gene product) and methylase (*menG* gene product) remain functional in the mutant strains. Furthermore, PQ-9 is retained when the *menA* deletion mutant strain is supplemented with 2-CO_2-1,4-naphthoquinone. Because the *menA* gene codes for phytyltransferase, we concluded that the phytyl group is important for binding the quinone into the site.

Reincorporation of PhQ also occurs with compounds such as 2-CH_3-1,4-naphthoquinone.[53] Supplementation with the deuterated derivative of 2-CD_3-1,4-naphthoquinone yields a d-PhQ product that still contains the CD_3 moiety. This shows that the deuterated methyl group is unaffected by the phytyl- and methyltransferase enzymes. The addition of 1,4-napthoquinone led to the detection by LC-MS of a mixture of phytylated and phytylated/methylated molecules.[53] However, there was clear EPR evidence for *in vivo* incorporation of 1,4-naphthoquinone into the PhQ site with an orientation similar to that of PhQ in the wild type. This was an unexpected result, considering that previous *in vitro* incorporation of 1,4-naphthoquinone in solvent-extracted PS I complexes led to the incorporation of 1,4-naphthoquinone with an altered orientation.[49,58]

It may even be possible to incorporate 1,2-naphthoquinone into the PhQ site.[54] Growth media supplementation with unsubstituted 1,2-naphthoquinone led to an admixture of phytylated and methylated/phytylated naphthoquinone molecules as well as to the retention of significant amounts of PQ-9 when assayed by LC-MS. The replacement of PQ-9 with phytylated 1,2-naphthoquinone was therefore low (<50%) in the *menB*26 mutant strain. The chlorophyll-to-quinone ratio was 63, which is higher than that for the wild-type Chl:Q_T of 42.[59] This suggests, although it does not prove, the presence of a subpopulation of PS I that lacks a bound quinone molecule. The contribution of the 3 ms $P700^+$

backreaction drops to <10% in the 1,2-naphthoquinone supplemented cells. Two new phases were observed, with lifetimes of 10 ms and 34 ms in a 1:1 ratio, totaling 50% of the total decay. Photoaccumulation of Q^- at 200 K revealed a complex EPR spectrum, suggesting that PQ-9 and a 1,2-naphthoquinone derivative are reduced. More work is obviously required, but this experiment hints at the promise of biological incorporation of novel quinones into the PhQ binding site of PS I.

Finally, a double gene knockout of the *menB* and *menG* genes has been generated (*menBG*). This mutant strain has the potential to phytylate naphthoquinones without additional methylation. The *menBG* mutant strain should allow for comparisons of novel, phytylated quinones in the PhQ binding site, with or without an accompanying methyl group. The *menBG* mutant strain, therefore, adds an additional option for probing the structure and function of molecules in the PhQ binding site of PS I.

120.1 Introduction

There is no need to emphasize that without light, life on our planet as we know it would not exist. Solar radiation, in fact, is a fundamental source of energy for all photosynthetic organisms and microorganisms, and photosynthesis is one of the most important biological processes on earth, which, by consuming carbon dioxide and liberating oxygen, has made the world into the livable place we know today. Light is also a sensory stimulus that provides vital information on the environment to all living beings, terrestrial and aquatic, diurnal and nocturnal, prey and predators, to creatures provided with "eyes" and nervous systems, as well as to aneural life forms like plants, fungi, and unicellular microorganisms, such as bacteria, algae, and protozoa.

Many freely motile microorganisms are provided with a photoreceptor apparatus able to perceive the quantity and the quality of light (propagation direction, fluence rate, spectral composition, polarization) in the environment and to transform the absorption of a photon into a biophysical/biochemical signal that can be recognized, elaborated, and transduced to the motor apparatus. Light constitutes, therefore, an information signal that controls their movement and eventually brings the cells to accumulate into settings in which the illumination conditions are best for their growth, survival, and development.[1]

In this chapter, we will focus our attention on the general features of photomovements of freely motile microorganisms, referring to the chapters of other authors for deeper insight into some of the most important case studies (see Chapters 116 and 121–124).

120.2 Photobehavioral Responses of Microorganisms

The main photobehavioral responses are, according to the terminology of Diehn et al.,[2] photophobic reactions, phototaxis, and photokinesis.

In photophobic responses, the sensory stimulus consists of a sudden change in light intensity, which elicits a transient variation in the motor activity of the microorganisms. Step-up and step-down photophobic responses are caused by a step-wise increase or, respectively, decrease in photon flux. Usually,

0-8493-1348-1/04/$0.00+$1.50

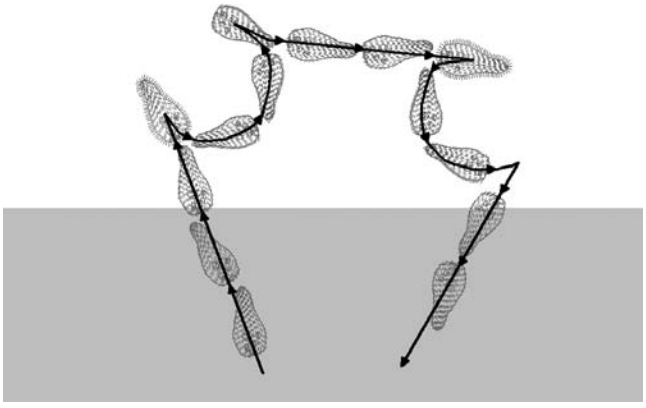

FIGURE 120.1 The step-up photophobic response exhibited by a cell (namely, in this case, the ciliate *Blepharisma japonicum*) upon crossing a dark(gray)-light(white) border.

both photophobic responses consist of a brief cessation of forward movement (stop response) followed by a random change of the direction of movement or, mainly in bacteria, by a variation of the frequency of tumbling/movement inversion. The response pattern depends on the morphology of the microorganism and is independent of light direction. A photophobic response can typically last for several seconds or even a few minutes, after which the microorganism can become adapted to the new illumination conditions. When a swimming cell crosses a dark-light (light-dark) border, it can experience a sudden change in light intensity that triggers a step-up (step-down) photophobic response. The final outcome of these sensory reactions is an avoidance of the lighted (shady) region and accumulation in shaded (lightened) areas (photodispersal or, respectively, photoaccumulation). Usually step-up photophobic reactions occur with a time lag with respect to the stimulus application. This delay decreases with increasing photon flux density and depends on the stimulating wavelength. Similarly, in the case of a step-down photophobic response, the stimulus, now an abrupt decrease in light intensity, finally brings the cells to escape from shadowed areas and to accumulate in lighted regions (photoaccumulation). In Figure 120.1, a schematic reconstruction of a step-up photophobic response is presented.

Phototaxis results from the detection of the direction of light propagation and is a directional response. It is defined as positive or negative according to whether the oriented movement is toward or away from the source. Such a response implies the existence of a sophisticated photoreceptor apparatus. To perceive the position of the light source, in fact, an asymmetry in the photoreceptor apparatus, which allows the cell to sense the vectorial characteristics of the light signal, is required. This can be accomplished, for instance, by means of a single photosensing unit coupled to a screening device that periodically shades the photoreceptor proper.

In photokinesis, light intensity affects the absolute value of the microorganism velocity. If the velocity increases (decreases) when the organism is exposed to light, photokinesis is positive (negative) and causes photodispersal (photoaccumulation).

It is worth noting that the same organism may be able to exhibit more than one photoresponse, which, in some cases, causes the same result (e.g., photodispersal induced by negative phototaxis and step-up photophobic responses) and, in other cases, depends on the environmental illumination condition (e.g., positive or negative phototaxis elicited by low- or high-light intensities).

Consequently, photoaccumulation and photodispersal of cell populations can be the result of phobic, kinetic, and tactic responses, and drawing conclusions on behavioral strategies can be difficult.

Reported in Figure 120.2 is a schematic block diagram of a typical experimental apparatus for measuring photomotile responses in microorganisms. Monitoring IR radiation, which is not perceived by the microorganisms, allows the operator to observe the cells without "disturbing" them. To quantitatively measure photoresponses, population methods and single-cell track (usually computer-assisted[3]) analyses

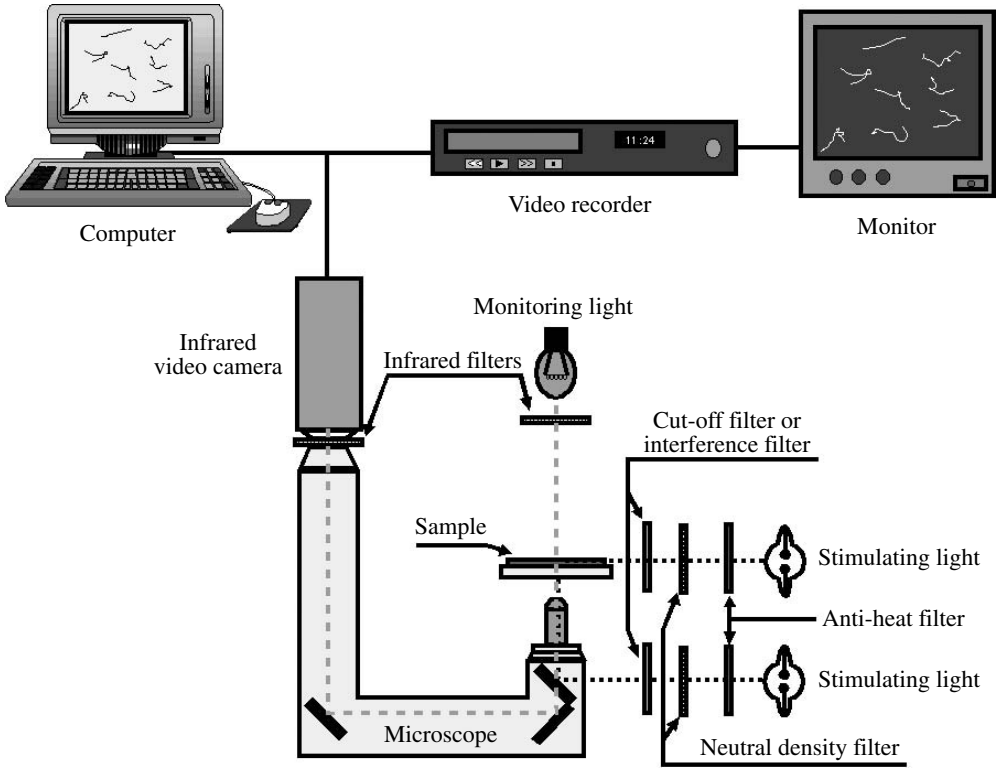

FIGURE 120.2 A typical experimental apparatus for studying photobehavioral responses in microorganisms.

are currently used. Both have advantages and drawbacks, and here, we only want to point out that these measurements deserve an accurate choice of meaningful parameters with which to reliably discriminate among different reactions. As explained above, photodispersal (photoaccumulation) may result not only from true negative (positive) phototaxis but also from a series of step-up (step-down) photophobic reactions, as well as from positive (negative) photokinesis. A still useful, even if "old-fashioned," experimental setup to discriminate between, for example, step-up photophobic responses and negative phototaxis, was used in the case of ciliate *Stentor coeruleus*[4,5] and is reported in Figure 120.3.

Photomotile responses allow photosynthetic bacteria and microalgae to gather in environments in which light is bright enough to efficiently drive the photosynthetic process but, at the same time, not too intense to lead to photoinhibition or photobleaching. However, even for microorganisms that do not harvest and convert light energy directly for their metabolism, like ciliates, for example, light can be an environmental cue to accumulate into habitats that can be favorable for reproduction or propitious for their prey and, in general, for food.[6] In microorganisms containing endogenous photosensitizers, used as defensive pigments against predators (e.g., *Blepharisma japonicum* and *Stentor coeruleus*, see Chapter 122), even relatively dim light can cause severe damage. Their ability to escape lighted spots is directly linked to their survival.[7]

Some microorganisms, finally, have been shown to be able to perceive and transduce short-wavelength ultraviolet radiation (UV-B = 280 – 315 nm). As in aquatic ecosystems and, in particular, in microorganisms, UV-B has been shown to impair photosynthetic activity, curb growth and metabolic rates, damage DNA, spoil photo- and gravi-orientation in the water column, and hurt cell viability and motility (see Chapter 116). This ability of cells to elaborate UV-B photons as environmental sensory stimuli can directly lead the cells into sheltered areas, thus avoiding harmful UV irradiation.[8,9]

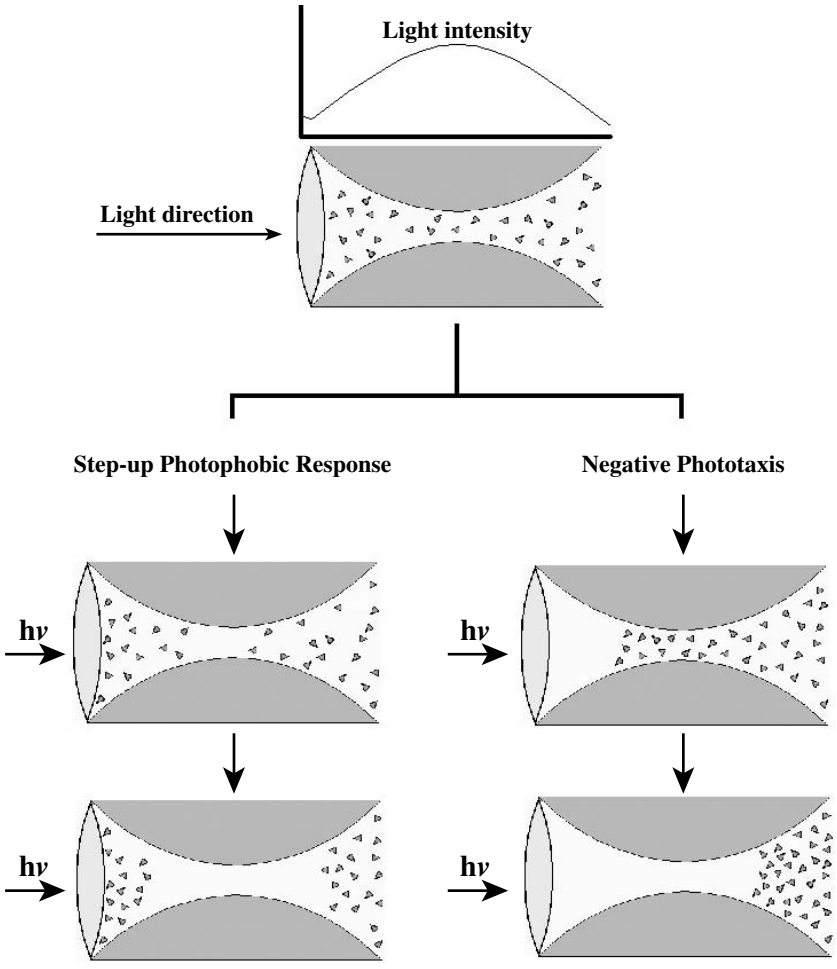

FIGURE 120.3 Cell distribution in the light field produced by a convex lens in the case of negative phototaxis and step-up photophobic responses.

120.3 Photosensory Transduction Chains

In Figure 120.4, the block diagram of the photosensory transduction chain is reported: following absorption of a photon, the photosensing chromophore undergoes molecular modifications leading to the formation of the signaling state that triggers the transduction chain, eventually acting on the motor apparatus.

In what follows, we will go through the different blocks, trying to highlight the main and most promising experimental approaches to the different problems. It is worth noting that because of their intrinsic multidisciplinary character, most key problems encountered in these kinds of studies can best be faced using different experimental techniques and methodologies.

To identify the chromophore responsible for the absorption of the photon triggering the whole photosensory process, action spectroscopy[10] is an unmatched, effective nondestructive technique (see Chapter 115). If not affected by artifacts (screening and reflecting organelles, energy transfer processes, multiple sensing chromophores, etc.) and not made unreliable by wrongly choosing the behavioral parameters describing photoresponsiveness, the structure of an action spectrum is proportional to that

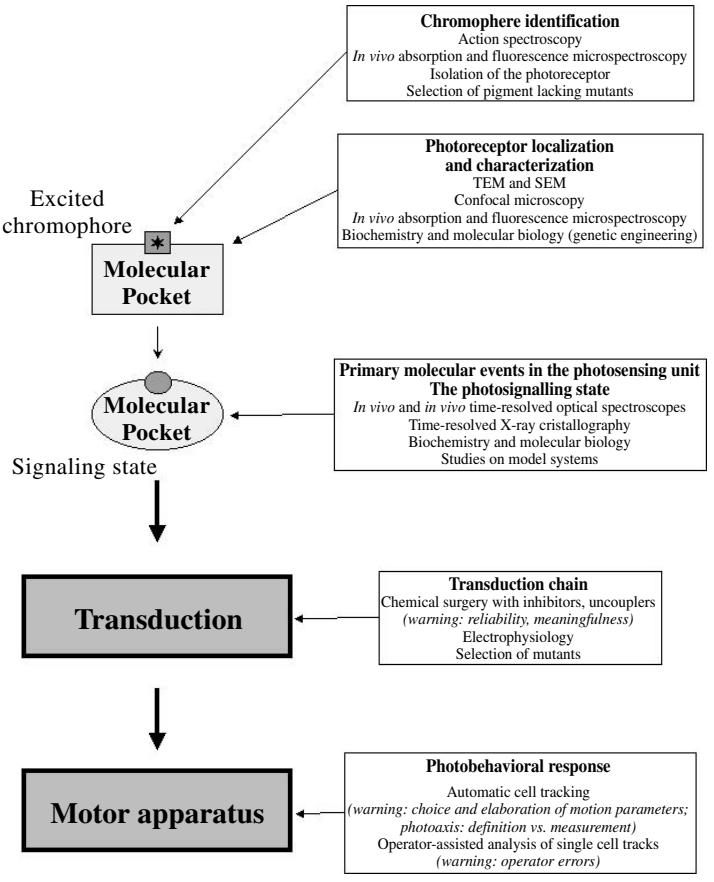

FIGURE 120.4 The photosensory transduction chain in photomotile microorganisms.

of the chromophore absorption spectrum. Action spectra, moreover, relate photoresponsiveness to the wavelength of the stimulating light, thus directly linking the functional absorption of photons by the presumed photoreceptor pigment to the observed physiological reaction. Even if it has some limitations and can be painstakingly time-consuming, nonetheless, action spectroscopy provides direct information about the photoreceptor pigment, is noninvasive, usually requires simple and nonexpensive instrumentation, and is one of the most, and once the only one, used techniques for studying photoresponses in microorganisms.

Whenever it is possible to extract the chromophore, or better, to isolate the integral photoreceptor unit, all chemical, biochemical, and physicochemical assays can be used to carefully characterize the structural and functional properties of the chromophore. The chromophore, for instance, can be purified by HPLC, and its molecular weight and structure can be determined by mass, IR, and NMR spectroscopy.[11,12] Information on the apoprotein–chromophore complex, as another example, can be obtained by means of column chromatographies, mono- and bidimensional gel electrophoresis, and enzymatic assays. When reliable hypotheses are available on the chemical nature of the sensing chromophore, specific inhibitors of its biosynthesis can advantageously be employed.[13]

Mutants lacking one or more photopigments can allow discrimination, which is responsible for the photobehavioral reaction. In mutants with a photosensing unit deprived of the light-detecting chromophore (blind mutants), exogenous addition of chromophores restoring the photoresponse can bring identification of the nature of the molecule with the role of perception and transduction of light stimuli.[14]

Electron microscopy and *in vivo* absorption and emission microspectroscopy and confocal microscopy allow detailed morphological information on the photoreceptor unit to be obtained and the spectroscopic characteristics of the candidate sensing chromophores in their physiological molecular environment to be determined. *In vivo* absorption and emission microspectroscopy and confocal microscopy also permit the photosensing units to be localized within the cell and, in some cases, the maps of their spatial and spectral distributions to be determined.

Time-resolved optical spectroscopies *in vitro*, x-ray crystallography, and microspectroscopies *in vivo* can provide thorough information on the kind and the time-scale of primary molecular reactions occurring in the photoreceptor unit, up to some tiny detail of molecular rearrangements following the absorption of the photon.[15]

These studies on biological structures and substructures can profitably be complemented with studies on model systems. Artificial models of natural photoreceptors have, in fact, been widely utilized, with the aims of elucidating the molecular mechanisms of light-driven biological processes[16] and of devising synthetic tools able to mimic the performance of biological light detectors and transducers and suitable for technological applications.[17] The study of model photosensing and phototransducing systems not only helps clarify the relationships between light-induced modifications in the photopigment and subsequent biophysical/biochemical signal transduction steps but can also yield impressive advancements in natural pigments-based photonic devices for applications in holography, neural network optical computing, and optical memories[18,19] (see Chapters 134, 135, and 139).

Mutants deficient in one or more biochemical pathways, or engineered organisms, can supply data for understanding the molecular machinery operating in the transduction process. Similar figures can be achieved by means of chemical surgery with metabolic drugs, such as, for example, inhibitors and uncouplers. Of course, any drug can severely affect not only the specific pathway presumed to be involved in the sensory process but also many others, and cell viability in general, so that extreme care has to be taken to avoid unreliable results and misleading conclusions.

Electrophysiological techniques, in particular, patch-clamp, may be difficult to use with microorganisms, the dimensions of which vary from a few hundreds to a few μm. They are the only techniques (with the exception of some special fluorescent probes, like ion-specific fluorescent indicators), however, that allow photoelectric effects, like light-induced membrane depolarizations, action potentials, and photic receptor potentials, to be measured. Then, these data can be related to light-induced modification of the motor (flagella and cilia) activity.[20]

Electrophysiological studies are also possible on intact cells, by performing photoelectric measurements in cell suspensions.[21]

Chromophores

As photomotile microorganisms belong to almost every phyletic group that includes unicellular organisms, it is not unexpected that a multiplicity of chromophores with completely different molecular structures and spectroscopic features can act as the prosthetic group of the photoreceptor. To whatever class the organisms belong, in order to be able to detect light over a large range of the solar spectrum, their chromophores usually have broad absorption bands with high molecular extinction coefficients. In some cases, the spectral sensitivity can be widened, if different chromophores, absorbing in contiguous spectral ranges, are spatially assembled in molecular frameworks to maximize the collective interaction among them.

The presently known chromophores are 4-hydroxy-cinnamic acid (e.g., in *Ectothiorhodospira halophila*, now reclassified as *Halorhodospira halophila* see Chapter 123), carotenoids (e.g., retinal in *Halobacterium salinarum*, see Chapter 124), pterins and flavins (e.g., in *Euglena gracilis*, see Chapter 115), and dianthronic molecules (e.g., stentorin in *S. coeruleus* and blepharismins in *B. japonicum*, see Chapter 122).

These chemically different chromophores undergo different, early, light-induced molecular transformations: photoinduced charge transfer (flavins, stentorin, and blepharismins), *cis-trans* photoisomerization (retinals, 4-hydroxy-cinnamic acid), and energy transfer (pterins–flavins).

Primary Reactions and Signaling States

A chromophore acts as a photosensing-phototransducing biological device, because it is not isolated but rather embedded in and interacting with a molecular framework (an apoprotein, in most cases) that "senses" the molecular modifications induced by light in the chromophore and, in its turn, gives rise to the signaling state.[22] The intermolecular interactions between the chromophore and its surrounding microenvironment (its "molecular pocket") can severely affect its photophysical and photochemical properties, the probability of radiationless and radiative transitions from the first excited singlet and triplet states, and the yields of energy and charge transfer processes from excited and metastable states. Study of them can, therefore, lead to the formulation of hypotheses on the primary mechanisms operating in the photosensing-phototransducing process.

Photoreceptor Organelles

A chromophore coupled to a transducing protein without any further "superstructure" is a simple photosensory system seldom found in microorganisms. Instead, to efficiently harvest and transduce the information carried by light, in most microorganisms, the photosensors are organized in ordered structures, with complexity that amazingly varies between prokaryotes and eukaryotes and within eukaryotes. This wide variety of ordered structures is due not only to their different origins, generally regarded as polyphyletic even within the same class, but also to their functional requirements. The photoreceptor organelles must usually operate over a wide range of light incidence angles and intensities and discriminate between different wavelengths to reduce the environmental noise. Above all, it must match the cell morphology and locomotion pattern, especially if detection of the direction of light is required. In phototactic (able to perceive the direction of light) flagellated microalgae, the essential components of a photoreceptor apparatus are the stigma (or eyespot) and the photoreceptor proper. The main role of the stigma is, thanks to the helical movement of the cell, to periodically shade the photosensing structure, so that the stigma–photosensor system constitutes a highly directional apparatus. The modulation of the photic stimulus on the photosensor allows the cell to track the light source and correct its trajectory, finally pointing toward (positive phototaxis) or away from (negative phototaxis) the light source.[23]

In ciliates, the capability of responding to directional light stimuli depends on the structural properties of the photoreceptor (see Chapter 122), and different subcellular organelles have been suggested to be decisive factors in photomovements of the cells: from pigment granules to stigmas, from watchglass (Lieberkuehn) to composed crystalline organelles.[24]

In bacteria, finally, the photoreceptor molecules can be embedded into the cell membrane (as is the case of sensory rhodopsins in *H. salinarum,* see Chapter 124) or can simply be located in the cytoplasm (as is the case of PYP in *H. halophila*, see Chapter 123).

Dark Steps

As shown in the block diagram of Figure 120.4, the light stimulus is converted by the photoreceptor, through its primary molecular reactions, into an intracellular signal that must travel up to the motor apparatus in order to alter the motile behavior of the cell. The intracellular events of the signal transduction chain triggered but not directly driven by the photic stimulus are called "dark steps." In general, they encompass processes for signal amplification without adding noise and feedback mechanisms, in order to extend dynamic ranges, improve accuracy, prevent overloads, and prevent signal reduction and uncontrolled fluctuations.[25]

The large variety of photoreceptor systems of unicellular microorganisms entails a wide diversity of possible mechanisms of signal transduction. Moreover, notwithstanding their apparent "simplicity," microorganisms show a significant richness and complexity of sensory pathways originated by the need to balance multiple environmental signals (oxygen, carbon and nitrogen sources, pH, light, etc.), to move toward or maintain themselves in the optimum environment for growth.

Among bacteria, the halophilic archaebacterium *H. salinarum* has been thoroughly studied, and many of the molecular processes at the basis of its phototransducing mechanisms were clarified (see Chapter 124). In this cell, the light stimulus is transduced through mechanisms similar to those discovered in bacterial chemotaxis. The sensory rhodopsins I and II play their roles of photosensors, thanks to their complexation with the corresponding transducer proteins, HtrI and HtrII, respectively, all of them inserted into the membrane. The transducer proteins modulate the kinase activity that, in turn, controls, through a cytoplasmic phosphoregulator, probably a fumarate molecule, the flagellar motor switching which is placed in the membrane.[26]

In the case of the purple-sulfur bacterium *H. halophila*, the molecular mechanisms responsible for signal generation were comprehensively studied and clarified (see Chapter 123), but the signal transduction pathway from PYP to the flagella still needs to be identified.

As far as microalgae are concerned, the structural components and the signaling cascade initiated by the photoreceptor excitation have not yet been definitely ascertained (see Chapter 121). Electrophysiology measurements can provide crucial complementary information on the light-initiated and light-dependent processes in green flagellated algae. Unfortunately, algal cells do not usually exceed 10 to 20 μm in diameter, which makes microelectrode recording problematic. In several cases, however, thanks to the asymmetric localization of the signal sources within the cell, the photoinduced electrical signals involved in phototaxis and photophobic response in green flagellates could be measured extracellularly from individual cells and from cell suspensions.[21]

In *C. reinhardtii*, different lines of evidence point to the presence of heterotrimeric G-proteins for coupling between the rhodopsin and the ion channels. In analogy to the invertebrate visual system, IP_3 may be a good candidate for a messenger, mediating activation of the ion channels in the plasma membrane.[27]

Recently, in the photoreceptor organelle of *Euglena gracilis*, a new type of blue-light receptor flavoprotein, photoactivated adenylyl cyclase (PAC) (see Chapters 115 and 121), was discovered and biochemically characterized, indicating cAMP as the second messenger for step-up photophobic response of this green alga. It constitutes a unique case of a protein performing two different functions simultaneously: photoreception and transduction (cAMP synthesis catalysis).[28]

Among ciliates, particularly interesting are the cases of *B. japonicum* and *S. coeruleus*, for the richness of the data available and because of the difficulty in depicting a unitary framework. In fact, two main hypotheses are, at present, available. The first hypothesis was that, following light stimulation, an intracellular increase of proton concentration could lead to the opening of calcium channels, indirectly by depolarizing the membrane or directly by altering the conductance of specific calcium channels.[29] More recent results cast doubt on this simple model, suggesting the involvement of amplification and transduction steps similar to those operating in the visual process of metazoans. The fact that in *B. japonicum* and *S. coeruleus* the light-induced ciliary beating stop occurs with a delay up to 1 sec (significantly long in comparison with the millisecond lag-time of mechanoresponses in the same organisms) has been considered indicative of specific time-limiting biochemical processes involving G-proteins and second messengers as cGMP or IP_3.[30–32] Among the most important questions to clarify in this framework is the mechanism of G-protein activation in *B. japonicum* and *S. coeruleus*. The presently available experimental results bring us to hypothesize that the G-protein could be activated by the intracellular pH variation following the release of protons from the photoreceptor, but a direct interaction between the excited photoreceptor and the G-protein cannot be discarded, even though its nature is currently unknown (see Chapter 122). It is, finally, worth noting that a substantial number of data allow us to set up a satisfactory picture of the electrophysiological basis of photosensory transduction in *B. japonicum* and *S. coeruleus*.[20]

120.4 Concluding Remarks

This introductory chapter should provide basic knowledge for better understanding and enjoying the following chapters devoted to the photobehaviors of some characteristic unicells. In those chapters,

further details about the richness of the chromophore molecular structures and pockets and of the "dark steps" involved in microorganism photosensory perception and transduction will be presented.

In nature, of course, light is not the only environmental signal affecting the behavior of microorganisms, and their motile responses result from the integration of "internal needs" (such as, for instance, metabolism and cell cycle) with a diversity of external stimuli (chemical, mechanical, gravitational, photic, etc.). Integrated investigations of their motile responses to different environmental signals (chemical and photic, for example) might, therefore, offer clues for a deeper understanding of sensory processes in microorganisms.

Finally, we would like to retake a general consideration on the lack of an unitary description of the mechanisms at the basis of photomovements of microorganisms.[33] At present, it looks like (as it does for almost every single unicell) an *ad hoc* model holds: specific photosensing chromophores embedded in and interacting with particular molecular pockets, distinctive signaling states triggering unique and different molecular cascades. The question then becomes, is the cause of such a multiplicity of interpretations a consequence of our low level of knowledge and understanding or is it an intrinsic feature of these natural phenomena?

121.1 Introduction

Information is essential for all forms of life — so it is important to understand how information is perceived, how it is stored, how it is passed on, and how it is used by organisms as they live and reproduce. In the world of photosynthetic microorganisms, where virtually all life depends on solar energy, light becomes a source of information, used to orient microorganisms spatially and to guide their movements or growth. The full exploitation of this information necessitates proper perceiving devices, able to change the small signal represented by the light falling upon them into a larger signal and response of an entirely different physical nature, i.e., these devices must perform perception, transduction, and amplification.

The most primitive photoreceptors are represented by extensive two-dimensional patches of photopigment, which probably exist in the Chlorophyta; whereas more complex photoreceptors, such as three-dimensional crystals of proteins, are present in the Euglenophyta and Chrysophyta. The photosensory proteins in these algal structures occur only in small amounts because they are used to detect light not to collect it. They are concentrated in photoreceptive structures and do not contribute to the color of the organism. This is an important consideration because a primary, historical criterion for algal taxonomy and phylogeny has been bulk pigment composition. Yet, sensory pigments played no role in these determinations, because it is generally believed that different algal groups have different photosensory pigments; furthermore, the association of particular sensory pigments with particular algal groups was based largely upon the examination of only one or a few species.

For a long time, the behavior of microalgae in response to light stimuli attracted the attention of scientists, who hoped that the simplicity of the material would make this phenomenon easy to investigate. On the contrary, the undertaking turned out to be more difficult than expected, and to date, a clear

0-8493-1348-1/04/$0.00+$1.50

understanding of the phenomenon has still to be attained, while the comprehension of the visual process in humans is extensive. Initial ideas on the chemical nature of receptors for photobehavioral responses were gained by measurements of their spectral sensitivity. Action spectroscopy results were then screened and supported by other methods, such as biochemistry, absorption spectroscopy, and molecular biology, that integrated different investigative approaches and shed more light on photoreceptive pigments.

In this chapter, we present a classification of algae and photosensitive apparatus, explain the theoretical basis of their functioning, introduce the methods used to study visual pigments and to compare their different performances, and conclude with a survey of the visual pigments thus far characterized in algae, emphasizing gaps and discrepancies in current knowledge. Our approach will be focused only on the "vision" phenomenon in motile microalgae, i.e., the processing (transduction) of a photic stimulus into an oriented movement; for an overall survey of other phenomena still controlled by photoreceptors, e.g., phototropism, photomorphogenesis, and circadian clock setting, the reader is referred to Chapters 132 and 133 of this book. For more detailed insight into the different photoreceptors evolved in algae, which regulate their growth and development, the reader is referred to the review by Hegemann.[1]

121.2 Phylogenesis and Classification of Algae

The algae are a polyphyletic, noncohesive, and artificial assemblage of O_2-evolving, photosynthetic organisms that includes macroalgae and other highly diverse groups of microorganisms known as microalgae. Most algae are aquatic in fresh or marine waters, but some species may be found growing in such diverse habitats as tree trunks, snowbanks, hot springs, and even within desert rocks. They can be motile and unicellular or pluricellular and nonmotile at some stage of their life cycle. The number of algal species was estimated at between one to 10 million, and most are microalgae. This assemblage of organisms includes prokaryotic blue-green algae (cyanobacteria), prochlorophytes, and eukaryotic algae. Eukaryotic algae represent a minimum of five phyletic assemblages: green algae, red algae, euglenoids, chromophyte algae, and dinoflagellates (Figure 121.1). In eukaryotic algae, which represent at least five distinct evolutionary lineages, there are also protists, traditionally recognized as fungi and protozoa.[2]

All biologists agree that unicellular eukaryotes have prokaryotic ancestors. Among the algae, fossil records show the blue-green algae lineage arising early in the Precambrian period. Euglenoids, red and green lineages, date from the middle to late Precambrian period. Chromophyte algae are first seen in the Paleozoic period. While, dinoflagellates date from early to late Mesozoic period.[3–5]

Historically, the major groups of algae are classified into divisions (equivalent to the zoological phylum) on the basis of pigmentation, chemical nature of photosynthetic storage product, photosynthetic membranes (thylakoid) organization and other features of the chloroplasts, chemistry and structure of cell wall, number, arrangement and ultrastructure of flagella (if any), and the occurrence of any other special features.[6] The information in Figure 121.2 can help us summarize the phylogenetic relationship of microalgae. The starting point of this scheme is an ancestral prokaryote that gave rise to at least two types of organisms: a blue-green alga[7] and an ancestral heterotrophic flagellate.[8] The derivative of the ancestral prokaryote captured a coccoid blue-green alga cell and retained it as a symbiont. As result, the blue-green alga became a system of thylakoids. This association eventually gave rise to red algae. Thereafter, a single-cell red alga was taken up by an ancestral flagellate, so generating chromophytes. Another symbiotic affair between a blue-green alga and an ancestral flagellate gave origin to green algae, and successively to Land Plants. Euglenoids are considered a direct derivative of the ancestral flagellate, with successive symbiotic events for taking up chloroplasts. Finally, the ancestral flagellates, with a relatively recent acquisition of a plastid, generated dinoflagellates.[9,10] Among the approximately 2500 described species of blue-green algae, there are unicellular coccoid, colonial, and filamentous forms, with or without branching or differentiation of specialized cells, such as akinetes (spores) and heterocysts (anaerobic N_2-fixing cells). Eukaryotic microalgae, basically flagellate, also contain some members that are nonmotile (e.g., coccoid) or filamentous, although flagellate stages may be involved in reproduction. Most are unicellular, although a range of colonial types that can be found in the Chlorophyceae and palmmelloid phases are present in the Cryptophyceae.[11]

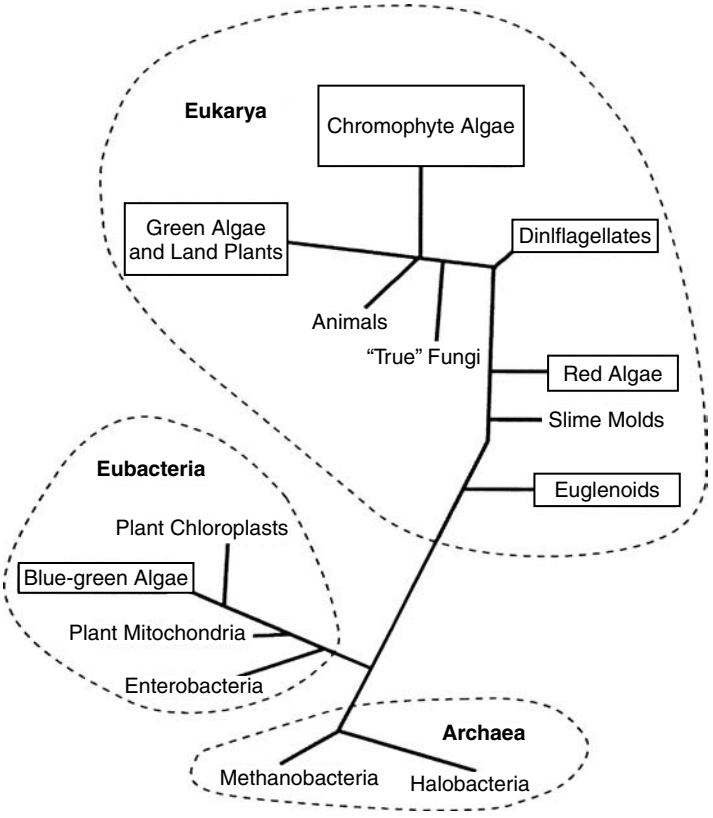

FIGURE 121.1 Phylogenetic relatedness of some group of algae. Lengths of segments are proportional to evolutionary distance based on analysis of ribosomal RNA gene sequences (modified from Gualtieri, 2001).

Eukaryotic cells are usually provided with at least one flagellum, and there may be as many as six.[12] The basic number is two, but in some species, only one emerges from the cell. There is normally one nucleus, although two are found in some dinoflagellates. The cell is covered by a basic plasma membrane; in addition to it, there may be scales or spines, a cell wall, a complex pellicle, or a theca.[13]

121.3 Classification of Photosensitive Apparatus

True vision involves production of a focused image of the external world, and the optical requirements for an eye probably cannot be satisfied by microorganisms, requiring true multicellularity with cell specialization and division of labor. Still, microalgae "eyes" have many similarities with the complex vision systems of higher organisms, because they possess optics, photoreceptors, and signal transduction chain components. The essential elements of these "eyes" are the screening devices, for example, the eyespot, and the detector, i.e., the photoreceptors. Often, the photoreceptor cannot be identified by optical microscopy, while the eyespot can be seen easily because of its size and color, usually orange-red. Sometimes the eyespot function is performed by the whole cell body, and the photosensitive function is demanded by the whole cell membrane.

The eyespot is a roundish shield, inwardly or outwardly concave, and made up of one or more layers of lipidic globules closely packed. The individual globules are not membrane bound, and the eyespot as a whole is not bound to any membrane. These globules principally contain carotenoids that can play the shading role thanks to their strong absorbance.[14] Although the pigments of the eyespot are always

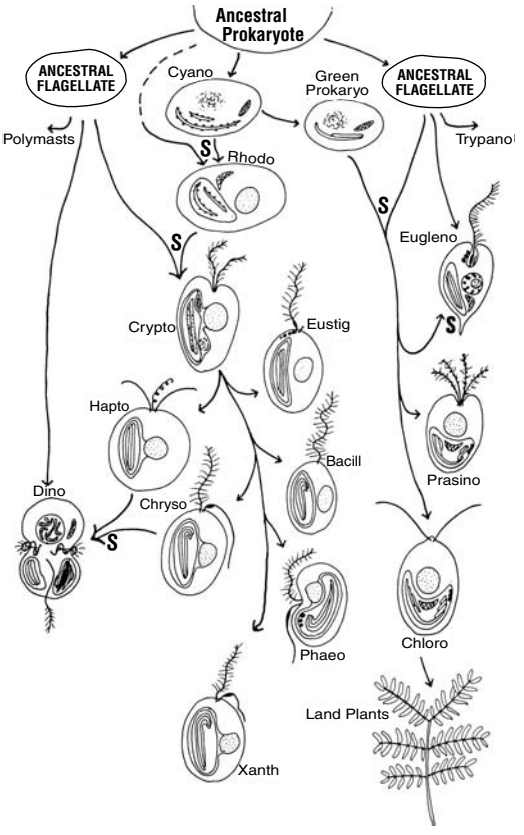

FIGURE 121.2 Phylogenetic relationships of algal groups. S indicates that a symbiotic event occurred (modified from Gualtieri, 2001).

synthesized inside a chloroplast, the globules can be located near its surface or be completely separated from the chloroplast. The photoreceptor, when visible, appears as a swelling of the basal portion of one flagellum or as a separate organelle (the ocellus).

Dodge[15] grouped the different kinds of eyespots into four categories. Keeping in mind this classification, the structure of the photoreceptive systems, and the optical design and molecular organization of photoreceptive proteins, we can divide the photosensitive apparatus of algae into three types[16]:

- Type I, single layer: A single layer of photoreceptor molecules is present inside the whole cell membrane or is located in just the patch of membrane that covers the eyespot. The eyespot, if present, is independent of the flagella and generally multilayered and inwardly concave. If the eyespot is absent, the whole cell body performs the shading function. This means that algae perceive light, even though their photoreceptive systems are not visible.
- Type II, multiple layers: Photoreceptor molecules form a multilayered membrane structure or a three-dimensional membrane protein crystal. The eyespot is outwardly concave and is located close to this structure.
- Type III, multiple layers plus lens: The photoreceptor is more specialized and can be considered an ocelloid. It consists of a lens of complex design and a retinoid. Between the lens and the retinoid, a chamber lined by the plasma membrane is interposed. The eyespot is a pigmented cup wrapping the retinoid.

121.4 Theoretical Considerations

No physical quantity regulates and stimulates the developments of microalgae as strongly as light. Light is electromagnetic radiation characterized by its quality (different wavelengths) and intensity. To measure both parameters and react to them, the microalgae photoreceptor system has to satisfy three main requirements: it should be a photon counter, it should detect either spatial or temporal patterns of light, and it should transmit the detected signal in order to modify the cell behavior. The interpretation of these photoreactions rests upon two postulates:

1. Only the light actually absorbed is effective.
2. Only one quantum is involved in a primary reaction.

Keeping these two postulates in mind, in the following, we discuss a few general principles concerning the functional properties of photoreceptors.

Sensitivity

The ability to perceive and adapt to changing light conditions is critical to the life and growth of photosynthetic microorganisms. Light quality and quantity vary on any given day because of changes in the cloud cover and pollution. Competition for light in an aquatic environment may be particularly fierce because of shading among the different organisms and rapid absorption of light in the water column. Hence, detecting light as low as possible (i.e., a single photon) becomes an adaptive advantage, because a photosynthetic organism in dim light can obtain more metabolic energy if it is able to move to more lighted and suitable areas.

For detecting the direction of light of a specific spectral range, a photoreceptor demands a high density of chromophore molecules (with a high absorption cross section and low thermal noise) organized in a lattice structure. For detecting patterns of light, the number and location of photoreceptors having fixed size and exposure time must be viewed according to the pattern of motion of microalgae. For transmitting the detected signal, a photoreceptor must generate a potential difference, or a current.[17]

All known photoreception systems (those identified with no doubts) are based on rhodopsin-like protein molecules embedded in a membrane (i.e., packed chromophores showing the same parallel orientation relative to the plane of the membrane surface). They can generate a proton motive force or current, thus controlling ion fluxes. The simplest photoreception system consists of a patch of these molecules in the plasma membrane (Type I). In the cases examined,[18] the density of packing of these molecules appears to be about 20,000 to 30,000 molecules/μm^2 of membrane, with a molar absorption coefficient ε of 40,000 to 60,000 M^{-1} cm^{-1} and a dark noise (see after) approximately equal to zero. The number of embedded molecules per μm^2 of membrane, the absorption cross section, and the dark noise are at the best of theoretical limits. Nevertheless, the fraction of photon absorbed from a single layer of these molecules is less than 0.05% (each layer contributes approximately 0.005 OD).

Let us calculate how many photons this simple but real photoreception system can absorb (Type I). On a sunny day, 10^{18} photons per square meter per second per nanometer are emitted by the sun; on a cloudy day, the number of photons lowers to 10^{17}.[19] This means that a photoreceptor of 1 μm^2 can catch at most 10^8 photons per second in its 100 nm absorbance window on the sunniest day. Considering absorption and reflection effects of water, we can correct this figure to 10^7 photons per second striking the photoreceptor surface.[19] Because only 0.05% of the incident radiation will be effectively absorbed by a single-layer photoreceptor, the amount of photons lowers to about 10^3 photons per second. In the case of microalgae, which often use "sequential sampling" (see after), the true signal consists of the number of photons absorbed by the photoreceptor when it is illuminated (for about 400 ms) minus the number of photons absorbed by the photoreceptor when it is shaded by a 50% screen (for about 600 ms). In the case of the sunniest day, the highest signal is about 100 photons per second, which lowers to about 10 photons per second on a cloudy day. Even on the sunniest day, the number of photons absorbed for detecting light direction is very low. Because this photoreceptor does not form any image but detects

only light intensity, this amount of photons is enough; however, this photoreceptor must possess a very low threshold and a very low or negligible dark noise. As a matter of fact, Schaller and coworkers[20] demonstrated that single photons induce transient direction changes and that fluence rates as low as 1 photon $cell^{-1}$ sec^{-1} can actually lead to a persistent orientation in *Chlamydomonas* (Chlorophyceae).

Strategies evolved to increase the sensitivity of a photoreceptor, such as stacking many pigment-containing membranes in the direction of the light path (*Euglena gracilis* is a wonderful example of such a solution) or exploiting the reflecting properties of the eyespot, as in *Chlamydomonas*[21,22] and in different species of dinoflagellates.[23] The effectiveness of the multilayer strategy was experimentally tested by researchers of the W.M. Keck Center of the Syracuse University (R.R. Birge, personal communication). The absorption value recorded on a preparation of precisely ordered bacteriorhodopsin multilayers was close to that recorded on the photoreceptor crystal of Euglena,[24] which consists of more than 100 layers of proteins.[25]

Noise

The ability to detect light is limited by noise.[26,27] Organisms must deal with noise of various kinds:

- Dark noise is the noise inherent in a receptor, constant and independent of light level. It arises from thermal and molecular noises.
- Photon noise (also known as shot noise) is due to the quantum nature of the light stimulus and to the resulting statistical fluctuation in the capture of a photon. This noise can be accurately estimated as the square root of the number of photons captured.
- Response noise leads to random variations in the locomotory response of the microorganism. Response noise can be further divided into motor noise, in which variations occur in locomotion from one time to another in an individual; and developmental noise, in which variations occur between individuals, as a bias to turn toward one side.
- Environmental noise consists of extraneous signals arising from sources other than those of the true signal.

In general, photoreceptors have a noise signal even in absence of a true signal. The problem is to decide whether or not a signal is present, when a given intensity is observed. In the simplest case, the problem becomes that of determining the threshold intensity upon which to make the decision. Usually, a situation is not so well defined that an optimal threshold intensity can be chosen, because the signal and noise distributions overlap. The degree of overlapping is measured by the signal-to-noise (S/N) ratio. Another complication is that the cost of missing a signal may be different from the cost of falsely concluding that a signal is present. For example, the cost of missing an alarm call may be death, whereas the cost of falsely sensing light is only a waste of time and energy. Because in the case of microalgae the cost of missing an alarm is negligible, the evolutive pressure lowered the probability of sensing a false signal.

Let us calculate the number of distinguishable intensities, **I**, in an algal photoreceptor in such a way as to relate intensity and noise.[28] The light stimulus that maximizes information transmission is intrinsically random and has a standard deviation of $\mathbf{S}_{sd}$. Then, if a photoreceptor has a noise level of $\mathbf{N}_{sd}$, the number of distinguishable intensity levels can be estimated. We assume that two intensity levels must differ by $2N_{sd}$ to be distinguishable, and this corresponds to approximately 95% reliability. Therefore, the number of distinguishable intensity levels is closely related to the ratio of the variances of the signal and noise, as in the following:

$$I \cong (1 + S_{sd}^2/N_{sd}^2)^{1/2}$$

In microalgae, the number of intensity levels is reduced to two (dark and light), so we can write:

$$S_{sd}/N_{sd} \cong 2$$

On the basis of this equation and, once calculated, the number of photons on the sunniest and cloudiest days, we can state that the simplest photoreceptor system of most microalgae could recognize light from

dark even on a cloudy day, but this is possible only if the dark noise is close to zero. In the case of higher levels of dark noise, such recognition is impossible, even on the sunniest days.

Direction

To determine the direction of a light source, a microalga must possess a light detector and a light screen to provide directional selectivity. Such a screen can be an absorbing element that prevents light coming from a certain direction from reaching the detector or a refractive element that focuses light onto the detector only from specific directions.[19]

Most bacteria (prokaryotes) are too small compared to the wavelength of light to create differential light intensity; hence, they cannot determine the direction of a light source. Still, these microorganisms can use light but can only measure its intensity and move in a light-intensity gradient. Gliding filamentous prokaryotes that move slowly can compare light intensity at different positions and make directed turns. In contrast, microalgae are large enough to determine light direction and move along a beam of light by scanning the environment with their directionally sensitive receptor as they rotate while swimming.

Guiding

To determine the orientation of a stimulus field, an organism has to measure the stimulus intensity at different positions. The two fundamental alternative strategies for obtaining information are as follows[19]:

1. Stimulus sampling by multiple separated receptors positioned on different parts of the organism surface — In this case, the organism directly measures the spatial gradient by comparing the intensities at different positions.
2. Sequential sampling by a single receptor that moves from one place to another — In this situation, the organism directly measures a temporal gradient, then infers the spatial gradient from the information on the movements of the receptor.

The simultaneous comparison of signals requires widely spaced receptors to detect intensity gradients, which makes large body size advantageous. On the other hand, sequential sampling requires a coherent pattern of movement, such as locomotion in a helical path. Sequential sampling also requires some form of memory to allow for comparison with previously recorded intensities.

Another fundamental distinction is based on whether an organism is able to make turns in its motion path, which will direct it toward its destination. Depending on the characteristics of the stimulus and the abilities of the microorganism, guiding may be direct, in the sense of taking a straight-line path to the destination, or indirect, as in the case of a biased random walk, to reach the vicinity of the destination.

Phototaxis is the behavior that involves orientation in response to light stimuli that carry the information. This behavior consists of a migration oriented with respect to the stimulus direction, which is established and maintained by direct turns. (Phototaxis is different from phototropism. Phototropism is frequently used for the behavior in which the organisms respond to the light with an oriented growth.) Photokinesis is the behavior that comprises undirected responses dependent on the intensity or temporal changes in intensity of the stimulus.

Trajectory Control

Control characteristics, and thus behavioral peculiarities, are connected with the functioning of the propelling structure of the cell.[14] If the cell is asymmetric, it advances spinning along its axis; it can correct its trajectory only by sudden steering obtained by changing the insertion angle of flagella. This behavior can be attributed to all heterokont (e.g., *Euglena*) or monocont microalgae. In the case of a symmetric cell, it can accomplish a gradual smooth correction of its trajectory going forward without spinning (or rotating for a long period), and displacing the baricenter of the motor couple. This behavior can be attributed to all isokont cells (e.g., *Chlamydomonas*).

121.5 Photoreceptive Proteins

Nature evolved a limited number of photoreceptive molecules in the different evolutionary branches of the tree of life because of the closely similar needs of organisms to detect the external world. Two photoreceptor molecules are considered as underlying "vision" in microalgae: rhodopsins and flavins.

Rhodopsins

These retinal-based proteins seem to be used by motile algae (in their vegetative and reproductive stages) as well as in the motile stages of sessile macroalgae, because they must respond rapidly on a time scale of milliseconds to seconds as environmental conditions change or as the organism changes position relative to its static surroundings. The photoreception systems based on rhodopsins are fast, hence, the intracellular response is immediately reset so that the system is prepared for a new light signal. Evidence for a retinal-based photoreceptor was reported in one lineage of prokaryotes (*Leptolyngbya* sp.,[29] *Anabaena* sp.,[30]) and in at least three lineages of eukaryotic algae (*Chlamydomonas* sp.,[31] *Dunaliella* sp.,[32] *Spermatozopsis* sp.,[33] *Volvox* sp.,[34] *Euglena* sp.,[35] *Ochromonas* sp.,[36] and *Silvetia* sp.[37]).

We will present, in detail, the case of *Euglena*. The investigations so far performed on this microalga led to conflicting results on the nature of its photoreceptor, leaving open the debate of flavin versus rhodopsin. The flagellate *Euglena gracilis* dwells in natural shallow ponds and uses sunlight as a source of energy and information. Its chloroplasts are the energy-supplying devices, whereas a simple but sophisticated system is used as a light detector. This system consists of a locomotory flagellum, a stigma, and a photoreceptor.[38–40] In general, as the cell rotates while swimming, the stigma comes between the light source and the photoreceptor, thus modulating the light that reaches it and regulating the steering of the locomotory flagellum. This configuration of stigma, photoreceptor, and flagellum can be considered a simple but complete visual system.

The photoreceptor, a three-dimensional proteic crystal, is composed of a stack of more than 100 crystalline sheets with a regular organization of component proteins. Fourier analysis suggests that the unit cells of proteic subunits within these sheets have a parallelogram shape. The dimensions of the monoclinic unit cell (or distorted hexagon, because , = 107°) of the sheet are about 50 Å × 40 Å. The layer seems to be constituted of the same protein, and the height of this integral membrane protein is about 70 Å. No other proteic structures or peripheral proteins could be seen between the layers.[25]

In 1989, Gualtieri and coworkers,[24] and subsequently in 1992, Crescitelli and coworkers,[41] measured the absorption spectrum of a single *Euglena* paraflagellar swelling. Due to the great similarity between these spectra and the absorption curve of rhodopsin ·-band centered around 510 nm, both research groups suggested a pigment based on a rhodopsin-like protein. Successive experiments on inhibition of the formation of the swelling and cellular photo-orientation by means of hydroxylamine and nicotine showed that retinal is the chromophore present in the photoreceptor.[42,43] The extraction of retinal from intact cells and from photoreceptors isolated from demembranated cells further strengthened the hypothesis of a rhodopsin-like protein.[35] The estimated number of proteins, on the basis of the number of retinal molecules and of photoreceptor integrated optical density, is about 10^7 molecules. In 1997, Barsanti and coworkers reported the presence of a photochromic pigment in the paraflagellar swelling of *Euglena gracilis*, which undergoes repeated and reversible fluorescence changes with a determinate kinetics.[44] According to these authors, the paraflagellar swelling possesses optical bistability, i.e., the nonfluorescent parent form (first conformer) of its molecules upon photoexcitation generates a fluorescent stable intermediate (second conformer) that can be photochemically driven back to the parent form. The quantum yields of the forward and reverse reactions are almost the same and close to unit.[44] In 2000, Barsanti et al.[45] isolated the photoreceptors of Euglena in very high yield (see Figure 1 in Barsanti et al.[45]) and performed the purification of the photoactive protein from this sample. Spectroscopically, the 27 kDa protein they obtained showed a well-defined absorption band centered around 510 nm. This spectrum can be superimposed on the *in vivo* absorption spectrum recorded on the photoreceptor by Gualtieri et al.[24] and by James et al.[41] and on the absorption spectrum of sensory rhodopsin II from *Natronobacterium pharaonis*.[46]

To confirm the hypothesis that the extracted protein was a rhodopsin-like protein, it was treated with hydroxylamine and sodium borohydride. The former is known to combine with retinal molecules released in the bleaching of rhodopsin or to displace the retinal from opsin to form oximes; the latter reacts rapidly with bleached rhodopsin in solution by reducing the retinylidene linkage. The effect of both compounds on the protein was comparable: both produced a dramatic fading of the absorption band centered around 510 nm. This clearly indicated that the chromophore is an aldehyde, possibly the extracted retinal. Moreover, the emission features of the native protein reproduced exactly the *in vivo* photoreceptor photocycle, with a nonfluorescent parent form and a green-fluorescent stable intermediate. All of these experimental data allowed Gualtieri's group to identify the crystalline paraflagellar swelling as the true rhodopsin-based photoreceptor of *Euglena gracilis*.

Flavoproteins

The proposition that these proteins could function as a near-UV-visible-light detector dates back more than 40 years. Despite the ubiquity and ancient origins of flavins, their role in acquiring information from the radiation environment still remains a complex area of study. Apart from difficulties in their identification, much of the reason for the lack of understanding lies in their diversity of function.

Most of the investigations to verify the presence of flavoproteins in microalgae were performed on the genus *Euglena*. The literature contains an extensive choice of papers on this argument, but we will limit our references to the most recent works. Häder and Lebert[47] reported a case of phototaxis reconstruction in *E. gracilis* strains with low flavin content by adding riboflavin and roseoflavin, the latter shifting the action spectrum to longer wavelength. Recently, Iseki et al.[48] biochemically characterized a new type of blue-light receptor flavoprotein, a photoactivated adenyl cyclase, in the photoreceptor organelle of *Euglena*. They concluded that this protein, with a molecular mass of 400,000 and FAD as prosthetic group, is the major constituent of the *Euglena* photoreceptor. It acts as photoreceptor for the step-up photophobic response (transition from dark to light), but it is not involved in the step-down photophobic response (transition from light to dark).

Even though the isolation procedure of Iseki and colleagues had a poor yield of paraflagellar bodies (see Figure 1 in Iseki et al.[48]), the authors were able to isolate and purify a 400K flavoprotein with a $(105K)_2(90K)_2$ heterotetrameric structure. By immunostaining *Euglena* cells with a polyclonal antibody against oligopeptides synthesized in accordance with the carboxyterminal sequence of the protein polypeptides, they localized the 105K subunit in the paraflagellar body. The purified flavoprotein was identified as a photoactivated adenylyl cyclase; this protein has no apparent transmembrane helices, does not possess a photocycle, and is not fluorescent under native conditions, because the fluorescence of the protein-bound flavin was quenched by the surrounding protein matrix. In our opinion, the protein isolated by Iseki et al. is not consistent with the ultrastructure characteristics[25] and the fluorescence behavior of *Euglena* photoreceptor,[44] which possesses a clearly detectable emission and undergoes an unquestionable photocycle.[44] Another fluorescent protein might therefore be present in this organelle to justify its fluorescence. The disappearance of the phobic response[48] may not necessarily mean that this protein is the light-detecting protein, because it could act as an amplification factor, as one of the segments of the phototactic response chain. This means that the photodetecting role could be assigned to another protein, and nothing prevents us from saying that this role may be played by the protein isolated by Barsanti et al.[45]

121.6 Methods for Studying Photoreceptor Proteins

Here, we briefly describe and compare spectroscopic and biochemical techniques that were used to define the light-absorbing properties of visual pigments, either *in vivo* (single cell or cell population) or *in vitro* (extracted material). To provide a clear perspective on the efficacy of different techniques as tools for the study of photoreceptive structures, a discussion of the pros and cons, the advantages and limitations, of each technique is included (see also Chapter 9).

Action Spectroscopy

Action spectroscopy represents the classic way to investigate photopigments. By means of action spectroscopy, the photosensitivity of a cell at different wavelengths can be measured, thus providing information on the nature of the pigments involved in photoreception[49] (see Chapters 1 and 4). It is still a common belief that this approach represents the only feasible way to study the photosensory pigments of a large number of species. However, direct measure of an action spectrum is much more difficult than that of an absorption spectrum. Moreover, action spectra may not be directly correlated with the absorption peaks of the pigments involved in photoreception, because light scattering can cause several errors.[50] When many pigments with similar absorption characteristics in the same visible range are present, action spectroscopy often fails to discriminate between them. Even when there is only one predominant pigment, it is not always possible to identify it. To obtain more reliable results, threshold action spectra should be preferred. They eliminate adaptation phenomena and screening modulation, limiting the utilization of action spectroscopy, which is limited to the study of changes or increases in the photosensitivity of a mutant cell, after the exogenous addition of a presumptive photoreceptor pigment the cell lacks.[51] It may be hasty to indicate the nature of a photoreceptor only on the basis of data obtained from action spectroscopy. This is especially true in the case of photoreceptors, such as rhodopsins, which have retinal as the chromophoric group. Retinal absorption can be fine-tuned by amino acid charges of the retinal pocket, which allows the entire spectrum between 360 and 635 nm to be covered.[52,53] Moreover, the presence or formation of photointermediates may shift the absorption maxima and make the interpretation of the action spectrum difficult.

Absorption and Fluorescence Microspectroscopy

These techniques do not disturb the integrity of the organism or subcellular components, and allow the examination of an uninjured system with its physiological functions intact [41,54]. The spectroscopic overshadowing of one pigment by another cannot occur since each pigment is packed in a different structure. Thus, cellular structures can be easily correlated with pigment type by direct observation. It is possible to make exact quantitative determinations of a) various reactions at the time of their occurrence in the sample, b) the progressive changes in these reactions, and c) their relationships to different conditions in the external medium [55]. Because of the fundamental connection between optical parameters and properties of molecular structures, microspectroscopy allows assessments of minute changes in the state of the molecules of various substances in the organism, the degree of their aggregation, and the interconversions of various forms of pigments and other important biochemical compounds with characteristic spectra. In many cases the lability and reversibility of such changes make microspectroscopy the only possible method of investigation. There is virtually no light scattering problem associated with microspectroscopic measurements, even if the analyzed structure has a dimension of one μm. Obviously, the absorption spectrum cannot provide adequate information about the photochemical action of photons as a function of their fundamental energy; however, the identification of the chromophores in the photoreceptive structures does provide information about possible mechanisms of energy transfer. The measurements are very difficult when small changes in absorption have to be measured in the presence of a strong total signal (luminous background), since photon noise is proportional to the square root of the intensity of the incident light. Then, fluorescence spectroscopy is recommended: it can achieve more reliable results compared to absorption spectroscopy, since the background emission is much reduced. In this case the sensitivity of detection is not limited by the signal-to-noise ratio, but rather by the presence, virtually unavoidable, of fluorescent contaminants [55,56].

Biochemical and Spectroscopic Study of Extracted Visual Pigments

Extraction of visual pigments (chromophore and/or protein), either by means of detergents such as digitonin and Triton [57], or by organic solvents, could be the best method for providing large quantities of photoreceptive pigments in an accessible "*in vitro*" form for subsequent detailed biochemical analysis.

Such samples allow a very accurate determination of spectroscopic parameters. Spectroscopy of solubilized pigment may be complicated, however, by the simultaneous extraction of several other pigments in the cell, which cause distortion of absolute spectra and necessitate special procedures of purification. These problems can be solved by separating the different pigments after extraction, e.g., by High Performance Liquid Chromatography (HPLC) and final identification with Gas Chromatograpy - Mass Spectrography (GC-MS) for chromophores [58], or affinity chromatography for proteins [59]. Since the pigment extraction permanently removes the identifying link to a particular cell structure and may change the spectroscopic properties of a receptor because native interactions are disrupted, these detrimental factors mandate a careful evaluation of the results obtained by this method.

Molecular Biology Investigations

DNA hybridization is useful in attempting to determine phylogenetic interrelationship between species. The rationale is that similarities between DNA structure correlate to interrelatedness. It is used to detect and isolate specific sequences and to measure the extent of homology between nucleic acids [60]. It represents an alternative to the study of visual pigments at the protein level, since the genes encoding these proteins can be identified, their sequences determined, and the comparative genetic information assessed. Genomic Southern blot hybridization is used to probe the genomes of a variety of species in a manner analogous to that reported for other protein families. The potential for using bovine rhodopsin opsin complementary DNA (cDNA) probe to identify homologous genes in other species was demonstrated by Martin et al. [61]. These authors identified coding regions of bovine opsin that are homologous with visual pigment genes of vertebrate, invertebrate, and phototactic unicellular species. Successful application of this method requires closely homologous genes, and in general additional criteria, such as protein sequence information, is desirable for eliminating false positives on Southern blots. A molecular biology approach has been used also by Sineshchekov et al. [62] in *Chlamydomonas*. These authors identified gene fragments with homology to the archaeal rhodopsin apoprotein genes in the expressed sequence-tag data bank of *C. reinhardtii*. Two quite similar genes were identified having almost all the residues in the retinal-binding site of bacteriorhodopsin. The authors suspected that these genes were related to the putative retinal-based pigments already suggested for *Chlamydomonas* [63].

However, to show that the pigments are a part of the genuine signaling system, ideally one would like to delete each gene by using homologous recombination, but it is not easy to do such gene knockouts in any algal species. The problem can be overcome partially by using RNA interference (RNAi) technology to preferentially suppress the synthesis of the pigments to convincingly show that the pigment is a genuine segment of the algal phototactic response.

121.7 Concluding Remark

Understanding the molecular mechanism used by algal cells to "see the light," as we have tried to explain, is a very difficult task. At least a century has been wasted without any success. It is discouraging to think that even if the algae are not as intelligent as men are, they have "understood" very well how to orientate themselves in their light environment, and do it very efficiently. Maybe the compass mechanism they use is too simple for our complex brain…

Photomovements in Ciliates

Istituto di BioFisica CNR

122.1 Introduction

Ciliates are one of the most important components of the food chain on our planet: they constitute, in fact, a relevant fraction of the total microzooplankton and represent the main food of zooplankton and higher aquatic organisms.[1] Along evolution, ciliates (and protozoa in general) discovered and occupied new ecological niches (acting as primary and secondary consumers) and became the link between the *microbial loop* (the food chain in the microscopic world) and the *macrobial loop* (the chain involving higher organisms), because they are the preferred food of the larval stages of fishes, crustaceans. This was exploited in water culture systems for fishes and other organisms. Ciliates (and protozoa in general) represent the connecting ring through which energy and organic matter produced by the primary producers are transferred to secondary consumers.[3]

Ciliates are diffused everywhere in the world and have colonized almost all aquatic environments: from freshwaters to salt marshes, from the sea to lagoons and other hypersaline or saltish ponds. They can even be found in soil. Their contribution to the ecology of the planet is fundamental; for instance, being natural predators of flagellated algae and bacteria, they are often able to stop the exponential growth of these organisms.

The evolutionary success of ciliates is a direct consequence of their high plasticity and adaptation capability. In fact, ciliates are often much more complex than cells of pluricellular organisms, which are, on the other hand, more specialized.

The integration of these organisms in their environment is remarkable, as shown by their enhanced capability to perceive and react to external physical (light, temperature, pressure, etc.) and chemical (such as food attractants) stimuli. This allows them to explore the environment searching for the best conditions for survival, be it looking for food or avoiding potentially harmful situations.

Ciliates integrated in the same cell many different functions that in higher organisms are carried out by different cells; they can, in fact, perceive simultaneously different stimuli, elaborate them, and respond

0-8493-1348-1/04/$0.00+$1.50

with a suitable motile reaction. This integration capability has prompted some to call ciliates "walking neurons."

Among the environmental stimuli, light certainly is one of the most important. After all, almost all living species evolved in a world dominated by light. It is somehow intriguing, however, to understand why ciliates evolved the capability of altering their motion in response to luminous stimuli. In fact, different from some bacterial species or from green algae, they cannot use light as a source of energy. They can, however, use light as a source of information; in some cases, this is used to avoid harmful light levels; in other cases, this can tell them where a photosynthetic prey is more likely to be found. The study of photomotile reactions of ciliates is, therefore, quite useful for obtaining clues on the functioning of ecological systems.

The investigation of the photomotile responses in these organisms requires careful attention; many stimuli, in fact, are often present at the same time, so that it is necessary to be able to isolate the response relative to only one stimulus, and rule out the contribution of others. In the study of photomotile reactions, this is usually done by trying to keep under control, as much as possible, all the environmental conditions (temperature, pH, chemicals) and by varying the characteristics of light (fluence rate, spectral composition, polarization) at will.

In the present section, we will start by describing the different types of photomotile responses in ciliates, then we will move on to a short description of the photoreceptor organelles and will consider in some detail phototaxis and possible light-tracking mechanisms. We will then briefly consider the main experimental techniques used in this field of research and will discuss some aspects of the photosensory transduction chain (for a general introduction, see Chapter 9). At the end of this chapter, we will give a somewhat more detailed description of the state of the art of our knowledge on two case studies, that were investigated by our research group in the last years.

122.2 Photomotile Responses

There is general consensus that photomotile responses can be divided into three main types[4,5]:

- *Photokinesis*, where the average speed of microorganisms is affected by light exposure
- *Photophobic reactions*, where the microorganisms perform an avoiding reaction when the ambient light intensity suddenly increases (*step-up photophobic response*) or decreases (*step-down photophobic response*)
- *Phototaxis*, where a microorganism exposed to unidirectional light orients its motion toward (positive phototaxis) or away from (negative phototaxis) the light source

Some further classifications can be used, for example, *diaphototaxis* (i.e., the orientation orthogonal to light direction) shown by *Urotricha* sp.,[6] but we will not consider them further in what follows.

As we have seen above, photomotile responses in ciliates are not easily understood from an evolutionary and adaptive point of view, they are complex and often vary with the stage of the life cycle or with the degree of starvation. Among photomotile responses, the most interesting, for its implication from an evolutionary and adaptative point of view, is surely phototaxis, because it controls the movement of cell populations in the water column and across large areas of the oceans. Photomovements can contribute to cell survival, because, even if ciliates are not photosynthetic, their preferred food is often constituted by algae or other photosynthetic organisms that move to illuminated regions; therefore, the capability of tracking light for a ciliate can be useful to track food.

The sensitivity to light varies considerably among ciliates: some ciliates do not respond to light or perform only photophobic reactions but not phototaxis; some others are phototactically responsive only during a particular phase of their life cycle, or they are responsive only when starved but not after food uptake. An interesting correlation exists between phylogenetic relationships, photomotile behavior, and the ultrastructural photoreceptive elements: phylogenetical clusters of ciliates often show similar photobehavior.[7]

Many ciliates have life cycles formed by several different stages, in which they can change cell shape and functions. Some of these stages, such as cysts, are defensive and are entered only when the surrounding environment changes toward unfavorable conditions. In these stages, ciliates transform into much simpler cells, in which subcellular organelles or ultrastructural elements seems to be "packed" or, sometimes, disappear: cilia are suppressed, and the cell shows, of course, no motile responses in this stage.

Besides defensive stages, there are other stages in which the ciliate can be photoresponsive or not. For example, the ciliate *O. flava*, which we will discuss in detail later, shows a strong positive phototactic response during the stage of *theront*, when the cell is starved; while in the stage of *trophont* (immediately after food uptake), it shows no photoresponsiveness.

It is apparent, therefore, that the investigation of the photomotile reactions in ciliates is often strictly related to their stage in the life cycle, besides being strongly affected by the environmental conditions; the results obtained in a system can, thus, hardly be generalized.

Photoreceptor Organelles

Photoresponsive ciliates have a large variety of photoreceptor structures. In some cases, there is no apparent organelle dedicated to light detection. In other cases, stigma-like structures may be present, and in a few cases, more complex structures are found, as in *Porpostoma notatum*, which bears a composed crystalline organelle,[8] or in all species of the genus *Ophryoglena*, which possess a watchglass organelle, called Lieberkühn organelle.[7]

Among the photoresponsive ciliates that do not seem to have specialized photoreceptor organelles, there is *Paramecium bursaria* that is transparent, and when *Chlorella* deprived, it shows "*in vivo*" no detectable candidate pigment, as determined by microspectrophotometry or microfluorometry. Even if there is strong evidence in favor of the presence of a rhodopsin-like photoreceptor pigment,[9,10] no strong indication has been found on a possible spatial arrangement of it that could justify the existence of a directional antenna. Rhodopsin-like pigment is, in fact, localized on the cell cilia and on the ventral part of the cell body.[10] In the marine heterotrich ciliate *Fabrea salina*, there are two candidate photopigments, a rhodopsin-like molecule localized on the cell membrane, and a hypericin-like molecule localized in pigment granules that are just below the cell membrane and in certain cases in conjunction with it. Both molecules can be responsible for the photoresponses of this ciliate (positive phototaxis and photophobic step-down reaction), but both are uniformly diffused, and no proper photoreceptor organelle can be detected. Shown in Figure 122.1 is the structure of such pigment granules, with detail that shows the intimate junction between the granule and the cell membrane, which can suggest a functional meaning. Similar structures can also be found in *Blepharisma japonicum* and *Stentor coeruleus.*[11,12]

Other ciliates, like *Chlamydodon mnemosyne* and *Nassula citrea,* show the presence of a stigma-like organelle, made by a cluster of colored vesicles.[13] Its function as photoreceptive organelle is, however, dubious, because cells that possess a low amount of these vesicles are still capable, in certain cases, of performing phototaxis.[7] Probably, similar to what happens in flagellated algae, the stigma-like structure is not the photoreceptor proper, but acts, more likely, as a screening device that may help orient cells toward light.

A typical representative of ciliates possessing watchglass organelles is *Ophryoglena flava* (Figure 122.2), which will be treated in detail in the last section of this chapter. Behavioral experiments showed that the Lieberkühn organelle is involved in tracking light direction,[13] but its role and the orientation mechanism are still debated. The removal of this organelle from the cells, in fact, causes a significant, but not total, reduction of the phototactic responsiveness of the cells that recover their phototactic activity within 24 h, a time period that is long enough for a new Lieberkühn organelle to form.

The ciliate *Porpostoma notatum* belongs to the group of ciliates bearing complex photoreceptive organelle composed by alternate layers of cytoplasm and flattened crystals. This kind of receptor reminds the structure of a quarter-wave optical reflector, described in the stigma of some flagellated algae, such as *Chlamydomonas reinhardtii.*[14,15] In this alga, it was suggested that the stigma may be involved in the

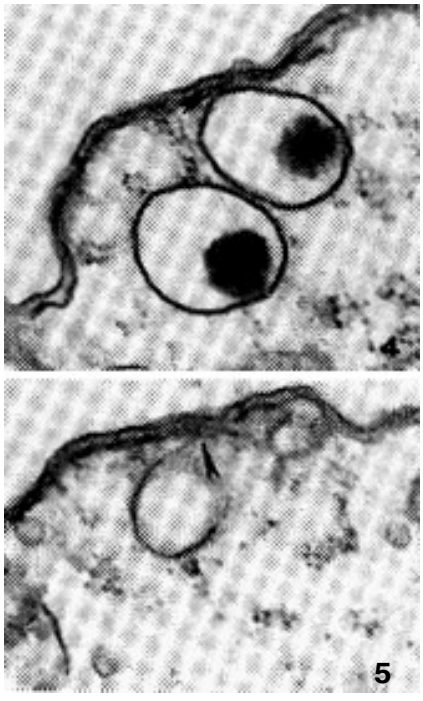

FIGURE 122.1 Pigment granules in *Fabrea salina*, and, below, a detail of the intimate association of them with the cell membrane.

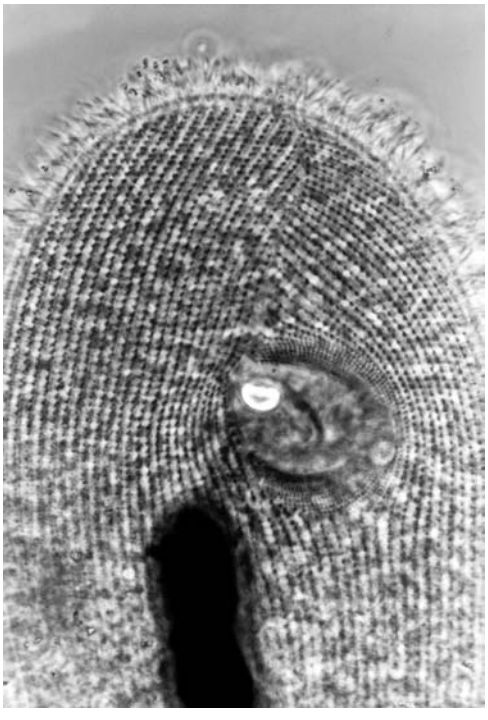

FIGURE 122.2 Detail of the Lieberkün organelle in *Ophryoglena flava*.

orientation of cells toward light. This is based upon calculations of the amount of light reflected by the quarter-wave structure on the photoreceptor that depends on the orientation of the cell body with respect to unilateral light; this, together with the helical swimming of the cells, gives rise to a directional detector.

Light-Tracking Strategies

The word "phototaxis" usually indicates the following:

- From a "sensorial" point of view, the perception of the light propagation vector
- From a "motile" point of view, the capability to actively orient cell swimming with respect to light direction

These two definitions are apparently equivalent, but this requires a more thorough consideration. There are orientation strategies in which the cells use the light propagation vector as input but do not actively control the swimming direction. A possible approach to this problem is to model the swimming behavior of microorganisms as a random walk. In such a model, the trajectories described by the cells can often be simply approximated by using straight-line segments connected together. Three independent variables can completely describe the motile behavior of such models: cell speed, frequency of directional changes, and distribution of the angles of directional changes (i.e., the probability to choose a defined angle at each directional change). By setting the parameters in a suitable way, a simple computer program can easily generate tracks that are similar to the real ones. In these conditions, the simulated cells move randomly and uniformly along all possible directions. Phototaxis can be simply simulated by introducing a directional anisotropy in one of these parameters:

- If the bias is set on speed, the cells will move *rapidly* only when they are swimming along certain defined directions.
- If the bias is set on frequency of directional changes, the cells will *hold* a defined direction once they have found it by chance.
- If the bias is set on the distribution of the angles of directional changes, the cells will *choose*, at each step, angles that reduce the angular distance between the swimming direction and the light direction; this can be considered as the true, active, orientation mechanism.

These three mechanisms lead to an orientation of the trajectories of the cells with respect to light direction and, in all cases, light direction represents the input signal. With respect to the definitions given in the literature, only the last mechanism should be called phototaxis, while the others are usually known as photokinesis and klinokinesis, respectively. In practice, it is difficult to distinguish experimentally the parameter primarily involved in the orientation mechanism. There are, in fact, some experimental problems and sources of noise that can make it difficult to decide if one is dealing with a "true" phototaxis or not:

- The finite dimensions of the experimental chamber that can greatly influence the swimming of the cells
- The finite (and often low) number of cells present in the experimental sample
- The limited possibility of exactly reconstructing single cell trajectories for a sufficient time — this is essentially due to technical problems: the experimental techniques currently used to track cells do it for a time too short to have statistical significance; sometimes, they are unable to always follow the same cell, so that what appears to be a single trajectory is actually the summation of the trajectories described by different cells
- The image digitalization, which transforms continuous trajectories into discrete ones; the choice of the frequency of spatial sampling is of fundamental importance for the measurement of the random walk parameters that strongly depend on it

Because of these difficulties, the problem of the orientation mechanism has been studied only in a theoretical way, but with few practical applications. In a work of Marangoni et al.,[16] the problem of

orientation strategy was discussed in terms of biased random walk, with a practical application to the phototaxis of the marine ciliate *Fabrea salina*. In this work, the authors, starting from the experimental result that this ciliate did not show photokinesis, studied two possible orientation models: in one (M1), the cells are able to correct their swimming direction; in the second model (M2), the cells can only vary the frequency of directional changes, locking their swimming to light direction, once it has been found by chance. By means of computer simulations, the authors generated virtual populations of cells that used the M1 or M2 orientation models: the response of these simulated populations to unidirectional light was determined, in order to detect possible different macroscopic behaviors. The authors proved that, depending on the orientation parameter chosen, these two models have different macroscopic behaviors, even though they produce similar simulated single cell trajectories. Comparison with the experiments suggested that *F. salina* performs phototaxis using an M2 mechanism. This conclusion was confirmed by other studies, where real single cell trajectories were analyzed (Marangoni et al., in preparation). It is not easy to conclude if the phototactic response of *F. salina* is a "true" phototaxis or a klinokinesis: polarograms (i.e., the distribution of the cells' fraction moving along a direction) measured during a phototaxis experiment are significant, but this protozoa seems to be unable to actively modify the swimming direction; on the contrary, it is more reasonable that it decreases the frequency of directional changes once it is already swimming in a direction close to that of light. Preliminary measurements on the freshwater ciliate *O. flava* seem to show, on the contrary, that this ciliate is capable of actively orienting toward the light source.

These different behaviors might result from the different ultrastructural organizations of the photoperceptive organelle. The existence in *O. flava* of a specific watchglass organelle, which can act as directional antenna, may confer to this organism a direction control system. On the contrary, *F. salina* does not have any oriented structure (see above), and it is, therefore, unable to actively change its swimming direction. In this case, we can hypothesize that the cell body shape, which is not symmetric, could be responsible for the motion directionality under unilateral illumination.

Further studies are being carried on to clarify this point and to better understand the phototactic orientation mechanisms in ciliates.

122.3 Experimental Techniques

Action spectra determination has certainly been one of the most used approaches to gain hints as to the nature of the photoreceptor pigments involved in the photomotile response (see Chapters 112 and 115). To put it schematically, an action spectrum is a measure of the relative effectiveness of the different wavelengths in inducing the desired photoresponse. A thorough discussion of the theory underlying action spectra determination[17–20] goes beyond the purpose of this chapter, and therefore, we will limit ourselves to a short discussion of the meaningfulness of the results that this methodology can give.

Let us assume that after absorption of a photon of light the photoreceptor pigment P undergoes a series of dark reactions, say,

$$P \xrightarrow{h\nu} P^* \xrightarrow{k_1} P_1 \xrightarrow{k_2} \ldots\ldots \xrightarrow{k_i} P_i \xrightarrow{k_j} P_j \longrightarrow \ldots$$

if P_j is the signaling state for the photoresponse, its concentration will be directly related to the intensity of the response. In its turn, P_j depends on the number of P molecules that underwent the expected photoreactions (say, a photoisomerization) and from the constants of the various dark reactions. For a mole of pigment, the rate constant k_1 of the primary photoreaction, $P^* \rightarrow P_1$, depends on the light fluence rate, on the molar extinction coefficient of P, ε, and on the quantum efficiency ϕ of the phototransformation, so that $k_{1\lambda} = I \cdot \varepsilon_\lambda \cdot \phi_\lambda$, where ε and ϕ depend on the energy of the impinging photon. If the ks are the same at two different wavelengths λ, then the amounts of the signaling state P_j will also be equal, and consequently, the same will hold for the measured photoresponses. If the quantum efficiencies do not strongly depend on λ, we have that $k_{\lambda a} = k_{\lambda b}$ or $R_{\lambda a} = R_{\lambda b} \Rightarrow \varepsilon_{\lambda a}:\varepsilon_{\lambda b} = 1/F_{\lambda a}:1/F_{\lambda b}$, where R represents

the measured photoresponse. To say it in different words, if a certain wavelength λ_a is more effective than another λ_b, a lower number of photons at λ_a than at λ_b will be needed to elicit the same response *R*. This is the main conclusion of a simplified theory of action spectra, which only holds if certain requirements are fulfilled. The first requirement is that the signaling state be formed from *P* according to the scheme given above. If, on the contrary, P_j is formed, as shown in the scheme,

$$P \xrightarrow{h\nu} P^* \xrightarrow{k_1} P_1 \xrightarrow{k_2} \ldots\ldots \xrightarrow{k_i} P_i \xrightarrow{h\nu} P_i^* \xrightarrow{k_j} P_j \longrightarrow \ldots.$$

by light absorption of one of the intermediates, say P_i, then its amount will not only depend on k_1 but also on k_j, and subsequently, the action spectrum will reflect the absorption properties of both forms and will be limited to the spectral region where both species absorb.

Further requirements are that λ-dependent light scattering must be small, and that shading effects between the photoreceptor pigments be negligible.

When all these conditions are verified, an action spectrum gives useful information on the *in vivo* absorption spectrum of the photoreceptor pigment. This spectrum is then compared to known absorption spectra of photoreceptor pigments in a database, and conclusions can then be drawn on the nature of the molecules involved. An unambiguous identification of a photoreceptor pigment, however, cannot normally be obtained by relying only on action spectra determination, and other experimental evidence is required, such as pigment isolation and characterization, possibly accompanied by gene isolation and cloning.

If the photoreceptor pigment is localized, as is the case in Euglena, microspectrophotometry can give reliable information on its nature.[21] If the pigment is fluorescent, steady state and time-resolved spectrofluorometry and microspectrofluorometry can help in getting hints on its chemical structure and on possible de-excitation pathways.[22,23] Microfluorescence and confocal microscopy can be used to reveal the pigment location in the cell, even if the pigment is not fluorescent, by linking it to fluorescent antibodies, as done, for instance, in *Paramecium bursaria*[11] and in *Fabrea salina*.[22] Fluorescent antibodies can also be used for immunoblotting or immunocytochemistry to identify the photoreceptor molecules or other components of the sensory transduction chain.[11,24] The high spatial resolution of electron microscopy allowed detailed investigation of the structure of the pigment granules in *Stentor*,[11] Blepharisma,[12] and *Fabrea*,[25] while the chemical structure of blepharismin, the chromophore of *B. japonicum*, was determined by NMR.[26]

Molecular biology has been hardly utilized in this field of study in ciliates, but the genome sequences of some ciliates should soon be available. This could make it possible to search them for the presence of putative photoreceptor genes and, as already done for some flagellates, to try to express these genes in bacteria and to study the spectroscopic and biochemical properties of the proteins for which they code. Another, more interesting, possibility might be to block the synthesis of this pigment *in vivo* (for instance, by means of the RNAi technique[27]) and to study the light response in cells thus modified.

122.4 Photosensory Transduction Chain

Photoreceptor Pigments

The identification and isolation of the photoreceptor pigments in ciliates is still an open problem; in a few cases, in particular in some heterotrichs such as *Stentor coeruleus* and *Blepharisma japonicum*, a good amount of information is available, also thanks to the fact that in these cells, the presumed photoreceptor pigments, which belong to the family of hypericin-like molecules, are present in large quantities. Just to give an idea, while in cells like *Euglena gracilis* or *Chlamydomonas reinhardtii* the amount of photoreceptor molecules per cell is estimated to be of the order of 10^6–10^7, in these ciliates, that are deeply colored, a reasonable estimate may be as high as 10^9–10^{10} (Lenci, private communication). This makes it, of course, relatively easier to isolate and purify the photoreceptor molecules, even if, as we are going to see in the

following, not all the questions have been satisfactorily answered. It may be interesting to note that the large amount of pigments present poses a problem: why is it necessary to have such a large amount of pigments for a photosensory system? The metabolic cost for the synthesis of these molecules is probably high, and one could think that this may be evolutionarily justified only if it gives the cells a higher chance of survival in their environment. Both *Stentor* and *Blepharisma* may be killed by an exposure to prolonged illumination just because of the presence of these pigments, though blue *Blepharisma* require much higher doses than red *Blepharisma*. It is also true that blepharismin, the chromophore found in *Blepharisma*, can act as a defensive substance against predators.[28] This does not seem to be true of stentorin (which is the chromophore of *Stentor*), but the defensive role of stentorin is less investigated. It was also suggested that only a small subset of the pigment present could play the role of light sensing, but this answer, in fact, leaves open all the problems indicated before. For a more detailed discussion on this point, see Wood.[29]

Both stentorin and blepharismin chromophores have chemical proprieties and structures similar to those of hypericin and are substituted forms of phenanthroperylene quinones.[30] In *B. japonicum*, five homologs of the chromophore blepharismin were isolated.[31,32] Under the action of light, this chromophore changes its chemical structure *in vitro*[26] and *in vivo*,[33,34] becoming oxidized, and it also changes its absorption spectrum; in fact, living cells change their red color to a bluish one, similar to that of *Stentor*. In this oxidized form, it is called oxyblepharismin, and its chemical structure is more similar to that of stentorin and hypericin than to that of the dark form, blepharismin. Strangely enough, both forms of pigments seem to be able to activate the photosensory transduction in *Blepharisma*, at least according to the action spectra determined. In fact, the action spectra for the step-up photophobic response of red and blue cells overlap well the absorption spectra of blepharismin and oxyblepharismin, respectively.[33,34]

Though the chemical, physical, and photophysical properties of the chromophore in *Blepharisma* were widely investigated, there is not yet a consensus on the structure of the protein moiety of the photoreceptor. Two photoreceptor proteins, one with a molecular weight of about 30 KDa[35] and another with a molecular weight of about 200 KDa[36] were isolated in this ciliate. According to the Japanese authors, the protein they isolated is a monomer, as shown by denaturation experiments.[31] The situation seems to be better known in *Stentor*, where two chromoproteins, called stentorin-1 and stentorin-2, respectively, were isolated. Stentorin-1 can be easily extracted with ethanol from cell suspensions, is strongly fluorescent, and has a peak in absorption at 608 nm. It is a small complex composed of at least two heterologous subunits corresponding to apparent molecular weights of 46 kDa and 52 kDa.[37] Stentorin-2, which is more difficult to isolate, is also composed of two subunits; it is thought to be the functional receptor. In particular, the subunit called stentorin-2B, covalently bound to the chromophore, has a molecular weight of 50 kDa.[38]

In other ciliates, which show photomotile responses, the picture is even less clear. In some cases, the formation of pigmented structures seems to depend on the nutritional state of the cells. This is true, for example, in *Chlamydodon mnemosyne*, where phototaxis and pigment granules appear at the same time when the cells are starved for 24 to 48 h.[39] In this ciliate, the action spectrum for negative phototaxis[40] resembles the absorption spectrum of flavins. Furthermore, the wavelengths efficiently exciting the fluorescence of a region of the plasma membrane adjacent to the stigma of the cell[39] coincide reasonably well with the peaks in the action spectrum for negative phototaxis.[40] However, it should be noted that the fluorescence faded so rapidly that it was not possible to measure a fluorescence excitation spectrum. Also in *Loxodes*,[41] the action spectrum of photomotile reactions, determined using the rate of escape from oxic water to quantify photoresponsiveness, suggests a flavin as the photoreceptor. This is further supported by the fact that when *Loxodes* pigment is illuminated in the presence of O_2, the superoxide ion O_2^- is photodynamically produced, as is reasonably expected by a flavin, which is an efficient photosensitizer of a wide range of substrates. In other ciliate, it is not clear where the receptor pigments might be localized, as is the case for *Fabrea salina* or *Ophryoglena flava*. Until now, no attempt to isolate and characterize these photoreceptor proteins was described.

The hypothesis that rhodopsin-like molecules could be involved in photoreception in ciliates was put forward in the early 1990s by Japanese researchers[42,10] who suggested the presence of this pigment in the colorless ciliate *Paramecium bursaria*, based on the results of biochemical and immunocytochemical experiments. The authors were able to extract retinal by using HPLC[42] and to isolate a rhodopsin-like protein from *P. bursaria*.[10] The HPLC elution profile of the extract showed four peaks. Three of these were comparable to the peaks derived from the elution of standard all-*trans*, 9-*cis*, 11-*cis*, and 13-*cis*-retinal. The presence of 9-*cis*-retinal was ascribed by the authors to a thermal isomerization taking place during the separation process. The copresence of other isomers in light-adapted and in dark-adapted cell extracts does not allow for any conclusion to be drawn as to the process of retinal isomerization in *P. bursaria*; in other words, it is not possible to establish whether the isomerization process is similar to that of higher organisms or to that of *Halobacterium salinarum*. The rhodopsin hypothesis is further supported by other experiments with hydroxylamine, where the phototactic response decreased to about 30% of untreated samples. Furthermore, a polyclonal antibody raised in rabbit against frog rhodopsin was found by immunoelectrophoresis to cross-react with a 63 kDa protein of *P. bursaria,* and when the cells were treated with an anti-frog-rhodopsin antibody obtained from rabbit, the measurements of immunofluorescence microscopy, made using FITC-conjugated goat anti-rabbit IgG (FITC = fluorescein isothiocyanate), showed intense cell fluorescence, especially in the cilia. Similar results were obtained by immuno-electron microscopy. These results and those obtained by electrophysiological recordings in ciliated and deciliated cells give further evidence that the pigment is a rhodopsin, and that a great part of this pigment is localized into the cilia in the antero-ventral region of *P. bursaria*.[10]

There is also some evidence that a rhodopsin-like molecule could be the photoreceptor pigment for phototaxis in *Fabrea salina*, as will be discussed below.

Dark Reactions Steps in the Sensory Transduction Chain

Not much is known of the primary photophysical events taking place after photon absorption. If the pigment belongs to the rhodopsin family, the primary event is most likely a photoisomerization. In the case of hypericin-like pigments, as in *Stentor* and *Blepharisma* (and possibly *Fabrea salina*), some primary photophysical events of the photosensory transduction chain were possibly identified, the main hypothesis being that of an electron transfer from the pigment singlet excited state.[43,44]

The knowledge of the molecular steps of the sensory transduction chain in ciliates is limited to some indirect proofs obtained in *B. japonicum*, in *S. coeruleus*,[45] and in *P. bursaria*.[46] The main idea behind this approach is to test the effects of some metabolic drugs known to inhibit more or less specifically some steps of the sensory transduction chain of vertebrates and invertebrates. In some experiments, cells were treated with 8-Br-cGMP or *N*-2-*o*-dibutyryl-cGMP, which are membrane-penetrating, slowly hydrolyzable analogs of cGMP, with the final effect of an increase of cGMP intracellular levels. When exposed to light, the cells showed a decreased responsiveness to light stimulation and an increased latency time, T_L, defined as the time between light stimulation and the stop reaction.[47,48] This latency time seems to be characteristic of the photophobic responses and resembles the latency time occurring in intracellular recordings of action potentials. Furthermore, chemicals known to lower the activity of PDE (phosphodiesterase) brought about an effect similar to that caused by cGMP analogs. In fact, in *B. japonicum* and in *S. coeruleus*, the incubation with IBMX (isobutylmethylxanthine), a specific inhibitor of PDE, decreased the percentage of cells that react to light stimuli and increased the latency T_L. In *B. japonicum*, a similar effect was induced by the treatment with CTX (cholera toxin) or with PTX (pertussis toxin). Treatments of cells of *S. coeruleus* with theophylline (1,3-dimethylxanthine) and with zaprinast (1,4-dihydro-5-[2-propoxyphenyl]-7H-1,2,3-triazolo[4,5-*d*]pyrimidine-7-one), a highly specific cGMP-PDE inhibitor, have the same effect as IBMX. Zaprinast seems to be the most effective drug in affecting the photophobic response. In *B. japonicum* and in *S. coeruleus*, LY 83583, an inhibitor of guanylate cyclase, which should lower the cytoplasmatic level of cGMP, caused a marked increase in responsiveness to light stimulation and a reduction of the latency time T_L.

In *P. Bursaria*, the injection of GDP-beta-S abolished the light-induced inward current,[46] and a GTP-binding protein (57 kDa) was detected by immunostaining.

To summarize, these results could suggest that the photosensory transduction chain in these ciliates is similar to that of vertebrates.

However, results of other experiments on *B. japonicum* seem to complicate this picture. In fact, the photobehavior of this ciliate is also affected by treatment with chemicals, such as neomycin, heparin, and Li^+ ions, that bind phosphoinositides interfering with the phospholipase (PLC) activity and, thus, reducing the inositol and diacylglycerol intracellular levels. The parameters measured in this set of experiments are the latency time T_L, and the inverse of the light-stimulus intensity eliciting photophobic responses in 50% of the cell population.[49] Neomycin, heparin, and Li^+ have similar effects, causing an increase of T_L and of the light intensity eliciting the required (50%) response with respect to the controls. The effect depends on the concentration of the drug and incubation time. Mastoparan, which activates small G-proteins and increases inositol triphosphate levels ($InsP_3$), mimics the effect of light in *B. japonicum* cells. For instance, the administration of 0.5 μM mastoparan in the close vicinity of a dark-adapted cell in control medium elicited a ciliary reversal with a latency time similar to that of the photophobic response. The effect of mastoparan, together with the results obtained by immunoblotting on extracts of the cortex fraction of the cells,[49] demonstrates that *B. japonicum* possesses a G-protein.

These results could suggest that in *B. japonicum* the transduction chain resembles the invertebrate visual transduction chain, where the activated G-protein activates PLC that in turn produces $InsP_3$.

In summary, the photobehavior of *B. japonicum* seems to depend on two different mechanisms. One is linked to cGMP intracellular level and PDE activity, as is the case in vertebrates, and the other is linked to the activation of a G-protein and $InsP_3$ concentration, as in invertebrates.

It may be interesting to recall that in ventral photoreceptor cells of *Limulus*, the photoreceptor current has three different components that are controlled by three different enzymatic pathways, using three different terminal transmitters (cGMP, cAMP, and $InsP_3$). Until now, the details of these enzymatic pathways were not clarified, and it is not known whether there is a unique photoreceptor or distinct photoreceptors for each different pathway.[50] It is thus possible that phototransduction in ciliates follows the same mechanisms as in *Limulus*.

We think it may be appropriate at this point to make some general comments on the use of drugs and the interpretation of their effects in ciliates and, more in general, on microorganisms. Ciliates are unicellular microorganisms, meaning that, unlike photoreceptor cells of higher organisms, phototransduction is not the main or only function of the cell. Furthermore, many different physiological pathways probably have the same final output, a voltage-dependent inward Ca^{2+} current, and some intermediates could be common between different pathways, be they sensorial or not. Chemicals act by modifying the intracellular level of these intermediates and their effects on ciliates could not be as specific as in other organisms. This problem is, e.g., less important in rod cells, because almost all enzymatic pathways are involved in photosensory transduction. Even if the measure of the latency time of the photophobic response, T_L, should give reasonably unambiguous information on the effect of drugs in these ciliates, intracellular recordings of currents or voltage changes and molecular biological experiments could help in confirming this interpretation.

122.5 Two Case Studies

In the following, we will summarize the results obtained by our research group on two ciliates, *F. salina* and *O. flava*.

Fabrea Salina

Fabrea salina is a heterotrich marine ciliate found only in concentrated saltwater that actively swims along a left-handed helix. It belongs to the same order as the photomotile ciliates *Stentor coeruleus* and *Blepharisma japonicum*, but it is different from them in that it is not apparently pigmented. The cells

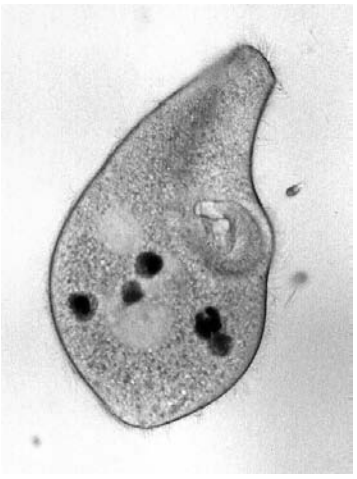

FIGURE 122.3 A view of *Fabrea salina* taken under optic microscope (original magnification × 200): the adoral zone of membranelles and the digestive vacuoles are clearly visible.

have a typical pear-shaped body, the surface of which is densely covered with cilia; the adoral zone is characterized by a deep spiral-shaped invagination, on the edge of which adoral membranelles can easily be seen (Figure 122.3). The cell cytoplasm of the cells grown in our laboratory is apparently colorless; sometimes green food vacuoles, containing the rests of ingested *D. salina* cells, are visible (Figure 122.3). The motion of *F. salina* in the dark can be simply described as a random walk: the cells move along straight lines interrupted by sudden directional changes. *F. salina* reacts to light stimuli by showing step-down photophobic reactions and positive phototaxis but apparently no photokinesis. Phototaxis depends only on light direction and cannot be induced by spatial gradients of light. A discussion of the possible mechanisms by which the cells can track light direction was given in Section 122.2.2. Because the cells respond to light stimuli, they must possess one or more photoreceptor pigments. The phototactic sensitivity curve of *F. salina* given in W/m^2 units as a function of the fluence rate at 600 nm can be fitted by a hyperbolic function of the form $R = (R_m \cdot I)/(I + I_{R/2})$, where R is the phototactic response, I is the light fluence rate, R_m is the level of saturation of the response; $I_{R/2}$, the light fluence rate corresponding to half maximum response, is of the order of 1.0 W/m^2.

As we already mentioned, one of the main techniques used to try and have some hints as to the possible nature of the photoreceptor pigment is action spectrum determination. The equal-response action spectrum calculated on the basis of the dose–response curves is shown in Figure 122.4.[51] This action spectrum is similar to that of photoaccumulation and membrane depolarization of the colorless ciliate *P. bursaria*.[9] As we have seen, in this system, there are indications of the presence of a rhodopsin-like pigment. The similarity between the action spectra of *F. salina* and *P. bursaria* might suggest that the photoreceptor pigment of *F. salina* is a rhodopsin-like molecule. It is, however, difficult to understand why there are two peaks in the action spectrum, if the pigment is a rhodopsin. It could be that two different photoreceptors are present in *F. salina*. If so, they must drive the same sensory transduction chain, as we were unable to find any experimental condition in which the responses at 420 and 580 nm could be affected to a different extent. Foster[20] recalculated the action spectrum of *F. salina* and concluded that it is compatible with the sum of two rhodopsins. However, it should be noted that the authors of the paper cited by Foster decided not to use his method to determine the action spectrum because of the high level of errors involved.

The saturation level of the dose response curves at 420 is higher than that at 580 nm, indicating that blue light is more efficient than green-orange light in inducing cell orientation toward light. At the same fluence rate, white light is as efficient as colored light in inducing phototaxis; this indicates that if there are two different pigments, they do not interfere with each other, and it is likely that *F. salina* cannot discriminate the colors of light.

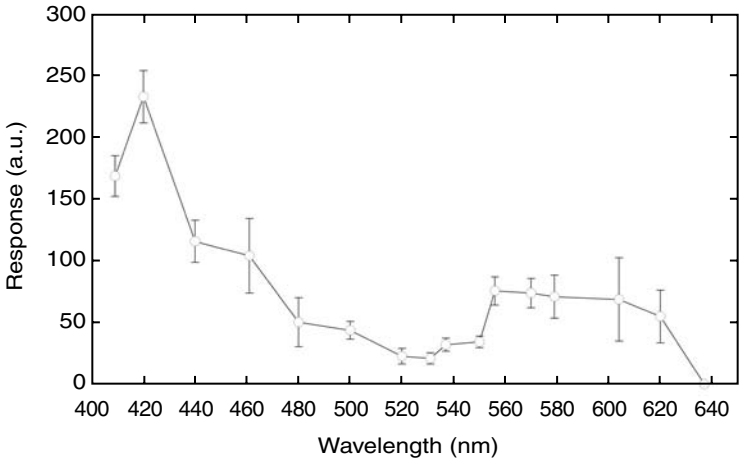

FIGURE 122.4 Action spectrum for the positive phototaxis in *Fabrea salina*.

The possibility that a rhodopsin might be the pigment for phototaxis in *F. salina* prompted us to use immunofluorescence to reveal the presence of a rhodopsin-like molecule on its plasma membrane.

Our study shows that there is immunostaining of *F. salina* cells with a polyclonal antiserum raised in sheep against bovine rhodopsin. The role of specific antibodies in cell staining is demonstrated by the evidence that incubation with FITC-labeled nonimmune sheep serum does not alter the endogenous cell-fluorescence. This implies that none of the serum components, other than the antibodies, is able to nonspecifically bind the cell membrane and that the cell fixation procedure does not alter the membrane permeability in such a way as to allow free access of the fluoresceinated serum molecules to the cytosol.[52] In addition, the binding of the antiserum to the cell membrane was established by confocal microscopy.[22] The theoretical possibility that antibodies other than the anti-opsin are present in the sheep antiserum and able to bind unknown antigens at the cell surface is negligible. Although these findings are consistent with the presence of a rhodopsin antigen activity on the plasma membrane of *F. salina*, they do not unequivocally prove the identity of the protozoan surface antigen to a rhodopsin molecule.

We then ran preliminary experiments looking for the possible presence of a rhodopsin-like gene in *F. salina* by means of the PCR (polymerase chain reaction), performed using two different pairs of primers, based, respectively, on the rhodopsin sequence of the halophilic archæobacterium *H. salinarum* and on the more conserved regions of known rhodopsin sequences of higher organisms. The latter pair of primers allowed the amplification of a sequence in *F. salina* corresponding to a fragment of a rhodopsin-like gene, more similar to the genes of higher organisms and of some flagellated algae than to those of *Halobacteria*.[53]

F. salina possesses, however, another type of pigment. In fact, fluorescence microscopy and imaging of living cells reveal a hardly detectable emission, but dead cells (either treated with various chemicals or dried) are characterized by a strong red fluorescence indicating the presence of an endogenous fluorescent pigment.[22] Single-cell microspectrofluorometry, fluorescence imaging, and laser confocal microscopy studies, together with time-gated fluorescence spectroscopy of cell suspensions, were performed in order to investigate the nature of this pigment and its topological localization. The fluorescence emission spectrum at different excitation wavelengths (from 337 to 425 nm) exhibits two peaks: the main one in the range 590 to about 615 nm, depending on the cell treatment, and the other one at about 655 nm. The time decay of fluorescence shows three distinct components, with lifetimes ranging from a few hundred picoseconds to some nanoseconds, and relative contributions varying with the chemical treatment. Time-gated spectroscopy also allows us to observe differences in the spectral features of the distinct emitting species. Laser confocal microscopy reveals that the pigment is localized just below the cell membrane. The spectral and temporal fluorescence features of the endogenous pigment present in *F.*

salina are similar to the ones of blepharismin, the pigment of *Blepharisma japonicum,*[54] thus suggesting that the *F. salina* pigment might be a hypericin-like pigment, too. The fact that the red fluorescence becomes detectable after cell death suggests a possible photoreceptor role of the pigment in living cells, where most of the energy absorbed by the pigment could be funneled into physiologically active processes, such as a light-induced motile response, and not be available for fluorescence. After death, damage to the cell structures could favor energy dissipation mainly via fluorescence. A similar situation was described in the case of *Blepharisma*, in which damage and rupture of the cell membrane cause a strong increase in emission intensity.[54] For the pigment present in *Fabrea*, as already for blepharismin, the change from nonradiative to radiative deactivation mechanisms can probably be related to differences in the environment of the pigment, which in living cells is embedded in granules, and after cell death could be, at least in part, released.

To summarize, *F. salina* contains two different types of pigments, one probably a rhodopsin and the other a hypericin-like pigment. Though the phototaxis action spectrum is similar to that of *Paramecium bursaria* and, therefore, by analogy, suggestive of a rhodopsin, its shape is not fully incompatible with a hypericin pigment, even though the structure of the spectrum, especially at the red wavelengths, is much less resolved.

There are, however, other pieces of evidence that may indirectly suggest a role for a rhodopsin photoreceptor in *Fabrea salina*. In fact, preliminary experiments have shown that phototaxis is drastically reduced in the presence of hydroxylamine, which is known to interfere with the retinal-lysine binding in rhodopsins, and is strongly affected in the presence of zaprinast, a specific inhibitor of the phosphodiesterase known to be an essential component of the sensory transduction in vertebrate vision. In both cases, cell motility is not affected by the presence of the drugs.

Moreover, we also have indirect evidence that phototaxis is strongly dependent on the conductance state of the membrane.[55] Cells were exposed to potassium concentrations higher than those of the growth medium (from 20 to 60 mM); for about 5 h their swimming changed, going to a tumbly behavior; after this time, the cells, on the average, resumed normal swimming. This is considered typical of cells with the membrane potential of which transiently depolarizes and then goes back to normal, thanks to a change of potassium (and possibly other ions) channel conductance. This has been shown to be true in *Paramecium caudatum* cells.[56] In this condition, the phototactic response of *F. salina* increases at least by a factor of two, while the step-down photophobic reaction disappears. In *P. bursaria*, intracellular recording of photoreceptor potential showed that light stimulation affects membrane conductance.[57] It is thus reasonable to infer that phototaxis is controlled by membrane channel conductance changes. This might, in turn, be related to the action of a rhodopsin-like pigment that could trigger upon illumination a chain of events ultimately leading to opening or closing of ion channels, as happens with rhodopsin in vertebrates and in invertebrates.

In summary, the body of evidence currently available for *F. salina* indicates that these cells possess two different types of putative photoreceptors, a rhodopsin-like and a hypericin-like pigment. The hypothesis that a rhodopsin pigment is responsible for phototaxis is supported by several pieces of evidence based on the similarity of its action spectrum to that of *P. bursaria*, by the effect of metabolic inhibitors such as hydroxylamine and zaprinast, by gene analysis, and by the suggested effect of light on membrane conductance.

Ophryoglena Flava

As we have seen, several histophagous ciliates, belonging to the order Hymenostomatida, among which *Ophryoglena flava* (Figure 122.5), contain a watchglass organelle, the so-called Lieberkühn's organelle, and show a clear phototactic response to light, the sign of which depends on the state of cell starvation.[8] Cells are negatively phototactic in the well-fed state, and positively phototactic during mild starvation. In order to get information on the dependence of phototaxis on light fluence rate, with attention to the possible emergence of negative phototaxis at high fluence rates, and on possible chromatic effects of the photoreceptor pigment, we determined the fluence-rate response curves in mildly starved, positively

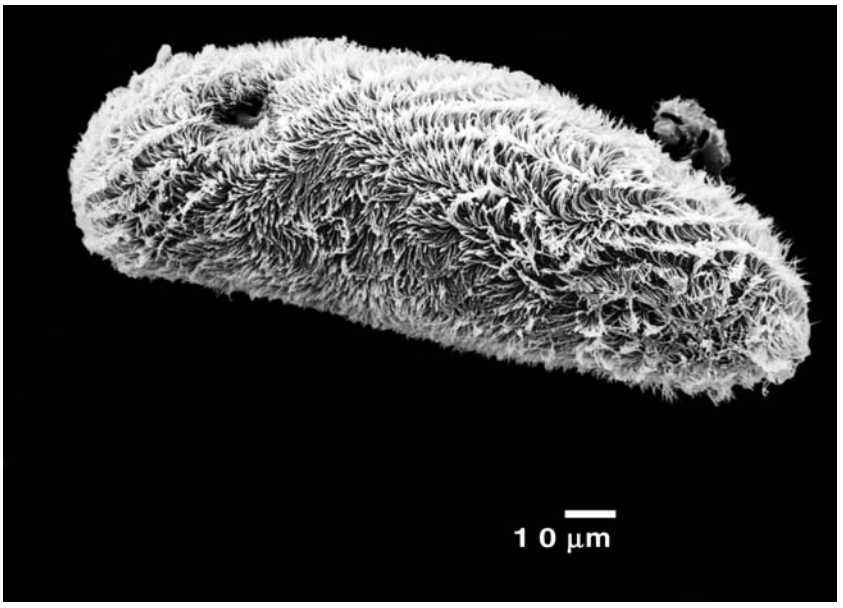

FIGURE 122.5 SEM of the freshwater ciliate *Ophryoglena flava*. The adoral zone is clearly visible.

phototactic, cells of *Ophryoglena flava* in white light and in broadband blue and red light. We then measured fluence-rate response under narrow-band quasi-monochromatic light in the wavelength range 400 to 650 nm. On the basis of these curves, we determined the action spectrum for positive phototaxis (Figure 122.6).[58]

The general trend of the fluence rate-response curve shows that, within the irradiance range investigated, there is no decline of positive phototaxis with light fluence rate. The curve can be fitted by a simple hyperbolic saturation function, and the saturation value is comparable to those obtained under broadband and narrow-band excitation light.[58] This indicates that in our experimental conditions, there is no negative phototaxis, no receptor pigment bleaching, and no saturation of the light tracking system. The first two conclusions are straightforward: if negative phototaxis was elicited at high-light irradiances, we should expect a bell-shaped fluence rate-response, which is not our case; the same holds true in the case of bleaching of the photoreceptor pigment. The third point needs some more discussion. There is general consensus that phototaxis requires some mechanism of light tracking from the cells; the simplest one is that brought about by a periodical shading of the photoreceptor pigment by some screening device. In the case of colorless ciliates, such as *O. flava*, the shading structure is probably the cell body. At high-light irradiances, the cell body could be unable to provide the modulation required to detect light direction (cfr. the argument as discussed by Selbach et al.[40]) because of a sort of overloading of the photoreceptor. In the case of *C. mnemosyne*, which is also a colorless ciliate, the authors report a white light irradiance of 10 Klux as the turning point of the fluence rate-response curve.[40] Even if it is difficult to compare Klux and W/m,^{2} we can use a rough conversion factor given by Lenci and Colombetti,[4] according to whom a white light of 10^2 Klux from a tungsten lamp with a color temperature of about 3000 K corresponds to approximately 60 W/m.^{2} By applying this conversion factor to the present case, the inversion irradiance found by Selbach et al.[40] is of the order of 6 W/m,^{2} whereas *O. flava* shows no decline in positive phototaxis up to 25 W/m.^{2} This could indicate that the light-tracking mechanism of *O. flava* is more robust than that of *C. mnemosyne*, due, for example, to a higher screening capability of its cell body, or that in the case of *C. mnemosyne*, there is some bleaching of the photoreceptor pigments. Moreover, the saturation behavior of the fluence rate-response curve together with the observation that cells continue to show phototaxis even when kept under unilateral illumination for long times is a strong indication that cells do not adapt to this kind of stimulus.

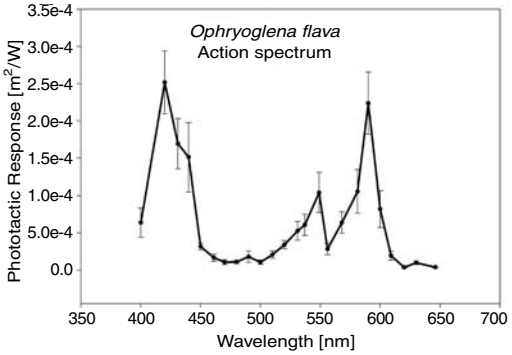

FIGURE 122.6 Action spectrum for the positive phototaxis in *O. flava*.

The fluence rate-response curves in broadband blue and red light are characterized by the same hyperbolic shape as in *F. salina*; they have the same saturation level within the experimental error ($R_{m_{blue}}$ = 0.14, $R_{m_{red}}$ = 0.18); the $I_{R/2}$ parameter in blue light is significantly smaller than that in red light ($I_{R/2blue}$ = 0.03 W/m^2, $I_{R/2red}$ = 0.18 W/m^2), indicating that the cells are more sensitive to blue than to red light. The fact that fluence rate-response curves in white light and broadband blue and red light follow the same trend, that they can be fitted by the same hyperbolic saturation function. and that at the same fluence rate white light is as efficient as colored light in inducing cell orientation toward light indicates that there is no chromaticity effect (in other words, *O. flava* cannot discriminate the colors of light) and that the pigments act independently of each other.

Also, the fluence rate-response curves in narrow-band monochromatic light follow the same hyperbolic saturation behavior, while the saturation level is the same for all wavelengths, within experimental errors. This indicates that if there is more than one type of photoreceptor pigment, they are functionally equivalent (same fluence rate-response curve, same saturation level). A simpler, and perhaps simplistic, solution is that we are dealing with only one type of pigment.

It may be interesting to compare the value of $I_{R/2}$ calculated for *Ophryoglena* in red light, which is of the order of 0.2 W/m^2 with that measured in *Fabrea* (see above), which is of about 1.0 W/m^2.

The action spectrum shown in Figure 122.6 clearly has two major peaks, one at 420 nm and one at 590 nm; a third, minor peak, is possibly present at about 560 nm. This action spectrum resembles, in its two major peaks, the ones measured for photoaccumulation and membrane depolarization in *P. bursaria*, and also that for phototaxis in *F. salina*, though in the latter case there is no well-defined peak in the green-orange region of the spectrum but rather a broad, unresolved band. In the cases of *P. bursaria* and of *F. salina*, a rhodopsin-like receptor pigment was proposed, as discussed above. One could thus tentatively conclude that the pigment responsible for phototaxis in *O. flava* might be a rhodopsin-like molecule, as well. This tentative conclusion faces, however, the same problem as in *F. salina*; no rhodopsin-like molecule can give rise to two peaks in the action spectrum, and the only alternative explanation is that *O. flava* possesses two spectroscopically different, but functionally equivalent, rhodopsins. It should also be noted that there is a similarity between the action spectrum of *O. flava* and that of the *B. japonicum* or *S. coeruleus*. There is, however, no indication that *O. flava* might contain hypericin-like pigments, and preliminary measurements carried out with microspectrofluorometry show no detectable presence of such pigments. Moreover, electron microscopy did not reveal any structure comparable to the pigment granules containing hypericin-like pigments, commonly found in heterotrich ciliates.

122.6 Conclusions

To summarize what is known of the nature of the photoreceptor pigments involved in photomotile responses in ciliates, the results reported in the literature seem to roughly indicate three main types of photoreceptor pigments.[58]

In *Loxodes striatus* and *C. mnemosyne*, it was suggested that the pigment involved might be a flavin. For *S. coeruleus* and *B. japonicum* (probably the best-known and most thoroughly investigated ciliates), from the point of view of photoreception, there is consensus that the pigment responsible for photomotile responses in the former and photophobic step-up response in the latter is due to hypericin-like molecules, stentorin and blepharismin, respectively. In the case of *P. bursaria*, there is some convincing evidence that a rhodopsin-like molecule is present in the cells. It should be noted, as briefly discussed above, that the presence of such a molecule is not *per se* a proof that it also plays the role of photoreceptor pigment, and that if a single rhodopsin is present, it should give rise to only one peak in the action spectrum. In *P. bursaria*, however, there are two peaks that might point to two different rhodopsins, a blue one and a red one, essentially equivalent. Now, the idea that in such a unicellular organism there may be more than one rhodopsin is not surprising; after all, a much smaller cell, such as *Halobacterium salinarum* contains four different rhodopsins,[59] two of which play different receptor roles. The same arguments also hold true for the case of *F. salina*, where there is some evidence in favor of the presence of a rhodopsin molecule, and where a hypericin-like pigment is present. In the case of *O. flava*, the action spectrum resembles those of *F. salina* and *P. bursaria* except for the presence of the smaller peak at about 540 nm. In this ciliate, no hypericin-like molecule was detected, for which we can tentatively say that the action spectrum might give some indication that a rhodopsin is present, but further work is necessary to substantiate this hypothesis.

The results reported and discussed above allow us to conclude that ciliates probably evolved more than one type of photoreceptor pigment and that the most common photoreceptors likely belong to the families of flavins, rhodopsins, and hypericins.

The way in which these photoreceptor molecules seem to be organized in photoreceptor structures and how these structures control the motile apparatus to generate motile responses to light, is apparently linked with the phylogenetic group, reflecting similar adaptation necessities of the organisms. Probably, the light perception strategies properly belong to the evolutionary necessities of survival and best fitness with the surrounding environment.

Photoactive Yellow Protein, the Prototype Xanthopsin

Johnny Hendriks

University of Amsterdam

123.1 Introduction

Discovery and Biological Context of the Photoactive Yellow Protein

In 1985 several ferredoxins and other chromophoric proteins from the halophilic phototrophic bacterium *Ectothiorhodospira halophila* were isolated.[1] One of the "other chromophoric proteins" was yellow and was named "photoactive yellow protein" in a subsequent study.[2] *E. halophila* was reclassified in 1996 to its current name *Halorhodospira halophila*.[3] *H. halophila* is a unicellular prokaryote, or more specifically, a phototrophic purple sulfur spirillum that deposits sulfur extracellularly. It was first isolated and classified from salt-encrusted mud taken from the shores of Summer Lake, Lake County, Oregon.[4,5] Later, it was also isolated from the extremely saline lakes of the Wadi el Natrun in Egypt.[6] Both locations are salt lakes, and *H. halophila* only thrives in extremely salty environments.

0-8493-1348-1/04/$0.00+$1.50

As a phototrophic organism, *H. halophila* exploits the free energy available from light to survive. However, like most organisms, *H. halophila* is not immune to the effects of UV radiation. It is, therefore, essential for *H. halophila* to find a place to live where there is enough light to grow but where the amount of UV radiation is at a minimum. Like most phototrophic organisms, *H. halophila* has mechanisms to perceive the available light climate. It is not only attracted by (infra)red (i.e., photosynthetic) light, but it also has a blue-light response that steers it away from potentially harmful places, rich in blue light. This blue-light repellent response has a wavelength dependence that fits the absorption spectrum of the photoactive yellow protein (PYP).[7] This is the first evidence that PYP is the sensor in the blue-light response of *H. halophila*. Further evidence for the function of PYP in *H. halophila* can be provided via genetic techniques. However, their application in extremophilic prokaryotes like *H. halophila* is not well developed, which is why genetic proof for the function of PYP is not yet available.

Interestingly, the function of PYP is similar to that of the sensory rhodopsins, and in particular, to sensory rhodopsin II, which is also a sensor for a negative tactile response to blue light (in *Halobacterium salinarum*, an archaebacterium that can also be found in salt lakes). The family of the rhodopsins is a large family. Its members are found in all kingdoms of life, from unicellular organisms to complex ones such as *Homo sapiens sapiens*. It is the most extensively studied family of photoactive proteins available. Its best-known members are the visual rhodopsins, which allow us to see, and bacteriorhodopsin, which is a light-activated proton pump found in *H. salinarum*. Sensory rhodopsins are close relatives to bacteriorhodopsin and can be found in the same organism. In fact, the most notable difference between bacteriorhodopsin and the sensory rhodopsins is their function. Bacteriorhodopsin provides the cell with means of harvesting light energy, whereas the sensory rhodopsins are light detectors that make sure the organisms can find a location where bacteriorhodopsin can do its work safely. The possible similarity between PYP and the sensory rhodopsins was already noted after the first characterization of PYP.[2] There is, however, one major difference with sensory rhodopsins that boosted the study of PYP— it is highly water soluble, whereas the rhodopsins, being membrane proteins, are not. As we shall see later, PYP and the sensory rhodopsins belong to structurally completely different families of proteins, which are only similar in function. For more information on the rhodopsins, the reader is referred to several excellent reviews on this topic.[8–10]

Xanthopsins: The Family of Photoactive Yellow Proteins

Halorhodospira halophila is not the only organism in which a photoactive yellow protein has been discovered. There are five other organisms — all purple bacteria — that also contain a protein similar to PYP from *H. halophila*. This family of photoactive yellow proteins was named the Xanthopsin family.[11] Presently, the six known Xanthopsins can be divided into three subgroups, according to their mutual similarity in primary structure. The first group is formed by proteins found in *Halorhodospira halophila* (synonymous to *Ectothiorhodospira halophila*),[1] *Rhodothalassium salexigens* (synonymous to *Rhodospirillum salexigens*),[12] and *Halochromatium salexigens* (synonymous to *Chromatium salexigens*).[13] The second group is formed by proteins found in *Rhodobacter sphaeroides*,[11] and *Rhodobacter capsulatus*.[14] The third group consists of a single protein found in *Rhodospirillum centenum*.[15] In the latter, the Xanthopsin is the amino-terminal domain of a larger phytochrome-like protein.

Though all these Xanthopsins can absorb blue light, their roles in various organisms differ. In *H. halophila*, PYP induces a photophobic tactile response.[7] For *Rb. sphaeroides*, genetic evidence is available that indicates that the blue-light-induced photophobic tactile response in that organism is not mediated by the Xanthopsin present in that organism, provided no genetic redundancy exists.[16] The Xanthopsin found in *Rs. centenum* regulates chalcone synthase gene expression.[15] These different functions of the Xanthopsin members coincide with the subgroup assignments. Though the function of all the known Xanthopsins has not yet been elucidated, it is likely that the members within the different subgroups of Xanthopsins, distinguished based on sequence similarity, have a similar function, while these functions differ between the subgroups.

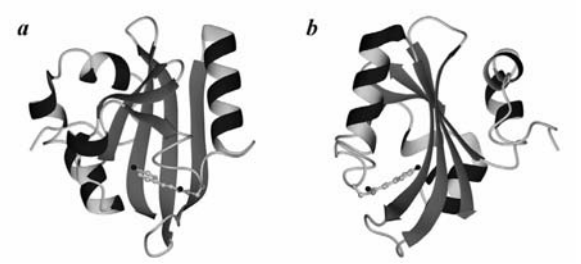

FIGURE 123.1 *Tertiary structure of the Photoactive Yellow Protein*. Two orientations of a ribbon representation of the Photoactive Yellow Protein from *Halorhodospira halophila* are presented. Panel *a* clearly shows the β-sheet with the chromophore in front of it. Shown in Panel *b* is a side view of the orientation in Panel *a*, visualizing both sides of the β-sheet. The figure was prepared using the program MOLMOL[82] using the structure coordinate file deposited at the Protein Data Bank[50] (http://www.rcsb.org/pdb) with PDB ID: 2PHY.[20] The program POV-Ray™ (http://www.povray.org) was used to render the images.

Photoactive Yellow Protein: The Prototypical PAS Domain

As described above, PYP is part of a family of proteins named Xanthopsins, which thus far have only been identified in proteobacteria. Nevertheless, PYP also shows striking similarities to the much larger family of PAS domains. These PAS domains were identified in proteins from all three kingdoms of life, i.e., in the *Bacteria*, the *Archaea*, and the *Eucarya*. PAS is an acronym formed from the names of the proteins in which the PAS motive was first recognized:[17] the *Drosophila* period clock protein (PER), the vertebrate aryl hydrocarbon receptor nuclear translocator (ARNT), and the *Drosophila* single-minded protein (SIM).

Proteins containing PAS domains are predominantly involved in signal transduction. Over 200 proteins have been identified that contain a PAS domain.[18] Most of these are receptors, signal transducers, or transcriptional regulators. Strikingly, at present, PAS domains have only been identified in the cytoplasmic compartment. PAS domains are usually present in proteins with a multidomain architecture. Furthermore, a single protein can have more than one PAS domain. In fact, proteins were identified containing up to six. In contrast, the entire photoactive yellow protein from *H. halophila* can be considered a single PAS domain. As it is the first protein from the PAS domain family for which the three-dimensional structure was elucidated, it was proposed that PYP is the structural prototype of the PAS domain fold.[19]

123.2 Structure

The backbone of photoactive yellow protein contains an α/β-fold with a six-stranded antiparallel β-sheet as a scaffold, which is flanked by several helices.[20] The loop containing helices α3 and α4, and the loop containing helix α5, fold on top of the central β-sheet to form the major hydrophobic core and a pocket in which the chromophore resides. The *N*-terminal segment, containing helices α1 and α2, folds behind the central β-sheet to form a smaller hydrophobic core. The tertiary structure is shown more clearly in Figure 123.1, where in Panel *a,* the structure is oriented such that the β-sheet is oriented similar to the schematic drawing shown in Figure 123.2. The view in Panel *b* of Figure 123.1 shows how the different α-helix-containing loops fold around the central β-sheet.

In photoactive proteins, the chromophore is at the heart of its functional characteristics. The type of chromophore in a photoactive protein typically corresponds with the wavelength range in which the holoprotein needs to be active.[21] In agreement with this, the Xanthopsins were shown to use an aromatic chromophore. This chromophore was identified in *Halorhodospira halophila* in 1994 as 4-hydroxycinnamic acid, covalently bound to the apoprotein via a thiol ester linkage with Cys69.[22,23]

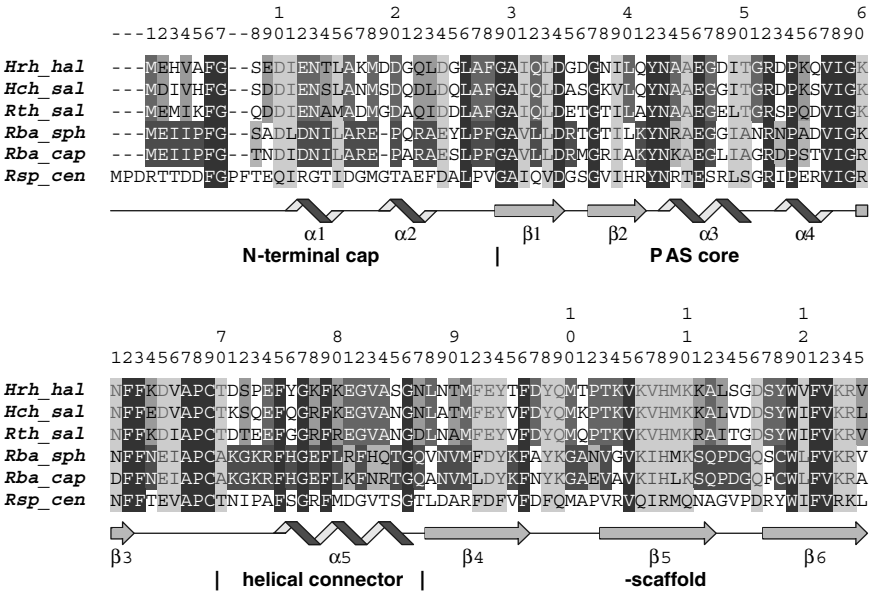

FIGURE 123.2 *Sequence alignment of the Xanthopsins.* An alignment of all currently known Xanthopsins is presented, where the following abbreviations stand for the organism in which the Xanthopsin was found, with the accession number for the primary sequence in parentheses: `Hrh_hal`, *Halorhodospira halophila* (X98887); `Hch_sal`, *Halochromatium salexigens* (P81046); `Rth_sal`, *Rhodothalassium salexigens* (X98888); `Rba_sph`, *Rhodobacter sphaeroides* (AJ002398); `Rba_cap`, *Rhodobacter capsulatus* (AF064095); and `Rsp_cen`, *Rhodospirillum centenum* (AF064527). Only the residues from `Hrh_hal`, `Hch_sal`, and `Rth_sal` are correctly numbered, for the correct numbering of the other sequences, you need to correct for deletions (Residue 19 in `Rba_sph` and `Rba_cap`) and insertions (up to Residue 8 in `Rsp_cen`) in the sequence. The location of the α-helices and β-strands for the `Hrh_hal` sequence are shown via cartoons below the sequence alignment, together with the names of the PAS-domain, subdomains.

The color code for the alignment is as follows. The base color is a white highlight with black letter; any other color has a special meaning for the alignment. Residues that are conserved throughout the currently known Xanthopsins have a black highlight and white letter. Residues that have conserved substitutions are shown with a light gray highlight. Residues that are conserved for the Xanthopsin subgroup containing `Hrh_hal`, `Hch_sal`, and `Rth_sal`, but are not conserved in all currently known Xanthopsins, have a medium dark gray highlight with white letter. If they are part of conserved substitutions for all Xanthopsins, they have a light gray highlight with medium dark gray letter. Conserved substitutions in this subgroup are given a medium gray highlight. Residues that are conserved for the Xanthopsin subgroup containing `Rba_sph` and `Rba_cap`, but are not conserved in all currently known Xanthopsins, have a dark gray highlight with white letter. If they are part of conserved substitutions for all Xanthopsins, they have a light gray highlight with dark gray letter. Conserved substitutions in this subgroup are given a medium light gray highlight.

This figure was prepared using information obtained from several alignments performed with ClustalW[83] (http://www.ebi.ac.uk/clustalw/).

Primary, Secondary, and Tertiary Structure

The chromophore plays a crucial role in the activity of PYP. The amino acids containing atoms that line the chromophore pocket are (in the order in which they appear in the sequence): Val120, Val122, Ile31, Tyr42, Glu46, Thr50, Arg52, Phe62, Val66, Ala67, Cys69, Thr70, Phe96, Asp97, Tyr98, and Met100. This pocket is completely buried in the major hydrophobic core of the protein and has no direct contact with solvent.

In the ground state of PYP, the phenolic oxygen of the chromophore is deprotonated.[23,24] The resulting negative charge of the phenolate is completely buried in the hydrophobic core of the protein and is

stabilized via a hydrogen-bonding network and by the positive charge of the nearby Arg52.[20,25,26] The negative charge of the phenolate is delocalized over the chromophore via an extensive π-orbital system. The hydrogen-bonding network is made up of the residues Tyr42, Glu46, and Thr50, where O_{η} from Tyr42 and $O_{\varepsilon,2}$ from Glu46 form a direct hydrogen bond with the chromophore. $O_{\gamma,1}$ from Thr50 hydrogen bonds with O_{η} from Tyr42 but does not line the chromophore pocket.

Solution Structure vs. Crystal Structure

Until now, we only looked at the structure of PYP in the confines of a crystal lattice. *In vivo*, the protein is located in the cytoplasm, where it may have more freedom for dynamical alterations in its structure, and where it may be more like the conditions used for most *in vitro* experiments. It is, therefore, relevant to know whether there are differences between its structure in a crystal and in aqueous solution. It is important, however, to keep in mind that in the intact cell, the protein may also be confined or partly constrained in its movements by, e.g., a transducer protein. The *in vivo* situation may, therefore, be a situation that is in between the situation in the crystal lattice and the situation in solution.

The solution structure of PYP was determined via multidimensional NMR spectroscopy.[27] This structure is similar to the structure determined with x-ray crystallography. When one compares the elements of secondary structure in the two structures, it turns out that most are present in both, though they may start and end one to two residues earlier or later. Different are helix α2 and the π-helix, which are not defined in the solution structure. There are three poorly defined regions in the solution structure comprising residues 1–5, 17–23, and 113–117. This is caused by lack of structural constraints in the NMR dataset, which might be caused by fast internal motions in those regions, or in other words, by high side-chain or backbone mobility.[27] In the crystal structure, the same regions also have higher values for the B-factor, which expresses the mean-square fluctuations of atoms from their average positions.

From an ensemble of structures, such as those obtained with NMR or via molecular dynamics, it is possible to determine eigenvectors that describe the path along which the different protein elements may move.[28,29] Using these eigenvectors, or modes of flexibility, it is possible to transform the solution structure into the crystal structure, indicating that the observed differences are within the confines of the intrinsic flexibility of the protein. This is further corroborated by the fact that when PYP is crystallized in the $P6_5$ space group,[29] instead of the $P6_3$ space group,[20] these structures are different but are within the confines of the intrinsic modes of flexibility of the protein.

The structure determined with NMR confirms the presence of the hydrogen-bonding network in the chromophore-binding pocket. However, there is one striking difference with the crystal structure. Residue Arg52 is present in two conformations: One in which Arg52 is clustered about 4 Å above the aromatic ring of the chromophore; and the other in which the guanidinium group of Arg52 positioned about 4 Å above the aromatic ring of Tyr98.[27] This latter position is in line with the observation that positively charged amino groups like to pack within 3.4 to 6 Å of the centroids of aromatic rings (the so-called -stacking[30]). The conformation for Arg52 and Tyr98 found in the crystal is different from the two conformations for Arg52 and the conformation of Tyr98 found in solution.

The Xanthopsins Compared

The Xanthopsins can be divided into three subgroups based on their primary structure. Subgroup I contains Xanthopsins found in *Halorhodospira halophila*, *Rhodothalassium salexigens*, and *Halochromatium salexigens*. Subgroup II contains Xanthopsins found in *Rhodobacter sphaeroides* and *Rhodobacter capsulatus*. Subgroup III contains the Xanthopsin found in *Rhodospirillum centenum*. The primary structures within the subgroups are similar, with identities around 75% (87% similarity, i.e., including conserved substitutions) in pair-wise alignments. In a comparison of Xanthopsins from Subgroup I with Xanthopsins from other groups, the alignments become worse with identities around 45% (67% similarity). Comparison of Xanthopsins from Subgroup II with those from Subgroup III provides even poorer results, with identities around 33% (57% similarity). When all currently known Xanthopsins are aligned, an identity of 23% (46% similarity) is obtained.

Because the Xanthopsin subgroups were defined based on sequence similarity, these results should not be surprising. However, by looking at subdomains of the sequence alignments, better insight is obtained on which domains make up a Xanthopsin and which domains are important for the function the Xanthopsin has in the organism it resides in. Above, PYP was proposed to be a prototype for the PAS domain. The family of PAS domains is large and spans all three kingdoms of life. A PAS domain is not so much defined by its primary structure but more by its secondary and tertiary structural elements. The PAS domain can be divided into four subdomains: the *N*-terminal cap, the PAS core, the helical connector, and the β-scaffold. In PYP from *Halorhodospira halophila*, these subdomains comprise residues 1–28, 29–69, 70–87, and 88–125, respectively.[19] Thus, the *N*-terminal cap contains helices α1 and α2; the PAS core contains the β-strands, β1, β2, and β3, and the helices α3 and α4; the helical connector contains helix α5; and the β-scaffold contains the β-strands, β4, β5, and β6. The residues that form the chromophore pocket are all contained within the PAS core and β-scaffold, which are sandwiched together.

Within the Xanthopsin subgroups, no distinction can be made between the degrees of homology between the different PAS subgroups, indicating that the mutations are spread evenly over the entire protein. However, in a comparison of all Xanthopsins, a clear distinction can be made between the PAS subgroups when looking at the percentage of similarity. The PAS-core and β-scaffold have similarities of 66 and 50%, respectively, whereas the *N*-terminal cap and helical connector have similarities of 25 and 34%, respectively. This suggests that the PAS-core and β-scaffold are what makes a Xanthopsin, and that the *N*-terminal cap and the helical connector determine the specific function of a particular Xanthopsin. When the same analysis is done with only the Xanthopsin Subgroups I and II, the picture becomes slightly different. The PAS-core is best conserved with a similarity of 71%, the *N*-terminal cap and β-scaffold have similarities of 50 and 53%, respectively, and the helical connector has a similarity of 33%. The most remarkable difference here is that the *N*-terminal cap has a considerably increased percentage of similarity that has become close to the one of the β-scaffold. This difference can be explained by the fact that Xanthopsins from Subgroups I and II are complete proteins, whereas the Xanthopsin from Subgroup III is a subdomain of a larger protein. This could indicate that the *N*-terminal cap may play an important part in signal transduction, because this is probably one of the biggest differences between Xanthopsins from Subgroups I plus II, as compared with Subgroup III.

123.3 Photoactivity of the Xanthopsins

Photoactivity of the Xanthopsins expresses itself in the form of a photocycle. When a Xanthopsin in the ground state absorbs a photon of the proper wavelength, structural changes occur in the protein that lead to a signaling state that can be "read" by the organism in which it resides. Within a second, the Xanthopsin spontaneously returns to its stable ground state. This self-regenerative cycle requires only that the holoprotein be in hydrated form, and it does not require the presence of a membrane, additional proteins, or cofactors, etc. Most Xanthopsin research is focused on this photocycle or a part of it. The best-studied Xanthopsin by far is PYP from *Halorhodospira halophila*. Therefore, the photocycle of this protein will be discussed in detail.

The Basic Photocycle

Models of the photocycle of PYP have become more complex over the years (see Figure 123.3). Nonetheless, the key states involved are as follows:

1. The ground- or dark-adapted state, pG, in which the chromophore is deprotonated and the isomerization state of the chromophore is *trans*
2. A spectrally red-shifted state, pR, that is formed on a nanosecond timescale (In this state, the chromophore is still deprotonated, but its configuration changed to *cis*.)
3. A spectrally blue-shifted state, pB, with respect to the ground state, which is formed on a microsecond timescale (This species is presumed to be the signaling state of the photoreceptor. It is

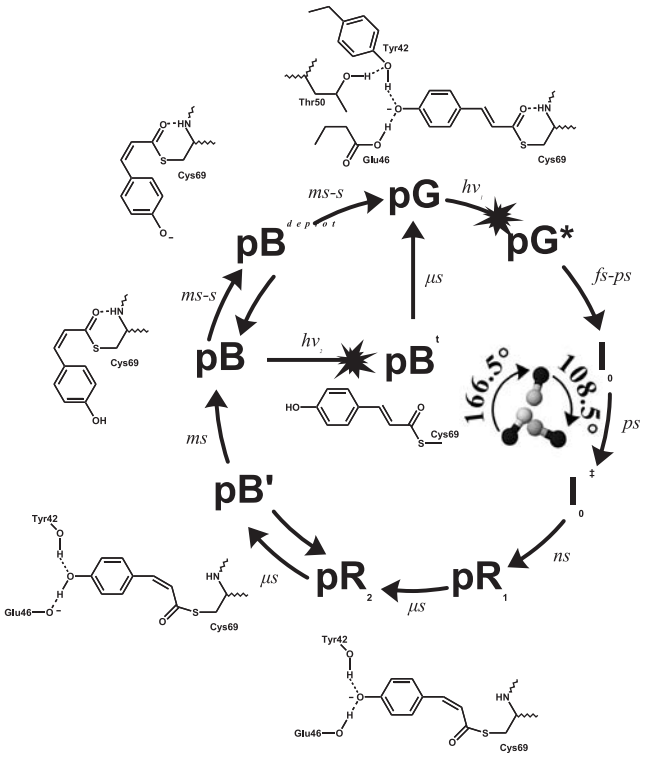

FIGURE 123.3 *Up-to-date description of the photocycle of PYP.* An up-to-date complete description of the photocycle events at room temperature is shown. In addition, the chromophore and its interactions with the protein were added. The drawings represent the situation in the intermediate it is placed next to. For the primary events, the rotation of the carbonyl group is illustrated instead. This inset was prepared using the program MOLMOL[82] using the structure coordinate file deposited at the Protein Data Bank[50] (http://www.rcsb.org/pdb) with PDB ID: 2PHY,[20] 3PYP,[44] 2PYR.[49] The program POV-Ray™ (http://www.povray.org) was used to render the image.

stable enough to allow for a signal to be processed by the organism. In pB, the chromophore has become protonated, while it retains the *cis* configuration. The holoprotein subsequently recovers to its ground state on the millisecond timescale.)

These three major steps — isomerization, protonation change, and recovery — are also observed in the sensory rhodopsins, which have a similar cellular function as PYP but are structurally different. It is interesting to note that although the Xanthopsins and sensory rhodopsins evolved separately, the photochemical mechanism they use to generate a signal from an absorbed photon is essentially the same.

Photocycle Nomenclature

Over the years, several nomenclatures for the photocycle intermediates were introduced. As the photocycle models become more complex, so does the nomenclature. Unfortunately, there is not a single nomenclature that is able to handle all the new intermediates being discovered. Also, not all intermediates are related to color changes of the chromophore. All the different nomenclatures contain the above-mentioned three basic photocycle species and can, therefore, be compared using these three species as a reference. Initially, the ground, red-shifted, and blue-shifted states were called *P*, I_1, and I_2.[31] In 1995, the names pG, pR, and pB were introduced by Hoff et al.[32] Yet another nomenclature[33] was introduced in 1996, in which these species were called PYP, PYP_L, and PYP_M, based upon the photocycle nomenclature of bacteriorhodopsin. The nomenclatures are made even more complicated by the use of additional subscripts that state a specific property of the species (e.g., the absorption maximum). Such a property

can be dependent on the measurement conditions used. As a consequence, different subscripts are used for the same species. Furthermore, an increasing number of different techniques are used to analyze the photocycle. As a result, more photocycle species are discovered that were previously undetectable. To provide these new intermediates a new name that fits logically within one of the existing nomenclatures is close to impossible.

Experimental Context

It is of crucial importance to take the experimental context of an experiment into consideration when comparing different experiments. Four different experimental parameters are of basic importance: temperature, nature of the solvent, mesoscopic context (or phase), and illumination conditions. The first, temperature, is obviously important when comparing kinetic experiments. But, temperature may also allow one to trap certain photocycle species[33,34] and prevent others from being formed. The second, the nature of the solvent, is also very important and is usually different between different experiments. Though pH is probably the most important solvent feature that has an effect on, e.g., the kinetics of the photocycle,[35,36] other solvent features, such as hydrophobicity of the solvent,[31] type and concentration of solutes present,[31,37] and the nature of the solvent (e.g., water versus deuterium oxide[35]) also can have their effects on the data. The third experimental parameter is the mesoscopic context or phase. In the crystalline phase (or lattice), no large structural change is observed in the protein upon formation of the signaling state, whereas when the protein is in solution, such a significant overall structural change is observed.[38] Furthermore, illumination conditions can have pronounced effects on the data, particularly, its color and intensity are important. The choice of wavelength can have an effect on which photocycle species are formed.[33,34] Also, the duration of the excitation pulse can have an effect. Longer illumination allows the possibility of photoactivation of photocycle species other than the ground state[39] and may lead to hysteresis effects in the recovery (Gensch et al., unpublished). The probe beam can also influence the data.

Mutants and Hybrids

PYP can be engineered genetically, via site-directed mutagenesis, and chemically, e.g., through the use of chromophore derivatives. The types of proteins obtained in these two approaches are referred to as mutant and hybrid, respectively. Many of the residues that interact with the chromophore (e.g., Tyr 42, Glu46, and Thr50) have already been mutated, and various chromophore analogs, particularly with ring substituents, have been used for holoprotein reconstitution.

123.4 The Photocycle of Photoactive Yellow Protein

Initial Events

In the first basic step of the photocycle of PYP, the chromophore isomerizes. The description of this process is still a puzzle. Though several models were suggested, it is not clear which, if any, of these models is correct. Nevertheless, several features are known. At least two different fluorescent states are formed after photoexcitation of PYP. One of these fluorescent states has a chromophore configuration that is different from the ground state configuration, which presents as an anisotropy difference with respect to the ground state.[40] It is unclear if both fluorescent states are actual photocycle intermediates that lead to progression of the photocycle, are photocycle dead ends, or are both (i.e., upon formation they can return to the ground state directly or indirectly via the photocycle).

The first step in the photocycle is completed upon formation of pR. At least one photocycle intermediate is formed between the excited (fluorescent) state and pR at room temperature. This intermediate, called I_0, is formed on a picosecond timescale and decays to pR on a nanosecond timescale. An additional intermediate with similar absorption characteristics as those of I_0, called $I_0^{\ddagger}$, exists between I_0 and pR.[40,41] At cryogenic temperatures, more intermediates can be distinguished. Here a branched pathway exists,

with each branch containing two intermediates, one of which can be assigned to the room temperature intermediate I_0. The two branches join upon formation of pR. Because the absorption characteristics of the intermediates of one of the branches are similar to those of the ground state, it is difficult to confirm their existence at room temperature. Nevertheless, this has been suggested for one of them.[42]

A bias for one of the branches in the low-temperature photocycle can be obtained via adjustment of the excitation wavelength. The branch with the I_0-like intermediate is preferred when shorter wavelengths are used for excitation.[34,43] It is, however, unclear if this is caused by the characteristics of PYP or by the fact that the I_0 intermediate can be photoconverted back to pG, which occurs at longer wavelengths. Similarly, the PYP_H intermediate can be photoconverted back to pG, which occurs at shorter wavelengths.[33] Here, we are confronted with one of the pitfalls of cryotrapping photocycle intermediates. The photoactivity of the protein is not limited to its ground state. Photocycle intermediates are photoactive as well. To accumulate a cryotrapped intermediate, the sample is usually illuminated for an extended period of time. As a result, the intermediate being cryotrapped is also illuminated and can thus be photoactively converted as well. The intermediate may return to the ground state. However, it is also possible that other intermediates, not normally part of the photocycle, are formed. Such an intermediate may be the fluorescent species F_{430}, which is possibly formed from the PYP_H intermediate.[34] It is, therefore, vital to take into account the illumination conditions when interpreting and comparing results obtained with cryotrapping.

Though the correct spectroscopic identification of the different intermediates is important, it is more interesting to understand their structural bases. From what is known, it is clear that the protein part shows little structural change during the first step of the photocycle. Also, the aromatic ring of the chromophore stays more or less at the same position.[44–46] The only way to facilitate isomerization of the chromophore under these conditions is by rotating the thiol-ester carbonyl. This carbonyl flip can be interpreted as a double isomerization around the $C_7 = C_8$ double bond and the C_9–S_γ single bond, i.e., the chromophore configuration changes from $C_7 = C_8$-*trans* C_9–S_γ-*cis* to $C_7 = C_8$-*cis* C_9–S_γ-*trans*. This model was first introduced on the basis of low-temperature FTIR spectroscopy,[47] and later confirmed.[38,45,48]

PYP is the first protein for which the structure of photocycle intermediates has been determined with x-ray crystallography. The structure of two intermediates from the first step in the photocycle was determined, i.e., PYP_{BL} and pR. For both intermediates, the structural changes are limited to the immediate surroundings of the chromophore. The structure of the PYP_{BL} intermediate was obtained via cryotrapping and resolved with a resolution of 0.85 Å. Based on the temperature and illumination conditions used, together with measurement of the absorption spectrum of the sample, it was concluded that PYP_{BL} was the cryotrapped intermediate.[44] However, it cannot be excluded that PYP_{HL} was also formed and, thus, that a mixture of intermediates was present. From the resolved structure, it is evident that the chromophore is in a *cis* configuration, be it a distorted one that has barely crossed the *trans* to *cis* transition point. The most important conclusion from this structure is that the chromophore is isomerized in such a way as to cause as little as possible movement of the chromophore within the chromophore pocket. Isomerization is achieved by rotating the carbonyl function 166.5° (see inset Figure 123.3), with respect to the aromatic ring, breaking the hydrogen bond between the carbonyl function and the backbone amide group of Cys69.

The structure of the pR intermediate was obtained via time-resolved x-ray crystallography at near room temperature, with 1.9 Å resolution.[49] The structure was determined from the 1 ns time-slice of a dataset encompassing time-slices up to 1 ms. Though initially the obtained structure was assigned to pR, this was revised in a subsequent paper describing the complete dataset of the time-resolved x-ray diffraction experiment.[46] The recorded 1 ns time-slice overlapped with the excitation laser pulse, which could result in the presence of multiple intermediates that are in photoequilibrium. Besides pG and pR, intermediates that occur between these two in the photocycle could also be present. The structure deposited at the Protein Data Bank[50] (http://www.rcsb.org/pdb) with PDB ID: 2PYR[49] has been refined, but was not updated or replaced. Where in the deposited structure the hydrogen-bonding network is

disrupted, in the refined structure, the hydrogen-bonding network stays intact, as is also suggested by experiments with other techniques, e.g., 47, 48. However, the position of the chromophore carbonyl function remains similar. The deposited pR structure has a completely *cis* isomerized chromophore for the $C_7 = C_8$ double bond. In this structure, the carbonyl function rotated an additional 108.5° with respect to the cryotrapped intermediate PYP_{BL} (see inset Figure 123.3). This may allow the formation of a hydrogen bond between the carbonyl and the backbone amide of Tyr98.

Recently, an extensive study on the photoexcitation and isomerization of PYP was published.[26] In this study, a combination of molecular dynamics simulation techniques and time-dependent density functional theory calculations were used. Several interesting results were obtained. Out of five separate simulations that were performed of the excited state, two showed a twisted configuration of the chromophore, and in three, the chromophore retained its *trans* configuration. This could explain the two different excited states observed in the ultrafast absorption measurement (see above).

The (free) energy content of PYP increased 120 to 160 $kJ \cdot mol^{-1}$ upon formation of pR.[51,52] This means that about half the energy of an absorbed photon is stored in the holoprotein at this point (a photon with a wavelength of 446 nm has an energy content of 268 $kJ \cdot mol^{-1}$). This amount of energy should then be enough to drive the remainder of the photocycle. This also implies that half the energy of the absorbed photon is lost in, e.g., thermal relaxations. FTIR analysis of the cryotrapped intermediates in the first step of the photocycle, suggests that there is little structural difference between these intermediates.[45] Thus, small movements induced by thermal relaxations may dictate the exact isomerization route of the chromophore.

Signaling State Formation and Ground State Recovery

In the signaling state, PYP interacts with a putative transducer protein to signal the cell that a blue photon was absorbed. Therefore, this state needs to have a relatively long lifetime to allow for this communication. Because the interacting transducer protein was not yet identified, all experiments have so far been performed on the purified PYP. It is possible that certain characteristics of the signaling state will change when transducer protein is added. An example of the effect that a transducer protein can have on a photosensor can be observed in sensory rhodopsin I. Here, in the absence of the transducer protein, the sensor protein acts as a proton pump, while in the presence of the transducer protein, the proton pump activity is lost.[53] Also, the pH dependence of the photocycle kinetics changes upon removal of the transducer protein.[53] This does not imply that measurements on just the isolated photosensor are obsolete. On the contrary, any differences between the characteristics in the absence and presence of the accompanying transducer may lead to a better understanding of how a signal might be transmitted.

In the formation of the signaling state of PYP, two key events were identified. One is protonation of the chromophore, neutralizing its negative charge, and the other is structural change of the protein. In the last basic step of the photocycle, the ground state is recovered, i.e., the chromophore has to be deprotonated and re-isomerized, and the protein part has to return to its ground state structure. Though knowledge about the formation of the signaling state increased significantly over the past few years, little is known about the specifics of the recovery of the ground state.

The Photocycle Model

Recently, photocycle models changed significantly with respect to events that occur after the formation of the pR intermediate (pre-pR events are discussed in detail in Section 123.4.1). Much of the early work assumed a simple three-state photocycle model, i.e., with the pG, pR, and pB states only. In these models, formation of the signaling state, pB (from pR), was described as a kinetically biexponential and as a monoexponential event. Actually, the first detailed analysis of the photocycle of PYP[37] postulated a photocycle containing an additional intermediate with similar spectral properties as pB, because of the observed biexponential kinetic character of pB formation. However, this model was abandoned in a

subsequent paper.[31] Recently, the intermediate pB′ was introduced as an intermediate in the pR to pB photocycle step based on results obtained with FTIR spectroscopy.[38] A subsequent detailed laser-induced transient UV/Vis spectroscopic kinetic analysis of the photocycle confirmed the existence of this intermediate and showed it has spectroscopic properties similar to those of pB.[35] Here, it was also revealed that the pB′ intermediate is in equilibrium with pR, which explains the previously observed biexponential character of the pR to pB photocycle step.[37,54]

Recovery of the ground state can be achieved spontaneously in the dark or light-induced via an accelerated path. In the latter, a photon absorbed by pB′ and pB, photoisomerizes the chromophore, thereby allowing a thousand-fold increase in the rate of recovery, with respect to the rate of recovery in the dark.[55] It may be useful to note that the measuring light can also induce this branching reaction, and hence, influence data.Though for the dark recovery, it has been suggested that before isomerization can take place, the chromophore must first be deprotonated and, thus, an intermediate must exist between pB and pG,[56] This was not experimentally demonstrated until recently, in an extensive series of measurements of the kinetic deuterium isotope effect of photocycle transitions in PYP.[35]

Structural Relaxation of pR

Recently, it was found that additional relaxation events in the protein occur after pR formed.[57,58] Through the use of the transient grating and pulsed-laser photoacoustic methods, it was shown that a μs dynamic component exists during the lifetime of pR. This indicates that after the structural changes in and immediately around the chromophore are completed, additional structural changes occur in the protein away from the chromophore. Thus, pR can be split into the two intermediates pR_1 and pR_2. Though the transition from pR_1 to pR_2 is claimed to be spectrally silent, a similar transition was observed earlier in UV/Vis data.[54] However, as this transition only contributed a small amount to the total signal, no confident assignment could be made, and the feature was not further discussed. In a recent analysis of UV/Vis data,[35] reaction kinetics were obtained that fit the pR_1 to pR_2 transition observed via transient grating. Though the obtained spectra for both pR intermediates are similar, pR_1 seems to have a slightly higher extinction coefficient than pR_2, whereas the λ_{max} values are indistinguishable.

Protonation Change upon pB′ Formation

The first event that takes place after the formation of the pR intermediate is protonation of the chromophore, which results in the formation of pB′. Because the UV/Vis spectroscopic properties of pB′ are similar to those of pB, the first experimental evidence for the existence of this intermediate was obtained in FTIR measurements.[38] It was shown that deprotonation of Glu46 and protonation of the chromophore are simultaneous events, which are followed by a structural change of the protein. Because the absorption changes monitored with UV/Vis spectroscopy mainly represent changes of the chromophore and its immediate surroundings and far less of the structure of the surrounding protein, it is difficult to distinguish between pB′ and pB on the basis of UV/Vis spectroscopy. With proof for the existence of a pB′ intermediate available, it was incorporated in a photocycle model, which was used to analyze UV/Vis data in a study on the kinetic deuterium isotope effect in the photocycle of PYP.[35] From these analyses, it was evident that pR and pB′ exist in an equilibrium that shifts toward pB′ upon going to the extremes of pH (both low and high). The observed kinetic Deuterium Isotope Effect is in line with a proton transfer from Glu46 to the chromophore for the whole pH range that was investigated (pH 5 to 11). However, for the return reaction, the situation is more complex. Here, formation of pR from pB′ can occur via different routes, dependent on pH.

With the reversible character of the pR to pB′ transition, a plausible explanation for the biexponential behavior of pB formation, previously observed with UV/Vis spectroscopy,[37,54] is now available. The shift of this equilibrium toward pB′, when going to the pH extremes, also explains the shift toward monoexponential behavior for the formation of pB at these latter pH values.

Structural Change upon pB Formation

From the strongly nonlinear Arrhenius kinetics of the recovery reaction of pG,[59] it was concluded that the signaling state of PYP is at least partly unfolded. In a mutant with the first 25 *N*-terminal amino acids removed,[60] the deviation from normal Arrhenius behavior was largely gone. Therefore, it seems that the *N*-terminal region of PYP is largely responsible for the large structural change upon formation of the signaling state. Several other methods, like, e.g., CD, NMR, fluorescence, and FTIR spectroscopy, confirmed this partial unfolding.

Hydrogen–deuterium (H/D) exchange measurements, in particular, contributed to the insight into the structural change that is at the basis of signaling state formation in PYP. Whereas a buried hydrogen atom may take days to exchange, an exposed hydrogen atom may be exchanged within seconds. PYP contains 235 potentially exchangeable hydrogen atoms, 42 of which are from (de)protonatable groups. In a study with electrospray ionization mass spectrometry,[61] it was shown that in the dark, less hydrogen atoms were exchanged for deuterium atoms compared to an experiment performed in the presence of light. Also, in apoPYP, 29 potential exchange sites resist exchange, which can be interpreted as that 29 or less of the 42 (de)protonatable groups are deprotonated. Additionally, it may mean that apoPYP has a certain degree of structure, depending on the actual number of deprotonated groups. The light-induced H/D exchange was independently confirmed using FTIR difference spectroscopy.[61] Though these experiments show that there is a difference between the ground and signaling state of PYP with respect to H/D exchange protection, they do not pinpoint the areas of the protein responsible for the observed differences. However, it is possible to obtain more specific information with NMR spectroscopy.[62] Even though it was only possible to obtain specific information for the backbone amide exchangeable hydrogen of 51 residues, 14 of these showed a significant change in protection (i.e., resistance against exchange) upon formation of the signaling state pB, i.e., only two less than the number predicted by mass spectrometry, which was not limited to the backbone amide hydrogen atoms. The residues with the most significant loss in protection are Phe28, Glu46, and Thr70. The latter two are close to the chromophore, whereas Phe28 is close to Glu46.

In an NMR study of the pB intermediate in solution, it was shown that pB exhibits structural and dynamic disorder with respect to the ground state.[63] Interestingly, a subsequent NMR study of pB_{dark} formation[62] showed that pB_{dark} and the photocycle intermediate pB are similar. It was also made clear that upon formation of pB_{dark}, the protein can be divided into three parts: a relatively stable core (residues 32–41, 80–94, and 113–122) and two areas that display large structural perturbation; the *N*-terminus (residues 6–18, and 26–29); and the area around the chromophore binding site (residues 42–58, 69–78, and 95–100). As discussed above, the structural perturbations of the *N*-terminus are largely responsible for the observed non-Arrhenius behavior of the photocycle kinetics. Furthermore, the NMR data suggest that the pB intermediate is a mixture of structurally perturbed forms and a form structurally similar to the ground state, or more specifically, similar to the pB crystal structure.[64]

The trigger for the major structural change upon formation of pB is the formation of a buried negative charge on Glu46 when it donates its proton to the chromophore.[38] After formation of pB′, the buried negative charge, initially located on the chromophore, is centered on Glu46. Whereas on the chromophore, the negative charge can be effectively neutralized by delocalization of the charge, the hydrogen-bonding network, and possibly the positive charge on Arg52. On Glu46, the buried negative charge cannot be effectively neutralized. This leads to a stress situation within the protein, which can be relieved via several routes. One is return to the pR state, reflecting the reversible nature of pB′ formation (see above). Other routes lead to the formation of pB. The extent of the structural change upon formation of the pB intermediate depends on the route taken. One route to take to relieve the buried negative charge is to expose it to solvent, which requires structural change of the protein. Another route is to protonate the Glu46, but not via the chromophore, because that would lead to the reformation of pR. Once Glu46 is protonated, the stress situation is relieved, and a large structural change is no longer necessary. Because protonation changes play a key role, it is to be expected that these events are pH dependent. Thus, depending on the pH, one route may dominate over the other. In fact, a pH dependence of the extent

of structural change was observed to coincide with protonation of Glu46 (J. Hendriks and A. Xie et al., unpublished results). Of course, both routes to pB mentioned here assume that pB′ is formed as an intermediate. It is also possible that a direct, or alternative, route from pR to pB exists. In such a route, Glu46 may stay protonated, i.e., it does not donate a proton to the chromophore. The chromophore then becomes protonated only after exposure to the solvent, or via another residue (e.g., Tyr42). Such a route would require little structural change of the protein and might be preferred in the crystal environment. All mentioned routes are possibilities, and depending on the conditions, one particular route may dominate. The key factor in all these routes is what happens to the protonation state of Glu46 and the chromophore. In fact, it was shown that for the Glu46Gln mutant in solution, the structural change upon formation of pB is significantly less compared to the wild-type situation.[38] In this mutant, Residue 46 can no longer donate a proton to the chromophore, and thus, no buried negative charge is formed on Residue 46, and hence, less driving force for structural change is generated. Though Residue 46 plays an essential role in the amount of structural change that takes place, other residues may also have influence, e.g., His108 also has influence on the extent of structural change, as it was shown that the mutant His108Phe exhibits less structural change compared to the wild-type protein.[65]

The pH dependence of structural change was also shown to exist via transient probe binding,[66] showing less structural change at low pH. Together with experiments monitoring the pH-dependent net proton uptake and release of PYP during pB formation,[67] and pH-dependent FTIR results (J. Hendriks and A. Xie et al., unpublished results), it is likely the pK_a of Glu46 in pB is 5.5, where above pH 5.5 more structural change occurs than below pH 5.5.

In a recent molecular dynamics study, the effect of protonation of the chromophore by Glu46 on the stability of the protein was simulated.[68] Though the simulation was run for only 4 ns after the proton transfer, it is clear that this event induces structural changes in the protein. For one, the proton transfer causes the hydrogen-bonding network with the chromophore to collapse, which results in a shift of the negative charge, which becomes localized on Glu46, an energetically unfavorable situation. Furthermore, the *N*-terminal domain is affected in the simulation as well as α-helix 3. These domains were also shown to be involved in structural change based on NMR measurements (see above and Craven et al.[62]).

Recovery of the Ground State

During the recovery of the ground state of PYP, several events have to take place. The chromophore has to re-isomerize to the *trans* form, the protonation states of several residues and the chromophore have to be changed, and the protein needs to return to its original fold. Though these are seemingly distinct steps, until recently, they appeared to occur simultaneously. On the basis of measurements of the kinetic deuterium isotope effect,[35] it was shown that deprotonation of the chromophore occurs before its isomerization. Hence, an intermediate named pB^{deprot} is formed "en route" from pB to pG. Though deprotonation of the chromophore aids the re-isomerization of the chromophore tremendously,[69] this re-isomerization is still a rate-controlling step, in which the protein fold likely plays a crucial part. The pB^{deprot} intermediate is, therefore, characterized by a deprotonated chromophore and a folding state that allows re-isomerization of the chromophore. This latter characteristic is important, as this intermediate possibly has an absorption spectrum similar to that of the ground state of PYP and not one that is similar to the pB intermediate at high pH, which also has a deprotonated chromophore but has its absorption maximum around 430 nm.[35,67] An absorption spectrum similar to the ground state for the pB^{deprot} intermediate also explains why it was not observed before.

When re-isomerization of the chromophore is accelerated with a short flash of 350 nm light, the rate of recovery of the ground state is increased a thousand-fold.[55] In this branching reaction, an intermediate pB^t is formed instantaneously on the nanosecond timescale. A slight blue shift of pB^t, with respect to pB, can be explained by the difference in isomerization state of the chromophore, i.e., *cis* (pB) versus *trans* (pB^t). No other intermediates are observed with UV/Vis spectroscopy in going from pB^t to pG, indicating that change of the protein fold and the protonation state of several residues can be achieved quickly once the chromophore is isomerized. The existence of this branching reaction can influence data

because of the presence of light that can be absorbed by any of the pB intermediates. This may allow recovery kinetics to appear faster than they really are in the absence of this probe light.[70] This light accelerated recovery can be exploited in the study of the very-slow recovery variants, like M100A.

Several studies were done to study refolding of PYP. Mostly, these studies employ a denaturant to aid the initial unfolding of the protein. The exception is an NMR study,[63] where recovery of the ground state was measured solely on the basis of light-induced unfolding of the protein. For the recovery, a differential refolding was observed where the central β-sheet and parts of the α-helical structure refold slightly faster, after which the region around the chromophore returns to the ground state fold. The differences between the rates are small, and it is unclear if the accompanying error allows one to differentiate between the rates. But, the observed trend is in line with the idea that in order to facilitate re-isomerization of the chromophore, the chromophore not only needs to be deprotonated, but also the protein needs to be in a relatively folded state.

In a study utilizing the denaturants urea and guanidinium·HCl, refolding was studied in unfolded ground state protein and in the unfolded signaling state.[71] The major difference between these two denatured forms of the protein is the isomerization state of the chromophore. Where refolding from the denatured ground state is a monoexponential event, refolding from the denatured signaling state is a biexponential event. Here, the fast component is identical to refolding from the denatured ground state, and the slow exponent has a rate similar to the photocycle ground-state recovery rate under similar conditions. This indicates that after the signaling state renatures, it recovers to the ground state through normal photocyclic events. Interestingly, extrapolation of the obtained refolding kinetics to the absence of denaturant shows close to a thousand-fold faster rate for refolding for protein with the chromophore in the *trans* state compared to protein with the chromophore in the *cis* state. This is similar to the rate difference observed between the ground state recovery in the dark and photoactivated ground state recovery via the branching reaction.[55]

Similar experiments with the acid denatured state of PYP were also performed.[72] Similar results as with the denaturants as described above were obtained, where refolding from the acid denatured state with the chromophore in the *trans* state, i.e., pB_{dark}, is three to five orders of magnitude faster compared to the acid denatured state with the chromophore in the *cis* state. Interestingly, it was shown with temperature denaturation that, when in the acid denatured state, the chromophore is in the *cis* state, and the protein is more stable than when the chromophore is in the *trans* state. Furthermore, it was shown that the acid denatured state with the chromophore in the *cis* state is similar to the photocycle intermediate pB.

For a few mutants of PYP, a dramatic decrease in recovery rate was observed, i.e., Glu46Asp,[73] Met100Ala,[74] and Met100Leu.[75] This indicates that Glu46 and Met100 are important for recovery. Met100 is important for the re-isomerization of the chromophore, as indicated by the dramatic increase in rate of recovery when the chromophore is photochemically re-isomerized in the Met100Ala mutant.[74] In a recent study, it was argued that the electron-donating character of the residue at position 100 influences the rate of recovery through interaction with another residue, most likely Arg52.[76] With the Glu46Asp mutant, such a dramatic increase in recovery rate was not observed upon photochemical re-isomerization of the chromophore.[73] As such, it is likely that Glu46 is important for refolding of the protein, though it may still be involved in dark re-isomerization of the chromophore.

123.5 Spectral Tuning of Photoactive Yellow Protein

Tuning of the UV/Vis absorption band of PYP, away from the values of neutral or anionic coumaric acid, is of interest for several reasons. First, there is the tuning of the absorption band of the ground state structure. Here, the contribution of specific structural characteristics must be analyzed. However, during the photocycle of PYP, the absorption spectrum changes as well. These changes, therefore, contain valuable information regarding the chromophore and its surroundings in the respective photocycle states. A proper understanding of the tuning of PYP will, therefore, aid in understanding events that occur during the photocycle.

Ground State Tuning

The interaction of the chromophore and protein part of PYP produces an absorption band with 446 nm as its maximum. As the free chromophore, *trans*-4-hydroxycinnamic acid, has an absorption maximum at 284 nm (in aqueous solvent around neutral pH),[77] this interaction of the chromophore with the protein induces a large red shift. Several specific interactions can be distinguished. For one, the thiol ester link of the chromophore with Cys69 causes a red shift of ~5713 cm^{-1} (from 284 to 339 nm). This follows from a comparison of the absorption maximum of 4-hydroxycinnamic acid and the denatured form of PYP in aqueous solution at pH 7.[78] An additional red shift of 4310 cm^{-1} (from 339 to 397 nm) occurs when the chromophore becomes deprotonated, which follows from a comparison of the absorption maximum of the denatured form of PYP in aqueous solution at pH 7 and 11.[78] This leaves a red shift of ~2767 cm^{-1} (from 397 to 446 nm) that is due to interactions with the protein. Though this description is illustrative, it does not provide specific insight regarding the nature of the interactions between the chromophore and the protein.

In a recent study, a closer look was taken at the mechanisms that lead to the spectroscopic tuning of PYP in its ground state.[25] Two model compounds were used for comparison, i.e., a propyl ester and a propyl-thiol ester of 4-hydroxycinnamic acid. The thiol ester model compound was consistently red-shifted by ~1000 cm,$^{-1}$ with respect to the ester model compound, irrespective of the protonation state of the chromophore. With regard to tuning in PYP, three tuning contributions were considered, i.e., a medium effect of the protein matrix (700 cm^{-1}), a counterion effect (5300 cm^{-1}), and a hydrogen-bonding effect (~1600 cm^{-1}). The medium effect of the protein matrix takes into account nonspecific solvent effects. For the model compounds, the absorption maximum shifted with the solvent that was used, e.g., for the thiol ester model compound, the absorption maximum ranged from 34,800 cm^{-1} (287 nm) in pentane to 31,500 cm^{-1} (317 nm) in pyridine. This difference is mainly caused by differences in the dielectric constant and refractive index between the solvents. To determine the medium effect in PYP, these values were estimated for the protein. Absorption maxima of the thiol ester model compound in hexane and protein were calculated. Note that only the solvent properties of the protein are considered here (the counterion and hydrogen-bonding effects are not). This leads to a contribution of ~700 cm^{-1} to the tuning of the chromophore in the protein. The counterion effect considers the difference in position of the counterion of the thiol ester model compound in solution (sodium ion at 2.5 Å in a straight line from the phenolate oxygen bond) and in the protein (position of Arg52 in the crystal structure PDB ID: 2PHY[20]). Here, protein solvent conditions were used in the calculation of the absorption maxima. This leads to a contribution of ~5300 cm^{-1} to the tuning of the chromophore. The hydrogen-bonding effect was determined by placing methanol at the positions of the hydroxy groups of residues Tyr42, Glu46, and Thr50, which are involved in the hydrogen-bonding network with the chromophore, in the calculations. By comparing the situation incorporating the medium effect of the protein matrix and the counterion effect, with the situation that also takes into account the hydrogen-bonding effect, the contribution of the latter was calculated as a blue shift of ~1600 cm^{-1}. Furthermore, with regard to the counterion effect, an interesting observation was made. The position of the Arg52 is such that it appears that the counterion is infinitely far apart from the chromophore, i.e., it does not contribute to the tuning. Movement of the counterion toward the thiol ester linkage would result in a red shift, whereas movement toward the phenolate oxygen would result in a blue shift. From NMR measurements[27] and molecular dynamics studies,[26] it is evident that Arg52 may have two distinct positions in the ground state. Here, the two distinct positions obtained with the molecular dynamics studies result in a difference of 20 nm between the absorption maxima of the two conformers.[26]

When the hydrogen-bonding network in PYP is weakened (by replacing the bridging hydrogen atoms with deuterium atoms), a small red shift is observed, which would be expected when the hydrogen-bonding effect contributes a smaller blue shift to the total tuning. Furthermore, the residues involved in the hydrogen-bonding network (Tyr42, Glu46, and Thr50) were altered through mutagenesis. Mutants in Tyr42, Glu46, and Thr50 result in red shifts (e.g., Tyr42Ala, Tyr42Phe, Glu46Gln, Glu46Ala, Thr50Val, and Thr50Ala[36,73,79–81]) reflecting the weaker hydrogen-bonding effect in these mutants. In some mutants

though, protein stability was severely affected, as indicated by a major, additional, blue-shifted absorption band (Tyr42Phe, Tyr42Ala, and Glu46Ala).

Several mutants of residue Arg52 were also prepared. The Arg52Ala mutant is slightly red shifted,[36] while the Arg52Gln mutant shows no shift of the absorption maximum.[79] As described above, removal of the counterion would not lead to a change in absorption maximum, which is what is observed in the Arg52Gln mutant. A small red shift that is observed in the Arg52Ala mutant may be explained by a more open structure of the chromophore-binding pocket, possibly allowing a solvent cation to act as a counterion.

Spectral Tuning in Photocycle Intermediates

The negative charge on the chromophore is most effectively delocalized if the chromophore is planar. During isomerization, planarity is lost, and the negative charge is not as efficiently delocalized, which results in a red shift of the absorption spectrum. This would explain why the intermediates I_0 and $I_0^{\ddagger}$ are more red shifted than pR, as in those intermediates, isomerization was not yet completed, and the chromophore may be in a twisted form. In pR, the chromophore is still not quite planar due to steric hindrance between the carboxylic oxygen and atoms of the phenolate ring,[68] explaining the red shift. Additionally, in pR, the chromophore contracted ~0.5 Å,[68] while the structure of the protein is similar to that of the ground state. Such a contraction could lead the counterion Arg52 to become located closer to the phenolate oxygen of the chromophore, which would also lead to a red shift.

Protonation of the chromophore leads to a large blue shift, which is what is observed. In pB′, the structure of the protein is still similar to that of pR, and thus to the ground state. Therefore, interactions with the protein are likely. When pB is formed, the structure of the protein has dramatically changed (in solution), where the interaction of the protein with the chromophore has likely diminished, which is also illustrated by the slight additional blue shift of the pB intermediate with respect to pB′. However, even though the chromophore has become more exposed in pB, its absorption maximum is still slightly red shifted compared to the situation in denatured protein.[71] The chromophore is, therefore, still tuned in pB, through interactions with the protein. The presence of these interactions is further demonstrated by the pK_a of the chromophore in pB, which is ~10 and not 8.7 as is the case in fully denatured protein.[35]

Before re-isomerization can take place, the chromophore needs to be deprotonated first. This leads to a large red shift, with respect to pB, as is demonstrated by the pB spectrum at high pH, where its absorption maximum shifts to ~430 nm.[35,67] However, for isomerization to take place, the folding state of the protein also needs to be correct. When that condition is also met, we refer to the intermediate pB^{deprot}. As an intermediate with an absorption maximum of 430 nm has not been observed during the recovery of PYP, it is unlikely that the absorption spectrum of pB^{deprot} is similar to that of pB at high pH. More likely is that, due to interaction with the protein, the absorption band of pB^{deprot} is even more similar to that of the ground state.[35]

123.6 Summary and Future Perspective

After excitation of the ground state of PYP, a twisted, excited state configuration will be formed that results in formation of the I_0 photocycle intermediate. In this latter intermediate, the chromophore has already achieved the *cis* configuration, though it is still twisted. Further relaxation in the protein leads to formation of $I_0^{\ddagger}$ and, subsequently, pR. Isomerization is achieved with a minimal amount of movement of the chromophore, i.e., through a concerted rotation around several bonds that can be described as a $C_7 = C_8$-*trans* C_9-S_γ-*cis* to $C_7 = C_8$-*cis* C_9-S_γ-*trans* multiple-bond isomerization, or "a rotation" of the chromophore carbonyl oxygen. Isomerization of the chromophore increases the probability of a proton transfer from Glu46 to the chromophore. When this occurs, the intermediate pB′ is formed. As a result, the negative charge — which was stabilized when it resided on the chromophore via delocalization, a hydrogen-bonding network, and a counterion — now resides on Glu46, where it is localized. This is an energetically unfavorable situation resolved by formation of pB, in which structural changes took place

in the *N*-terminal domain and around the chromophore. Particularly, the involvement of the more or less independently folded *N*-terminus in the partial unfolding is remarkable. Together with the sequence comparisons within the PAS domains, this may suggest that the *N*-terminus is important for signaling. The extent of these structural changes depends on sample conditions and can range from very little structural change in crystals, at low temperature, and in insufficiently hydrated films, to large structural changes in solution and sufficiently hydrated films.

After formation of the signaling state, the photocycle enters the recovery phase. For recovery to take place, the chromophore has to be re-isomerized, and the protein needs to return to its ground state fold. Before re-isomerization can take place, the chromophore needs to be deprotonated, and the protein needs to adopt a specific fold that allows for the re-isomerization to take place. This situation is represented by the pB^{deprot} intermediate, which is in equilibrium with pB. In addition to this recovery in the dark, it is also possible to re-isomerize the chromophore photochemically, which results in a rate of recovery that is three orders of magnitude faster than dark recovery.

Through the years, PYP has become popular as a model system. This is easily demonstrated by a literature search with the key words "Photoactive Yellow Protein." Where only a few years ago, the search result would contain mostly papers on PYP itself, nowadays, studies on many other proteins are included, for which PYP is seen as a model or reference system. Three areas of research in particular are relevant for this role-model function:

1. The study of signaling state formation in PAS-domains
2. The study of functional protein unfolding
3. The study of the primary photochemistry of photoreceptors

This popularity is based on the favorable handling characteristics, the availability of high-resolution structures, and the relatively simple structure of the chromophore of PYP.

Nevertheless, several additional fields may benefit from efforts made to understand the details of signaling in PYP. The first is molecular dynamics modeling, because this approach may benefit from the availability of transient reference structures from time-resolved x-ray diffraction. Furthermore, recently a number of biophysical approaches were used to estimate the rate of translational diffusion of PYP in its ground and signaling states. As the values obtained varied among the techniques used (e.g., K.J. Hellingwerf, J. Hendriks, and T. Gensch[84]), further detail about the assumptions and approximations used in these techniques may be revealed.

Beyond all this, of course, the field of signal transduction in photobiology could benefit enormously from the detailed insight into the mechanism that leads to signal generation within PYP. However, that aspect will blossom only when additional signal transduction components that link PYP to the flagellar apparatus are identified.

Microbial Rhodopsins: Transport and Sensory Proteins throughout the Three Domains of Life

Kwang-Hwan Jung
University of Texas

John L. Spudich
University of Texas

124.1 Summary

Archaeal rhodopsins, photoactive seven transmembrane helix proteins that use all-*trans* retinal as their chromophore, have been known for three decades and extensively studied in extreme halophiles. In the past 3 years, microbial genome sequencing and environmental genomics revealed archaeal rhodopsin homologs in the other two domains of life as well, namely, Bacteria and Eucarya. Microorganisms containing these genes inhabit diverse environments, including salt flats, soil, freshwater, and the world's oceans. They comprise a broad phylogenetic range of microbial life, including haloarchaea, proteobacteria, cyanobacteria, fungi, and algae. Analyses of the new microbial rhodopsins by genetic, biochemical, and structural techniques are beginning to reveal a variety of photosensory signaling and light-driven transport mechanisms in diverse life forms.

124.2 Introduction

In the 1970s and early 1980s, four rhodopsins were discovered in the cytoplasmic membrane of the archaeon *Halobacterium salinarum*: the light-driven ion pumps bacteriorhodopsin (BR[1]) and halorhodopsin (HR[2,3]), and the phototaxis receptors sensory rhodopsin I (SRI[4]), and sensory rhodopsin II (SRII[5]). Many laboratories extensively characterized this family of proteins with a battery of diverse techniques, because they provide excellent model systems for the two fundamental functions of membranes: active transport and sensory signaling. Twenty-nine variants of BR, HR, SRI, and SRII were documented in related extremely halophilic archaea, such as *Natronomonas pharaonis* and *Haloarcula vallismortis*. Members of the "archaeal rhodopsin family" were generally assumed to be only in the haloarchaea and appeared to be restricted to the extreme halophilic environments of solar evaporation ponds and other regions of near-saturated salt concentration.

0-8493-1348-1/04/$0.00+$1.50

Our understanding of the abundance and diversity of this family was radically transformed by findings over the past 3 years. Genome projects on a number of microbes revealed archaeal rhodopsin homologs in the other two domains of life as well, namely, bacteria and eukaryotes. Organisms containing these homologs live in such diverse environments as soil, freshwater, and ocean waters, and they include a broad range of microbial life, including proteobacteria, cyanobacteria, fungi, and algae (Table 124.1). Analysis of the sequences of the new microbial rhodopsins, their heterologous expression and study, and spectroscopic analysis of environmental samples showed that they fulfill ion transport and sensory functions in these organisms. The purpose of this review is to summarize what we learned regarding the rapidly expanding group of retinylidene pigments we now call the "microbial rhodopsin family."

124.3 Microbial Rhodopsins

Archaeal Rhodopsins

As evidenced by the many incisive articles in this issue, the archaeal rhodopsins rank among the best-understood membrane proteins in terms of structure and function. Atomic resolution structures, which exist for only a handful of membrane proteins, were obtained from electron and x-ray crystallography of three of the archaeal rhodopsins: bacteriorhodopsin,[6–8] halorhodopsin,[9] and recently, sensory rhodopsin II (NpSRII from *N. pharaonis*[10,11b,11c]). The transport and sensory rhodopsins share a common design of seven transmembrane helices forming an interior pocket for the chromophore all-*trans* retinal. The retinal binding pocket is comprised of residues from each of the seven helices, and it is the conservation of these residues that provides the most definitive identification of archaeal rhodopsin homologs in other organisms. Conservation outside of the pocket is sparse but recognizable (Figure 124.1). Even between members of the archaeal branch, conservation outside the pocket is limited. For example, the *N. pharaonis* phototaxis receptor NpSRII is 27% identical to BR in amino acid sequence and exhibits typically ~40% identity with other sensory rhodopsins; all four archaeal rhodopsins exhibit ~80% identity in the 22 residues that form the retinal binding pockets in BR, HR, and NpSRII. In the new rhodopsins, 55 to 75% identity is found in retinal binding pocket residues (Figure 124.1).

The functions of the four archaeal rhodopsins were well characterized. BR (λ_{max} 568 nm) and HR (λ_{max} 576 nm) are light-driven ion pumps for protons and chloride, respectively, absorbing maximally in the green-orange region of the spectrum.[12,13] Their electrogenic transport cycles provide energy to the cell under conditions in which respiratory electron transport activity is low. Accordingly, their production in the cells is induced when oxygen is depleted in late exponential/early stationary phase cultures. BR and HR hyperpolarize the membrane to generate a positive outside membrane potential, thereby creating inwardly directed proton motive force. HR further contributes to pH homeostasis by hyperpolarizing the membrane by electrogenic chloride uptake rather than proton ejection, thereby providing an electrical potential for net proton uptake, which is especially important in alkaline conditions.

SRI and SRII are phototaxis receptors controlling the cell's swimming behavior in response to changes in light intensity and color.[14] SRI (λ_{max} 587 nm) is also induced in cells in late exponential/early stationary phase and attracts the cells to orange light, which is useful to the transport rhodopsins. To avoid guiding the cells into light containing harmful near-UV radiation, SRI has a color-discriminating mechanism that ensures that the cells will be attracted to orange light only if that light is not accompanied by near-UV wavelengths.[15] The mechanism is based on photochromic reactions. If SRI absorbs a single photon (maximal absorption in the orange), it produces a photointermediate species called SRI-M or S_{373} (λ_{max} 373 nm) that is interpreted by the cell's signal transduction machinery as an attractant signal. However, if S_{373} is photoexcited, it generates a repellent signaling photointermediate. Therefore, single-photon excitation of SRI, such as occurs in orange light, attracts the cells, whereas two-photon excitation, as occurs in white light, repels the cells. SRII absorbs in the mid-visible range (λ_{max} 487 nm) and appears to serve only a repellent function.[16] It is the only rhodopsin in *H. salinarum* produced in cells during vigorous aerobic grow when light is not being used for energy and is best avoided.

TABLE 124.1 List of microbial rhodopsins with database accession numbers. (BR: bacteriorhodopsin, HR: halorhodopsin, SRI & II: sensory rhodopsin I & II, NR: *Neurospora* rhodopsin, CSRA & B: *Chlamydomonas* sensory rhodopsin A & B)

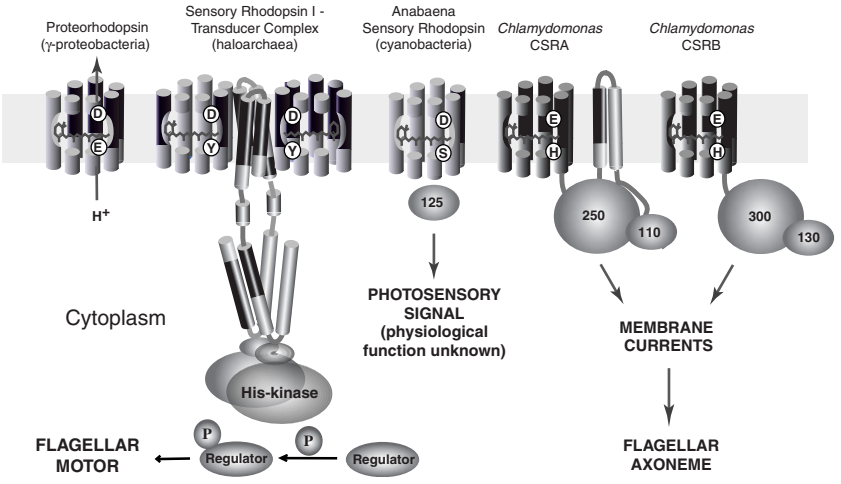

FIGURE 124.1 Diversity among the archaeal-type rhodopsins. Domains of the two sensory rhodopsins from *Chlamydomonas reinhardtii,* CSRA and CSRB, compared with those for proteorhodopsin and sensory rhodopsin I (in a dimeric complex with its cognate dimeric transducer) from haloarchaea, and a cyanobacterial sensory rhodopsin from *Anabaena*. The domains for CSRA, CSRB, and *Anabaena* sensory rhodopsin are based on known crystal structures of microbial rhodopsins and secondary structure predictions. The drawing for the sensory rhodopsin I transducer, HtrI, is based on biochemical data and secondary structure predictions. All of the rhodopsins shown were demonstrated to contain an all-*trans* retinal chromophore covalently linked to a conserved lysine residue in the seventh transmembrane helix. Amino acid variations within or near the retinal-binding pocket contribute to differences in the absorption spectrum of each pigment or specialized function. Residues in the third transmembrane helix of bacteriorhodopsin that are important for proton translocation (Asp85 and Asp96), and the amino acid differences at their corresponding positions in the other rhodopsins, are highlighted. For CSRA and CSRB, the numbers correspond to the number of amino acid residues in each domain. The cyanobacterial sensory rhodopsin and its cognate 125-residue putative transducer protein are based on Reference 34.

Comparison of the primary sequence (Figure 124.1) gives hints to distinguishing properties of different microbial rhodopsins, but most properties cannot be deduced from primary structure alone. An exemplary case is that of NpSRII, which is unusual in that its maximal absorption is shifted 70 to 90 nm to the blue of the other archaeal pigments.[17] Mutagenic substitution of 10 residues, in or near the retinal-binding pocket with their corresponding BR residues, produced only a 28 nm red shift of the NpSRII absorption maximum.[18,19] Structural differences responsible for the shift are evident in the 2.4 Å resolution structure.[11] One notable change is a displacement of the guanidinium group of Arg72 by 1.1 Å coupled with a rotation away from the Schiff base in NpSRII. This increase in distance reduces the influence of Arg72 on the counterion, thus strengthening the Schiff base–counterion interaction, shifting the absorption to shorter wavelengths. In addition, the position of the positive charge destabilizes the excited state, contributing further blue shift.[20] Arg72 is repositioned as a consequence of several factors, including movement of its helix backbone by 0.9 Å and the cavity created by changes from BR: Phe208 → Ile197, Glu194 → Pro183, and Glu204 → Asp192. Hence, the spectral tuning results from precise positioning of retinal-binding pocket residues and the guanidinium of Arg72, which could not be deduced from primary structure but required atomic-resolution tertiary structure information.

Differences between Sensory and Transport Rhodopsins

A fundamental question is how the common design of microbial rhodopsin proteins adapted to carry out their two distinct functions (Figure 124.2). Transport rhodopsins function independently of interaction with other proteins and translocate ions through an intramolecular channel. The archaeal sensory rhodopsins, on the other hand, transmit signals by protein–protein interaction with transducer proteins that control cytoplasmic enzymatic activity.[21–23] In HsSRI and HsSRII, the receptors form a molecular

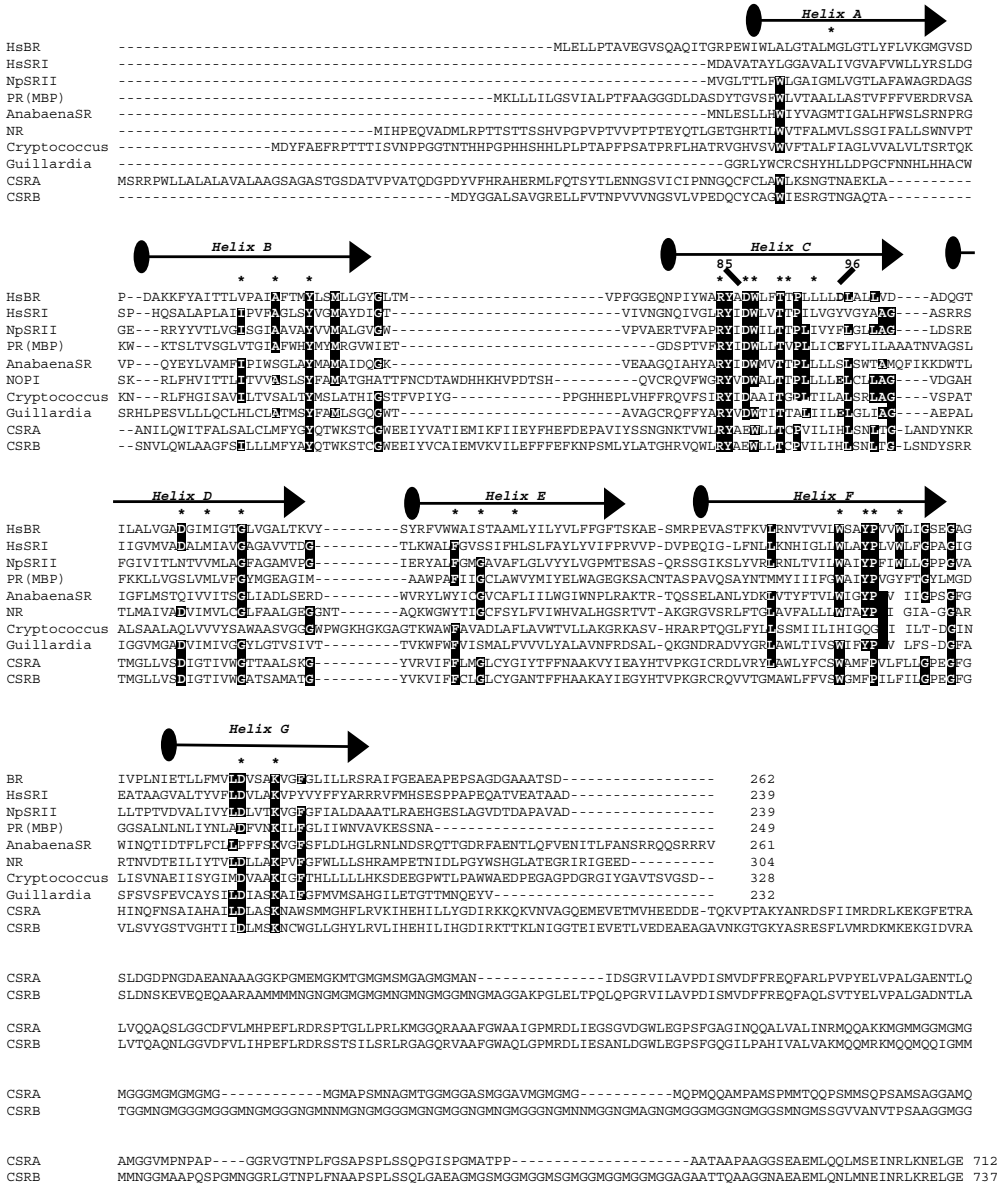

FIGURE 124.2 Primary sequence comparison of the microbial rhodopsins. (Hs: *Halobacterium salinarum*, Np: *Natronomonas pharaonis,* BR: bacteriorhodopsin, SR: sensory rhodopsin, PR: proteorhodopsin, NR: *Neurospora* rhodopsin, CSRA and CSRB: *Chlamydomonas* sensory rhodopsins A and B) Conserved residues are marked with black boxes, and residues in the retinal-binding pocket are marked with an asterisk.

complex with their cognate integral membrane transducer proteins, HtrI and HtrII, respectively, which, in turn, modulate a cytoplasmic phosphorylation[24] pathway that controls the cell's motility apparatus. Deletion and chimera experiments with the *H. salinarum* transducers showed that the interaction specificities of SRI with HtrI and SRII with HtrII are determined by the transmembrane helices of the Htr subunits,[25,26] indicating that interaction occurs within or near the membrane. A fragment of NpHtrII lacking most of the cytoplasmic domain interacts with NpSRII *in vitro*,[27,28] and functionally *in vivo*,[29] supporting that transmembrane helix–helix interactions occur also in the *N. pharaonis* pair and is seen in NpSRII/NpHtrII cocrystals (IIc).

Important to the analysis of the new rhodopsins is whether clues can be found in their primary sequences and spectroscopic properties as to whether they carry out transport or sensory functions. One difference in the primary sequence between BR, HR, and the SRs stands out. Asp96 in BR functions as a proton donor, returning a proton to the Schiff base from the cytoplasmic side of the protein during the pumping cycle. This proton transfer improves the pumping efficiency of BR by accelerating the decay of its unprotonated Schiff base photocycle intermediate, M, and is present in all BR homologs in the haloarchaea. In the sensory rhodopsins, the corresponding M intermediates are signaling states of the receptor proteins (demonstrated unequivocally only for HsSRI), and longer M lifetimes increase the signaling efficiencies of the receptors. Accordingly, each of the five known sensory rhodopsin sequences lacks a carboxylate residue at the position corresponding to Asp96 and contains Tyr or Phe instead. The residue corresponding to Asp85, which is the proton acceptor from the Schiff base, is a carboxylate residue in BR, SRI, and SRII, and in each of the newly identified rhodopsins (Figure 124.1). HR, not shown in the figure, does not produced an unprotonated Schiff base intermediate in its photocycle and, therefore, does not contain a carboxylic acid residue in the positions corresponding to Asp96 and Asp85. It is likely that the presence of a carboxylate at the position corresponding to Asp96 in BR is necessary, but not sufficient, for identification of a new rhodopsin as a proton pump.

More than order-of-magnitude faster photocycling rates distinguish the transport from the sensory pigments; the latter, in fact, were initially called "slow-cycling rhodopsins" for this reason.[4,30] The transport rhodopsins are characterized by photocycles typically <30 ms, whereas sensory rhodopsins are slow-cycling pigments with photocycle halftimes typically >300 ms.[31] This large kinetic difference is functionally important, because a rapid photocycling rate is advantageous for efficient ion pumping, whereas a slower cycle provides more efficient light detection, because signaling states persist for longer times.

Bacterial Rhodopsins

Proteorhodopsins

A gene encoding a bacterial homolog of the archaeal rhodopsins was revealed by genomic analysis of environmental samples of marine picoplankton from Monterey Bay, California.[32] The gene was functionally expressed in *Escherichia coli* and bound retinal to form an active, light-driven proton pump. The rRNA sequence on the same DNA fragment identified the organism as an uncultivated γ-proteobacterium (the SAR86 group), and the expressed protein was named proteorhodopsin. A phylogenetic comparison with archaeal rhodopsins placed proteorhodopsin on an independent long branch. The new rhodopsin (λ_{max} 527 nm) exhibited a photochemical reaction cycle with intermediates and kinetics characteristic of archaeal proton-pumping rhodopsins. The efficient proton pumping and rapid photocycle (15 ms halftime) of the new pigment strongly suggests that proteorhodopsin functions as a proton pump in its natural environment.

Retinylidene pigmentation with photocycle characteristics identical to that of the *E. coli*-expressed proteorhodopsin gene was subsequently demonstrated by flash spectroscopy in membranes prepared from Monterey Bay picoplankton.[33] Estimated from flash-induced absorbance changes, a high density of proteorhodopsin in the SAR86 membrane is indicated by the data, arguing for a significant role of the protein in the physiology of these bacteria. The flash photolysis data provided direct physical evidence for the existence of proteorhodopsin-like pigments and endogenous retinal molecules in the prokaryotic fraction of the Monterey Bay coastal surface waters. Furthermore, genomic analysis of bacterioplankton of Antarctica and the central North Pacific Ocean near Hawaii (both surface and 75 m deep waters) revealed proteorhodopsin variants in these different ocean environments. The Hawaiian deep proteorhodopsin variant exhibits a blue-shifted absorption (λ_{max} 490 nm) matching the blue-shifted incident light at that depth. Therefore, the protein pigments comprising this family are spectrally tuned to different habitats, absorbing light at different wavelengths in accordance with light available in the environment. The abundance and widespread presence of proteorhodopsin variants throughout the world's oceans indicate proteorhodopsin light-driven proton pumping is a globally significant oceanic microbial process (33b).

Anabaena Sensory Rhodopsin

A rhodopsin pigment in a cyanobacterium establishes that sensory rhodopsins also exist in eubacteria. A gene encoding a homolog of the archaeal rhodopsins was found via a genome sequencing project of *Anabaena (Nostoc)* sp. PCC7120 at Kazusa Institute, Japan (http://www.kazusa.or.jp/). The opsin gene was expressed in *E. coli* and bound all-*trans* retinal to form a pink pigment (λ_{max} 543 nm). The *Anabaena* rhodopsin in *E. coli* membranes exhibited a photochemical reaction cycle with an M-like photointermediate and 110 ms half-life at pH 6.8.[34]

The opsin gene and another open reading frame separated by 16 base pairs under the same promoter were found in the genome. This operon is predicted to encode a 261-residue (opsin) and a 125-residue (14 kDa) protein. The rate of the photocycle is increased ~20% when the *Anabaena* rhodopsin and the soluble protein are coexpressed in *E. coli*,[34] indicating physical interaction between the two proteins. We also confirmed binding of 14 kDa protein to *Anabaena* rhodopsin by affinity enrichment measurements and Biacore interaction analysis. The pigment did not exhibit detectable proton transport activity when expressed in *E. coli*, and Asp96, the proton donor of BR, is replaced with Ser86 in *Anabaena* rhodopsin. These observations are compelling in that *Anabaena* opsin functions as a photosensory receptor in its natural environment, and that the 125-residue cytoplasmic soluble protein transduces a signal from the receptor, unlike the archaeal sensory rhodopsins that transmit signals by transmembrane helix–helix interactions with integral membrane transducers.

Magnetospirillum Rhodopsin

Genome sequencing of the α-proteobacterium *Magnetospirillum magnetotacticum* revealed a microbial opsin gene (Table 124.1), preceded by a homolog of *brp*, which encodes an enzyme for synthesis of retinal from β-carotenene in *H. salinarum*.[35] The two-gene operon contains a single promoter.

Eukaryotic Rhodopsins

Fungal Rhodopsins

A sequencing project on the genome of the filamentous fungus *Neurospora crassa* revealed the first of the eukaryotic homologs designated NOP-1.[36] A search of genome databases currently in progress indicates the presence of archaeal rhodopsin homologs in various fungi, including plant and human pathogens — Ascomycetes: *Botrytis cinerea, Botryotinia fuckeliana* (anamorph *Botrytis cinerea*), *Fusarium sporotrichioides, Gibberella zeae* (anamorph *Fusarium graminearum*), *Leptosphaeria maculans*, *Mycosphaerella graminicola* (two opsin homologs); and Basidiomycetes: *Cryptococcus neoformans*. Each of these organisms contains genes predicted to encode proteins with the retinal-binding lysine in the seventh helix and high identity in the retinal-binding pocket. The Asp Schiff base counterion and proton acceptor (Asp85 in BR) are conserved among all fungal opsin homologs, and the carboxylate proton donor specific to proton pumps (Asp96 in BR) is also either Asp or Glu, except in *Cryptococcus*, which contains an Ala residue.

The *nop-1* gene was heterologously expressed in the yeast *Pichia pastoris*, and it encodes a membrane protein that forms with all-*trans* retinal a green light-absorbing pigment (λ_{max} 534 nm) with a spectral shape and bandwidth typical of rhodopsins.[37] Laser flash kinetic spectroscopy of the retinal-reconstituted NOP-1 pigment (i.e., *Neurospora* rhodopsin) in *Pichia* membranes revealed that it undergoes a seconds-long photocycle with M and O intermediates spectrally similar to intermediates detected in BR and SRII.

The physiological function of *Neurospora* rhodopsin has not yet been identified. Based on the long lifetime of the intermediates in its photocycle and its apparent lack of ion transport activities (at least when heterologously expressed[38]), it seems likely to serve as a sensory receptor for one or more of the several different light responses exhibited by the organism, such as photocarotenogenesis or light-enhanced conidiation. *Neurospora* is nonmotile, but phototaxis by zoospores of the motile fungus *Allomyces reticulatus* was shown to be retinal dependent,[39] and therefore, photomotility modulation is a likely photosensory function of rhodopsins in this particular fungal species.

Algal Rhodopsins

Recently, we identified short cDNA sequences in an EST database at Kazusa Institute (http://www.kazusa.or.jp/) and, based on this information, cloned two archaeal-type opsin genes from a cDNA library (provided from the *Chlamydomonas* Genetics Center). A microbial rhodopsin homolog gene is also present in *Guillardia theta,* which is a small biflagellate organism considered a protozoan and an alga (Figure 124.1) and is also found in the dinoflagellate *Pyrocystis lunula*. The *csoA* and *csoB* (*Chlamydomonas* sensory opsin A and B) genes encode 712 and 737 amino acid proteins (Figure 124.1). The *N*-terminal 300 residues have a significant homology to archaeal rhodopsins with seven transmembrane helices and the conserved retinal binding pocket (Figure 124.1). The *Chlamydomonas* rhodopsins provide the first examples of evolution fusing the microbial rhodopsin motif with other domains.

Early work established that the green alga *Chlamydomonas* uses retinylidene receptors for photomotility responses. Restoration of photomotility responses by retinal addition to a pigment-deficient mutant of *Chlamydomonas reinhardtii* first indicated a retinal-containing photoreceptor.[40] Subsequent *in vivo* reconstitution studies with retinal analogs prevented from isomerizing around specific bonds ("isomer-locked retinals") in several laboratories further established that the *Chlamydomonas* rhodopsins governing phototaxis and the photophobic response have the same isomeric configuration (all-*trans*), photoisomerization across the C13–C14 double bond (all-*trans* to *13-cis*), and 6-*s*-*trans* ring-chain conformation (coplanar) as the archaeal rhodopsins.[41–45]

The proteins encoded by *csoA* and *csoB* complexed with retinal (called CSRA and CSRB) are the first of the eukaryotic archaeal-type rhodopsins for which we can assign physiological roles.[46] We found by RNA*i* suppression of gene expression that the *Chlamydomonas* rhodopsins CSRA and CSRB mediate photomotility responses (phototaxis and photophobic reactions) to high- and low-intensity light, respectively. The functions of the two rhodopsins were demonstrated by analysis of electrical currents and motility responses in transformants with RNA*i* directed against each of rhodopsin genes. CSRA has an absorption maximum near 510 nm and mediates a fast photoreceptor current that saturates at high-light intensity. In contrast, CSRB absorbs maximally at 470 nm and generates a slow current saturating at low-light intensity.[46] The saturation at different light fluence levels extends the range of light intensity to which the organism can respond.

A protein that binds radiolabeled retinal was isolated from *Chlamydomonas* eyespot preparations.[47] For several years, this abundant protein in the eyespot membranes was considered the photoreceptor for photomotile responses.[48] However, its gene-predicted primary sequence, as well as that of a similar *Volvox* protein,[49] suggest two to four transmembrane helices and no homology to archaeal opsins. Moreover, recently, the so-called "chlamyrhodopsin" was ruled out as a photoreceptor pigment for phototaxis or photophobic responses in *Chlamydomonas*.[50]

Opsin-Related Proteins

Several other genes in the fungi *N. crassa* (YRO2), *Aspergillus nidulans*, *Saccharomyces cerevisiae*, *Schizosaccharomyces pombe*, *Coccidioides immitis*, *Coriolus versicolor*, and in the plant *Sorghum bicolor* (Corn) encode proteins that exhibit significant homology to microbial rhodopsins, but they are missing the critical lysine residue in the seventh helix that forms the covalent linkage with retinal. The microbial-opsin-related proteins are, therefore, not likely to form photoactive pigments with retinal. The most conserved region in these proteins is along Helix C, E, and the middle of Helix F. It is intriguing that one of the yeast opsin-related proteins, HSP30 (heat shock protein 30), is implicated as interacting with a proton transport protein, the H^+ATPase. HSP30 downregulates stress stimulation of H^+ATPase activity under heat shock conditions.[51,52] Probably, the conformational switching properties of the archaeal rhodopsins were preserved in these opsin-related proteins, while the photoactive site was lost and replaced presumably by another input module, such as a protein–protein interaction domain.

124.4 Future Directions

Because microbial rhodopsins are present in all three domains of life, progenitors of these proteins may have existed in the early phases of evolution, before the divergence of archaea, eubacteria, and eukaryotes.

Is so, light-driven ion transport as a means of obtaining cellular energy may well have predated the development of photosynthesis and represents one of the earliest means by which organisms tapped solar radiation as an energy source. As more rhodopsins are identified, their evolution and dissemination into such a wide variety of organisms, whether by divergence from a common progenitor or horizontal gene transfer, should become clearer.

There is much work to be done to understand the physiological roles and molecular mechanisms of the rhodopsins so far identified in the various microbial species. It seems likely that we will see even more members of this family, as genomic sequencing becomes ever more rapid. The vast majority of microbial species have never been cultivated in a laboratory. Therefore, the use of microbial rhodopsin probes in environmental genomics, which expands the search for orthologous genes in uncultivated organisms, is likely to be especially fruitful.

125.1 Introduction

The visual transduction process in rod photoreceptor cells for scotopic vision begins with absorption of a photon by a rhodopsin molecule, which is a seven-transmembrane α-helical protein having 11-*cis*-retinal as a chromophore. Light isomerizes the 11-*cis*-retinal into all-*trans* form,[1] resulting in conformational changes of the protein moiety to form an enzymatically active intermediate, metarhodopsin II (meta II).[2–4] The meta II then activates retinal G protein, transducin,[3,4] which in turn, activates the signal transduction cascade that eventually generates an electrical response of the rod photoreceptor cells.[5]

Rhodopsin is one of the members of G protein-coupled receptors (GPCRs) in the sense that it can activate retinal G protein, transducin. However, it is unique in the sense that it can be activated not by chemical stimulus but by light, a physical stimulus. Several lines of evidence indicated that rhodopsin exhibits an extremely high photosensitivity, an effective activation of G protein, and an inert character in the dark.[6] These properties are the parts of the molecular mechanisms in which a rod photoreceptor cell works as a single photon counter with an extremely low level of noise in the dark. Because the functional expression of the photoreceptor cell is totally different from those of the cells that are activated by hormones, neurotransmitters, and so on, the molecular mechanism of G protein activation by rhodopsin was thought to be somewhat different from those by other ligand-binding GPCRs.[7] However, accumulated evidence reveals that the chromophore of rhodopsin acts as an inverse agonist,[8,9] and light fulfils a role in converting the inverse agonist into the agonist, all-*trans*-retinal, within the protein moiety, suggesting that the G protein activation mechanism is similar between rhodopsin and other GPCRs. Therefore, elucidation of the activation mechanism of the G protein by rhodopsin would give insight into the common mechanism of G protein activation by GPCRs. In this chapter, we summarize the structural and spectroscopic studies of rhodopsin, focusing on the role of the chromophore in the mechanisms of photon absorption and G protein activation by rhodopsin.

125.2 Structures of Retinal Chromophore and its Binding Site in Rhodopsin

As already described, rhodopsin is a ~40 kDa membrane protein that consists of a single polypeptide opsin and a chromophore, 11-*cis*-retinal.[1] Opsin contains seven transmembrane α-helices, the structural motif typical of the GPCRs.[10] The primary structure (amino acid sequence) of bovine rhodopsin was first determined in 1983 by three groups, based on sequencing the peptide fragments[11,12] and complementary DNA (cDNA) cloning.[13] Then the helical alignment of bovine rhodopsin was determined by means of electron cryomicroscopy using a two-dimensional rhodopsin crystal.[14,15] Recently, a three-dimensional crystal of bovine rhodopsin was successfully developed,[16] and its atomic structure was analyzed by x-ray crystallography (Figure 125.1).[17] This provides a comprehensive structural basis for giving insight into the functional roles of rhodopsin.

Because it is an essential function for rhodopsin to receive a visible light, elucidation of the mechanism regulating the absorption maximum of rhodopsin (spectral tuning mechanism of rhodopsin) is important. Opsin and 11-*cis*-retinal show no absorbance at the visible region, but binding of 11-*cis*-retinal to the opsin causes generation of rhodopsin having absorption maximum at about 500 nm.

Earlier studies indicated that 11-*cis*-retinal forms a protonated Schiff base with Lys296 of opsin,[11,12,18] and the proton on the Schiff base is stabilized by a negatively charged glutamate at position 113 (Glu113).[19–21] Crystal structure of rhodopsin confirmed that the retinal is really bound to Lys296, and Glu113 is located at 3.2 Å from the Schiff base nitrogen.[17]

The structural information on such a short distance between the Schiff base and the counterion has led to confusion among researchers. This is because many researchers believed that a water molecule should be present between the Schiff base and the counterion, as in the case of bacteriorhodopsin.[22] In general, pKa of a Schiff base is higher than that of a glutamate, so that a proton on the Schiff base should be transferred to the glutamate if these two molecules interact directly with each other. Moreover, there is ample evidence that a water molecule is present and forms a hydrogen-bonding network near the Schiff base and the counterion.[23–25] Therefore, a water molecule was speculated to be located between the Schiff

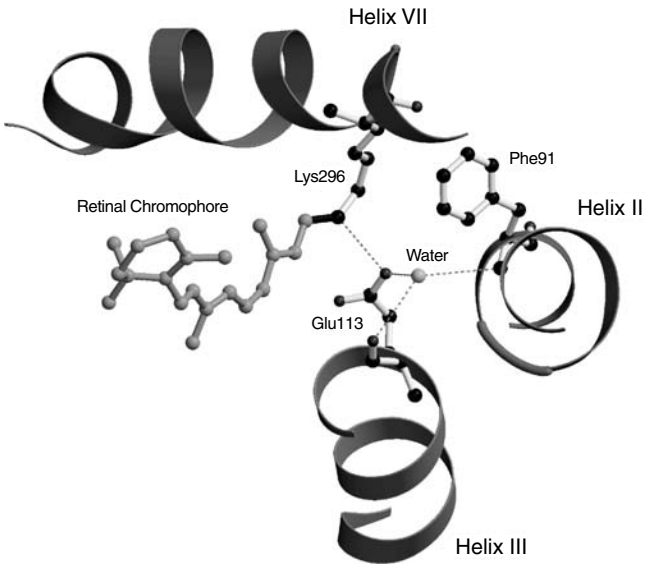

FIGURE 125.2 Water molecule in chromophore binding site.[27] The water molecule is located not between the Schiff base and the counterion, but on the carboxyl and peptide carbonyl groups of Glu113. The coordinate (IL9H) was retrieved from the Protein Data Bank.

base and the counterion, even in the theoretical model of the rhodopsin[26] constructed on the basis of the three-dimensional Cα-structure model of the transmembrane helices of opsin.[10]

Recently, the spatial resolution of the diffraction of the rhodopsin crystal was improved to visualize water molecules in the rhodopsin molecule.[27] The results showed that a water molecule is located not in between the Schiff base and the counterion, but on the carboxyl and peptide carbonyl groups of the glutamate at position 113 (Figure 125.2). These results suggest that the water molecule would have a role of stabilizing the proton on the Schiff base by reducing the negative charge of the carboxylate of the glutamate.

The crystal structure of rhodopsin also shows that the second extracellular loop forms an antiparallel β-sheet, and that one of the strands (β4) is in the proximity of the chromophore (Figure 125.1).[17] This indicates that a part of the second extracellular loop forms a chromophore binding site. Furthermore, one of the oxygen atoms of Glu181 is located close (about 4.5 Å) to the C12 position of retinal, which could affect the absorption characteristics of the chromophore. Our recent study clearly showed the existence of a water molecule between the side chains of Glu181 and Ser186.[27] The location of the water molecule is significant in terms of the mechanism of color regulation in retinal proteins, including cone visual pigments. In the long-wavelength cone visual pigments (human green and red), a histidine residue at the position of the Glu181 in bovine rhodopsin was demonstrated to bind a chloride ion,[28] shifting the absorption maximum to the red.[29–31] The presence of the water molecule in these chloride-binding pigments was suggested by our FTIR study on the chicken red pigment (iodopsin).[32] Moreover, our recent study of squid retinal photoisomerase retinochrome showed that Glu181 can directly act as a counterion of the protonated Schiff base.[33] In bovine rhodopsin, Glu181 is located in the middle of a cluster of three polar residues, Tyr191, Tyr192, and Tyr268, with hydroxyl groups that cover a part of the retinal binding pocket near C9. Thus, we found a continuous hydrogen-bonding network that lies in the extracellular side of the chromophore-binding site, covering a distance of >17 Å from the hydroxyl group of Tyr192 to the peptide amide of Phe91.[27] This observation of the network implies that replacement of a single amino acid at a given position in this region would induce long-range effects on the spectral properties of visual pigments.

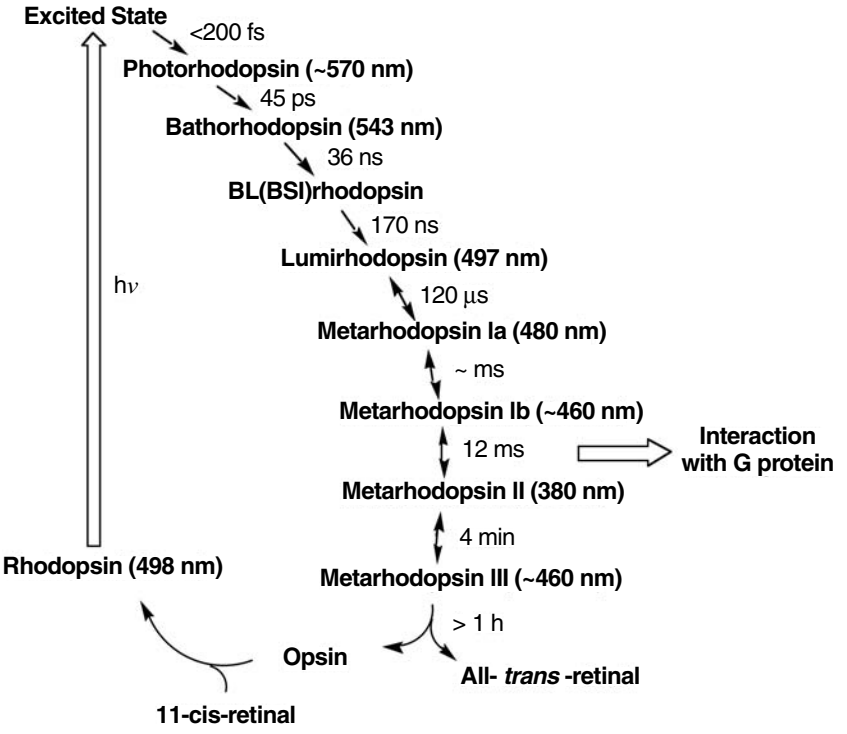

FIGURE 125.3 Photobleaching process of bovine rhodopsin. The times denoted at the right-hand side of the arrows are decay time constants of the intermediates. The absorption maxima of rhodopsin and its intermediates are shown in parentheses.

125.3 *Cis-Trans* Isomerization Mechanism of Chromophore in Rhodopsin

On absorption of light, rhodopsin changes its absorption maximum from 500 to 380 nm, fading in color from red to pale yellow. This photobleaching process of rhodopsin is composed of photoreaction (photochemical reaction) and subsequent thermal reactions. How efficiently the photoreaction occurs is closely connected with a trapping yield of light signal, that is, the absolute photosensitivity of rhodopsin, while subsequent thermal reactions are important for generating an active state that transduces a light signal to a retinal G protein. Because the chromophore acts as an intrinsic probe to monitor conformational changes of the protein during the thermal reactions of rhodopsin, each step of the change was confirmed by detection of an intermediate state having specific absorption spectrum. Historically, low-temperature spectroscopy was applied to detect the distinctive intermediate states, such as bathorhodopsin, lumirhodopsin, metarhodopsin I to III.[1,34] Subsequently, kinetic experiments using an ultrashort laser pulse identified photorhodopsin as the primary intermediate[35] and then observed the excited state of rhodopsin.[36] Recent kinetic experiments using laser photolysis at room temperature and time-resolved low-temperature spectroscopy showed that other intermediates exist between the originally identified intermediates.[37,38] Thus, the bleaching process of rhodopsin could be summarized in Figure 125.3.

The initial event of rhodopsin after absorption of a photon is now confirmed to be a *cis-trans* isomerization of the retinal chromophore. Originally, the *cis-trans* isomerization hypothesis was based on the experimental facts that irradiation of rhodopsin at liquid nitrogen temperature yields a photo-steady-state mixture containing rhodopsin, bathorhodopsin, and isorhodopsin (Figure 125.4).[34] Because rhodopsin and isorhodopsin contain 11-*cis*- and 9-*cis*-retinals, respectively, as their chromophores, bathorhodopsin should have an intermediate configuration, that is, a twisted all-*trans*-retinal,

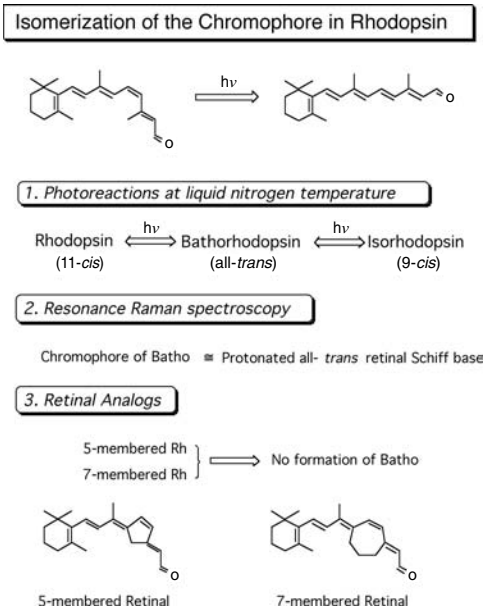

FIGURE 125.4 Experimental evidence that supports the *cis-trans* isomerization of the retinal chromophore of rhodopsin as an initial event after absorption of a photon.

as its chromophore. Later experiments using resonance Raman spectroscopy indicated that the chromophore of bathorhodopsin is similar to the protonated all-*trans*-retinal Schiff base in solution.[39] The more sophisticated evidence that the *cis-trans* isomerization is essential for the formation of bathorhodopsin was obtained from the experiments using retinal analogs with 11–12 double bonds fixed by ring structures. That is, no formation of bathorhodopsin is observed when 11–12 double bonds are fixed.[40,41]

Several lines of evidence indicated that photoreceptor cells are able to respond to a single photon stimulus. The pioneering studies by Dartnall[42] showed that the quantum yields of isomerization of rhodopsins are extraordinarily high (0.67) compared with those of the protonated retinylidene Schiff base in organic solution (~0.2).[43] Therefore, it is of interest to investigate how efficiently the isomerization occurs.

Because the high quantum yield originates from the high-rate isomerization, which competes with other relaxation processes in the excited state of rhodopsin, ultrafast laser spectroscopies were applied to investigate the isomerization process of the retinal chromophore. Picosecond time-resolved spectroscopy was applied to the photochemistry of rhodopsin, and the formation of the primary intermediates was reported, such as photorhodopsin and bathorhodopsin at room temperature.[35,44,45] However, the time resolution needed to be improved in order to detect the *cis-trans* isomerization process in the excited state of rhodopsin. The direct observation of the rhodopsin excited state was reported in 1991, in which the primary intermediate photorhodopsin formed from the excited state of rhodopsin within 200 fs.[36] Later, the effects of oscillatory features with a period of 550 fs (60 cm^{-1}) on the formation kinetics of photorhodopsin,[46] were observed, suggesting that the primary step in vision is a vibrationally coherent process.

The femtosecond spectroscopies described above are so-called transient absorption (pump probe) spectroscopy. To probe the excited-state dynamics of rhodopsin, however, the absorption spectroscopy may not be advantageous, because other spectral features, such as ground-state depletion and product absorption, are possibly superimposed on the excited-state spectral features in the data obtained. In order to monitor the excited-state dynamics of rhodopsin more directly, we attempted to apply femtoseconds up-conversion spectroscopy to detect it in real time.[47,48]

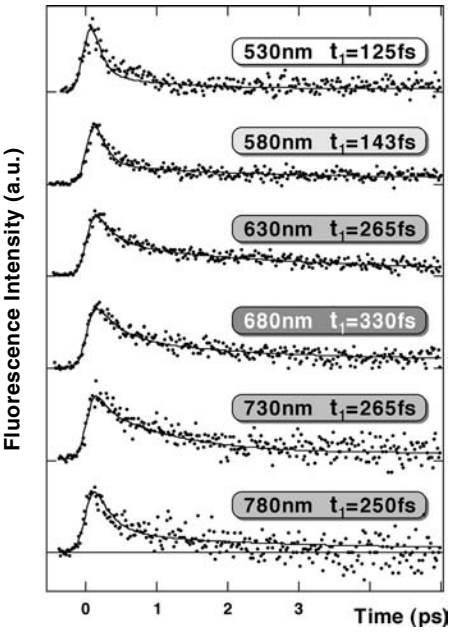

FIGURE 125.5 Fluorescence dynamics of bovine rhodopsin excited at 430 nm and monitored at 530, 580, 630, 680, 730, and 780 nm. The photon counts at maximum position for each monitoring wavelength are 133, 145, 204, 169, 106 and 60, respectively. Smooth curves are the best fits obtained by deconvolution procedure with the instrumental response function (full width of half maximum: 210 fs). Three kinetic components are used in the fitting: fs (125 to 330 fs), early ps (1.0 to 2.4 ps) and >50 ps components, among which the fs component is major (58 to 87%). The fs components are shown in the figure. (Modified from Kandori, H., Furutani, Y., Nishimura, S., Shichida, Y., Chosrowjan, H., Shibata, Y., and Mataga, N., *Chem. Phys. Lett.*, 334, 271, 2001.)

Shown in Figure 125.5 are the fluorescence dynamics of rhodopsin excited at 430 nm and observed at various wavelengths.[48] In addition to the observed decay curves, smooth curves simulated by superposing exponential decay function, taking into consideration the instrumental response, are indicated. The decay kinetics clearly showed nonexponential nature, where components of femtoseconds (125 to 330 fs) and early picoseconds (1.0 to 2.3 ps) were predominantly obtained as the best fit. The rises of fluorescence were rapid, and the fs components of the fluorescence at blue (530 and 580 nm) and red (780 nm) sides of the spectrum decayed faster than those at the center. These results suggest that the conversion from the Frank–Condon state to the fluorescence state occurs within the time resolution of the apparatus (<100 fs), owing to coupling with intrachromophore high-frequency modes; and faster initial decay is due to the sharpening of the band shape caused by a decrease of amplitudes of high-frequency modes along the reaction coordinate of twisting.[48] It should be noted that the average amplitude of the fs components among six wavelengths was about 70%, being close to the quantum yield of photoisomerization of rhodopsin (0.67). Thus, the components in the 100 fs regime are probably correlated with the ultrafast coherent isomerization process, which leads to formation of photorhodopsin within 200 fs. On the other hand, the slow components (~30%) in the ps regime would originate from the nonreactive excited state of rhodopsin.

In order to get more insight into the excited state dynamics of rhodopsin, we analyzed the excited-state dynamics of rhodopsin by means of FTOA (Fourier transform optical absorption) method.[49,50] In this method, the time-correlation function between the wavepacket of the Franck–Condon state and that at a certain time after propagation from the Franck–Condon state, was calculated by Fourier transform of absorption spectrum of rhodopsin that was measured by conventional spectrophotometer. It was then used for estimating the propagation of wavepacket in the excited state.

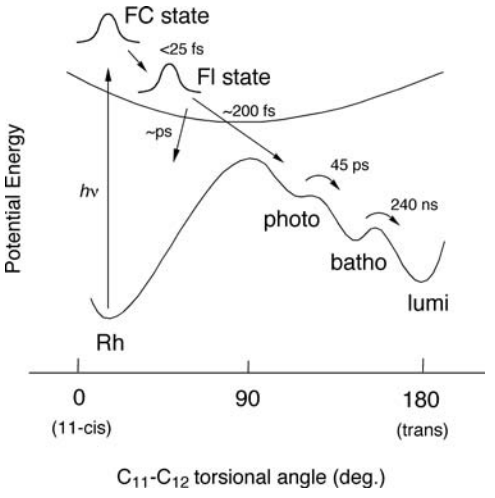

FIGURE 125.6 The primary process of rhodopsin.

The results showed that the wavepacket rapidly moves from the Franck–Condon state within about 25 fs, and it goes to the ground state at about 170 fs. The lifetime of the excited state of rhodopsin estimated by this calculation is in agreement with that directly observed by means of fs spectroscopy.[48]

We then investigated the excited-state dynamics by analyzing deuterium substitution effects for hydrogen atoms bonded to C11 and C12 of the retinal chromophore.[51] The substitution effects do not appear significantly in the excited-state dynamics until about 60 fs, but they appear after 60 fs. The mode of isomerization at C11–C12 double bond would couple with the mode of hydrogen-out-of-plane and, therefore, isomerization would start at about 60 fs after photon absorption of rhodopsin.

The primary process of rhodopsin is summarized in Figure 125.6. Rhodopsin goes to the Franck–Condon state (FC state) by photon absorption. Then, the Franck–Condon state moves rapidly to a fluorescent state (Fl state) within 25 fs. The fluorescent state then goes to the ground state intermediate photorhodopsin, within about 200 fs.

125.4 Protein-Directed Isomerization Mechanism of Rhodopsin

After the *cis-trans* photoisomerization of the retinal chromophore, rhodopsin changes its protein conformation to a G-protein-activating state. Because the conformational change of the protein needs chemical-free energy, light energy absorbed by the chromophore should be converted to chemical energy.

Because formations of photorhodopsin and bathorhodopsin after photon absorption of rhodopsin are extremely rapid (200 and 45 ps, respectively), it is easily believed that only minor rearrangements of amino acid residues constituting the chromophore-binding site would occur. The isomerization causes an extension of the longitudinal length of the chromophore, resulting in a highly twisted conformation of the chromophore in the restricted chromophore binding pocket. This may cause an elevation of the potential energy.[34] In fact, calorimetric study showed that about 60% of photon energy (~30 kcal) is stored as an increase in enthalpy.[52]

In order to get insight into chromophore conformation of the primary intermediates as well as the energy storage mechanism, we conducted the picosecond laser photolysis experiments using rhodopsin analogs having retinal analogs, as shown in Figure 125.7.[41,53] All the analogs have a locked structure of the C11–C12 double bond but differ from each other in the manner of prohibition of the isomerization around the C11–C12 double bond.

The five-membered ring is a completely planar and rigid ring, so that C11–C12 double bond cannot be distorted any more. The picosecond experiments of the five-membered rhodopsin (Rh5) showed that

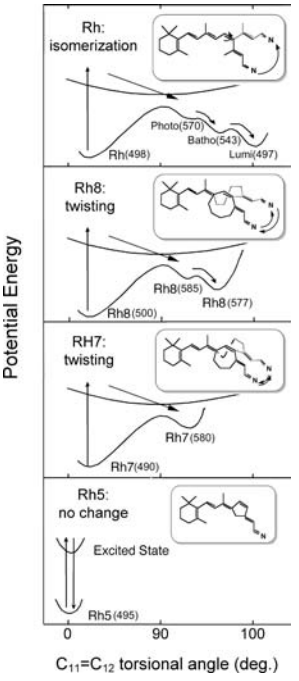

FIGURE 125.7 Ground- and excited-state potential surfaces along the 11-ene torsional coordinate of the chromophore of rhodopsin (Rh), eight-membered rhodopsin (Rh8), seven-membered rhodopsin (Rh7), and five-membered rhodopsin (Rh5).[53] Values in parentheses denote difference absorption maxima between original pigments and the respective intermediates. Dotted structures for Rh8 and Rh7 simply denote the formation of transoid double bonds in the ring. (Modified from Mizukami, T., Kandori, H., Shichida, Y., Chen, A.H., Derguini, F., Caldwell, C.G., Biffe, C.F., Nakanishi, K., and Yoshizawa, T., *Proc. Natl. Acad. Sci. USA*, 90, 4072, 1993.)

only the excited state was produced and went back to the original state. On the other hand, a seven-membered ring is a relatively flexible ring, and the 11–12 double bond or the nearby single bonds can be distorted to some extent. The experimental results of the seven-membered rhodopsin (Rh7) showed formation of a photorhodopsin-like intermediate from the excited state, and the intermediate went back to the original state directly. The eight-membered rhodopsin that has more flexible conformation in eight-membered ring went to an excited state and converted to photorhodopsin-like and then to bathorhodopsin-like intermediates. These results clearly show that the formation of the primary intermediates depends on the flexibility of the 11–12 double bond. From these results, we have two important conclusions: One is that the primary intermediates have a highly twisted all-*trans* chromophore in the restricted chromophore binding pocket. This means that the light energy is converted to a potential energy, owing to the distortion of the retinal chromophore. The other is that the appearance of the early intermediate is dependent on the flexibility of the moiety comprising the C11–C12 double bond and the photoisomerization proceeds by sequential interaction between the chromophore and the protein, resulting in stepwise relaxation of the highly strained all-*trans* retinal chromophore. That is, the isomerization of the chromophore is protein directed.

125.5 Changes in Chromophore–Opsin Interaction in Bleaching Process of Rhodopsin

The state that activates retinal G protein was thought to be Meta II,[2–4] the conformation of the protein that was investigated by various techniques with great enthusiasm. The most prominent difference

between Meta II and the other intermediates is their protonation states of the Schiff base chromophore, that is, Meta II is the only intermediate with a retinylidene Schiff base that is deprotonated.[54] As already described, the proton on the Schiff base in rhodopsin mediates the interaction between the chromophore and the counterion E113. Thus, the transfer of the proton to the counterion results in the loss of interaction, inducing a flexible conformation near the Schiff base.[8] Recently, important experimental evidence was reported from site-directed spin-labeling studies, where a separation in cytoplasmic ends between Helices III and VI, as rigid bodies, occurs upon formation of Meta II.[55] The separation between the helices then unmasks the G protein-binding sites located in the third cytoplasmic loop (C-III in Figure Chapter 125.1).[56] Thus, the next investigation was how the energy stored in the chromophore can transfer the protein moiety for inducing the helical movements of the protein.

Recently, an important finding about the energy transfer from the chromophore to the protein was obtained by cross-linking studies using a retinal analog having a diazo-keto residue as a photoaffinity substituent in its β-ionone ring.[57] The reconstituted rhodopsin with the retinal analog as its chromophore was irradiated with a ultraviolet light, resulting in cross-link of the β-ionone ring and we can crosslink the β-ionone ring with nearby amino acid residue. Before the cross-link, we prepared several intermediates of the reconstituted rhodopsin by irradiation at various temperatures, and then, these intermediates were irradiated with ultraviolet light to cross-link the β-ionone ring with nearby amino acid residue. Then, the protein moiety was cleaved by CNBr, followed by separation of the peptides to be analyzed.

In the rhodopsin state, the β-ionone ring was cross-linked with the tryptophan at position 265 of the Helix VI. This result is consistent with that previously reported using different retinal analog.[58] Then, we performed the cross-linking experiments in the intermediate states. In bathorhodopsin state, the same tryptophan residue was cross-linked, suggesting that the β-ionone ring does not move during the *cis-trans* photoisomerization of the chromophore. We previously reported on the basis of an experiment using the fluorinated retinal analogs, that the isomerization of the chromophore would proceed by movement of the half of the polyene chain containing the Schiff base.[59] Thus, it is reasonable to speculate that the first rearrangement of the amino acid residues would occur near the protonated Schiff base in the chromophore. Then, we applied the cross-linking experiments to the lumirhodopsin state and found that the alanine residue at position 169 of Helix 4 was newly cross-linked.[57] From these results, the β-ionone ring changes its cross-linked position from Helix VI to Helix IV during the batho-to-lumi transition. Although the previous studies using the ring-truncated retinal analogs already suggested the change of the protein conformation near the β-ionone ring region of the chromophore,[60] the present results demonstrate that the more dramatic changes in chromophore–opsin interaction occurs in the lumirhodopsin state. The cross-linked residue did not change during the lumi-to-Meta I and Meta I-to-Meta II transitions.[57] These results indicate that the relative position between the β-ionone ring of the chromophore and the Ala169 did not change. However, analog studies suggested the occurrence of the protein conformational changes near the 9-methyl group of the chromophore during the lumi-to-Meta I transition[61] and that of the deprotonation of the Schiff base chromophore during the meta I-to-meta II transitions, respectively.

Figure 125.8 shows a schematic drawing of the structures of rhodopsin, bathorhodopsin, lumirhodopsin and metarhodopsin II, the active state of rhodopsin.[57] Rhodopsin has an 11-*cis*-retinal as its chromophore. It forms a protonated Schiff base with Lys296 of the helix VII and the β-ionone ring of the chromophore interacts with Trp265 of the helix VI. The β-ionone ring becomes cross-linked to Ala169 in helix IV when bathorhodopsin converts to lumirhodopsin. Our experiments suggest that flip-over of the β-ionone ring of the chromophore causes loss of interaction between β-ionone ring and the tryptophan residue and pushes the helix III to the outside. This would be the reason why helices III and VI change their positions. In other words, the large movements of the chromophore trigger conformational changes of the helices to interact with G protein.

To further understand the molecular mechanism of light absorption and G protein activation by rhodopsin, it is important to determine structural changes in the bleaching process of rhodopsin at atomic resolution. Recent success of the preparation of the rhodopsin crystal enables us to determine the crystal structure of the intermediates upon irradiation of the crystal at adequate temperature.[27]

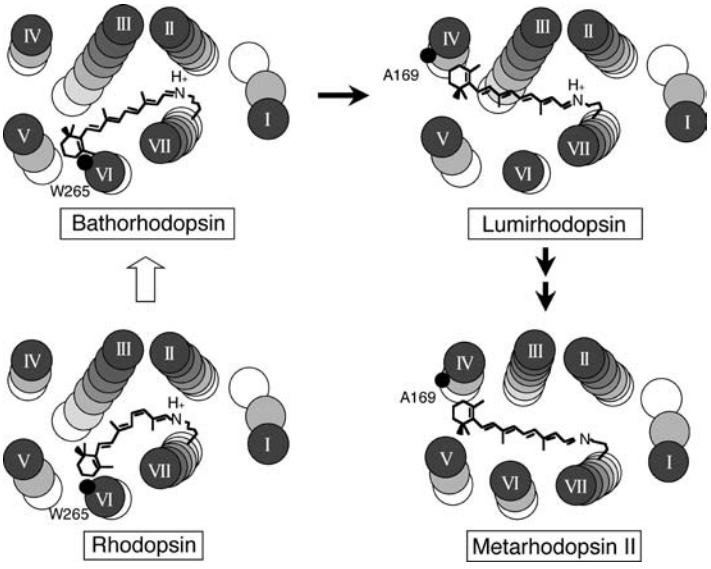

FIGURE 125.8 Opsin conformational movements triggered by 11-*cis* to all-*trans* photoisomerization of the chromophore.[57] In rhodopsin and bathorhodopsin, the β-ionone ring is close to Trp265 in Helix VI, but in lumirhodopsin and metarhodopsin II, it becomes cross-linked to Ala169. Thus, during the batho-to-lumi transition, the β-ionone ring of the chromophore flips over in the helical bundle using the energy stored as a highly strained chromophore structure in bathorhodopsin.

Therefore, we will be in a stage that mechanisms of photon absorption and G protein activation by rhodopsin will be elucidated at atomic resolution.

Acknowledgments

The authors thank Dr. Tetsuji Okada for help preparing Figure 125.1 and Figure 125.2. The authors also thank Drs., T. Okada, H. Kandori, A. Terakita, and H. Imai for their valuable discussions during the preparation of the manuscript. The Bleaching of Visual Pigments

Thomas Ebrey
University of Washington

126.1 Introduction

The focus of this chapter is on the series of photochemical transformations of vertebrate visual pigments, after the initial photoproduct has been formed, that lead to the pigment losing its color as the chromophore, retinal, is hydrolyzed from its Schiff base linkage. This sequence of events is often called the bleaching of the visual pigment, and the members of the sequence are called the bleaching intermediates or the photoproducts. The intermediates are usually defined by their absorption maxima, but are also characterized by their vibrational spectra, either the vibrations of the chromophore, the apoprotein, or even of the bound water molecules in the pigment.

There are five families of vertebrate visual pigments, some found mostly in rods, others mostly in cones, but there seem to be exceptions for every family.[1] So, while one cannot accurately talk about "rod" or "cone" pigments, it is convenient to talk about members of the RH1 (rhodopsin) family as "rod" pigments, the Short-Wavelength Sensitive 1 (SWS1) and Mid- and Long-Wavelength Sensitive (M/LWS) as UV/blue cone and green/red cone pigments. The RH2 (rhodopsin-like) and SWS2 (Short Wavelength Sensitive 2) families are not found in mammals and have no tradition of being called rod or cone pigments; like the others, they were found in rods and cones and in the salamander retina in both rods and cones at the same time.[2] It is believed that the bleaching process is similar for all the families, but there are some interesting differences that will be discussed after a more general review.

126.2 Outlines of the Bleaching Process

The literature on the bleaching of the visual pigments has been the topic of several recent reviews.[3–8] In addition, Szundi et al.[9] presented a global analysis of the light-induced kinetics of bleaching; the approach promises to help sort some of the complexities noted below. The following is a rough summary of what characterizes each intermediate. The primary photoproduct, bathorhodopsin, starts to decay within a nanosecond or so after it is formed by the isomerization of the 11-*cis*-retinal chromophore of the pigment to the all-*trans*-conformation. In most pigments, batho rapidly equilibrates with a blue-shifted intermediate (BSI) that decays to lumirhodopsin. Lumi decays to Meta I, which decays to Meta II, which decays

0-8493-1348-1/04/$0.00+$1.50

to Meta III, which then decays finally to all-*trans*-retinal plus opsin. Alternative decay pathways, backreactions, and the effects of various photointermediates interacting with other proteins all change this simple picture. The most important tentative revision is a branching after lumi that decays to Meta I but also can decay directly to a UV-absorbing intermediate, but one distinct from Meta II. This UV species was called Meta I(380) and it decays to the more conventional Meta II.

The primary photoproduct, bathorhodopsin, absorbs at longer wavelengths than rhodopsin, and its vibrational spectrum is unique.[10] The bathochromic shift for the primary photoproduct was seen for every visual pigment investigated and, except for the now considered unlikely model of charge separation for the primary photoreaction,[11] there is no explanation for this universal shift. For bovine rhodopsin, the default visual pigment system, batho decays to and equilibrates with the BSI in about 70 ns in the physiological temperature range.[13] BSI has its absorption maxima at ca. 475 nm.[12] The lifetimes from batho to BSI to lumi are all roughly the same at room temperature.[13,14] While batho is stable at temperatures lower than 130 K, BSI cannot be trapped at low temperatures due to its thermodynamic properties.[14,15] Bovine lumirhodopsin has its absorption maximum at ca. 495 nm.[16,17]

There is some uncertainty as to the rate at which lumi decays to Meta I. This may be because these transitions have not been well characterized spectrally, due to the differences in lifetimes for pigments measured in membranes versus in detergent and, to a lesser extent, the way the data are analyzed. The lifetimes reported for this transition are in the range of 50 to 300 μs at temperatures in the 20 to 27°C range in rods.[17] Meta I absorbs at slightly shorter wavelengths than lumi and has a lower extinction coefficient.[16,18,19] The resonance Raman spectra of lumi, Meta I, and Meta II are distinctive and show that the former is a protonated Schiff base and the latter is deprotonated.[20] If the sample is desiccated sufficiently, then its bleaching is stopped at the Meta I stage.[21]

126.3 Formation and Equilibration of Meta II

The Meta I-to-Meta II transition was perhaps the best studied of the latter portion of the bleaching process. This transition involves the deprotonation of the Schiff base of the chromophore shifting the absorption spectrum from the visible (478 nm for Meta I) to that of Meta II, 380 nm. For most species, Meta II is formed in ca. 1 to 2 ms at room temperature and probably about 70 μs at 37°C[22,23]; it is this time constant that could contribute to the shaping of the kinetics of the receptor potential of rods.[24] The transition from Meta I (and lumi) to Meta II represents a change from a form of rhodopsin that probably has no special affinity to transducin and cannot activate transducin to a form that binds transducin and can catalyze the exchange of GDP for GTP, activating transducin. This binding greatly alters the equilibrium concentration of the two intermediates, shifting it toward Meta II.[25]

There have to be several changes that take place in rhodopsin before it can activate transducin, and these all have to take place by the time of the formation of Meta II. The first change is the photoisomerization of the chromophore from the 11-*cis* to the all-*trans* configuration (see Chapter 125 and Mathies and Lugtenburg[10]). The second required change seems to be the neutralization of the counterion to the protonated Schiff base of the chromophore.[26,27] In vertebrates, this is Glu113 in the bovine rhodopsin residue numbering system. In invertebrates, this residue is a tyrosine or a phenylalanine and is thought to already be neutral in the unphotolyzed pigment.[28] Finally, there is gathering evidence that a substantial conformational change involving at least two of the transmembrane helices of rhodopsin moving apart must occur, at the Meta II stage, for the photolyzed pigment to be able to activate transducin.[29]

Meta II seems to have multiple pathways of decay, either going on to a longer-wavelength intermediate Meta III or decaying directly to the free all-*trans*-retinal plus opsin.[30] The decay of Meta II *in situ* appears to be slow[22,31] and may be the rate-limiting step in the normal regeneration of the visual pigment.

Meta I is in pH- and temperature-dependent equilibrium with Meta II.[18] The observed pH dependence was at first surprising in that one might expect that the equilibrium between a protonated and unprotonated Schiff base would favor the protonated Schiff base with increasing proton concentration. Instead, the equilibrium is shifted toward Meta II with increasing proton concentration. This suggests that the protonation state of one or more groups, other than the Schiff base, can shift the equilibrium from Meta

I to Meta II. It was shown that when light initiates events that lead to Schiff base deprotonation, the proton is transferred to its counterion, Glu113.[32] The Meta I–Meta II transition is identified with this proton transfer. More recently, the x-ray structure of bovine rhodopsin[33] has shown that another carboxylic acid, Glu181, is also close to the Schiff base. Studies on an invertebrate pigment, retinochrome, suggest it can be in its anionic form so that it can, in some circumstances, act as a counterion.[34]

In early reports, the formation of Meta II, monitored spectroscopically at 380 nm, was fitted as a single exponential. Others found the process to be multiexponential, even in ROS (summarized in Abrahamson[35]). More recent reports share the finding that there are two or three components of Meta II formation for rhodopsin in ROS or digitonin at 15 to 25°C (see, e.g., Jäger et al.[36,37]). An explanation for the complexity may lie in the observation, as noted above, that there is a Meta-II-like species formed directly from lumi.[38] In addition, Hofmann and coworkers[39,40] provided convincing evidence for two Meta IIs in series, with the transition to the second involving the picking up of a proton.

126.4 The Role of Protons in Forming Meta II

As noted above, the equilibrium between Meta I and Meta II is pH dependent, with the higher concentration of protons favoring the deprotonated form of the Schiff base (Meta II). Because the formation of Meta II reflects the intraprotein proton transfer between the Schiff base and Glu113,[32] the origin of the pH dependence of this equilibrium is not obvious; it must reflect the role of another protonatable groups. The Meta I/Meta II equilibrium was studied in detail by Liebman and coworkers,[41,42] who made careful measurements of the thermodynamics and kinetics of the Meta I to Meta II transition between pH 5.9 and 8.1. Their results suggested that a single proton is taken up during the formation of Meta II. Note that with this technique, only protons taken up or released that control the Meta I/Meta II equilibrium are measured. Liebman and coworkers called these "essential protons." Arnis and Hofmann[39] examined the kinetics of Meta II formation at different pHs and formulated a model in which Meta II formation is divided into two steps: Schiff base deprotonation/Glu113 protonation and then proton uptake (see below). They proposed that there are two Meta IIs in series, Meta I $\leftrightarrow$ Meta II_a $\leftrightarrow$ Meta II_b, with the proton being taken up in the second step. Thus, of the three exponential phases reported in the 1 μs to 500 ms time range, the fastest can be assigned to the lumi-to-Meta-I transition, while the other two are assigned to the Meta I $\leftrightarrow$ Meta II_a $\leftrightarrow$ Meta II_b. However, an examination of the pH dependence of the Meta I $\leftrightarrow$ Meta II_a $\leftrightarrow$ Meta II_b sequence finds that both components of the Meta I decay are pH dependent,[31] so that an even more complex model than that proposed by Hofmann and co-workers must obtain. A similar need for complexity was found in the careful study of Szundi et al.[44]

Meta II takes minutes to decay. The lifetime of the active form of rhodopsin is not set by the lifetime of Meta II, for soon after it is formed, Meta II is inactivated by being phosphorylated and binding arrestin. Therefore, a discussion of the role of the lifetime of Meta II in controlling physiological processes in rods and cones is misleading, because the "spectroscopic" species is not the active species *in vivo*. *In vivo*, soon after it is formed, most Meta II is inactivated without its absorption spectrum changing.

Stoichiometry of the Protonation Changes Associated with Meta II Formation

The pH dependence of the Meta I/Meta II equilibrium provides evidence of transient protonation changes upon light activation of rhodopsin. Accurate determination of the stoichiometry and the kinetics of proton binding and release from light-activated rhodopsin are complicated by many seemingly contradictory results that may depend on the experimental preparation used. Below, I summarize these results; a more detailed discussion can be found in Kuwata et al.[43] Matthews et al.[19] found that the pK_a of the group that controlled the equilibrium between Meta I and Meta II is ca. 6.4. Several paths of research were then pursued. One line of investigation was to measure, near room temperature, the number of protons taken up or released from light-activated rhodopsin. Emrich[46] was the first to report results with pH-sensitive dyes and found a light-initiated proton uptake for ROS membranes using bromocresol purple as an indicator. Similarly, Wong and Ostroy[47] used a pH indicator dye, bromocresol green, to

measure light-induced changes for rhodopsin in digitonin at low temperatures, e.g., -10°C and found that one proton was taken up during Meta II formation and released later, in times of the order of minutes at 25°C. Bennett[48] reported that over the pH range 6 to 8, two protons are taken up per Meta II formed in ROS membranes at 3°C. At warmer temperatures, the Meta II decays but also loses protons, so that now an "unprotonated" Meta II is formed. The pH changes were measured with a pH electrode. Using the pH-sensitive dye bromocresol purple, washed ROS membranes, and reasonable time resolution (ms at 20°C), Bennett[49] reported that two protons were taken up as Meta II was formed, but that at pHs greater than 5, one of the protons was released before Meta II decayed, so that the H+/Meta II stoichiometry = 2 only at low pHs. Later, Arnis and Hofmann[39,40] found that two protons are taken up per Meta II at pH 6, none for pH 7.5, and a net release at higher pHs.

Another method used to determine the number of protons taken up and released upon Meta II formation is photocalorimetry. Cooper and Converse[50] measured the amount of heat released from a solution of ROS membranes after photolysis in several different buffers with differing heats of proton ionization. They found that there were no protonation changes during Meta II formation at pH = 8.0, and only one proton was taken up during Meta II formation at pH = 5.4.

To summarize, several experiments following light-induced protonation changes with pH-sensitive dyes or pH electrodes,[45,46,51] pH effects on the Meta I/Meta II equilibrium,[42] and photocalorimetric experiments,[50] find that just one proton is taken up in forming Meta II at lower pHs. In contrast, Bennett[52] and Arnis and Hofmann[39] found that up to two protons are taken up per Meta II at lower pHs. While some experiments would only measure the protons that must be taken up to allow Meta II formation (the "essential" protons[42]), others measure all the protons taken up, essential and nonessential. This could explain part of the discrepancy. We tentatively assume that the simpler, more comprehensive set of data is accurate, and that only one proton is taken up in going from Meta I to Meta II in ROS membranes.

Kinetics of the Protonation Changes in Photolyzed Rhodopsin

Several of the techniques used to measure the stoichiometry of the protonation changes were also used to measure the time course with which the proton is taken up during the photolysis of rhodopsin. With measurements taken in ROS membranes or rhodopsin in digitonin,[47,48,53] it was found that proton uptake fairly well matched the Meta-I-to-Meta-II transition rate, although resolution and precision were limited. Bennett[52] reported good time resolution data for proton uptake (bromocresol purple) and Meta II formation (absorbance at 365 nm), and found that they matched. Kaupp et al.[54] used the pH indicator bromocresol purple to show that in sonicated ROS membranes, proton uptake and Meta II formation times were identical at 20°C.

In 1993, Arnis and Hofmann[39] solubilized bovine rhodopsin in two different detergents, octyl glucoside or dodecyl maltoside (in these detergents, Meta II formation is greatly accelerated compared to ROS or digitonin solutions), and showed that at some temperatures, the light-induced proton uptake signal from bromocresol purple lagged significantly behind Meta II formation. Their experiments were performed at such a low temperature (3°C) that their time base was fast enough to detect any possible deprotonation associated with Meta II on the 1 to 10 s time scale. Thus, their plausible explanation is that they are looking at two consecutive Meta IIs, with the uptake of a proton only associated with the formation of the second Meta II. More complex kinetics of proton release and uptake are reported by Szundi et al.[44]

There is another way to potentially follow proton kinetics in intact ROS and that is to use the early receptor potential (ERP) or the early receptor current (ERC). The ERP is a very fast potential/current evoked from oriented photoreceptors with bright flashes (reviewed in Cone and Pak[55] and Sullivan and Shukla[56]). At room temperature, two phases can be easily observed for the ERP, a somewhat faster (sub msec) corneal negative R1 and a bit slower (1 to 10 msec) potential of opposite sign, R2. For rhodopsin, Cone[57,58] showed that the kinetics of appearance of R2 and Meta II were identical within experimental error (this correlation was also reported by Spalink and Stieve[59] for bovine retinas at 37°C). This finding, along with R2's temperature dependence, led Cone[57,58] to propose that R2 was due to charge movements associated with the Meta-I-to-Meta-II transition. (R1 was similarly linked to the RH to Meta I transitions.)

Cone[57,58] argued that because R2 is caused by charge movement associated with Meta II formation, and because it is known that at least one proton is taken up when Meta II is formed, that such a proton uptake could contribute to the charge movement associated with Meta II formation. (Movement of charged groups or dipoles within the pigment could also contribute to the observed electrical signal and must be the source of R1.) Two recent studies seemed to demonstrate this assignment. Dickopf et al.[37] studied oriented ROS membrane fragments incorporated into lipid vesicles. They found that the rise of the light-evoked electrical current could be resolved into two components with similar time constants, 1.1 and 3.0 ms at 22°C, pH = 7.8. Together, these probably correspond to R2; R1 was not observed, perhaps because the recording method used makes very fast events difficult to detect. The photocurrent's amplitude and time course were pH dependent, with the amplitude falling with increasing pH. These changes seemed to track the pH dependence of the amplitude Meta II produced, although both determinations did not quite match what was reported in other studies. However, this may be because of the unusual environment of the rhodopsin, in sonicated membrane fragments attached to a lipid support membrane. Sullivan[60] titrated the R2 component for rhodopsin expressed and then incorporated into HEK293S cells. He found that ¾ of the R2 amplitude disappeared upon raising the pH with a pK_a of 6.3, again suggesting that a large part of R2 is due to proton uptake by the photolyzed rhodopsin in forming Meta II.

In summary, using three kinds of techniques for measuring proton kinetics — pH electrode, pH sensitive dyes, and the shape of the R2 component of the ERP — it was found that the formation of Meta II is intimately and kinetically associated with the uptake of a proton. Arnis and Hofmann[39] showed that in some unusual circumstances, proton uptake can lag behind Meta II formation. Moreover, titration data for the equilibrium between Meta I and Meta II, along with the titration of the fast photocurrent due to proton uptake associated with Meta II formation, proved that the pK_a of the group binding the proton is approximately 6.4 in 150 mM salt.

Site of Proton Uptake

Arnis and coworkers[40] showed that the light-induced proton uptake by rhodopsin was completely abolished in a mutant in which Glu134 was changed to a neutral residue. The authors reasonably enough argued that this shows that Glu134 is the site of proton uptake. The uptake of a proton by Glu134, located on the cytoplasmic surface of the pigment,[33] would be of the right sign to contribute to the R2 photovoltage from rods. In addition, using FTIR spectroscopy, Fahmy et al.[61] recently showed that Glu134 is likely deprotonated in the dark but is protonated in Meta II in the presence of transducin. Can we identify Glu134 as the site that, when it takes up a proton, shifts the equilibrium between Meta I and Meta II toward Meta II? This seems plausible. Because Arnis et al. worked in the context that there were two protons taken up in Meta II formation, they had to posit that the alteration of one locus for proton uptake, Glu134, affected the second locus. If we assume that there is only one proton taken up, then this awkward problem disappears. Although it appears the proton uptake site is Glu134, other residues may be involved, and so to avoid making premature conclusions, we will call the proton uptake group, Z.

126.5 The Bleaching Intermediates of the "Cone" Pigments

The photochemical transformations of pigments other than rhodopsins are not as well studied, but an increasing number of contributions to this area of inquiry has been made. The best-studied M/LWS pigments are chicken P571 (iodopsin) and gecko P521. Low-temperature experiments showed that chicken iodopsin (562 nm) forms bathoiodopsin (640 nm) upon light absorption (see Shichida and Yoshizawa, Chapter 125, Reference 10). When the temperature is raised to -180°C, bathoiodopsin reverts to iodopsin instead of going on to lumi as rhodopsin does.[52] At warmer temperatures, a lumiiodopsin is formed.[63] An unusual feature of the M/LWS family is that almost all members use the binding of chloride to shift the spectrum to longer wavelengths and to raise the pK of the pigment's Schiff base. Many other properties are also affected by the chloride, such as the reversion mentioned just above.[64] Another example

is that the equilibrium between the batho product and the BSI product of gecko P521 is chloride dependent.[65] It was proposed that the bleaching of iodopsin is accompanied by the release of Cl^-,[64] but so far, there is no direct evidence for this. Analogues of most of the other bleaching intermediates were seen for iodopsin[63,66] and gecko P521.[73]

There are several recent papers on the very short wavelength SWS1 pigment family. The UV-absorbing members of this family seem to have an unprotonated Schiff base linkage, while the longer wavelength ("blue," Abs. Ma. 400 to 440 nm) probably all have protonated Schiff bases.[67,68] Birge and coworkers studied the bleaching sequence of both types of pigments[68,69] and developed a fascinating story that indicates that both types of pigments have bathochromically shifted primary photoproducts (i.e., we can still call them bathorhodopsins). And for the UV pigment with its initially unprotonated Schiff base, by at least the lumi stage, the Schiff base becomes protonated.

With respect to members of the other pigment families, the Kyoto group[63] purified and studied chicken[70] and gecko[71] RH2 pigments and the chicken SWS2 pigment.[72] All seem to have the same set of bleaching intermediates as the rhodopsin-type (RH1) pigments.

Studies of the Phosphorylation of Visual Pigments

Zsolt Ablonczy

Medical University of South Carolina

127.1 Introduction

A key question in the biology of vision is that of the role of phosphorylation in the regulation of the activity of the photosensitive visual pigments.[1–3] There are two types of light-sensitive cells in the retina: rods that are sensitive to dim light and cones that are responsible for color vision. Rhodopsin, the protein that absorbs light in the rod, is the most thoroughly studied of the visual pigments due to its abundance, and it has proven to be a valuable model for the whole G-protein coupled receptor superfamily.[4–7] Two main factors control the activity of rhodopsin: the ligand (or chromophore), which is 11-*cis* retinal,[8,9] and phosphorylation.[10–14] Although rhodopsin phosphorylation was characterized using numerous different methods, currently mass spectrometry is probably the most sensitive analytical tool for its quantitation. We describe here our results from recent studies on the determination of phosphorylation of rhodopsin.

127.2 Visual Pigments and the Visual Cycle

The ligand of visual pigments, 11-*cis* retinal or 3,4-dehydroretinal, is covalently bonded to the rod and cone apoprotein, opsin, and has two roles. First, this molecule acts as a chromophore, positioning the rod or cone opsin to be activated by light of specific wavelengths. Second, this ligand controls the activity of these G-protein coupled receptors by changing the conformation of the protein.[15] In the dark-adapted photoreceptor, the ligand 11-*cis* retinal is covalently bound to the apoprotein opsin, acting as a reverse agonist and locking rhodopsin in its inactive form. Upon excitation with light, the chromophore (11-*cis* retinal) isomerizes to all-*trans* conformation, which now acts as an agonist and initiates structural changes in the protein that lead to activation followed by deactivation by subsequent phosphorylation, dissociation of all-*trans* retinal, dephosphorylation, and regeneration with 11-*cis* retinal (Figure 127.1).

As a first step toward its deactivation, the *C*-terminal end of activated pigment is phosphorylated by the respective kinase. For rhodopsin, that enzyme is rhodopsin kinase (G-protein-coupled receptor kinase 1, GRK1).[16] The phosphorylation sites are the numerous hydroxyl amino acids, serine (S) and threonine

0-8493-1348-1/04/$0.00+$1.50

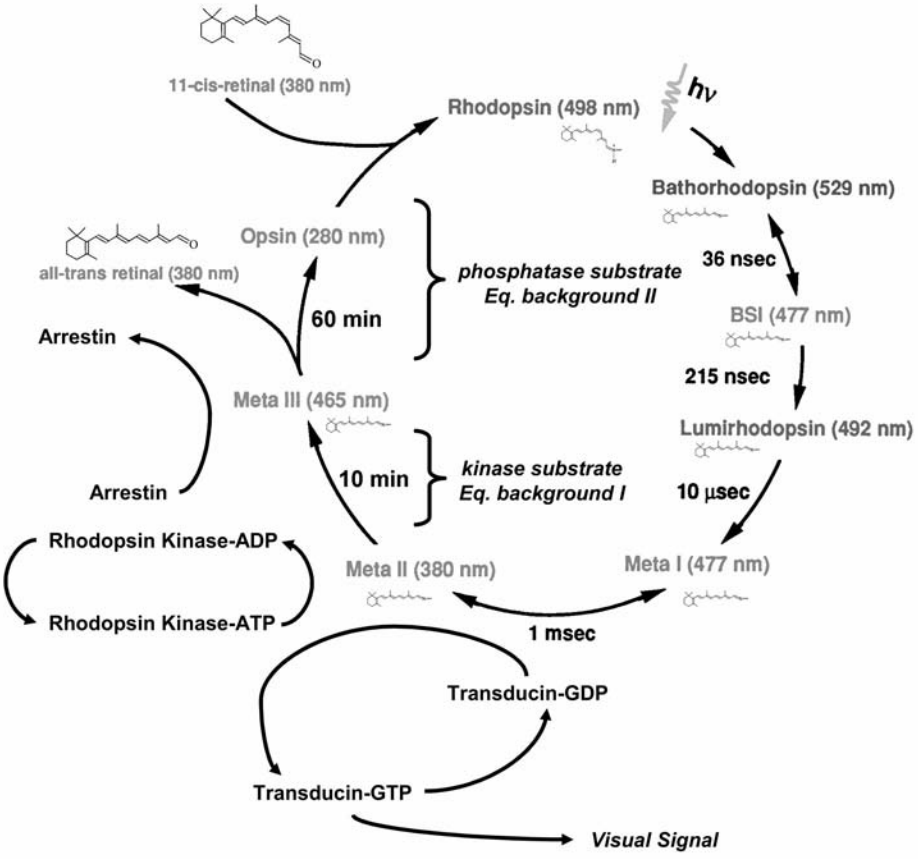

FIGURE 127.1 The photocycle of rhodopsin.

(T), that lie in this region of the protein.[10,17,18] *In vitro*, it was demonstrated that bleached rhodopsin can incorporate up to nine moles of phosphate per mole of bovine rhodopsin.[19] However, the first *in vitro* mass spectrometric experiments identified only single sites of rhodopsin phosphorylation.[10,11] Recently, it was shown by mass spectrometric experiments that *in vivo* phosphorylation involves multiple sites.[14,20,21] Multiple phosphorylation is necessary for a rapid deactivation of rhodopsin and return of visual sensitivity.[13] The key factor in the deactivation process is that the increasing multiplicity of phosphorylation simultaneously decreases the binding strength of transducin[22,23] and increases the binding strength of arrestin.[22,24] Therefore, by multiple phosphorylation, the activity of signal transduction (which requires the binding of transducin) is completely suppressed.[25,26]

After the dissociation of arrestin (initiated by the removal of all-*trans* retinal from the pigment-binding pocket) transducin can again (although to a lesser extent) bind to opsin, as long as it is not regenerated with 11-*cis* retinal.[27–29] This results in the activity generally assigned to bleached opsin.[30,31] In moderate light levels, dephosphorylation and regeneration occur simultaneously,[14] leaving no free bleached opsin (the protein part of rhodopsin) that could potentially activate the signal transduction cascade. Although it is clear that phosphorylation regulates the activity of rhodopsin, the interpretation of the measured levels and multiplicity of phosphorylation, and how it correlates with physiological visual activity measurements, is still an open question. In a recent study, it was shown that the phosphorylation of activated rhodopsin could be correlated to an early phase of a decreasing equivalent background light in the reduction of photoreceptor sensitivity, while the dephosphorylation of opsin correlates to a late phase, diminishing parallel to the regeneration of opsin to rhodopsin and the restoration of visual sensitivity.[14] On the other hand, it has to be noted that phosphorylation does not promote but quenches activity in activated rhodopsin and bleached opsin.[26,32]

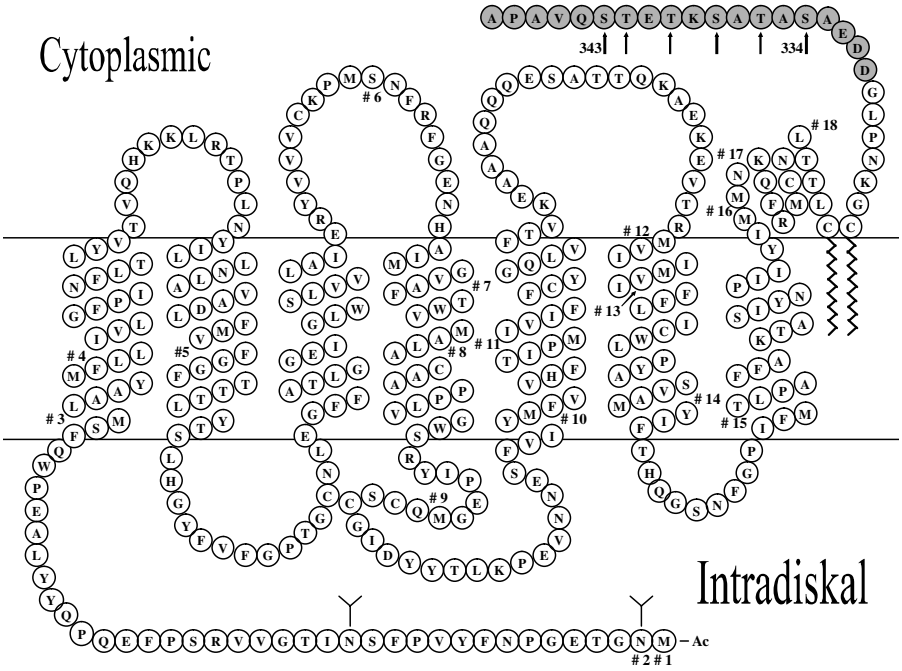

FIGURE 127.2 Two-dimensional model and amino sequence of rat rhodopsin. The sites of CNBr cleavage are marked. The *C*-terminus that can be cleaved with ASPN is shaded. Arrows indicate the possible sites of phosphorylation.

127.3 Mass Spectrometric Studies

We applied a series of mass spectrometric (MS) methods to the analysis of the phosphorylation of rhodopsin.[10,33,34] Our most recent methods employ HPLC-electrospray ionization (ESI) tandem mass spectrometry (MS-MS) using ion-trap mass spectrometers. Our studies were all performed on the rod pigment, rhodopsin. MS is a powerful technique for analyzing the primary structures of proteins. The analytical approach combines enzymatic or chemical fragmentation of the intact proteins and HPLC separation of the digest mixture prior to online MS-MS. Although MS analysis was used for soluble proteins for some years, special methodology had to be developed for the mapping of integral membrane proteins. We employed reduction and alkylation of cysteines prior to the removal of the protein from the membrane, ethanol delipidation, and CNBr digestion as a means to prepare soluble fragments of these hydrophobic materials. By applying these fragment peptide mixtures to a reversed-phase HPLC column in a large volume of a low% organic mobile phase (2.5%), we were able to achieve complete sequence and posttranslational modification mapping with rhodopsin from a single swine eye (~50 μg) (Figure 127.2). We have now used this methodology for mapping rhodopsin from several species.[20,21,33,35,36]

127.4 Rhodopsin Phosphorylation

Phosphorylation is identified by a mass shift of +80 Da for HPO_3 (or its appropriate multiple for multiple phosphorylation) on the rhodopsin *C*-terminal 19-mer fragment that was cleaved by the Asp-N enzyme. In order to identify the sites of phosphorylation, tandem mass spectral data were also collected. Examples of the data obtained are shown in Figure 127.3.

When the animals (rats or mice) were dark-adapted before sacrifice, a 1 to 3% background phosphorylation was observed, similar to the analysis of other laboratories.[21,37] If the animals were in dim light before sacrifice,

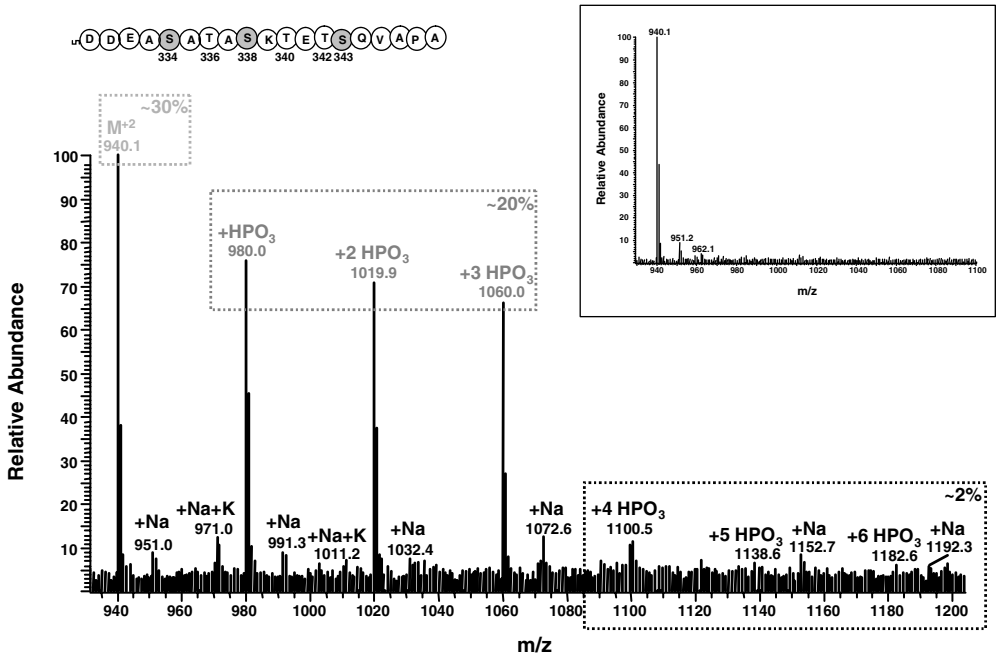

FIGURE 127.3 Phosphorylation pattern of rhodopsin. A mass spectrum of the rat rhodopsin AspN cleavage peptide ion. The ions are doubly charged in samples exposed to 30 min intense visible light (1500 lux) starting at 5 p.m. The sequence indicates the phosphorylation sites, with shading on the most prominent ones. All possible sites were phosphorylated, but up to triple phosphorylation, the levels were elevated. As shown in the insert, dark adaptation completely removes phosphorylation.

the detected phosphorylation levels did not exceed the background.[34] However, if the animals were exposed to moderate or bright light, multiple *in vivo* (mono-hexa) phosphorylation was detected.[20,21] The multiplicity and levels of phosphorylation depended on the light intensity and the available number of sites.

Three main sites of phosphorylation were identified in light-damaged rats: T336, S334, and S338. These animals were kept in light-saturated chambers for extended periods of time. The phosphorylation of the di- and triphosphorylated states was found at various combinations of these sites. Tetraphosphorylation was also present.[21]

Interestingly, porcine retina, dissected in a brightly lit operation room, also showed mono- to triphosphorylation at levels only slightly below those found in light-damaged rats.[20] However, in contrast to rat rhodopsin, which contains six sites, porcine rhodopsin contains eight potential phosphorylation sites. Because all the possible sites may be phosphorylated in a sequential manner, there may be more phosphorylation with the additional potential sites by similar intensities of light. This may be a potential reason for the high level of phosphorylation observed with less-intense light exposure in the porcine model.

127.5 Opsin Phosphorylation

Opsin is the apoprotein of rhodopsin that can result from exposure of the protein to light (termed bleached opsin) or from lack of the availability of the 11-*cis* retinal (termed virgin opsin) (Figure 127.4). There is, however, a physiological difference at these two forms of opsin. Bleached opsin is induced by light exposure of rhodopsin and is phosphorylated by rhodopsin kinase. Bleached opsin was shown to have residual activity that reduces visual sensitivity.[27–30] On the other hand, the characteristics of opsin that has not previously bound 11-*cis* retinal, because it was not available due to a disruption in the retinoid metabolism[38,39] and prior to its developmental occurrence,[40] or because it was unable to bind the ligand and form rhodopsin,[32] are different from those of the opsin resulting from the photoactivation

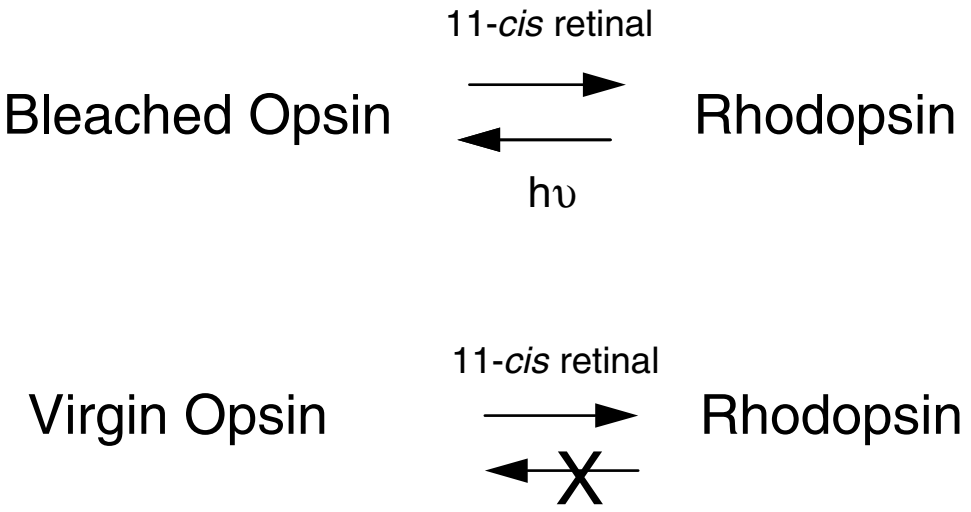

FIGURE 127.4 Bleached versus virgin opsin.

of rhodopsin. This "virgin opsin" is constitutively phosphorylated by an unidentified kinase, and the phosphorylation is only removed if a ligand (e.g., 9- or 11-*cis* retinal) is made available. RPE65 is a major protein of the retinal pigment epithelium (RPE),[41] also identified in cone photoreceptors.[42,43] The photoreceptors of *Rpe65*$^{-/-}$ mice are almost completely depleted of 11-*cis* retinal, resulting in minimal levels of rhodopsin and the deterioration of photosensitivity.[38] This is a useful animal model for the study of "virgin opsin," because almost the full opsin content of the animal has never been exposed to its ligand. The opsin is otherwise structurally intact, and photoreceptor function can be partially restored by supplying exogenous ligand.[36,39,44] The kinetics of the *Rpe65*$^{-/-}$ rods do not resemble those expected of bleached rods,[27,45] but rather those of a dark-adapted rod, showing that, in contrast to bleached opsin, virgin opsin is inactive. In other words, opsin that has never been exposed to its native ligand has the kinetics of a receptor containing its inverse agonist, probably due to its constitutive phosphorylation. Therefore, the constitutive phosphorylation of opsin could possibly be a protective mechanism, shutting off the transduction cascade normally activated by bleached opsin.

Our MS measurements (Figure 127.5) show that the *C*-terminal opsin phosphorylation in dark-adapted *Rpe65*$^{-/-}$ mice was approximately eight-fold higher than in opsin from WT mice (24 versus 3%).[36] This monophosphorylation was independent of light exposure and age (1 month to 18 months) with the most prominent sites of phosphorylation being S334 and S343. However, this constitutive phosphorylation was dose-dependently affected by the administration of 11-*cis* retinal. At 24 h after intraperitoneal 11-*cis* retinal injections, the opsin phosphorylation was significantly reduced in light-exposed and dark-adapted retinas without changing the sites of phosphorylation (to 13 ± 3%). The *in vivo* observations were confirmed under *in vitro* conditions. *In vitro* addition of excess 11-*cis* retinal also resulted in dephosphorylation (10 ± 1%). Similar agonist-independent phosphorylation was reported in other G-protein coupled receptors (bradykinin B_2 receptor,[46] α_2 adrenegeric receptor[47]). The mechanism of the phosphorylation of "virgin opsin" remains to be elucidated. If there is a parallel with agonist-independent desensitization suggested for other G-protein coupled receptors, then protein kinase C may be a candidate, as it is known to phosphorylate rhodopsin,[48] but its role in the visual process *in vivo* is yet unclear.

127.6 Summary

The MS analysis of the *C*-terminus of rhodopsin and opsin uncovered unexpected differences between their phosphorylation patterns. These new results may increase our knowledge of how phosphorylation

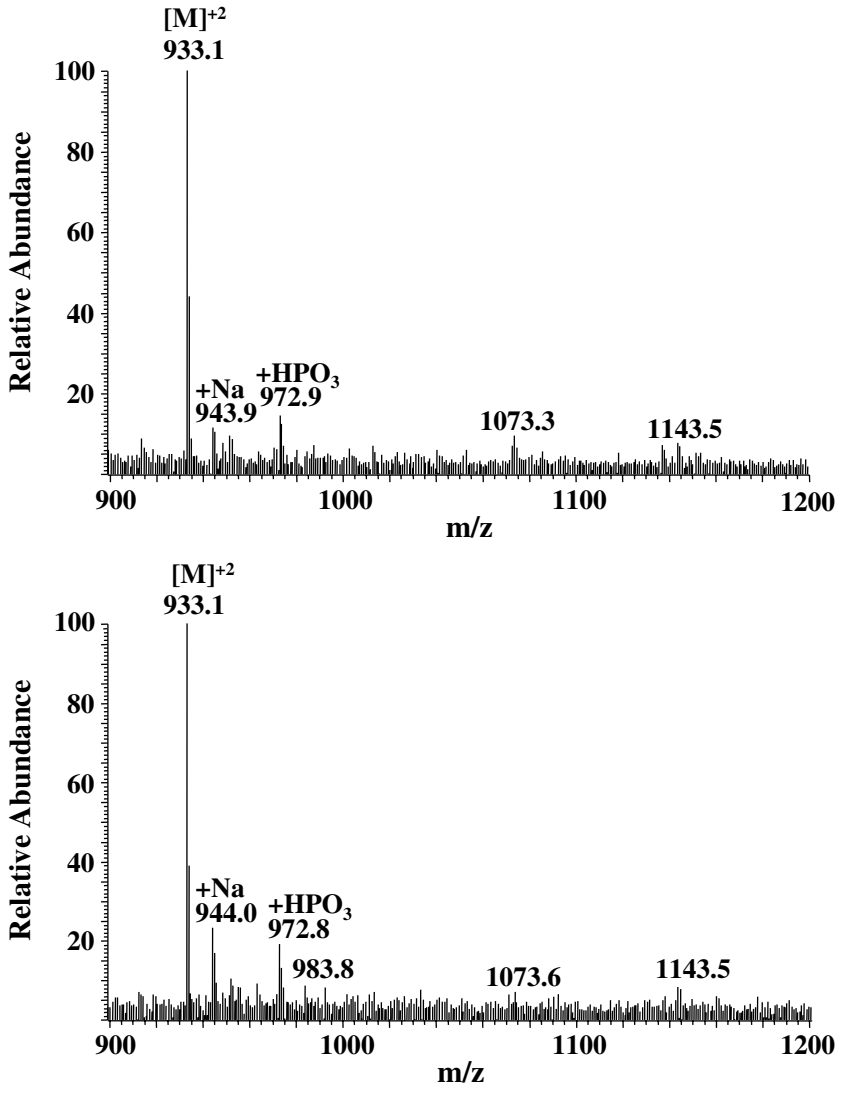

FIGURE 127.5 Phosphorylation pattern of opsin. Mass spectra of the rhodopsin AspN cleavage peptide ion from RPE65-deficient mice. Light exposure (A), 24 h dark-adaptation (B), and age do not influence the level or pattern of opsin phosphorylation.

and the availability of the chromophore mutually regulate the activity of rhodopsin and thereby the physiological responses of the visual signal transduction cascade.

Acknowledgments

Funding was provided by grants from NIH EY-04939 and EY-08239, Office of Naval Research, Foundation Fighting Blindness, and an unrestricted grant to MUSC from Research to Prevent Blindness, Inc., New York, NY. The mass spectrometry was performed in the MUSC Mass Spectrometry Institutional Research Resource Facility.

The Early Receptor Potential and its Analog in Bacteriorhodopsin Membranes

Felix T. Hong
Wayne State University School of Medicine

128.1 Introduction

Almost four decades ago, Brown and Murakami[1,2] discovered a tiny electrical signal in the retina of Cymolgus monkey, when they stimulated the retina with an intense millisecond flash light. The photosignal appeared almost instantaneously upon light stimulation; the latency was undetectable and was estimated to be less than 1 μs (Figure 128.1). This signal was thought to be a new type of bioelectric phenomenon (for earlier reviews, see the literature[3–9]). It was named the early receptor potential (ERP) so as to distinguish it from the then-known receptor potential in the retina — the *a*-wave of the electroretinogram (ERG).[10] The latter has a latency of about 1.7 ms, and was then renamed the late receptor potential (LRP). Unlike LRP, ERP is small in amplitude and requires a significantly more intense flash light to elicit. While LRP can be abolished by anoxia or by other treatments that disrupt the supply of metabolic energy, ERP persists under these rough treatments.

ERP consists of two separate signal components: R1 and R2. The fast component, R1, has a cornea-positive polarity, whereas the slow component, R2, has the opposite polarity. R2 can be reversibly inhibited by low temperature, but R1 persists even at -35°C [Figure 128.1(C) through Figure 128.1(E)].[11,12] ERP from cone photoreceptors is similar: it consists of a brief depolarizing phase (R1) followed by a hyperpolarizing R2 phase.[13–15] ERP-like signals were also found in plant leaves and other pigmented animal tissues.[16] ERP and ERP-like photosignals were generically referred to as fast photovoltages or displacement photocurrents.

Before the discovery of ERP, all known bioelectric signals were generated by ionic diffusion. For example, LRP is associated with the light-induced Na^+ influx at the outer segment of the retinal photoreceptor.[17] The latency of ERP is too short to be accounted for by ionic diffusion. Investigators concluded

0-8493-1348-1/04/$0.00+$1.50

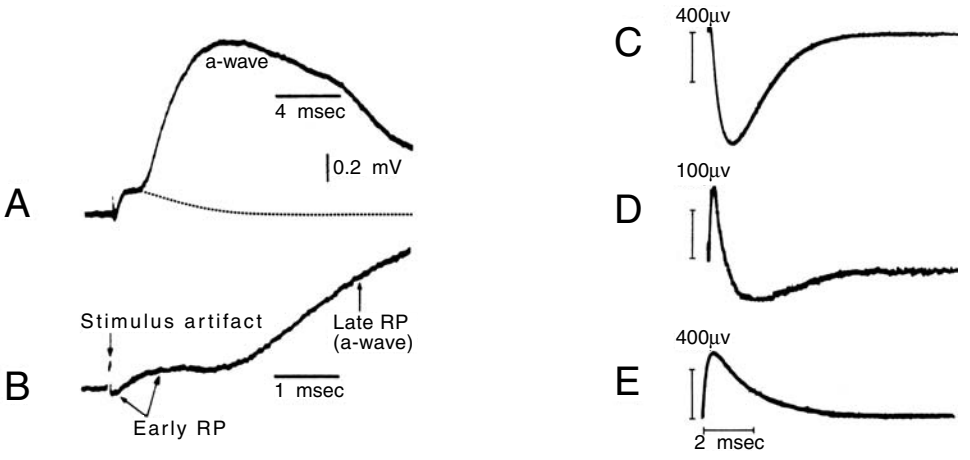

FIGURE 128.1 The early receptor potential from the retina of a Cynmolgus monkey (A and B) and from an albino rat (C, D, and E). In Records A and B, the stimulus was a 20-μs flash, and the ERP appears without an appreciable delay after the light stimulus and merges into the ERG *a*-wave (also known as the late receptor potential). The late receptor potential can be abolished by anoxia, leaving the ERP intact, as shown by the dotted line in Record A. Records C, D, and E show the ERP at 35, 25, and 0°C, respectively. [From Brown, K.T., Watanabe, K., and Murakami, M., *Cold Spring Harbor Symp. Quant. Biol.*, 30, 457, 1965 (A and B); Pak, W.L. and Cone, R.A., *Nature*, 204, 836, 1964 (C,D,E). With permission.]

that ERP is generated by charge displacements caused by a light-induced conformational change of rhodopsin.[18–20] After more than a decade of intense research, investigators were unable to associate ERP with any known physiological function of the retina. ERP was thus regarded as an epiphenomenon — a by-product of photochemical reaction of visual pigment and an evolutionary vestige with no important physiological function. Interests in ERP eventually subsided. However, Pak[6] did not completely rule out the possibility of still unidentified and silent processes intervening between the generation of ERP and the excitation of the rods.

The interest in investigating ERP was revived by the discovery of fabricating artificial black lipid membranes (BLM), by Rudin and his coworkers in 1962.[21] Shortly after, Tien[22] demonstrated a transient photosignal in an artificial BLM reconstituted from a chloroplast extract. Subsequently, similar photosignals appeared in BLM reconstituted with various kinds of organic dyes or pigments, including the chromophore of visual pigments, retinal, and a related compound, retinoic acid[23] (for a recent review, see Tien and Ottova-Leitmannova,[24] Chapter 9). Most of these reconstitution studies involved small organic molecules. The first successful incorporation of a protein molecule into BLM was reported by Takagi and coworkers.[25] The original method of fabricating BLM is not suitable for incorporation of proteins into a BLM because of the use of organic solvents in the process of forming a BLM. Takagi and coworkers used an ingenious technique to incorporate rhodopsin into a BLM. What they did was first incorporate rhodopsin into a monolayer on a specially designed Langmuir trough. A BLM was then formed by fusing two solvent-free monolayers into a bilayer. This method was subsequently improved by Montal and Mueller.[26] A direct observation of ERP-like signal in a reconstituted BLM that contains rhodopsin was reported by Montal and Korenbrot.[27] However, the detected signal was too small to be accurately analyzed. The small amplitude was thought to be the consequence of current shunting caused by a leaky BLM. Enhanced signals were subsequently obtained by Trissl et al.[28] by depositing an oriented layer of visual membrane fragments on a thin (6 μm) Teflon film. The placement of a Teflon film prevents shunting but also precludes the recording of any DC electric signal. They called the ERP-like signal in a reconstituted rhodopsin membrane early receptor current (ERC), because the photosignal was measured as a current instead of a voltage. The ability to detect an electric signal under this condition supported the interpretation that ERP is a manifestation of light-induced charge displacements. In other words,

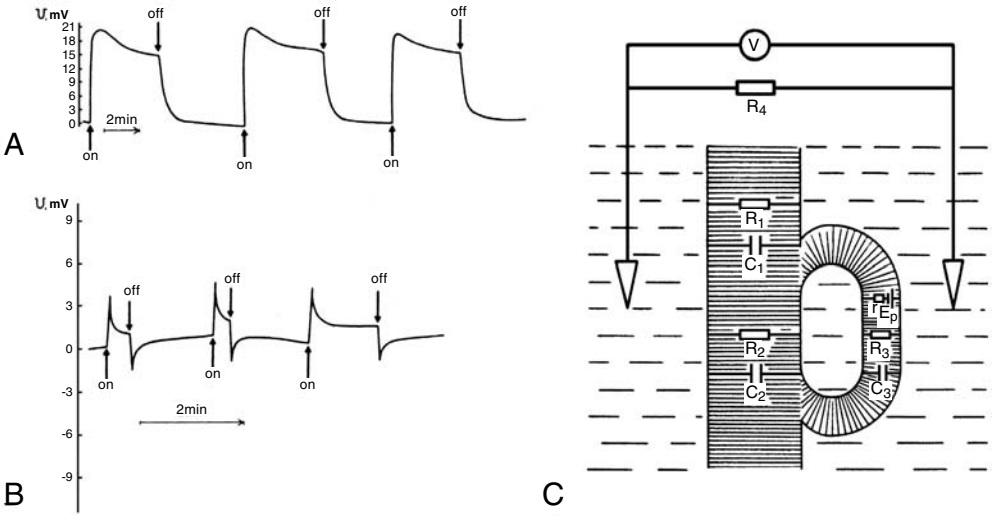

FIGURE 128.2 Differential responsivity. (A) Open-circuit photovoltages of a reconstituted bacteriorhodopsin membrane to a long square-wave light pulse, measured before (Record A) and after (Record B) addition of 0.2 μ*M* of CCCP, are shown. Shunting with an external resistor has a similar effect. The spikes appearing upon the onset and cessation of illumination are known as differential responsivity. (B) An explanation of differential responsivity proposed by Drachev et al. Fusion of bacteriorhodopsin-containing vesicles with the planar BLM is incomplete, thus forming a button-like structure. Capacitors for three regions — regular planar BLM, contact region, and vesicle — are represented by C_1, C_2, and C_3, respectively. Here, C_3 is series capacitor which, together with resistor *r* in the vesicle region, forms a linear high-pass RC filter. [From Drachev, L.A., Kaulen, A.D., Ostroumov, S.A., and Skulachev, V.P., *FEBS Lett.*, 39, 43, 1974 (A, B); Drachev, L.A., Frolov, V.N., Kaulen, A.D., Liberman, E.A., Ostroumov, S.A., Plakunova, V.G., Semenov, A.Yu., and Skulachev, V.P., *J. Biol. Chem.*, 251, 7059, 1976 (C). With permission.]

ERP is a capacitative signal — an AC-coupled electric signal. In contrast, most diffusion-generated bioelectric signals are DC-coupled electric signals. (However, the well-known gating current detected in a squid axon is a voltage-induced displacement current.)

At about the same time, Oesterhelt and Stoeckenius[29] discovered a retinal-containing protein in a halophilic bacterium *Halobacterium salinarum* (formerly *Halobacterium halobium*). This molecule, known as bacteriorhodopsin, resembles rhodopsin in its chemical structure but is actually a photosynthetic pigment — a light-driven proton pump (for recent reviews, see the literature[30–33]). The first report of the photoelectric effect in a reconstituted bacteriorhodopsin membrane was published by Skulachev and coworkers in 1974.[34,35] These investigators first loaded spherical liposomes with bacteriorhodopsin, and then allowed these vesicles to fuse with a planar BLM that did not contain any pigment initially. They then delivered a long square-wave light pulse to illuminate the membrane, and they observed a sustained photovoltage during illumination [Figure 128.2(A)]. This sustained photovoltage reflected mainly the DC-coupled signal caused by a net transport of protons. In addition, they reported a peculiar finding: upon the addition of a proton ionophore CCCP (carbonyl cyanide-*m*-chlorophenylhydrazone), the monotonic waveform was transformed into a signal with a spike at the onset of illumination and an inverted spike at the cessation of stimulation [Figure 128.2(B)]. They interpreted the waveform as being indicative of a peculiar membrane structure that resulted from incomplete fusion of vesicles with a planar BLM [Figure 128.2(C)].[36] Alternatively, Hong[37] interpreted the CCCP-induced waveform change as an indication of the concurrent presence of a light-induced capacitative current, an ERP-like signal, so to speak. Subsequently, by depositing an oriented layer of bacteriorhodopsin membrane fragments on a Teflon film (as in the aforementioned Teflon-supported reconstituted system), Trissl and Montal[38] found a fast electric signal upon illuminating the preparation with a millisecond flash light. What they observed was a signal analogous to R2. Using a microsecond laser light pulse, Hong and Montal[39] reported an even faster signal with a submicrosecond rise time in addition to the R2-like signal. (The rise time was

subsequently determined by Simmeth and Rayfield[40] and by Groma and coworkers[41] to be in the picosecond range.) The slower R2-like component could be reversibly inhibited by low temperature, whereas the faster component persisted at 5°C. They referred to the fast and the slow components as the B1 and the B2 components, respectively, because their temperature sensitivities are similar to that of the R1 and the R2 components, respectively. A sizable literature accumulated during the past quarter century and continues to expand. The literature provides a wealth of information for elucidating ERP, if bacteriorhodopsin can be regarded as a surrogate molecule for rhodopsin. Data from a reconstituted bacteriorhodopsin membrane were easier and faster to collect because of bacteriorhodopsin's legendary stability and cyclicity. Unlike rhodopsin that is bleached by illumination, bacteriorhodopsin is regenerated after illumination via a photocycle. The cyclicity allows a virtually unlimited number of measurements to be made on the same preparation and allows signal averaging to be performed on the measured data. Bacteriorhodopsin can withstand high temperature and extreme acidity and allows experiments to be performed under extreme conditions. The difficulty in collecting quality data of ERP from a unicellular system was recently alleviated by cloning rhodopsin in an expression system using recombinant DNA technology.[42,43]

In this chapter, the focus is on the electrophysiological analysis of ERP based on data of rhodopsin and bacteriorhodopsin, and the mechanistic interpretation. The elucidation of the above-mentioned problems requires a combined electrochemical and electrophysiological approach. The results of our analysis suggest that ERP might function as a molecular switch for visual transduction. A mechanistic explanation will be integrated with the contemporary understanding of the biochemical mechanism of visual transduction. The subject of molecular switches has important technological implications and is discussed in Chapter 134. The lesson so learned also includes how risky it could be if an established electrophysiological technique and an established method of analysis in solution-phase photochemistry were indiscriminately transplanted to heterogeneous photochemistry — a system that involves a membrane phase and two solution phases.

128.2 Mechanistic Models of ERP Generation

Light-induced ion diffusion across the membrane is not sufficiently fast to account for the short latency of ERP. The obvious alternative possibility is light-induced charge displacements. This conclusion is further supported by two experimental observations. Hagins and McGaughy[18] found that the electric current associated with ERP satisfies the following condition:

$$\int_0^\infty I(t)\,dt = 0 \tag{128.1}$$

where $I(t)$ is the time course of the photocurrent. This condition, which suggests that ERP reflects reversible charge displacements in rhodopsin, will be referred to as the zero time-integral condition. Currents generated by diffusion through ion channels do not satisfy this condition, but reversible charge displacements that result in an AC-coupled signal do. The idea of reversible charge displacements was also supported by Cone's finding of the *photoreversal potential* [Figure 128.3(A)]:[20] the visual membrane, which was first enriched with predominantly the metarhodopsin photointermediate from prior illumination, responds to a second light flash with a signal that resembles ERP in waveform but has a reversed polarity. Light stimulation that drives an intermediate back to the ground state may reverse the time-sequence of charge movements.

A commonly envisioned picture of these charge displacements is the movement of charged groups in the amino acid side chains of rhodopsin as a result of a sequence of light-induced conformational changes (photobleaching sequence).[44] Because rhodopsin maintains a fixed orientation with respect to the membrane, such charge movements naturally lead to the formation of an array of transient electric dipoles. The appearance and disappearance of such electric dipoles thus gives rise to a photocurrent that satisfies the

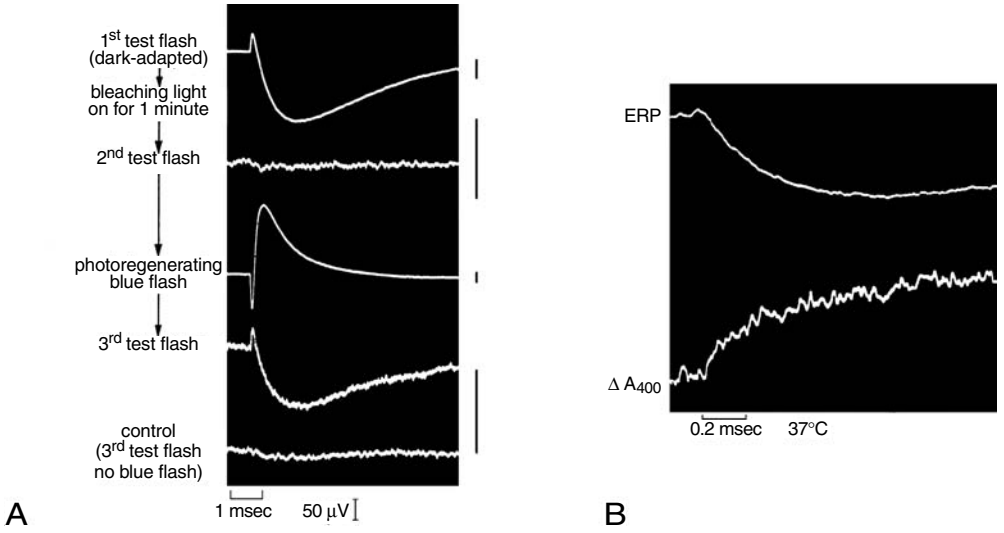

FIGURE 128.3 Salient features of ERP. (A) Photoreversal potential can be elicited by illuminating photointermediates with a blue light flash. Photosignals were measured from excised eye of albino rat at 27°C. Three test flashes contained long wavelengths primarily absorbed by rhodopsin. Blue photoregenerating flash contained wavelengths absorbed by longer-lived intermediates. Control trace was obtained from a second eye, subjected to the same bleaching exposure and test flashes but without the blue flash. (B) The appearance of the R2 component of ERP and the formation of metarhodopsin II are time-correlated. The latter was monitored by absorbance change at 400 nm. The flash duration was 0.1 ms. [From Cone, R.A., *Science*, 155, 1128, 1967 (A); Cone, R.A., in Reichardt, W., Ed., *Proceedings of International School of Physics "Enrico Fermi," Course XLIII*, Academic Press, New York, 1969 (B). With permission.]

zero time-integral condition, Equation 128.1. Illuminating photointermediates with blue light causes a conformational change of rhodopsin in the reversed time-sequence, thus generating the photoreversal potential. This widely accepted mechanistic explanation is known in the ERP literature as the dipole mechanism or, more precisely, the *oriented dipole* (OD) mechanism (Figure 128.4). Thus, in its original form, the dipole mechanism tacitly acknowledged the capacitative nature of ERP; the notion of charge displacements implies charge separation and subsequent recombination. However, this important idea was subsequently forgotten when investigators investigated ERP-like signals in bacteriorhodopsin (see later).

The oriented dipole mechanism is, however, not the only possible mechanism with which to generate charge displacements. In a model membrane system with a membrane-bound magnesium porphyrin (magnesium octaethylporphyrin or amyl ester of magnesium mesoporphyrin IX) and a redox gradient of water-soluble electron acceptor, ferricyanide, and electron donor, ferrocyanide, Hong and Mauzerall[45,46] demonstrated a capacitative photoelectric signal that reflects light-induced electron transfer from magnesium porphyrin to ferricyanide: an heterogeneous electron transfer reaction across a single-membrane–water interface. In this reaction, the separated charges are essentially magnesium porphyrin monocation, in the membrane phase, and ferrocyanide, in the adjacent aqueous phase. While magnesium porphyrin monocation remains essentially fixed in location during the time course of the measured fast photosignal, ferrocyanide ions are free to diffuse. Strictly speaking, the pair does not form an electric dipole in the usual sense. One is a fixed positive charge in the membrane near its surface, whereas the other joins a layer of diffuse negative charges distributed in the double-layer region. Yet, the fast photoelectric signal so generated exhibits all major characteristics of the ERP.[47] Indeed, an interfacial electron transfer (or, more generally, interfacial charge transfer) constitutes another kind of charge separation. When the absorbed photon ejects an electron from the membrane-bound magnesium porphyrin to the aqueous-borne acceptor ferricyanide ion, the oxidized pigment molecule remains in the membrane phase

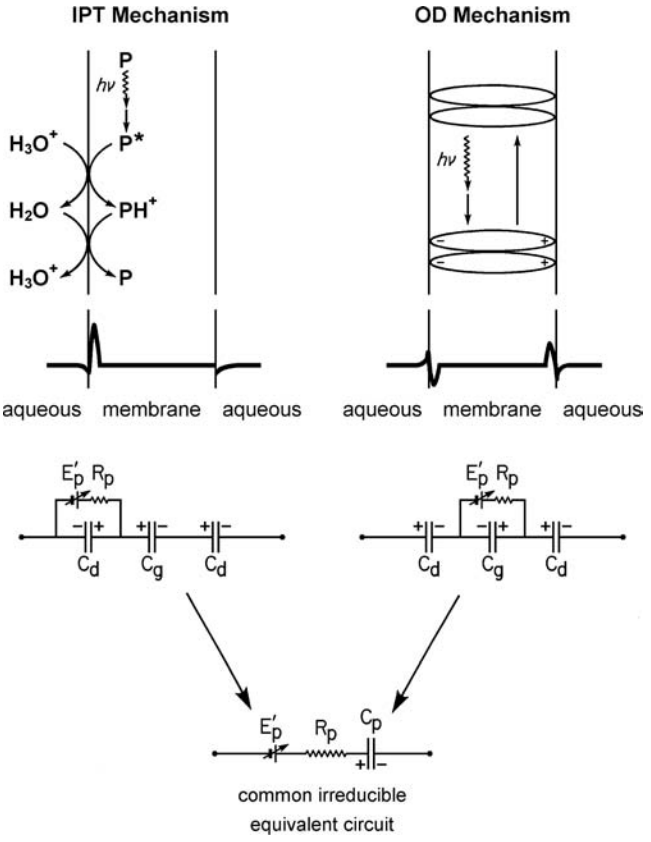

FIGURE 128.4 Interfacial proton transfer (IPT) mechanism and oriented dipole (OD) mechanism. IPT mechanism describes transfer of proton from the adjacent aqueous phase to the membrane phase, while leaving counterion behind in the aqueous phase. Ground-state pigment is designated as *P*. Excited pigment that binds proton from the aqueous phase is designated as *P**. The charge-density profile is also shown, along with two slightly different equivalent circuits. OD mechanism describes light-induced generation of a transient array of oriented electric dipoles, inside the membrane. The diagram is self-explanatory. These two circuits can be further reduced to a common irreducible one (bottom of diagram). (From Hong, F.T., *Bioelectrochem. Bioenerg.*, 5, 425, 1978. With permission.)

and, together with other such molecules, forms a layer of fixed positive surface charges, while electron jumps to ferricyanide to form a mobile counterion. Similarly, when a proton is taken up by photostimulated membrane-bound pigment, the mobile counterion is left behind in the adjacent aqueous phase, and, again, charge separation takes place at the interface. There is no evidence of interfacial electron transfer in visual membranes, but an interfacial proton transfer takes place at the membrane–water surface.

It has long been known that the metarhodopsin-I-to-metarhodopsin-II transition in the photobleaching sequence of rhodopsin involves a net uptake of a single proton from the aqueous phase.[48] Furthermore, Cone[5,49] demonstrated that the R2 component appears at the same time when the photointermediate metarhodopsin I is converted to metarhodopsin II [Figure 128.3(B)]. Ostroy and co-workers[50] further demonstrated that the amplitude of the R2 component varies linearly with the amount of metarhodopsin II produced. Thus, in principle, the R2 component can be generated by interfacial proton transfer. This mechanism will be referred to as the *interfacial proton transfer* (IPT) mechanism (Figure 128.4). At least two components of ERP-like signals could be generated by such a mechanism in bacteriorhodopsin membranes. Being a light-driven proton pump, bacteriorhodopsin is obligated to bind protons from the cytoplasmic side and release them to the extracellular side, thus generating two signal components that reflect charge separation at the two respective membrane–water interfaces. For some time, it was not

clear at which side of the two aqueous phases proton uptake takes place in rhodopsin. Using phospholipid vesicles reconstituted from rhodopsin, Ostrovsky and coworkers[51,52] found that illumination caused a transient pH increase of the bathing solution in a sample of normally oriented vesicles (with the *C*-terminus of rhodopsin facing the bathing solution) but no corresponding pH decrease in a sample of inverted vesicles (with the *N*-terminus of rhodopsin facing the bathing solution). They concluded that the proton uptake takes place at the cytoplasmic side, but no proton uptake or release takes place at the opposite (intradiscal) side. They further concluded that there is no net light-induced proton transport across the membrane. Their observations and conclusions are consistent with the role of rhodopsin being a photon energy sensor rather than a photon energy converter — there is no need to move protons all the way across the membrane. Although this latter reasoning sounds suspiciously teleological, it makes evolutionary sense.

Thus, in principle, ERP can be generated by the OD or the IPT mechanism. In addition, there is no compelling reason that R1 and R2 must be generated by the same mechanism. The question is: which one is for which? Answering this question requires some understanding of the relationship between the macroscopically measured photosignal and the underlying microscopic mechanistic event. A natural linkage between the two events can be established by equivalent circuit analysis. The two simple models shown in Figure 128.4 offer a starting point. The process of charge separation and recombination in the direction perpendicular to the membrane surface is tantamount to charging and discharging a capacitance. However, the capacitance being charged and discharged is not the ordinary membrane capacitance that is commonly encountered in classical electrophysiology. This can be made clear by analyzing the two models in terms of Guoy–Chapman's theory of diffuse double layers.[47,53] The two models give rise to two slightly different equivalent circuits (Figure 128.4). Notably, the charge distribution patterns on the three elementary capacitances — one geometric capacitance of the inert bilayer and two diffuse double-layer capacitances — are different. These patterns are also different from those of an ordinary membrane capacitance. That the three distinct patterns cannot be converted into one another was established by a simple geometric argument published elsewhere.[54,55] However, on a macroscopic level, these two equivalent circuits are equivalent to the same common irreducible equivalent circuit shown at the bottom of Figure 128.4. The most salient feature of this circuit is the inclusion of a capacitance C_p that is connected in series to the photogenerator, E_p. In contrast, the ordinary membrane capacitance, C_m is connected in parallel to E_p. Thus, C_p is fundamentally different from C_m (not shown in Figure 128.4). C_p was named *chemical capacitance*, because charging or discharging of this capacitance is accomplished by photochemical reactions instead of physical flows of ions. Here, we shall not pursue the theoretical implications of the subtle difference between C_p and C_m, as detailed analysis can be found in the literature.[54,55]

128.3 An Apparent Paradox

The above analysis suggests that the OD and the IPT mechanisms are electrically indistinguishable. However, the differentiation can be made by chemical means. In the formation of a transient oriented electric dipole, the separated pair of charges remains on the same molecule, and their locations remain correlated. The charge recombination, therefore, follows a first-order kinetics of chemical reaction. But when the charge separation takes place across the membrane–water interface, one of the separated charges quickly gets lost in the adjacent aqueous phase because of rapid ionic cloud relaxation in water, while the other remains fixed in the membrane phase at the surface. The locations of the pair of separated charges become quickly decorrelated, and the recombination thus follows a second-order or a pseudo first-order kinetics (the two charges that recombine need not be the two from the same pair that was previously separated). For the interfacial proton transfer during the metarhodopsin I to Metarhodopsin II transition, proton is one of the two reactants. By virtue of the law of mass action, the reaction is expected be strongly pH-dependent. Thus, the recombination — a proton rerelease back to the aqueous phase on the same surface — is expected to be a second-order process in an unbuffered aqueous solution. But, it will be a pseudo-first-order process if the aqueous phase is buffered; the pseudo-first-order rate

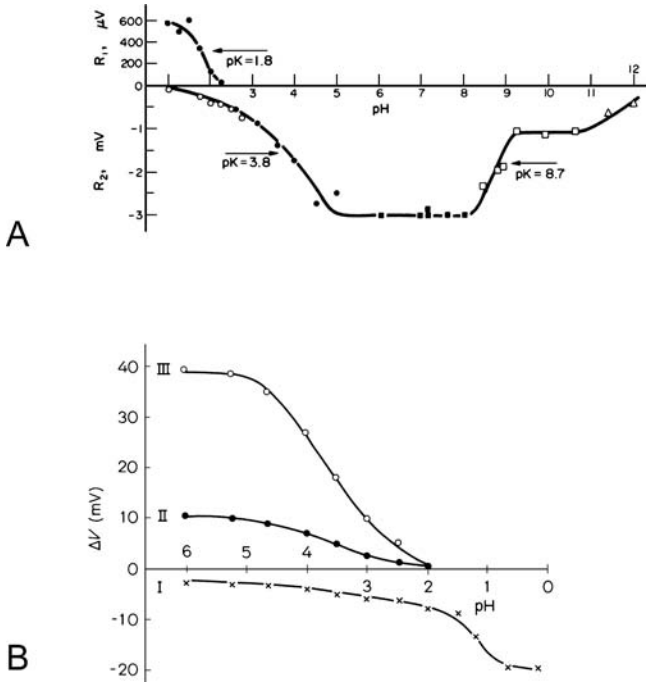

FIGURE 128.5 pH dependence of amplitudes of fast photovoltages from rhodopsin (A) and bacteriorhodopsin (B), measured under open-circuit conditions. ERP was decomposed into R_+ (i.e., R1) and R2. Analogous signal from bacteriorhodopsin was decomposed into Components I, II, and III. [From Trissl, H.-W., *Photochem. Photobiol.*, 29, 579, 1979 (A); Drachev, L.A., Kaulen, A.D., Khitrina, L.V., and Skulachev, V.P., *Eur. J. Biochem.*, 117,461, 1981 (B). With permission.]

constant is expected to be pH-dependent, possibly linearly. Actually, Cone[20] and Ostroy[9] once considered proton uptake as a possible mechanism, but the idea was eventually abandoned presumably because R2 had not exhibited the expected pH dependence (summarized in Reference 6).

The availability of reconstitution techniques for incorporating rhodopsin into a BLM made it possible to reexamine this problem under rigorously controlled conditions in a reduced system — the major advantage of the reductionist approach. Figure 128.5(A) shows the amplitude of R1 and R2 components as a function of the aqueous pH, measured in a reconstituted rhodopsin membrane.[44] However, no striking pH dependence was evident. A similar result was found in a reconstituted bacteriorhodopsin membrane [Figure 128.5(B)].[38,56] In both cases, the amplitudes are largely pH insensitive, except at pH below 2 (and above 8). When pH approaches 2 and below, R2 declines in amplitude, while R1 rises reciprocally. Similarly, as Components II and III of a bacteriorhodopsin membrane decline, the amplitude of Component I increases. If we identify Component I as the R1 analog, whereas Component II or III is identified as the R2 analog, the similarity becomes apparent. This lack of pH sensitivity runs against our intuitive expectation. The reciprocal relationship between R1 and R2 amplitudes also looks suspiciously correlated. The apparent paradox thus demands an explanation.

The investigation of reconstituted model systems greatly facilitated detailed kinetic analysis of fast photovoltages, but the initial results did not clear the apparent paradox, instead, they compounded the puzzle. It was found that the observed relaxation time constants differ drastically from laboratory to laboratory. The discrepancies between laboratories amount to a factor as much as 1000 and could hardly be explained by variations of common experimental conditions such as temperature, pH, etc. (see Table 1 in Okajima and Hong[57]). Apparently, the variation of a hidden parameter is the culprit. Using the same type of reconstitution method previously used by Trissl and Montal,[38] Hong and Montal[39] found that the measured time course of the ERP-like signal of a bacteriorhodopsin membrane under an open-circuit

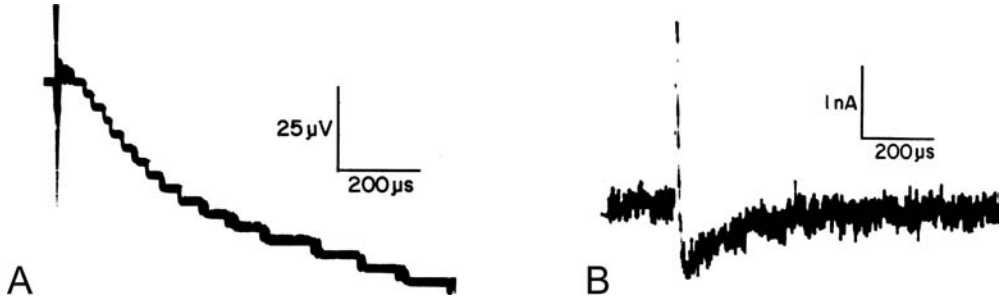

FIGURE 128.6 ERP-like photosignals measured from a reconstituted bacteriorhodopsin membrane under open-circuit conditions (A) and under near-short-circuit conditions (B). The access impedance was 1 kΩ. The light source is a microsecond dye laser pulse. The negative spike in Record A is a stimulus artifact. (From Hong, F.T. and Montal, M., *Biophys. J.*, 25, 465, 1979. With permission.)

condition differs drastically from that measured under a near-short-circuit condition. Specifically, the B1 component is smaller than the B2 component under the open-circuit condition, but the reverse is true under the near-short-circuit condition (Figure 128.6). Furthermore, the apparent relaxation time is considerably faster under the near-short-circuit condition than under the open-circuit condition. Similar observations pertaining to a reconstituted rhodopsin membrane were reported by Ostrovsky's group, when the membrane was short-circuited by shunting (Figure 128.7).[58] The latter observation suggests that changes of measurement conditions — shunting alters the measurement condition — affect the photoelectric kinetics similarly in reconstituted bacteriorhodopsin and rhodopsin membranes.[52] Conventional approaches could offer no satisfactory explanation for the observed kinetic variations. The two questions of how the measurement device interacts with the signal generating system in general and how short-circuiting of the membrane affects the waveform of fast photoelectric signals are readily understood by means of equivalent circuit analysis.

128.4 Equivalent Circuit Analysis

The key to resolving the above-mentioned apparent paradox is to recognize the heterogeneous nature of photochemical reactions in biomembranes. Intuitively, the electric currents generated by photoreactions must interact with the inert supporting structure — the lipid bilayer — as well as the measuring device. Equivalent circuit analysis thus provides a shortcut to a better understanding.

Let us start with the irreducible equivalent circuit, shown in Figure 128.4, that provides a description of the electrical event stemming from heterogeneous photochemical reactions. Additional features representing the inert supporting structure of the lipid bilayer must be added to this circuit [Figure 128.8(A)]. In a reconstituted model membrane, the lipid bilayer portion provides ion channels or leakage pathways for currents to go through the membrane, and the pathways are collectively represented by the membrane resistance, R_m (or its reciprocal, the membrane conductance, $G_m = 1/R_m$). When an ionophore is added to the membrane, R_m decreases. The membrane capacitance, C_m, holds transported charges; the potential across C_m represents the transmembrane voltage (open-circuit voltage). Thus, there are two parallel pathways for electric currents to go through the membrane: the photochemical pathway comprised of the irreducible circuit, as shown in Figure 128.4, and the inert RC circuit (R_mC_m) formed by the bilayer's conductance and capacitance. An additional element, R_s, is added to the photochemical pathway in order to account for the passage of the DC photocurrent. The value of R_s can be set to infinity in the case of visual membranes, because a transmembrane photoconduction pathway does not exist. The parameter R_e is usually referred to as the access impedance. It represents the combined impedance of the input impedance of the measuring device, the impedance of electrodes, and the impedance of the intervening solution between the membrane surfaces and the electrodes. The latter, though small in most electrophysiological measures, can at times become significant, and must be included in the equivalent circuit

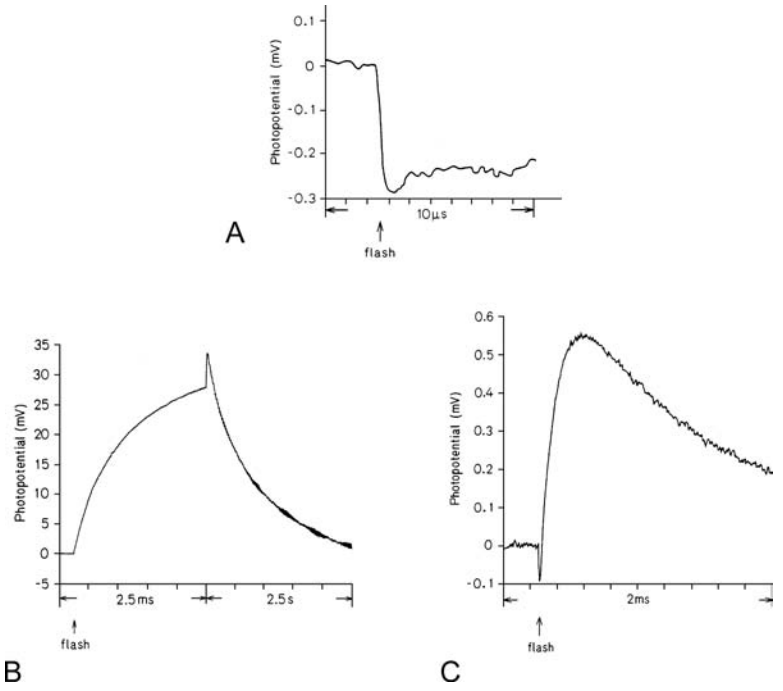

FIGURE 128.7 Effect of shunting on ERP. Rhodopsin was reconstituted into a Collodion membrane. Photosignals were elicited with 15 ns laser pulse at 530 nm (A and B), or at 500 nm (C). Records A and B show ERP at three different time scales. Fast negative Phase I (seen in Record A) corresponds to R1. Slow positive Phases II and III (seen in Record B) correspond to R2. Resistance of Collodion membrane was 50 MΩ-cm^2 in Records A and B but was shunted with external resistance of 2 kΩ-cm^2 in Record C. Experimental conditions in Record C were otherwise identical to those in Records A and B. Amplitude ratio R1/R2 of two components was 0.014 before shunting but became 0.16 after shunting. (From Drachev, L.A., Kalamkarov, G.R., Kaulen, A.D., Ostrovsky, M.A., and Skulachev, V.P., *Eur. J. Biochem.*, 117, 471, 1981. With permission.)

analysis. As far as photocurrent generation is concerned, R_e and R_m are placed in parallel and compete for the passage of photocurrents. It is the neglect of this access impedance that caused almost all of the confusion in the literature of photoelectric effects.

In standard electrophysiological measurements, two conditions are usually considered: voltage-clamp (short-circuit) or current-clamp (open-circuit) conditions. In the case of short-circuit measurements, R_e is much smaller than the combined impedance of R_m and C_m, the photogenerated electric current preferentially goes through R_e, and the R_mC_m circuit drops out of the picture and can be ignored. As expected, the photovoltage is zero or is held at a fixed (clamped) value (dictated by the voltage-clamping amplifier), and what is being measured is the photocurrent. If a brief light pulse is so short as to be effectively a mathematical delta function, an initial surge of photocurrent appears [left panel of Figure 128.8(B)]. The initial spike is then followed by an almost immediate reversal of polarity; the reversed photocurrent then relaxes with a characteristic exponential time constant, τ_p:

$$\frac{1}{\tau_p} = \frac{1}{R_pC_p} + \frac{1}{R_sC_p} \tag{128.2}$$

Because R_s is infinite for a visual membrane, and R_s is much larger than R_p for a bacteriorhodopsin membrane, the value of τ_p becomes approximately $1/R_pC_p$: the intrinsic photoelectric relaxation time constant.

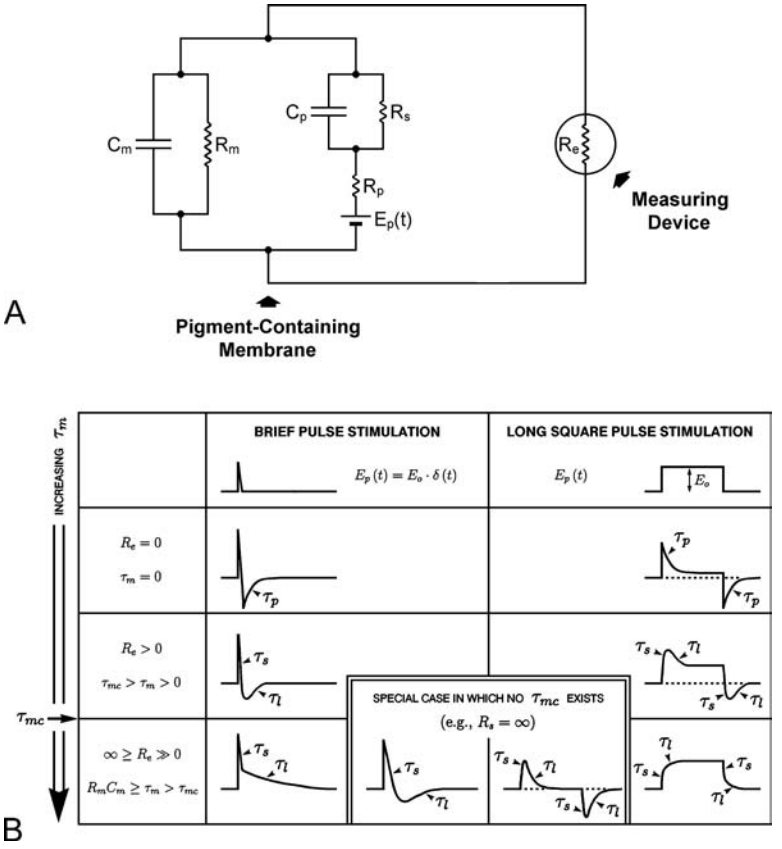

FIGURE 128.8 Universal equivalent circuit for the photoelectric effect, and its predicted responses to two different regimes of illumination. (A) In the equivalent circuit, a photochemical event is represented by an RC network including photoemf $E_p(t)$, internal resistance R_p of $E_p(t)$, chemical capacitance C_p, and transmembrane resistance R_s. With the exception of strictly short-circuit measurements, the time course of the photoelectric signal is further shaped via interaction with another RC network, formed by membrane resistance R_m, membrane capacitance C_m, and access resistance R_e. See text for further explanation. (B) Photosignal relaxation time courses are calculated in accordance with equivalent circuit. Two different regimes of illumination are considered: a brief δ-function-like light pulse and a long square-wave light pulse. Note that the relaxation time course varies with a change of the discharging time constant, τ_m, as defined by Equation 128.4. Under open-circuit conditions (i.e., $R_e = \infty$), the photosignal relaxes with two exponential time constants, τ_s and τ_l, of which the longer one, τ_l, approaches the membrane RC relaxation time constant, R_mC_m. Under short-circuit or near-short-circuit conditions, a photosignal in response to a long square-wave light pulse exhibits "on" spike and "off" spike, as expected in a linear high-pass RC filter. This characteristic waveform may disappear, if τ_m exceeds a critical value, τ_{mc}. (From Hong, F.T., in *Bioelectrochemistry: Ions, Surfaces, Membranes*, Blank, M., Ed., American Chemical Society, Washington, DC, 1980. With permission.)

In the case of open-circuit measurements, R_e is much larger than the combined impedance of R_m and C_m. Therefore, the photocurrent goes almost exclusively to R_mC_m to charge the membrane voltage; only a minute current goes through R_e, just enough to make the photovoltage measurable. The measured photovoltage thus rises abruptly but decays with two time constants: τ_s and τ_l (see References 47 and 55 for a detailed analysis). The longer time constant, τ_l, is nothing but the RC relaxation time constant of the inert structure: $1/R_mC_m$. In a record that captures the long time constant τ_l, the shorter time constant, τ_s, is usually too fast to be detected.

A third condition of measurements can be found when the source impedance of the membrane matches the value of R_e so that neither an open-circuit nor a short-circuit condition is met. The photocurrent thus splits into two branches: one goes to charge the membrane RC network, and the other goes to the

measuring device R_e. The measured quantity could be either the photocurrent or the photovoltage, depending on the configuration of the measuring equipment (the photovoltage is the product of the photocurrent and the access impedance, in accordance with Ohm's law). Again, the photocurrent, $I(t)$, rises abruptly but usually relaxes in two exponential terms:

$$I(t) = \frac{\frac{1}{\tau_s} - \frac{1}{R_s C_p}}{R_e C_m \left(\frac{1}{\tau_s} - \frac{1}{\tau_l}\right)} \int_0^t \frac{E_p(u)}{R_p} \exp\left(\frac{u-t}{\tau_s}\right) du \quad - \quad \frac{\frac{1}{\tau_l} - \frac{1}{R_s C_p}}{R_e C_m \left(\frac{1}{\tau_s} - \frac{1}{\tau_l}\right)} \int_0^t \frac{E_p(u)}{R_p} \exp\left(\frac{u-t}{\tau_l}\right) du \quad (128.3)$$

where $E_p(t)$ is the photo emf representing the photocurrent generator, and τ_m, τ_s, and τ_l are defined by the following equations:

$$\frac{1}{\tau_m} = \frac{1}{R_e C_m} + \frac{1}{R_m C_m} \quad (128.4)$$

$$\frac{1}{\tau_s} = \frac{1}{2}\left[\left(\frac{1}{R_p C_m} + \frac{1}{\tau_p} + \frac{1}{\tau_m}\right) + \sqrt{\left(\frac{1}{R_p C_m} + \frac{1}{\tau_p} + \frac{1}{\tau_m}\right)^2 - 4\left(\frac{1}{R_p C_m R_s C_p} + \frac{1}{\tau_p \tau_m}\right)}\right] \quad (128.5)$$

$$\frac{1}{\tau_l} = \frac{1}{2}\left[\left(\frac{1}{R_p C_m} + \frac{1}{\tau_p} + \frac{1}{\tau_m}\right) - \sqrt{\left(\frac{1}{R_p C_m} + \frac{1}{\tau_p} + \frac{1}{\tau_m}\right)^2 - 4\left(\frac{1}{R_p C_m R_s C_p} + \frac{1}{\tau_p \tau_m}\right)}\right] \quad (128.6)$$

The relaxation time constants, τ_s and τ_l, are neither τ_p nor τ_m but are a mixture of various RC constants. This third condition of measurement — collectively, it covers all measurement conditions that are neither strictly short-circuit nor open-circuit — is by no means fictitious. It could arise unwittingly in many photoelectric measurements. The awareness of its existence usually came as hindsight. Some earlier photocurrent measurements were performed with a picoammeter with an input impedance of about 100 kΩ, which is adequate to measure DC currents or low-frequency AC currents.[44] But, it becomes problematic in high-frequency measurements. The presence of a novel capacitance C_p that is connected in series with the photovoltage source E_p diminishes the source impedance of the membrane to about 20 kΩ. Thus, a current amplifier designed for low-frequency or DC measurements could not meet the condition of low-input impedance (as compared to the source impedance). Under this circumstance, although the measured signal was expressed in the unit of electric current, the measurement condition was actually closer to open circuit than short circuit. Thus, the variations of relaxation kinetics and the discrepancies between different laboratories can be accounted for by the variation of this hidden parameter — the access impedance. However, despite the variation of apparent relaxation time courses, the fundamental parameter τ_p can be recovered by deconvolution and remains unchanged: measurements made at two different access impedances gave rise to essentially the same value of τ_p, although two significantly different time courses of B1 were recorded.[57]

So far, we considered only the time course of photoresponses to a brief delta-function-like light pulse. The equivalent circuit also predicts the time course of photoresponses when the membrane is illuminated with a long square-wave light pulse, such as that shown in Figure 128.2(A) and Figure 128.2(B). In fact, it explains why a monotonic waveform of Figure 128.2(A) can be converted to a waveform with sharp spikes at the onset and the cessation of illumination, when shunting reduces the relaxation time constant τ_m to below a critical value τ_{mc} [right panel of Figure 128.8(B)]. The equivalent circuit predicts a pair of symmetric spikes. Upon closer examination of Figure 128.2(B), a slight asymmetric pattern of the two spikes is revealed. An explanation of this asymmetry is deferred to Chapter 134.

Now, we will explain why R2 exhibits no apparent pH dependence. Because the relaxation of an open-circuit photovoltage reflects mainly the membrane RC relaxation as explained above, it is, therefore, a poor indicator of the intrinsic photokinetic relaxation. Because most previous measurements of fast photoelectric signals were carried out under open-circuit conditions, the apparent lack of pH dependence is thus more expected than surprising.[59] Photoelectric measurements under open-circuit conditions pick up two relaxation time constants: τ_s reflects a distorted intrinsic relaxation, whereas τ_l reflects mainly the RC relaxation of the inert supporting lipid bilayer. Because τ_s and τ_l often differ by as many as six orders of magnitude (cf. Table 1 of Okajima and Hong[57]), they usually do not show up concurrently in the same (single) measurement record. Liu and Ebrey[60] indicated that photovoltages are good for the study of very fast kinetics, because photovoltage measurements are less sensitive to ionic strength and amplifier impedance. Ironically, the perceived merit is actually weakness of the method. The insensitivity to ionic strength is a consequence of the relaxation's tracking of the irrelevant RC relaxation of the supporting bilayer instead of the relevant photochemical relaxation. In fact, while open-circuit measurements failed to detect any ionic strength effect,[38] a near-short-circuit measurement showed demonstrable ionic strength effect.[57] Regarding the sensitivity to amplifier impedance that makes up a major contribution to the access impedance, it is easier to achieve rigorous open-circuit conditions than short-circuit conditions. For example, Hong and Mauzerall measured the fast photosignal of a magnesium-porphyrin BLM at an access impedance of 380 Ω, but the short-circuit condition is still not met rigorously (see Figure 3 of Hong and Mauzerall[61]). That the latter measurement condition was not exactly short-circuit can be seen from the apparent relaxation time course: the photocurrent did not reverse its polarity upon the cessation of the laser pulse, as dictated by the analysis shown in Figure 128.8(B) (the laser pulse ended at around 0.7 μs, but the photocurrent had not reversed its polarity 3 μs after the onset of the laser pulse or 2.3 μs after the cessation of light stimulation.) The sensitivity of short-circuit measurements to the access impedance (which includes the amplifier impedance) is an asset rather than a nuisance, because the access impedance can be tuned to match the source impedance so that the relaxation time course can be deconvoluted more reliably to yield intrinsic kinetics, as we routinely did. Therefore, we called this approach tunable voltage clamp method.[61] It is very difficult, if not impossible, to recover intrinsic kinetic information by deconvoluting an open-circuit photovoltage, mainly because of the low information content regarding intrinsic photochemical processes.

The reciprocal change of amplitude of the B1 and B2 components, as the aqueous pH approaches 2 and below, as shown in Figure 128.5(B), is no coincident but is actually an illusion. This point can be made clear by examining a schematic diagram shown in Figure 128.9. Because of the partial overlap of the decay of B1 and the rise of B2, and because they have opposite polarities, the coexistence of B2 partially cancels the amplitude of B1. Thus, inhibition of B2 leads to an apparent increase of the B1 amplitude. That this is not merely a speculation can be seen in the pH dependence of isolated B1, as compared to that of a composite signal (B1 + B2). Figure 128.10(A) shows reciprocal changes of peak amplitudes of a composite signal when the aqueous pH was varied. Unlike Figure 128.5(B), the composite signal exhibits significant pH sensitivity over a wide pH range, where bacteriorhodopsin remains stable. In contrast, an isolated B1 record shows no trace of pH dependence over the same range [Figure 128.10(B)]. I suspected that the reciprocal changes of the amplitude of the two ERP components could be similarly explained [Figure 128.5(A)]. Actually, a similar reciprocal change of R1 and R2 peaks, as temperature is lowered, was observed by Pak and Cone[12] [Figure 128.1(C) through Figure 128.1(E)]. They correctly attributed the temperature effect to R2 alone. Again, a similar reciprocal change of amplitudes appears in the ERP-like signals from bacteriorhodopsin, as temperature is lowered[62] [Figure 128.10(C)]. However, as shown in Figure 128.10(D), an isolated B1 exhibits almost no temperature dependence. A closer examination reveals that there is a small temperature effect on B1. The small changes shown in Figure 128.10(D) between 5 to 45°C are real and reproducible. The temperature dependence of $1/\tau_p$ on $1/T$ (where T is the absolute temperature) obeys the Arrhenius relationship.[57] Whether similar temperature dependence exists in R1 or not remains a speculation. It is important to realize that such a small temperature dependence could not have been detected at the time when ERP was being actively investigated because of technical difficulties encountered in an *in vivo* measurement

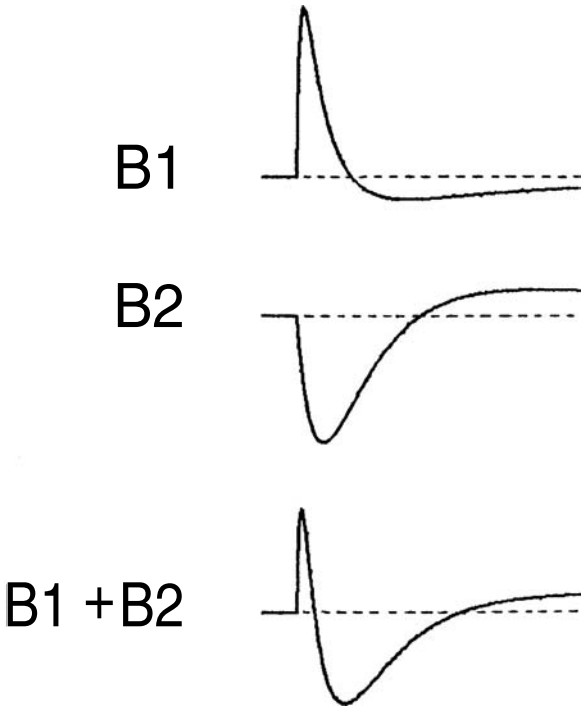

FIGURE 128.9 The decomposition of an ERP-like signal in a reconstituted bacteriorhodopsin membrane, according to equivalent circuit analysis. Each component decays with two exponential time constants, and each satisfies zero time-integral condition Equation 128.1. Note the partial overlapping of the decay of B1 and the rise of B2. (From Okajima, T. and Hong, F.T., *Biophys. J.*, 50, 901, 1986. With permission.)

and because of insufficient signal-to-noise ratio. The recent development of an expression system by Sullivan and Shukla[42,43] offered a hope of seeing such a subtle change. Of course, a prerequisite is the development of a technique to isolate the pure R1 component.

In isolating B1, we used a drastic procedure: multiple oriented bacteriorhodopsin layers were first deposited on a Teflon film, and the preparation was allowed to dry for four days.[63] Such a drastic procedure is almost certainly going to denature rhodopsin. Alternatively, we used chemical modification to suppress B2, but the suppression was not complete because of the limitation of our choice of chemical reagent fluorescamine, which hydrolyzes rapidly.[64] We were able to suppress the B2 component completely within the pH range from 6 to 9 by means of site-directed mutagenesis.[65] Thus, the rhodopsin expression system used by Sullivan and Shukla remains the most promising approach. Still, I must caution here that the conventional approach of curve-fitting the measured signal with multiple exponential relaxation terms almost certainly will not work. The reason will be presented in the next section.

128.5 A Critique on the Multiexponential Analysis

In the literature of photoelectric effects, investigators often used computer-assisted curve-fitting procedure to decompose a transient photoelectric signal into multiple components of exponential decays.[66–68] Each component is then associated with a known spectral transition in the photocycle. Mainstream investigators gradually realized the distortion effect of the membrane RC relaxation process and have begun to acknowledge the presence of the pure membrane RC time constant among the time constants determined by exponential analysis.[60,69–71] But the extent of distortion has not been fully appreciated — just about every time constant is affected.

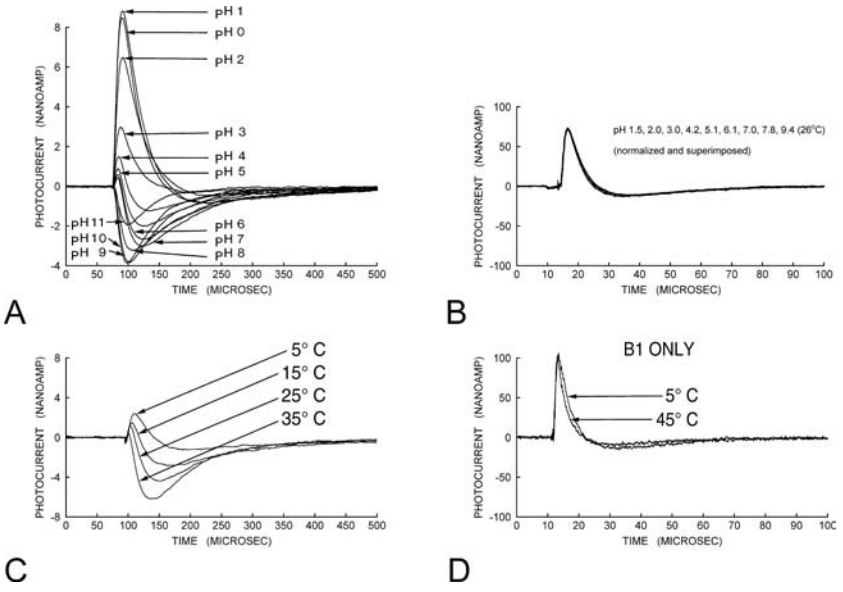

FIGURE 128.10 Effect of pH and temperature on B1 and B2. (A) The data illustrate effects of varying pH on a composite signal consisting of B1 and B2, at 25°C. (B) The data illustrate the total lack of pH dependence of an isolated B1 signal. (C) The data show the temperature dependence of the composite signal (B1 and B2) at neutral pH. (D) The data show a small temperature dependence of an isolated B1 signal. The temperature effect is reversible. For detailed experimental conditions, consult the cited sources. Although associating each exponential term with a photochemical relaxation process appears to be an innocuous and acceptable practice in solution-phase photochemistry, it is fundamentally flawed to apply the same approach to heterogeneous reactions involving a membrane phase and two aqueous phases for the following reason. A signal component in the form of a single exponential decay obviously cannot possibly satisfy the zero-time integral condition. This can be made clear by examining Figure 128.11, which was constructed to illustrate the generation of a capacitative signal by a single step of charge shift inside the membrane.[72] The charge shift during the transition from state E_i to state E_{i+1} is shown to be represented by an impulsive rise of the photocurrent that decays with a characteristic time constant τ_i. Time integration of the photocurrent thus yields the amount of charges that shifts in the direction perpendicular to the membrane surface as a function of time. It is apparent that the result shows that the charges separated during this transition never recombine [Figure 128.11(C)]. The latter conclusion directly contradicts the notion of capacitative current, because integration of the area under the curve gives rise to a nonzero value, thus violating Equation 128.1. In other words, a capacitative current cannot possibly be represented by a single exponential term without leading to a self-contradiction. In contrast, the waveforms as described in Figure 128.8(B) satisfy the zero time-integral condition.

Common sense in electronics engineering leads to a second objection. The membrane that is capable of generating an ERP-like capacitative current resembles an electronic device in which the current (or voltage) generator is embedded in a thin-film matrix. It is, therefore, inconceivable that the photosignal relaxation can be analyzed and interpreted without, at the same time, considering the interaction between the active current generator and the passive RC network. Here, the RC network is formed by the inert supporting substrate — the phospholipid bilayer membrane. Hagins and Rüppel[8] and Govardovskii[73] once proposed equivalent circuit models (cable models with RC networks) for an intact rod cell and attempted to account for the waveform of ERP. Hochstrate et al.[74] recognized the shaping effect of the

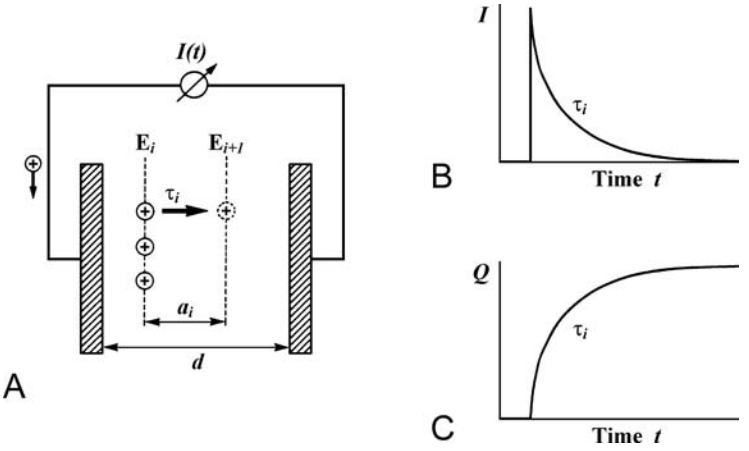

FIGURE 128.11 Principle of capacitative coupling, according to the mainstream approach. (A) Membrane is represented by dielectric layer, which is interposed between two plates of parallel-plate capacitor. Under short-circuit conditions, flash excitation creates an initial unstable state E_i, which relaxes to a stable product state E_{i+1} with the time constant τ_i. (B) The process leads to measurable transient photocurrent I, which decays to zero with same time constant as that of transition $E_i \rightarrow E_{i+1}$. C. Time-integration of the photocurrent generates a curve that represents accumulation of separated charges Q as a function of time. According to this interpretation, capacitance is charged with a rising exponential time course to steady level but is never discharged. Thus, charges are separated but never recombined — a description contradicting the notion of capacitative coupling. (From Läuger, P., *Electrogenic Ion Pumps*, Sinauer Associates, Inc., Sunderland, MA, 1991. With permission.)

RC property of the photoreceptor membrane and proposed a two-capacitor model to account for the ERP waveform. However, they associated the second (series) capacitor with the capacitor of the nonpigmented portion of plasma membrane. As we shall see, this second capacitor exists. It even persists in reconstituted systems, where the distorting effect of nonpigmented plasma membrane is absent, and it can be identified as the chemical capacitance in Figure 128.8(A). The effect of the RC network formed by the photoreceptor membrane (essentially a linear RC filter) on the time course of the observed ERP was also recognized by Brindley and Gardner-Medwin,[75] but was apparently ignored or neglected by most investigators working on the ERP-like signal elicited in reconstituted bacteriorhodopsin membranes.

It is of interest to note that Hodgkin and O'Bryan[13] proposed the following equation to describe the waveform of R1 and R2, measured intracellularly in a turtle cone receptor:

$$j(t) = -NK\delta_o(t) + BNKa_3 \exp(-a_3 t) \tag{128.7}$$

where $\delta_o(t)$ is the unit impulse (δ-function at $t = 0$), B, K, and a_3 are constants, N is the number of excited molecules, and $j(t)$ is the outward current representing the ERP (called early receptor current). Had the parameter B been set to unity, the waveform defined by Equation 128.7 would have satisfied the zero time-integral condition (Equation 128.1).

A lingering question is if multiexponential analysis cannot guarantee a meaningful model, why did most of these models fit the data reasonably well? The answer lies in what it takes to accomplish curve fitting. It is a well-known mathematical fact that any curve can be fit, to any degree of accuracy, with a polynomial function, as long as there is no limit as to how many terms can be used (Weirstrass' theorem). Of course, polynomials are not the only class of function serving this purpose. In effect, just like any three-dimensional vector can be expressed in terms of a linear combination of three orthogonal basis vectors (coordinates), any curve can be expressed with a linear combination of infinitely many orthogonal functions, of which the orthogonal set of polynomials is but one. Deconvolution of a curve in terms of an infinite series of polynomials, of course, makes little physical sense in chemical relaxation; deconvolution in exponential terms makes more sense. The process is tantamount to a Laplace transform, which

converts a function in the time domain into another function in the frequency domain. A peak in the latter curve in the frequency domain represents a discrete exponential decay. As long as there is no noise, the process appears to be innocuous. In the presence of noise, spurious peaks are not uncommon. This is the reason why detailed curve fitting often yields conformational substates,[66] which may or may not be physically meaningful depending on independent corroboration from data obtained by means of a drastically different way — independent corroboration from different laboratories using the same approach is often insufficient. Previously, Gauch[76] presented an illuminating analysis concerning fitting experimental data to a mathematical model. He pointed out that there is a balance between the accuracy and the parsimony of mathematical models. Over-fitting data to a model with an ever-increasing number of parameters can result in fitting the model more to noise than to real data — a well-known fact in systems analysis theory. Therefore, data imposes no constraint on multiexponential analysis. The agreement with data is no proof of the validity of a particular model under consideration. If associating each exponential decay with a chemical relaxation process seems the only possibility, multiexponential analysis will be admissible. This is the reason why applying multiexponential analysis to solution-phase photochemical relaxation never led to any difficulty in interpretation. In the case of heterogeneous photochemical relaxation in a three-phase system, alternative interpretations must be sought for and eliminated before one jumps to the conclusion of proving the model. A detailed discussion of the validity of curve-fitting or model-fitting was published elsewhere.[55,77]

In contrast, in the above-described equivalent circuit analysis, we first separated the individual components by physical means, using various reconstitution methods. Contrary to common impressions, our data of isolated components was subjected to multiexponential analysis to obtain the time constants, such as τ_s and τ_l. These deconvoluted data are then tested with the equivalent circuit. The equivalent circuit imposes a constraint that the investigator cannot manipulate or overcome by "massaging" the data. Equation 128.3 can be simplified by using a brief light pulse so that $E_p(t) = E_0 \cdot \delta(t)$, where $\delta(t)$ is the mathematical delta function:

$$I(t) = A_s \cdot \exp\left(-\frac{t}{\tau_s}\right) - A_l \cdot \exp\left(-\frac{t}{\tau_l}\right) \tag{128.8}$$

where the preexponential factors (amplitudes) satisfy the following relation:

$$\frac{A_s}{A_l} = \frac{\tau_l}{\tau_s} \tag{128.9}$$

For a pure, isolated photoelectric current component, Equation 128.9 must be satisfied. Taken together, Equation 128.8 and Equation 128.9 satisfy the zero time-integral condition (Equation 128.1). It is, therefore, not surprising that the definition of capacitative current provides the crucial constraint. It is also not surprising that the conventional multiexponential analysis is so misleading in membrane-phase photochemistry; capacitative events are a major feature of interfacial photochemistry.

128.6 Molecular Interpretation of Fast Photoelectric Signals

There is little doubt that fast photoelectric signals are electrical manifestation of light-induced charge separation and recombination. For a macromolecule with a multistep reaction sequence as complex as rhodopsin or bacteriorhodopsin, there are many candidates for generating a fast photoelectric signal component. In principle, each step of reversible reaction can contribute a component. Fast photokinetic measurements have a tendency to pick up faster processes. We identified three fast components in reconstituted bacteriorhodopsin membranes: B1, B2, and a B2-like signal, which we called B2′ component. Like B2, the B2′ component is generated by interfacial proton transfer — the proton release and reuptake at the extracellular surface.[62] This does not mean that slower components do not exist. In fact,

other investigators identified many slower components. The problem is that all of these data were subjected to multiexponential analysis alone. It is difficult to make sensible comments other than point out the inadequacy of multiexponential analysis.

The fast rise time of the R1 component of ERP and the corresponding B1 component of its bacteriorhodopsin analog suggest that they are associated with early events in the photobleaching sequence of rhodopsin and the photocycle of bacteriorhodopsin, respectively. Trissl[78] measured the rise time of the R1 component to be about 0.8 μs at 0°C and 1.6 μs at 37°C in an intact cat photoreceptor. The corresponding value of isolated outer segments attached to Millipore filters was 90 ns. Trissl concluded that the R1 component might be associated with an early charge separation as fast as the *cis-trans* isomerization of the retinal chromophore. Using an ultrafast measurement method, Groma and coworkers[41] found the rise time of ERP-like signals from bacteriorhodopsin membranes to be between 2.5 to 5 ps for the forward charge separation (ground-state bacteriorhodopsin to K transition) and 3.5 ps for the charge separation driven by reverse phototransition (K to bacteriorhodopsin). Liu et al.[79] showed that bacteriorhodopsin reconstituted with a modified all-*trans* retinal that cannot isomerize to 13-*cis* retinal does not have this component. Therefore, B1, and perhaps also R1, are mostly likely to be associated with the earliest photolytic event of photoisomerization of the chromophore. By analyzing the temperature dependence of the first-order relaxation time constant of τ_p of the B1 component, Okajima and Hong[57] determined the value of τ_p to be 12.3 ± 0.7 μs and the activation energy to be 2.54 ± 0.24 kcal/mol. These values are not affected by overnight exchange of H_2O/D_2O, a change of ionic strength by replacing 0.1 M of KCl with 3 M of KCl. Note that the latter was not a measurement of rise time but rather the time constant of charge recombination following the initial rise. However, there is no known activation energy among the photocycle intermediates that matches the value of activation energy. Therefore, its molecular interpretation remains unclear.

In our equivalent circuit analysis, the B2 component was found to have the following properties. It is sensitive to pH[57] and to ionic strength[62] of the bathing solutions. Its relaxation kinetics are reversibly slowed by overnight exchange of H_2O/D_2O.[57] It is almost abolished by a water-soluble chemical label, fluorescamine, which specifically attacks primary amine of exposed amino acid residues.[64] This latter finding supports the interpretation that B2 reflects light-induced interfacial proton uptake because fluorescamine quickly hydrolyzes in water and is, therefore, incapable of attacking amino acids buried inside the membrane. It was further found that the B2 component changes polarity at pH 2.7.[80] Below pH 2.7, B2 was found to be sensitive to Cl^- concentration, whereas it was found to be sensitive to Ca^{2+} and Mg^{2+} concentrations above pH 2.7.[81] The R2 component is most likely associated with the light-induced proton uptake of the metarhodopsin-I-to-metarhodopsin-II transition of the photobleaching sequence. No further detailed interpretation could be made on the basis of the existing ERP literature.

More recently, Kaulen[82] attempted to integrate photoelectric data with newly obtained structural information of bacteriorhodopsin. He noted that discrepancies of reported photoelectric measurements exist not only between model membranes constructed by drastically different methods but also in membranes constructed with "analogous" methods. Attempts to seek explanations in terms of different reconstitution methods seem misdirected. The true culprit is probably the exact condition of measurements. However, by continuing to ignore the presence of chemical capacitance, one tends to overlook the resulting reduction of the source impedance at microsecond and submicrosecond time ranges, and the most crucial parameter — access impedance — remains missing in data reporting. Differentiating valid conclusions from dubious ones, based on correlation of photoelectric data with structural data, remains a daunting task for readers.

128.7 Discussion and Conclusions

Most vision researchers treat ERP as an epiphenomenon. Two reasons have often been singled out to discredit the possible physiological importance of ERP: the amplitude of ERP is too small, and the ERP-like signals are ubiquitous. Shortly after the discovery of ERP, similar fast photoelectric signals were found in many different pigment-containing tissues, such as pigmented epithelia of the eyes and chloroplasts.

ERP-like signals were also found in BLM reconstituted with various kinds of pigments or organic dyes, provided that some inherent asymmetry (i.e., a membrane containing a pigment with a fixed orientation or facing two asymmetric aqueous solutions) exists. The ubiquity suggests that ERP is nothing unique for vision and perhaps serves no physiological function. But the reasoning was flawed. In hindsight, the ubiquity is understandable. Most dyes or pigments respond to light stimulation by ejecting electrons, and reverse reactions are common in chemical reactions. Thus, dye or pigment membranes that have some inherent asymmetry always respond to light with a fast photoelectric signal. In hindsight, the fast photoelectric effect is biologically relevant, because the primary event in vision and in photosynthesis is light-induced charge separation. However, these signals cannot be expected to always be functionally significant. Just because stick-like structures are ubiquitous does not mean some cannot be used to write, to point, or to be used as a weapon. Likewise, the ubiquity of ERP-like signals alone does not rule out a possible physiological function. A dismissal of ERP as an epiphenomenon may be premature. In fact, it may remain forever premature until proved otherwise, because absence of evidence is not evidence of absence.

Next, a dismissal of ERP's possible physiological role based on its small amplitude may be misleading. This is because ERP may not be small at the vicinity of the (cytoplasmic) membrane surface, where action is. Physiologists often discussed bioelectric phenomena in terms of transmembrane potentials, but what really matters at the molecular level is the local electric field. In other words, what really matters is the potential gradient across the membrane rather than the transmembrane potential and, in the case of interfacial phenomena, the potential gradient in the diffuse double-layer region: $E = -dV(x)/dx$, where x is the coordinate in the direction perpendicular to the membrane, and $V(x)$ is the electric potential profile. Surface potentials are rather short-ranged in action. Because of charge screening, the potential profile at the vicinity of the membrane surface is steep. This is because the fixed charges on the membrane surface are completed neutralized by the net counterions in the double-layer regions (strictly speaking, it takes counterions of both double layers on opposite sides of the membrane to neutralize the fixed charges on a single surface).[83] As a result, the local electric field fades exponentially, as the distance from the membrane increases, instead of the more gradual fashion prescribed by the inverse-square law. A surface potential is small if viewed from outside of the double-layer regions, but it is locally intense, because the surface potential must drop to zero over a distance that is of the same order as the Debye length. Therefore, the slope of the potential profile must be steep, and the force must be locally intense. Years ago, Hong speculated about the possible appearance and disappearance of a large surface potential accompanying the appearance and disappearance of R2.[53] Hong cited an actual example of a reconstituted membrane that exhibited an open-circuit photovoltage of 1.4 mV, but the calculated surface potential amounted to 50 mV. If a surface potential of this modest amplitude presides over a double layer of a Debye length of the order of 5 Å (a deliberate underestimate), it would give rise to a local electric field comparable to that generated by a transmembrane potential of 600 mV inside the membrane. This speculated surface potential and the associated intense electric field were subsequently observed by Cafiso and Hubbell,[84,85] using a spin-label to probe the local electric field. Thus, the intensity of the local electric field near the membrane surface cannot be judged by the size of the corresponding potential measured externally. The highly localized nature of electric field generated by ERP may just be what is needed for an effective trigger.

Just imagine the requirement of a mechanistic trigger of visual phototransduction. Because a trigger is an event prior to the biochemical amplification process, it must be linear and localized near the site of illuminated rhodopsin. The R2 component fulfills this requirement. It is linear in view of the equivalent circuit presented in this article. Its local nature was demonstrated by Hagins and McGaughy.[19] As mentioned earlier, Ostrovsky and coworkers demonstrated that the proton uptake takes place at the cytoplasmic surface. Furthermore, the polarity of the R2 signal is consistent with a proton binding at the cytoplasmic side.[86] Thus, the surface potential associated with R2 appears at the right place at the right time to trigger binding of transducin to metarhodopsin II. Based on these considerations, Hong[87] proposed a surface potential-based mechanism for triggering the cyclic GMP cascade. The plausibility of a mechanistic switch based on light-induced surface potential was demonstrated by Drain et al.[88] (cited

TABLE 128.1 A Hypothetical ERP-Based Electrostatic Trigger Mechanism

1. The cyclic GMP cascade takes place at the cytoplasmic surface.
2. Binding of transducin to metarhodopsin II leads to its activation.
3. The formation of metarhodopsin II involves the net uptake of a proton at the cytoplasmic side.
4. The rise phase of the ERP R2 component is time-correlated with the formation of metarhodopsin II.
5. The polarity of the R2 component is consistent with the proton uptake at the cytoplasmic surface.
6. The photophosphorylation of rhodopsin at its cytoplasmic surface occurs during the deactivation of visual transduction.
7. The above events are associated with a surface-potential change at the cytoplasmic surface.

Source: From Hong, F.T., *J. Mol. Electron.*, 5, 163, 1989. With permission.

in Figure 32.4 of Hong[89]). Their experimental model membrane shows that a light-induced surface potential can operate like a phototransistor (or light-activated field effect transistor). Thus, the positive surface potential associated with R2 may be the mechanistic "on" trigger of visual phototransduction. By the same line of reasoning, the mechanistic "off" trigger for the termination of the cyclic GMP cascade may be provided by the negative surface potential generated by subsequent photophosphorylation of up to nine amino acid residues at rhodopsin's cytoplasmic domain.[90] The lines of circumstantial evidence suggesting a surface potential-based trigger for the initiation and termination of visual transduction is listed in Table 128.1.

Here, we restrict our consideration to electrostatic interactions. As we shall see in Chapter 134, the real-life situation is, of course, more complex. In addition to electrostatic interactions, other noncovalent bond interactions must be taken into account. But the possible role of ERP should not been overlooked. Investigators familiar with the biochemistry of visual transduction and electrophysiology may argue that ERP plays no such role, because most, if not all, of the biochemical experiments regarding the cyclic GMP cascade were performed in the solution phase, where no membrane potential can be sustained. However, one should not overlook an important difference between ERP and other well-known bioelectric phenomena. While diffusion potentials vanish instantly upon the rupture of a membrane, surface potentials, being localized, persist even in a broken membrane. In fact, the equivalent circuit shown in Figure 128.4 was derived mathematically under a short-circuit condition, which is fulfilled by a broken membrane (see Appendix of Hong[53] or Section 8 of Hong[55] for a rigorous derivation). Cafiso and Hubbell[84,85] once used spin-label to monitor interfacial potentials of vesicles made of rod disk membranes. The same methodology can be used for broken membranes. Therefore, the case remains open until more convincing evidence appears, one way or the other. It is, therefore, of interest to see how a possible role of ERP measures up in light of the current understanding of the biochemical mechanism of visual phototransduction. This topic will be treated in Chapter 134.

As for the role of ERP-like photosignals in bacteriorhodopsin membranes, we can only speculate here. From a bioenergetic point of view, signals such as B2 and B2′ represent processes that are counterproductive; charge recombination has the same effect as internal short-circuiting of a battery. In view of the universal presence of reverse reactions, ERP-like signals cannot be eliminated. However, their presence does not prevent a net light-induced transfer of proton across the bacteriorhodpsin membrane. Although the presence of a reverse reaction implies that the reaction stops upon reaching chemical equilibrium, a light-pumped system, such as the purple membrane, never reaches equilibrium but reaches a steady state; the continuing input of photon energy ensures that the net proton pumping goes forward in spite of reverse reactions. Still, nature strove to minimize the reverse reaction, and nature's strategy is a sophisticated scheme of optimization. We shall also consider how nature enhances solar energy conversion by means of noncovalent bond interactions of photosynthetic components.

Finally, a comment regarding photoelectric effects is in order. The study of ERP and ERP-like photosignals offers a proving ground with which to try various approaches of interpreting the measured photosignals. In this chapter, the peril of extrapolating and transplanting methodology established in the solution phase to a heterogeneous three-phase system as well as the peril of applying methodology established in classical electrophysiology to systems in which light plays a crucial role were pointed out. For over a quarter century, investigators could not reach a consensus regarding the interpretation of

measured photosignals. The dispute eventually subsided, and some investigators viewed both approaches — the multiexponential analysis and the analysis based on the concept of chemical capacitance — as complementary to each other. But a detailed comparison reveals that the two approaches are fundamentally incompatible. Although the present approach requires a more complicated equivalent circuit model than the conventional multiexponential approach, it is more general than the latter. Here, only a single equivalent circuit model is used to explain virtually all electric phenomena arising from light-induced charge separation in membranes. In contrast, an ad hoc model must be concocted for each experimental system in the alternative approach. The latter approach also lacks a predictive power and often leads to conflicting interpretations from different laboratories. In the light of increasing interest in possible technological applications of the photoelectric effect of bacteriorhodopsin and other biopigments, the present approach seems to offer a distinct advantage as a design tool of molecular devices because of its predictive power.

129.1 Introduction

Light is energy and is an information source for plant growth and development. The absolute requirement of light is the key feature that distinguishes the plants from the animals. Phytochromes are the well-characterized plant proteins that perceive the light as an environmental signal to control growth and development. The phytochromes belonging to the principal family of red/far-red light signal-transducing photoreceptors undergo photochromic transformation between the inactive (Pr) and the active (Pfr) forms to mediate the growth and development of plants.[1,2] The red light-absorbing Pr form (λ_{max} 666 nm) and the far-red light-absorbing Pfr form (λ_{max} 730 nm) are manifested by the photoreversible isomerization of the linear tetrapyrrole 3E-phytochromobilin covalently attached to the cystein residue of polypeptides.[3–5] Light signals perceived by phytochromes are transmitted to the downstream, and they trigger gene expression and cellular modification for growth and developmental changes, such as germination, seedling establishment, development of photosynthetic machinery, suppression of shade avoidance, setting of flowering time, and development of reproductive structures.[6,7]

Phytochromes exist as dimers and are known to have two structural subdomains: a globular amino terminal chromophore binding domain (~65 kDa) and a structurally extended carboxy terminal domain (~60 kDa), which are connected by a flexible and protease-sensitive hinge region.[8–10] Each domain has unique functions. The *N*-terminal domain perceives light signals of red/far-red wavelength quality, intensity, duration, and direction. The *N*-terminal domain of phytochromes carries the light sensory motifs required for light signal transduction.[9] The *C*-terminal domain contains the dimerization and regulatory sites.[1] Although the molecular mechanism and biological function of dimerization are not well known, studies indicate that dimerization is crucial for phytochrome action in plants.[11,12] The regulatory sites in the *C*-terminal domain interact with the signal transducer proteins, such as the recently identified Phytochrome Interacting Factor 3 (PIF3),[13,14] Nucleoside Diphosphate Kinase 2 (NDPK2),[15] and Phytochrome Kinase Substrate 1 (PKS1).[16] Some other phytochrome-interacting proteins are being characterized by several laboratories. Several conserved motifs for regulatory roles were identified in the *C*-terminal domain, such as Ser/Thr kinase in the *C*-terminal end and Per-Arnt-Sim (PAS) motifs around

0-8493-1348-1/04/$0.00+$1.50

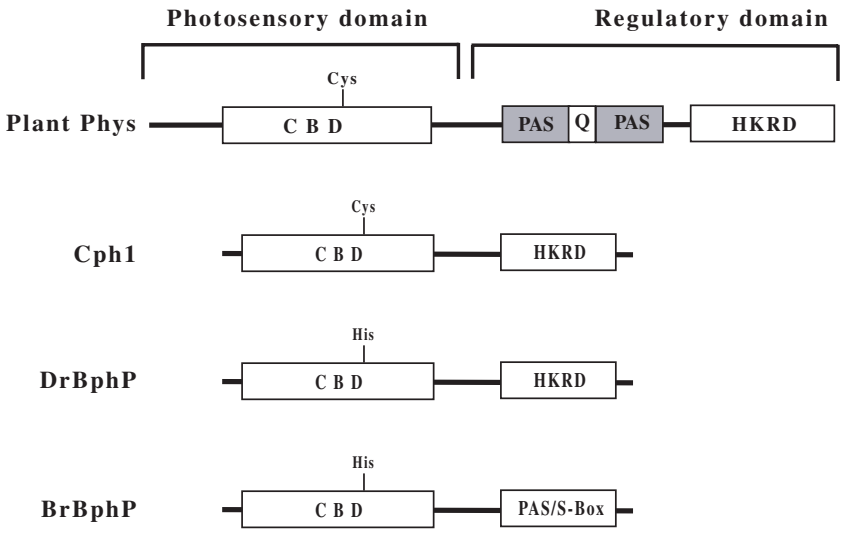

FIGURE 129.1 *Structural and functional motifs of the phytochromes*. Phytochromes have a two-domain structure: the photosensory *N*-terminal domain and the regulatory *C*-terminal domain. Structural and functional motifs of the plant phytochromes, the *Synechocystis* Cph1, and bacteriophytochromes from eubacterial DrBphP and photosynthetic bacterial BrBphP are compared, including the *N*-terminal chromophore-binding domain (CBD) and the *C*-terminal regulatory domain that are connected via the hinge region. The *C*-terminal regulatory domain includes the regulatory core region and the histidine-kinase-related domain (HKRD). The regulatory core region contains Quail box (Q) and two PAS repeat. The DrBphP and BrBphP phytochromes do not have the conserved cysteine residue in the chromophore-binding domain. The His-260, rather than the Cys residue, is the chromophore-binding site in the DrBphP.[19] BrBphP has a Per-Arnt-Sim (PAS) motif in the *C*-terminal domain. The regulatory core region of plant phytochromes, including two PAS motifs, undergoes detectable conformational changes in the phototransformation.

the regulatory core region. Recently identified prokaryotic phytochromes, the cyanobacterial Cph1,[17,18] eubacterial DrBphP,[19,20] and symbiotic bacterial BrBphP,[21] also share similar structural and functional organizations (Figure 129.1).

129.2 Conformational Changes and Surface Topography

The Pr to Pfr phototransformation induces specific changes in the secondary and tertiary structures of phytochromes, and its chromophore topography induces through photoisomerization and interdomain interactions.[22–27] The chromophore appears to move out of its hydrophobic pocket upon Pr to Pfr phototransformation. This chromophore movement is modulated by the helix-forming 6 kDa *N*-terminal peptide and triggers the conformational changes during phototransformation.[28,29] The helix-forming peptide causes a series of conformational changes by interacting directly with the chromophore and possibly with other structural motifs, especially the *C*-terminal motifs. The *N*-terminal domain is known to be more exposed in the Pr form than the Pfr form, and the connecting hinge region is preferentially exposed in the Pfr form.[10] Prokaryotic phytochromes such as Cph1 and DrBphP do not have these structural differences between the Pr and the Pfr forms, primarily because of sequence truncations.[30]

The surface topographies of Pr- and Pfr-phytochromes also exhibit differential exposures and microenvironments around the tryptophan residues. During the phototransformation, subtle conformational changes are detected in the region around Trp-569 and Trp-572.[31] These two tryptophans are located close to the Ser-598 that is preferentially phosphorylated in the Pfr form *in vivo*.[16] Two more tryptophans, Trp-773 and Trp-777, are also modified by HNB-Br preferentially in the Pfr form, indicating that the surroundings of these two Trp residues undergo significant changes and rearrangements of surface

topography during the phototransformation.[24,32] These observations suggest that the light-induced conformational changes and their resultant changes in surface topography are important for interdomain cross-talk in light signal transduction mediated by phytochrome activation.

129.3 Structural Motifs and Interdomain Interactions

Eukaryotic and prokaryotic phytochromes are similar in their structural and functional molecular architectures. Although some structural motifs are missing or are substituted in prokaryotic phytochromes, the chromophore-binding *N*-terminal domains carry determinants for phytochrome individuality followed by functionally interchangeable regulatory *C*-terminal domains (Figure 129.1).[9,18,19,21,33] PAS and kinase motifs in the *C*-terminal domain of plant phytochromes are also identified in prokaryotic phytochromes with similar regulatory functions.[16,21,34] These observations suggest that regulatory motifs in the *C*-terminal domain share common molecular mechanisms for interactions with downstream signaling components.

Recently identified phytochrome-interacting proteins interact with different structural motifs in the *C*-terminal domain. PKS1 interacts with the Ser/Thr kinase motif.[16] PIF3 and NDPK2 interact with the regulatory "Quail box" containing PAS motifs.[13,15] The NDPK2-phytochrome interaction seems to be different from the PIF3-phytochrome interaction. The latter occurs through the interaction between the PAS motifs.[13,15] Both NDPK2 and PIF3 bind to the phytochrome *C*-terminal domains preferentially in the Pfr form.[13,15] Their interactions confirm the preferential exposure of *C*-terminal domain around Trp-773 and Trp-777 in the Pfr form.[32] However, PIF3 and NDPK2 seem to interact differently, in that the NDPK2 interaction requires the *N*-terminal and the *C*-terminal domains for full binding activity.[13,14] PIF3, isolated in yeast using two hybrid screening with the phytochrome *C*-terminal domain as bait, also binds the *N*-terminal domain. It binds more strongly to the full-size phytochrome, indicating that direct interdomain interactions are required for the phytochrome–PIF3 association.[13,14] PKS1 binds to the *C*-terminal Ser/Thr kinase motif independent of the Pr/Pfr phototransformation, suggesting that this motif is not changed during phototransformation.[16] However, PKS1 phosphorylation and phytochrome autophosphorylation are increased 2 to 2.5 times in the Pfr form, indicating that the phosphorylation is an important factor for phytochrome signal transduction through phytochrome-PKS1 interaction. Therefore, phytochrome interacting proteins seem to be recognized by specific *C*-terminal regulatory motifs activated by differential interdomain interactions (Figure 129.2).

The Pfr form of phytochromes is considered to be a biologically active form, in most cases, in higher plants. Recent studies, however, show the possibility that the Pr form of phytochrome could be the active form in some cases. The Pr form of Cph1 exhibits autophosphorylation activity.[18] Also, the Pr form of BrBphP accelerates the synthesis of complete photosynthetic apparatus.[21] The Pr form of Phytochrome B was also suggested to be the regulatory active form in seed germination.[35,36] PIF3 and NDPK2, however, bind preferentially to the Pfr form to regulate phytochrome signaling.[13–15] The Pfr form of DrBphP also exhibited increased autophosphorylation and phosphate transfer activity.[34] This active Pr/active Pfr signaling could be explained by the intermolecular or by the intramolecular pathway in which the photoactivated Pfr signals induce the release of a Pr-specific factor from regulatory motifs.[37] The released Pr-specific factor then transfers "Pr signal" to the downstream signaling components, whereas the phytochrome interacts with a Pfr-specific factor to transfer "Pfr signal" to the downstream of the signal transduction pathway (Figure 129.3).

129.4 Phytochrome Phosphorylation and Signal Transduction

Until recently, the hypothesis that the phytochrome is a kinase has been controversial.[38–40] The finding that the Cph1 has histidine kinase activity triggered the reexamination of plant phytochrome kinase activity and confirmed that plant phytochromes are Ser/Thr kinases.[16,18,41–44] The Ser-7 of Phytochrome A is phosphorylated *in vivo* in Pr and Pfr forms, but the Ser-17 is phosphorylated *in vitro* in the Pr

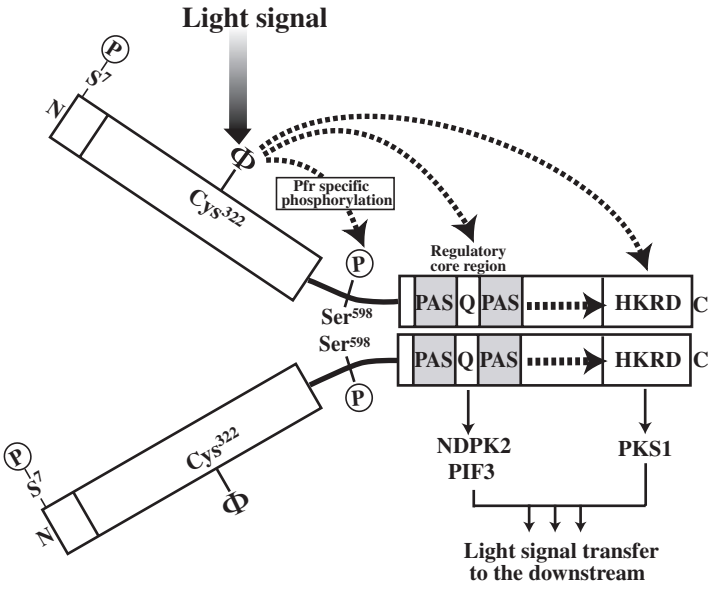

FIGURE 129.2 *Interdomain signal transmission in a dimeric oat phytochrome A*. The Ser-7 is phosphorylated *in vivo*. The Ser-598 is located in the hinge region and phosphorylated preferentially in the Pfr form. The Pfr-dependent conformational changes are generated through the chromophore photoisomerization by absorbing red light (R) in the *N*-terminal domain, and they trigger subtle conformational changes through the whole phytochrome molecule. The conformational signals are subsequently transmitted through the regulatory domain (Q) and HKRD either directly or indirectly to the downstream signal-transducing molecules. The photoactivated or uncovered Quail box (see Figure 129.3) interacts directly with the NDPK2 and the PIF3. The PKS1 seems to associate with the HKRD motif.

form.[45–47] Also, the protein kinase activity of Phytochrome A autophosphorylates Ser-17 (unpublished data). The Ser-598 is light-dependently phosphorylated, mainly in the Pfr form, *in vivo* and transfers the phosphate to the substrate.[47] Mutation of this serine abolishes the light dependency of phosphorylation and phosphate transfer, indicating that the phosphorylation of Ser-598 could be a molecular switch in the interdomain interactions (Figure 129.2).[16]

Phytochrome phosphorylation appears to regulate conformational changes and modulates the cross-talks between the *N*-terminal and *C*-terminal domains as well. Phytochrome interacting proteins might be activated through phosphorylation by phytochrome kinase, regulation of subcellular location, or regulation of interaction with other components. The light-dependent phosphate transfers between Cph1 and Rcp1 in *Synechocystis*,[43] and between DrBphP and DrBphR in *Deinococcus radiodurans*,[34] are well characterized *in vitro*. The phytochrome-mediated photoreversible phosphorylation of PKS1 is similar to the Cph1-Rcp1 phospho-relay system.[16] The PKS1 is phosphorylated about twofold higher on a serine or threonine residue by the Pfr form of phytochrome. The kinase activity of NDPK2 is also increased twofold by the Pfr form of phytochrome.[15] Taken together, light-induced conformational changes accompany the interdomain cross-talks by protein phosphorylation and modulate the signaling through interactions with downstream signaling components (Figure 129.3).

129.5 Evolution of Structural Motifs and Functions of Phytochrome

Until recently, phytochromes were thought to be restricted to photosynthetic organisms.[20,48] However, recent studies based on DNA sequencing databases uncovered many phytochrome-like genes in prokaryotic organisms, such as *Synechocystis*,[17,41] *Bradyrhizobium*,[21] and *Deinicoccus*.[19] Protein sequence comparison shows that the chromophore bearing *N*-terminal domains are conserved in all known phytochromes,

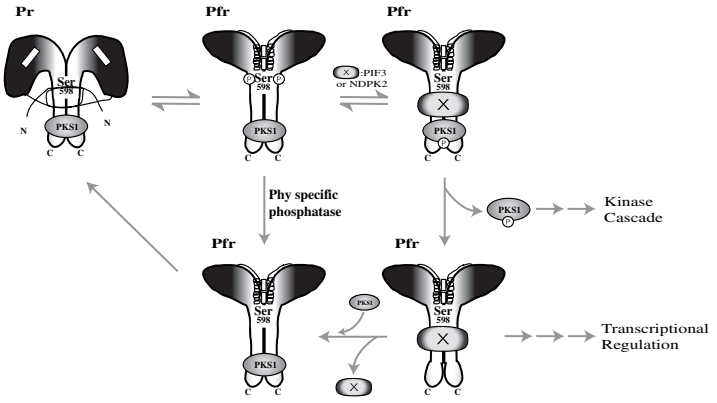

FIGURE 129.3 Conformational changes and interdomain interactions in the phytochrome photoactivation. The photoactivation of the phytochrome includes changes in the domain conformation and in the surface topography triggered by apoprotein–chromophore interactions. The *N*-terminal 6 kDa-peptide region forms an α-helix conformation in the Pfr but a random coil conformation in the Pr. The proximity between the *N*- and the *C*-termini in the Pr form is to depict the covered Quail box and to shield the hinge region. Upon photoactivation, the hinge region is exposed, and the Ser-598 may be phosphorylated. The Pfr phytochrome phosphorylated at Ser-598 is not an active form, but it accelerates the association of the PIF3 or NDPK2 and phosphorylation of the PKS1. The phospho-PKS1 is subsequently released from the photoactivated phytochrome to give light signals to the downstream, presumably through the kinase cascade. The factor X also transmits the signal directly or indirectly to the downstream. The Ser-598 phosphorylation is proposed as a mechanism to desensitize the Pfr activity in combination with an unidentified phytochrome specific protein phosphatase.

but *C*-terminal domains of prokaryotic phytochromes are shorter and missing regulatory motifs of plant phytochromes. The *C*-terminal domains of prokaryotic phytochromes have either a kinase motif or a PAS motif (Figure 129.1). Even though all phytochromes bind bilin-type chromophores covalently to the *N*-terminal domains, bacteriophytochromes, designated as BphPs, seem to bind biliverdin through different binding modes.[19,34] All known eukaryotic phytochromes including Cph1 have the conserved chromophore-binding cystein followed by the conserved histidine that is essential residue for chromophore-binding activity.[49] However, BphPs have no aligned chromophore-binding cystein substituted by hydrophobic residues but have absolutely conserved adjacent histidine (Figure 129.1).[19,34] Biochemical and molecular biological studies suggested that the chromophore attachments of BphPs are through a Schiff's-base-type linkage to a histidine rather than a thio-ether linkage to the cystein, the chromophore attachment site in plant phytochrome and Cph1.[19]

Whereas the phytochromobilin and phycocyanobilin are the chromophores of plant phytochrome and Cph1, BphPs prefer to bind biliverdin as a chromophore with perfect spectral properties except substantial red shift; the absorbance maxima for the Pr and Pfr forms of biliverdin-bound BphPs are at 698 and 750 nm, respectively.[34] This shift can be easily explained by the increased double-bond conjugation in biliverdin as compared to phytochromobilin and phycocyanobilin. A recent report further supports that biliverdin is the chromophore of BphPs. The bacteriophytochrome of *Bradyrhizobium* (BrBphP) binds biliverdin. The BrBphP controls the synthesis of photosynthetic apparatus using 750 nm of light, instead of 730 nm for plant phytochrome and 712 nm for Cph1, for photoconversion.[21] Unlike the case in other BphPs, the *C*-terminal domain of BrBphP has no conserved histidine kinase motif but has an S-box motif that corresponds to a strongly conserved region in PAS motif.[21] This BrBphP seems to transfer the light signals through biliverdin-bound BphP to its downstream component PpsR, the transcription factor that represses the expression of bacteriochlorophyll and light-harvesting II complex structural genes in anaerobic purple bacteria to regulate the photosystem synthesis.[21,50] BphP and PpsR interact using PAS motif present in both proteins, and they transfer light signals directly to the target genes.[21,51] This scheme is conserved during the evolution of phytochromes, in that light signals are transferred directly through a

phytochrome to PIF3, for example, bound to the target genes.[52] The kinase activity of DrBphP for its substrate BphR resembles the kinase activity of plant phytochrome for PKS1.[16,34] Thus, structural motifs as well as functional mechanisms of plant phytochromes evolved from the primitive bacteriophytochromes, suggesting that the bacteriophytochromes are the progenitors of plant phytochromes.

129.6 Conclusions

Although the biochemical and molecular biological properties of phytochromes have been well studied, the three-dimensional structure and light signal transduction pathways are not well understood. The questions as to how phytochromes perceive light signals and how light signals are transmitted to downstream molecules are now beginning to be recognized. One of the proposed models depicts that the phototransformation of the chromophore triggered by light signals modulates the interactions between the chromophore and apoprotein. This is followed by conformational changes throughout the whole phytochrome molecule via interdomain cross-talks or communications within the phytochrome molecules, in analogy to the well-understood rhodopsin visual receptor system in animals.[8,53,54]

130.1 Introduction

It was very difficult to characterize the molecular structure of large, labile proteins like spectrally photoreversible phytochromes (phy) by the methods of conventional protein chemistry. Our knowledge of the primary structure and biogenesis of phy apoproteins (PHY), however, progressed greatly after the PHY genes (*PHY*) were isolated and sequenced (for reviews, see the literature[1,2]). The first cloning of phy cDNA was the essential step in the molecular approach and was followed by differential screening of *Avena* cDNA clones, using either enriched or depleted probes for *PHY*.[3] Once the sequence of *PHY* genes was known, it became significantly easier to clone *PHY* from other plants. To date, *PHY* genes were isolated not only from various species of seed plants[4] but also ferns,[5] mosses,[6] and algae.[7] Furthermore, recent development of the genome sequencing projects resulted in the discovery of prokaryotic phytochromes in cyanobacteria,[8,9] purple bacteria, nonphotosynthetic eubacteria, and fungi, so that we can discuss the origin and molecular evolution of *PHY*.[10] We are also able to apply various gene technologies to analyze the structure/function *in vitro*[11] and *in vivo*[12] of these tetrapyrrole-sensing photoreceptor proteins.

130.2 Structure and Evolution of Phytochrome Genes

Since the discovery of phy,[13] this red/far-red photoreversible pigment has been spectrophotometrically detected in a wide range of eukaryotic green plants.[14] The universal distribution of phytochromes was further confirmed by the cloning and sequencing of full- or partial-length cDNAs and genomic DNAs of *PHY* genes with seed plants[15] and were extended to various species of lower plants and prokaryotes.[10] The sequence analyses indicate that the *PHY* gene in seed plants contains six exons and five introns, including one intron in each of the two untranslated regions at the 5′ and 3′ ends of the sequence.[15] It also provided evidence for the presence of multiple *PHY* gene families (Figure 130.1). Five *PHY* genes, named *PHYA, PHYB, PHYC, PHYD*, and *PHYE*, were first identified in the Arabidopsis genome,[16,17] and then *PHYA*,[18] *PHYB*,[19] and *PHYC*[20] in rice. Recently published genome sequences of Arabidopsis and rice clearly confirmed the above five *PHY* genes in Arabidopsis genome (The Kazusa *Arabidopsis* data site home page: http://www.kazusa.or.jp/kaos/), and the three in *Oryza sativa* L. ssp. *japonica*.[21] The Arabidopsis *PHY* genes are located on the different chromosomes (Chr.); namely *PHYA* on Chr. 1, *PHYB* on Chr. 2, *PHYC* on Chr. 5, and *PHYD* and *PHYE* on Chr. 4. On the other hand, all three rice *PHY* genes

Values from 100 bootstrap replicates are given above branches. (From Mathews, S. and Sharrock, R.A., Phytochrome gene diversity, *Plant Cell Env.*, 20, 666, 1997. With permission.)

are located on Chr. 3.[22] Estimated amino acid sequences show only 50% identity each with *PHYA*, *PHYB*, and *PHYC* in Arabidopsis,[16] but the identity with *PHY* from other plants is diverse.[4] In Gymnosperms, two different types of *PHY* genes were identified in *Picea abies* and *Pinus sylvestris*, and they appeared to diverge from the two main lineages of angiosperm phytochromes[23] (Figure 130.1).

The discovery of genes that code for PHY-homologous proteins in prokaryotes gave us great insight into the phy evolution. This example was first identified in the cyanobacteria *Fremyella*.[24] Until now, few mutual domains of phy-related proteins were found in not only cyanobacteria but also in purple bacteria *Rhodospirillum*,[25] nonphotosynthetic bacteria *Deinococcus*,[26] and soil bacterium *Agrobacterium*.[27] These prokaryotic photoreceptors possess the conserved chromophore-bearing domain (CBD) to which the bilin chromophore is covalently attached (Figure 130.2), though there is the exception of a purple bacteria *R. centenum* that possesses the photoactive yellow protein (PYP) domain.[25]

The histidine kinase-related domain (HKRD) is present in the *C*-terminal regulatory region of the plant phy (Figure 130.2). Most bacteriophytochromes also contain histidine kinase domain (HKD) of bacterial two-component system at the *C*-terminal region. Moreover, light-regulated histidine kinase activity was clearly demonstrated in cyanobacterial phy.[8] These results strongly support the concept that phy is a light-modulated kinase.[10]

130.3 Expression of Phytochrome Genes

Since cloned *PHY* genes became available as specific tools, spatial and temporal analyses of gene expression of individual members of the phy family were carried out at various stages of plant development.[15] The mRNA abundance of *PHY* genes was not uniform, depending upon plant species, types of tissues and organs, or environmental conditions where plants grew. For example, in rice seedlings, *PHYA*-mRNA was twofold higher in leaves than in roots when grown in the dark, whereas roots contained higher levels of the mRNA than leaves in fully green plants.[28] In etiolated pea seedlings, the abundance of the *PHYA*-mRNA was significantly higher in the shoot apex and the cotyledons than in the other parts.[29] In transgenic

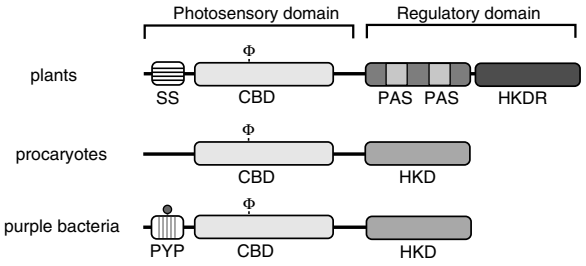

FIGURE 130.2 Domain structures of prokaryotic and plant phytochromes. Phytochromes have two functional domains, the *N*-terminal photosensory domain and the *C*-terminal regulatory domain. CBD, chromophore-bearing domain; HKRD, histidine kinase-related domain; HKD, histidine kinase domain; PAS, Pas (Per/Arndt/Sim) domain; SS, serine-rich domain; PYP, photoactive yellow protein domain similar to PAS domain; **Φ**, bilin-chromophore. (Modified from Frankhauser, C., Phytochromes as light-modulated protein kinases, Figure 1, *Seminars in Cell and Developmental Biology,* 11, 468, 2000. With permission from Elsevier Science.)

Petunia seedlings that have the pea *PHYA*-GUS fusion reporter gene, the expression level of this reporter gene was highest in the apical region, lower in a declining gradient down the hypocotyl, and barely detectable in the root when grown in the dark.[30] This level was red/far-red photoreversibly regulated.[30]

In the early 1980s, workers became aware of the fact[31] that the contents of translatable *PHY*-mRNA measured using an *in vitro* translation system were lowered by exposure of oat to white or red light. This phenomenon was confirmed by quantitative hybridization of *PHY*-mRNA using *PHY*-cDNA as a probe in oat[32] and rice.[33] The photoinduced downregulation of *PHYA* expression was more complex in dicots than in monocots. The single-copy gene coding for pea *PHYA* produces three distinct transcripts differing in the length of the 5′-noncoding sequence, when detected by S1 nuclease protection assay.[34] With respect to the abundance of these three *PHYA*-mRNAs, the shortest and the second shortest transcripts decreased rapidly after brief irradiation with red light, and the red-light-induced effect was reversed by subsequent irradiation with far-red light, indicating a Type II phy regulation.[35] Later, this was confirmed in etiolated Arabidopsis seedlings.[36] Further, when the seedlings of *phya*-deficient Arabidopsis mutant were exposed to far-red light, the far-red-light-induced downregulation of *PHYA* expression was not observed. In the *phyb*-deficient mutant, the red-light-induced downregulation also failed. These results clearly indicated that *phya* and *phyb* mediate the downregulation of *PHYA* expression in Arabidopsis seedlings.[36]

In contrast, *PHYB* and *PHYC* are constitutively expressed, regardless of the environmental light condition, as shown by Northern blot analysis using transcript-specific probes with Arabidopsis[16] and rice.[19] Densitometric analysis shows that *PHYA*-mRNA is fivefold more abundant than *PHYB*-mRNA in etiolated rice seedlings, whereas these two mRNAs are equally abundant in green tissues because of light-induced decline of *PHYA* transcript.[19] In tobacco, expression of *PHYB* gene is regulated mainly, while that of *PHYA* genes is regulated partially at the level of transcription.[37]

Recently, the circadian clock-regulated expression of *PHY* genes in Arabidopsis was clearly demonstrated through the studies of transgenic Arabidopsis plants carrying *PHY* promoter fused to the luciferase (LUC) reporter.[38,39] The transgenic seedlings carrying each *PHY*promoter::LUC showed diurnal rhythmic expression under 12-h-light/12-h-dark photoperiods and, except for *PHYC*::LUC, these oscillations persisted under constant conditions. Moreover, detailed studies of each PHY expression confirmed that expression of all *PHY*s is under the control of the circadian clock. Interestingly, each *PHY* showed the maximum level of mRNA expression at different timings.[39] These results indicated that the plant circadian clock controls the mRNA expression of PHY.

130.4 Application of Phytochrome Genes

Techniques of gene engineering were applied for studies on *in vitro* assembly of variously mutated PHY to a bilin chromophore,[40] overexpression of recombinant *PHY*s in transgenic plants,[41,42] and structure/function analysis of PHY[43] and the linear tetrapyrrole (bilin) chromophore.[11]

The preparation of PHY apoproteins has been most difficult since the discovery of phy, because the chromophore is attached covalently to a cysteinyl residue of photobiologically active holophytochromes.[44] However, the recent success of expressing recombinant *PHYA*-cDNA in bacteria[45] and yeast,[46,47] and *PHYB*-cDNA in yeast[47] made it possible to provide sufficient amounts of each PHY apoprotein with or without the chromophore. Using such PHYs, red/far-red photoreversible adducts of full-length PHYA in pea,[49] oat,[46] and tobacco[48] were synthesized *in vitro*. Furthermore, truncation of the *N*-terminal tail to residue 70 amino acid residues does not appear to be crucial for the assembly,[50] but the deletion of *N*-terminal 80 amino acids or more shows no assembly *in vivo* or *in vitro*.[51] A mutant *phyA* comprised of a deletion of the *C*-terminus to residue 548 showed bilin incorporation and red/far-red photoreversible spectral changes, indicating that the *C*-terminal half domain of PHYA is not required for chromophore assembly *in vitro*[40] and in transgenic plants.[51] The kinetic analysis of the *in vitro* assembly with PHYA[52] and PHYB[48] revealed a similar pseudo-first-order rate constant.

To analyze the structural requirements of bilin chromophore for the photoreversible spectral properties of PhyB, chemically synthesized 20 bilin analogs were reconstituted *in vitro* with PHYB.[11] Each ring of tetrapyrrole has different roles for the assembly; namely, the A-ring of bilin acts mainly as the anchor for ligation to PHYB, whereas the side-chains of the B- and C-rings are crucial to position the bilins properly in the chromophore pocket of PHYB. The side-chain of the D-ring is required for the photoreversible spectral change of the adducts.

Structure and biological function analysis of phy was made extensively using transgenic techniques by expressing a cloned *PHY* gene. Earlier, biological activity of the transgenes was demonstrated only when full-length *PHY* was overexpressed in transgenic plants, while any modification of *PHY* structure fails to induce any biological functions.[41,42] The biological activity of rice phyA in transgenic tobacco seedlings demonstrated clearly that rice PHYA assembles with tobacco phytochromobilin *in vivo* and forms spectrophotometrically active phy,[42] which regulates hypocotyl elongation in transgenic tobacco seedlings.[53] Because the *N*-terminus of PHYA in several plant species is always rich in serine residue, the first 10 serine codons of rice *PHYA* were changed to alanine codons. This mutant *phyA* gene as well as the WT *PHYA* was transferred into the tobacco genome, finding that the serine/alanine mutant responded to dim light with more sensitivity than the wild type (WT).[51]

Phy molecules have two functional domains: the chromophore-bearing photosensory *N*-terminal domain and the signaling *C*-terminal domain. To probe the intramolecular determinants for photosensory specificity of phyA and phyB, the physiological results of reciprocal *PHYA/PHYB* generic chimeras were examined under continuous red and far-red light conditions. The results[43] evidently suggested that *N*-terminal domain determined the photosensory specificity of phyA or phyB for growth responses to far-red or red light, respectively, in Arabidopsis. The far-red light sensitivity of phyA depends on the structure of not only apoproteins but also bilin chromophore. By reconstitution of holophytochrome *in vivo* through feeding various synthetic bilins to chromophore-deficient mutants of Arabidopsis, the requirement for a double bond on the bilin D-ring for rescuing PhyA function was established.[12]

130.5 Conclusions

It is evident that molecular biological approaches using *PHY* genes have opened a promising new way to apply both basic photobiology and applied photosciences. First of all, if the full-length *PHY* genes have not been cloned, it would be impossible to estimate the amino acid sequences of full-length PHY and then, subsequently, the *PHY* gene family. Second, if the different phy subfamilies were not known, the inconsistency between spectrophotometrically measured amounts and states of phy *in vivo* and the physiologically determined responses of phy[2,54] would never be solved. Third, the amounts of phyB, phyC, and others, if any, in plant tissues are so low[55] that the study of their molecular properties by conventional techniques is not possible. The expression of recombinant *PHY* in bacteria and yeasts and the *in vitro* assembly techniques with *PHY*s to the bilin chromophore, however, now provided us with measurable amounts of spectrally active phytochromes for studying their physical and chemical properties. A number of photomorphogenetic mutants were isolated and characterized in terms of relevant genes, finding

chromophore-deficient mutants,[56] apophytochrome-related mutants,[57] and downstream signaling mutants.[58] The application of gene engineering to phytochrome studies has been very fruitful, but new techniques will initiate further development in this field.

Università di Pisa

131.1 Introduction

Already in the early 20th century, it was shown that light controls growth and development of plants through the action of a signaling photoreceptor separate from the photosynthetic activity.[1,2] These studies provided the starting point of an exciting field of research that was subsequently designated photomorphogenesis. In the natural environment, plants are subjected to an array of external signals, such as temperature, gravity, wind, light, and water conditions. Because plants are anchored by their roots to one place for their entire lives, they have to adapt to various changing environmental conditions where they are located.[3,4] Thus, postembryonic growth and development of plants are characterized by remarkable plasticity that requires plants to have abilities that allow them to integrate and respond to metabolic, developmental, and environmental signals. The plants, to grow and develop optimally, evolved sophisticated systems of receptors and signaling networks that provides them with an enormous ability to perceive and process information from their biotic and abiotic environments. Light is the only source of energy; therefore, it is not surprising that light plays a major signaling role in plant development.

The diverse light-induced responses of plants require precise sensing of quantity, quality, direction, and duration of light.[4] Thus, plants evolved arrays of light-sensing molecules that, according to their action spectra, can be assigned to at least three different photoreceptor classes: red/far-red photoreceptors (phytochromes); blue/UVA photoreceptors (cryptochromes, phototropin, zeaxantin, and rhodopsin?),

0-8493-1348-1/04/$0.00+$1.50

and UVB photoreceptors.[5] The combined actions of several photoreceptors allow a plant to utilize a broad spectrum of solar radiation, from ultraviolet to far-red light, to control different aspects of growth and development from seed germination to flowering. In spite of the diffuse, initial skepticism (for instance, phytochrome was defined as a pigment of imagination), photomorphogenesis developed as a relevant sector of plant physiology. The attribution of a variety of light-regulated responses to a single photoreceptor was and still is one of the problems with photomorphogenic research. Furthermore, genetic analysis has shown that there is a complex web of interactions, not only between the phytochromes but also between phytochromes, UVB, and the UVA-blue-light-absorbing photoreceptors, including redundancy, antagonism, and effector/modulator relationships.[6]

In the present review, we discuss studies in which photomorphogenic tomato mutants implicated specific photoreceptors, and the interaction of signaling pathways was activated by different photoreceptors in various light-dependent responses.

131.2 Functional Photoreceptors of Photomorphogenesis in Higher Plants

Phytochromes

Phytochromes are the best-characterized plant photosensors. Individual plants contain multiple functional phytochromes. Five phytochrome genes were characterized in Arabidopsis *(PHYA, PHYB, PHYC, PHYD, and PHYE)*[7,8] and in tomato (*PHYA, PHYB1, PHYB2, PHYE*, and *PHYF*).[9] Arabidopsis *PHYA, PHYB, PHYC*, and *PHYE* encode proteins that share 46 to 53% amino acid sequence identity, while *PHYD* encoded apoprotein (phyD) shares 80% amino acid sequence identity with phyB, and therefore, it is a member of the same subfamily.[9]

Thus, these five *PHY* genes were assigned to four subfamilies: *A*, *B* (which includes *PHYD*), *C*, and *E*. Phytochromes are dimers composed of two ~125 kDa polypeptides, with each monomer carrying a single chromophore (a linear tetrapyrrole) in its amino terminal domain. The photosensory function of a phytochrome molecule is due to its ability to photointerconvert between two stable isomers, a red-light-absorbing form, Pr (λ_{max} = 660 nm) and a far-red-light-absorbing form, Pfr (λ_{max} = 730 nm). Upon exposure to red light, Pr is converted to Pfr; upon exposure to far-red light, Pfr is converted back to Pr. Under any light conditions, phytochromes are always present in an equilibrium of the two forms that is λ dependent (photoequilibrium) and is established in a few seconds in the presence of enough radiant energy.

The classical phytochrome-mediated responses are induced by a pulse of red light interrupting darkness and reversed by a subsequent immediate pulse of far-red light. These responses include photoregulation of seed germination, inhibition of stem elongation, promotion of cotyledon expansion, flowering, gene expression, etc. Therefore, phytochrome acts as a light-regulated molecular switch, and Pfr, which is formed after a pulse of red light, is generally thought of as being the active form.

Soon after the discovery of phytochrome, the Beltsville group (H. Borthwick, S.B. Hendricks, and M.W. Parker) proposed that phytochrome might be an enzyme, however, determining the identity of this enzymatic activity has proven difficult.[5] Finally, it was demonstrated that phytochrome acts as a serine kinase and can autophosphorylate itself or transphosphorylate its partner proteins.[10] Even the subcellular localization of phytochrome appears to be affected by light.

Recently, it was shown that there is distinct light-dependent nuclear transport of phyA and phyB.[11] In dark-grown seedlings or dark-adapted light-grown plants, phyA and phyB are localized in the cytosol. Nuclear translocation of phyB is inducible by red light and shows the classical red/far-red reversibility characteristic of phytochrome-mediated responses, whereas, import of phyA in the nucleus was induced by far-red light with light pulses or with prolonged irradiation. That de-etiolation requires light-regulated gene expression is in agreement with the light-dependent nuclear translocation of phytochromes, where two phytochrome-signaling proteins, SPA1 and PIF3, were identified. It is worth noting that light

perception by phytochromes in the cytosol activates phototransduction pathways involving Ca^{2+} and cGmp.[12] Thus, it appears that phytochromes activate two distinct but coordinated circuits: cytosolic and nuclear.

Based on biochemical and physiological properties, phytochromes were grouped into two classes, Type I and Type II.[13] Type I phytochrome is light labile, indeed, its Pfr form is unstable, and following red irradiation Pfr is rapidly degraded. It is generally believed that phyA is the only Type I (labile) phytochrome, whereas the remaining phytochrome species constitute Type II (light-stable) phytochrome. The dramatic >100-fold drop in phyA levels in light-grown tissues is furthered by light-induced inhibition of transcription and degradation of mRNA. The phyA protein level is, therefore, regulated by light with coordinated transcriptional and posttranscriptional regulation. As a result of this, phyA accumulates prevalently in etiolated seedlings, whereas the other more stable phytochrome species are predominantly present in light-grown mature plants.

There are at least three distinct modes of phytochrome action that can be distinguished according to their light fluence requirement: the very low fluence responses (VLFR, requiring <0.1 nmol/m^2 light); the low fluence responses (LFRs, requiring 1 mmol/m^2 light); and responses to prolonged red and far-red light known as high irradiance responses (HIR, requiring >10 mmol/m^2).[14] VLFR and HIR to continuous far-red light were attributed to labile phyA, while LFR and HIR to continuous red light were attributed mainly to stable phytochromes.[15] Thus, different phytochrome species have distinct photosensory and physiological roles in controlling plant growth and development. It is worth noting that the above-mentioned conclusions were obtained almost completely from studies with the model plant Arabidopsis and that individual tomato phytochromes may not be hortologous to the Arabidopsis counterpart and have functions similar but not identical to their Arabidopsis homologs.[16,17,18] Furthermore, evidence was provided that angiosperm phytochrome gene subfamilies and different regions of the phytochrome protein are evolving differentially.[19] The fast rate of evolution of the signal transduction/dimerization domain of phytochrome apoprotein is presumably related to acquisition of new molecular functions.[20] Taking into account the fact that *PHY* gene family and size differ significantly among flowering plants, it appears that the extrapolation of the information obtained with Arabidopsis to other species could be misleading.

Blue-UVA Photoreceptors

For more than one century, it has been known that blue light induces phototropic responses in plants. Nowadays, it is well known that blue and UVA regions of the solar spectrum control a large number of responses in plants: inhibition of stem elongation, leaf expansion, stomatal opening, phototropism, and gene expression. But, it was only in the last decade that four blue-light photoreceptors were characterized in plants, cryptochrome 1, cryptochrome 2, phototropin, and zeaxanthin.[21] It is widely believed that the current list of photoreceptors perceiving blue-UVA regions of the spectrum is not complete.[21] On the other hand, all-*trans*-retinal was identified in tomato plants at physiological levels.[22] Because retinal is the ligand of a G-protein-linked receptor, it appears worthwhile to verify whether or not a rhodopsin-like protein can be one of the blue-light photoreceptors in higher plants.

Cryptochromes

Cryptochromes are blue-light photoreceptors found in plants and animals. Already in the year 1950, Galston[23] proposed flavins as the blue-light-absorbing chromophores. But it was only the isolation of an Arabidopsis mutant, *hy4* (now named *CRY1*), that has an elongated hypocotyl in blue light, that allowed for the isolation of the first flavin-type blue-light photoreceptor.[24] The *CRY1*-encoded protein shows substantial homology to prokaryotic DNA photolyases that catalyze blue/UVA-dependent DNA repairing. *CRY1* encodes a 75 kD protein that binds a flavin (FAD) and a pterin chromophore, as do Class I photolyases, but does not have photorepair activity. The results of overexpression studies, in Arabidopsis and tobacco, showed that plants containing elevated levels of cry1 have short hypocotyl in UVA and blue light, further supporting the conclusion that cry1 is a blue receptor mediating blue-light inhibition of

hypocotyl elongation.[25] Mutants at the *CRY1* locus also showed reduced blue-light induction of the expression of several genes. Besides *CRY1,* a second cryptochrome gene, *CRY2,* was isolated in plants and animals. These genes show sequence similarity, mainly in the *N*-terminal photolyase-like domains, but little similarity in their *C*-terminal domains. In plants, the physiological functions of cry1 and cry2 appear to partly overlap — mediated inhibition of hypocotyl elongation, induction of anthocyanin synthesis, and entrainment of the circadian clock[26,27] — whereas only cry2 is involved in the control of cotyledon expansion and flowering timing.[28] In *Adianthum capillus-veneris*, at least two cryptochromes are localized in the nucleus.[29]

Phototropins

It was only in 1995 that a genetic locus, named *NPH1* (Nonphototropic Hypocotyl 1), encoding a plasma membrane protein essential for most phototropic responses to blue light was isolated in Arabidopsis.[30] Since then, a number of phototropin homologs were identified in several species. All the putative phototropin proteins contain in the *N*-terminal two LOV domains (they are activated by light, oxygen, or voltage) that bind FMN as a chromophore and a serine/threonine kinase in the *C*-terminal; they show light-activated autophosporylation.[5] It appears that different phototropins can mediate photropism in response to different fluence rates of light. It was agreed to designate the phototropic photoreceptors as phot1, phot2, and so on.

131.3 Tomato as Model Plant for Photomorphogenesis Studies

Tomato, *Solanum lycopersicum* L., is considered a model plant system alternative to Arabidopsis for the study of photomorphogenesis.[17] Tomato has a growth habit that is different from Arabidopsis, it produces large seeds, seedlings, and fruits that make it easier to use in the laboratory. The phytochrome family of tomato was characterized, and, in particular, the temporal and photoregulated expression of all known tomato phytochrome genes was shown.[31,32,33] The two cryptochrome genes of tomato were cloned and sequenced,[34] and several photomorphogenic mutants are available. Therefore, tomato is now a comparative experimental system to Arabidopsis for studying the functions of phytochromes and cryptochromes throughout the whole plant life cycle — from seed germination to fruit ripening.[35,36]

The Phytochrome Gene Family in Tomato

The genome of the tomato contains five phytochrome genes, each encoding a different apoprotein.[9,20] In tomato, the five cloned phytochrome genes are distributed over different chromosomes of the genome.[37] *PHYA, PHYB1, PHYB2, PHYE*, and *PHYF* are located on Chromosomes 10, 1, 5, 2, and 7, respectively. *PHYA*, *PHYB1*, and *PHYB2* genes are organized into four exons interrupted by three introns.[38,39,40] The five identified tomato phytochrome (*PHY*) genes were designated *PHYA*, *PHYB1*, *PHYB2*, *PHYE*, and *PHYF*, as a function of their amino acid similarity to the five Arabidopsis phytochromes. Tomato *PHYA* fragments and the polypeptides it encodes share 82% nucleotide and 98% amino acid identity with Arabidopsis *PHYA*; tomato *PHYB1* shares 80% nucleotide and 96% amino acid identity with Arabidopsis *PHYB*; tomato *PHYB2* shares 79% nucleotide and 91% amino acid identity with Arabidopsis *PHYB*; tomato *PHYE* shares 79% nucleotide and 88% amino acid identity with Arabidopsis *PHYE*; and tomato *PHYF* shares only 61 to 73% nucleotide and 65 to 72% amino acid with Arabidopsis phytochromes. Tomato *PHYB1* and *PHYB2* share 85% nucleotide and 90% amino acid identity.

Hauser et al.[31] determined the abundance of *PHY* mRNAs for dry seeds and for different organs of seedlings and mature tomato plants. In dry tomato seeds, each of the five *PHY* mRNAs was detectable, *PHYB1* mRNA being predominant. It is worth noting that the amount of *PHY* mRNA in dry tomato seeds is very low (about 1 to 5 μmol/mol mRNA). In greenhouse-grown tomato seedlings, the expression patterns of *PHYB1* and *PHYE* are almost indistinguishable, whereas each of the other *PHY* transcripts differed from one another. Except for *PHYA* mRNA, which shows the highest level in the root, the abundance of all the other *PHY* transcripts is maximal in the hypocotyl. In seedlings the abundance of

each *PHY* mRNA changes two- to threefold among organs. The order of decreasing abundance of the five transcripts in young seedlings is *PHYA* > *PHYB1* = *PHYE* > *PHYB2* > *PHYF*. Mature plants show a different picture. Whereas *PHYA, PHYB1*, and *PHYE* mRNAs display similar patterns of expression in different organs, the levels of *PHYB2* and *PHYF* mRNA show a larger variability, up to 15-fold. In particular, *PHYB2* and *PHYF* are expressed maximally in ripening fruits. The fact that the abundance of each of the five tomato *PHY* shows a significant variability among organs, suggests an organ-dependent biological activity of each phytochrome species.[31]

The same authors[33] subsequently followed the changes of the absolute transcript amount of the five *PHY* throughout the tomato plant life cycle, during a normal day cycle, and in response to light conditions. Their measurements were on whole plant basis; therefore, these data do not provide any further information about the above-mentioned variability of the abundance of each of the five *PHY* mRNAs among organs. Dry seeds contain the lowest amount of mRNAs transcribed from each of the five phytochrome genes. All five transcripts increase by 10- to 1000-fold during the first 24 h after imbibition, irrespective of light conditions. The early and dramatic increase of all five transcripts indicates that, although in dry tomato seeds there are physiological levels of Pfr sufficient to promote dark seed germination,[41] the *PHY* mRNAs occurring in dry tomato seeds are probably not sufficient to provide seedlings growing underground with an amount of photosensors adequate to perceive the small number of photons transmitted through the soil.[33] In darkness, after the peak at 24 h, *PHYA, PHYB1*, and *PHYB2* continue to increase to Day 5, while the abundance of *PHYE* and *PHYF* changes relatively little. After 5 days in darkness, *PHYA* abundance reaches approximately 2500 a mol μg^{-1} poly(A)$^+$-enriched RNA, whereas the abundance of the transcripts of the other *PHY* was more than one order of magnitude lower.

By contrast, when tomato seedlings are grown in greenhouse under natural photoperiod, there is, even though at lower rates, a constant increase in all but *PHYF* mRNAs throughout Day 6. In light-grown seedlings, *PHYA* transcripts are still the most abundant, even with a 10-fold decrease in comparison to etiolated seedlings. The analysis of transcript levels from sowing time to 56-day-old tomato plants shows a similar pattern for the levels of *PHYA, PHYB1, PHYB2*, and *PHYF* transcripts, characterized by a maximum peak at Day 6 followed by a decreasing phase until Day 14 and relatively constant levels thereafter. The data from Hauser et al.[35] suggest that besides the well-established roles of phyA and phyB1, even phyB2 and phyF could have roles in young tomato seedlings. The different pattern of *PHYE* mRNA that increases continuously for 3 weeks after sowing until a maximum plateau is reached that is maintained constant in mature plants suggests a main role of phyE in mature plants. The similarity of *PHYA* and *PHYB2* patterns of expression represented the most unexpected result. Both *PHYA* and *PHYB2* showed largest enhancements in expression after a light-to-dark transfer, the greatest decline following a dark-to-light transfer, and a similar variation during the daily natural light–dark cycle.[33] *PHYA* and *PHYB2* exhibit maximum values around midnight and minimal values around noon. Thus, a gene encoding for the labile phyA shows the same pattern of expression of a gene encoding for the stable phyB2. Characteristically, *PHYB1* transcripts attain maximum level in the afternoon and minimal levels just before dawn. On the other hand, the levels of *PHYE* and *PHYF* transcripts are almost constant during the 24 h. The fact that *PHYA*, *PHYB1*, and *PHYB2* present diurnal-dependent levels of expression, could suggest that these phytochromes are involved in rhythmic responses linked to various environmental parameters.[33]

Cryptochromes Family of Tomato

In tomato, two *CRY* genes — *CRY1* and *CRY2* — were characterized.[34] They map to Chromosomes 4 and 9, respectively, and encode proteins of 679 and 635 amino acids. Tomato cry1 and cry2 apoproteins display higher similarity to Arabidopsis crys than to each other.

Photomorphogenic Mutants of Tomato

Whereas only 10 years ago (in 1992), no mutations were isolated in phytochrome genes, in any plant, nowadays a number of phytochrome and photomorphogenic mutants are available. The availability of

mutations in genes involved in sensing and transducing light signal has contributed much to the fast-paced progress of our understanding of phytochrome functions that occurred in the last few years. Clearly, the fastest and easiest way to isolate photomorphogenic mutant is to screen under different light conditions the phenotype of mutagenized seeds at the seedling stage. Seedling development of higher plants follows two contrasting patterns: photomorphogenesis, which is exhibited in the light, and skotomorphogenesis (dark development or etiolation), which is the pathway followed upon germination in darkness. A seedling growing in darkness is characterized by long hypocotyl, unexpanded, closed, and pale cotyledons on an apical hook, absence of chlorophyll and anthocyanin biosynthesis, and true leaf development. When exposed to light, the seedling switches from skotomorphogenesis to photomorphogenesis, the elongation rate of the hypocotyl decreases, cotyledons green and enlarge, the shoot apical meristem is activated, anthocyanin biosynthesis starts, and the first true leaves emerge. The light-mediated transition from skotomorphogenesis to photomorphogenesis requires photoreceptor-mediated gene expression. Hypocotyl elongation, anthocyanin accumulation, and cotyledon expansion are the light-dependent responses most extensively used for the isolation of photomorphogenic mutants.

In Arabidopsis, there are two general classes of photomorphogenic mutants: light-insensitive mutants and mutants that undergo photomorphogenesis in the dark.[11] Tomato mutants differ substantially from Arabidopsis mutants in many aspects; in particular, no tomato mutants were isolated that exhibited visible photomorphogenic phenotype when the plants are grown in the dark.[17] Therefore, tomato mutants affected in-light regulated physiological responses fall in two different classes in comparison to Arabidopsis. One class includes mutants with impaired photomorphogenesis with a morphology, in the light, that shows aspects of dark-grown plants, while the mutants belonging to the other class show enhanced photomorphogenic responses in the light and etiolated phenotype in the dark. Mutants with a morphology that resembles that of dark-grown plants, although grown in the light, identify positive regulatory components of photomorphogenesis. This class of mutants shows lesions in genes that control chromophore biosynthesis or encode the photoreceptor's apoproteins. Mutants that exhibit enhanced light-dependent responses identify negative regulators of light signal transduction. In tomato, a large number of mutants are available, covering all stages of plant life from seed to fruit ripening and senescence, therefore, a more complete picture about the role of photomorphogenic photoreceptors during entire plant cycle can be depicted.[17]

Tomato Mutants Affected in Light Perception

Several photomorphogenic mutants of tomato were isolated by screening performed under low fluence rate of white, blue, red, or far-red light. In this section, we will describe briefly the molecular nature of the mutations in specific genes encoding photoreceptor apoproteins of mutants that have impaired light perception. Their effects in different phases and photomorphogenic responses of plants during their life cycle will be discussed separately.

Far-red-light insensitive (*fri*^{1} *and fri*^{2}, now named *phyA*), phytochrome-A-deficient mutants of tomato were obtained by treating seeds with ethyl methane sulfonate (EMS).[37] *Fri* mutations and *PHYA* were mapped at the same location on Chromosome 10.[37] Both *fri*^{1} and *fri*^{2} mutants have an identical point mutation in *PHYA*, A_{2327}-to-T.[38] The two *PHYA* mutants produce less than 1% of phyA apoprotein.

With the same mutagenetic approach, three mutant alleles in tomato (*tri*^{1,2,4}) were isolated with slightly longer hypocotyl under white light in comparison to wild type.[37,43] A fourth mutant was isolated as a somaclonal variant of the cv. Money Maker. The *TRI* locus and the *PHYB1* gene locus were located to Chromosome 1, and it was concluded that the *TRI* locus is the gene encoding the apoprotein of phytochrome B1. Each mutation appears to be the result of a different, single-base substitution in *PHYB1* that affects transcript and protein size and abundance.[39] *Tri*^{1} is considered a null mutant, and in the next pages, we will consider only the *tri*^{1} mutant as the *phyB1* mutant. In particular, it was shown that this mutant has a nucleotide substitution that results in a stop signal at codon 92.[39,43]

Subsequently, double mutants *phyA/phyB1* were obtained from segregating populations derived from crosses of the monogenic mutants.[40] The double mutant does not contain immunochemically detectable phyA and phyB1 polypeptides, its phenotype in white light is similar to that of *phyB1* mutant. From M_2

populations, obtained from γ-mutagenized *phyA/phyB1* double mutants, two new mutants were isolated with elongated hypocotyls and reduced anthocyanin content. Both mutants were found to have molecular lesions in *PHYB2* that produced apoproteins lacking a significant part of the *C*-terminal region.[40] The mature plants of the triple mutant *phyA/phyB1/phyB2* were characterized by dramatically elongated stem internodes, fruit trusses, pedicels and peduncles, and by pale stem and leaves.[35,36]

By a combination of phenotypic and PCR-based screening of the back-cross of the triple mutant (*phyA/phyB1/phyB2*) lines to the wild-type, monogenic *phyB2* mutants and double *phyA/phyB2* and *phyB1/phyB2* mutants were isolated. The phenotype of *phyB2* mutant is almost indistinguishable from that of wild-type tomato, as seedlings under red light or as mature plants grown in greenhouse. Furthermore, the effect of *phyB2* mutation on a *phyA* background, i.e., in the case of *phyA/phyB2* double mutation, is limited, almost null. By contrast, the phenotype of double mutant *phyB1/phyB2* showed, in comparison to wild-type or either single mutant, enhanced stem elongation and lower chlorophyll content. At seedling stage, under continuous red light, loss of phyB2 dramatically affected tomato phenotype only in a *phyB1* background.

The progeny from transgenic plants with lowered tomato CRY1 mRNA and protein levels, obtained by using an antisense mRNA approach, show elongated hypocotyl and decreased anthocyanins accumulation under blue light, providing the first direct evidence of a cryptochrome role in tomato photomorphogenesis.[44]

With further studies on M_2 populations, obtained from γ-mutagenized *phyA/phyB1* double mutants, recessive mutants with increased hypocotyl length, reduced chlorophyll content, and retarded hook opening were isolated.[36] These mutants showed reduced responsiveness to blue light in comparison to their *phyA/phyB1* progenitor as a result of lesions in the gene encoding the blue-light receptor Cryptochrome 1. The cross of the triple mutant *phyA/phyB1/cry1* to wild-type allowed the isolation of new photoreceptor mutant combinations: monogenic *cry1* and the double mutants *cry1/phyA* and *cry1/phyB1*.[36] Quadruple mutants were subsequently isolated in F_2 progenies of a cross between *phya/phyB1/phyB2* and *phyA/phyB1/cry1* mutants.[36] The quadruple mutants were characterized by an extreme phenotype: dramatically elongated and severely chlorophyll- and anthocyanin-deficient hypocotyl, and small cotyledons in comparison to all the other genotypes. The quadruple mutant did not survive until seed production. From the comparison of all these genotypes, it appears that cry1, phyA, phyB1, and phyB2 contribute to blue-light-mediated responses.[36]

Important clues concerning photoreceptor function may be uncovered by overexpressing single photoreceptors. Boylan and Quail[45] showed that ectopic expression of oat phyA in tomato induced dramatic phenotypic effects in seedlings (short hypocotyls and elevated anthocyanin contents) and in mature plants (dwarf, with dark green foliage and fruits).

A subclass of photoreceptor mutants includes the phytochrome chromophore-deficient mutants that are impaired in their ability to synthesize the linear tetrapyrrole chromophore of phytochrome.[46] Because all the phytochromes utilize the same chromophore, the chromophore mutants like *aurea* (*au*) and *yellow green-2* (*yg-2*) are affected in several phytochrome species. For instance, in etiolated *au* seedlings, three holophytochrome species are lost.[47] Thus, in etiolated seedlings, there is no spectrophotometrically detectable phytochrome, while mature plants of the *au* mutant contain about 60% of WT phytochrome level.[48] An antibody raised to pea phyB detected the same amount of photoactive phyB in green leaves in both *au* and WT plants.[49] The phenotype of these mutants is characterized by elongated and pale hypocotyl in white light, and even adult plants show more or less dramatic yellow gold color and elongated phenotype, depending on the genetic background.[50,51] In contrast, *au* fruits are normally pigmented. The pale phenotype is due to feedback inhibition of chlorophyll synthesis. The *au* mutant was used extensively for phytochrome signaling studies, because it was thought to be specifically deficient in phyA.[12,52]

Tomato Mutants Affected In Light Signaling

Several light-oversensitive mutants were isolated in tomato: high pigment (*hp-1* and *hp-2*), atroviolacea (*atv*), and intense pigmentation (*Ip*).[17] The *hp-1* locus was mapped to tomato Chromosome 2,[53] whereas the *hp-2* locus was mapped to Chromosome 1.[37] The two mutants did not display light phenotypes in

TABLE 131.1 Percentage of Seed Germination Recorded 5 and 10 Days after Sowing, at 25°C, in Darkness or under Continuous Red, Far-Red or Blue Light (Fluence Rate 5 $\mu molm^{-2}s^{-1}$)

	Dark		Red		Far-Red		Blue	
	5 Days	10 Days	5 Days	10 Days	5 Days	10 Days	5 Days	10 Days
MM	96	97	52	100	0	0	11	81
PhyA	95	96	93	100	1	5	83	89
$phyB_1$	23	31	11	35	0	0	0	3
$phyB_2$	9	11	12	95	0	0	0	0
phyA $phyB_1$	67	83	85	96	12	20	71	87
phyA $phyB_2$	13	16	97	99	1	1	7	11
$phyB_1$ $phyB_2$	4	7	12	85	0	0	0	0
phyA $phyB_1$ $phyB_2$	0	0	16	24	0	0	0	0

darkness, whereas, when grown in the presence of light, they showed shorter hypocotyls, higher anthocyanin accumulation, and more pigmented fruit in comparison to their wild-type; i.e., exaggerated light responsiveness. The analysis of double mutants *phyA hp-1* and *phyB1 hp-1* provided evidence that *hp-1* mutation enhances the effectiveness of both phytochromes.[54,55] On the other hand, it was shown that the *hp-1* phenotype was repressed in the double mutant *au hp-1*, confirming that *hp-1* phenotype requires an active phytochrome. The *hp-1* mutant presents a similar phytochrome content as that of the wild-type tomato. The *HP-2* gene was cloned and found to encode the tomato homolog of DET1 from Arabidopsis.[56] Even in the case of *hp-2* mutant, the mutation is expressed only in the presence of activated functional photoreceptors.

131.4 Photomorphogenic Responses in Different Phases of Tomato Life Cycle

The growth habits and the sizes of tomato plants make it easy to follow the photomorphogenic effects of light and the relative roles of different photoreceptors and of components of the light transduction chains at different stages of plant growth and development. In this review, we will cover seed germination, hypocotyl growth and differentiation, stem growth, and fruit ripening.

Photoregulation of Tomato Seed Germination

Although tomato seed germination in the dark is fairly good, phytochrome involvement was established. Different tomato cultivars show different sensitivities to light.[41,57] For instance, continuous red light promotes the germination of the line UC-105,[58] but the same light significantly decreases the rate of the germination process in the cv Money Maker (Table 131.1). Therefore, we will discuss separately the photoregulation of seed germination of distinct tomato lines.

Seed germination of line UC-105 is promoted, in comparison to the dark, by continuous and cyclic red light, whereas it is inhibited by continuous and cyclic far-red light and by continuous long-wavelength far-red light, 758 nm.[58] In cyclic irradiation, far-red pulses reverse almost completely the promoting effect of the preceding red light pulses. By contrast, seed germination of the *au* mutant, obtained from UC-105 genetic background, is promoted by continuous irradiation with red, far-red, and long-wavelength far-red (758 nm) as well as by cyclic irradiations with red and far-red lights. The promoting effect (in the *au* mutant), and the inhibitory effect (in wild-type) of continuous far-red light does not show photon fluence rate dependence in the range of 0.02 nmol $m^{-2}s^{-1}$ to 20 $\mu mol\ m^{-2}\ s^{-1}$. Consequently, the HIR of phytochrome is not involved.[58] The fluence-rate-independent inhibitory effect of continuous far-red and continuous 758 nm in UC-105 line can be attributed to the removal of almost all the Pfrs from seed cells, and consequently, to the fact that the LFR, requiring high phytochrome photoequilibrium, cannot take place. On the other hand, seed germination in *au* mutant is promoted by irradiation with 758 nm that establishes low phytochrome photoequilibria, <0.001, falling in a range compatible with VLFR of

phytochrome. Thus, it is possible to conclude that seed germination in UC-105 genetic background can be controlled by LFR and VLFR of phytochrome. The fact that the VLFR is manifested only in the *au* mutant that lacks at least three phytochromes, indicates that in WT tomato, some likely act antagonistically to those involved in VLFR. The involvement of LFR in the photocontrol of seed germination of wild-type tomato was confirmed by osmotic presowing treatments given under different light conditions. Unfortunately, seeds of the *au* mutant do not germinate after osmoconditioning.[59] Osmotic presowing treatment (osmoconditioning) is a method widely used to improve germination behavior in many species that we use to study the role of the phytochrome system in the photoregulation of tomato seed germination in UC-105 genetic background. During osmoconditioning of tomato seed, the limited water content of cells allows for phytochrome synthesis and phytochrome photoconversion but does not allow seed germination. Thus, it has been possible to separate the light effects on the phytochrome system from the Pfrs effect on the final physiological response, i.e., seed germination. The osmoconditioning in the dark or under continuous red light induces the capability for seed germination, even under the usually inhibitory far-red light. These results indicate that osmoconditioning in dark and in red light enables the transformation of phytochrome intermediates to Pfr (in the dark) and of old and new Pr to Pfr (in red light), which can exert its action during the osmotic inhibition of seed germination. In other words, the initial action of phytochrome, as far as germination is concerned, occurs during the osmotic treatment and, therefore, cannot be reversed by subsequent continuous far-red light. The same argument explains the inhibition of seed germination induced by far-red light, following osmoconditioning under far-red light. Continuous far-red light during seed osmoconditioning removes almost all the Pfr from the cells, and obviously, the initial action of Pfr, in the LFR mode, cannot occur. Thus, seed germination after osmoconditioning in far-red light is still under the control of the LFR (far-red light reversible) of phytochrome. The involvement of a high irradiance response in the control of seed germination in UC-105 genetic background is therefore excluded.

The analysis of the photoregulation of seed germination in Money Maker (MM) genetic background, i.e., in a genotype in which red light inhibits seed germination, produces a different picture (Table 131.1). Seeds of WT, i.e., MM, show the highest velocity of germination in darkness. Furthermore, only with a delay of several days is a high germination percentage of germinated seeds reached by red- and blue-germinated seeds. In the dark, *phyA* mutant shows a pattern of seed germination similar to wild-type, whereas seed germination of the other phytochrome mutants (*phyB1, phyB2, phyA/phyB1, phyA/phyB2, phyB1/phyB2, phyA/phyB1/phyB2*) is impaired (Table 131.1). Under continuous red light, seed germination velocity of p*hyA, phyA/phyB1,* and *phyA/phyB2* mutants was greater than in wild-type; whereas, those of *phyB2, phyB1, phyB1/phyB2,* and *phyA/phyB1/phyB2* mutants were lower. The fact that only the mutants lacking phyA or phyA in addition to phyB1 or phyB2 show red-light-promoted seed germination in comparison to wild-type, clearly indicates that phyA exerts an antagonistic action toward phyB1 and phyB2, and that phyB2 and phyB1 play major roles in the regulation of tomato seed germination by red light. Under continuous blue light, seed germination of MM is dramatically inhibited in comparison to the dark, by contrast it is promoted in *phyA* and *phyA/phyB1* mutants. These results indicate again an antagonistic action of phyA toward phyB2, the late one appears to have a major role in blue-light-regulated germination of tomato seeds. The fact that continuous far-red light inhibits seed germination in absence of phyA, phyB1, and phyB2 in MM genetic background, clearly indicates that in this cv, the inhibitory effect of continuous far-red does not involve the phyA-mediated HIR but is merely the result of the low photoequilibrium established by this waveband that is below the threshold required for seed germination. Conversely, the fairly good germination in the dark can be ascribed to the substantial levels of dry Pfrs present in dry tomato seeds.

The inhibition of tomato seed germination by far-red light was further studied in *hp-1*, *hp-1/phyA*, and *hp-1/phyB1* mutants.[60] Unfortunately, the genetic backgrounds of these mutants were not reported, making a comparison with the results previously described impossible. Anyway, the analysis of time-dependent effectiveness of far-red light pulse or of continuous far-red light provides the first evidence that an HIR response of phytochrome can be involved in the photoregulation of tomato seed germination. It appears that inhibition of seed germination in *hp-1* mutant of tomato is the result of LFR at an early

stage and of an HIR at a later stage, this one being mediated by phyA. In conclusion, it appears that the phytochrome family of photoreceptors, acting through VLFR, LFR, and HIR, controls tomato seed germination by means of at least four phys (phyA, phyB1, phyB2, and another one phyE or phyF?). PhyA appears to inhibit seed germination by acting antagonistically to phyB1 and phyB2 (Table 131.1), as well by an HIR at a later stage of the germination process. Both phyB1 and phyB2 play crucial roles in sensing red light, and phyB2 has a crucial role in sensing blue light.

Photocontrol of Hypocotyl Elongation Growth

The availability of several photomorphogenic mutants and the use of hypocotyl extension as a model system allowed for a genetic dissection of light sensing in young seedlings of tomato that uncovered many facets of physiological interactions among photoreceptors.[35,36,61–66] For sake of brevity and clarity, we will refer only to selected light conditions.

Continuous Red Light

Inhibition of hypocotyl elongation by low fluence rates of continuous red light is slightly, albeit significantly, reduced in *phyA* mutant, while the loss of phyB1 causes a large and substantial decrease of hypocotyl growth inhibition.[35] No detectable effect of phyB2 is displayed on MM or on a *phyA* background. On the other hand, under red light, a remarkable effect of phyB2 is shown in the absence of phyB1, indicating the presence of partial redundancy between the two phytochromes.[36] When three phytochromes, phyA, phyB1, and phyB2 are absent, the hypocotyl length after several days under different fluence rates of red light is similar to that of WT in the dark.

At first glance, these results could suggest that only the three above-mentioned phytochromes are involved in red-induced inhibition of growth in tomato hypocotyl.[36] A different picture emerges with a different experimental approach that takes into account the fact that in tomato seedlings, blue light is the region of visible light with the strongest effect on hypocotyl elongation; and that activation of blue-light photoreceptors enhances responsiveness to phytochrome.[65] Thus, in an experiment comparing the effects of red and dichromatic red plus blue light in *phyA/phyB1/phyB2* and *phyA/phyB1/phyB2/hp-1* mutants, the data revealed residual phytochrome responses in the *phyA/phyB1/phyB2* triple mutant, suggesting that at least one of the two remaining phytochromes (phyE or phyF) has a role in red-light sensing.[35] In conclusion, as long as red-light-induced inhibition of hypocotyl elongation is concerned, available data indicate that phyB1 and phyB2 mediate the HIR to red light, whereas the small effect of phyA appears to be a multiple LFR independent of the presence of phyB1 and phyB2.

The four mutants in the light signal transduction chains, *hp-1*, *hp-2*, *atv*, and *Ip* showed enhanced inhibition of hypocotyl growth in comparison to WT when grown under continuous red light.[17]

Continuous Far-Red Light

The inhibitory effect of continuous far-red light on hypocotyl elongation was studied in a number of tomato mutants. Under continuous far-red light, the kinetic of hypocotyl growth of *phyB1* mutant is indistinguishable from that of the wild-type, whereas *phyA* and *au* mutants appear to be blind to far-red light (there is no difference in hypocotyl length between *phyA* and *au* seedlings grown in darkness and those grown under continuous far-red light). The obvious conclusion is that phyA is the only phytochrome responsible of the HIR to continuous far-red light. *hp-1, hp-2, atv*, and *Ip* mutants showed enhanced inhibition of hypocotyl growth in comparison to WT when grown under continuous far-red light.[17]

Continuous Blue Light

The effect of continuous blue light on hypocotyl elongation was genetically dissected in tomato by using mutants deficient in phyA, phyB1, and phyB2 and cry 1.[36] From this genetic approach, it appears that it is not possible to obtain reliable evaluation of the contributions of each photoreceptor when single mutants are used. For instance, in previous papers, the kinetics of hypocotyl elongation under blue light showed substantial inhibition of hypocotyl growth in *phyA* and *au* mutants, even though reduced in

comparison to wild-type tomato, whereas the kinetic of hypocotyl growth of *phyB1* mutant was indistinguishable from that of the wild type.[47] These results were only partially confirmed by Weller et al.[36] by using an isogenic series of all mutant combinations among *phyA*, *phyB1*, *phyB2*, and *cry1*. In particular, it was shown that only *phyA* and *cry1* display significant roles in blue-induced inhibition of hypocotyl growth in a WT background. The role of *phyB1* emerges only in the absence of *phyA* and *phyB2*, and furthermore, the effect of *phyB2* is detectable only in the absence of *phyB1*. Phytochrome A and *cry1* act additively to control hypocotyl elongation, and together they are responsible for about 35% of the WT response. Instead, the triple mutant *cry1*/*phyA*/*phyB1* shows a 72% reduction of responsiveness to blue light in comparison to WT. While the quadruple mutant (*cry1*/*phyA*/*phyB1*/*phyB2)* loses totally the responsiveness to monochromatic blue light. Furthermore, the quadruple mutant does not survive long enough to reproduce.

Continuous UV Radiation

The effect of UV radiation on the elongation growth of tomato hypocotyl was characterized by comparing the responses of wild-type and *au* mutant tomato seedlings.[61–63] The experimental evidence provided in several reports suggests different relative roles of phytochrome and of a specific UVB photoreceptor in the UV-induced inhibition of hypocotyl elongation. Both WT and *au* mutant of tomato show similar patterns of the time courses of growth inhibition in response to UV radiation in etiolated as well as in de-etiolated seedlings. UV radiation that includes the UVB part (<320 nm) is the most effective, partial (305 nm cutoff filter) or almost total removal of the UVB band (320 nm filter) produces an intermediate and slower inhibitory effect in the case of a 305 nm filter, while in the presence of a 320 nm filter, a small inhibition of growth was found only in dark-grown hypocotyls. It is worth noting that de-etiolation increases the growth inhibition caused by short UVB radiation, but it decreases inhibition by long (>305 and >320 nm) radiation (by 40 and 90%, respectively). Therefore, it appears that irradiation from sowing time, with yellow light, that establishes a high phytochrome photoequilibrium and does not activate blue-UVA photoreceptors, enhances the UV-dependent inhibition of hypocotyl elongation, probably through a phytochrome-mediated enhancement of responsiveness to signals from UVB photoreceptor. The *au* mutant displays an UVB-mediated inhibition of hypocotyl growth that is usually hidden by the overriding action of phytochrome.[61,62] Therefore, it could be suggested that each of the photoreceptive systems capable of interacting with UVB radiation can acquire a pivotal role in the absence of one another. The presence of one or more photosensors that can substitute for one another is an obvious advantage for the adaptive ability of higher plants.

Photocontrol of Anthocyanins and Flavonoids Accumulation in Tomato Seedlings

Light-dependent anthocyanin synthesis is one of the photomorphogenic responses of tomato seedling that involves action and interaction of several photoreceptors and several modes of action of phytochromes.[63–65] Anthocyanins are absent in dark-grown hypocotyls of tomato, in contrast, significant levels of UV-absorbing compound are present in dark-grown hypocotyls.[65] The involvement of the phytochrome system in light-dependent anthocyanins accumulation was demonstrated by pulse experiments, showing red/far-red reversible and nonreversible responses, involving phyA and phyB1, respectively. The preactivation of blue-light photoreceptors induces a large responsiveness amplification to Pfr,[64] while the preactivation of phytochrome enhances the UVB-induced accumulation of flavonoids.[63] For sake of brevity and clarity, in the next paragraphs, we will refer only to selected light conditions.

Continuous Red Light

In etiolated WT tomato seedlings, the fluence-rate response curve for anthocyanin accumulation with 24 h monochromatic red light shows that is possible to isolate two components: a low fluence rate response (multiple LFR) and a fluence rate-dependent high irradiance response (HIR).[35,36] *Phy A* mutant shows only the R-HIR component and lacks the LFR response to red light. On the contrary, *phyB1* mutant lacks the R-HIR component. Etiolated *phyA phyB1* mutant lacks any detectable response. The absence

of phyB2 does not significantly affect the accumulation of anthocyanins.[36] Obviously, from these results, it is concluded that phyA mediates the LFR to red light, whereas phyB1 mediates the R-HIR. These conclusions were further supported by results obtained with a transgenic tomato line overexpressing the oat *PHYA3* gene.[55]

On the other hand, the results and the consequent attribution of distinct roles to specific phytochromes is completely different, if the seedlings are germinated and grown for several days under continuous red light.[36] The anthocyanin content of 12-day-old tomato hypocotyl is maximal in *phyA* mutant and low when phyB1 is absent alone or in combination with the absence of phyA and phyB2. Even in the absence of phyA and phyB2, the accumulation of anthocyanin is increased in comparison to WT. These results imply an antagonistic action of phyA toward phyB1 and a crucial promoting role of phyB1 on anthocyanin accumulation. The results obtained when phyB2 is absent, alone, or in combination with phyA or phyB1, confirm the negligible contribution of phyB2 under red light.

Continuous Far-Red Light

The dose response curves for anthocyanin accumulation under 24 h monochromatic far-red light, 708 and 728 nm, are similar in WT and *phyB1/phyB2* double mutant. Etiolated hypocotyls of *phyA* and *phyA/phyB1* mutants do not accumulate anthocyanins under a wide range of far-red light irradiance, confirming the need for phyA in FR-HIR mediated responses.[36]

Continuous Blue Light

The synthesis of anthocyanins in etiolated hypocotyl of tomato in response to 24 h irradiation with 10 μmol m^{-2} s^{-1} blue appears to be under the almost total control of phyA and cry1. In the double mutant *phyA/cry1*, there is a reduction of about 95% in anthocyanin accumulation in comparison to WT.[36] The two photoreceptors act additively but at different irradiance ranges: between 0.001 and 3 μmol m^{-2} s^{-1} phyA is the functional photoreceptor, whereas *cry1* is active at irradiances above 3 μmol m^{-2} s^{-1}, thus, providing tomato plants with a wide range of sensitivity to blue light. The effect of *phyB1* is small, and it is manifested only at high irradiances. The effect of *phyB2* is negligible on WT background, but it becomes substantial at high irradiance, when *phyA/phyB1* and *phyA/phyB1/phyB2* mutants are compared. In the quadruple mutant *phyA/phyB1/phyB2/cry1*, there is no measurable synthesis of anthocyanin in response to blue light.[36]

Continuous UV Radiation

The effect of UV radiation on the production of anthocyanins and UV-absorbing compounds was characterized in etiolated hypocotyls of wild-type and *au* mutant tomato seedlings.[65] Only prolonged exposures to UV radiation induce low but detectable levels of anthocyanins in the *au* mutant and large accumulation of the pigments in WT. Further to this, the differences in the time courses of UV-induced accumulation of anthocyanins and UV-absorbing compounds (putatively flavonoids and phenolic acids) indicate that different photoregulatory mechanisms are involved for each of these two groups of pigments.

The dramatic difference found between the wild-type and the *au* mutant strongly indicates the involvement of phytochromes as functional photoreceptors for the photoinduction of anthocyanin accumulation in tomato hypocotyls. The UVB photoreceptor could only marginally replace the action of phytochrome (as far as anthocyanin accumulation is concerned) when the functional phytochrome pool is missing, as in the *au* mutant. The general picture of UV-mediated induction of UV-absorbing compounds shows only one macroscopic difference between wild-type and the *au* mutant of tomato: the higher initial level (in darkness) of these compounds in the wild-type in comparison to the *au* mutant. There is substantial UV-induced accumulation of UV-absorbing compounds in both genotypes, and the largest increment is displayed by *au* mutant, even though the levels in the *au* mutant never reach those of the WT under the same UV exposure. Therefore, the fact that an UVB-absorbing photoreceptor is able to establish high responsiveness for the UV-induced flavonoid accumulation, even in the absence of three phytochromes, i.e., in the *au* mutant, strongly indicate that a UVB photoreceptor plays a crucial role in the photoregulation of UV-absorbing compound accumulation. It appears that in WT hypocotyls,

several photosensors could be involved, while in the *au* mutant, the massive accumulation of UV-absorbing compounds is mediated mainly by a UVB photoreceptor, and the absence of functional phytochromes determines an increase of the effectiveness of UVB photoreceptor.

Tomato seedlings de-etiolated under monochromatic yellow light showed a significant enhancement of shorter UVB wavelength efficiency in production of UV-absorbing compounds in *au* mutant and WT.[63] Irradiation from sowing time, with yellow light, which establishes a high phytochrome photoequilibrium, shortens the apparent lag phase and increases the rate of pigment accumulation, probably through a phytochrome-mediated increase of responsiveness to UVB radiation. The fact that de-etiolated seedlings show faster and enhanced responses, mainly to the shorter wavelengths and, therefore, to the potentially most damaging UV radiation, indicates that the interaction between phytochrome and UVB photoreceptor may have crucial adaptive functions.

Photocontrol of Nuclear Structure of Tomato Hypocotyl

Etiolated hypocotyl of 4-day-old tomato seedlings of WT and *au* mutant of tomato, show different frequencies of chromosome endoreduplication.[66] The cultivar UC-105 (WT) presents a mean cell ploidy level lower than *au*. This could be due to the phytochrome content in the seed, which is very low in the *au* mutant compared to WT, cv. UC-105. It was shown that dry tomato seeds contain physiological levels of phytochrome, and seeds germinating in the dark show 40% of phytochrome in the active Pfr form.[41] Thus, active Pfr in the seed might prevent chromosome endoreduplication during the first phases of germination.

Exposures of 4-day-old tomato seedlings, WT and *au* mutant, to UV or white light influence chromosome endoreduplication and chromatin conformation differently in the two genotypes.[66] A 3 h white light treatment has no effect on the mean ploidy level in the WT, but it increased the ploidy level in the *au* mutant. Therefore, it may be concluded that in the WT, fluorescent white light (mainly blue + red wavebands) has no effect on ploidy levels because of antagonistic effects of different photoreceptors (phytochromes and blue photoreceptors). In fact, in the *au* mutant (which at seedling stage has undetectable phytochrome levels), white light induces higher ploidy levels than darkness, probably because of the action of blue-light photoreceptors, which in this mutant are not opposed by phytochrome. Only in the WT, compared to darkness or white light, are higher ploidy levels induced after exposure to UV for 3 h. The fact that in the *au* mutant UV radiation induces the same chromosome endoreduplication as white light, indicates that the UV effect may be due again to the action of cryptochromes, which are activated by the blue-UVA energy emitted by the UV source or by the action of a specific UVB photoreceptor. White light and UV transiently increased heterochromatin amounts only in the diploid nuclei of WT. It is, therefore, suggested that this response is mediated by phytochrome, because it is lacking in the *au* mutant.

Photocontrol of Regenerative Capability from Tomato Hypocotyl

In tomato hypocotyl, the transition from a genetically totipotent vascular parenchyma cell to different stages of a committed cell, and the subsequent ontogeny of an adventitious shoot, involves developmental events with a molecular nature that is still mostly unknown.[67] Formation of adventitious buds from hypocotyl segments occurs in hormone-free medium, and light is essential during the *in vitro* culture. Hormones added to the growing medium cannot overcome the need for light of hypocotyl explants.[67–70] In tomato hypocotyl, the frequency of shoot formation depends also on light conditions during seedling growth preceding the *in vitro* culture and on the cell's position along the hypocotyl.[70] Light-dependent acquisition of competence is acquired before the transfer of explants *in vitro*. The comparison of the photoregulation of *in vitro* shoot formation from excised hypocotyl of *phyA* and *phyB1* mutants of tomato and their wild-type indicates that the light-dependent acquisition of competence for shoot regeneration in tomato hypocotyl is controlled only by the phytochrome system, and it is mediated at least by two distinct phytochrome species: phyB1 and phyA.[70] The action of phyB1 during seedling growth appears

to be essential, and the lower regenerative capability of middle and basal explants of tomato hypocotyl appears to correlate with phyB1 levels. Furthermore, it appears that phyA and phyB1 are not necessary for LFR- and VLFR-induced acquisition of competence in apical segments of hypocotyl, whereas they are essential for the VLFR of middle and basal segments.[18] The blue-light induction of competence for shoot regeneration does not appear to involve the cryptochrome family, rather it appears to be mediated by the phytochrome system as well. A network of photoreceptor interactions coupled to the effects of the wounds, made to separate the hypocotyl segment hypocotyl, plays a pivotal role in the acquisition of competence for shoot formation and, subsequently, on the expression of this developmental potential.

Photocontrol of Stem Elongation of Green Mature Tomato Plants

The kinetics of stem elongation of 3- to 4-week-old tomato plants were studied by using linear voltage transducers connected to personal computers.[71–73] Thanks to the high sensitivity of the transducers, it was possible to characterize accurately and for several days the time courses of light-induced changes of stem growth in the same tomato plant by measuring: very fast growth responses (in the order of a few minutes); very slow responses (in the order of hours and days); short- and long-lasting responses; and the specific light effects on the different growth phases occurring in the presence of light and in darkness during the daily cycle.

Kinetics of Stem Elongation under 12 h White Light/12 h Dark Cycles

The analysis of short- and long-term stem elongation responses of WT and *au* mutant tomato plants to different photosynthetically active radiation (PAR) provided novel information about stem elongation, even in light conditions similar to those found in the greenhouse by tomato crops.[71] WT plants display PAR-dependent (in the range of 100 to 800 μmol $m^{-2}s^{-1}$) inhibition of growth during the day and during the night. In contrast, the *au* mutant shows a fluence-rate-dependent promotion of growth during the dark periods, in the range of 10 to 400 μmol $m^{-2}s^{-1}$. Large, fast, and opposite changes in stem elongation rate at the light–dark and dark–light transitions are present in both genotypes. The internode elongation rate in the first half of the night is always modest in WT tomato, whereas it increases rapidly in the *au* mutant. Stem elongation rate of WT starts to increase after about 6 h in darkness, showing the typical time course of escape from Pfr-mediated inhibition of elongation by an end-of-day response. Measurements of leaf gas exchange parameters showed no significant differences in all the photosynthetic quantities between WT and *au* mutant, in the range between 100 and 800 μmol $m^{-2}s^{-1}$ PAR. However, PAR levels influence the stem elongation of the two genotypes differently. Even though an adequate photosynthetic level plays a central role in stem growth, the similar photosynthetic behavior of the WT and *au* mutant suggests that photomorphogenic responses are responsible for the differences between the two genotypes. The fluence-rate-dependent inhibition of stem growth is absent in *au* mutant plants also at fluence rates of white light as high as 800 μmol $m^{-2}s^{-1}$. The absence or reduction of fluence-rate-dependent inhibition of stem growth in light-grown and etiolated *au* mutants strongly suggests that phytochrome is one of the functional photoreceptors sensing light quantity in etiolated and in green plants.[71] The PAR-dependent reduction of internode growth displayed during the dark periods by WT tomato is totally absent in the *au* mutant and is, therefore, likely regulated by some of the lacking phytochromes. It appears, therefore, that the fluence-rate-dependent inhibition of stem elongation found in WT plants during the dark period could be the result of an HIR-induced increase in effectiveness of end-of-day response of phytochrome. The fluence-rate-dependent inhibition of elongation in the WT during the light periods might be due to an HIR response that is overriding the promotion of growth induced by the large pool of photosynthates available for stem growth. No PAR-dependent inhibition of elongation was found in the mutant, even at a fluence rate as high as 800 μmol $m^{-2}s^{-1}$. If we take into account that the light-grown *au* mutant contains 60% of the phytochrome found in the WT,[48] and if a direct relationships exists between concentration of phytochrome and extent of the response, the effect of irradiations with 800 μmol $m^{-2}s^{-1}$ on *au* mutant should be similar to that of 480 μmol $m^{-2}s^{-1}$ on WT.

The results presented by Bertram and Lercari[71] show that dose-response curves differ significantly from that expected from these calculations. Therefore, the difference between the two genotypes cannot be explained only on the basis of phytochrome content. Rather, they suggest that the *au* mutant is lacking the fluence-rate-dependent response not because it has a lower concentration of phytochrome, but because it is missing the phytochrome type involved in sensing light quantity. On the other hand, if all functional photoreceptors for the regulation of stem growth were missing in the *au* mutant, one should expect larger growth with higher PAR also during the light period, but this is not the case. Therefore, besides phytochrome, even the blue-light-absorbing photoreceptor is involved in the fluence-rate-dependent photoregulation of stem growth of tomato during the light period.

Kinetics of Stem Elongation following Transfer in Continuous Darkness

Substantial differences in stem growth of green tomato plants transferred to continuous darkness were displayed by different genotypes, showing the decreasing order: *phyB1* > WT = *phyA* > *au* > *hp1*.[73] The differences of stem growth in darkness are due to two factors: the different stem elongation rate and the different duration of the growing phase among the genotypes. In darkness, the stem growth of *au* and *hp1* mutants lasted for about 18 h, whereas it continued for the whole experimental period (36 h) in the other genotypes.

Kinetics of Stem Elongation under Continuous UV Radiation

The UVB irradiation drastically reduced stem growth of 21-day-old tomato plants (4.5 μmol $m^{-2}s^{-1}$ being more effective than 0.1 μmol $m^{-2}s^{-1}$).[73] Both irradiances of UVB induced a detectable reduction of SER after 15 min of irradiation. *PhyA*, *phyB1*, and WT tomato showed similar UVB-induced inhibition of growth, confirming the previous conclusion that UVB-induced inhibition of stem growth in tomato is not mediated by phytochrome.[61,62] Consistent with the above-mentioned results, the *hp1* mutant showed responsiveness to UVB similar to that shown by WT, *phyA*, and *phyB1* mutants.[73] The *au* mutant showed the highest UVB-induced growth inhibition during the 12 h of irradiation with both fluence rates, further confirming that UVB-induced inhibition of stem growth in tomato does not involve phytochrome. The results of dichromatic irradiations UVB + red or UVB + far-red indicate the presence of an addictive effect of UVB photoreceptor and the phytochrome system.

Phytochrome and Tomato Fruit Ripening

Already in 1954, Piringer and Heinze[74] showed that harvested mature-green tomato fruits accumulate a yellow pigment (putatively flavonoids) following a daily exposure of a few minutes to red light. The promoting effect of red-light pulse was almost completely reversed by a following irradiation with far-red light, which is classical evidence for a LFR of phytochrome. The promoting role of the phytochrome system was further supported by a genetic dissection. The *hp1* mutant showed a 13-fold increase in quercetin accumulation in comparison to WT.[53] A comparison of flavonoids content in WT (Money Maker), phyA, phyB1, and *au* mutants grown in a glasshouse, showed the following decreasing order: MM > phyA > phyB1 > *au* (Lercari unpublished data). These different amounts of total flavonoids are resultant of the differences in the patterns of accumulation of distinct molecular species: rutin is the main flavonoid found in MM and phyA, whereas naringenin is the one most present in phyB1 and *au*. The concentration of rutin and quercetin followed the same order: MM > phyA > phyB1 > *au*, whereas narigenin showed the opposite order: *au* > phyB1 > phyA > MM (Lercari, unpublished results). It appears, therefore, that distinct phytochromes can control the accumulation of different flavonoids in tomato fruits.

The fruit of the mutant *hp1* contains enhanced levels of carotenoids and sucrose in comparison to wild-type. Alba et al.[75] demonstrated that fruit-localized phytochromes control lycopene accumulation in tomato pericarp during fruit ripening but do not regulate ethylene biosynthesis and many other aspects of fruit ripening in tomato. Their obvious conclusion was that fruit-localized phytochromes are not global regulators of tomato fruit ripening.

131.5 Conclusions

From the few examples presented in this review and from many other data present in the pertinent literature, it appears that different phytochromes can have distinct functions, and that they act additively or antagonistically toward each other according to their localization in the cell, to cell position in the plant, to the moment of the day, to previous plant history, and to present environmental conditions. Furthermore, it is well established that in tomato, blue light substantially influences the effectiveness of phytochrome-dependent responses. On the other hand, light, acting through phytochrome, enhances the responsiveness of tomato cells to UVB photoreceptor signals. Therefore, by using mutants, which are supposed to provide a simplified experimental system, because they lack one or more component of light signaling, a complex web of signaling networks, which provide tomato plants and likely all the other green plants with an enormous flux of information about the surrounding environment, was unraveled. The continuous input of information-producing signals moving in the signaling web allows for continuous and fine-tuning of plant growth and development. The interacting genes and gene products, creating a complex but flexible, unstable network interposed between the unitary genetic element and the phenotype (epistasis, polygenic, and pleiotropic effects) are integrated with networks that transduce a plethora of internal and external signals.[76] The identification and characterization of "check points" of signal fluxes will probably provide new insight on the mechanisms controlling plant growth and development.

Acknowledgments

We are most grateful to R.E. Kendrick for providing most of the seeds of mutants discussed in this chapter. We appreciate the copyright permission granted from the American Society for Photobiology for the paper.[71]

Phototropism

132.1 Introduction

Plants and fungi are capable of directing their growth toward or away from light. The phenomenon of oriented plant growth, including phototropism, has been known for centuries, if not millennia. Common people as well as great luminaries from the sciences and arts commented about it or made it the subject of elaborate investigations. Theophrastos (372 to 287 BC), a pupil of Aristotle and acknowledged founder of botany, reported on this and related phenomena, such as leave movements in his volumes, *Inquiry into Plants* and *Growth of Plants*. One may safely conclude that astute observers as the Arabian scientist Hanifa Ad-Dinawari (d. 895 AD) and Albertus Magnus (1200 to 1280), both of whom described the nyktinastic movements of leaves and petals,[1] were also aware of phototropism without explicitly describing it. The well-known sun tracking of sunflowers was mentioned by the French playwright, Jean-Baptiste Molière (1622 to 1673), in his play "Le malade imaginaire."[2]

Altar paintings of the 15th and 16th century are a rich source of plant pictures. While most of these paintings are sufficiently precise to allow their identification, very few, alas, depict the physiological properties of plants. The cathedral of Ghent houses the painting "The adoration of the lamb" (about 1430) by the brothers Hubert and Jan Eyck, in which several inflorescences of the Salomon's seal (*Polygonatum odoratum*) show clear phototropic orientation. The most impressive display of phototropisms of various flowers and shrubs can be found in the painting "Madonna in the grotto" (Louvre, Paris) by Leonardo da Vinci (1452 to 1519). The depicted setting, which is rich in shaded and bright areas including sunflecks, clearly provides the asymmetric illumination required for phototropic bending. That the depicted growth pattern is not accidental is further proven by the fact that Leonardo comments in one of his scientific diaries on the light-seeking and directed growth of tree branches.

Systematic studies of phototropism appear with the beginning of the 19th century. As early as 1817, the Italian Poggioli succeeded in showing that seedlings of *Brassica* and *Raphanus* bend more effectively to blue than to red light.[2] His study represents the first attempt to generate a crude action spectrum. Early investigators were greatly influenced by the developments in physics and photochemistry. Wiesner, who was among the first to use a clinostat and who wrote probably the first long treatise on phototropism,[3] emphasized that the photochemical processes in the plant should obey, in principle, the same physicochemical laws that were described by Bunsen and Roscoe for photochemical reactions of the gases Cl_2 and H_2.[3] Particularly the Bunsen–Roscoe law of reciprocity, which was originally described for the photochemical reactions occurring upon exposure of camera films, had a great impact on the early and later physiologists and is one major reason why investigations of dose-response relationships are usually performed with pulse stimuli rather than with long-term irradiations. In 1878, Vines published the first study on the phototropism of a single-celled organism, the zygomycete *Phycomyces*,[3] after Wilhelm Hoffmeister mentioned in 1867 the phenomenon in his textbook *Die Pflanzenzelle*. The most famous and still quoted work of this period is, however, the book by Charles and Francis Darwin from 1880, *The Power of Movement in Plants*, which includes numerous classic observations including the tip light sensitivity of grass coleoptiles and the distinction between signal perception and signal transduction.

With the discovery of auxins in the 1920s, the field was largely dominated by biochemical and physiological analyses of this growth regulator. The systematic application of action spectroscopy during the second half of the 20th century led to the recognition that phototropisms as well as numerous reactions of photomorphogenesis are controlled by one or more ubiquitous blue-light photoreceptors, since 1980 often called cryptochromes. For several of these investigators, phototropism has been mainly a tool rather than the prime motivation for hunting the then-elusive blue-light receptors. With the isolation of Cryptochrome 1 in 1993 by Ahmad and Cashmore[4] and of phototropin in 1998 by Briggs and associates,[5] rapid advances were made in the blue-light field, which has become amenable to detailed photophysical analysis at the molecular and atomic levels.

Major treatises on phototropism are available for every decade of the past 100 years, so that interested readers can easily get access to historical aspects.[2,6,7] The reviews by du Buy and Nuernbergk[3] cover *in extenso* the literature of the 20th, 19th, and even earlier centuries. The most recent and detailed treatise on phototropism is that by Iino.[8]

132.2 Relation between Phototropism and Growth

Phototropism of Bowing Organisms Requires the Differential Modulation of Growth Rates

Phototropism, the directed growth toward or away from the light source, can be caused by bulging or by bowing (bending). Bulging is typical for moss and fern protonemata, which reorient the apical growth point in response to unilateral light in such a way that the axis of the cells is aligned to the light beam. No differential growth rates of the cell walls are required in this case. Bowing or bending is typical for multicellular organs, such as seedlings, grass coleoptiles, roots, and macromycete fungi, as well as single-celled sporangiophores of the zygomycete fungi, *Phycomyces* and *Pilobolus*. In these organisms, phototropism is caused by differential growth rates of the organ sides proximal and distal to the light source. During bending, the growth rate of the proximal side can be retarded, while the distal side is accelerated relative to the time prior to unilateral irradiation. Such a symmetric redistribution of growth rates was observed for *Zea* coleoptiles, *Pisum* epicotyls, and for sporangiophores of *Phycomyces.*[6,7,9,10] For phototropism to occur, however, it is sufficient if the growth rate of only one side is modulated. For example, when *Avena* coleoptiles are irradiated continuously from one side, then the growth of the proximal side can be arrested completely, while the distal side continues to elongate with the same growth rate.[6,7]

Light-Growth and Dark-Growth Responses: The Phototropism Paradox

Phototropism is related to the so-called light-growth and dark-growth responses that represent transient modulations of the growth rates in response to symmetric or even asymmetric changes of irradiance. In *Avena* coleoptiles, a step up of the fluence rate causes a transient diminution of the growth rate that lasts about 40 min.[10] In *Phycomyces*, a step up of the irradiance elicits a transient increase of the growth rate that subsides after some 40 min.[9,10] A step down of the fluence rate causes in grass coleoptiles a transient increase and in *Phycomyces* a transient decrease of the growth rate.[9,10] The described transient growth responses are not related to the well-known light-induced growth inhibition of hypocotyl growth, which is a nonadaptive response and is not related to phototropism. One can, for example, kinetically separate the phototropism of *Cumumis* seedlings from the blue-light-induced inhibition of stem elongation.[10]

Mutants that affect the phototropism of *Phycomyces* affect, at the same time, the light- and dark-growth responses.[9] The growth responses are thus mechanistically related to phototropism. A fundamental difference between the two responses is that the growth responses are adaptive, while the phototropism is not. With special mechanical devices such as a tropostat,[9] the phototropism can be maintained almost indefinitely, showing that the redistribution of growth rates is nonadaptive. The phototropism paradox appears to hold for all phototropic organisms. The solution of the paradox requires the postulate of "cross-talk" between the proximal and distal sides of the bending organ. Localized autonomous growth reactions cannot possibly explain phototropism, because bending would subside due to the adaptive properties of the growth reactions.

132.3 Perception of Light Direction

Phototropism Requires Spatial Irradiance Differences

A prerequisite for the establishment of differential growth rates is an internal asymmetry of irradiance inside the bending organ. For opaque plant organs like hypocotyls or grass coleoptiles, the proximal side receives a higher irradiance than the distal one. The opaqueness of the material generates a light gradient that translates into differential growth rates. Carotenoids, which contribute to the opaqueness of *Zea* coleoptiles, cause a steeper light gradient and increase, at the same time, the phototropic responsiveness but not, however, the absolute sensitivity.[7,10] It is immaterial how the irradiance difference is generated. One can, for example, irradiate *Avena* coleoptiles with light guides from inside or irradiate only one half

of the organ from above.[2,6–8] Split-field irradiation with filaments of *Vaucheria geminata* yielded similar results, because the filaments always bend to the side of the irradiated area.[2] These experiments demonstrate that the bending organs sense the irradiance difference between the irradiated and the shaded side rather than sense the direction of the light source.

In the transparent sporangiophore of *Phycomyces*, the irradiance difference is caused by its lens property that leads to focusing of unilateral light in a bright band on the distal side. The elevated irradiance in the focal band is responsible for the elevated growth rate at the distal side, causing positive phototropism.[9] Lens effects that are relevant for phototropism also occur in other hyaline cells, such as in chloronemata of ferns and mosses.

The minimal difference of two opposed light sources that can induce bending is called the discrimination threshold. For *Phycomyces*, it is near 8%, while *Avena* coleoptiles can resolve a fluence difference of some 3 to 4%.[10]

Resultant Law

When a phototropic organism is irradiated asymmetrically with two light sources of equal intensity, it bends in a plane bisecting the angle that is formed by the organism and the light sources (Resultantengesetz, resultant law).[3] The zygomycete fungus, *Pilobolus*, is violating this law in that it bends to either one or the other light source, if they form an angle with the sporangiophore that is steeper than 7°.[3]

Polarotropism

Chloronemata of some algae, mosses, and ferns are able to react to plane polarized light. The organisms, which are typically cultured on an agar plate, are irradiated with polarized light from "above," i.e., in a plane perpendicular to the plane of growth. The chloronemata grow perpendicular to the plane of the electric vector of the incident polarized light. Rhizoids of *Dryopteris* grow, however, parallel to it.[2,6] The behavior is explained by the assumption that the photoreceptor is dichroic and localized in the plasmalemma. Depending on the orientation of the electrical vector, an asymmetric distribution of excited photoreceptors (phytochrome) is generated, which in turn, causes a reorientation of the growing tip. The polarotropism of chloronemata represents a special case in that an internal irradiance difference is absent. There is evidence that the photoreceptors of *Phycomyces* are also dichroically oriented.[2,10] In this organism, an internal irradiance asymmetry is, however, prerequisite for phototropic bending.

132.4 Perception of Temporal Irradiance Changes

Visual Range and Temporal Irradiance Changes

In nature, plants and fungi bend in an environment that is continuously changing with respect to irradiance. The internal spatial irradiance differences have, therefore, to be perceived on a fluctuating background. The organism must thus possess a mechanism that adjusts the prevailing sensitivity to the changing background irradiances (range adjustment). The visual range of phototropic organisms is enormous and can cover, as in the case of *Phycomyces*, more than 10 orders of magnitude (see below and Figure 132.2). The capacity for range adjustment is ascribed to sensory adaptation.[11,12] The status of the sensory adaptation (level of adaptation; can be inferred from the prevailing sensitivity that is defined as the reciprocal of the prevailing threshold, or from the phototropic latency, which is discussed below). The molecular mechanisms of sensory adaptation in plants and fungi are practically unknown. Mutant analysis in *Phycomyces* indicates that at least part of the sensory adaptation is processed at the level of the photoreceptor.[11,12]

Phototropic Latency

For dark-adapted organisms, the phototropic latency, i.e., the time that elapses between the onset of the unilateral light pulse and the first observable bending, depends over a wide range on the logarithm of

the fluence. This relationship was investigated for *Phycomyces* and *Avena* coleoptiles.[10] When the pre-adapting light and the unilateral stimulus light are of equal fluence rate, then the lag time is about 4 to 6 min for *Phycomyces*, the exact value depending also on the intensity range and wavelength.[9,11] For *Vaucheria*, the latency is about 1 to 2 min.[2]

Phototropic Dark and Light Adaptation

Beside the fluence of the actinic light, the phototropic latency largely depends on the light pretreatment prior to light stimulus. The light pretreatment determines the status of sensory adaptation, and the phototropic latency can be used to determine the level of adaptation. Protocols for the measurement of the so-called dark-adaptation kinetics employ basically the following treatment: the organisms are irradiated for a "long" time omnilaterally with blue light and are then exposed to unilateral light of variable irradiances of lower fluence rate than the adapting light (step down). The phototropic latency increases with the logarithm of the magnitude of the step down. When the fluence rate of the unilateral light that elicits phototropism is plotted versus the duration of the phototropic latency, one can reconstruct the kinetics of dark adaptation. *Phycomyces*, *Avena*, and *Zea* display for this type of protocol biexponential decay kinetics.[9,11,12]

Protocols for the measurement of light-adaptation kinetics that are based on the measurement of phototropic latencies are elaborate. These kinetics are much faster than the corresponding dark-adaptation kinetics. A characteristic feature of the kinetics for large steps up of the fluence rate is the fact that the level of adaptation appears to overshoot the actual fluence rate, a property that holds true for *Phycomyces* as well as for *Avena* coleoptiles.[10,11] For oat seedlings, there is evidence that the processes that entail sensory adaptation are related to the phosphorylation of the putative photoreceptor.[13]

132.5 Dependence on Irradiance

The irradiance dependence for phototropism can be tested with light pulses or with continuous irradiation. Phototropism was investigated mostly by employing pulses of unilateral light. Only few data exist for phototropism elicited by continuous irradiation. Long-term irradiation is more relevant to the irradiance conditions and responses prevailing in nature. On the other side, irradiation with light pulses has certain analytic advantages and is thus prevalent in the requisite literature.

Pulse-Induced Phototropism: Fluence-Response Curves

Fluence-response curves for the phototropism of grass coleoptiles are complex [Figure 132.1(A)]. For *Avena* coleoptiles, one can distinguish three distinct response types (nomenclature of Iino[7,8]): the first pulse-induced positive phototropism (fPIPP) (called first positive phototropism in the older literature), a pulse-induced negative phototropism (PINP), and the second pulse-induced positive phototropism (sPIPP) (second positive phototropism in the older literature). Provided the fluences are delivered in pulses of short duration (1 to 30 s), then reciprocity holds for the entire range, i.e., 10^{-3} to 10^{4} μmol m^{-2}, including thus fPIPP, sPIPP, and PINP.[7,8] Reciprocity holds for the fPIPP, i.e., the response depends on the product of fluence rate times pulse duration [Figure 132.1(B)].[7,8,14] In contrast, PINP and sPIPP are greatly dependent on the duration of the irradiation. Reciprocity breaks down when the duration of the pulses exceeds a critical duration (above 30 s). In this case, the response becomes greatly time dependent, i.e., long irradiations of low fluences elicit greater bending angles than short irradiations of elevated fluences [Figure 132.1(B)]. This behavior is called time-dependent phototropism (TDP),[7,8] and it corresponds to the "second positive curvature," a term used by earlier authors.[14]

A time-limiting step is responsible for the optimum curve of the fPIPP. When the fluence eliciting the fPIPP of *Arabidopsis* or of *Avena* coleoptiles is delivered by a sequence of small individual pulses instead of a large single one, the response can be substantially increased.[6–8] The response thus depends not only on the number of absorbed quanta but also on the time interval between the individual pulses. The PINP

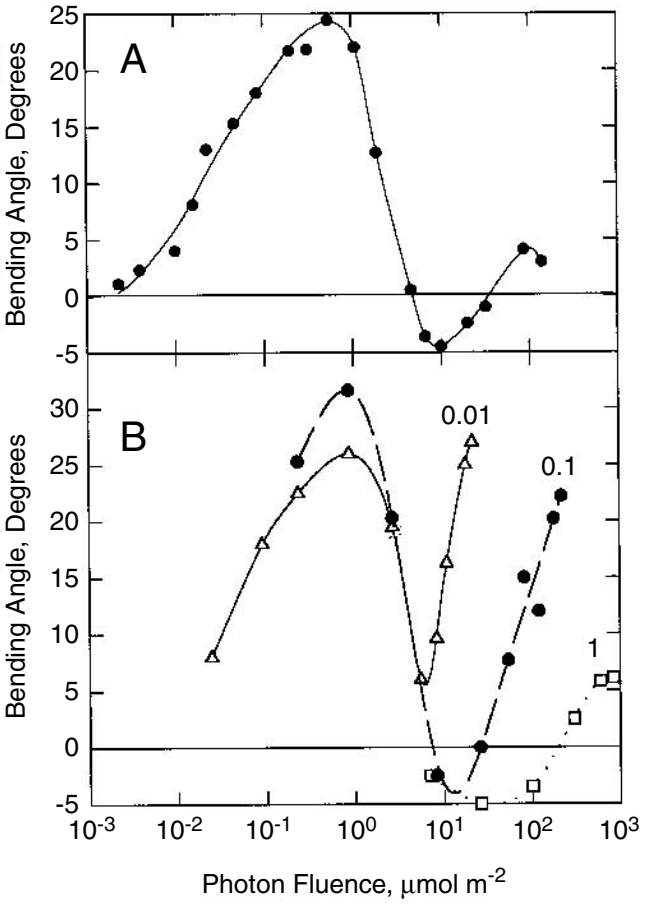

FIGURE 132.1 Photon fluence-response curves for phototropic bending of *Avena* coleoptiles. (A) Coleoptiles were irradiated unilaterally with a blue-light pulse (458 nm) of constant duration (30 s) and variable photon-fluence rates.[14] (B) Irradiation with constant photon-fluence rates (0.01, 0.1, and 1 μmol m^{-2} s^{-1}) and variable pulse duration.[8] Bending angles were measured 2 h after the unilateral light pulse.

is characteristic for *Avena* and is absent for *Zea* coleoptiles. It was, however, observed even in *Phycomyces*[10] and *Vaucheria*.[2,7,8]

Numerous phototropic organisms display fluence-response relationships that are similar to those of grass coleoptiles. These include various monocots and dicots, *Phycomyces*, *Pilobolus*, *Arabidopsis*, *Vaucheria*, and chloronemata of the fern Dryopteris.[2,6–8,10] The fluence-response curves for the phototropism of *Raphanus* seedlings appear less typical in that a classical bell-shaped curve for the first positive phototropism is absent. Kinetic models for the complex dose-response relationships were proposed by several authors.[7,8]

Pulse-Induced Phototropism: Dependence on Adaptation

A preirradiation with a strong pulse of blue light desensitizes transiently *Avena* coleoptiles and causes a shift of the entire bell-shaped fluence-response curve for fPIPP.[7,8] In *Zea* coleoptiles, preirradiation reduces mainly the phototropic responsivity, not however, the absolute threshold. After about 120 min in darkness, the responsivity recovers, and the original bell-shaped curve for the fPIPP is reestablished, indicating that the full sensitivity has recovered.[7,8,11,12] Earlier authors who worked with a sequence of strong conditioning pulses and subsequent unilateral pulses of lesser irradiance similarly found evidence for

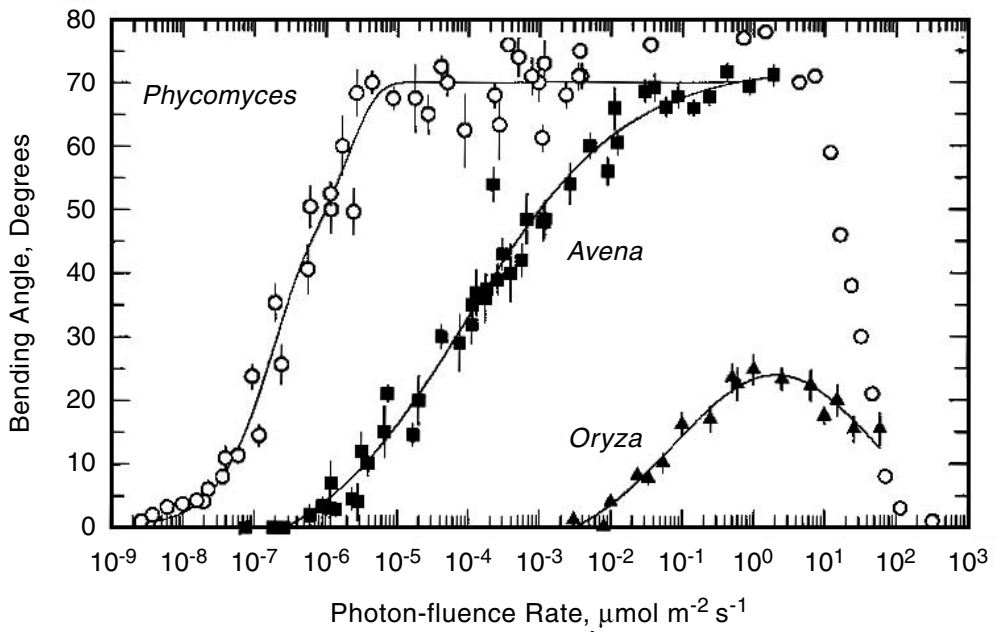

FIGURE 132.2 Photon-fluence rate-response curves for photogravitropic equilibrium. Sporangiophores of *Phycomyces*: unilateral irradiation for 8 h (465 nm)[21]; above 10^{-2} µmol m^{-2} s^{-1}: irradiation for 6 h with broad-band blue light.[22] Coleoptiles of *Avena*: unilateral irradiation for 8 h (465 nm).[20] Coleoptiles of *Oryza*: unilateral irradiation for 5 h with broad-band blue light.[17]

sensitivity recovery in darkness. Such results were obtained with *Avena* and *Zea* coleoptiles, hypocotyls of *Arabidopsis*, and sporangiophores of *Pilobolus.*[7,8,11,12] The desensitizations caused by blue and red light (132.5.3) are mediated by different photoreceptor systems and are distinguished kinetically.

Pulse-Induced Phototropism: Effect of Red Light, Phytochrome

A pretreatment of dark-grown *Avena* or *Zea* coleoptiles with red light exerts a dual effect on fPIPP: it raises the threshold of fluence-response curves; in fact, the entire curve with the ascending and descending arms of the fPIPP is shifted to elevated fluences, and it slightly increases the maximal bending angle[2,6–8].

Red light is thus desensitizing the coleoptiles to subsequent irradiation (rise of threshold) while it enhances the responsiveness (rise of bending angle). The effect requires low fluences and is probably mediated by phytochrome and represent a "very low-fluence response" that can be elicited also with far-red light. An action spectrum for the enhancement of responsiveness made with *Arabidopsis* indicates phytochrome as photoreceptor.[7,8] The effect is mediated mainly by the Pr-form of PhyA. However, PhyB also plays a role when PhyA is absent.[15]

Continuous Irradiation: Fluence-Rate-Response Curves

Continuous unilateral irradiation establishes a photogravitropic equilibrium, in which the two stimuli, light and gravity, balance each other (132.6.2). *Avena* coleoptiles[16] and sporangiophores of *Phycomyces*[9,10] that were irradiated unilaterally for 7 to 8 h show fluence-rate-response curves that can be fitted to raising exponential or hyperbolic functions. For blue light, the threshold values for *Avena* is near 3×10^{-7} and that of *Phycomyces* near 3×10^{-9} µmol m^{-2} s^{-1} (Figure 132.2). For both organisms, maximal bending angles of 70 to 75° are reached. Coleoptiles of *Oryza* possess a threshold near 5×10^{-3} µmol m^{-2} s^{-1} and moderate bending angles of some 25°[17] (Figure 132.2). Fluence-rate-response curves such as those shown in Figure 132.2 are characterized by a low-irradiance threshold and a high-irradiance threshold. At low

fluence rates, the number of hit photoreceptors is limiting; at very high fluence rates, the photoreceptors at the proximal and distal sides are hit at the same rate, and differential growth, i.e., bending, is thus rendered impossible.

Continuous Irradiation: Dependence on Adaptation

Dark adaptation greatly affects the shape of fluence-rate-response curves of phototropism of light-grown *Avena* coleoptiles that are exposed for 2 h to unilateral blue light. With extending periods of darkness prior to unilateral irradiation, the threshold drops exponentially, and the maximal bending angle increases concomitantly. Darkness thus sensitizes (drop of threshold) and enhances the responsiveness (increase of bending angle).[16] The same behaviors are also found for *Phycomyces* (Galland, unpublished).

132.6 Interaction between Gravitropism and Phototropism

In nature and under almost all experimental conditions, phototropism always occurs together with gravitropism. This is unavoidable, because as soon as phototropic bending occurs, a gravitropic stimulus is concomitantly established. Phototropism unaffected by gravitropism can be measured only under weightlessness or on a clinostat, which neutralizes the gravitropic bending, even though it does not eliminate (omnilateral) gravitropic stimulation.

The Effect of Gravity on Pulse-Induced Phototropism

When *Avena* coleoptiles are clinostatted horizontally after phototropic stimulation with pulse stimuli (fPIPP or sPIPP), then phototropic bending occurs faster and greater curvature is observed, showing that gravitropism interferes with the phototropic bending.[6–8] Similar results were also obtained with coleoptiles of *Triticum* and seedlings of *Helianthus*.[6,8] After unilateral light pulses, maximal curvature is normally reached after about 2 h. When *Zea* coleoptiles were kept on a clinostat after the pulse stimulus, the bending could be maintained for over 20 h.[6] The use of clinostatting has to be evaluated with care, because clinostatting before the application of the phototropic stimulus may also affect the phototropic bending.

Photogravitropic Equilibrium

During continuous unilateral irradiation, plants and fungi reach a so-called photogravitropic equilibrium angle. This angle represents an equilibrium of two antagonistic stimuli, i.e., light eliciting positive bending and gravity eliciting negative gravitropism. Time-dependent phototropism (TDP) is, therefore, always the result of two responses. The photogravitropic equilibrium angle of *Phycomyces* could be substantially enhanced by clinostatting the sporangiophores "head-over," i.e., in a plane, where the tip of the sporangiophore is positioned in the center of rotation and the base of the sporangiophore at the circumference. The absolute threshold is, however, not affected by clinostatting,[18] a result that was also obtained with coleoptiles of *Avena*.[16]

Quantitative Relationship between Gravitropism and Phototropism

The threshold value for photogravitropic equilibrium (Figure 132.2) depends on the strength of gravitropic stimulus generated by the earth gravitational field ($1 \times g$). When the earth gravitational field is substituted by centrifugal accelerations that exceed the value of $1 \times$ g, one finds that the threshold raises exponentially with the gravitational stimulus, g. The following empirical relationship was observed for sporangiophores of *Phycomyces*:

$$I = I_0\, a \exp\,(b\, g) \qquad (1)$$

where I is the threshold fluence rate at elevated g, I_0 is the threshold fluence rate at $1 \times g$, g is the centrifugal acceleration (expressed as multiples of the earth's gravitational acceleration), and a and b are adjustable parameters. A linear increase of g results in an exponential increase of the threshold fluence rate ("exponential law").[18]

The exponential relationship is also valid under natural conditions, i.e., for unilateral irradiation of vertical or inclined organisms. The gravitropic stimulus, S, and the elicited response depend (in darkness) on the sine of the initial inclination angle (sine law of Julius Sachs[6]):

$$S = g \sin \gamma \tag{2}$$

where S is the gravitropic stimulus, g is the earth gravitational acceleration, and γ the initial inclination angle. The sine law holds reasonably well for coleoptiles of *Zea* and *Oryza*[19] and *Avena*,[20] and also for the sporangiophores of *Phycomyces*.[21]

To counterbalance the negative gravitropism of an inclined organ with unilateral light, one can choose an experimental setup, in which the unilateral light is always impinging at a right angle. One can then determine the fluence rate that can compensate the negative gravitropism and thus keep the inclined organ permanently in the same straight position. For this setup, one finds that the inclination angle and the compensating fluence rate are also obeying a simple "exponential law," which is described by the following equation:

$$I = I_0 \, a \exp \, (b \times g \sin \gamma) \tag{3}$$

where I is the compensating fluence rate that counterbalances an inclined organ, I_0 is the absolute threshold as determined with fluence-rate-response curves of photogravitropic equilibrium under standard conditions (Figure 132.2), a and b are adjustable parameters, g is the earth gravitational acceleration, and γ is the inclination angle at the beginning and the end of the experiment. The validity of this relation was shown for *Phycomyces*[21] as well as for *Avena* coleoptiles.[20]

In contrast to the experimental setup described above (Equation 132.3), photogravitropic equilibrium is normally established in a dynamic situation, in which the incidence angle of the unilateral light decreases from 90° to values of some 20° (*Phycomyces* and *Avena* in Figure 132.2). The amount of absorbed light depends on the cosine square of the incidence angle (cosine square law). The final photogravitropic equilibrium angle is thus determined by three empirical laws: the sine law, the exponential law, and the cosine square law.[20,21]

132.7 Action Spectra

The spectral sensitivities of various phototropic plants and fungi are listed in Table 132.1. Higher plants and fungi are generally sensitive only to near-UV and blue, not however, to red light. An exception is the phytochrome-mediated phototropism of the mesocotyl of Zea.[6–8] Action spectra for the phototropism of most organisms indicate a ubiquitous flavin-like blue-light receptor with absorption in the UVB, UVA, and blue spectral regions. To date, the only isolated and well-characterized phototropism receptor is phototropin from *Arabidopsis*, a flavin-photoreceptor with kinase activity (see below).

The phototropism and polarotropism of mosses and ferns can be elicited by blue and red light, the latter being mediated by phytochrome. Filaments of the algae *Mougeotia* and *Vaucheria* are bending toward or away from blue light; apical cells of *Mougeotia* can bend toward red light (Table 132.1).

Action Spectra for Pulse-Induced Phototropism

Action spectra for the fPIPP of *Medicago* hypocotyls[32] display a major peak near 450 and smaller peaks near 280 and 370 nm (Figure 132.3). Action spectra for *Avena* coleoptiles display similar peak positions in the near-UV and blue spectral regions.[2,7,8]

TABLE 132.1 Spectral Sensitivities for Phototropism and Polarotropism of Various Organisms

Organism	Organ	Type of Phototropism	Spectral Sensitivity	Ref.
Mougeotia	Filaments	Negative	Blue	2
Mougeotia	Apical cell	Positive	Red	2
Vaucheria	Filaments	Positive	Blue	2
Vaucheria	Filaments	Negative	Blue above 60 Wm^{-2}	23
Boergesinia	Rhizoid	Positive	Blue	2,6
Ceratodon	Chloronema	Polarotropism	Red	24
Funaria	Chloronema	Polarotropism	Red	2,6
Physcomitrium	Chloronema	Positive	Red	2
Physcomitrella	Chloronema	Positive	Blue, red	25
Physcomitrella	Chloronema	Polarotropism	Blue, red	25
Sphaerocarpus	Chloronema	Polarotropism	UVA, blue	2
Sphaerocarpus	Seta	Positive	Blue	2
Adiantum	Chloronema	Positive	Blue, red	26,27
Adiantum	Chloronema	Polarotropism	Blue, red	26,27
Pteridium	Chloronema	Positive	Red	2
Pteris	Chloronema	Polarotropism	Blue	28
Dryopteris	Rhizoids	Negative	Red	2
Dryopteris	Rhizoids	Polarotropism	Red	2
Dryopteris	Chloronema	Positive	Blue, red	2
Dryopteris	Chloronema	Polarotropism	UVA, blue, red	2
Arabidopsis	Hypocotyl	Positive	UVA, blue	29
Avena	Coleoptile	Positive	UVA, blue	2,7
Avena	Coleoptile	Positive	UVB	2,8
Celosia	Hypocotyl	Positive	UVA, blue, green	2
Helianthus	Hypocotyl	Positive	UVA, blue	2
Lepidium	Hypocotyl	Positive	UVA, blue	2
Medicago	Hypocotyl	Positive	UVB, UVA, blue	2
Zea	Mesocotyl	Positive	Red	6–8
Conidiobolus	Conidiophore	Positive	Blue, red	2
Coprinus	Fruiting body	Positive	Blue	30
Entomophthora	Conidiophore	Positive	Blue, red	2
Neurospora	Perithecial beak	Positive	Blue	31
Phycomyces	Sporangiophore	Positive	UVA, blue	9,10
Phycomyces	Sporangiophore	Negative	UVB	9,10
Pilobolus	Sporangiophore	Positive	UVA, blue	2
Pilobolus	Sporangiophore	Negative	UVB	2

Action Spectra for Photogravitropic Equilibrium

Action spectra that were generated on the basis of fluence-rate-response curves (continuous irradiation for several hours) exist mostly for *Phycomyces*.[9] The fine structures of these action spectra differ from those of the balance action spectra in that the UVA peak is much higher. Everett and Thiman[8] analyzed the so-called second positive phototropic response that is time dependent. All of these action spectra have in common a steep drop of the effectiveness above 500 nm.

Mutants of *Phycomyces* with defects in the genes *madB* and *madC* have an about 100-fold greater effect on the near-UV than on the blue-light sensitivity, indicating that more than the photoreceptor may be involved in near-UV and blue-light perception.[9] Similar conclusions can be drawn from the observation that the *nph-2* mutant of *Arabidopsis* affects the blue-light sensitivity more profoundly than the one for near-UV.[29]

The sensitivity to UVB was analyzed in only a few cases. *Phycomyces* shows negative phototropism to wavelengths below 300 nm (Figure 132.3).[33] The UVB sensitivity appears to be mediated by a photoreceptor other than the one mediating near-UV and blue-light phototropism, because mutants with defects in the genes *madD, E, F, G* affect the UVB sensitivity only little, while they almost completely eliminate the near-UV and blue-light sensitivity.[9] Also, the fact that UVB and red light strongly interact

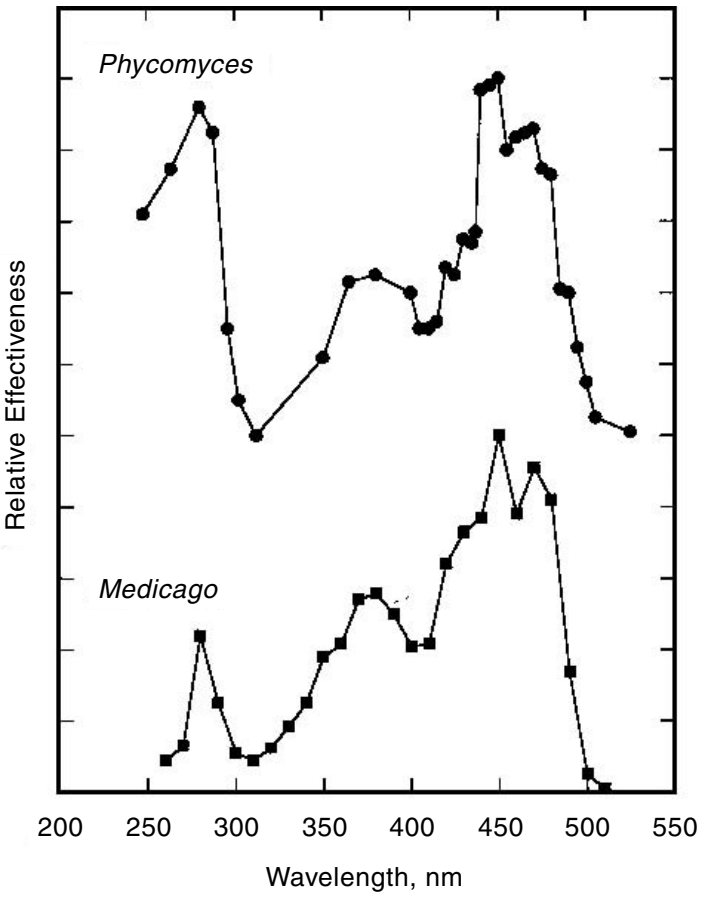

FIGURE 132.3 Action spectra of phototropism. *Phycomyces* sporangiophores: phototropic balance action spectrum. The relative effectiveness was determined by achieving phototropic balance with two opposing light sources consisting of a test light of variable wavelength and a broad-band blue reference light (460 nm). Below 300 nm, the sporangiophores bend away from the UV light.[33] *Medicago* hypocotyls: phototropic action spectrum determined on the basis of first pulse-induced phototropism.[32]

antagonistically in bichromatic irradiation, while red and blue light do not argue for two separate photoreceptor systems.[9]

Action spectra for the phototropism of *Phycomyces* and its related light-growth response display a very small peak near 600 to 610 nm that may indicate the lowest triplet state of a flavin-like blue-light receptor.[2,9] These older observations are pertinent in view of the recent finding that phototropin of *Arabidopsis* probably acts from the lowest excited triplet state.[34]

Action Spectra for Phototropic Balance

When plants or fungi are irradiated bilaterally with two light sources facing each other, they bend toward the light source that they recognize as the subjectively more effective one. Action spectra that were generated with the phototropic balance method display major peaks near 280, 370, and 450, thus indicating the presence of a flavin-like photoreceptor (Figure 132.3). Such action spectra exist for *Avena* coleoptiles,[2,7,16] *Lepidium*, *Helianthus*, and *Celosia*,[2] and *Phycomyces*.[9,10] A puzzling property of the balance action spectra of *Phycomyces* is that the height of near-UV and blue-light maxima depends on the intensity range that is chosen for balance. Near threshold (about 10^{-8} W m^{-2}, 450 nm), the near-UV peak disappears,

while it dominates the blue peak at elevated fluence rates.[9,10] A photoreceptor model implying only a single photoprimary response cannot possibly explain this observation.

132.8 Blue-Light Photoreceptors Controlling Phototropism and Growth

Two types of blue-light receptors were identified that control phototropism and growth of higher plants. These are phototropins (Phot)[5] and cryptochromes (Cry),[4] respectively. Besides phototropin, there must exist another phototropism photoreceptor of *Arabidopsis*, because the *nph1* mutant lacking Phot1 is not completely deficient but is still sensing unilateral light of high irradiance.[5,29] These results indicate that probably two light-signaling pathways are involved in the phototropism of *Arabidopsis*. There are conflicting reports as to whether or not cryptochromes play a role in phototropism. Roles for Cry1 and Cry2 in phototropism, which were inferred for first positive, not however, for second positive phototropism, are presently discussed controversially.[5,29,35]

Phototropins

The *Arabidopsis* phototropins, Phot1 and Phot2 (previously called *nph1* and *npl1*), contain 996 and 915 amino acids, respectively, and possess a *C*-terminal serine/threonine domain and, in addition, two *N*-terminal LOV (light-, oxygen-, voltage-sensitive) domains, each of which noncovalently binds an oxidized flavin mononucleotide (FMN).[5,36] Phot2 (*npl1*) is a paralogue of Phot1 (*nph1*), with about 60% sequence identity and with highly conserved LOV domains.[5,36] The crystal structure of the LOV2 domain of the *Adiantum* phytochrome/phototropin chimeric photoreceptor Phy3 was determined at a resolution of 2.73 Å.[5,36]

Upon irradiation, the FMN undergoes a self-contained photocycle, which entails the generation of a semistable intermediate, a flavin-C(4a)-cysteinyl adduct, that returns in darkness to the ground state. The covalent adduct is formed between the FMN and the cysteine residue, Cys39. In the adduct, which is generated *via* a S1-T1 intersystem crossing, the FMN is reduced, while the cysteine is oxidized.[5,34–37] The photocycle was characterized spectroscopically for the LOV2 domain of Phot1 of *Avena sativa*,[5,36] the LOV1 and LOV2 domains of Phot1 and Phot2 from *Chlamydomonas*,[34,37] *Arabidopsis*, and *Oryza*.[37] Phototropin-related flavoproteins are also present in prokaryotes. The protein YtvA from *Bacillus subtilis* contains a LOV domain with high homology to LOV domains of plant phototropins and similar spectroscopic features.[38]

Phot1 is a membrane-associated 120 kD serine/threonine kinase that undergoes autophosphorylation upon absorption of near-UV and blue light.[5,35,36] Both phototropins thus represent light-activated serine-threonine protein kinases. The formation of the flavin-C(4a)-cysteinyl adduct upon light absorption causes a conformational change of the apoprotein that is believed to activate the kinase activity.[5]

Functions of Phototropins

The phototropins Phot1 and Phot2 mediate phototropism of leaves, flowers, and seedlings,[5] chloroplast movement,[36] and opening of stomata.[39] Phot1 and Phot2 differ with respect to their light sensitivity: while Phot1 mediates phototropism and chloroplast relocation both to low- and high-fluence rates, Phot2 does so only in response to high-fluence rates.[36] The opening of guard cells is also under the redundant control of Phot1 and Phot2, because only double mutants, not single mutants, show the absence of blue-light-induced opening of stomata.[39] In *Arabidopsis*, Phot1 mediates blue-light-induced Ca^{2+}-influx by regulating Ca^{2+} uptake from the apoplast into the cytoplasm.[40] The hypocotyl growth of etiolated seedlings is unaffected by mutations in either of the *nph1* (Phot1) or *nph3* genes (see below).

Photoreceptor-Interacting Proteins and Elements Essential for Phototropism

In *Arabidopsis*, several mutations interrupt the phototropism transduction chain: *nph2* (nonphototropic hypocotyl), *rpt2* (root phototropism), and *nph3* (nonphototropic hypocotyl). *Nph3* codes for a

membrane-associated protein that interacts *via* at least two protein–protein interaction domains with Phot1, likely with its chromophore-binding domain. RPT2 is a signal transducer of the phototropic response in *Arabidopsis*.[5,35] The protein contains putative phosphorylation sites; it belongs to a large gene family that also includes the above-mentioned *nph3* gene.[5,35]

Cryptochromes

Cryptochromes regulate the growth of plant hypocotyls. Cry1 was first isolated from *Arabidopsis*.[4] Beside growth regulation, cryptochromes are also involved in the regulation of circadian rhythm of plants, animals, and cyanobacteria.[5,29] In *Arabidopsis*, cryptochromes are involved in the blue-light-induced inhibition of hypocotyl elongation, the accumulation of anthocyanin,[4] internode and petiole elongation, seed germination, and initiation of flowering time.[4]

Cryptochromes belong to the family of photolyases/cryptochromes. They share with the DNA photolyases (DNA repair enzymes) the chromophore-binding domains without possessing, however, the capacity of photolyases to monomerize pyrimidine dimers upon irradiation.[4,35] Cryptochromes contain as chromophores FAD and methenyltetrahydrofolate, both of which are noncovalently bound.[4,35] *Arabidopsis* possesses two cryptochromes, Cry1 and Cry2, which possess great sequence homology apart from a small *C*-terminal domain. The two cryptochromes differ in their stability: while Cry1 is stable, Cry2 is degraded upon irradiation.[2,29,35] Interestingly, Cry2 is more stable under monochromatic blue than under broad-band blue light.[41]

Because of the phylogenetic relation between cryptochromes and photolyases, it appears likely that cryptochromes also possess an electron transfer as primary photoresponse.[4,35] *In situ* and after isolation cryptochromes exist in a reduced form, because their absorption spectra are semiquinone-like. The action spectrum for hypocotyl inhibition, a Cry1-mediated response, resembles, however, the absorption spectrum of the oxidized form.[41] This observation could indicate that the active form of Cry1 exists *in situ* in the oxidized state, while the inactive form remains reduced.

132.9 Role of Hormones

Auxin, Indole-3-Acetic Acid

Unilateral irradiation of shoots and coleoptiles induces a lateral auxin transport away from the irradiated side and a concomitant asymmetry of auxin, which is a prerequisite for redistribution of growth and, thus, phototropic bending. This so-called Cholodny–Went theory of phototropism[2,6–8] survived several ups and downs and still provides an excellent basis for providing a molecular model for phototropism and also gravitropism of various plant materials.[42]

Red-light-grown *Zea* coleoptiles that are stimulated unilaterally with pulses of blue light display a slower growth rate at the irradiated half and a faster one at the shaded half.[6–8] This asymmetry of growth pattern correlates with an elevated auxin concentration in the shaded half and a reduced content in the irradiated half.[7,8,42] The phototropic growth responses of *Zea* travel basipetally at a speed that is comparable to the velocity of basipetal auxin transport.[43] In accordance with the Cholodny–Went theory, it was found that the establishment of an auxin asymmetry upon irradiation precedes the actual bending.[8,43] Also in accordance with the theory is the observation that saturating doses of exogenous auxin inhibit phototropism.[43] Finally, the *nph4* mutation of *Arabidopsis*, which confers reduced photo- and gravitropism, causes at the same time a reduced sensitivity to exogenously applied auxin.[29]

The lateral translocation can be explained by a light-induced inhibition of basipetal transport.[2,6–8,43] In accordance with this explanation are the observations that the action spectra for phototropism, light-growth response, and light-induced basipetal auxin transport resemble each other.[8,43]

In tobacco, unilateral irradiation caused an about twofold activation of auxin-responsive promoters in the shaded half of the stem relative to the irradiated side,[44] a result that was explained by the redistribution of auxin.[45]

Lateral translocation of exogenous auxin in response to unilateral irradiation was demonstrated early on with hypocotyls of radish and, subsequently, with *Zea* coleoptiles,[2] epicotyls of *Pisum*.[7,8,46] The apical part of coleoptiles (1 mm below the tip) represents the most light-sensitive zone, and at the same time, the zone that is most effective with respect to lateral auxin translocation.[2,6]

Participation of Growth Inhibitors

Tropic bending can, in principle, be generated by translocation of growth inhibitors or growth promoters. The existence of growth inhibitors appears well established for *Raphanus* hypocotyls, in which *cis*- and *trans*-raphanusanins inhibit growth when applied exogenously.[7,8,47] The inhibitor asymmetry is detectable after pulse-induced phototropism.[7,8] Two distinct inhibitors, Raphanusol A and B, are translocated laterally during pulse-induced phototropism.[7,8] The results indicate that in some organisms, phototropism may be exclusively explained by the action of growth inhibitors and their redistribution rather than by the action of growth promoters such as auxin. In seedlings of *Helianthus*, auxin remains evenly distributed after unilateral irradiation. The growth inhibitor, xanthoxin, accumulates, however, on the irradiated side.[7,8]

132.10 Role of Cytoskeleton

In chloronemata of *Ceratodon*, an irradiation with unilateral red light induces a reorientation of actin strands in the apical dome toward the point of the prospective outgrowth.[48] Cell-wall-associated microtubules and their orientations play an important role for growth. The reorientation of microtubules in the outer epidermal wall of *Zea* can be controlled by blue and red light as well as auxine.[49] During phototropism of *Zea*, coleoptiles and *Helianthus* hypocotyls cortical microtubules undergo reorientation.[49] On the irradiated side, the tubules reorient from the transverse to the longitudinal orientation. It is tempting to explain bending in terms of fibril reorientation: the light-induced longitudinal orientation would be less amenable to stretch and could thus explain the reduced growth rate at the irradiated side. A more detailed analysis has, however, shown that such a direct role of fibrils does not hold. While it is true that microtubules respond to phototropic stimulation, they do not control tropic curvature, because the two events can be experimentally separated.[49]

132.11 Transduction Chain: Phosphorylation, Proton Pumps, Calcium Ions

Blue-light irradiation of plant seedlings induces the phosphorylation of a 120 kD plasma membrane associated protein.[50] There is a strong correlation between the phosphorylation of this protein and phototropism.[50] The fluence requirement for the phosphorylation, its asymmetric distribution in the coleoptile after unilateral irradiation,[29] and its correlation with sensitivity changes[13] show that it is related to an early step of the phototropic transduction chain. The phosphorylated protein is the blue-light receptor proper, phototropin, because the photoreceptor mutant, *nph1* of *Arabidopsis* is lacking the phosphorylation, and the mutant is devoid of phototropism.[4,5] Blue light induces in *Neurospora crassa* bending of the protoperithecial beak and the dephosphorylation of a 33 kDa protein. Two mutants, *wc-1* and *wc-2* (white collar), that are defective in all blue-light responses, including phototropism, possess an abnormal dephosphorylation pattern.[51] The white-collar proteins are transcription regulators with PAS and LOV domains[52] that are also involved in the light control and maintenance of the circadian clock.[53]

Cell-wall loosening and a concomitant increase of growth rate can be elicited by acidification. It is assumed that auxin stimulates a plasma membrane H^+-ATPase that causes the acidification. A lateral translocation of auxin during unilateral irradiation would thus lead to differential acidification and thus differential growth. In *Zea* coleoptiles, auxin enhances the exocytosis and the synthesis of H^+-ATPase of the plasma membrane, and also the activation of existing H^+-ATPase was demonstrated.[54,55] The strong and critical points of this so-called acid-growth theory were discussed.[56]

In the epidermis of *Zea* coleoptiles, exogenous auxins elicits a rapid increase of cytosolic free Ca^{2+}, suggesting a role for this ion as second messenger.[57] In *Zea* coleoptiles, Ca^{2+} is translocated during phototropic bending from the convex to the concave side, the major part of the ions probably being located in the apoplast. Auxin transport inhibitors prevent the translocation, indicating that Ca^{2+} and auxin act in the same transduction chain.[58] In *Arabidopsis* and *Nicotiana*, the cytosolic free Ca^{2+} changes transiently about 30 sec after a short pulse of blue light. In the phototropism mutant *nph1*, which lacks the photoreceptor phototropin, this response was greatly affected.[59]

133.1 Introduction

Photonic proteins are ubiquitous in the biological world.[1] These include proteins involved in the transduction of light energy into chemical energy, the detection of light for sensing purposes, and the emission of light such as bioluminescence. For example, the major energy input into the biosphere is solar, with the exception of organisms that rely on geothermal energy, such as lithotrophic bacteria living near hydrothermal deep sea vents.[2,3] Many proteins evolved with the function of efficiently capturing the roughly 10^5 Terawatts of solar power that impinges on the earth's surface. This includes the well-known photosynthetic reaction center and light-harvesting proteins found in photosynthetic bacteria, algae, and plants,[4-6] as well as the light-driven bacteriorhodopsin (BR) proton pumps found in archaebacteria such as *Halobacteria salinarum*.[7] Recently, BR-like proton pumps were also discovered in marine bacteria,[8,9] indicating a much wider distribution of this family of light-energy-converting proteins.

Other proteins evolved as light receptors that play a critical role in bacterial phototaxis, plant phototropism, and visual sensing. Examples include the retinylidene-containing visual pigment rhodopsin, a family of G-coupled protein light receptors[10–12] involved in invertebrate and vertebrate vision. In the archaebacterial world, the rhodopsin counterpart, sensory rhodopsin, is also based on isomerization of the retinylidene chromophore, and it mediates phototaxis.[13] Additional examples are the red and far-red light sensing phytochromes receptors of plants[14,15] and the newly discovered phototropins, a family of proteins that mediates blue-light responses in plants.[16,17]

A third class of photonic proteins is made up of those that evolved a light-emitting role, such as the green fluorescent protein (GFP) found in Aequorea (jellyfish) and Renilla (sea pansy).[18] In nature, GFP is excited through radiationless energy transfer by the well-known chemiluminescent protein aequorin, also found in Aequorea. Currently, little is known about the function of GFP as compared to the light signaling function of the extensively studied chemiluminescent firefly luciferase.[19]

In this chapter, we review the new and emerging field of engineering artificial photonic proteins, which complements the classic study of natural photoproteins discussed above. The term artificial photonic

0-8493-1348-1/04/$0.00+$1.50

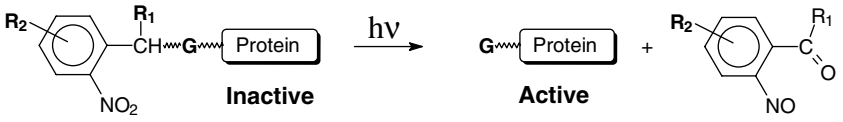

FIGURE 133.1 2-nitrobenzyl mediated photoactivation of proteins. Protein is initially inactivated by attaching 2-nitrobenzyl moiety to group G, involved in protein activity, rendering protein inactive. After illumination, the nitrobenzyl group is removed, the G group is regenerated, and protein becomes active.

proteins as used in this review is meant to represent examples of nonphotonic proteins that were engineered to have photonic functions and also photonic proteins completely designed de novo. Examples include proteins that were engineered to contain reporter groups at specific positions to detect conformational changes or to sense interaction with other biomolecules; proteins with functions that can be activated by light; and proteins that have similar functions to those in nature, including energy conversion, light sensing, and light signaling.

The engineering of artificial photonic proteins is becoming feasible in part because of the emergence of a number of powerful methods aimed at the incorporation of light absorbing, fluorescent, and photocleavable moieties into proteins. In addition to the well-established field of chemical labeling, methods based on genetic engineering, including tRNA-mediated protein engineering (TRAMPE) and protein ligation, have emerged. These techniques offer increasing ability to incorporate nonnative chemical moieties, including unnatural amino acids, into proteins at specific positions. As described in this review, this opened the door to many novel applications of photonic proteins in the fields of molecular biophysics, cell biology, diagnostics, drug discovery, and proteomics.

133.2 Chemical Engineering of Photonic Proteins

By far the simplest method with which to impart photonic properties to any given protein is via chemical labeling. For example, a photonic label can be covalently linked to an exposed lysine or cysteine residues on a target protein using amine-reactive reagents (NHS esters or isothiocyanates) or thiol-reactive reagents (iodoacetamides or maleimides). However, this approach leads to a heterogeneous nonuniform label distribution,[20] and in extreme cases, in complete loss of protein activity. In order to attach a photonic tag to a specific site on the protein, cysteine mutagenesis can be utilized, whereby a single reactive cysteine is incorporated into the protein.[21,22] A label is then attached using SH reactive groups, such as maleimides or iodoacetamides. However, this sometimes requires that native cysteines present in the protein be removed by site-directed mutagenesis, thereby altering its structure and function. Despite these limitations, there are many examples of applications of chemical labeling that led to the production of photonic proteins that fall into a variety of categories as described below.

Photoswitches

Chemical labeling was used extensively to create "photoswitchable" protein conjugates. Such proteins have the property that upon illumination, the photonic labels render the protein active/inactive or change its physicochemical properties. These photonic switches can be further subdivided into two categories: irreversible and reversible photoswitches.

Irreversible Photoactivation

Irreversible photoswitches consist mainly of "caged" proteins that upon illumination undergo a transition from an inactive (resting) to an active state. Normally, caging is accomplished by blocking reactive groups on the protein side chains (labeled G in Figure 133.1) with a photoremovable protective group, such as 2-nitrobenzyl or its derivatives. Upon illumination, the caging group is removed, and the protein activity is restored.

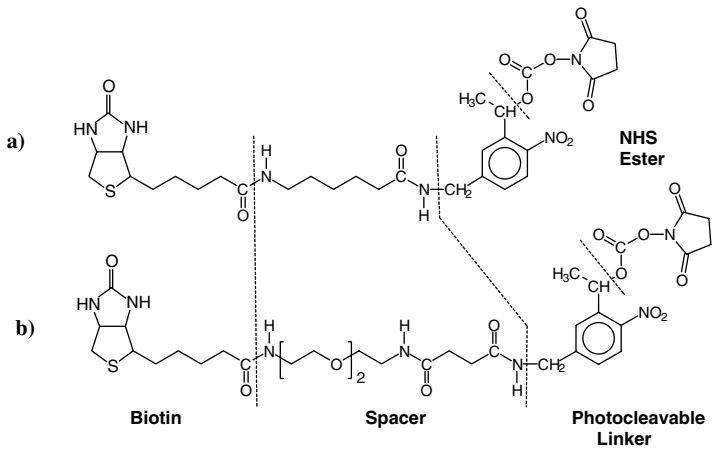

FIGURE 133.2 Design of photocleavable biotin (PC-Biotin) NHS reagents: (a) water insoluble PC-Biotin-NHS, (b) water soluble PC-Biotin NHS. After modification of biomolecule with PC-Biotin and binding of the conjugate to streptavidin, light can be used to release the target biomolecule or reactivate it.

The caging process was successfully employed for a number of proteins as well as for complex biological systems. For example, Thompson et al.[23] showed that up to 15 2-nitrobenzyl residues can be incorporated into bovine serum albumin and ~95% of them can be removed by exposure to near-UV light. Marriott[24,25] used 6-nitroveratryloxy-chloride (NVOC-Cl) to prepare caged G-actin in high yield. The conjugate was characterized by biochemical and absorption spectroscopic methods, in particular, the ability to polymerize into F-actin. Approximately 90% of activity was restored upon illumination with near-UV light. Caged G-actin labeled with tetramethylrhodamine or fluorescein at Cys374 was also prepared and characterized. These caged fluorescent G-actin conjugates can be used to generate fluorescent, polymerization-competent G-actin following light activation. Caged antibodies were first described by Self et al.[26] These conjugates were obtained by performing coupling of 1-(2-nitrophenyl)ethanol (Npe) to proteins using diphosgene. In addition to caging antibodies, the authors also performed caging of antigens and showed that light can be used to modulate the level of antibody-binding sites for antigen, antigen-binding sites for antibody, and antibody-Fc-binding sites for Protein A.

Kossel et al.[27] used 6-nitroveratryloxy-chloride (NVOC-Cl) to inactivate function-blocking monoclonal antibody against brain-derived neurotrophic factor (BDNF). This antibody was then used to study synaptic potentiation in brain slices under controlled concentration of BDNF. This is an example of caged antibody used as a precise spatiotemporal control of endogenous protein levels. The same compound (NVOC-Cl) was used by Minden et al.[28] to cage GAL4VP16, a potent transcriptional activator. The caged protein was then injected into drosophila embryos and used to locally activate the expression of a wide variety of GAL4 UAS transgenes with a brief exposure to near-UV light.

Macromolecular Complexes

Photoactive moieties can also be used to produce light-activated macromolecular complexes such as light-activated ionic pores in membranes. A photocleavable-biotin reagent, PC-biotin-NHS (see Figure 133.2), was synthesized[29] and used to reversibly modify lysine residues of α-hemolysin (α-HL), an exotoxin of *Staphylococcus aureus*, which forms pores in lipid bilayer membranes.[30] When α-hemolysin was incubated with 5- to 20-fold molar excess of PC-biotin-NHS at 0°C and pH 10.5 for 10 min, it exhibited a concentration-dependent loss of hemolytic activity. At 20-fold molar excess of PC-biotin-NHS, the activity was negligible. When the modified α-hemolysin was exposed to long-wavelength UV light (>300 nm) for 10 min, over 80% of its activity was regenerated. This "caging" effect is most likely due to the prevention of proper assembly of the individual α-hemolysin monomers into a heptameric ion channel that spans the lipid bilayer.

Moritz et al.[31] used PC-biotin-labeled antibodies to selectively isolate the γ-tubulin ring complex of *Drosophila*. After capture using streptavidin media, the structure of the complex was studied using electron microscopic tomography and metal shadowing.

As an example of using chemical engineering to produce a much larger light-activatable biomolecular assembly, Pandori et al.[32] used water-soluble photocleavable biotin (see Figure 133.2) to control the infectivity of adenoviral vectors. Upon treatment with PC-biotin, the infectivity of these vectors is almost completely eliminated and can be restored by short exposures to near-UV light (365 nm). This method was used to locally induce the expression of transgenes in the target cells *in vitro* and *in vivo*. This demonstration offers advantages in the field of gene therapy by providing a novel method to control viral infectivity.

Selective Chemical Labeling

In addition to random caging reactions, it is desirable to be able to specifically cage the particular amino acid residue involved in activity. This approach was demonstrated, again with α-HL, by using scanning cysteine mutagenesis and the cysteine specific caging reagent, 2-bromo-2-(2-nitrophenyl)acetic acid (BNPA).[33] Similar methodology was also used to generate caged, unprotected, cysteine-containing or thiophosphorylated peptides in aqueous solution with 2-nitrobenzyl bromides.[34,35] A similar highly directed reaction between a single thiophosphorylated threonine residue in the catalytic subunit of protein kinase A and 4-hydroxyphenacyl bromide was used to generate caged protein kinase A. This caged protein exhibited significantly reduced activity[36] that was restored up to 90% upon near-UV illumination.

Unlike most proteins, where precise control of the caging reaction is difficult to achieve, chemically synthesized peptides can be caged relatively easily at specific amino acids.[37–39] In one case, this approach was used to generate photoactivatable ribonuclease S.[40] This enzyme is composed of two units: S-peptide (Residues 1 to 20) and S-protein (Residues 21 to 124). A series of S-peptides carrying a 2-nitrobenzyl caging group on either Asp, Glu, Gln, or Lys side chains was prepared by chemical synthesis and chimeric RNAse S variants composed of these caged peptides assembled. In one case, a complete inactivation of RNAse S was achieved with 37% activity recovered upon illumination.

Photoactivatable fluorochromes or "caged" fluorescent moieties are useful for visualizing and tracking the movement of macromolecules inside living cells.[41,42] Caged fluorescent tubulin was extensively used to study microtubule formation, dynamics, and movement.[43–45]

Reversible Protein Photoactivation

In contrast to the previous discussion, some photonic protein switches are reversible. Reminiscent of several retinylidene-based rhodopsins, such as Sensory Rhodopsin I,[46,47] most of these systems are based on reversible photoisomerization. In this case, however, the chromophore is based on the azobenzene, cinnamate, or spiropyrane-merocyanine system. The photochemical reactions for these three classes of photonic switches are illustrated in Figure 133.3.

Both azobenzene and cinnamate derivatives were used as early as the 1960s and 1970s to photoregulate enzyme activity. This was accomplished by covalently modifying an enzyme's active site or by tethering these labels to specific enzyme inhibitors.[48] A recent interesting example includes caged thrombin,[49] which was photoactivated intravenously to produce localized thrombosis. Novel peptide-based photoswitchable inhibitors of α-chymotrypsin based on α-ketoester were also recently described.[50] In this case, the utilization of a peptide recognition sequence as well as an azobenzene moiety resulted in tighter binding and better photomodulation properties as opposed to nonpeptide inhibitors conjugated to azobenzene.

Ribonuclease S peptide containing an azobenzene switch at various positions was also recently synthesized and evaluated[51] but did not exhibit efficient photomodulation of activity. In contrast, site-specific incorporation of azobenzene switch into horseradish peroxidase using TRAMPE (for details see Section 133.3) allowed for efficient control of enzymatic activity.[52] Similarly, 90% photomodulation of horseradish peroxidase activity was achieved by covalent conjugation of the enzyme to carboxylated spiropyran dye.[53]

It is well known that the conjugation of proteins to chemical polymers can be used to improve protein stability or change its solubility. Ito et al.[54] conjugated subtilisin to spiropyran carrying polymethacrylate

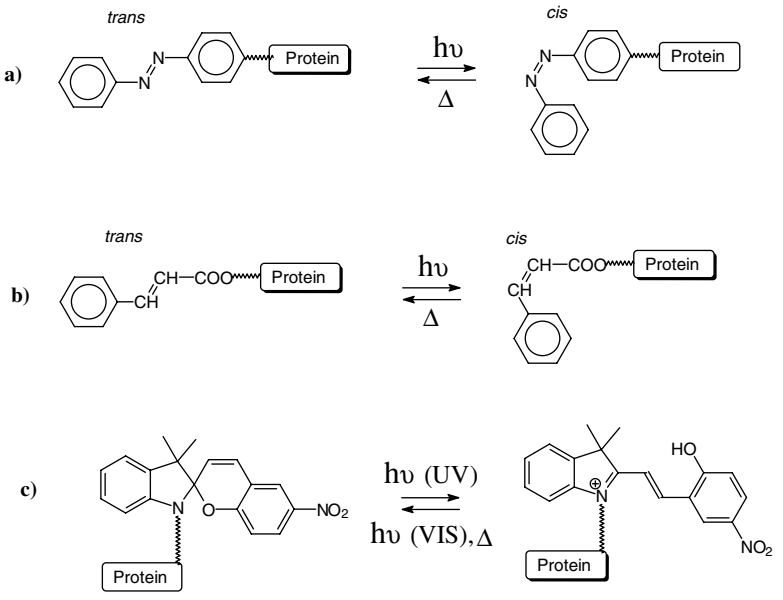

FIGURE 133.3 Reversible protein photoactivation. The attachment of azobenzene (a), cinnamate (b), or spiropyrane-merocyanine (c) to active sites in proteins enables reversible photomodulation of activity. These photoswitches involve reversible *cis-trans* isomerization (a–c) and cyclization (c) reactions.

that rendered the conjugate soluble in toluene while retaining 100% activity. The conjugate was precipitated upon exposure to UV light and could be resolubilized upon exposure to visible light.

In a similar approach, a single cysteine mutant N55C of endoglucanase 12A, was conjugated to the end of linear polymethacrylate grafted with azobenzene.[55] Two different means of azobenzene grafting onto the polymer (amide or ester) resulted in two different enzyme conjugates, which could be activated or deactivated using UV or visible light. Importantly, these conjugated enzymes exhibit ~50% of the activity of the native enzyme in the "on" state, while only 1 to 3% activity is observed in the "off" state.

In addition to photomodulation of enzymatic activity, an azobenzene moiety was incorporated into a model peptide antigen Glu-azoAla-Gly-Gly that allows for photoregulation of the antigen–antibody interaction.[56] More recently, incorporation of an azobenzene moiety was used to photomodulate peptide conformation.[57–62] The reader is referred to a recent review[63] for more examples of photoresponsive peptides produced using azobenzene or spiropyran moieties.

Photonics Probes

In addition to photonic switches, photonic proteins were engineered to contain fluorescent moieties that react to changes in a protein's local environment and to conformational changes. In this section, we review several examples of designing photonic probes that goes beyond simple chemical labeling and cysteine mutagenesis.

Protein Modifications

One novel approach involves incorporation of an epitope tag that assumes a α-helical motif. Furthermore, this tag contains a tetracysteine (CCXXCC) sequence that reacts with a specific fluorophore carrying a biarsenical moiety leading to a fluorescent conjugate.[64] In addition to the originally described reagent that produces a fluoroscein-like fluorescence (FlAsH, fluorescence emitting at 528 nm), two additional biarsenical analogues were developed with emission in the blue (CHoXAsH, 430 nm) and red (ReAsH, 608 nm).[65] A dual color-labeling approach utilizing FlAsH and ReAsH was also recently used for intracellular sequential labeling of connexin-43 and for monitoring its trafficking in and out of gap junctions.[66]

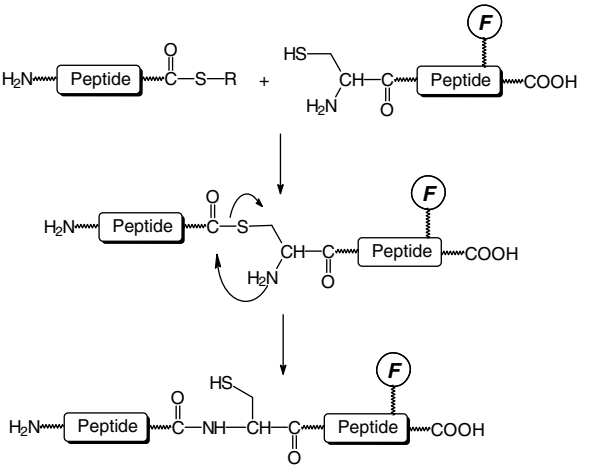

FIGURE 133.4 Incorporation of photonic probes into proteins *via e*xpressed protein ligation (F = fluorescent probe). This approach involves a very specific chemical reaction between thioester on one polypeptide fragment and the N-terminal cysteine moiety on the other. Initial intermediate cysteine thioester is converted into native peptide bond by intramolecular reaction. The original free SH group of the cysteine is also regenerated.

This approach allows for a determination of protein "age" within living cells as well as for a determination of expression level. A similar, environment-sensitive dye was used to monitor intracellular calmodulin conformational changes in response to Ca^{2+} concentration.[67]

An alternative approach to site-specific introduction of photonic probes relies on the selective oxidation of *N*-terminal serine or threonine to an aldehyde followed by specific reaction with aromatic amines or hydrazine derivatives (hydrazides, thiosemicarbazide).[68] Ketone moieties can also be generated by metal-catalyzed transamination reaction.[69]

As discussed previously, chemical synthesis allows a more general method of introducing site-specific photonic probes into polypeptides that is normally not possible using recombinant-DNA-based methods. However, chemical peptide synthesis is limited to peptides of 50 to 100 amino acid residues. In order to circumvent this limitation, an approach termed native chemical ligation[70] was developed, which is based on the chemoselective reaction of unprotected peptide segments in water at pH 7 to form amide-linked polypeptide products.

This approach requires, as illustrated in Figure 133.4, two peptide fragments, one with thioester at the *C*-terminus and the other with the *N*-terminal cysteine. The availability of the thioester peptide segments is facilitated by the discovery of the "defective intein" splicing system.[71,72] This approach was used, for example, to generate a fluorescent biosensor for Abl kinase activity.[73] In this work, the truncated version of the c-Crk-II protein was synthesized bearing rhodamine and fluorescein at two different sites. Upon phosphorylation, a conformational change induced alterations in the FRET signal observed between the two labels. In another example, two fluorescent amino acids with structures based on the nitrobenz-2-oxa-1,3-diazole (NBD) and coumarin fluorophores were incorporated into the Ras binding domain (RBD) of c-Raf1.[74,75] The binding of activated Ras protein could be detected by monitored fluorescence.

Using Native Fluorescent Proteins

Proteins that exhibit fluorescence in their native form were extensively studied and utilized in a variety of applications. One important example is green fluorescent protein[18] (GFP) of *Aequorea victoria* and its mutants (BFP, CFP, YFP), which exhibit blue, cyan, and yellow emissions, respectively.[76] In addition, a novel fluorescent protein, termed DsRed, was recently cloned and characterized.[77] These proteins are unique in having fluorophores formed from the natural amino acid side chains via cyclization. A major application for them is the creation and expression of fluorescent fusion proteins. Such fusion constructs were used in a variety of applications involving *in vitro* and *in vivo* spatial and temporal fluorescence

monitoring, especially involving use of fluorescence resonance energy transfer (FRET). For example, Chan et al.[78] demonstrated that the interactions between individual receptor chains of the tumor necrosis factor receptor (TNFR) family members in a cellular system can be detected using FRET. By fusing CFP and YFP to caspase substrates, apoptotic caspase activity can be monitored within single cells.[79–81] Protein–protein interactions, transport phenomena,[82] and conformational changes[83] in living cells can also be monitored using coexpression of GFP fusions and its variants. A protease assay utilizing two-photon cross-correlation and FRET between GFP and DsRed was described.[84] Unlike FRET, the method of dual-color cross-correlation is not limited to a specific range of distances between the fluorophores. By fusing CFP and YFP to kinase substrate, specific kinase activity inside living cells can be monitored.[85–87] A calmodulin-GFP fusion molecule was used as an *in vivo* real-time FRET-based sensor for monitoring Ca^{2+} concentration.[88]

Besides the GFP family, phycobiliproteins were used in a FRET-mediated FACS assay[89] and to construct a FRET-based glucose sensor.[90] However, a major difficulty with the use of phycobiliproteins is related to their oligomeric structure and the requirement for cofactors.[76]

133.3 tRNA-Mediated Engineering of Photonic Proteins

In addition to chemical engineering and site-directed mutagenesis described in the previous section, an approach based on tRNA-mediated protein engineering (TRAMPE) presents new opportunities for engineering photonic proteins. TRAMPE relies on the following:

1. Development of novel tRNAs and their misaminoacylation with custom-designed amino acids
2. Recognition of special codons by the tRNAs
3. Efficient expression of these modified proteins

Recent progress was made in all these areas (see Rothschild and Gite[91] for a detailed review), and a few representative examples that resulted in the production of photonic proteins are described below.

The Basics of TRAMPE

The pioneering studies of Khorana and Nirenberg in the early 1960s[92,93] provided scientists with the genetic code, the critical information necessary to engineer proteins at the genetic level. In addition, the ability of the translation machinery to accommodate amino acids outside the canonical 20 has been long known.[94] TRAMPE, by exploiting this fact, allows expansion of the genetic code so that custom-designed nonnative amino acids can be selectively introduced into proteins.

Misaminoacylated tRNAs

Early studies using TRAMPE were based on the chemical modification of aminoacyl-tRNAs prepared enzymatically with one of the 20 native amino acids. This approach, referred to here as nonnative amino acid replacement (NAAR), allows specific amino acids in the protein to be replaced by their derivatized analogs. For example, it was demonstrated by Johnson and coworkers that a $tRNA^{Lys}$ enzymatically aminoacylated with lysine could be derivatized with a light-activated cross-linking reagent to form N-ε-(5-azido-2-nitrobenzoyl)-Lys-$tRNA^{Lys}$.[95–97] Using these misacylated tRNAs in a cell-free protein synthesis system enabled investigation of secretory protein translocation across the ER membrane by photo-cross-linking techniques. More recently, effective methods were developed to incorporate nonnative amino acids at a specific point in a protein. This approach, called site-directed nonnative amino acid replacement (SNAAR), is based on the use of stop codons incorporated at specific positions in the DNA coding for proteins and complementary suppressor tRNAs, which cause the stop codon to be read-through.[98,99]

Illustrated in Figure 133.5 is the basic approach for the incorporation of nonnative amino acids at specific locations in a protein. The aminoacylation of a suppressor tRNA (Figure 133.5, top) is accomplished by using methods for chemical aminoacylation of tRNAs or by modifying an aminoacyl-tRNA aminoacylated enzymatically. In the chemical aminoacylation method, the nonnative amino acid of

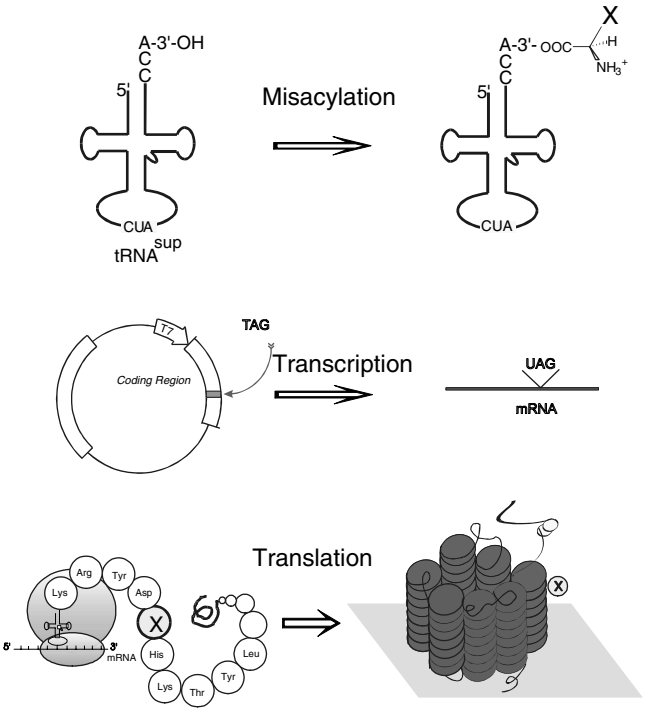

FIGURE 133.5 Steps for the incorporation of a non-native amino acid (X) into a protein by using SNAAR. Top: A suppressor tRNA with an anticodon corresponding to the amber codon UAG is misacylated with a non-native amino acid (X). Middle: The TAG stop codon is transcribed into an mRNA containing the UAG stop signal at a defined position. Bottom: Cell-free translation of the above mRNA results in incorporation of non-native amino acid, X, into the nascent protein at a specific position.

interest is used to acylate the dinucleotide pdCpA and then is ligated to a truncated tRNA.[98,100] In contrast to enzymatic aminoacylation of tRNAs, which is generally limited to only natural amino acids or, in special cases, their analogs, it is possible to aminoacylate tRNAs with any nonnative amino acid by chemical aminoacylation. A third method is to misaminoacylate a tRNA using a native aminoacyl synthetase. However, this latter approach is restricted to a relatively small set of amino acid analogs, such as fluoro-phenylalanine[101] or the proline analog thiaproline.[102] The nonnative amino acid is then targeted to the proper position in the nascent protein by choosing a specific codon (out of the possible 64) that corresponds to the anticodon of the misaminoacylated tRNA. For example, for the purpose of SNAAR, a suppressor tRNA, which acts to suppress a stop codon (i.e., UAG, amber; UAA, ochre; or UGA, opal), can be placed at a specific position in the gene (Figure 133.5, middle). Finally, the protein is synthesized in a cell-free or cellular translation system to which the misaminoacylated tRNA is introduced (Figure 133.5, bottom).

In addition to the aforementioned methods, it is possible to use *in vitro* evolved ribozyme for tRNA aminoacylation.[103] The evolved ribozyme can be programmed for selectivity toward specific tRNAs. This method, therefore, has potential as a means of generating aminoacyl-tRNAs that are charged with nonnatural amino acids.

Frameshift Suppression

To avoid competition between endogenous release factor and suppressor tRNA, a new strategy based on frameshift suppression mutations was developed.[104–106] This strategy, based on the ability of tRNAs with extended anti-codons to suppress frameshift mutations, has two advantages over conventional suppression using the three-base amber, opal, and ochre stop codons: competition between tRNA and release factors (RF) is avoided, and this approach allows more than one unnatural amino acid to be incorporated

into a single protein by using two or more frameshift suppressor tRNAs. In fact, it was shown that not only four-base but even five-base anti-codon tRNAs are able to incorporate unnatural amino acids with efficiency up to 86%.[107–110]

Incorporating Photonic Reporter Groups

One attractive use of TRAMPE is the incorporation of reporter groups into molecules that can provide information about protein structure and conformational changes, especially in membrane proteins not easily analyzed by x-ray crystallography. One of the earliest demonstrations of this capability was the work of Johnson and coworkers, in which they were able to label proteins with fluorescent amino acid derivatives.[111] Cornish et al.[112] reported site-specific incorporation of spin-labeled, fluorescent, and photoactivatable amino acids into T4 lysozyme. More recently, Chamberlin and coworkers incorporated three different fluorescent analogs, 5-hydroxyltryptophan, 7-azatryptophan, and ε-dansyllysine into β-galactosidase.[113] One novel aspect of this work was the use of an *E. coli* S30 extract derived from a mutant strain producing a faulty release factor (RF1). The highest expression yield obtained was for 5'-OH Trp (7.6 μg/ml) using the suppressor $tRNA^{Gly}_{CUA}$, whereas much lower yields were observed for 7-azatryptophan and ε-dansyllysine.

As an example of a similar approach using *in vivo* SNAAR, Turcatti et al.[114,115] incorporated a fluorescent amino acid, 3-*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)-2,3-diaminopropionic acid (NBD-Dpr), at specific sites in the tachykinin neurokinin-2 receptor, a member of the large family of seven α-helix G-protein coupled receptors (GPCRs). The expression system, *Xenopus* oocytes, allowed for functional assays of the receptor. Structural information was obtained by measuring the intermolecular distance between the fluorescent amino acids placed at different sites and a fluorescently labeled heptapeptide antagonist using fluorescence resonance energy transfer (FRET).

Photonic Probes of Electrostatic Environment

The site-specific incorporation of a fluorescent amino acid, Aladan (Alanyl-6-dimethylamino-2-acyl-naphthalene), into soluble and membrane proteins was recently reported using TRAMPE.[116] **Aladan** was shown to be exceptionally sensitive to the polarity of its surroundings and could be incorporated site-selectively at buried and exposed sites, in soluble and membrane proteins. In one example of this capability, Aladan was incorporated at various sites into the Kir2.1 and Shaker potassium channels. These proteins showed normal activity, indicating that the incorporation of Aladan did not interfere with proper folding. In addition, Aladan was incorporated by solid-phase synthesis at four different sites in GB1, a highly thermostable IgG-binding domain that has been extensively characterized. In all cases, the fluorescence emission wavelength was dependent on the site of incorporation and local microenvironment.

N-Terminal Labeling of Nascent Proteins with Fluorescent Groups

A sensitive, nonisotopic, fluorescence-based method for the detection of nascent proteins directly in polyacrylamide gels was reported.[117] A fluorescent reporter group was incorporated at the *N*-terminus of nascent proteins using an *E. coli* initiator $tRNA^{fmet}$ misaminoacylated with methionine modified at the α-amino group. In addition to the normal formyl group, the protein translational machinery accepts BODIPY-FL, a relatively small fluorophore with a high fluorescent quantum yield, as an *N*-terminal modification. A direct visualization of a nascent protein bands with good sensitivity was achieved by using a fluorescence scanner or a conventional UV-transilluminator. This approach eliminates the need for radioactivity and provides rapid detection of the protein bands immediately after electrophoresis without any downstream processing.

C-Terminal Labeling of Nascent Proteins with Fluorescent Groups

Nemoto et al. developed a method for the fluorescence labeling of the *C*-terminal of nascent proteins using fluorescein-puromycin conjugates.[118] The fluorescent analog of puromycin (an antibiotic that inhibits protein synthesis by binding to the A site on the ribosome) forms a bond with the *C*-terminal amino acid residue of the protein but only when the coding sequence does not contain a termination

codon. This method was used to monitor protein–protein interactions by fluorescence polarization.[118] More recently, Doi et al.[119] used this method along with microarrays and fluorescence cross-correlation spectroscopy (FCCS) to monitor protein–protein interactions.

Detecting Ligand Binding, Protein Conformational Changes and Proteolysis

A four-base codon/anticodon (CGGG/CCCG) pair was recently used to incorporate fluorescent amino acid analogues at specific positions in streptavidin.[120] Streptavidin mutants with nonnatural amino acid were found to bind biotin, indicating that they retained their native conformation. When an anthryl group was incorporated at Residue 120, its fluorescence was markedly decreased upon biotin binding due to suppression of energy transfer from excited tryptophan. In addition, when the modified amino acid 7-methoxycoumaryl-alanine was incorporated at this position, the fluorescence intensity was modulated by biotin binding. More recently, this approach was used to incorporate a position-specific fluorophore-quencher pair (β-anthraniloyl-L-α,β-diaminopropionic acid [atnDap] as a fluorophore and *p*-nitrophenylalanine [ntrPhe] as a quencher) into streptavidin.[121] Such an approach holds great promise for designing photonic proteins that can "sense" binding of native and nonnative ligands present at very low concentrations.[122,123]

Another example of the incorporation of two unnatural photonic groups into a single protein was shown by Hecht and coworkers.[124] Dihydrofolate reductase (DHFR) was engineered with a fusion peptide at its *N*-terminus that contains the quencher (*N*β-dabcyl-1,2-diaminopropionic acid) and fluorophore (7-azatryptophan) flanking an HIV-1 protease cleavage site. *In vitro* expression involved use of an amber suppressor tRNA and a four-base anticodon tRNA. The resulting DHFR fusion complex exhibited an increase in fluorescence intensity upon treatment with HIV-protease.

Incorporating Light-Activated Residues

Photonic Switching of Protein Activity

In contrast to chemical labeling (Section 133.2), TRAMPE provides a method for engineering proteins with light-activated residues. For example, in early work, Schultz's group succeeded in engineering a photoactivatable T4 lysozyme by substituting nitrobenzyl caged Asp (NB-Asp) for Asp-20, a residue that is essential for catalytic activity.[125] While the modified protein was completely inactive, photolysis by 350 nm light rapidly restored the activity of lysozyme. More recently, a method for site-specific, nitrobenzyl-induced photochemical proteolysis of proteins expressed in living cells was reported by England et al.[126] This method is based on the chemistry of an unnatural amino acid (2-nitrophenyl)glycine (Npg), and its incorporation into nascent proteins in *Xenopus* oocytes using the *in vivo* nonsense codon suppression approach. This nonnative amino acid has the property that irradiation leads to site-specific, nitrobenzyl-induced photochemical proteolysis (SNIPP) along the polypeptide chain. Rapid inactivation of the voltage-activated Shaker B K^+ channel with incorporated Npg residues was achieved by light-induced cleavage of the structural domain responsible for inactivation. SNIPP was also used to cleave the Cys128-Cys142 disulfide loop of the nicotinic acetylcholine receptor, thereby demonstrating that the integrity of this loop is crucial for function.

An additional example of production using TRAMPE of a reversible photoactivatable enzyme was recently reported by Muranaka et al.[52] Horseradish peroxidase mutants containing L-*p*-phenylazophenylalanine (azoAla) at various positions were synthesized by using an *E. coli* cell-free translation system. Among the several mutants studied, four mutants containing a single azoAla residue at positions 6, 68, 142, and 179 retained peroxidase activity. Interestingly, the activity of the Phe68azoAla mutant was higher when the azobenzene group was in the *cis* form than when in the *trans* form. In contrast, the activity of the Phe179azoAla mutant disappeared when the azobenzene group was photoisomerized to the *cis* form but recovered in the *trans* form.

Light-Activated Channels

Caged proteins are useful in a wide variety of applications, including signal transduction.[24,25,36,37] Although most of the work in this area is based thus far on chemical modification of proteins, as discussed in

Section 133.2, TRAMPE can also be used for incorporation of caged amino acids residues. For example, Philipsson et al.[127] reported incorporation of a caged Cys or Tyr into the transmembrane segment of a membrane protein. The authors used suppressor tRNA to incorporate *o*-nitrobenzyl cysteine or *o*-nitrobenzyl tyrosine (caged Cys or Tyr) into Position 9 of the M2 transmembrane segment of the γ-subunit of the muscle nicotinic ACh receptor expressed in *Xenopus* oocytes. The caged amino acids replaced an endogenous Leu residue that was implicated previously in channel gating. Removal of the caging group from modified protein by UV-irradiation resulted in a substantial increase in the ACh-induced current. In addition, it was found that the incorporation of a bulky nitrobenzyl group does not prevent the assembly or trafficking of the ACh receptor. Similarly, Tong et al.[128] used a similar procedure to incorporate a caged tyrosine residue in place of the natural tyrosine at Position 242 of the inward rectifier channel Kir2.1 expressed in *Xenopus* oocytes. In this case, the tyrosine residue was chosen, because its side chain is known to participate in several distinct signaling pathways, including phosphorylation and membrane trafficking. The protein containing caged tyrosine was activated by exposure to near-UV light.

Monitoring Protein Expression

In addition to custom design of photonic proteins, which normally requires site-specific modifications at particular internal residues, TRAMPE can be used to incorporate photonic moieties at nonspecific positions, such as at random lysine residues or only at the *N*-terminal position of a protein. This approach can be useful in the fields of gene expression, proteomics, and even medical molecular diagnostics. For example, fluorescent labels can be used to monitor *in vitro* or even *in vivo* expression of proteins, to build arrays of proteins with which to detect specific protein–protein or drug–protein interactions, and even to detect genetic defects, which are expressed on the protein level.

Efficient *N*-Terminal Labeling with Photonic Groups

As described in Section 133.3, it is possible to label the *N*-terminus of proteins expressed in a cell-free translation system with a fluorescent tag using *E. coli* initiator $tRNA^{fmet}$.[117] Under optimal conditions, the incorporation of BODIPY-FL was found to be low (1 to 2%), even though it was sufficient to detect nascent proteins with good sensitivity using SDS-PAGE. For this reason, a more efficient method was developed[129] that utilizes an amber initiator suppressor tRNA chemically aminoacylated with a nonnative amino acid conjugate, which is introduced into an *E. coli* S30 cell-free translation system. The normal initiator codon (ATG) of the gene was replaced by an amber codon (TAG) in the DNA template. Using this approach, several fluorophores and affinity tags were incorporated at the *N*-terminus of various proteins, such as α-hemolysin, dihydrofolate reductase, and firefly luciferase. Typically, in this system, the specific labeling achieved was 25 to 50%, while protein yield was around 20% compared to the yield of wild-type protein translation. For the proteins studied, the presence of modifying groups at the *N*-terminus did not affect enzymatic activity. Protein translation was initiated with different labeled amino acids. In one case, lysine carrying two different labels on both amino groups was successfully incorporated at the *N*-terminus. The resulting protein had a fluorophore BODIPY-FL group on the ε-amino group and a biotin or PC-biotin on α-amino group of the *N*-terminal lysine.

Labeling at Specific Amino Acids with TRAMPE

A general method of incorporating fluorophores into nascent proteins can be based on the use of elongator tRNAs (e.g., lysyl-tRNA) misaminoacylated with fluorophores. For example, AmberGen, Inc. developed an approach based on the fluorescent reporter group BODIPY-FL,[130] which is randomly incorporated at lysine positions in the protein chain using an *E. coli* $tRNA^{lys}$ aminoacylated with lysine and modified at the ε-amino group.[131] This particular tRNA is available under the trade name Fluoro-Tect™-$Green_{Lys}$ from Promega Corp (Madison, WI). Similar to BODIPY-FL-Met-$tRNA^{fmet}$, BODIPY-FL-Lys-$trna^{lys}$ enables sensitive detection of cell-free synthesized proteins in a prokaryotic translation system (*E. coli* S30 extract) as well as eukaryotic translation systems (wheat germ and rabbit reticulocyte cell-

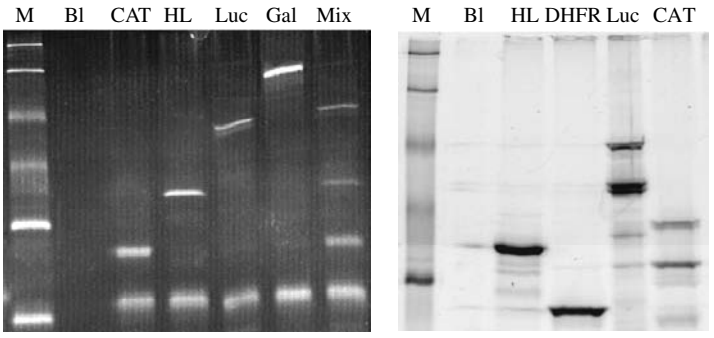

FIGURE 133.6 Fluorescent detection of *in vitro* expressed proteins. (A) Test proteins were labeled with BODIPY-FL-Lys-tRNA^{lys} in TNT wheat germ cell-free expression system and visualized using UV-transilluminator/CCD camera. (B) Test proteins were labeled using BODIPY-FL-Lys-tRNA^{lys} in *E. coli* S30 cell-free expression system and visualized using laser scanner (FluorImager). Lane M - fluorescent molecular weight markers, Bl - negative control-no DNA added; CAT - chloramphenicol acetyltransferase; HL - α-hemolysin; Luc - luciferase; Gal - β-galactosidase; DHFR - dihydrofolate reductase and Mix - a mixture of CAT, HL and Luc DNA.

free translation extracts).[132] Recently, this tRNA was used for high-throughput expression screening of various cDNA constructs.[133]

As an example of its application to monitor cell-free protein expression, shown in Figure 133.6 is the visualization of fluorescent bands from several proteins expressed in wheat germ and *E. coli* translation systems in the presence of BODIPY-FL-lysyl-tRNA^{lys}. In contrast to conventional radioactive detection, these proteins were detected on the gel immediately after SDS-PAGE. In particular, the gels did not require fixing, which normally is at least a 30 min procedure. The detection time using a conventional UV-transilluminator/CCD camera or a laser scanner (FluorImager, Molecular Dynamics) was less than 5 min, compared to several hours for autoradiography.

This tRNA (BODIPY-lysyl-tRNA^{lys}) was recently used to demonstrate the presence of coupled transcription and translation within the nuclei of mammalian cells.[134] This was achieved by incubating permeabilized mammalian cells with lysyl-transfer RNA tagged with BODIPY (BODIPY-lysyl-tRNA^{lys}). Although most nascent polypeptides were found in the cytoplasm, some were found in discrete nuclear sites known as transcription "factories." This coupling is simply explained, if nuclear ribosomes translate nascent transcripts as those transcripts emerge from still-engaged RNA polymerases, much as they do in bacteria.

In addition to nonspecific lysine labeling, Lien et al.[135] reported site-specific incorporation of a fluorescent tag into nascent proteins using a Cys-tRNA^{cys}. After aminoacylation of *E. coli* Cys-tRNA^{cys}, it was modified with a SH-reactive fluorophore (BODIPY-FL). This method may prove valuable when used in conjunction with site-directed mutagenesis to create protein containing single-cysteine residues by which one can prepare the nascent protein containing single fluorophore at a defined position.

Applications of TRAMPE to Molecular Diagnostics

Truncations in a protein can occur due to frameshift and point mutations that result in creating a prematured stop codon in the reading frame of a gene. Such truncated polypeptides can be detected by translating a specific region of the DNA (mRNA) corresponding to the target gene in a cell-free translation system in the presence of radioactive labels (e.g., ^{35}S-methionine or ^{14}C-leucine) and then by analyzing SDS-PAGE and autoradiography. Such an approach, known as the protein truncation test (PTT), was successfully used for the analysis of truncating mutations in a variety of cancer-linked genes, including BRCA1/BRCA2, ATM, MHS2, MLH1, and APC.[136–138] However, in conventional PTT, the use of radioactive isotopes presents several problems, including detection time (>8 h), which is critical for high-throughput analysis. For this reason, it would be highly advantageous to replace radioactivity with a

more rapid means of detection. In order to overcome this, a nonisotopic, high-throughput PTT method was developed using cell-free protein synthesis and incorporating biotin and BODIPY-FL.[131] The incorporation of fluorescent moieties into nascent proteins or protein fragments using TRAMPE allowed for the detection of premature chain-truncating mutations that occur in a variety of tumor suppressor proteins.

133.4 Future Perspectives

In this review, we described many of the emerging tools that can be used to build artificial photonic proteins. They include a repertoire of increasingly versatile and selective molecular engineering techniques for incorporating photonic molecules into nonphotonic proteins, including TRAMPE, chromophore-binding motifs, and selective chemical reactions. The creation of new and useful photonic molecules that can serve as chromophores for photonic proteins, such as isomerizable chromophore and photocleavable caging agents, is also contributing to this goal.

A second convergent path toward building functional photonic proteins not covered in this chapter is the progress occurring in the field of "designer proteins," e.g., de novo design of proteins.[139] The goal of researchers in this area is to develop the ability to build new proteins from the ground up, with specific functional properties, such as receptor, enzymatic, and ion transport. Progress includes the discovery of increasingly shorter amino acid sequences (~20) that fold into well-defined stable structure domains.[140] In addition, progress is also occurring in the understanding of the principles that govern protein folding, cooperativity, and conformational changes.[141] Such structures can serve as scaffolds on which to incorporate photonic moieties that serve as light sensors and light triggers, as discussed in this chapter.

A third factor contributing to the development of artificial photonic proteins is the increasing detail for which the mechanism of natural photonic proteins is understood. For example, in the case of bacteriorhodopsin, one of the most extensively studied photonic proteins, high-resolution three-dimensional structures along with spectroscopic probes of BR and its photocycle intermediates are providing an unprecedented look at hydrogen-bonded proton chains, helix movements, and chromophore isomerization, which underlie the light-driven proton transport function of this protein.[7,142,143] Similar progress is also occurring in the study of the related Sensory Rhodopsin II signal transduction protein and its associated transducer HtRII[144–147] (see Chapter 124) as well as many other light-activated proteins in nature. This knowledge, along with increased understanding of how such proteins fold stably in the membrane[148,149] and possess, in many cases, structural integrity at high temperatures,[150] will provide an increasingly firm basis for constructing biomimetic photonic proteins.

While many of the examples described in this review are already useful for basic research, it is expected that as the ability to build artificial photonic proteins continues to improve, they will find their way into many areas of biotechnology and medicine. One example described in the *Scientific American* article, "Building Doors into Cells," by H. Bayley,[151] is the use of engineered photonic proteins for targeted drug delivery. Using light-activated pores of α-hemolysin as an example , it is proposed that such photonic proteins could be incorporated into liposomes, which would serve as drug delivery vehicles. Once the liposome is distributed throughout the body, the drug can be delivered locally via photoinduced release of the drug from the liposome. A similar strategy applies to light-activated gene therapy, the basis of which was described by Pandori et al.[32]

Photonic proteins are also likely to become critical components of a new generation of biosensors. The ability to design proteins that contain fluorescent molecules at specific positions, such as within a binding pocket or inside a channel, facilitates the detection of specific molecular interactions, as discussed previously. One example where such an approach might be especially attractive and have a major impact is the detection of single nucleotides as an oligonucleotide as it transits through a nanopore. Dramatic progress was recently achieved in this direction by monitoring conductivity changes of oligonucleotides inside such a pore,[152,153] including the engineering of α-hemolysin for this purpose.[154] It is possible to envision a photonic version of a nanopore that could be used for rapid DNA sequencing and mutation detection. In such a system, fluorescence rather than electrical current would be monitored as individual

bases transiting past a molecularly engineered photonic read probe. In such a system, single molecule fluorescence detection could be utilized.[155] An array of such nanopores, each engineered to recognize different small sequences, could also be envisioned.

In the continuing endeavor to build photonic proteins evolve, cutting-edge progress in molecular biology, photochemistry, and photobiology will continue to be relied upon.

Acknowledgments

The authors wish to acknowledge the contributions from the Boston University Molecular Biophysics Laboratory and AmberGen, Inc., whose members contributed to the research described in this chapter, along with many of our collaborators, including H. Bayley, C. Cantor, W. DeGrip, H.G. Khorana, U.L. RajBhandary, J.L. Spudich, and T. Sano, who inspired our interest at an early stage in many of the concepts described here. This work was supported by grants from the NIH (EY05499) to KJR and SBIR awards to AmberGen, Inc., from the Army Research Office and the NIH (GM64912, CA83396, and GM63369). We also wish to thank the Photonics Center at Boston University and its Director, Don Fraser, for encouragement and infrastructure support.

Molecular Electronic Switches in Photobiology

Felix T. Hong
Wayne State University School of Medicine

134.1 Introduction

Light is used by bioorganisms for two major purposes: sensory perception and energy conversion. The functional requirements of molecular devices are drastically different for these two purposes. The former demands sensitivity and a wide dynamic range of photon energy detection, and the latter demands efficiency of photon energy conversion. Superficially, there seems to be a dichotomy of nature's choice of molecular materials for these two diverse functions: visual membranes utilize retinal as the chromophore, whereas photosynthetic membranes utilize magnesium porphyrin as the chromophore. Fundamentally, there are features in common to these two types of photobiological membranes. In Chapter 128, light-induced charge separation and the photoelectric effect are examined in detail. In this chapter, we will consider the molecular switching processes in these two diverse systems from a broad perspective.

The vertebrate rod is a highly sensitive photoreceptor. Hecht and coworkers[1] demonstrated that a single visible photon absorbed by a single molecule of rhodopsin is capable of eliciting an electrical response of the vertebrate rod photoreceptor. The energy required for the generation of a synaptic potential — the generator potential — is not provided by the absorbed photon alone. Rather, photon energy merely serves as the trigger for releasing previously stored energy in the form of transmembrane Na^+ gradient. The latter event constitutes the generator potential of a visual photoreceptor, which was identified with the *a* wave of the electroretinogram (ERG).[2] What transpires in the process of absorption–excitation coupling is an energy amplification of 100,000-fold. In this sense, rhodopsin is a light-sensitive molecular switch. In order for this switch to be reliable and useful, several requirements must be met in addition to an amplification mechanism. The rise time of the trigger signal must be fast. The

0-8493-1348-1/04/$0.00+$1.50

initial response must be localized and linear. In contrast, the generator potential is global and highly nonlinear. The wide dynamic range of photon sensing — nine orders of magnitude — is made possible partly by virtue of light–dark adaptation and partly by virtue of a logarithmic light-dependence of the generator potential. It was well established that the cyclic GMP cascade is the biochemical amplification process that converts the initial linear photoresponse to the logarithmic, nonlinear electrical response of the generate potential. Biochemically, molecular switching is accomplished by a sequence of conformational changes of several molecules of visual transduction: each step of switching contributes a significant factor of amplification.[3] Detailed knowledge of these conformational changes is now available because of elucidation of crystal structures of several key molecules, including rhodopsin. Of particular interest is the mechanistic aspect of molecular switching during the process of molecular recognition: molecular switching leads to enhanced recognition. As described in Chapter 128, the early receptor potential (ERP) appears to be a natural suspect of the initial mechanistic trigger, because it is linear and localized with an ultrafast rise time, and because it is in the right place at the right time. Lying between ERP and LRP is a gap of 1.5 to 1.7 ms of time delay. Previously, we speculated about its mechanistic role.[4,5] It is, therefore, of interest to reexamine the topic in light of the now-known detailed molecular events.

Photosynthesis, nature's other major photobiological function, is the conversion of the solar photon energy into chemical energy. Photosynthetic energy conversion starts as a light-induced vectorial charge separation across the photosynthetic membrane. These separated charges are stored on the membrane capacitor in the form of a transmembrane voltage and a transmembrane proton gradient. According to the chemiosmotic theory advanced by Mitchell[6] and by Williams,[7–9] the stored energy is then preferentially channeled to ATP synthase to drive the reaction of converting ADP and inorganic phosphate into ATP — the universal energy currency in the living world. Superficially, molecular switching function has little to do with photosynthetic energy conversion, because sensitivity is not the primary concern. In reality, switching function is important in bolstering the efficiency of energy conversion. In general, the efficiency of photon conversion is contingent on the relative fraction of separated charges that recombines through an external device so as to perform useful mechanical or chemical work. Any other route of charge recombination must be considered wasteful: short-circuiting, so to speak. Photosynthetic bacteria and higher plants evolved efficient photosynthetic apparatuses that manage to minimize such wasteful diversion of energy. Often, such improvement relies on well-orchestrated short-range noncovalent bond interactions, which include hydrogen bonding, electrostatic, hydrophobic, and van der Waals interactions.

Nature seldom adopted a single approach to improve physiological functions of a living organism. In addition, it is not uncommon that successful strategies in nature's repertoire are seen to repeat across the boundary between plants and animals, and, in particular, the boundary between vision and photosynthesis. The purple membrane of *Halobacterium salinarum*, a photosynthetic apparatus that utilizes a "visual" pigment, offers an unusual glimpse into common features in vision and photosynthesis.[10] This chapter begins with a general description of the role of noncovalent bond interactions in molecular recognition. Detailed molecular switching processes will be examined in two mobile electron carrier systems in photosynthesis (each residing on the opposite side of the photosynthetic membrane), three key molecules in visual transduction (rhodopsin, transducin, and arrestin), and bacteriorhodopsin.

An emerging interest in molecular electronic switches accompanies the advent of molecular electronics research — attempts to fabricate electronic devices based on organic materials. Computer scientist Michael Conrad[11] pointed out that the predominant feature of a biological information process is shape-based rather than switch-based. Absent a predominant role played by switches, Conrad found himself in a position to search for an explanation to reconcile how diffusion and random collisions of macromolecules can give rise to highly deterministic processes, such as decision making by human brains. Of course, there are switching processes in biology, as implied by visual transduction and, more generally, by phosphorylation as a major mechanism for enzyme activation. Even so, these switches are not as deterministic in operations as "gates" and "flip-flops" commonly used in computer technology. The intriguing question is: why did nature not make the processes less uncertain and more deterministic? Speculations will be presented to make some sense of nature's choice.

134.2 Short-Range Noncovalent Bond Interactions in Molecular Switching Processes

As Conrad[11] frequently emphasized, molecular recognition is primarily based on the lock–key principle of Emil Fischer. It is instructive to examine an example offered by cytochrome *c*.[12] Cytochrome *c*, a mobile electron carrier, shuttles between cytochrome b–c_1 complex and the cytochrome oxidase; it receives an electron from the former and passes it to the latter in the mitochondrial inner membrane. The recognition primarily involves a small number of matching ionic bonds (electrostatic interactions). Furthermore, the lock–key matching is not unique: cytochrome *c* utilizes two slightly different sets of ionic bonds to dock with the cytochrome b–c_1 complex and with cytochrome oxidase. Thus, shape fitting in macromolecular recognition is only approximate, and the geometric shapes of the two docking sites are not precisely complementary to each other. Apparently, perfect shape fitting in molecular recognition is neither desirable nor necessary. Perfect shape fitting would make molecular recognition an unacceptably slow process. Also, perfect shape fitting tends to make the complex much too stable to be able to come apart subsequently. In other words, perfect or near-perfect shape fitting confers an affinity (to the encountering partners) that is too high to make molecular recognition functionally useful.

Molecular recognition is determined in part by shape matching and in part by the matching of specifically aligned ionic bonds, hydrogen bonds, van der Waals contacts, and hydrophobic interactions. The docking process is achieved by minimizing the combined potential energy of all short-range noncovalent bond interactions. These noncovalent bonds are weaker than covalent bonds. However, depending on the total number of bonds, together they are sufficiently strong to overcome dislodging by thermal agitation.

The van der Waals forces, which are nonspecific, require close proximity of atoms (3 to 4 Å) for action. These forces contribute to the stability of complex formation but require close shape-match to exert effect. Hydrophobic forces are also nonspecific and confer no polarity of bonding. As we will see, a docking cavity is often lined with hydrophobic amino acid residues. Hydrogen and ionic bonds, however, exhibit "directionality" and require matching parts with opposite polarities, just like Velcro® fasteners' *loops* and *hooks*. These bonds thus confer some specificity on molecular recognition. However, as indicated by the action of cytochrome *c*, the specificity is not absolute and unique. Because these bonds are not highly specific, a "false" (imperfect or incorrect) match can occur with fewer, "accidentally" aligned, hydrogen or ionic bonds, thus settling in a *local* potential-energy minimum. However, a false match helps trap the encountering molecules and allows them to form a transient complex. As a result, the contact dwell time is significantly increased, and a three-dimensional searching process is converted into a two-dimensional one for the *global* potential-energy minimum. This trapping effect is known as the reduction-of-dimensionality principle.[13] Specificity of the correct docking position is provided by the *pattern* formed collectively by the geometric distribution of these bonds at the interface of the two complexing molecules. In other words, the complementary shape of the docking site, which often looks like a cavity in the larger one of the two partners, helps define the bond distribution pattern and, hence, its specificity. The shape of the docking site matters, because, with the exception of electrostatic interactions, the noncovalent bond interactions are extremely short-ranged (no more than a few Å) and, therefore, the shape of the docking site affects the distance between the matching recognition sites.

Is two-dimensional searching for the correct docking position purely random? Not necessarily. In operations research and human problem solving, approaching the task by trial and error and by examining every possible way is simply not realistic. This is because the number of possibilities rapidly increases beyond bound, as the complexity of the problem increases (a situation known as combinatorial explosion). A typical example is provided by the enormous number of possible moves, countermoves, countermoves against countermoves, etc., in a chess game, when a player tries to outsmart the opponent and searches for a strategic move by planning ahead at a search depth of several levels (or, rather, plies — half moves). Even IBM supercomputer Deep Blue, which defeated world chess champion Garry Kasparov in 1997, could not afford to explore the search space exhaustively.[14] Therefore, selective searching based

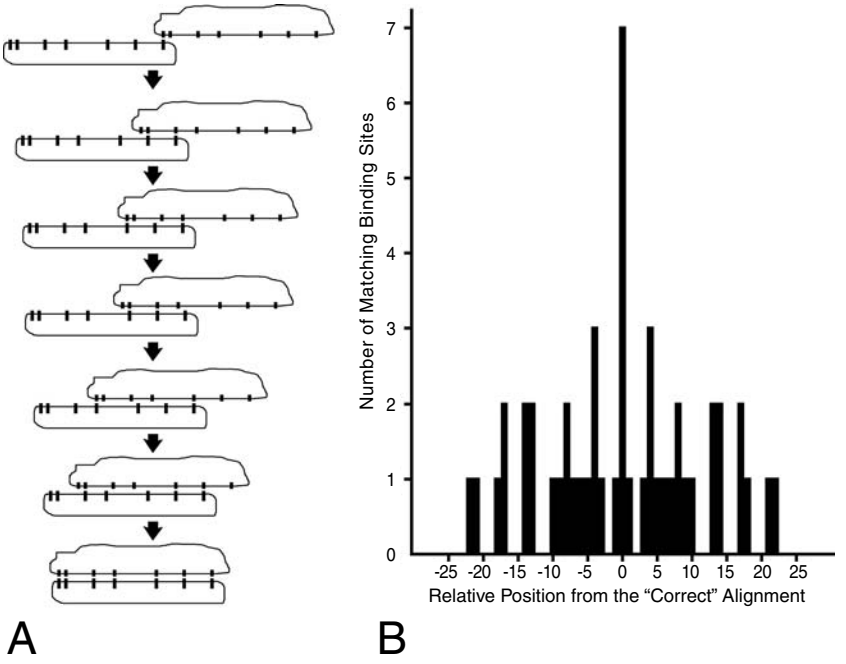

FIGURE 134.1 A gradient strategy of molecular recognition. (A) The schematic shows that any initial imperfect match between two encountering macromolecules locks them together, while a gradient of varying bonding strengths guides the two molecules to find the "intended match" by means of free energy minimization. Here, the shape factor is ignored, and the search for docking is restricted to one dimension for simplicity. Only one type of noncovalent bond interaction, such as ionic or hydrogen bonding, is considered, and the bond polarity is disregarded. The sequence shows unidirectional sliding, but in reality, the two encountering molecules slide against each other back and forth in Brownian motion. (B) The free energy landscape is, therefore, represented by a number of peaks that depict bonding at one, two, three, and seven sites. The initial search is conducted by means of two-dimensional random diffusion and collisions. When the two encountering parties slide along each other, some local peaks (i.e., local minima in the free energy landscape) of two- and three-site bonding are reached. If the two molecules overshoot the target and continue to slide in the same direction, the number of matching sites will decrease to three and two (separated by some one-site matches). If thermal agitation dislodges the two molecules from the global minimum, the gradient will "discourage" the two encountering molecules from sliding away from each other, thus prolonging the dwell-time of the encounter. On the other hand, thermal agitation prevents the encountering molecules from being trapped at any of the local minima.

on explicitly prescribed rules of thumb or *heuristics* often allows a problem to be solved in a reasonable length of time, whereas an undirected or trial-and-error search would require an enormous amount of time, and often could not be completed in a human lifetime. The approach is known as *heuristic searching* in cognitive science and operations research.[15]

Searching in molecular recognition and other biocomputing processes cannot be readily quantified as in chess games, but the implication of combinatorial explosion is no less alarming. As we shall see, nature was perfectly capable of evolving additional mechanisms, which are increasingly deterministic so as to avoid random searching. Variations in the number of hydrogen or ionic bonds permit fine-tuning of the overall bonding strength by evolution. Protein conformations offer virtually unlimited variations of the shape of contact surfaces. The variation in shape allows for variation in geometric distributions of noncovalent bonds. Thus, in principle, a *gradient* of bonding strengths could be evolutionarily arranged, and a *cascade* of local minima could be evolutionarily constructed to guide the two-dimensional searching process toward the global minimum instead of away from it (*biased* two-dimensional random searching or heuristic searching). Schematically, the gradient strategy can be implemented with a hypothetical

model, as shown in Figure 134.1, in which only electrostatic interactions in one dimension are considered. For simplicity, the bond polarity and the shape factor of the matching surfaces are ignored in the schematic diagram. When two (flat) matching surfaces slide over each other, down the potential-energy gradient, the initial match involves only one or two matching bonds, then three bonds, and finally all seven bonds. In reality, all of the noncovalent bond interactions are involved. Furthermore, the shape factor modulates the interactions, because noncovalent bond formation requires the proximity of matching sites.

The validity of the "gradient" strategy is supported by the following observations. A steering effect based on a two-step strategy was reported by Colson et al.[16] The reduction-of-dimensionality effect was observed in a Brownian dynamics simulation of cytochrome *c* and cytochrome *c* peroxidase complex formation.[17] A simulation of the free-energy landscape for two complexing proteins, reported by Camacho et al.,[18] showed that electrostatic interactions have a steering effect toward the correct mutual orientation in some cases, while desolvation energy (hydrophobic interaction) serves as an attracting and aligning force in other cases. Myosin globular heads were found to hop stochastically in steps from 5.5 to 27.5 nm (integral multiples of 5.5 nm) along an actin filament during muscle contraction.[19,20] Myosin globular heads sometimes even jumped backward instead of forward, but mostly forward. The existence of a gradient of varying binding constants along the actin filament is apparent; it was the thermal fluctuations that allowed the myosin globular heads to seek sites with higher binding constants.

An additional steering effect can take place at a greater distance than is possible to form ionic or hydrogen bonds, because the electrostatic force does not suddenly vanish but rather tapers off gradually, albeit at a rate that is still faster than that predicted by the inverse square law due to electrostatic charge screening. Two clusters of charges on two separate molecules can interact electrostatically at a considerably greater distance than is possible for other types of noncovalent bond interactions, because the collective magnitude of the clustered charges may be sufficiently large to make the force, though attenuated by distance and charge screening, still felt at a distance of more than just a few Å. However, the cluster of charges has to be regarded as a *point* source of charges under this circumstance. This is because the distance of separation between individual charges in the same cluster is small compared to the distance between the two macromolecules; every charge on a macromolecule is of about equal distance to any charge on another macromolecule at a distance. Thus, its docking partner at such a distance cannot recognize the detailed charge distribution pattern of the charged amino acid residues on the surface of a macromolecule. This type of electrostatic interaction shall be referred to as *global* electrostatics. In contrast, when the partners are within a few Å apart, each charged residue experiences mainly the attraction of another charged residue that is well-aligned to form a complementary pair together; attractions or repulsions due to other charged residues that are not aligned are weak by comparison (*charge pairing*). It is the pairing of complementary charges that helps define the specificity of the correct docking position. This type of electrostatic interaction shall be referred to as *local* electrostatics. Of course, other types of noncovalent bond interactions and the shape of the matching docking sites also contribute to the *local* specificity. In particular, hydrogen bonding provides another means of pairing for local specificity.

As we will see, mobile electron carriers often exhibit an asymmetry of charge distribution on their exposed surfaces so as to form a giant electric dipole. The interaction of two encountering electric dipoles thus helps align the two approaching partners for preferred mutual orientation prior to a collision. This type of interaction must be distinguished from interactions that form ionic bonds. The dipole–dipole interaction does not require charge pairing.

Thus, electrostatic interactions are invoked twice: for the purpose of homing (oriented collision) and for the purpose of defining the specificity of transient complex formation (docking). It is often referred to as long-range interactions in the biochemistry literature, even though it is mesoscopic in origin and it operates at a shorter range than prescribed by the inverse square law. The homing action during the first stage of activation of protein kinase C belongs to this type of steering effect.[21]

Electrostatic interactions are important mainly for the initial complex formation and crude alignment, but they are not the sole determinants for final orientation in an electron transfer reaction. Other types of interactions, such as hydrophobic interactions, are often called upon to finalize the docking process,

as was demonstrated in the interaction of the following redox partners: plastocyanin and cytochrome *f* complex[22] (of the cytochrome b_6–*f* complex), cytochrome c_6 and Photosystem I,[23] and ferredoxin and ferredoxin:NADP$^+$ reductase (FNR).[24,25] In fact, direct measurements of the ionic strength dependence of intracomplex electron transfer rate constants for several redox partners, such as yeast or horse cytochrome *c*–cytochrome *c* peroxidase, spinach ferredoxin–FNR, and bovine cytochrome *c*–cytochrome *c* oxidase, demonstrated that electrostatic forces are not the sole determinants of optimal electron transfer rates (reviewed by Tollin and Hazzard[26]). At low ionic strengths, the electrostatic interactions are enhanced, but the redox pairs are "frozen" into a nonoptimal electrostatically stabilized orientation. This is in part because charge pairing is not highly specific, and false matches are common. Excessive electrostatic interactions distort the delicate balance among various types of noncovalent bond interactions and increase the chance of trapping the redox partners in a local minimum, thus preventing them from reaching the global minimum in the free energy landscape. Additional experiments were performed to cross-link redox pairs at low ionic strengths and lock the pairs into electrostatically stabilized complexes. In all systems examined, which included cytochrome *c*–cytochrome *c* peroxidase, flavodoxin–FNR, and cytochrome *c*–cytochrome *c* oxidase, electron transfer rate constants were actually smaller for the covalent complex than for the transient complex formed upon collision at the optimum ionic strength. Apparently, a certain degree of flexibility of the docking process is required to allow for exploration of the optimal orientation. In other words, short-range interactions between the docking partners should be sufficiently strong to link them together so as to increase the contact dwell time but not so strong as to inhibit two-dimensional explorations for the optimal orientation.

134.3 Molecular Switching Processes in Major Photobiological Systems

Ferredoxin and Ferredoxin:NADP$^+$ Reductase

We will first consider the interactions between ferredoxin:NADP$^+$ reductase (FNR) and its redox partners: ferredoxin (Fd) and NADP$^+$. A ternary complex consisting of Fd, FNR, and NADP$^+$ was studied by Batie and Kamin.[27,28] It was proposed that a transient ternary complex involving Photosystem I, Fd, and FNR could be formed.[29] More recently, a complex of Fd and FNR was crystallized.[30] The complex is biologically relevant, because the structure agrees with what was inferred from studies in the solution phase. The two proteins can cocrystallize only with a molar excess of FNR over Fd, resulting in a ternary complex consisting of two reductases (named FNR1 and FNR2) and one Fd molecule. Fd is bound to a hydrophobic cavity provided by FNR1. The Fd [2Fe–2S] cluster is 7.4 Å apart from the exposed C8-isoalloxazine methyl group of the cofactor FAD of FNR1, which is sufficiently close to enable effective fast electron transfers. In contrast, Fd makes a contact with FNR2 at the site where NADP$^+$ is physiologically bound. The Fd iron cluster is too far from the FNR2-FAD (14.5 Å) to enable a fast electron transfer. Therefore, the complexation between Fd and FNR2 is probably a crystallographic artifact; the role of FNR2 could be to stabilize crystal packing by contacts with neighboring proteins. Morales et al.[30] pointed out that the interactions between Fd and FNR1 are far more specific than those between Fd and FNR2, as indicated by the following pairs of data: the number of hydrogen bonds and ion pairs (10 versus 3), van der Waals contacts (<4.1 Å) (54 versus 21), and buried area upon complex formation, i.e., cavity (1600 Å^2 versus 1100 Å^2). The molecular electric dipoles of Fd and FNR1 are nearly colinearly orientated, resulting in the negative pole of Fd being close to the positive pole of FNR1.[31] Additional arguments in support of the biological relevance of the Fd–FNR1 pair of the ternary crystal complex can be found in an important article by Gómez-Moreno and coworkers.[30]

Gómez-Moreno and coworkers extensively analyzed the effect of site-directed mutagenesis of FNR and its redox partners. Charged amino acids were replaced with neutral or amino acids with reversed charge polarity (and sometimes with concurrent side-chain elimination). These investigators found that some charged amino acids are absolutely critical for electron transfers, while replacements of other nearby

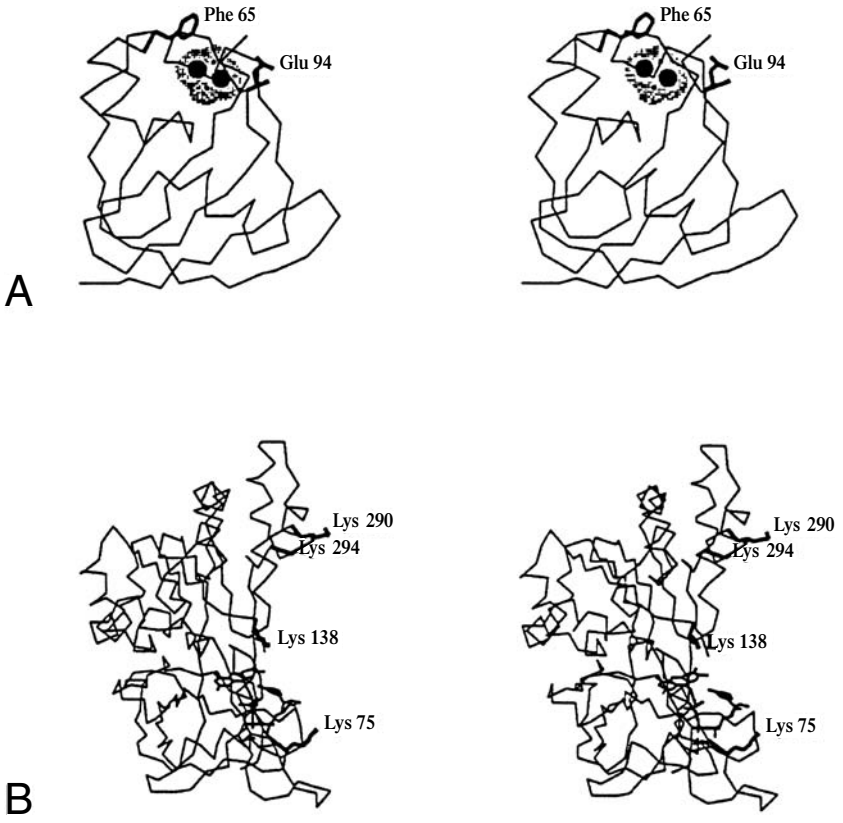

FIGURE 134.2 Stereoscopic views of ferredoxin (A) and FNR (B) of *Anabaena* PCC 7119 showing the positions of key amino acid residues that are critical for molecular recognition. (From Gómez-Moreno, C., Martínez-Júlvez, M., Fillat, M.F., Hurley, J.K., and Tollin, G., *Biochem. Soc. Trans.*, 24, 111, 1996. With permission.)

residues have moderate or no effect. For example, Phe65 and Glu94 on Fd are required for efficient electron transfers between Fd and FNR[32] [Figure 134.2(A)]. In contrast, nearby residues Glu95, Asp67, Asp68, and Asp69 play significant but less dominant roles in maintaining an appropriate protein–protein orientation (not shown; see Figure 1 of Hurley et al.[33]). These investigators suggested that charge pairing (ionic bonds) involving Glu94 is apparently important for maintaining a productive orientation — ionic bonds for docking — for electron transfers. The exact role of the aromatic residue Phe65 is not certain but is more likely involved in docking (hydrophobic interaction) than in the electron transfer pathway. Similarly, a cluster of hydrophobic residues (Leu76, Leu78, and Val136) on FNR was found to be critical for electron transfers between FNR and Fd but not between FNR and $NADP^+$.[25] Likewise, alterations of several basic residues on FNR that line the Fd-binding cavity (Lys75, Lys138, Lys290, and Lys294) also caused significant impairment of electron transfer between Fd and FNR, but the affinity of FNR for NADPH did not seem to change (NADPH binds to the opposite side of FNR) [see Figure 134.2(B)]. Viewing the stereoscopic structure of Fd and FNR on Figure 134.2 facilitates an appreciation of the spatial relationship of the two docking partners. A critical role was confirmed for Arg100 on FNR for the FNR–$NADP^+$ interaction, whereas Arg264 is not critical.[34] However, the mutant R264E (charge-reversal; positive Arg to negative Glu) showed an altered behavior in its interaction and electron transfer with Fd and flavodoxin. Here, it should be pointed out that Arg100 is near the binding pocket of FNR for $NADP^+$, whereas Arg264 is near the binding pocket of FNR for Fd (see Figures 1 and 6 of Martínez et al.[34], respectively).

In summary, there are two classes of amino acid residues: one involved in critical alignment of docking for electron transfers and the other involved in crude orientation or transient complex formation. Those involved in critical docking alignment tend to be different for the two substrates, Fd and those bound to opposite sides of FNR. Finally, hydrophobic clusters usually line the binding cavity and are critical for electron transfer. The situation with plastocyanin and cytochrome c_6 to be presented next is similar; the two independent sets of data demonstrate a common design scheme for redox partners of long-distance electron transfers.

Plastocyanin and Cytochrome c_6

We will now consider two mobile electron carriers that feed electrons from the cytochrome b_6–f complex to the oxidizing end of Photosystem I: plastocyanin and cytochrome c_6. In green plants, copper-containing plastocyanin is the sole mobile electron carrier between the cytochrome b_6–f complex and Photosystem I. Cyanobacteria and green algae, under the condition of a low copper concentration, can synthesize an alternate heme-containing mobile carrier, cytochrome c_6, to replace plastocyanin.[35,36] De la Rosa and coworkers[37] compared the structures and functions of these two electron carriers in two cyanobacteria (prokaryotes), *Synechocystis* and *Anabaena*, in a green alga (eukaryote) *Monoraphidium*, and in spinach chloroplast (eukaryote). These investigators found three different types of reaction mechanisms of the Photosystem I reduction: Type I (oriented collisional reaction mechanism), which involves an oriented collision between the two redox partners; Type II (a minimal two-step mechanism), which proceeds through the formation of a transient complex prior to electron transfer; and Type III, which requires an additional rearrangement step to make the redox centers orientate properly within the complex.

Cytochrome c_6 and plastocyanin are different in their basic structures. Their redox centers are heme and copper, respectively. The β-sheet structure of plastocyanin is absent in cytochrome c_6, which has several α-helices instead. However, there is analogous surface topology in these two mobile proteins. Both proteins feature a north hydrophobic pole around the redox center (Site 1) and an east face with charged groups (Site 2). The north pole is important in electron transfer, whereas the east face is important for orientation during the interaction of these proteins with Photosystem I but is not directly involved in electron transfer. As expected from their equivalent roles, the east face of plastocyanin and that of cytochrome c_6 are both acidic or both basic.

In cyanobacterium *Synechocystis*, both proteins contain an acidic patch at Site 2: the equivalent charges are Asp44 and Asp47 in plastocyanin and Asp70 and Asp72 in cytochrome c_6, respectively. When these charges were reversed by site-directed mutagenesis (e.g., plastocyanin mutants D44R and D47R, in which the respective negatively charged aspartate was changed to positively charged arginine), the electron transfer reaction was retarded but not abolished. The ionic strength dependence became the opposite of the wild type, i.e., the electron transfer rate was increased with increasing ionic strengths. Kinetic analysis revealed that the interactions followed the simple oriented collision (Type I). Apparently, these charged amino acids are not involved directly in the docking of the redox partners but are responsible for the generation of an electric dipole. This electric dipole helps orient the mobile electron carrier with the correct orientation toward the binding site on its redox partner. There was no evidence of transient complex formations in the interactions of Photosystem I and wild-type or mutant plastocyanin, such as D44R and D47R. The exception was the double mutant D44R/D47R .

The prokaryote *Anabaena* presents a different scenario. Site 2 of plastocyanin and cytochrome c_6 is positively charged. However, the function of Site 2 in plastocyanin is similar in *Anabaena* and *Synechocystis*. Alterations of these charges by site-directed mutagenesis (e.g., D49K, K58A, K58E) alter the surface potential distribution, thus allowing plastocyanin to modulate its kinetic rate of electron transfer: the more positively charged, the higher the rate constant.[38] Similar changes took place when the positively charged patch of cytochrome c_6 of *Anabaena* was altered by site-directed mutagenesis at Lys62 or Lys66.[23] Kinetic analysis by laser flash absorption spectroscopy indicated that these charges in plastocyanin and cytochrome c_6 are involved in the formation of a transient complex (Type III mechanism). Some mutations at the east face changed the kinetics to either Type I or Type II.

While alterations of charges in the east face modulate the electron transfer rate without completely abolishing electron transfer, alterations of charges at the north hydrophobic region are critical. Arg88 (adjacent to the copper ligand His87) in plastocyanin and Arg64 (close to the heme group) in cytochrome c_6 are required for efficient electron transfers.[23,38] These charges form part of the binding pocket and are critical for proper orientation of the redox partners.

In eukaryote green alga *Monoraphidium braunii*, plastocyanin and cytochrome c_6 contain acidic east faces, and both proteins exhibit a prominent electric dipole moment.[39] The reaction mechanism of electron transfer belongs to Type III: an additional arrangement is required after the formation of a transient complex. The postulated rearrangement can be a conformational change of the induced-fit type or elimination of water from the hydrophobic pocket (desolvation, involving reorganization energy, as stipulated by Marcus[40]), or a two-dimensional random walk, as stipulated in the reduction-of-dimensionality principle by Adam and Delbrück,[13] or both. As expected, cytochrome *f* (of the cytochrome b_6–*f* complex) also possesses an electric dipole moment; its docking surface with plastocyanin or cytochrome c_6 is negatively charged.[39]

In summary, studies of the structure–function relationships in the interactions of plastocyanin/cytochrome c_6 and their redox partners reveal the evolution of reaction mechanisms.[37] The north hydrophobic region is the *cavity* for lock–key style docking, whereas the east face is the site responsible for electrostatic interactions for mutual orientation and transient complex formation. In prokaryote *Synechocystis*, electrostatic interactions are invoked as a homing mechanism. The distribution of individual charges is not critical. The electron transfer process is made more deterministic by a proper orientation prior to collision (Type I). The overall electric dipole moment helps orient the mobile carrier via long-range electrostatic interactions. The Type II mechanism then evolved to increase the contact dwell time of the redox partners. In prokaryote *Anabaena*, eukaryote *Monoraphidium*, and higher plant, the reaction mechanism evolved to three steps: long-range electrostatic interactions for homing, a possible two-dimensional search or conformational rearrangement to refine the docking alignment, which requires shape fitting, and a final step of electron transfer. The mechanism of heuristic searching in molecular recognition is thus a product of evolution rather than an inherent feature of molecular interactions.

Rhodopsin, Transducin, and Arrestin

Three major proteins are involved in the initiation and termination of visual transduction: rhodopsin, transducin, and visual arrestin. Rhodopsin belongs to a large family of molecules known as the G-protein-coupled receptor superfamily[41] and is characterized by seven transmembrane α-helices. One of the partners, transducin (Gt), belongs to one of the most important classes of molecules in signal transduction: GTP-binding proteins (G proteins).[42,43] Visual arrestin is also a member of a large family of molecules involved in the deactivation of G proteins.

Like other G proteins, inactive transducin is a heterotrimer consisting of three subunits: Gα (which has a GTPase domain that binds a molecule of GDP, and two switch regions that initiate a major conformational change, once activated by its receptor), Gβ, and Gγ. Photoactivated rhodopsin — i.e., metarhodopsin II, or MII — binds the inactive transducin heterotrimer, triggers the switch regions, and causes the bound GDP to be released and a fresh GTP molecule to be bound to Gα. The GDP–GTP exchange then causes the three subunits of transducin to dissociate from metarhodopsin II and from one another, thus activating transducin and forming Gα-GTP and Gβγ. The activated Gα-GTP then triggers the cGMP cascade. Subsequent hydrolysis of the bound GTP in Gα then reassembles the three subunits into the inactive transducin heterotrimer.

The cGMP cascade is a nonlinear system that greatly amplifies the action of an absorbed photon on rhodopsin. Sitaramayya and Liebman[44] demonstrated that the termination of the cGMP cascade requires phosphorylation of rhodopsin. The phosphorylation of photoactivated rhodopsin is catalyzed by rhodopsin kinase[45] and takes place at the *C*-terminal region, where nine serine and threonine residues are phosphorylated.[46] Phosphorylation of rhodopsin reduces[47,48] or even blocks[49] Gt activation. This inhibitory effect is greatly enhanced by arrestin,[50] which binds specifically to phosphorylated MII.[48,51]

The investigations of molecular recognition between rhodopsin and its two reaction partners in the cGMP cascade were greatly facilitated by the elucidation of the crystal structures of rhodopsin,[52] transducin,[53–55] and arrestin.[56,57] More recently, using site-directed cysteine mutagenesis to place cross-linkers on rhodopsin, Khorana and coworkers[58,59] identified the contact sites of the photoactivated rhodopsin–transducin transient complex. Gα are cross-linked at residues 310 to 313 and 342 to 345 at the *C*-terminal region, which was previously known to be the receptor-binding domains,[60,61] and at residues 19 to 28 of the *N*-terminal region; both the *C*- and *N*-terminal regions are in contact with the third cytoplasmic loop of photoactivated rhodopsin, which was postulated to be the site that binds Gt.[62] The *N*-terminus of Gα and the *C*-terminus of Gγ are relatively close. Both are sites of lipid modification and are likely to be the sites of membrane attachment. The region around Glu134–Arg135–Tyr136 on Helix II of rhodopsin is surrounded by hydrophobic residues and is known to bind Gt.[52] However, this region is buried in the ground-state rhodopsin and is in no way to make contact with Gt. Therefore, this region must become exposed in the photoactivated rhodopsin via a conformational change. Definite conclusions regarding the docking of Gt with MII must await the elucidation of the crystal structure of photoactivated rhodopsin–transducin complex.

The *C*-terminal of MII is crucial for arrestin binding and rapid deactivation of the cGMP cascade, as could be demonstrated by abnormally prolonged responses in a rhodopsin mutant, of which 15 amino acid residues at the *C*-terminal region were truncated.[63] The truncated segment is apparently not needed for Gt binding and activation.[45,63,64] This *C*-terminal segment of rhodopsin is most likely the initial recognition site but not the ultimate binding site of arrestin, because excess Gt displaces arrestin from phosphorylated rhodopsin. Gt, which binds to phosphorylated and nonphosphorylated MII, apparently competes with arrestin for the same binding site.[48] Arrestin undergoes a conformational change after binding to the *C*-terminal of phosphorylated MII.[65–67] This change exposes a critical buried region of arrestin that enables it to bind to a second binding site on phosphorylated MII, which also binds Gt competitively. This interpretation is supported by an experiment with a synthetic peptide that mimics the *C*-terminal tail of phosphorylated MII. This synthetic peptide comprises the fully phosphorylated *C*-terminal phosphorylation region of bovine rhodopsin, residues 330 to 348 (known as 7P-peptide).[65] This peptide binds to arrestin, induces a conformational change that is similar to that induced by binding to phosphorylated MII, and activates it. Furthermore, this activated arrestin can then bind to photoactivated but *nonphosphorylated* rhodopsin, i.e., nonphosphorylated MII.

Thus, an electrostatic switching mechanism is implicated in at least the initial binding of arrestin to the phosphorylated *C*-terminal of MII. However, the multiple phosphate groups apparently do more than just provide negative charges, because synthetic peptides in which all potential phosphorylation sites were substituted with glutamic acid (7E-peptide) or with cysteic acid (7Cya-peptide) did not mimic the negative charge of phosphorylated amino acid residues.[68] Evidence of electrostatic effects came from kinetic analysis of the complexation between Gt and MII and between arrestin and MII. Investigations of the kinetics of rhodopsin–arrestin complexation were hampered by the similarity of the absorption spectra of free MII, MII–Gt complex, and MII–arrestin complex; they all have an absorption maximum at 390 nm and, therefore, the three forms of MII are not spectroscopically distinguishable. Because there exists an acid–base equilibrium between MI and MII, binding of Gt shifts the equilibrium to the right, by virtue of the law of mass action, thus stabilizing highly phosphorylated MII as a MII–Gt complex.[69,70] Similarly, binding of arrestin stabilizes phosphorylated MII as a MII–arrestin complex.[51] Both complexation processes increase absorption at 390 nm. The situation is further complicated by the finding that phosphorylation increases the MI–MII equilibrium constant.[71,72] Thus, the equilibrium of MI–MII is shifted to the right for two reasons: the change of the equilibrium constant and the effect of product removal. As a consequence, the relative proportions of free MII and its two complexed forms cannot be directly measured spectrophotometrically. These enhanced portions of MII formation are known as extra-metarhodopsin II.

Parkes et al.[73] subsequently developed a nonlinear least-square curve-fitting procedure (Simplex) to sort the three forms of MII amidst three concurrent equilibria. Using this approach, Gibson et al.[74] found

that the binding affinity of Gt to MII is dependent on ionic strengths, with maximum affinity at 200 m*M*. The affinity decreases toward higher and lower ionic strengths. Similar ionic strength dependence was found for the binding affinity of arrestin to MII, at various phosphorylation levels. The decrease of affinity at high ionic strengths is consistent with the effect of charge screening, but the decrease at lower ionic strengths is not. Gibson et al.[74] attributed the decrease to the possibility of two separate binding processes: binding to MII and to the photoreceptor membrane. However, similar decreases were observed in several mobile electron carriers in photosynthetic membranes; there is no compelling evidence to postulate an additional binding site on the photosynthetic membrane. In view of the ubiquity and possible universality of this type of ionic strength dependence among mobile electron carriers in photosynthetic membranes, we favor, instead, the interpretation, proposed by Tollin and Hazzard,[26] that excessive electrostatic stabilization of a docking complex hampers further interactions between the complexed partners by inhibiting exploration. This is especially relevant, because there appear to be two separate stages of arrestin binding to MII; an excessively stabilized complex of arrestin with the *C*-terminal binding site of phosphorylated MII would interfere with its binding to a second site. Tollin and Hazzard's interpretation is further justified by additional independent evidence suggesting that protein flexibility may be a universal necessity in macromolecular reactions. Garbers et al.[75] studied the electron transfer from negatively charged semiquinone $Q_A^{-\bullet}$ to oxidized quinone Q_B in Photosystem II. These investigators found that the extent of reoxidation of $Q_A^{-\bullet}$ starts to decrease below 275 K and is almost completely suppressed at 230 K. Detailed analyses of Mössbauer spectra measured at different temperatures in ^{57}Fe-enriched samples indicated that the onset of fluctuations between conformational subsets of the protein matrix occurs also at around 230 K. They suggested that the head group of plastoquinone-9 (a membrane-bound mobile electron carrier) bound to the Q_B-site in Photosystem II requires a structural reorientation for its reduction to the semiquinone.

The kinetic analysis of Gibson et al. also showed that Gt affinity for MII decreases with increasing phosphorylation, whereas arrestin affinity for MII increases almost linearly with increasing phosphorylation. The data were also consistent with the assumption of 1:1 binding stoichiometry for Gt–MII and for arrestin–MII. The reciprocal fashion of the phosphorylation dependence of Gt and arrestin-binding affinity is in keeping with their respective roles as the activator and the deactivator of the cGMP cascade, thus reflecting nature's way of optimization by means of simultaneous modulation of the two binding processes. The incremental change for each added phosphate indicates that the switches of visual transduction are not simple on–off switches but are similar to the kind of rotary switch (incremental switch) that allows for continuous adjustment of the brightness level of a lamp.[76]

Despite the similarity of affinity changes, the (second-order) binding rates of Gt and arrestin are different at equal concentrations. The kinetics of Gt binding to MII at 0.6 μ*M* Gt are exponential with a relaxation time constant near 1 s, whereas arrestin binding to MII at 0.6 μ*M* arrestin is much slower, with a relaxation time constant of more than 20 s.[74] This disparity of kinetics allows for a window of time for Gt to take action before deactivation prevails, thus avoiding shutting down the process prematurely.

Although phosphorylation does not cause global conformational changes of MII, local changes that include changes of the membrane surface potential and the membrane surface pH may affect the binding kinetics of Gt and arrestin.[72] The increased negativity of the membrane surface potential lowers the surface pH relative to the bulk pH. The ensuing lowering of pH can affect the protonation state (ionization state) of exposed charged amino acid residues in two possible ways: increasing reactant (proton) availability by virtue of the law of mass action and the direct effect of pH on the binding constant. The resulting change of the protonation state of charged amino acid residues at the membrane surface further changes the membrane surface potential. The interaction is therefore highly nonlinear. Using the nonlinear least-squares fitting scheme, Gibson et al.[74] determined the pH dependence of the respective binding affinity of Gt and of arrestin to MII at various levels of MII phosphorylation. They found a phosphorylation-dependent shift in the pH maximum for the binding affinity of Gt. While the Gt affinity for nonphosphorylated MII peaks at pH 8, the pH for the maximum binding affinity shifted to the alkaline values with increasing phosphorylation and became immeasurably high at 4.1 PO_4/rhodopsin or higher. This shift was more apparent than real, because

the shift disappeared if the binding affinity was plotted against the surface pH instead of the bulk pH. Thus, the Gt–MII interaction depends directly on the membrane surface pH. The maximum Gt affinity now peaks at the membrane surface pH of 7.5 at all levels of phosphorylation.

Gibson et al.[74] also determined the pH dependence of the binding affinity of arrestin to MII, at various levels of MII phosphorylation. The affinity of arrestin for MII increases more or less linearly with pH up to pH 8.5, beyond which no data were available because of technical difficulty. The arrestin-binding kinetics is also pH dependent. With increasing pH or decreasing phosphorylation levels, the speed of arrestin binding decreases, so that the reaction does not reach equilibrium in time between flashes of illumination. The effect of phosphorylation on the arrestin-binding kinetics is also mediated via its electrostatic effect on the membrane surface pH, according to the analysis of Gibson et al.

Considerably more specific local electrostatic interactions may be involved in arrestin action, as suggested by a recent model for the rhodopsin phosphorylation dependence of arrestin binding.[57,77,78] When analyzing the model, it can be suggested that the negative phosphate charges on the *C*-terminal tail of MII destabilize a series of salt bridges and hydrogen bonds in the polar core of arrestin (switch region), which has a strongly positive local electrostatic potential, thus causing the conformational change of arrestin upon its activation.

The recognition of MII by Gt and by arrestin apparently belongs to a Type III mechanism designated by Hervás et al.[37] (transient complex formation with molecular rearrangement). Gt and arrestin undergo major conformational changes after initial binding. Furthermore, arrestin eventually binds to a second site, which is close to or identical to the binding site of Gt. There are several sequences of contiguous cationic amino acids in arrestin, which can be identified as positively charged patches near the *N*-domain of arrestin,[56,57] the proposed rhodopsin binding site (see also Figure 11A of Gibson et al.[74]). The key residue Arg175 in the so-called polar core of arrestin allows arrestin to distinguish between phosphorylated and nonphosphorylated rhodopsin.[66,67] The complementarity of charge pairing is apparent. The putative binding surface of Gt is mostly negatively charged, with some small patches of positive potentials (Figure 11B of Gibson et al.[74]). Hamm[79] pointed out the overall charge complementarity between the cytoplasmic surface of rhodopsin (positively charged residues Lys248, Lys141, and Arg147) and the receptor-binding surface of Gα (negatively charged residues Asp311 and Glu212) (see Figure 2 of Hamm[79]). The charge distribution on the surfaces of Gt and that of arrestin do not suggest the presence of a sufficiently strong electric dipole moment to lead to oriented collisions. However, judging from the contrast of the overall negative surface of Gt and the patchy positive surface of arrestin, we suspect that the membrane surface potential may play an additional role in making the encounter of the partners more deterministic via long-range electrostatic interactions (homing mechanism). The largely positive cytoplasmic surface of rhodopsin favors attraction of Gt but not arrestin (see Figure 2 of Hamm[79]). The additional positive surface potential generated by the ERP (R2 component) probably adds little to the already positive potential. The electrostatic interactions caused by the ERP are probably local in nature. However, its role in triggering Gt binding cannot be completely ruled out. The membrane surface potential subsequently turns in favor of arrestin binding (homing mechanism); the dramatic buildup of negative surface charges brought about by phosphorylation is probably sufficient to overshadow the positive surface charges that were originally present on MII prior to phosphorylation. Of course, as suggested by Gibson et al.,[74] the opposite surface potentials can also influence the affinity of both proteins to MII (short-range electrostatic interactions). Their interpretation is supported by the data showing that the affinity of arrestin for MII increases linearly with pH between pH 7.0 and 8.5,[74] and that the negative photoreceptor membrane surface potential also increases linearly within this same pH range.[72]

In summary, the interactions between rhodopsin and its two partners, transducin and arrestin, echo the general scheme of interactions of mobile electron carriers, discussed earlier, despite the differences in terms of structures and functions. Again, nature deployed short-range noncovalent bond interactions to make collisions and reactions between encountering partners more deterministic than random processes. Nature also orchestrated the sequence of events with appropriate timing. When the interactions between Gt and MII need to be more deterministic, the interactions between arrestin and MII are made more random. Conversely, when the interactions between arrestin and MII need to be more deterministic,

the interactions between Gt and MII are made more random, all by means of the intricate interplays of the same set of fundamental forces. During visual transduction, electrostatic interactions are invoked in a number of different mechanisms: local and global, nonspecific and specific. Nature seemed to recruit whatever mechanisms were workable, in a highly flexible way, and did not stick to any particular "ideological" scheme. On the other hand, highly successful schemes were evolutionarily multiplied and perpetuated in different systems in the same organism and among different species of organisms, as exemplified by the huge family of G protein receptors and their partners, G proteins and arrestins.

Bacteriorhodopsin

Bacteriorhodopsin, like its sister molecule rhodopsin, is also a member of the G-protein-coupled receptor superfamily. As a one-molecule light-driven proton pump, bacteriorhodopsin essentially carries out the entire task of the photosynthetic reaction center of phototrophic purple bacteria — a far more complex chlorophyll–protein complex of several subunits. The mechanistic detail of its operation is of great interest in understanding photosynthesis. Bacteriorhodopsin is also a relevant model molecule for understanding electrogenic ion pumps; its light sensitivity provides an additional handle with which to probe its kinetic properties. In Chapter 128, we exploited its similarity to rhodopsin to enhance our understanding of ERP. In this section, we will examine the factors that enhance its efficiency of photon energy conversion.

At the molecular level, it is the light-induced *trans*-to-*cis* isomerization of the chromophore retinal that drives the vectorial proton transport. A detailed understanding of the molecular events leading to proton transport was greatly enhanced by elucidation of the crystal structures of ground-state bacteriorhodopsin and several intermediates of the photocycle. The detailed picture is gradually emerging but is still in a state of flux. Periodic reviews were provided by Lanyi.[80–84]

Like rhodopsin, photon absorbed by bacteriorhodopsin initiates isomerization of the chromophore. But unlike the open-ended photobleaching of rhodopsin, bacteriorhodopsin undergoes a cyclic sequence of reactions (photocycle). Photoisomerization causes the retinal Schiff base at lysine residue 216 (K216) to deprotonate. The primary acceptor of the Schiff base proton is aspartate 85 (D85). The remaining reactions of the photocycle are thermally driven. Transfer of a proton from the retinal Schiff base, first to D85 and then eventually to the extracellular aqueous phase, dominates the first half of the photocycle. The active site of this sequential transfer is the highly polarized bound water 402, which is coordinated by the protonated retinal Schiff base and two anionic aspartates, Asp212 and Asp85.[85] The release of proton from the deeply buried D85 to the extracellular space requires the participation of Arg82, Tyr57, Glu194, and Glu204 that, together with six bound water molecules, form a column of hydrogen-bonded network.[86] The second half of the photocycle is featured by reprotonation of the Schiff base from aspartate 96 (D96), which, in turn, accepts a proton from the cytoplasmic space via another hydrogen-bonded chain with four bound water molecules positioned in single file. Kinetically, the action of the protonation switch, from an extracellular access to an intracellular access, takes place during the $M_1 \rightarrow M_2$ step. The $M_1 \rightarrow M_2$ transition incurs a major conformational change and a large entropic change; the probability of charge recombination is greatly diminished by virtue of this protonation switch.[87] This transition is unidirectional under some conditions but reversible under others (summarized by Lanyi[81]).

Speaking about the unidirectionality or reversibility of the protonation switch, it is of interest to examine the macroscopic electrical behavior of the bacteriorhodopsin membrane. Despite the conventional practice of referring to bacteriorhodopsin as a photodiode,[88] direct evidence of rectification of proton conductance is lacking. An unequivocal experimental determination of the existence or absence of rectification is contingent on a clear-cut separation of the photovoltaic effect and the photoconductive effect. A detailed argument explaining why separation of these effects is important was presented elsewhere.[89,90] It suffices to say that the presence of photoemf renders classical electrophysiological methodology inadequate, because a voltage-clamp or a current-clamp measurement, together with Ohm's law, is insufficient to determine all four experimental variables: photoemf, membrane voltage, photoconductance, and photocurrent; an additional act of measurement is required. A null current method that combines the principle of potentiometry with the classical voltage-clamp method was specifically

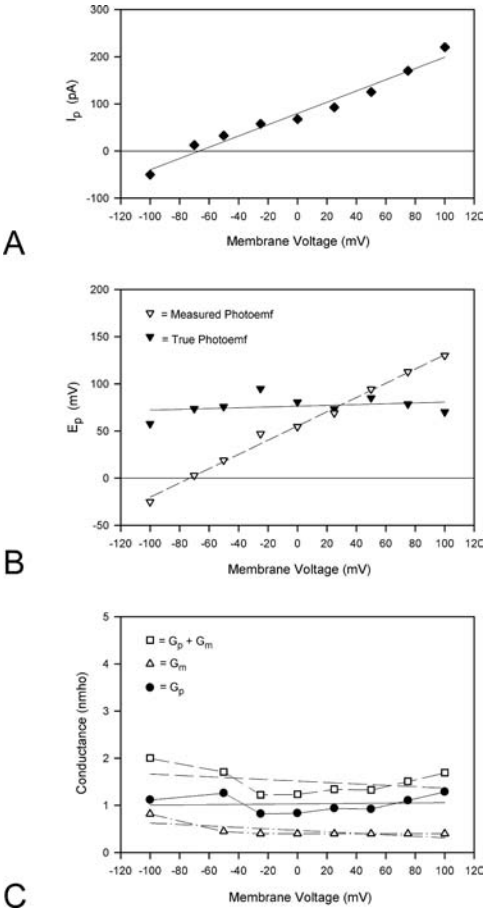

FIGURE 134.3 Steady-state photoelectric response of a bacteriorhodopsin-containing black lipid membrane. The aqueous solutions contained 0.1 *M* NaCl and 0.5 m*M* $CeCl_3$. Measurements were made at pH 6.9 and 24°C. (A) Measured photocurrent I_p is shown as a function of the transmembrane voltage. (B) Photoemf E_p, as determined by the null current method, is shown as a function of the membrane voltage. Apparent photoemf is shown as open inverted triangles, whereas true photoemf, corrected by eliminating voltage-driven photocurrent and shunting of G_m, is shown as filled inverted triangles. (C) Apparent photoconductance ($G_p + G_m$) (open squares), measured dark conductance (G_m) (open triangles), and true photoconductance (G_p) (filled circles), corrected for the shunting effect of G_m, are shown. All data were taken from the same membrane. (From Fuller, B.E., Okajima, T.L., and Hong, F.T., *Bioelectrochem. Bioenerg.*, 37, 109, 1995. With permission.)

designed for this purpose.[91] Determining the photoemf by invoking the principle of potentiometry constitutes the second act of measurement.

Drachev et al.[92,93] were the first to report that the photocurrent is linearly dependent on the transmembrane voltage. It was repeatedly observed by other investigators, and more than half a dozen interpretations were proposed. In view of Ohm's law, a voltage dependence of the photoemf and the photoconductance can both give rise to a voltage-dependent photocurrent. However, the result of null current analysis of photoelectric measurements made in reconstituted bacteriorhodopsin-containing black lipid membranes (BLM) indicates that the steady-state photoemf and photoconductance are not voltage dependent[89] (Figure 134.3). Furthermore, direct measurements of the conductance of the reconstituted BLM, during illumination and in the absence of illumination, together with a similar measurement using a "control" BLM without incorporated bacteriorhodopsin, showed that the proton conductance channel opens only during illumination. A reconstituted bacteriorhodopsin membrane in

the absence of illumination has the same low conductance as the "control." Essentially, it is a photon-gated conduction channel: it opens upon the onset of illumination but shuts off upon the cessation of illumination. Furthermore, the proton conduction channel created by illumination is available for the passage of the proton current driven by a transmembrane electrochemical potential difference. In other words, the measured photocurrent includes the light-driven current (generated by photochemical reactions) and the voltage-driven current (which merely takes advantage of the availability of a proton conduction channnel created by photoreactions). It is of interest to note that the light-driven portion constitutes an active transport of proton, capable of driving the current against an existing proton electrochemical gradient, whereas the voltage-driven current reflects a passive transport, similar to Na^+ and K^+ currents, commonly encountered in classical electrophysiology. Thus, a sufficiently intense transmembrane voltage or transmembrane pH difference can drive the proton current in the reverse direction. The voltage-driven current is, of course, voltage-dependent, but is counted as part of the measured photocurrent, because it exists only during illumination. In addition, the photoconductance is not rectified; the voltage-driven proton current encounters the same resistance in either direction during illumination. The photoconductance exhibits no voltage dependence. That is the reason the voltage-driven current is linearly dependent on the transmembrane voltage, in accordance with Ohm's law.

The generation of a transmembrane proton gradient is the intermediate step between photon energy conversion and bioenergetic synthesis of ATP. The formation of the transmembrane electrical gradient (i.e., the photovoltage) constitutes a situation similar to back-biasing of a photodiode. Back-biasing provides the driving force to drive protons back into the cell. In principle, there are several ways the electrochemical potential can drive protons from the extracellular space back into the cytoplasm:

1. Protons or other small ions reentering the cell via leakage through the phospholipid portion of the purple membrane, and thus dissipating the converted energy
2. Protons reentering the cell via a reverse proton flow through the same proton-translocating channel in bacteriorhodopsin (direct charge recombination)
3. Protons reentering the cell via the proton-transport channel of ATP synthase (in the reverse direction), thus synthesizing ATP
4. Protons reentering the cell via the flagella motor apparatus, and thus powering the motion of the flagellas
5. Protons reentering the cell to power a cotransport system (symport or antiport)

With the exception of the first two routes, all other routes of charge recombination do useful work for the bacterium. The wasteful dissipation of converted energy via leakage is minimized in the purple membrane by having a relatively small area of phospholipid portion in the two-dimensional crystalline structure of the purple membrane.[94,95] In the reconstituted bacteriorhodopsin BLM, G_p in the dark is considerably smaller than G_m. This property means that the insulation against a proton backflow, in the dark, via the proton-translocating channel, is more effective than the insulation of the phospholipid portion of the artificial BLM. During illumination, however, G_p of a reconstituted membrane is only comparable to G_m. Quantitative comparison of G_p and G_m in a native purple membrane is not available. But the ratio G_p/G_m should be much greater in the native purple membrane than in our experimental system, because reconstitution in our experimental system could not have achieved the same high density of bacteriorhodopsin packing as in the native purple membrane.

The direct charge recombination by a reversal of charge flow (Number 2 above) is the major problem to be overcome in artificial solar energy conversion. In the case of silicon photodiode, this problem is mitigated by rectification of the charge conduction channel; the resistance that the photocurrent encounters during (internal) charge recombination is much greater than the forward resistance encountered during charge separation. The null current analysis demonstrated that bacteriorhodopsin is a photocell but not a photodiode in the strict sense. As for achieving good energy conversion efficiency, bacteriorhodopsin apparently relies on a different strategy than rectification to prevent charge recombination. Let us take a close look at how bacteriorhodopsin and a photodiode differ in minimizing direct charge recombination.

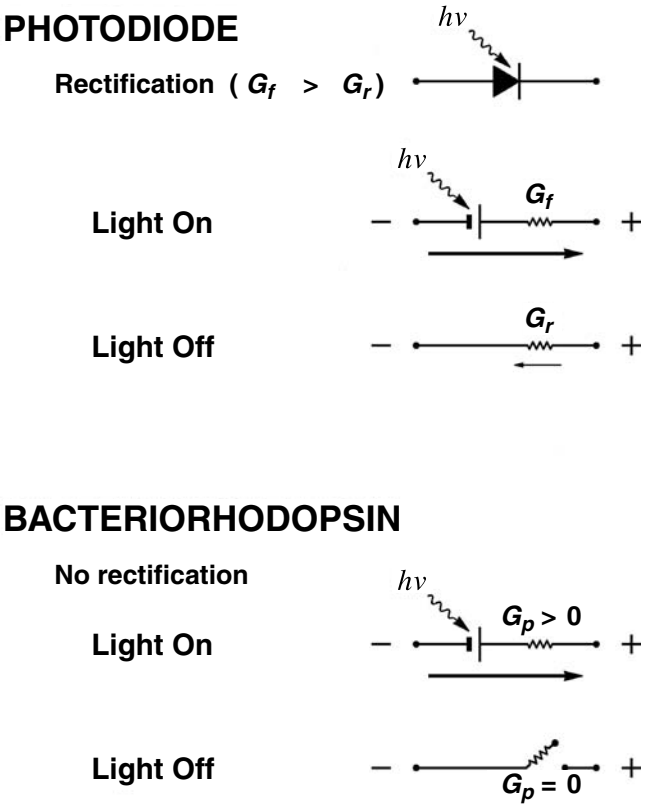

FIGURE 134.4 Comparison of rectification in a conventional photodiode and light-gated proton conduction in bacteriorhodopsin. Plus and minus signs indicate polarity of photovoltage under open-circuit conditions. G_f and G_r are forward conductance and reverse conductance of the photodiode, respectively. Photoactivation causes a photocurrent to flow in the forward direction, as indicated. Elicited photovoltage back-biases photodiode (under open-circuit conditions), and drives current in the reverse direction during illumination, thus canceling part of the (forward) photocurrent. But reverse current encounters much greater resistance than forward current (rectification: $G_f >> G_r$). In the photodiode, charge recombination in the dark is minimized because of rectification. There is no rectification in bacteriorhodopsin; forward photocurrent (driven by light and reverse current — driven by back-biasing voltage) encounters the same resistance ($1/G_p$). Note that externally observed photocurrent is actually the difference (algebraic sum) of voltage-independent light-driven current and voltage-driven (and, therefore, voltage-dependent) current. Constancy of the true photoemf, as membrane potential varies, indicates that illuminated bacteriorhodopsin's ability to maintain net "driving force" is not affected by back-biasing. In bacteriorhodopsin, charge recombination in dark is minimized because of closing of the proton conduction channel in the dark (G_p = 0 in dark). (From Hong, F.T., *Prog. Surface Sci.*, 62, 1, 1999. With permission.)

As shown in Figure 134.4, light-induced forward charge separation in a photodiode generates a photocurrent that encounters a resistance $1/G_f$. In contrast, charge recombination during illumination, as well as in the absence of illumination, encounters a much greater resistance $1/G_r$ (where $G_f >> G_r$). In this way, charge recombination is greatly minimized in a photodiode. Charge recombination in bacteriorhodopsin takes place by virtue of the ubiquitous reverse biochemical reactions. Although the $M_1 \rightarrow M_2$ transition is at times a one-way reaction, it does not make its presence evident as rectification. However, a one-way photochemical reaction is not an absolute requirement. As long as continuing input of photon energy is guaranteed, a photon-driven forward reaction continues to offset charge recombination caused by reverse reactions. As a consequence, a steady state is maintained, and an externally connected device can continue to drain energy to perform useful work. That a one-way reaction is not

required is experimentally demonstrated by an artificial magnesium porphyrin-containing BLM in which no provisions were instigated to minimize reverse electron transfer.[91]

From a mechanistic point of view, charge recombination in the dark is a more serious problem than charge recombination during illumination. While light-driven forward charge reaction continues to counterbalance charge recombination as long as illumination persists, charge recombination runs unopposed in the absence of illumination. A nonrectified conduction channel that remains open in the dark will eventually dissipate the entire amount of stored energy. The usefulness of a solar cell is contingent on its continuing operation in the absence of illumination. Bacteriorhodopsin's light-gated proton conduction channel thus meets this latter requirement. By completely shutting off the proton conduction channel, the peril of charge recombination in the dark is averted. Bacteriorhodopsin thus achieves the same goal (in the dark, at least), without rectification, as does a silicon photodiode with rectification. Regarding the photo-gating mechanism, a molecular interpretation is presently lacking. However, based on the crystal structure of dark-adapted bacteriorhodopsin and several photointermediates revealed by Lanyi's group, bound water and the associated hydrogen-bonded network are absent in the cytoplasmic half of the proton conduction channel, both in the absence of illumination and during the first half of the photocycle; bound water and the hydrogen-bonded network make their appearance only during the latter half of the photocycle as bacteriorhodopsin reprotonates its Schiff base from the cytoplasmic aqueous phase via Asp96.[86] These structural data imply that bacteriorhodopsin is an insulator in the dark and during the first half of the photocycle; photoconduction becomes activated during the latter half of the photocycle. But how the lack of rectification transpires in spite of the reprotonation switch remains unclear.

The null current analysis of proton conduction in bacteriorhodopsin also has important bearing on the fundamental bioenergetic principle. According to chemiosmotic theory, the converted energy by bacteriorhodopsin photoreactions is stored as a transmembrane voltage gradient (ΔV) and a transmembrane gradient of protons (ΔpH). The electrical and chemical components are equivalent and interconvertible, and both are available as sources of energy for ATP synthesis. The equivalence of the two types of gradients is made possible by the facts that the light-driven proton current and the voltage-driven proton current pass through the same conduction channel, and the proton current encounters the same resistance in either direction. In other words, by imposing a transmembrane voltage across the purple membrane, protons can be driven in either direction with equal ease, and a voltage gradient can be converted into an additional proton gradient to be added to or subtracted from an existing one. The lack of rectification guarantees the exchange between ΔV and ΔpH is conducted at an "equal exchange rate." Were there a rectification, the interconversion would not be equal, because the IR drop would be more in the back-biasing direction than in the forward-biasing direction (which is tantamount to a difference between buying and selling rates of currency exchange). Null current analysis thus furnished a quantitative demonstration that the two components of electrochemical energy are interchangeable.

The light-dependent gating mechanism of bacteriorhodopsin's proton conduction channel may also explain a long-standing puzzle. As shown in Figure 128.8(B), the equivalent circuit that contains chemical capacitance responds to a long square-wave light pulse by exhibiting a sharp spike of current upon the onset of illumination, and another spike with opposite polarity upon the cessation of illumination. This waveform is known as differential responsivity in the molecular sensor literature[96,97] [see, for example, that shown in Figure 128.2(B)]. It is the characteristic waveform of the output of a linear RC high-pass filter. The equivalent circuit shown in Figure 128.8(A) predicts such a waveform with two symmetric spikes (the RC circuit comprised of R_pC_p constitutes a high-pass filter). However, with few exceptions, the two spikes appeared asymmetric in many reconstituted pigment-containing membranes. The "on" spike is more prominent and decays faster than the "off" spike. The asymmetry is barely discernible in Figure 128.8(B) but is more prominently displayed in Figure 134.5. Note that by assuming $R_s = \infty$, the equivalent circuit predicts symmetric spikes. The asymmetric waveform can be explained, however, if the equivalent circuit is modified to reflect the presence of a light-gated proton conduction channel — i.e., R_s assumes a considerably smaller value during illumination than in the dark. Thus, the apparent decay time constant of a spike is shorter during illumination than in the dark. That the spikes are a manifestation of a capacitative response is reflected in the equality of the area enclosed by the spikes and

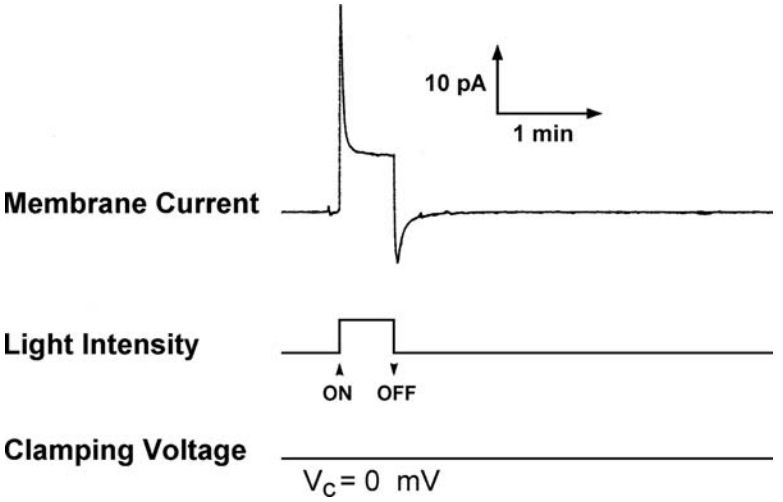

FIGURE 134.5 Photoelectric signals from a reconstituted bacteriorhodopsin black lipid membrane in response to a long square-wave light pulse (xenon arc lamp). The black lipid membrane permits steady-state photocurrent to pass through it. The photocurrent exhibits the characteristic "spikes" of a high-pass filter. See text for explanation. (From Fuller, B.E., Okajima, T.L., and Hong, F.T., *Bioelectrochem. Bioenerg.*, 37, 109, 1995. With permission.)

the baseline. Thus, the fast-decaying spike during illumination has a more prominent peak than the slower one, as is evident in Figure 134.5. It is also not difficult to understand why photogating of R_s is not apparent in measured ERP-like signals when a brief (δ-function) light pulse is used; the diminished source impedance (due to C_p) in the microsecond time range renders the change of R_s insignificant by comparison. The asymmetry of the two peaks appeared in many different types of reconstituted membranes (see Hong[98] for a summary) and is a constant feature rather than an artifact.

We further suspect that the photogating mechanism exhibited by bacteriorhodopsin may also be present in the electron-transfer channel of a chlorophyll-based photosynthetic membrane. As shown in Figure 134.6, asymmetry of the two transient spikes is evident in an *in vivo* voltage-clamp measurement of a giant chloroplast of *Peperomia metallica*.[99] Thus, the electron-conduction path in this giant chloroplast may also be activated only by light, thus preventing electron backflow in the dark. A direct determination of G_p (as compared to G_m) in *Peperomia metallica* is presently lacking. However, if this interpretation is correct, then it appears that nature implemented the same design principle by using completely different molecular constructs.

134.4 Lateral Mobility of Protons on the Membrane Surface

Although what is to be considered next is not a molecular switch, an omission of it makes the ongoing discussion incomplete. In addition to the energy loss due to charge recombination, there is yet another route of energy loss in photosynthesis. ATP synthase and the photosynthetic reaction center (or bacteriorhodopsin) are located side by side in the membrane. The transported protons must diffuse laterally in order to reach the site of ATP synthase, but they can also diffuse into the vast nearby aqueous solution, instead. Energetically speaking, this process of proton diffusion into the bulk solutions incurs an unacceptable loss of energy because of the dilution effect (known as the Pacific Ocean effect). It has long been a dispute between two camps of theoreticians — the localized[7–9,100] and the delocalized[6] version of chemiosmotic process (reviewed by Kell[101]). Somehow a switching function that allows protons to be diverted preferentially into the site of ATP synthase instead of the bulk aqueous solution would be advantageous. Without such a switch, photosynthesis would still work. However, advocates of the localized mechanism suspected that evolution could have eliminated this unnecessary energy loss. Kell speculated about the existence of some sort of barrier in the vicinity of the membrane surface, which converts the

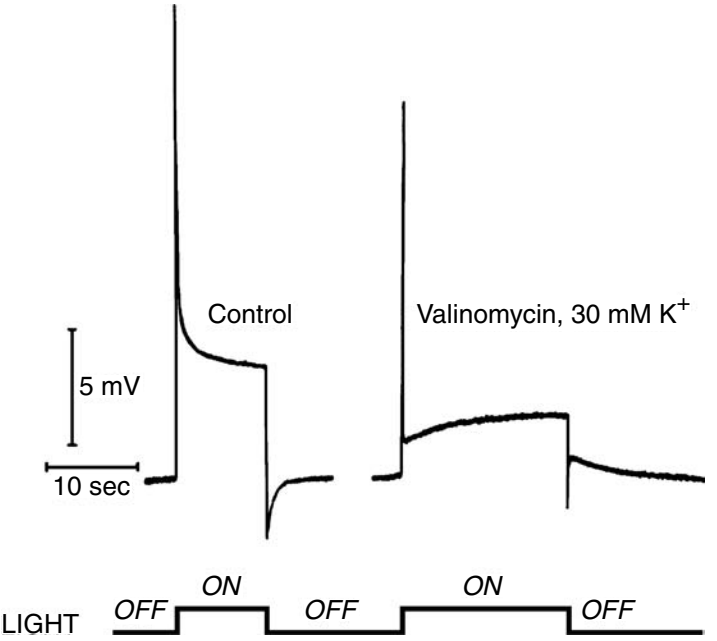

FIGURE 134.6 Photoelectric signals recorded *in vivo* from a photosynthetic membrane in response to a long square-wave light pulse. Open-circuit photovoltage was recorded intracellularly from an intact chloroplast of *Peperomia metallica*. Control signal, taken before addition of valinomycin, is shown at left, and effect of adding 1 μM valinomycin and 30 m*M* potassium ions in external medium is shown at right. See text for discussion. (From Vredenberg, W.J. and Bulychev, A.A., *Plant Sci. Lett.*, 7, 101, 1976. With permission.)

Pacific Ocean effect into a San Francisco Bay effect — an imperfect barrier that minimizes leakage of protons into the bulk solutions. Such a speculated barrier was realized by the discovery of Teissié and coworkers.[102,103] These investigators found that proton conduction is considerably faster on the membrane–water interface than in the bulk water. Subsequently, Alexiev et al.[104] found similar proton conduction on the surface of the purple membrane of *Halobacterium salinarum*.

Teissié and coworkers detected rapid lateral movement of protons on a phospholipid monolayer–water interface by a number of measurements: fluorescence from a pH indicator dye near the membrane surface, electrical surface conductance, and surface potential. These investigators found that the conduction of protons along the surface is considerably faster than proton conduction in the bulk phase (2 to 3 min versus 40 min for a comparable distance in their measurement setup). This novel conduction mechanism is proton-specific, as confirmed by a radioactive electrode measurement as well as by replacement with deuterated water. It is a consequence of cooperativity between neighboring phospholipid molecules; the conduction mechanism disappears when phospholipid molecules are not in contact with each other.

Teissié and coworkers indicated that the enhanced lateral proton movement occurs along a hydrogen-bonded network on the membrane surface in accordance with a mechanism previously proposed by Onsager[105] for proton conduction in ice crystals and by Nagle and Morowitz[106] for proton translocation in membranes. The hydrogen-bonded network is formed by the polar head-groups of phospholipid and the associated ordered water molecules at the membrane surface. Thus, a proton jumps from H_3O^+ to a neighboring H_2O. The newly formed H_3O^+ then rotates and becomes a new proton donor to its neighbor farther down the chain in the network. As a result, protons move considerably faster on the membrane surface than expected by classical diffusion. In fact, a similar mechanism was used to explain proton diffusion in the bulk phase, which is considerably faster than the diffusion of ions of comparable size in the same medium. Therefore, the "hop-and-turn" mechanism enhances proton movement at the interface and in the bulk phase. What makes the lateral proton movement on the membrane surface so much faster than proton diffusion in bulk water?

I think that there are at least two reasons. First, the proton movement at the membrane surface is two-dimensional, whereas the movement in bulk water is three-dimensional (reduction-of-dimensionality principle of Adam and Delbrück). It is true that simple diffusion in a two-dimensional space is faster than in a three-dimensional space according to the probability theory. It may also be true for the "hop-and-turn" mechanism. The second reason may be the increased surface concentration of protons as compared to the bulk concentration caused by a negative surface potential. The negative surface potential is primarily due to the net negative surface charges of the phospholipid polar head-groups. The increased concentration at the surface makes the "hop-and-turn" mechanism work better along the surface than in bulk water. Teissié's group showed that there is a steep gradient near the membrane surface (two pH units in less than 1.5 nm). However, these authors also observed similar facilitated lateral proton movement with monolayers formed from neutral and zwitterionic phospholipids. Therefore, the effect of a negative surface potential is probably secondary and supplementary but not essential.

134.5 Discussions and Conclusions

Webster's Third International Dictionary defines the verb "switch" as to change or shift things, places, methods, actions, or directions. This definition covers enzyme action at the molecular level, which helps channel branching reactions into a single pathway at the expense of other (side) reactions. This definition also covers shifting of attention or decision making of the whole organism at the systems level. An intriguing question that computer scientists and philosophers frequently ask is: how do seemingly random processes at the molecular level lead to decisive information processing at the systems level? A crude answer is that random molecular processes are punctuated by switching processes exemplified by enzyme or gene activation. A survey of major photobiological systems offers ample opportunity to probe this question, because light often serves as the trigger to activate switching processes. Included in the present discussion is the role played by noncovalent bond interactions in molecular recognition. These interactions help switch the processes from random diffusion and collisions to significantly more deterministic docking in molecular recognition.

Implied in the above definition are a sudden action, a threshold, a trigger, and an amplification mechanism. A switch falling short of these implied features is usually regarded as a bad switch, e.g., a "sticky" switch or hesitation. In visual photoreceptor membranes, the sudden, snapping action is implemented in terms of a sequence of the light-induced conformational changes of rhodopsin, which culminates in the formation of metarhodopsin II. In Chapter 128, the mechanistic events accompanying the appearance of the early receptor potential (ERP) are examined. The electrochemical aspect of ERP was amply discussed, while the molecular details remain unsettled. Some investigators attempted to make fairly definitive assignments of individual components of the ERP-like signal in reconstituted bacteriorhodopsin membranes. However, these assignments must be called into question, primarily because of the improper use of classical electrophysiological methodology and the indiscriminate use of multiexponential analysis. Although a major consensus — ERP plays no physiological role — was reached more than three decades ago, the mechanistic reinterpretation of ERP warrants a reexamination of the same old question: the possible physiological role, because absence of evidence is not evidence of absence. In light of the ever-increasing knowledge of the molecular detail of the cyclic GMP cascade, the time is ripe to launch a renewed inquiry. Our suspicion regarding a possible physiological role of ERP is reinforced rather than subdued in the intervening years: ERP still looks suspiciously like the mechanistic trigger prior to biochemical amplification, because ERP positions in the right place at the right time to serve as the mechanistic (electrostatic) trigger of visual transduction. Electrostatic interactions have the virtue of a snapping action — with a picosecond rise time and localized effect (limited to the diffuse double-layer region where light hits rhodopsin). However, correlation is, of course, no proof of causality. The present survey of visual and photosynthetic systems reveals that nature usually solved problems by recruiting and mobilizing every possible molecular interaction. As a result, the role played by each type of noncovalent bond interaction is obscured by the concurrent presence of various types of interactions. Although a survey of known structural and functional interactions between metarhodopsin, transducin, and

arrestin does not clarify the question, it seems promising to begin to dissect the event into separate contributions from various kinds of noncovalent bond interactions. At this moment, there is no compelling reason to sustain or overturn the old verdict.

The molecular switching processes in photosynthetic membranes serve the purpose of enhancing the efficiency of photon energy conversion rather than photon detection. The molecular switches are triggered directly or indirectly by absorbed photons. In the previous edition of this chapter,[5] photophosphorylation of light-harvesting chlorophyll-protein Complex II was cited to illustrate how nature utilized electrostatic interactions to dynamically allocate resources.[107] In the present article, the discussion is focused on mobile electron carrier systems that shuttle electrons from complex to complex in a photosynthetic membrane, as well as bacteriorhodopsin, which manages to perform almost the entire task of photosynthesis with a single molecule.

Because photon energy conversion in photobiological membranes involves light-induced charge separation, prevention of unproductive charge recombination enhances its efficiency. Charge recombination in bacteriorhodopsin and photosynthetic reaction centers takes place by virtue of the ubiquitous reverse biochemical reactions. Photochemical charge separation is not an equilibrium process but rather a steady state because of a continuing photon energy input during illumination. Strictly speaking, a one-way photochemical reaction is not an absolute requirement: as long as continuing input of photon energy is guaranteed, photon-driven forward reaction continues to offset charge recombination through reverse reactions. In practice, a molecular switch that minimizes reverse reactions is advantageous. In the case of a chlorophyll-based photosynthetic reaction center, Kuhn[108] proposed a molecular mechanism with which to minimize reverse electron transfer (see also Reference 5). In the case of bacteriorhodopsin, the major molecular switch is the protonation switch — conformational changes initiated by photoisomerization of the chromophore — that switches from an extracellular access during the first half of the photocycle to an intracellular access during the second half of the photocycle. The conformational changes minimize reverse proton transfer during illumination.

A conventional photodiode also converts energy by light-induced charge separation: the separation of electrons and holes over a barrier or an interface of different kinds of solid-state materials. Ideally, the separated charges recombine only through an external circuit that includes a lamp, an electric motor, or other electrically powered devices. Any charge recombination must be considered wasteful and unproductive and is usually referred to as short-circuiting. Short-circuiting via external circuits can readily be prevented by proper insulation and is usually not a serious technical problem. Internal short-circuiting due to direct charge recombination at the semiconductor junction is minimized by rectification. For quite some time, bacteriorhodopsin was regarded as a photodiode. Although rectification is quite common in ion channels, the same conclusion cannot be transferred to photosynthetic apparatus without the support of experimental evidence. Our experimental analysis of reconstituted bacteriorhodopsin membranes indicated that, contrary to common belief, the proton conduction channel of bacteriorhodopsin is not rectified. However, bacteriorhodopsin manages to minimize charge recombination in the absence of illumination by a different strategy: the proton conduction channel is gated by light and is completely shut off in the dark. Indirect evidence indicates that the same strategy might have been utilized in chlorophyll-based photosynthetic systems to minimize charge recombination in the dark.

Finally, we return to the question of why nature did not make molecular processes highly deterministic. It is noted that molecular recognition starts as exploration by means of random diffusion and collisions but switches to a more deterministic search once noncovalent bond interactions kick in. Why is this so? We can only speculate from what we know about the brain's higher function: cognition. Cognition, like molecular recognition, is a process of pattern recognition.[109] The brain's strategy of cognition is neither highly deterministic nor highly random. In other words, the brain solves novel problems not by preprogrammed, deterministic procedures or by trial and error but rather by heuristic searching — essentially an approach of the middle ground. This approach is reflected in cerebral lateralization, by means of which the brain uses the nondominant hemisphere (the right hemisphere in most individuals) for explorations and parallel processing of information, and the dominant hemisphere for decisive, focused sequential processing of information. In essence, cerebral lateralization makes heuristic searching feasible. This is the reason why the brain is fault tolerant, but a digital computer, which uses a deterministic

procedure for information processing, is not. Thus, when malfunctions occur, a digital computer degrades catastrophically, but the brain degrades gracefully.

135.1 Bacteriorhodopsin as a Photonic Material

Biomolecular electronics examines the use of biological molecules or biomimetic systems in electronic or photonic devices. The principal rationale for using biomolecular electronics is that natural selection already evolved materials with key properties desired for device applications. Organisms are required to continuously optimize the organic and inorganic components that are critical to their biological or survival functions. The assumption that biology cannot provide materials with sufficient stability or efficiency to compete with semiconductor technology is shortsighted. Many organisms generated materials capable of withstanding high thermal or photochemical stress while maintaining high efficiency, and the search for such materials in extremophiles (organisms that survive optimally under extreme variations in temperature, ion concentration, lack of oxygen, etc.) often yields successful results. Recent advances in molecular biology provide efficient methods of improving upon native materials through genetic engineering and directed evolution. Bacteriorhodopsin (BR) is a protein isolated from a halophilic organism that can be manipulated by genetic methods. The protein is synthesized by an archae extremophile to provide a source of photosynthetic energy for a salt-marsh bacterium that must survive in a

0-8493-1348-1/04/$0.00+$1.50

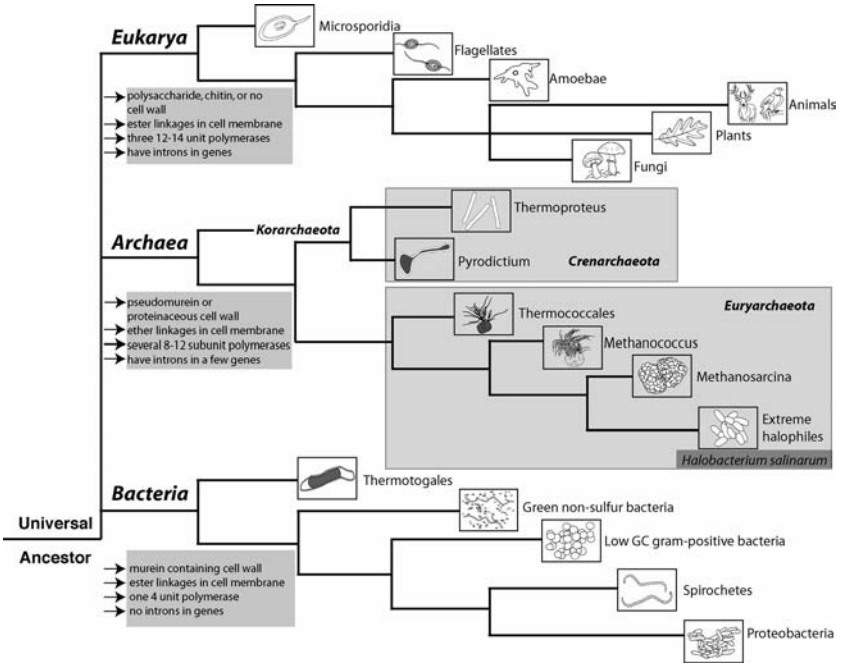

FIGURE 135.1 Phylogenetic tree showing selected representative organisms from major divisions. The three major kingdoms are the Eukarya, the Archaea, and the Bacteria. The Eukarya include microsporidia, flagellates, amoeba, fungi, plants, and animals. The Archaea include three phyla: Korarchaeota, Crenarchaeota, and Euryarchaeota. *Halobacterium salinarum*, which contains bacteriorhodopsin, is a member of the Euryarchaeota. Bacteria include Thermotogales, green non-sulfur bacteria, low GC content Gram-positive bacteria, spirochetes, and proteobacteria. Some key features of each kingdom are shown in boxes under the kingdom name.

hot, high solar flux environment.[1] The native protein is relatively stable and highly efficient in converting light into energy.[2–4] More recent work demonstrated that the properties of the protein can be improved dramatically for specific device applications through chemical modification or genetic engineering.[5–7]

Examined in this chapter is BR as a photonic material for a variety of device applications and materials. An introduction to the organism that produces this protein is provided. The structure and photocycle of the protein are discussed to provide a detailed explanation of the mechanism by which BR absorbs light. Three classes of BR-based devices are described: holographic memories, three-dimensional memories, and hybrid protein-semiconductors. Finally, current efforts and advances in optimization of BR via chemical and genetic methods are discussed.

The Salt Marsh Archaeon *Halobacterium salinarum* Generates a Photonic Material

Bacteriorhodopsin is the predominant protein found in the purple membrane of *Halobacterium salinarum* (also historically referred to as *Halobacterium halobium* or *Halobacterium salinarium*), a halophilic (e.g., "salt-loving") organism that functions in environments where native salt concentrations exceed 4 molar, or approximately six times that of seawater.[1,8] Introduced in this section are the phylogeny of the organism as well as the native environment of the organism.

Phylogeny of *Halobacterium salinarum*

Halobacterium salinarum is a member of the domain Archaea.[9,10] Some representative organisms of the modern kingdoms are shown in Figure 135.1. Based on sequence analysis of ribosomal RNA genes, life on earth was divided into three primary lineages (domains): Eukarya, Bacteria, and Archaea. Archaea is

a kingdom of prokaryotic single-celled organisms that share some of the common features of eukaryotes and prokaryotes and usually inhabit extreme environments. Based on sequence analysis of translation elongation factors, it was suggested that archaebacteria are more closely related to eukaryotes (organisms that contain a defined nucleus) than to bacteria. For this reason, the suffix "bacteria" was dropped from the domain name, yet the etymology of the word bacteriorhodopsin still contains reference to the older classification scheme.

The three major phyla of Archaea are the Crenarchaeota, the Euryarchaeota, and the Korarchaeota. The phylum Crenarchaeota includes thermophiles and hyperthermophiles; most of these organisms are anaerobes, but there are a few aerobic lineages. The Euryarchaeotes include all the methanogens, all the extreme halophiles, and some of the hyperthermophiles. Recently, new organisms were identified that possess ancestral characteristics of the other two lineages; these organisms are classified into the phylum Korarchaeota. Bacteriorhodopsin is found in the cell membrane of *Halobacterium salinarum* (*H. salinarum*), and these organisms are found in the phyla Euryarchaeota. A comparison of the main differences in the three domains of life is shown in Figure 135.1.

The Native Environment of a Halophile

The majority of the Euryarchaeotes adapted to survival under extreme environmental conditions. The thermophiles exist at extreme ranges in temperatures, while the halophiles exist at extremely high salt concentrations. *H. salinarum* grows maximally when sodium chloride (NaCl) concentrations are approximately 4 *M*; this concentration is equivalent to approximately 234 g of salt dissolved in 1 liter of water. This organism can be seen in salt marshes across the world (i.e., the Dead Sea, Owens Lake, California), and the formation of BR in the cell membrane can be associated with the purple hue characteristic of these briny marshes.

Evolution optimized BR for high photochemical efficiency, thermal stability, and cyclicity. The organism must be able to function in a hot, stagnant, and resource-limited environment. Under conditions of low oxygen availability and high light intensities, and under the coordinated regulation of other proteins, BR formation is induced. In the cell, formation of the protein and chromophore are controlled by other genes that are together referred to as the *bop* gene cluster, or regulon.[11,12] The bacterio-opsin (bop) regulon is not fully understood, but some of the key components were identified. Two upstream regulatory genes, *blh* and *brp*, were shown to respond to oxygen and light levels and are involved in regulating synthesis of the protein and chromophore. Abolishment of these regions results in no production of BR.[11] An overproducer strain was isolated that has a constitutive mutation in another upstream region, called *bat*. This strain (called S9 in the literature) synthesizes BR regardless of light intensity, making it an attractive candidate for growing large amounts of protein in the laboratory.

Structure of the Purple Membrane

Shown in Figure 135.2(A) and Figure 135.2(B) are cells of *H. salinarum*. The cells are rod-shaped and measure approximately 0.5 to 1 μM in diameter by 1 to 6 μM in length. The cells stain Gram negative, a feature characteristic of the Archaea that signifies that these organisms do not contain a high concentration of peptidoglycans in the cell membrane.

The purple membrane is comprised of a trimer of BR molecules arranged in a hexagonal two-dimensional lattice. Mature BR accounts for approximately 70 to 75% of the total membrane protein. The protein exists as a trimer in the organism, but trimers and monomers show no significant spectroscopic or kinetic differences in proton pumping ability.[13–15] Shown in Figure 135.2(C) are the lattice structure of BR and the surrounding phospholipid molecules. The importance of lipids on the stability, function, and photocycle of BR was demonstrated.[16–18] The major lipids in the membrane are the phospholipids PGP-Me, PG, and PGS, a sulfoglycolipid S-TGA-1, and squalene. The phospholipids and sulfoglycolipids contain an apolar archaeol moiety.[18]

The remarkable stability of BR is attributed to interactions between membrane lipids and the protein in the purple membrane. Removal of the protein or lipids by chemical means impacts the stability of the lattice. The purple membrane patches were shown to be stable up to 140°C and a wide range of pH

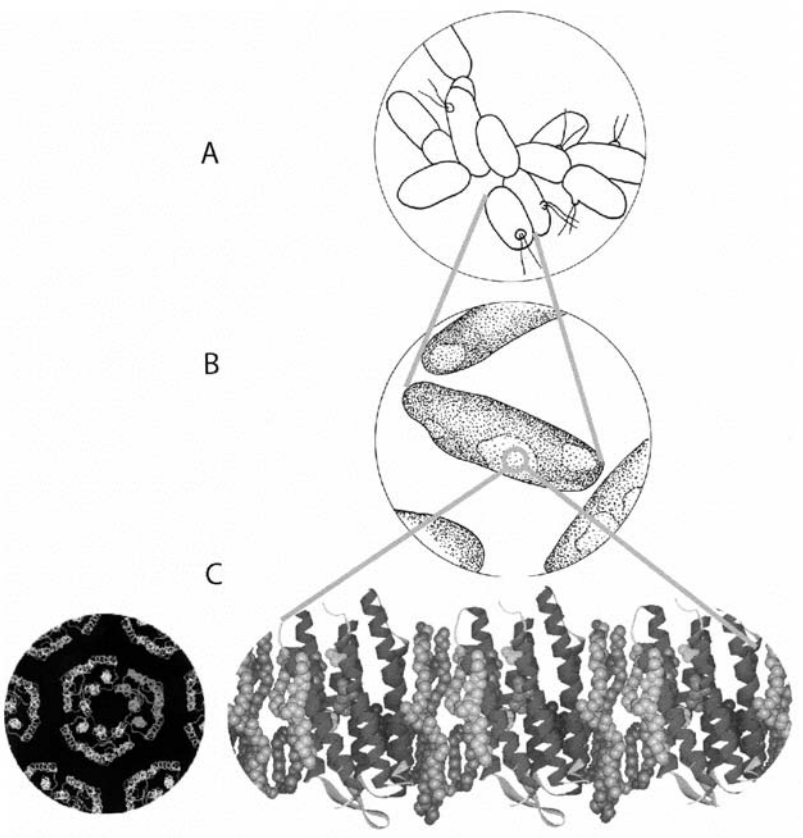

FIGURE 135.2 Magnification of *Halobacterium salinarum* from the native organism to the protein. (A) A rod-shaped cluster of H. salinarum. (B) A single cell of H. salinarum. (C) A top view and side view of the two-dimensional crystalline lattice from the cell membrane of H. salinarum. Bacteriorhodopsin forms a trimer within this lipid lattice.

values.[19,20] The high stability of BR under a wide range of conditions is a primary advantage for use of BR in device applications. It should be stressed, however, that the 140°C stability does not apply to most of the environments utilized for BR-based devices. In a majority of cases, photonic devices based on BR must operate at temperatures below 80°C.

The purple membrane is generated under conditions of low oxygen availability and is used for photosynthetic energy production. The BR photocycle results in the transport of protons from the intracellular to the extracellular surface of the membrane. This generates an electrochemical gradient that is used for energy production as protons enter the cell through ATP synthase channels. This process of nonphotosynthetic photophosphorylation is the only example found in nature. *H. salinarum* also respires by aerobic means when the concentration of oxygen is sufficient to sustain oxidative phosphorylation. The organism is quite harmless to humans and osmotically dissociates into harmless fragments when placed in low salt environments (<2 *M*). This property makes it easy to manipulate the organism in the laboratory without fear of contamination or generation of hazardous variants.

135.2 The Photocycle of Bacteriorhodopsin

Shown in Figure 135.3 is the molecular structure of BR, and highlighted are important residues involved in the photocycle. The BR monomer is a 26 kDa protein that contains seven membrane-spanning α-helices. A nonprotein moiety, retinal, is covalently linked to an internal lysine residue, Lys-216. This molecule is the light-absorbing molecule responsible for initiating photochemistry in the protein.

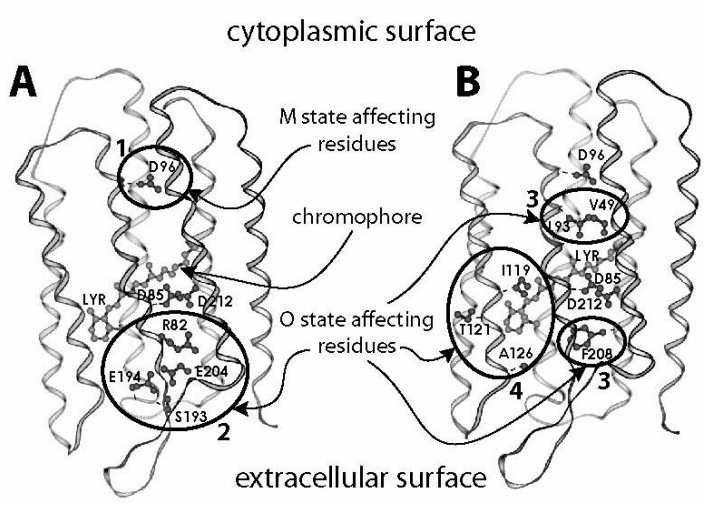

FIGURE 135.3 Bacteriorhodopsin, highlighting important residues and groups of mutation. (A) Group 1. Mutants to D96 affect the lifetime and yield of the M state. Group 2. Mutants to the proton release region consisting of R82, S193, E194, and E204 result in altered **O** state kinetics. (B) Group 3. Mutants that inhibit chromophore isomerization from 13-*cis* to all-*trans* can also affect the **O** state. Group 4. A novel semi-random mutant that has been found to lengthen the **O** state includes the residues I119, T121, and A126.

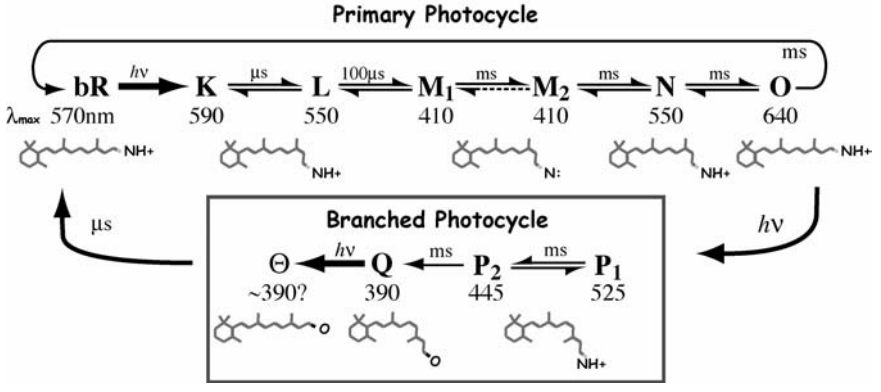

FIGURE 135.4 The main and branched photocycles of bacteriorhodopsin. The λ_{max} value for each intermediate is shown under the intermediate name. The chromophore conformation is shown for each intermediate: **bR**, **O**, and **Θ** have an all-*trans* chromophore; **K**, **L**, $\mathbf{M_1}$, $\mathbf{M_2}$, and **N** have a 13-*cis* chromophore; $\mathbf{P_1}$, $\mathbf{P_2}$, and **Q** have a 9-*cis* chromophore. $\mathbf{M_1}$ and $\mathbf{M_2}$ are the only intermediates which contain a deprotonated Schiff base. Q is characterized by a chromophore which has been detached from the Schiff base via a hydrolysis reaction.

The proton pumping process of bacteriorhodopsin commences when the protein-bound chromophore of the light-adapted form, the all-*trans* retinal Schiff base, absorbs light and undergoes the photocycle schematically shown in Figure 135.4. Although the complete proton pumping mechanism is not understood, many of the key amino acids participating in proton mobility were identified.[3,21] A photon of light is absorbed by the chromophore, inducing an isomerization from all-*trans* to 13-*cis*. This event produces the first trappable intermediate named K. The bR → K transition is the only light-dependent reaction. The remainder of the primary photocycle occurs via a series of thermal relaxations that form, in succession, the L, M, N, and O intermediates (see Figure 135.4).

TABLE 135.1 Protonation States of Key Residues during the Photocycle; Conformation of the Chromophore; pK_a Values for Selected Residues (in parentheses); Change in Protonation or Conformation State from the Previous Intermediate (Shown in Grey); Protonation States Not Assigned Experimentally [a]

	Intermediate						
Residue(s)	bR_{568}	M_{412}	N_{560}	O_{640}	P_{525}	P_{445}	Q_{390}
Retinal	all-*trans*	13-*cis*	13-*cis*	all-*trans*	9-*cis*	9-*cis*	9-*cis*
Asp-96 (10)	COOH	COOH	COO–	COOH	(COOH)	(COOH)	(COOH)
Schiff base (13)	NH+	N:	NH+	NH+	NH+	NH+	N/A
Asp-85 (2.5)	COO–	COOH	COOH	COOH	(COOH)	(COO–)	?
Leaving group (>9)	prot	unprot	unprot	unprot	?	?	?

[a] Those in parentheses are based on theory; those with a question mark are unexamined (Prot = protonated, Unprot = unprotonated).

Table 135.1 shows the protonation states of some of the key residues through the primary and branched photocycle intermediates in BR. Isomerization of the chromophore creates an electrostatic environment that destabilizes the protonated Schiff base. The Schiff base donates a proton to a nearby aspartic acid residue, Asp-85 (D85). Concomitant with the protonation of Asp-85 is a release of a proton from the proton release group, collectively referred to as "XH," because the process is still poorly understood. Deprotonation of "XH" involves the participation of Arg-82, Glu-194, Glu-204, and a hydrogen-bonded network of internal water molecules.[22,23] The proton movement from the Schiff base to Asp-85 generates the M state, which is blue-shifted, because the Schiff base is unprotonated. The O state is characterized by a deprotonated leaving group and an all-*trans* chromophore. The chromophore is reprotonated in the M → N transition by transfer of a proton from another nearby aspartic acid, Asp-96.

BR-based memory devices are primarily based on M-state or O-state photochemistry. Holographic devices are based on the blue-shifted M state, although a Q-state-based holography will be discussed. In three-dimensional memories, the write process is particularly dependent on O-state photochemistry.

Note in Figure 135.4 the presence of the branched photocycle intermediates P and Q. These intermediates will be discussed in more detail later in this section, but it should be pointed out that this branching reaction provides a potential "dead end" for the protein. Any protein that enters this branched photocycle will become unable to pump protons and is therefore considered functionally silent. As will be discussed in the section on BR-based three-dimensional memories, regeneration of the bR state from the Q state is possible and is responsible for resetting the memo bit. In the salt marsh, the P and Q states may serve as a photochemical sunscreen.[24]

Protonation State Changes Result in Altered Absorption Maxima

The absorption maxima listed in Figure 135.4 can be explained by differences in protonation states of key residues, chromophore isomerization, and by conformational changes in the protein. Other visual pigments such as rhodopsin and the cone pigments all vary one of more of these criteria to achieve a different maximal absorption in the resting state.[25–28] Protonation state changes in the vicinity of the Schiff base result in varied absorption maxima in BR. The bR resting state absorbs at 568 nm. During the course of the photocycle, it becomes as blue-shifted as 410 nm in the M state, and as red-shifted as 640 nm in the O state. Examined in this section are the molecular changes responsible for such disparate spectra, and their importance in the creation of BR-based biophotonic devices.

M-State Kinetics and Device Applications

The M state is the most blue-shifted of all intermediates in the primary BR photocycle, absorbing maximally at 410 nm (see Figure 135.4 and Table 135.1). Entry into the M state is characterized by a deprotonation of the Schiff base and a subsequent protonation of Asp-85. The deprotonated Schiff base

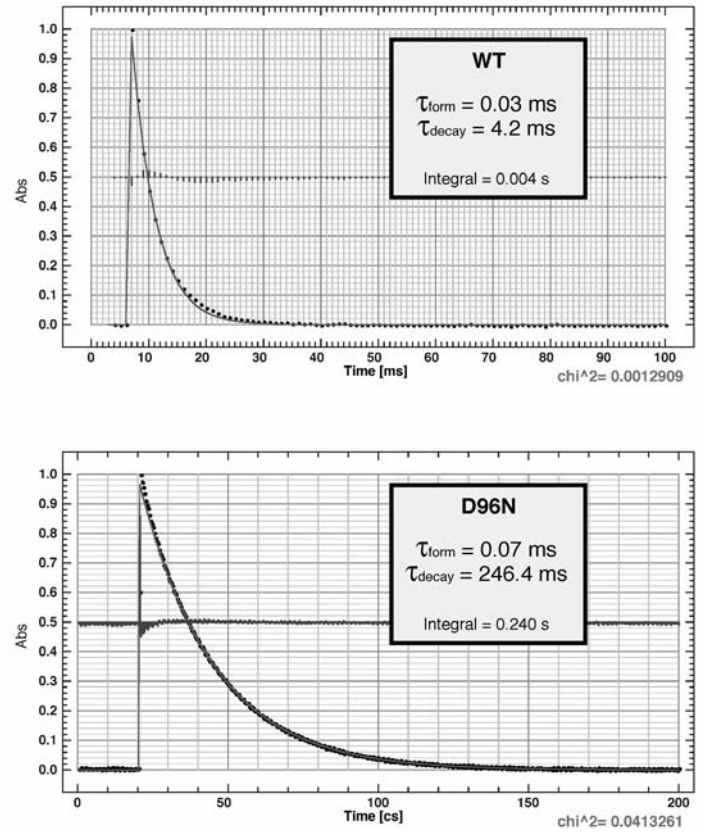

FIGURE 135.5 Normalized time-resolved spectra of wild-type (WT) and D96N protein, both obtained at pH 7. Formation and decay times are shown, as well as the integral under the curve. Note the time is registered in centiseconds for D96N, and milliseconds for WT.

is responsible for the blue shift of the protein. In wild-type BR, reprotonation of the Schiff base occurs from a protonated Asp-96. However, in the variant D96N, which contains no internal primary proton donor, the M-state lifetime increases significantly due to the absence of proton transfer from Asp-96 to the Schiff base [see Figure 135.3(A), Group 1). It is believed that the Schiff base is eventually reprotonated but from another source in the protein that requires significantly more time. Proton availability is the key step for exit from the M state. The D96N mutant can be chemically modified to produce lifetimes ranging from a few milliseconds to minutes. For this reason, and other reasons to be discussed, D96N has been the principle mutant used in holographic applications. A comparison of M-state kinetics for wild-type and D96N protein is shown in Figure 135.5.

O-State Kinetics and Device Applications

The O state is the most red-shifted of all the BR photocycle intermediates, having a maximum absorption of about 640 nm. The O-state intermediate is characterized by an all-*trans* chromophore and a protonated Asp-85. Exit from the O state (i.e., reformation of the resting state) requires proton transfer from Asp-85 to a deprotonated "XH" leaving group. Generation of the O-state intermediate is controlled by the protonation of numerous residues.[29,30] Inhibition of proton movement from Asp-85 to the leaving group was shown to lengthen the O state considerably.

Shown in Figure 135.3 are the main classes of residues for which mutants have been made that show altered photocycle kinetics. There are two classes of mutants that were shown to lengthen the O state. First, the O state can be lengthened by inhibiting chromophore isomerization from 13-*cis* to all-*trans*.

This was accomplished in the Val-49 and Leu-93 mutants, shown in Figure 135.3(B), Group 3.[31,32] However, these mutants are not optimal for use in BR-based three-dimensional memories, because the O → P transition requires all-*trans* to 9-*cis* photochemistry.[24,33] Thus, mutants that inhibit chromophore isomerization to all-*trans* will decrease the probability of entry into the branched photocycle.

The second class of mutants includes those that affect proton release in the Glu-194 and Glu-204 region, shown in Figure 135.3(A), Group 2. These mutants lengthen the O state by interfering with proton transfer from Asp-85, Arg-82, and a hydrogen-bonded network of water molecules to Glu-194 and Glu-204.[22,34–36] The O-state lifetime in WT is between 6 to 8 ms. The O-state lifetimes of E194Q and E204Q at neutral pH and ambient temperature are 70 ms and 125 ms, respectively. Progress in optimization of the O state using site-directed mutagenesis in the proton release region is discussed in Section 135.5.

The Branched Photocycle Intermediates P and Q

Shown in Figure 135.4 are the branched photocycle intermediates P and Q. The O state absorbs maximally at 640 nm; protein molecules that are in the O-state intermediate and absorb a photon enter the P state. The P state is actually a pair of distinct intermediates that will spontaneously form Q.[24] The P → Q transition is a hydrolysis reaction that results in detachment of the chromophore from the protein. Removal of water from the sample results in trapping of the P intermediate. The bR state can be regenerated from Q upon illumination with UV light. This bistable system is the basis for BR-based three-dimensional memories.

Biophotonics that Result from the Photocycle of Bacteriorhodopsin

A summary of BR-based processes and applications can be found in Hampp.[6] Most applications utilize the photochromic properties of BR. Two of these processes are discussed in this chapter: the two-dimensional holographic memory and the three-dimensional associative memory. However, other biomolecular photonic applications are currently being examined. BR is also being used in the process or formation of desalination of seawater, conversion of sunlight into electricity, artificial retinae, motion detection, optical filtering, neural networking, radiation detection, and biosensor applications.[6] The universal application of BR in many different biomaterials is testament to the flexibility and utility of the protein.

135.3 Holographic Applications

A few groups postulated the use of BR in photosensitive applications such as holographic devices.[37–39] A prototype system was established based on a genetic variant of the native protein, called D96N.[40,41] In this variant, the primary proton donor to the Schiff base, Asp-96, is replaced with asparagine, Asn.[42] This removes a functional charge from the molecule and removes an important proton channel participant [see Figure 135.3(A), Group 1]. In Figure 135.5, the kinetics of the M state in wild-type and D96N protein are shown.

D96N-Based Variant Systems

The lifetime of the M state in the D96N mutant is optimal for real-time holographic recording.[40,41,43,44] Oesterhelt, Brauchle, Hampp, and their coworkers exploited this mutant to make a number of holographic systems, some of which yielded commercial success.[6,41,43,45–47]

Real-time holographic recording relies on four attributes of the M state. First, the M state can be formed with high quantum efficiency (65%). Coupled with the broadband absorptivity and large oscillator strength of the 570 nm band of bR, the protein can be used to generate a high-sensitivity photochromic film. Second, the M state is shifted 158 nm to the blue to produce phase-based diffraction efficiencies of 3 to 8% or better. Third, the M state is a transient intermediate that decays back to the

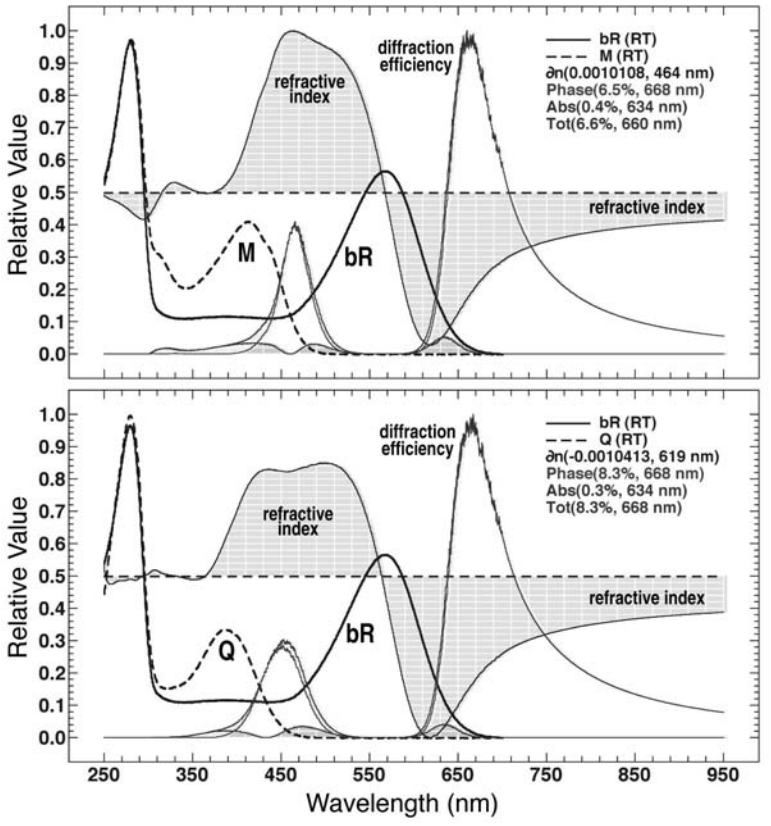

FIGURE 135.6 Comparison of the diffraction efficiency of an M-state photochromic system (top) versus a Q-state photochromic system (bottom). The diffraction efficiencies associated with phase and absorption are plotted as well as the total efficiency, and the maximum values and wavelength maxima are listed in the caption at the top right. The calculations assume 50% conversion using a write wavelength of 532 nm, a write angle of 10 degrees and a film thickness of 100 μm. The read angle was allowed to seek maximum diffraction.

resting state in roughly 100 ms. While this lifetime is far too short for long-term storage, it is optimal for real-time recording and storage of multiple holograms with temporal weighting. Fourth, the M state decay can be enhanced by using blue light or higher temperatures and can be slowed by lowering the temperature. Relatively long-term M state storage is possible at -30°C, a temperature well within the range of Peltier devices. The above attributes combine to make D96N one of the best real-time holographic materials known. In addition, D96N does not form observable amounts of the red-shifted O state, which can interfere with red light recording.

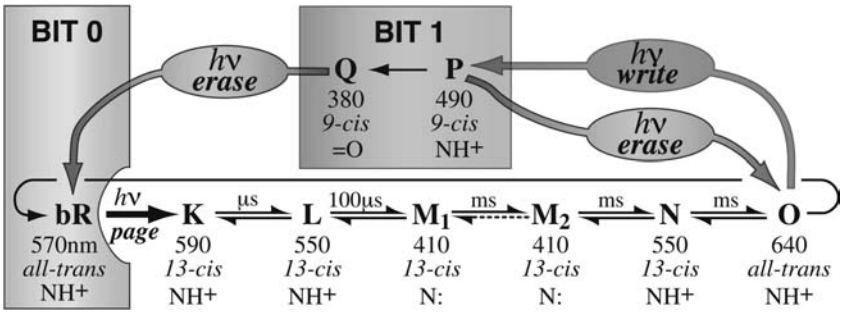
Q-Based Holographic Systems

The M state is not the optimal intermediate with which to create a hologram when using BR as a substrate. Despite many years of effort, methods to increase the stability of the M state have yet to achieve lifetimes of greater than a few months at ambient temperature.[5] It would appear that there are no intermediates within the main photocycle that are good candidates for long-term data storage, but as shown in Figure 135.6, the Q state provides a suitable candidate for long-term storage. To a first approximation, this state is stable for an indefinite period of time unless subjected to blue light. This Q state has a lifetime of many years at ambient temperature and can be formed in high yield under the appropriate conditions.[24] Most important, the Q state can be quantitatively erased under the appropriate conditions[24,44,48] despite earlier suggestions to the contrary.[49] Thus, holography can be based on the binary pair bR and Q instead

of bR and M photochemistry. There are advantages and disadvantages associated with the bR and Q binary pair. The advantages include long-term storage (7 years at 25°C) and increased holographic efficiency (8.3% versus 6.6% for a 5 OD, 100 μm film) (see Figure 135.6). The disadvantages include significantly lower sensitivity (the quantum yield for the O → Q photochemistry in the native protein is only 0.001) and the complexities of using a sequential two-photon write process. However, for volumetric layered holographic storage, the sequential two-photon requirement presents a significant advantage, leaving the problem of low quantum yield. Random mutagenesis is currently being used to find variants that provide higher quantum efficiencies for the O → P and Q photochemistry.

135.4 Three-Dimensional Bacteriorhodopsin-Based Memory Devices

Three-dimensional memory devices using BR as a substrate were demonstrated.[44,50,51] A schematic diagram of the optical system used to write, read, and erase information within a cuvette containing the protein is shown in Figure 135.7. The resting state (bR) is assigned to bit 0, and P and Q are assigned to bit 1 (bit 0 should not be confused with the O state):



SCHEME 1

As noted in Section 135.2, the P state as shown in Scheme 1 is more properly represented as a pair of P states in dynamic equilibrium.[52] But for the purposes of this discussion, these two states are simplified to a single state called P. The details of reading, writing, and erasing information are summarized in the caption for Figure 135.7. There are a number of complications associated with volumetric data storage, and the interested reader is referred to the literature[44] for detailed discussion. In this chapter, concentration will be on the protein, rather than on the optics, and various methods of optimizing the protein for volumetric data storage are discussed in the sections below.

135.5 Optimizing Bacteriorhodopsin for Biophotonic Devices

Although the native protein can be used in the branched-photocycle architecture, it is ineffective and improvements are necessary. The quantum efficiency of the O → P photoconversion ($\sim 2 \times 10^{-4}$) is low, and the O state has a low yield (~1 to 3% under ambient conditions). Mutations directed at optimizing these two photophysical properties suggest that significant improvements can be made to enhance conversion into the branched photocycle intermediates. Site-directed mutants were created that enhance the yield of the O state and the quantum efficiency of the O → P photoreaction. However, site-directed mutants are restricted to knowledge of the protein based on modeling information. Because there are many aspects of the photocycle yet to be discovered, more randomized mutagenesis methods are necessary to complete the optimization process. A summary of optimization methods is shown in Table 135.2.

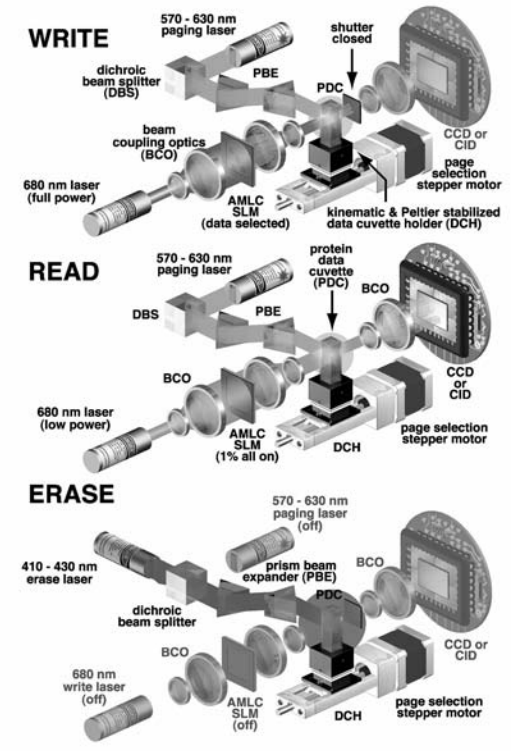


FIGURE 135.7 The write, read and erase operations of the bacteriorhodopsin-based branched-photocycle memory. The write and read operations are both initiated by using a paging beam to activate the photocycle in a thin region within the memory medium (green light). Upon formation of the **O** state in this page, a write beam is activated and the data imposed on the beam using a spatial light modulator (SLM). The read process is similar, but in this case the modulator is turned off so that just enough light gets through to image the page onto the CCD (or CID) array. Because the **O** state is the only species that absorbs the write beam, the read and write processes only involve interaction of the light beam with the **O** state in the paged regions. A blue laser erases an entire page. These processes are shown schematically in Scheme 1.

TABLE 135.2 Optimization Methods in BR; Genetic Mutagenesis Methods are Chosen Depending on Desired Specificity; Chemical Modification to the Protein can be Used to Alter Photocycle Intermediate Lifetimes

	Genetic					Chemical
Technique	Site-directed mutagenesis	Semirandomm utagenesis	Random mutagenesis	Directed Evolution 1	Directed Evolution 2	pH, additives, chromophore analogs
Specificity	Single amino acid	Local region of amino acids	Global *bop* gene	Individual colony or protein	Individual *H. salinarum* cell	Protein or membrane patch
Variability generated	Low	Medium	High	N/A	N/A	High
Primary use	Fine-tuning	Narrowing in on optimal mutation	New search	Colony/protein screening	Organism screening/ selection	Material optimization
Requires	Modeling, *a priori* knowledge	Manageable segments	No *a priori* knowledge	Medium-throughput screening	High-throughput screening	High-level characterization

Chemical Modification and Organic Cation Substitution

Chemical modification was used to stabilize BR photocycle intermediates, typically the M or O states. An increase in the lifetime of a particular intermediate is usually accompanied by a delay in proton mobility. The M-state lifetime can be enhanced by increasing pH, removing water, and adding amine compounds. Dried polymer films treated with organic amines can prolong the M state by several orders of magnitude (from microseconds to minutes).[44] The disadvantage of most chemicals added to BR is that they decrease the photochemical stability of the protein, which translates to a reduced cyclicity of the protein.

The yield and lifetime of the late photocycle intermediates are pH dependent.[29,53,54] The O-state yield increases and the lifetime decreases as the pH is dropped from 7 to 5. This is especially true for O-state mutants. The O-state lifetime can also be lengthened by adding glycerol and a slight decrease in pH, thereby inhibiting proton transfer.[33,55,56]

An alternative approach is to replace the native metal cations in the protein with synthetic organic cations known as "bolaforms" (see Birge et al.[44] for examples). Removal of native cations results in a purple to blue transition in the protein, caused by protonation of Asp-85. Cations are removed using EDTA (Sigma E 9884) or cation-exchange resins (BioRad AG MP-50 Resin).[57–59] Bolaforms are then added to the solution or the polymer matrix. Some bolaforms are capable of regenerating the purple form of BR and show an increased lifetime of the O-state intermediate. Glycerol and other poly-hydroxyl compounds may enhance the O $\rightarrow$ P transition (results not shown).

Genetic Modification is Used to Optimize Photocycle Properties

Site-directed mutagenesis was the traditional technique used to optimize BR for device application. However, this technique is dependent on information provided by protein modeling, x-ray crystallography, and other data. It is difficult to predict which mutations will have a desired photocycle effect, although some variants were created with successful results. In the development of the D96N mutant, currently used for holographic applications, a known participant in proton transfer from Asp-96 to the Schiff base was altered.[45,46] But for more complicated applications (i.e., BR-based three-dimensional memories), multiple variables must be optimized simultaneously. An optimal mutant must be one that optimizes the formation time of O state, the decay of O state, the quantum efficiency of the O $\rightarrow$ P photochemical transformation, the efficiency of the P $\rightarrow$ Q hydrolysis and the lifetime of the Q state. Current models are not sophisticated enough to predict which single or multiple mutations will accomplish these tasks simultaneously. Nevertheless, site-directed mutagenesis was successful in optimization of the O state.

Site-Directed Mutagenesis

Previous studies demonstrated that the Glu-194 and Glu-204 residues are actively involved in the proton release process. A series of mutations involving Glu-194 and Glu-204 residues were constructed, and all of these single and double mutations improved the yield and lengthened the lifetime of the O state. Shown in Figure 135.8 are kinetic spectra for the double mutant E194C/E204C. The double mutant E194C/E204C has an O-state lifetime of ~1 sec; this is the largest lifetime found for any O-state mutant, and it represents greater than a 100-fold increase in the O-state lifetime. The origin of this considerably lengthened O state is still unclear, but presumably involves formation of a covalent bond between two cysteine residues, thus removing any potential of these residues to participate in proton exchange.

Because there are so many variables to optimize, a quality value or "Q value" was developed to account for multiple parameters. It should be mentioned that the parameters of this value change depending on the characteristics being screened. An example of one Q value developed for mutant screens is shown below:

$$Q = \tau_0^{-1} \int_{t=0}^{t=\infty} [O] dt \tag{1}$$

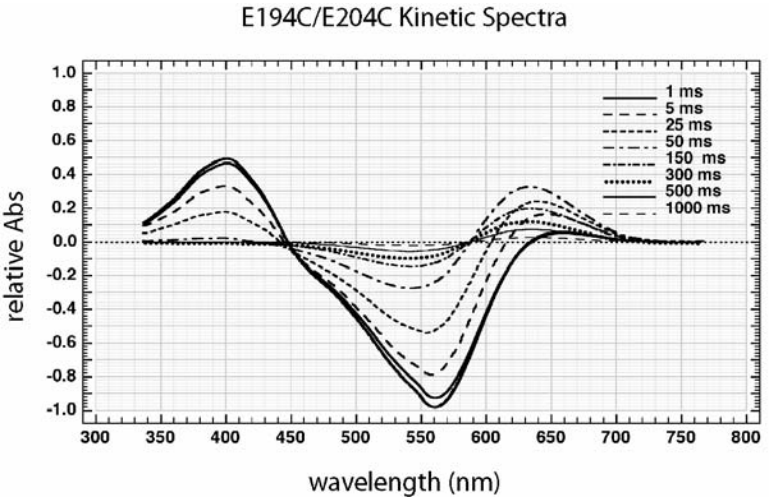

FIGURE 135.8 Standardized difference kinetic spectra of the double mutant E194C/E204C. A cuvette containing protein at OD 1.2 at λ_{max} was illuminated at 568 nm, and the resultant changes measured on an Olis rapid-scanning monochromator. Even after 1 second, the protein has yet to return to baseline.

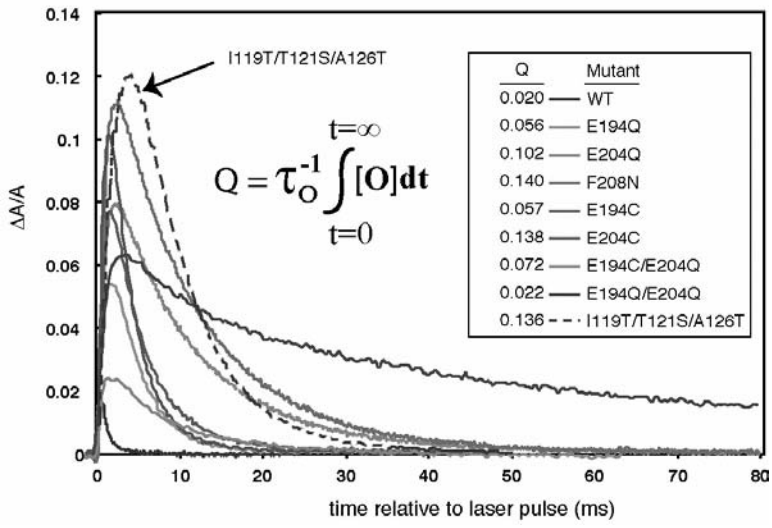

FIGURE 135.9 Single-wavelength spectra obtained for mutants proteins. The semi-random mutant, I119T/T121S/A126T yields more **O** state and has a higher Q value (see equation in text) than any site-directed mutant. Proteins were monitored at pH 6 at 650 nm following a laser pulse at 568 nm.

The Q stands for quality of mutation, and it is a coincidence that the higher the Q value, the more efficient is the Q-state formation process. A protein that produces a large amount of O state in the shortest time has the highest Q value. Despite E194C/E204C having the longest lifetime, other mutants have higher Q values, because they produce the largest amount of O state in the shortest time period. Note that the total lifetime is divided into the integral of the yield. Some Q values for a sample of mutants are shown in Figure 135.9. The wild type has the smallest integral and Q value of any of the proteins shown. This is not surprising, because *H. salinarum* optimized bacteriorhodopsin as a proton pump, not as a three-dimensional storage medium.

Random Mutagenesis

The next step in the genetic optimization process is to create random mutations. This process requires high-throughput screening of mutations, detection of optimized photophysical properties using spectroscopy, and determination of which mutants should be used as templates for further exploration. Random mutations are as likely to optimize or diminish photocycle intermediate lifetimes and yields as they are neutral in effect. The total number of unique mutations possible for a protein containing N amino acids for which M residues have been modified is:

$$\frac{19^M N!}{(N-M)!M!} \tag{2}$$

Because BR provides roughly 5000 single mutations and 11 million double mutations, it is clear that a single cycle is unlikely to produce an optimization. For this reason, a restriction of mutations to a local region (also know as "saturation mutagenesis") was used to generate controlled numbers of mutants in 10 to 15 amino acid regions, a process called semirandom mutagenesis.

SemiRandom Mutagenesis

Semirandom mutagenesis essentially combines site-directed and random mutagenesis techniques. In this technique, a narrow window of roughly 15 amino acids (this number can be varied) is mutated without disturbing the surrounding sequence. The complete BR protein sequence can be divided into 17 such segments that span the entire range of the protein. This method of mutagenesis is less specific than site-directed mutagenesis but grants the opportunity to partition the gene into 17 manageable segments. Details on how these mutants are created can be found in the literature.[7] This medium-throughput method can be used to generate and screen small amounts of proteins in 96-well plate format.

Results of a spectral scan and O-state lifetime screen for a 96-well plate of mutants are shown in Figure 135.10. Each well contained approximately 0.06 mg amount of protein. Photocycle lifetimes were collected for each mutant, and Q values were calculated (see Equation 135.1). One triple mutant, I119T/T121S/A126T showed a Q value that was higher than any other mutant yet discovered. The residues involved in this mutation are shown in Figure 135.3(B), Group 4.

Calculations suggest that this mutant is lengthening the O state in a functionally different way than other known O-state mutants. In the I119T/T121S/A126T mutant, an electrostatic field appears to be stabilizing Arg-82 farther away from the binding site than in wild type. Stabilizing Arg-82 in the "down" position presumably lengthens the O state by inhibiting reprotonation of the proton release group. Further kinetic studies are currently being conducted on this interesting mutant. This mutant endorses the use of semirandom mutagenesis to locate unpredictable mutants that result in optimized protein.

Directed Evolution

Combinatorial methods were used to optimize materials.[60–63] Some useful biophotonic materials have already been refined through evolution; in the case of BR, nature optimized a durable and efficient proton pump. This is evidenced by the fact that greater than 90% of mutants result in an increased lifetime of a photocycle intermediate, thereby decreasing the overall speed of the proton pump. However, some mutants were created that shorten a photocycle intermediate lifetime; this indicates that it is possible to improve BR for device applications given the proper mutagenesis techniques. The challenge in using directed evolution for materials optimization is establishing a selection method that focuses on the desired properties of the material generated by the host. In the case of BR, developing a screen to detect optimized proteins in the host *H. salinarum* is essential for development of high-throughput methods.

The directed evolution of BR is divided into two classes: Type I and Type II. These stages are not discrete but rather represent a continuum of procedures that start with a screening process and end with a selection process. The different optimization levels are shown in Table 135.2. Type I directed evolution includes screening of protein variants at the colony or protein level, whereas Type II includes screening/selection of BR in individual archaea. Each round consists of starting with those variants that were most

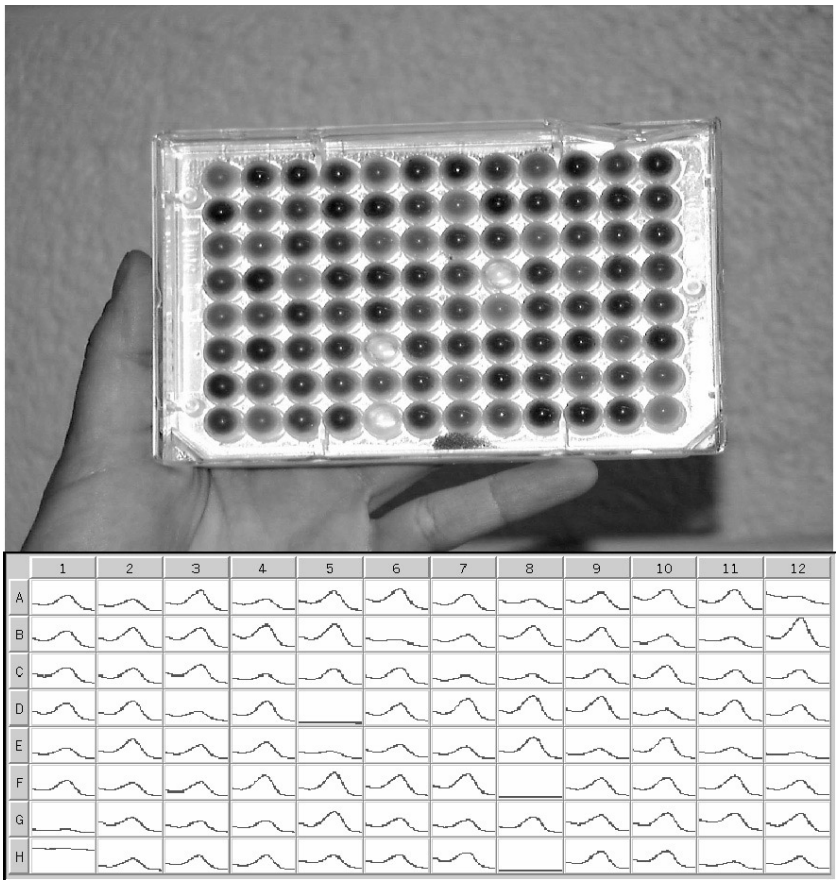

FIGURE 135.10 A 96-well plate containing 93 unique proteins created using semi-random mutagenesis (3 wells did not purify well and were not included in this plate). Corresponding UV-vis spectra were taken using a Bio-tek® μQuant 96-well plate reader. Each mutant was then studied by using time-resolved pump-probe spectroscopy to assign the formation and decay times of the **M** and **O** intermediates.

optimal from the previous round, as defined by the Q value of choice. The essence of directed evolution is that a determined subset of protein representatives is used as the starting point in the next mutational round. Each new round provides an iterative improvement and shifted distribution of characteristics from the previous round.

Type I directed evolution is a medium-throughput method that involves screening purified protein or colonies in 96-well plate, medium-throughput levels. Shown in Figure 135.10 are the results of a screen done on a Type I evolution process in 96-well plate format. Type II directed evolution is currently being developed and involves selecting individual archaea using a flow cytometer. Those organisms that meet a given photocycle optimization criteria are shunted to a collection vessel, while those that do not are discarded.

The choice of optimization method is dependent on the desired level of variation. To explore small changes, site-directed mutagenesis is used to mutate a single residue. To examine larger mutational effects, semirandom and random mutagenesis are used. Results from different optimization methods can be used in tandem; a favorable result from one technique can be combined with variants from another source. Proton release mutants developed from site-directed mutagenesis in the Glu-194 and Glu-204 regions are now being combined with the triple mutant I119T/T121S/A126T to test for synergistic optimization.

135.6 Hybrid Protein-Semiconductor Devices

The high quantum efficiency, large oscillator strength, broadband absorptivity, thermal stability, and fast photovoltaic response of BR make it an attractive material for the photoactive element in high-speed photodetectors.[38] Such applications include high-speed tracking, motion and edge detection, as well as high-resolution imaging.[38,64–67] The significant potential of BR as a light-transducing material was recently shown in a hybrid protein-semiconductor monolithically integrated transimpedance photoreceiver.[68] In this device, the photovoltage generated by the protein biases the gate of an amplifying field effect transistor (FET), creating a photocurrent signal further amplified as a current or voltage signal in subsequent transistor-based amplifying stages. The optoelectronic integrated circuit (OEIC) uses the protein as a photodetector, demonstrating performance characteristics comparable to, or better than, all-semiconductor OEIC photoreceivers.[69]

The utility of this protein in hybrid protein-semiconductor devices derives added value from the sensitivity of the protein to external molecular stimuli.[70–84] Thus, it is possible to use the photocycle kinetics[76,78,79] or photovoltaic responsivity[71,72,83] to monitor the concentration of volatile species. Most of the work to date concentrated on anesthetics, but these and other studies indicate that many organic compounds will directly bind to BR and alter the photophysical properties.[71,74,82] It can be concluded that the complexity of the photovoltaic signal and the sensitivity of this signal to external media combine to make BR a strong candidate for the design of hybrid protein-semiconductor sensors.

Before any of the above hybrid devices can be created reproducibly, the protein–metal and protein–semiconductor surfaces must be optimized. A few years ago, this was viewed as a fairly straightforward challenge upon the discovery that organic cations could be used to prevent protein–semiconductor cross contamination.[85] More recent work demonstrated that the homogeneity of the protein and the long-term stability of the protein, when attached to surfaces, is a complex variable dependent upon hydration, pH, surface charge, surface conditions, applied charge, preparation history, and genetic variation (results to be published). Of great interest and importance to the viability of protein-based sensors is the observation that some mutants produce a "Swiss-cheese" matrix with numerous ~50 to 100 nm diameter holes that extend through the entire membrane. The presence of these defects was not observed in purple membrane patches containing wild-type BR and deposited in the same way. The above observations are from research being done in Professor Ronald Reiffenberger's laboratory in the Department of Physics at Purdue University. The origin and solution for these problems remain to be discovered and are an area of active research.

135.7 Future Direction and Conclusions

Bacteriorhodopsin is an example of a biophotonic material that shows considerable promise as a template for a number of device applications. The above examples are illustrative but not exhaustive, and interest in the use of this protein for devices shows exponential growth. The enthusiasm stems not from the intrinsic characteristics of the native protein but rather the ability to modify the protein for specific applications with an efficiency that far exceeds that possible using organic chemistry. Current medium-throughput optimization screens of BR mutants resulted in significant alterations to photocycle lifetimes and yields. However, high-throughput optimization and directed evolution are necessary tools if BR is ever to reach full potential. The implementation of directed evolution and other systematic genetic methods might enhance the utility of BR an additional order of magnitude.

Acknowledgments

The authors would like to thank Virge Kask for her artistry in Figures 135.1 and 135.2. The authors would also like to thank Dr. Kenneth Noll at the University of Connecticut for his contribution to Figure 135.1.

Bacterial Bioluminescence: Biochemistry

Shiao-Chun Tu
University of Houston

136.1 Introduction

Most photobiological processes are triggered by light absorption. A wide range of biochemical reactions and physiological functions can be initiated by the capture of photons at an appropriate energy level by specific sensing or receptor molecules. In contrast, bioluminescence is an unusual subfield of photobiology; energy derived from biochemical reactions is coupled to the generation of excited states and, in turn, emission of visible light with high quantum yields, usually in the range of 0.1 to near unity. Bioluminescent species are found in prokaryotes and eukaryotes. The underlying biological and chemical principles for the expression and regulation of bioluminescence were the subject for active basic and applied research for several decades. Among known bioluminescent systems, bacterial bioluminescence is one of the most extensively studied few with respect to biochemistry. A chapter by this author on the subject of biochemistry of bacterial bioluminescence was published in the 1995 edition of this book.[1] In order for the present chapter to be self-sustaining, some salient points from the previous chapter are again briefly summarized. Comprehensive coverage of all important aspects of the biochemistry of bacterial bioluminescence is not intended. The *lux* operon induction by the quorum-sensing autoinducer, mechanisms of luciferase protein folding, functions of bioluminescence-related fluorescent proteins, structures and mechanisms of aldehyde synthesizing enzymes and NAD(P)H-dependent flavin reductases, mechanisms of reduced flavin transfer to luciferase, and applications of luciferase and *lux* genes in basic research and technological development are notably among areas of omission.

Most known luminous bacteria are from the marine ecosystem. They are free living or symbionts. Among them, *Vibrio harveyi* (initially designated MAV or *Benekea harveyi*), *Vibrio fischeri* (formerly *Photobacterium fischeri*), and *Photobacterium phosphoreum* are the three most extensively studied strains. *Xenorhabdus* (later reclassified as *Photorhabdus*) *luminescens* is a notable exception, with strains isolated from human wounds or as nematode symbionts. Essential enzymes for bacterial bioluminescence *in vivo* are shown in Scheme 136.1. The light-emitting reaction is catalyzed by luciferase, a flavin-dependent

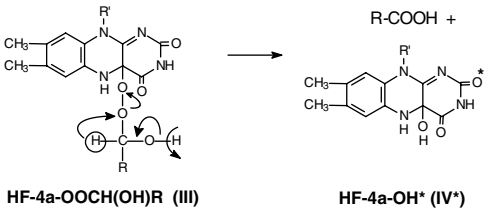
monooxygenase. The emission peak wavelength is around 490 nm, which could be shifted *in vitro* and *in vivo* to a shorter (~476 nm) or longer (~530 nm) wavelength in the presence of a lumazine- or flavin-containing fluorescence protein. The required substrate-reduced flavin mononucleotide ($FMNH_2$) is believed to be provided *in vivo* by flavin reductases using NADH or NADPH as a reductant. Structures and properties of flavin reductases and mechanisms of reduced flavin transfer to luciferase were recently reviewed.[2] The long-chain aliphatic aldehyde substrate can be obtained from reduction of fatty acid catalyzed by a reductase complex.

136.2 Luciferase Mechanism

Intermediates and Chemical Mechanism

The foundation for the chemical mechanism of bacterial luciferase is primarily laid by the work of Hastings and colleagues.[3–8] These studies and the work of others were the subjects of a number of reviews. Main features of the luciferase chemical mechanism are summarized in Scheme 136.2. The luciferase-bound N1-deprotonated $FMNH^-$ (Intermediate I) reacts with oxygen to generate the 4a-hydroperoxy-FMNH (HF-4a-OOH; Intermediate II), which undergoes a dark decay to form FMN and H_2O_2 in the absence of aldehyde or reacts with aldehyde to form the 4a-peroxyhemiacetalFMNH (Intermediate III).

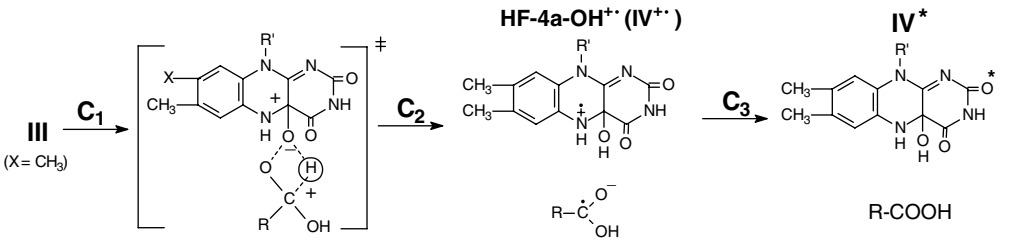


SCHEME 3

Intermediate III undergoes a still poorly understood reaction to generate 4a-hydroxyFMNH at the excited state (Intermediate IV*) and fatty acid. The relaxation of IV* is accompanied by light emission. The final decay of Ground State IV produces FMN and water and releases free luciferase.

An NMR study revealed that the luciferase-bound $FMNH_2$ is in the N1-deprotonated state.[9] In this connection, a computational analysis demonstrated that the N1-deprotonated $FMNH^-$ is significantly more active than $FMNH_2$, and the flavin 4a-position is the preferred site in reacting with oxygen to form II.[10] In a flavin model system, II is initially formed as HF-4a-OO^-, which undergoes an energy barrier-free conversion to HF-4a-OOH.[10] In the enzymatic reaction, which form of II is stabilized by luciferase is unclear. However, HF-4a-OO^- is expected to react with aldehyde to generate III. The substrate hydroxylation activities of flavoprotein monooxygenases in general and the bioluminescence activity of luciferase in particular depend on an efficient fission of the O–O bond over the C(4a)–O bond of flavin-4a-hydroperoxide or, in the case of luciferase, flavin-4a-peroxyhemiacetal. The energy of these reactions was studied using flavin models.[11–13] The O–O bond dissociation enthalpies for HO-OH, CH_3O-OH, CH_3O-OCH_3, $CH_3C(O)O$-$OC(O)CH_3$, and flavin-4a-O-OH were found to be, respectively, 51, 45, 38, 30, and <26 kcal/mol.[12] Clearly, flavin-4a-hydroperoxide is effective in activating the O–O bond. Furthermore, in flavin-4a-hydroperoxide, the free energies of the O–O bond and the C(4a)–O bond fission were determined to be 16 and 21 kcal/mol, respectively.[11,13] Hence, the O–O bond breakage is favored over that of the C(4a)–O bond. The O–O bond in flavin-4a-peroxyhemiacetal is even weaker than that in flavin-4a-hydroperoxide by 7 kcal/mol.[12] All of the cases mentioned above indicate that the O–O bond in flavin-4a-hydroperoxide and flavin-4a-peroxyhemiacetal is highly activated for the light-emitting reaction. The converse was also shown for the C(4a)–O bond fission. Using the wild-type luciferase and 18 mutants, we demonstrated an inverse linear correlation between the bioluminescence activity and the rate of Intermediate II dark decay involving the C(4a)–O bond fission.[14] By the use of fluorescent aldehyde substrates, it was also demonstrated that IV* instead of activated aliphatic carboxylic or carbonyl species is generated as the primary excited state.[15] As reviewed earlier,[1] a large body of studies provided supporting evidence for the existence of Intermediates II and IV and documentation of their spectral and chemical properties.

The most intriguing but also the least understood reaction in Scheme 136.2 is the formation of the excited 4a-hydroxyFMNH emitter (Step C). Thus far, two major types of mechanisms were postulated, namely, the Baeyer–Villiger (BV) mechanism and the Chemically Initiated Electron Exchange Luminescence (CIEEL) or Electron/Charge Transfer (ECT) mechanism. First, the BV mechanism[5] is depicted in Scheme 136.3. The abstraction of a proton from the OH in Intermediate III sets off the electron and hydride transfers as shown to generate IV* and carboxylic acid. The main attraction of this mechanism is that it is based on a well-established reaction mechanism. However, a potential major problem with this mechanism for luciferase is that energy released from multiple steps of bond rearrangement must be pooled together at the same time to elevate 4a–hydroxyFMNH to its excited state. Similar to luciferase, cyclohexanone monooxygenase is a member of flavin-dependent monooxygenases and was shown to follow the Baeyer–Villiger mechanism.[16] Boronic acids can be used by cyclohexanone monooxygenase as substrates to produce the corresponding boric acids as products. In contrast, such a mechanistic probe cannot be utilized by luciferase for boric acid formation or light emission.[17] The results obtained from a study using eight-substituted flavin analogs as mechanistic probes are also opposite to what is expected



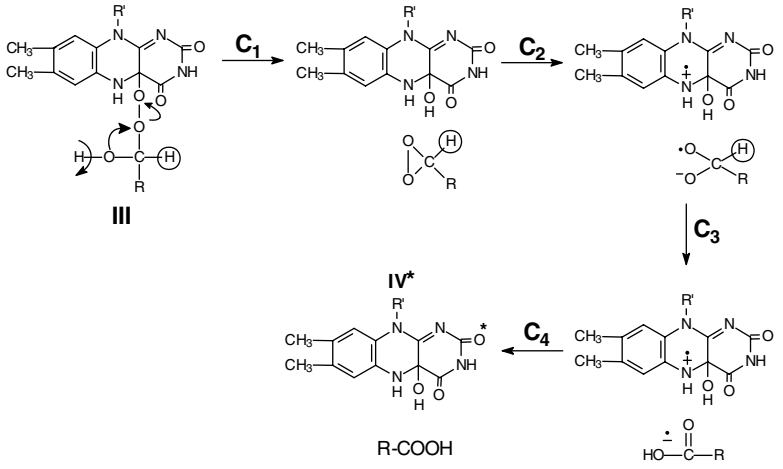
SCHEME 4

for a BV mechanism.[8] This will be discussed in more detail below. Since its original introduction in 1972,[5] the BV mechanism has not gained wide support, despite a formidable effort for its resurrection.[18]

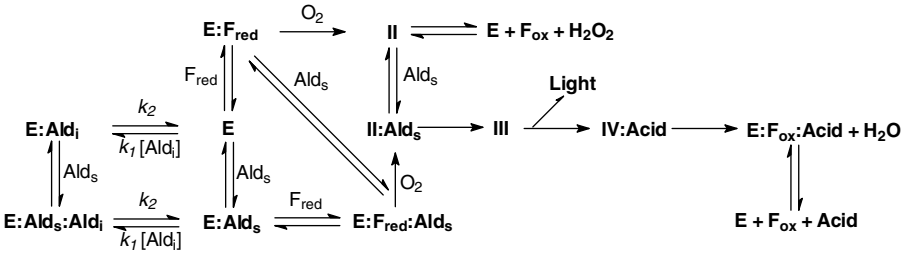
Next, two versions of mechanisms following the principle of CIEEL[19] were proposed. In the original CIEEL mechanism formulated for bacterial luciferase,[8,20–23] a fission of the O–O bond in Intermediate III and transfers of electron and proton take place, resulting in the formation of a caged pair of one-electron-reduced carboxylic acid radical R-C(OH)$O^{-\bullet}$ and a novel 4a-hydroxyFMNH radical cation (HF-4a-OH)$^{+\bullet}$ (Intermediate $IV^{+\bullet}$). A subsequent electron transfer from the carboxylic acid radical to $IV^{+\bullet}$ generates the fatty acid and excited 4a-hydroxyFMNH (IV*). There are a few minor variations regarding how the caged radical pair of R-C(OH)$O^{-\bullet}$ and $IV^{+\bullet}$ are formed from III. Our updated version[13,24] is shown in Scheme 136.4. This scheme involves a full one-electron separation in the formation of the radical pair and a subsequent radical annihilation, but it can be modified to involve charge transfers instead.[1,25,26] Conceptually, it should be considered an ECT mechanism.[1]

Several major aspects of this mechanism are strongly supported by experimental results or theoretical consideration. The formation of the IV* emitter is proposed to occur in a single step of radical annihilation, an efficient process for generating an excited state. A key intermediate in this mechanism is the novel 4a-hydroxyFMNH radical cation ($IV^{+\bullet}$). The formation and characterization of this type of radicals from flavin models were achieved by electrochemical oxidation,[11] chemical comproportionation,[27] and pulse radiolysis.[13] The absorption spectra and redox potentials of several 4a-hydroxyflavin radical cations were determined.[11,13] Moreover, the annihilation between a 4a-hydroxyflavin radical and a one-electron-reduced carboxylic acid radical was calculated to release ~90 kcal/mol of energy,[13] in excess of the 67 kcal/mol required for generating the excited emitter IV*. In fact, chemical[28] and electrochemical[29] reduction of preformed 5-ethyl-4a-hydroxyflavin radical cations are found to emit chemiluminescence in model systems. Other important supporting evidence is a study to correlate the redox potentials of flavin analogs with the luciferase light decay rates.[8,30,31] By making different substitutions at Position 8 (marked as *X* in Scheme 136.4), redox potentials of a series of flavin analogs are varied. A lower one-electron oxidation potential of the flavin is expected to enhance its tendency to form the 4a-hydroxyflavin radical cation and, in turn, the luminescence reaction rate. Indeed, such a trend was observed in this study. This observation is consistent with the CIEEL/ECT mechanism but is opposite to what is expected for the BV mechanism. Also consistent with the CIEEL/ECT mechanism is the observation that superoxide anion is able to increase the rate of light decay, presumably by reacting with and removing the Intermediate III in competition with the productive Step C2 in Scheme 136.4.[32]

The same principle of CIEEL/ECT mechanism has also been adapted for a mechanism[33,34] (Scheme 136.5) involving dioxirane[35] as an intermediate. Key aspects of this dioxirane mechanism are similar to the CIEEL/ECT mechanism mentioned above. The exited emitter formation involves the same annihilation of radicals (Step C4). The same 4a-hydroxyFMNH radical cation proposed earlier in the CIEEL/ECT mechanism is again formulated as a key intermediate. Hence, the correlation of flavin redox potentials with the luciferase light decay rates also supports this dioxirane version of the CIEEL/ECT mechanism. One difference between the two mechanisms shown in Schemes 136.4 and 136.5 is that a dioxirane species is depicted as an intermediate in the latter. As a test, dimethyldioxirane was reacted



SCHEME 5 Adapted with permission from Francisco, W.A., Abu-Soud, H.M., DelMonte, A.J., Singleton, D.A., Baldwin, T.O., and Raushel, F.M., *Biochemistry,* 37, 2596, 1998.



SCHEME 6

with 5-ethyl-4a-hydroxy-3-methyl-4a,5-dihydrolumiflavin. Only trace chemiluminescence was detectable, which cannot be enhanced by the addition of the highly fluorescent 3-methyllumiflavin as a sensitizer.[23] While this does not rule out the dioxirane mechanism as shown in Scheme 136.5, the observation certainly does not provide any support to this mechanism. Another difference is related to deuterium kinetic isotope effects arising from the substitution of the circled hydrogen in Intermediate III by deuterium by using [1-^{2}H]-labeled aldehyde substrate. This kinetic isotope effect will be discussed later. The dioxirane mechanism also requires that 4a-hydroxyFMNH is first formed at the ground state before the rate-limiting step of the generation of the corresponding radical cation.[34] In subsequent steps, 4a-hydroxyFMNH is again formed, in excited state and finally the ground state. The first appearance of 4a-hydroxyFMNH is proposed to be before the rate-limiting step and, hence, should be detectable before the light emission. Thus far, the luciferase-bound 4a-hydroxyFMNH intermediate was only detected as a ground state product of the emitter, not before the formation of the emitter.[7,36–39] These considerations should be incorporated into the evaluation of this dioxirane mechanism.

Kinetic Mechanism and Aldehyde Inhibition

The kinetic mechanism will be confined to *V. harveyi* luciferase, the most extensively studied bacterial luciferase to date. Our version of the kinetic scheme is shown in Scheme 136.6. Aside from the aldehyde

inhibition, most of this scheme should be of general relevance to other bacterial luciferase species. Intermediates II, III, and IV are the same as defined in Scheme 136.2. F_{red}, F_{ox}, Ald_s, and Ald_i are, respectively, reduced FMN, oxidized FMN, aldehyde substrate, and aldehyde inhibitor.

Luciferase follows a random binding of F_{red} and Ald_s to form the ternary complex of $E:F_{red}:Ald_s$. This complex reacts with oxygen to generate $II:Ald_s$ complex that is subsequently converted to III. In fact, Ald_s can also bind to II to form the same $II:Ald_s$ complex and, subsequently, III. The random binding of Ald_s and F_{red} to form a productive intermediate was first noted by Holzman and Baldwin,[40] but the same group later published another scheme in which prior binding of aldehyde to luciferase prevents the binding of $FMNH_2$ by luciferase (see below). Our more recent results are consistent with the random binding of Ald_s and F_{red}.[41] The reaction of bound F_{red} with oxygen to form II was documented first by kinetic evidence[3] and, later, most definitively by the isolation of this intermediate.[6] Using the isolated II, it was established that Ald_s can directly react with II for light production[6,42–44] in an oxygen-independent reaction.[45] In the absence of Ald_s, II undergoes a dark decay to yield equal molar F_{ox} and H_2O_2.[42,44] The addition of H_2O_2 to F_{ox} in the presence of luciferase can also generate II in a low-yield reaction.[46] Once III is formed, subsequent reactions take place to form the excited emitter (not shown in Scheme 136.6 for simplicity) and, in turn, light and ground state IV in complex with the carboxylic acid product. While the carboxylic acid is still bound, the decay of 4a-hydroxyFMNH gives rise to F_{ox} and water. Finally, F_{ox} and carboxylic acid are released as the final products, and luciferase is liberated for the next catalytic cycle. The carboxylic acid remains in the luciferase-bound form until the final step in the scheme. This was demonstrated for the *P. luminescens* luciferase,[47] and the same is assumed for the similar *V. harveyi* enzyme.

The *V. harveyi* luciferase was long known to be inhibited by high concentrations of aldehyde[48] when added to luciferase before $FMNH_2$.[49] The *P. luminescens* luciferase was also shown to be inhibited by high concentrations of aldehyde.[50] There are three schemes for aldehyde inhibition. The first mechanism[40] involves the sequential binding of two aldehydes, herein referred to as the "Two-Site Sequential" (TSS) mechanism. The first aldehyde is bound as a substrate. Subsequently, a second aldehyde, as an inhibitor, binds to the initial luciferase:aldehyde complex to trap the enzyme in an inactive $luciferase:(aldehyde)_2$ form. This scheme also depicts a random binding of the aldehyde and $FMNH_2$ substrates. The TSS scheme was later replaced by a second kinetic mechanism,[51] in which only one aldehyde is shown in luciferase-bound form. In this "One-Site" (OS) scheme, luciferase can bind $FMNH_2$ or aldehyde first. However, when aldehyde is bound first, the luciferase:aldehyde complex is incapable of binding $FMNH_2$. Moreover, the dissociation of the aldehyde from the inactive luciferase:aldehyde complex is slower than the autooxidation of $FMNH_2$, thus in a nonturnover assay, little or no free $FMNH_2$ would be available when enzyme is liberated from the luciferase:aldehyde complex. Hence, active enzyme intermediates can be formed only when $FMNH_2$ is bound to luciferase prior to aldehyde. We proposed a "Two-Site Random" (TSR) mechanism[41] (part of Scheme 136.6) for aldehyde inhibition with the following key features:

1. The binding of substrates F_{red} and Ald_s by luciferase is random.
2. Luciferase can bind one Ald_s and one Ald_i per $\alpha\beta$ dimer, at two presumably independent sites.
3. The Ald_s has a higher binding affinity than that of the Ald_i.
4. Ald_i is a competitive inhibitor against $FMNH_2$. While $E:Ald_s$ is active, both $E:Ald_i$ and $E:Ald_s:Ald_i$ are inactive.
5. The on and off constants for the Ald_i binding are substantially slower than not only those of the $FMNH_2$ binding but also those of the Ald_s binding.

Results of equilibrium binding, chemical relaxation analysis, and activity and inhibition kinetic measurements are all consistent with this scheme.[41]

The TSS and our TSR scheme share the common features of random binding of Ald_s and F_{red} substrates and two aldehyde sites per $\alpha\beta$ luciferase. However, TSS is based on a sequential binding, whereas our mechanism involves a random binding of the two aldehydes. Subsequent to the proposal of the TSS scheme,[40] a different OS scheme[51] was published involving a common author for both publications. Apparently, the latter OS scheme is favored by these researchers over the first mechanism. The OS and our TSR mechanisms are consistent with respect to two points:

1. Once an aldehyde inhibitor is bound to luciferase, the enzyme can no longer bind the F_{red} substrate.
2. The dissociation of the aldehyde inhibitor from luciferase is slower than the autooxidation of F_{red}.

However, the OS scheme differs from TSS and TSR in depicting the binding of only one aldehyde by luciferase. This is inconsistent with the binding of two aldehydes by luciferase measured under aldehyde concentrations suitable for inhibition.[41] Another questionable feature of the OS scheme is the report of $k_{19} = 9.1 \times 10^5\ M^{-1}s^{-1}$ and $k_{20} = 5.8\ s^{-1}$ for the on and off rate constants for the binding of decanal inhibitor to luciferase[51,52] Using decanal, the on and off rate constants for the binding of the aldehyde inhibitor to luciferase or to E:Ald_s complex are determined by us by chemical relaxation to be $k_1 = 3.5 \times 10^3\ M^{-1}s^{-1}$ and $k_2 = 0.038\ s^{-1}$, respectively (Scheme 136.6). In our study, a limiting amount of luciferase was equilibrated with aldehyde at several concentrations suitable for inhibition. The samples were each diluted with buffer for the dissociation of aldehyde until a new equilibrium was reached. The measured relaxation times are in the range of tens of seconds.[41] If the k_{19} and k_{20} of the OS scheme were used, the relaxation times would be ≤0.1 s, clearly inconsistent with our experimental observations. Interestingly, a similar dilution experiment was reported in the inset in Figure 1 in the paper for the TSS scheme,[40] and tens of seconds were required for the dissociation of the aldehyde inhibitor. Last, aldehyde inhibition was shown in our study to arise from the ability of Ald_i functioning as a competitive inhibitor against $FMNH_2$ substrate. This feature was not addressed or established for the TSS mechanism or the OS mechanism.

Deuterium Kinetic Isotope Effect of Aldehyde

Deuterium isotope effects of up to 1.7 of [1-^{2}H]-labeled aldehydes on the luciferase light decay were first noted more than 20 years ago.[53,54] Results of these earlier studies are likely complicated by aldehyde inhibition or flavin semiquinone formation. Nonetheless, these findings demonstrated that the excited emitter formation is coupled to the aldehyde oxidation and the abstraction of C1-H from aldehyde, presumably at a point after the formation of Intermediate III is at least partially rate limiting. Using an assay without the complication of aldehyde inhibition, Tu et al. determined the kinetic isotope effects of [1-^{2}H]-decanal on the light decay rate (^{D}k) and quantum yield (^{D}Q) of the *V. harveyi* luciferase reaction.[55] By allowing a light-emitting reaction (with k_1) and a competing dark decay (with k_2) branching out from II:Ald_s complex or III, the following relationships are obtained:

$$^Dk = (k_{1H} + k_2)/(k_{1D} + k_2) \quad (136.1)$$

$$^DQ = (k_{1H})(k_{1D} + k_2)/(k_{1D})(k_{1H} + k_2) \quad (136.2)$$

When light pathway is predominant (i.e., $k_1 >> k_2$), $^Dk \cong k_{1H}/k_{1D}$ and $^DQ \cong 1.0$. If $k_2 >> k_1$, $^DQ \cong k_{1H}/k_{1D}$ and $^Dk \cong 1.0$. When the light and the dark pathways are significant, then $^Dk < k_{1H}/k_{1D}$ and $^DQ > 1.0$. Using $FMNH_2$ and decanal as substrates in a low concentration (i.e., 0.02 *M*) phosphate buffer, light reaction is predominant as evident from $^Dk = 1.4$ and $^DQ = 1.1$. However, when reduced riboflavin or 2,3-diacetylFMN are used as the flavin substrate, the dark decay becomes dominating, as shown by $^Dk = 1.0$ and $^DQ = 1.4$. The dark decay is also enhanced at higher phosphate concentrations and, especially, in Tris buffers.

Macheroux et al. also examined the deuterium isotope effects of [1-^{2}H]-labeled octanal and dodecanal by reacting with isolated luciferase Intermediate II.[56] Three kinetic phases were detected, and isotope effects of 1.23 to 1.62 were observed for the second kinetic phase and the parallel light decay. Importantly, the first kinetic phase is free from deuterium isotope effect. This optically and kinetically definable phase is postulated to correspond to the luciferase flavin-4a-peroxyhemiacetal Intermediate III, detected for the first time in this work.

More recently, Francisco et al. carried out a detailed deuterium isotope effect study at pH 6 to 9 using different [1-^{2}H]-labeled aldehydes, flavin analogs, and wild-type and mutated luciferases.[34] An important conclusion from this work is that the observed deuterium isotope effects of aldehyde arise from the change of rate of a single kinetic step. It is also estimated that deuterium isotope effect of aldehyde after the formation of the Intermediate III is ~1.9.

TABLE 136.1 Compatibility of Subunits in Forming Active Heterodimeric Luciferase Hybrids[a]

	Vhβ	Vfβ	Pluβ	Pleβ	Ppβ

Pluα	nd	+[59]	++	nd	nd
Pleα	−[60,61]	+[60,61]	nd	++	+[60]
Ppα	−[58,60]	−[60,61]	nd	+[60]	++

[a] Abbreviations for cell strains are as follows: Vh, *Vibrio harveyi*; Vf, *Vibrio fischeri*; Plu, *Photorhabdus luminescens*, Ple, *Photobacterium leiognathi*; Pp, *Photobacterium phosphoreum*. The bacterium strain is followed by the designation of the luciferase subunit. Active luciferase heterodimers are indicated by ++ for the native enzymes and + for the hybrid enzymes. Inactive hybrids are indicated by the negative sign.

[b] Not determined.

The observed deuterium isotope effects of aldehydes as mentioned above have important mechanistic implications. The Baeyer–Villiger mechanism (Scheme 136.3) and the CIEEL/ECT mechanism (Scheme 136.4) involve the transfer of the hydrogen or deuterium in the circled position. This could give rise to a primary kinetic isotope effect. The observed deuterium isotope effects of different aldehydes are in the range of 1.4 to 1.9, which are consistent with the usual sizes of primary deuterium isotope effects arising from a partially rate-limiting step. In contrast, the dioxirane mechanism depicts Reaction C2 in Scheme 136.5 as the isotope-sensitive rate-limiting step. This C2 step is associated with a secondary deuterium kinetic isotope effect that is usually much smaller than the 1.88 observed by Francisco et al.[34] Arguments were presented by these authors to account for this unusually large secondary isotope effect. Nonetheless, it is easier to account for the observed 1.4 to 1.9 isotope effects on the basis of a primary isotope effect on a partially rate-limiting reaction step.

136.3 Luciferase Structure

Subunits and Three-Dimensional Structure

All known bacterial luciferases are αβ heterodimers. The two subunits are bound tightly through non-covalent interactions. Luciferases from different luminous bacteria all have an α subunit (molecular weight 40,100 to 41,400) and a slightly smaller β subunit (molecular weight 36,400 to 37,700). Based on sequences of seven species of bacterial luciferase,[57] the α subunits are better conserved (54 to 88% identity) than the β subunits (45 to 77% identity). Also, α and β are believed to arise from gene duplication, consistent with the ≥30% sequence identity between the two subunits. Although there are considerable sequence identities among the α subunits and among the β subunits, interspecies hybrids of the two types of luciferase subunits do not always yield active enzyme[58–61] (Table 136.1). Some inconsistent results were reported for the hybrids consisting of the *V. harveyi* α and the β from *V. fischeri*, *P. phosphoreum*, and *Photobacterium leiognathi*. In general, the β subunit of the *V. harveyi* luciferase seems to be more specific for the counter-α subunit in forming an active enzyme. The signal for this higher degree of specificity was shown to come from the *N*-terminal segment of the *V. harveyi* β.[61]

The α and β subunits can be separated chromatographically under partial denaturing conditions and can be renatured after isolation. Alternatively, the two subunits can be expressed individually using recombinant plasmids harboring a single *luxA* or *luxB* gene. Individual α and β are reported to be active in bioluminescence, at levels about four to five orders of magnitude lower than that of the αβ dimer.[62] The active species were identified to be α monomer and β_2 dimer.[63] The existence of β_2 homodimer was observed more than 30 years ago for the *V. fischeri*[64] and *V. harveyi*[48] luciferases. In the latter case, the homodimer was initially referred to as α_2-based chromatographic behavior and was later reclassified as β_2 based on subunit size to be consistent with the now widely accepted criterion for luciferase subunit

classification. In the absence of α, the dissociation constant of β_2 was estimated to be 10^{-16} M at 18°C.[65] The αβ native luciferase requires one $FMNH_2$[66] and one aldehyde[40,67] as substrates. As mentioned above, *V. harveyi* αβ luciferase has a second aldehyde inhibitor site. It is highly intriguing that *V. harveyi* α and β_2 each also has one $FMNH_2$ site, one aldehyde substrate site, and one aldehyde inhibitor site.[63] How α and β_2 are able to maintain the same binding stoichiometry for substrates and aldehyde inhibitor as that of the native αβ, and why αβ is four to five orders of magnitude higher in bioluminescence activity than α and β_2 are important questions that remain to be answered. More recently, the *V. harveyi* α was also shown to undergo a dimerization with a dissociation constant of 15 μ*M* at 18°C.[68]

A major advancement is the elucidation of the structure of *V. harveyi* luciferase, at 2.4 Å[69] and 1.5 Å resolution,[70] with key structural features summarized and discussed.[71] Each subunit assumes a $(\beta/\alpha)_8$ barrel structure, originally shown for the structure of triosephosphate isomerase (TIM).[72] There are considerable structural similarities between the α and β subunits; the main chains of these two subunits show good superposition.[69] The structure of *V. harveyi* luciferase β_2 was also solved.[73,74] The four *C*-terminal residues (321–324) of β that are not resolved in the original αβ structure were determined. In general, the secondary and tertiary structures of β_2 are quite similar to those of αβ. The intersubunit areas for β_2 and αβ are also similar, except that the former is smaller. The two subunits in β_2 are highly homologous but not identical in structure; the root-mean-square difference between the main β chains in β_2 is 0.45 Å.[73] A possible FMN site in β_2 is discussed.[73]

In *P. leiognathi* and *P. phosphoreum*, a nonfluorescent protein (NFP) is coded by the *luxF* gene. NFP has 16 and 30% sequence identities with, respectively, the α and β subunits of the *P. leiognathi* luciferase. The function of NFP is still unknown, but the structure of NFP from *P. leiognathi* was determined.[75,76] It is a homodimer and is homologous to luciferase in folding. However, one β strand and three α helices are missing in comparison with a typical $(\beta/\alpha)_8$ barrel protein. Moreover, each monomer binds two molecules of an unusual FMN, in which the C6 of the flavin isoalloxazine ring is covalently linked to the C3′ of a myristic acid. It was cautioned that the mode of flavin binding by NFP is likely not representative of the flavin site in luciferase.[70] Other TIM barrel flavoproteins include old yellow enzyme,[77] glycolate oxidase,[78] flavocytochrome b_2,[79] trimethylamine oxidase,[80] and dihydroorotate dehydrogenase.[81] These enzymes all have a bound FMN cofactor. In contrast, bacterial luciferase does not contain any flavin cofactor. Instead, it utilizes $FMNH_2$ as a substrate. Luciferase also contains a nonprolyl *cis* peptide bond between A74 and A75.[70] Recently, methylenetetrahydromethanoprotein reductase (Mer) was shown to be most similar to luciferase in a three-dimensional structure.[82] Mer exists as a homodimer or tetramer consisting of two loosely associated dimers. Despite a relatively low sequence identity of 22%, the general folding of the Mer dimer is similar to luciferase αβ or β_2. The subunit interface of Mer is related to that of luciferase αβ. Mer does not have any bound flavin prosthetic group and requires a 5-deazaflavin (namely, F_{420}) as substrate. Moreover, Mer also has a nonprolyl *cis* peptide bond at a location equivalent to that in luciferase. However, the structure of the presumed active site in Mer is significantly different from the equivalent site in luciferase. This is the first example of a flavin-dependent enzyme that shows a high degree of structural similarity to luciferase. Thus far, in the family of proteins that contain a bound flavin prosthetic group or require flavin as a cofactor or substrate, bacterial luciferase remains unique in its ability to catalyze a light-emitting reaction.

Active Site and Structure–Function Relationships

Active Site

Luciferase structure was determined without any bound flavin or aldehyde substrate or specific inhibitor. Hence, the exact structural features of the active site remain to be established. However, the general location of the luciferase active site was postulated to be in a pocket next to the *C*-terminal end of the β barrel in the α subunit.[69,70] This postulation is based on three considerations. First, a phosphate or sulfate is bound to the α subunit. The position of the bound phosphate is proposed to correspond to the phosphate moiety of FMN.[69] Second, the proposed luciferase active site pocket is extrapolated from the fact that all $(\beta/\alpha)_8$ barrel enzymes have their active site at the *C*-terminal end of the β barrel. Third,

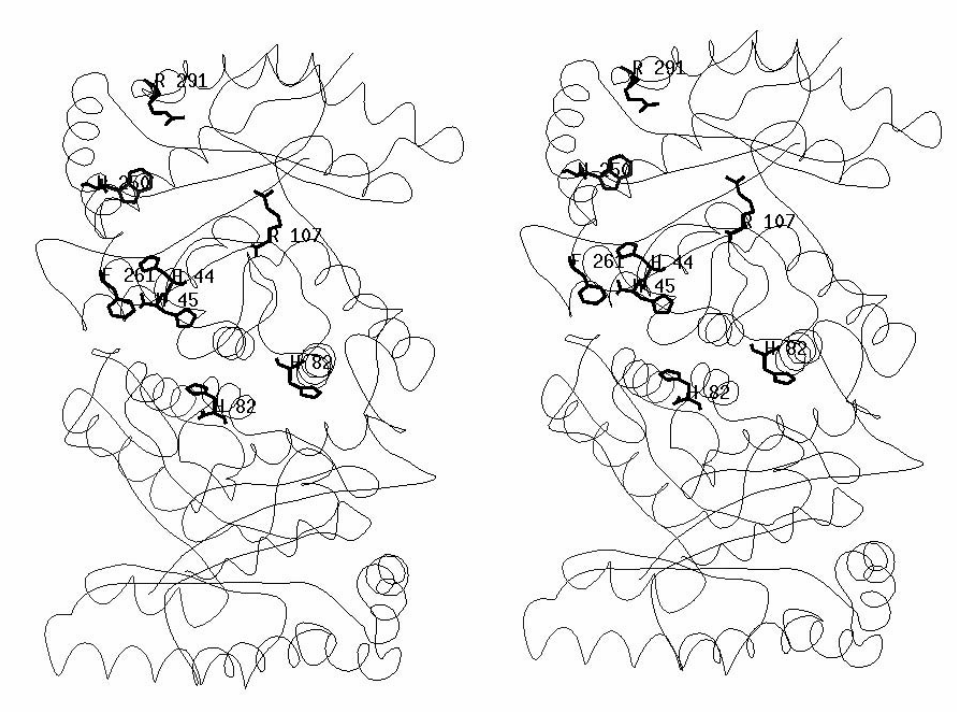

FIGURE 136.1 Proposed luciferase active site and some critical residues. The structure of luciferase is based on the coordinates from the Protein Data Bank file 1LUC.[70] The α subunit is at the top, and the β subunit is at the bottom.

a nonprolyl *cis* peptide bond connecting A74 and A75 is found in luciferase α subunit. The existence of nonprolyl *cis* peptide bond is generally rare, and such a bond is usually critical in positioning key residues required for ligand binding or catalysis. In the case of luciferase, this *cis* peptide bond is at the end of β_3 at the *C*-terminal end of the β barrel. This proposed luciferase active site location is generally supported by computational modeling and experimental results. Figure 136.1 shows a stereo view of this proposed active site pocket and some of the critical residues.

Critical Residues on α

On the same assumption that the bound phosphate or sulfate corresponds to the phosphate moiety of bound FMN, computer models for the FMN binding and aldehyde binding were recently reported.[83] The FMN site in this model is consistent with the active site pocket proposed earlier. It should be noted, however, that the modes of FMN and $FMNH_2$ binding are likely to have some differences. The α-bound phosphate or sulfate interacts with αR107 through a slat linkage.[69] This αR107 was mutated to alanine, serine, and glutamate, and the resulting luciferase variants were characterized with respect to K_m for decanal, $FMNH_2$, and reduced riboflavin in low (0.01 or 0.05 *M*) and high (0.3 *M*) phosphate buffers.[84] Results are consistent with a critical role of αR107 in interacting with the phosphate group of $FMNH_2$. The αW250 was also shown by mutagenesis study to be important in interactions with the flavin isoalloxazine ring and aldehyde.[85]

Chemical modifications of the αC106 (not shown in Figure 136.1) result in luciferase inactivation. This residue is believed to be at or near the aldehyde inhibitor site[41] but is not essential to the binding of $FMNH_2$ or decanal[67] or catalysis.[86,87]

Mutations of five conserved histidine residues (at Positions 44, 45, 82, 224, and 285) on the α were shown to result in markedly different degrees of luciferase inactivation.[88] Residues αH44 and αH45 are particularly critical; their mutations can individually result in four to six orders of magnitude of activity reduction. Although αH44 and αH45 are adjacent residues, they are associated with different functions.

TABLE 136.2 Relative Yields of Reaction Intermediates and Light Output by Luciferase Mutants in Comparison with Wild-Type *V. harveyi* Luciferase

	Relative Yield (= Mutant/Wild Type)								
Enzyme	Φ	=	Y_{II}	×	Y_{III}	×	$Y_{IV}+\bullet \times Y_{IV^*}$	×	Φ_{IV^*}
αF261D	1.0×10^{-5}		0.42		~1		0.1		$\sim 2 \times 10^{-4}$
αG275P	2.4×10^{-4}		0.73		~1		0.2		$\sim 2 \times 10^{-3}$

αH45 is important to the formation of the catalytically active 4a-hydroperoxyFMNH Intermediate II.[14] On the other hand, the extremely low activity of the luciferase αH44A variant can be rescued by exogenously added imidazole or simple amines. Hence, αH44 of luciferase was identified as a catalytic base.[89] Moreover, αH44 participates in the catalysis at a point subsequent to the formation of Intermediate II. Conceivably, αH44 could function in the abstraction of a proton from Intermediate III from the boxed or circled position (Scheme 136.2). In addition, theoretical calculation indicates that the conversion of HF-4a-OO^- to HF-4a-OOH is barrier free.[10] However, the former should be the active species in attacking aldehyde to form Intermediate III. αH44 could also be required to maintain Intermediate II in the HF-4a-OO^- form. Thus far, αH44 is the only case for which a catalytic residue was identified for bacterial luciferase.

Residues 257–291 of the luciferase α subunit are a highly conserved, protease labile, and disordered loop. In the 1.5 Å structure of luciferase, residues between αF261 and αR291 within this loop are not resolved (Figure 136.1). Also, the 29-residue segment from α258 to α286 is not found in the β sequence. This luciferase loop region is next to the opening of the proposed luciferase active site pocket and was postulated to act as a shield for catalytic intermediates.[71] This postulation is supported by a mutagenesis study using a luciferase variant in which the 29-residue disordered loop is deleted from the α subunit.[90] This mutant retains the ability to bind substrates and to catalyze the normal luciferase chemical reaction with an efficiency similar to that of the wild-type luciferase. However, the bioluminescence quantum yield is about two orders of magnitude lower. In a more thorough mutagenesis study,[91] conserved residues αG284 and, particularly, αF261 and αG275 in this loop were found to be critical to luciferase activity. Moreover, the 10^{-5} activity of αF261D can be gradually restored when the side chain increases in size and hydrophobicity as shown by αF261S, αF261A, and αF261Y. Also, the greatly reduced activity of αG275P can be compensated by changing the side chain to a smaller and more flexible residue, as shown by αG275F, αG275I, and αG275A.

The bioluminescence quantum yield (Φ) of luciferase can be expressed as in Equation 136.3:

$$\Phi = Y_{II}\, Y_{III}\, Y_{IV}+\bullet\, Y_{IV^*}\, \Phi_{IV^*} \tag{136.3}$$

where each *Y* is the yield of a particular intermediate (as designated by the subscript) from its immediate precursor intermediate and Φ_{IV^*} is the quantum yield of the excited emitter. Mutants αF261D and αG275P were examined in detail[91] according to Equation 136.3 on the basis of relative yield, defined as the ratio of the yield of mutant over that of the wild-type luciferase (Table 136.2). The quantum yield (Φ) is based on (bioluminescence peak intensity)/(light decay rate). Yields of Intermediate II were determined by stopped-flow measurements. Yields of Intermediate III are estimated as (light decay rate)/[(light decay rate) + (dark decay rate of II)]. The light decay rate is used in place of the true rate for III formation from II. The two rates should be the same if the III formation is rate limiting in the overall reaction of light emission. Otherwise, the III formation rate will be faster than the light decay rate. Hence, the yield of III determined as stated above is a lower limit of the true value. Individual $Y_{IV}+\bullet$ and Y_{IV^*} values cannot be determined, but the overall yield of these two intermediates can be estimated from the yield of carboxylic acid from aldehyde. An important finding from such analyses is that the predominant factor in the reduction of bioluminescence activities of αF261D and αG275P is the three to four orders of magnitude reductions of the emission quantum yields of the excited emitter (Φ_{IV^*}). In comparison with a $\Phi_{IV^*} = 0.18$ for the wild-type emitter,[44] the fluorescence quantum yields of free 4a-hydroxyflavin models are four orders of magnitude lower[29] but can be enhanced by freezing or a hydrophobic environment.[92]

Clearly, the emission quantum yield of excited 4a-hydroxyflavin is highly sensitive to binding by luciferase. As an important demonstration, the fluorescence quantum yield of a 5-decyl-4a-hydroxyFMN model was weak but could be enhanced to 0.08 with a λ_{max} at 440 nm upon binding to luciferase.[93] Our mutagenesis study indicates that a major function of αF261 is to maintain a high degree of hydrophobicity of the luciferase active site so that the bound emitter can undergo a highly efficient emission relaxation. We also propose that αG275 is important in keeping the α262-α290 loop mobile. Possibly, the loop assumes an open conformation in the resting state but will change to a closed conformation to block the opening of the active site pocket during catalysis. This closed conformation can conceivably retard the dark decay of II, enhance the yield of III, and, most importantly, enhance the emission quantum yield of IV*.

Critical Residues on β and Intersubunit Communication

Although αβ dimer is required for the high efficiency of bioluminescence of luciferase, the specific function of β is not clear. Earlier results indicate that β is important in keeping luciferase in a thermally stable form[94,95] or in involving substrate binding.[58,96] In a later site-specific mutagenesis study, mutations of the conserved βH81 and βH82 to several other residues resulted in decreases in V_{max} by about one to two orders of magnitude and decreases in $V_{max}/K_{m,flavin}$ by one to three orders of magnitude.[97] These decreased bioluminescence activities can be correlated with lower yields of II, lower yields of IV*, and enhanced quenching of the emitter IV*. This is the first demonstration that mutations of a specific single residue in β can substantially decrease the luciferase activity. Moreover, in comparison with the wild-type luciferase, αH82K and βH82K were associated with higher values of $K_{m,flavin}$ and increased rates of urea or thermal inactivation. Interestingly, these adverse effects of αH82K and βH82K mutations were compensated to various degrees by the double mutation of βH82D and αH82D, respectively. Hence, it was demonstrated[97] that communication exists between α and β subunits with respect to structural and functional information. The choice of αH82 and βH82 for such mutational studies was based on sequence analysis. The x-ray structure of luciferase[69,70] later revealed that βH82 and αH82 are close to the luciferase subunit interface (Figure 136.1). Recently, protein equilibrium unfolding studies were carried out using luciferase variants containing mutations of residues near the subunit interface.[98] Results obtained with βH81A, βH82A, and αA81H again show that β is able to communicate structural information to α.

Photobiology of Circadian Rhythms

David E. Somers
Ohio State University

137.1 Introduction

One consequence of the daily rotation of the earth was the evolution of a 24-h-based (circadian) timing mechanism in most organisms. A wide range of behavioral, physiological, and molecular processes is under the control of a circadian clock. In mammals, the wheel-running rhythm in mice and the familiar jet lag experienced by air travelers are both controlled by the circadian clock. Many aspects of human physiology, including core body temperature, oscillate with a near 24 h rhythm.[1] Similarly, *Drosophila* eclosion (emergence from the pupa) and locomotor activity are clock regulated, presumably to optimize survival and energy use under natural conditions. In plants, the circadian clock helps to coordinate the developmental switch from vegetative to reproductive growth that occurs in response to changes in day length. At the cellular level, stomatal cell expansion and contraction oscillates with a 24 h rhythm. The clock also regulates gene expression at the transcriptional and translational levels. These include key photosynthetic genes, which show peak expression near dawn, and entire biosynthetic pathways (e.g., phenylpropanoid biosynthesis), in which the gene expression level of all the key enzymes cycles with identical phase.[2] This phenomenon is seen in the extreme in cyanobacteria, in which the expression of the entire genome is under circadian control.[3] Overall, the circadian clock system can be viewed as having at least two functions. It can allow an organism to anticipate the regular daily changes of light and dark, and it can act as a buffer against random or transitory environmental fluctuations. The former role helps maximize use of predictable and favorable environmental conditions by preparing (through new syntheses or mobilizations) in advance of its actual occurrence. The latter function would guard against being too responsive to a short-lived environmental condition, where resources put into adjusting to the condition would be wasted.

The circadian clock is defined by a number of characteristics.[4] First, the endogenous period is approximately 24 h *(circa*dian). The period becomes exactly 24 h only when a 24 h environmental cycle is imposed on the organism. Within limits, a non-24 h environmental cycle (e.g., 10 h light:10 h dark) can constrain the clock to oscillate with an altered period length (i.e., 20 h). This occurs through a second characteristic, the process of entrainment, whereby the clock is synchronized to the outside world. The primary entraining stimuli are temperature and light. Diurnal oscillations in temperature (high/low) or

0-8493-1348-1/04/$0.00+$1.50

light (light/dark) are the cues (zeitgebers) that adjust the circadian system in each cycle by changing the phase of the oscillation.[4] In some organisms (e.g., *Drosophila*), a short 15 min light pulse can fully reset the phase of the clock, whereas plants often require 3 to 4 h of illumination.

A third, unique, characteristic of circadian rhythms is temperature compensation. Whereas a temperature shift up or down can reset the phase of the clock, this new temperature regime has little effect on endogenous period. Most biochemical processes are sensitive to temperature, with reaction rates doubling or tripling with each 10°C change in temperature ($Q_{10} = 2 - 3$).[5] The Q_{10}s of circadian rhythms lie between 0.8 to 1.4.[6]

The fourth feature, the persistence of rhythmicity in the absence of periodic input, is the most intriguing aspect of circadian biology. Most research focused on identifying clock components and the interactions that allow the maintenance of a self-sustained oscillation in a nonperiodic environment.[7–12]

The current, simplified, working model of the circadian system consists of three components. The input pathway is the signal transduction chain that links the environmental light or temperature variations to the second component, the central oscillator. Without some form of link between the environment and a pacemaker, there is no meaningful time-keeping function of a clock. Similarly, a link from the pacemaker to the overt output processes is the third component of the circadian system.[5,13] The changes in behavior, physiology, or gene expression that are actually being controlled by the clock are considered "outputs," and clearly without a connection between the oscillator and these processes, a clock has no influence.

Recently, molecular analyses of many of the circadian model systems are demonstrating that a simple linear flow from input to oscillator to output is not a realistic view. There is evidence that the oscillator can control the sensitivity of the input pathway, potentially through the circadian modulation of photoreceptor expression.[14–16] This review summarizes the current state of knowledge of circadian photoperception in the five model systems. What is becoming clear in many systems is the close molecular connection between the primary photoperception events and the central oscillator. Other recent reviews on this topic focus on different elements of the circadian photoperception field.[17–20]

137.2 Cyanobacteria

Investigation of the circadian clock in cyanobacteria (*Synechococcus* sp. PCC 7942) came relatively late for the field but then progressed rapidly at the molecular level. This came about largely through the use of promoter-luciferase reporters. It became quickly apparent that the promoters of nearly the entire genome are under circadian regulation, as all random promoterless-luciferase insertions showed robust rhythmic expression.[3] A mutagenic approach screening for period mutants using a clock-controlled promoter-luciferase reporter then identified a three-gene operon, *kai* (*kaiA*, *kaiB*, and *kaiC*) that is responsible for establishing rhythmicity and setting period length. The transcripts of all three cycle robustly in constant light, as do the protein levels of *kaiB* and *kaiC*. None are DNA-binding proteins, and the precise biochemical role for none has been identified. The three proteins can undergo homotypic and heterotypic dimerizations; one period mutation is due to an aberrant KaiA/KaiB interaction. KaiC can autophosphorylate and contains an ATP/GTP binding domain (P-loop motif), which was shown to bind these nucleotides and to cause arrhythmicity when mutated.[21] There are no apparent homologues between the *kai* genes and known clock-associated proteins in eukaryotes. An additional class of proteins, Group 2 σ-factors, is also involved in setting period and phase. Interestingly, expression from only certain promoters are affected when specific factors are knocked out or overexpressed, leading to the conclusion that these σ-factors act as a consortium, via independent timing circuits, to control circadian output as a whole.[22] All evidence suggests that, in comparison to eukaryotes, different genes are involved, and likely a different mechanism evolved in the development of circadian control in cyanobacteria.

Like eukaryotes, light is the primary entraining stimulus in cyanobacteria. Surprisingly, cyanobacteria possess no unequivocal circadian photoreceptors that correspond to the phytochromes, cryptochromes, or *white collar* genes that are part of the circadian signaling system in eukaryotes. However, two components that may be part of an input pathway were identified. SasA is a histidine protein kinase that was

identified as a KaiC interaction partner in a yeast two-hybrid screen. This protein has the primary structure of the sensory component of a two-component sensory kinase system, with the cognate response regulator still unknown. SasA contains a KaiB-like sensory domain, which is sufficient for interactions with KaiC and likely connects to the primary circadian elements through this interaction. Loss of SasA strongly reduces the amplitude of *kai* expression rhythms and shortens the period, whereas overexpression causes arrhythmicity, through suppression of *kaiBC* promoter activity.[23] Growth under light and dark cycles is severely disrupted in *sasA* mutants, suggesting that it may have a role outside of circadian regulation as well. Two models were proposed for the point of action for SasA. One places it acting on the input pathway as an amplifier of circadian phototransduction, because the amplitudes of the oscillations are more light sensitive in the mutant than in the wild type. Alternatively, SasA may act as one of the first elements of the output pathway that also feeds back on the expression of the *kai* gene cluster.[23] In either case, SasA is not an essential element of the central oscillator but a modulator of clock activity.

The second candidate, *cikA* (circadian input kinase), also affects circadian period and output amplitude but is more closely related to previously known phototransduction components. Like *sasA*, inactivation of *cikA* shortens the circadian period of gene expression rhythms (by approximately 2 h), and reduces the amplitude of cyclic gene expression. In addition, *cikA* mutations change the phasing of a subset of rhythms and nearly abolish phase resetting by dark pulses.[24] It is this loss of light-mediated phase resetting coupled with the protein sequence that strongly suggests a role for CikA in the input pathway. CikA is a divergent bacteriophytochrome with characteristic histidine protein kinase motifs and a carboxy terminal response regulator domain. However, it lacks the essential Cys to which the phytochromiblin chromophore normally covalently attaches in plant phytochromes, and an adjacent conserved His residue, to which bilins can bind in bacteriophytochromes.[24] Hence, either CikA does not bind a bilin or it does so in a manner different from that of known proteins. Similarly, the response regulator motif of CikA lacks the characteristic Asp that is the normal phosphotransfer site. Here too, either another residue receives the phosphate, or this motif plays a different, unknown role. Taken together, CikA appears to be a key component of phototransduction input to the circadian oscillator, but its precise function remains unclear.

137.3 Neurospora

The *Neurospora* circadian clock was extensively studied for more than 30 years. Three core elements necessary for sustained function of the system were identified and well characterized. *Frequency* (*frq*) was the first locus defined and proved to be an essential element for robust and sustained circadian cycling. The *frq* protein (FRQ) contains a nuclear localization signal (NLS), a putative helix-turn-helix DNA binding domain, and highly charged domains.[12] The precise biochemical function of FRQ is unclear, but it is involved in transcription activation and in transcription complex disruption, positioning it as a central element of two interlocked feedback loops that comprise the *Neurospora* circadian system.[12] The *white collar-1* (*wc-1*) and the *white collar-2* (*wc-2*) are equally essential, but unlike *frq*, they play important noncircadian roles as well. Both genes were initially identified in genetic screens for blue-light photoperception mutants, the only wavelengths to which *Neurospora* is known to respond. To date, these are still the only two loci that, when either is disrupted, confer photic insensitivity to a wide range of physiological responses. They have long been the best candidates for blue-light photoreceptors and as photoreceptor complexes for circadian entrainment. Loss-of-function mutations in either gene cause arrhythmicity under standard conditions. This suggests a close link between photoperception and clock function. Both proteins are putative transcription factors, containing GATA-type zinc fingers, and they are able to bind promoter regions of the light-inducible *al-3* and *frq* genes.[25,26]

The 54 kDa *wc-2* protein (WC-2) contains a nuclear-targeting domain and a PAS domain.[25,26] Both the mRNA and protein are constitutively expressed, and the polypeptide appears to undergo no circadian phase-dependent modifications,[26] though it is phosphorylated in response to light.[27] The WC-2 PAS domain dimerizes with itself and with WC-1 via its PAS domain, forming hetero- and homodimers *in vitro*[28] and *in vivo*.[26,29] Together, WC-1 and WC-2 form the white collar complex (WCC) in which both proteins appear in a 1:1 stoichiometry.[26,29] This differs from the cellular concentrations of the two

components, in which WC-2 is in significantly greater abundance than WC-1. While FRQ, WC-1, and WC-2 are normally found complexed together, FRQ and WC-1 are unable to associate in the absence of WC-2, leading to the view that WC-2 acts as a scaffold by which FRQ and WC-1 can interact.[30]

WC-1 is a 125 kDa protein that contains a glutamine-rich putative transcription activation domain and two PAS domains. One of the PAS domains is similar (ca. 40% amino acid identity) to the LOV/PAS domain found in the plant blue-light receptors phot1 and phot2.[31] Of these two proteins, phot1 is the best characterized, and purified protein can catalyze blue-light dependent autophosphorylation *in vitro*.[31] Although there is no evidence that WC-1 possesses kinase activity, *in vivo*, it is transiently and progressively phosphorylated in response to light, which appears to facilitate its degradation.[26,27] The LOV/PAS domain in phot1 binds flavin mononucleotide (FMN),[31] and crystallization of this domain showed that it folds to form an FMN binding pocket with a three-dimensional structure bearing strong similarity to previously crystallized PAS domains.[32] By virtue of the high degree of amino acid identity, WC-1 was expected to fold to form a similar structure and possibly bind a flavin as well. This was recently confirmed by two separate approaches. He and colleagues[10] removed the LOV domain from WC-1 and showed that all light responses are lost, including light entrainment of the circadian clock. They further purified the native WC-1/WC-2 (WCC) complex and showed that both molecules associate in a 1:1 stoichiometry and that flavin adenine dinucleotide (FAD) is noncovalently bound to the 200 kDa complex.[29] Interestingly, the WC-1 LOV domain contains an additional nine amino acid insertion, relative to the phototropin LOV domain, which is predicted to extend one region of the flavin-binding pocket. This may serve to accommodate the larger dinucleotide moiety of FAD not found in FMN. In a different study, Froehlich and colleagues[15] used gel mobility shift assays to show that the native WCC can bind specifically to the *frq* promoter. When *in vitro* translated, both components still bind, showing that additional factors are not necessary for the mobility shift. An additional blue-light-induced change in the mobility of the DNA–WCC complex required the presence of FAD, and its addition during the WC-1 translation reaction was sufficient to effect the shift.[25] Together, these two studies conclusively demonstrate that the WCC, specifically WC-1, binds FAD and is the primary blue-light photoreceptor for the circadian clock system in *Neurospora*. This does not exclude the presence of other photoreceptors. A recent report demonstrated residual photoresponses in the *wc-1*, *wc-2*, and the double mutants, suggesting the presence of one or more additional photoreceptors. These responses include the ability to synchronize conidiation in response to light and dark cycles and the light induction of *frq* mRNA.[33]

An additional protein, VIVID (VVD), plays a role in modifying the response of the *Neurospora* circadian clock to light.[34] Remarkably, 50% of the small (20 kDa) VVD polypeptide consists of a PAS/LOV domain, with a high degree of identity to the phototropin and WC-1 LOV domains.[35] The loss-of-function mutant phenotype is characterized by an increased sensitivity to light, and VVD's role appears to be as a clock-regulated repressor of light-regulated genes. The ability of the clock to modulate the effects of light on the clock, known as gating, is also affected by mutations in VVD. Light-induced induction of FRQ and VVD in *vvd* mutants is substantially increased over the circadian time course, and light-induced resetting of the clock, as assessed by changes in the phase-response curve, is significantly altered.[35] One model consistent with these data places VVD as a negative modulator of the WCC, possibly through a dimeric interaction with the WC-1 LOV domain. Given that light, via the WCC, induces VVD expression, this places VVD as a negative feedback regulator of its own expression and as a modulator of light input to the circadian system.[35]

Taken together, the accumulated evidence is that the WCC complex plays the role of the primary photoreceptor of the *Neurospora* circadian clock but is inextricably linked to the function of the clock. In light, the WCC upregulates FRQ, WC-1, and VVD transcription, while FRQ feeds back to block the transcriptional activity of the WCC, thereby downregulating its own transcription. However, FRQ also promotes WC-1 synthesis, indirectly contributing to increased WCC levels, because WC-1 is the limiting partner of the pair. VVD also acts to limit WCC complex activity. The interacting feedback loops of these complex interactions form the core of the clock. What remains to be added are the full temporal and spatial descriptions that sum to a 24 h cycle.

137.4 Plants

Most of the progress in identifying plant photoreceptors and understanding their signal transductions has come from genetic screens for mutations that alter development, such as stem elongation and bending. The best-characterized visible light photoreceptors in plants are the phytochromes, cryptochromes, and phototropins. The phytochromes are large (ca. 120 kDa) polypeptides that reversibly mediate red and far-red light photoperception. There are two empirically determined classes of phytochrome molecules; light-labile and light-stable forms. Phytochrome A (phyA) encodes the light-labile phytochrome, which is degraded rapidly in the presence of light. Four additional genes encode phyB, C, D, and E in *Arabidopsis* and are light-stable molecules. Most of the phytochrome in the plant is phyA and phyB, and mutant analyses confirm that phyC, D, and E are largely additive to the effects of phyB.[36,37]

The two cryptochrome proteins, cry1 and cry2, are related to DNA photolyases. These are blue-light-activated DNA repair enzymes that catalyze the repair of UV-induced thymine dimers in prokaryotes and eukaryotes. Like the photolyases, the cryptochromes have two chromophores, a light-harvesting folate or deazaflavin, and a catalytic flavin adenine dinucleotide (FAD), responsible for the blue-light absorbance and action spectra. The two *Arabidopsis* cry proteins are 51% identical and have distinct, but overlapping, roles in plant development.[38]

The role of the phytochromes and cryptochromes in circadian photoperception was effectively addressed by using null mutations in both classes of photoreceptors in *Arabidopsis*. Fluence-rate response tests in the different mutant backgrounds were used to define the range of light intensities over which each photoreceptor acts. This was possible, because the relationship between light intensity and period in *Arabidopsis* follows Aschoff's rule for diurnal organisms: free-running period increases with decreasing light intensity.[39,40] Relative to wild type, loss of phyB lengthens the period at high-red-light intensities (>5.0 μmol m^{-2} s^{-1}), but under blue light, there is no effect. Conversely, phyA mutants show period lengthening only under low-fluence-red (<1.5 μmol m^{-2} s^{-1}) or blue light (<5.0 μmol m^{-2} s^{-1}).[41] Both results are consistent with other studies showing that the role of phyB is primarily at higher-red-light fluences, and that of phyA is at low-red, far-red, and blue-light intensities.[37] The period of the *phyA phyB* double mutant is consistently 2 to 3 h longer than wild type over a 100-fold range of red-light intensity (1 to 150 μmol m^{-2} s^{-1}). These results demonstrate that the separate domains of high- and low-light intensity over which the two phytochromes operate are additive, and that over some fluence rates (1.5 to 10 μmol m^{-2} s^{-1}), they act redundantly.[42] Triple mutants (*phyA phyB phyD* and *phyA phyB phyE*) still show increased period shortening at high-red-light fluence rates, indicating an overlap with phyB function among the more minor forms of phytochrome.[42]

Parallel studies using *cry1* and *cry2* null mutants under blue and red light outlined the relationship between the two cryptochrome proteins and between the phys and crys, to some extent. A cry1 deficiency lengthens the period by 2 h over a 40-fold range of fluence rates, with the exception of a mid-range (between 4 and 10 μmol m^{-2} s^{-1}), where there is no effect.[41,42] The absence of cry2 has little to no affect on the free-running period in blue light, but the *cry1 cry2* double mutant causes a clear and consistent 3 to 4 h lengthening of period over the entire fluence range tested. The slope of the fluence-rate-response curve in blue light in wild-type plants is shallow, in some experiments it is zero, so the relative contribution of the cryptochromes is difficult to assess: are other blue-light receptors active in the absence of the crys? The *phyA cry1* double mutant tested in white light had period effects only over the same intensity range as the *cry1* mutant, suggesting that the two photoreceptors act in the same pathway. Other evidence showing a physical interaction between phyA and the crys, including a phyA-red-light-dependent phosphorylation of cry1,[19] is consistent with cry1 acting immediately downstream of phyA action. However, a triple *phyA cry1 cry2* mutant would be a desirable combination to further test in blue light. Of the other blue-light photoreceptors, such as the phototropins, only a deficiency in *phot1* (*nph1*) was shown to have no effect on free-running period (D.E. Somers, unpublished data). Although all evidence suggests that phototropins are involved exclusively in phototropisms,[31] multiple mutant combinations between the crys and phototropins might prove to be revealing.

The redundancy of plant photoreceptor input to the clock was also demonstrated using the *phyAphyBcry1cry2* quadruple mutant. In white light, robust leaf movement rhythms were evident, indicating that other photopigments, likely the remaining three phys, are able to sustain sufficient photic input to the oscillator.[43]

Although current evidence suggests that no single photoreceptor or photoreceptor class is an essential element of the plant circadian oscillator, more may be learned about their connection to the clock by examining whether the expressions of these receptors undergo circadian regulation and whether their intracellular localization changes over time. Using a firefly luciferase (luc) reporter, promoter-luc fusions were made with all five *Arabidopsis* phytochromes and both cryptochromes.[14] Most fusions showed a distinct circadian control of promoter activity, with different phases of peak promoter activity. All showed maximal expression during the subjective photoperiod, with the most light-labile of the receptors (phyA and cry2) peaking near subjective dusk. Only the phyC-luc reporter showed no sign of circadian regulation, although *phyC* mRNA was cyclic under LL, indicating circadian regulation at a posttranscriptional level.[14] Interestingly, although this study and others[44] demonstrate the clock-controlled regulation of photoreceptor promoters, there is still no evidence of cyclic changes in global phy or cry protein levels. However, temporal changes in intracellular localization were recently reported using GFP-phytochrome reporters. Under an 8/16 white light/dark cycle, there was a diurnal variation in the number of nuclear GFP speckles seen for four of the GFP–phy fusions. Importantly, there was a clear increase in the number of nuclear speckles in anticipation of lights-on, which increased throughout the light period and subsequently decreased during the dark.[45] This increase in anticipation of lights-on strongly suggests that circadian regulation of photoreceptor nuclear import may play a role in the spatial and temporal localizations of the phytochromes. One inconsistency between the promoter-luc studies and the GFP-phytochrome work lies in phasing. All GFP-phytochromes showed similar timing and kinetics with respect to nuclear import; nuclear accumulation was clearly beginning prior to lights-on. The five phy–luc fusions showed different phasing of maximum expression among them; some phased early in the day (e.g., phyC, D, and E) and others late in the day (e.g., phyA). Higher-resolution studies, conducted throughout the circadian cycle, will be necessary to resolve this discrepancy.

Apart from the photoreceptors, there were few other components implicated in the circadian phototransduction pathway. Most intriguing is the *ZEITLUPE* (*ZTL*) gene family.[46–49] These three closely related proteins (ZTL, FKF1, LKP2; also reported as *ADO* genes[50]) appear to be a special type of F-box protein, a class of polypeptides involved in proteasome-dependent proteolysis.[51] In most F-box proteins, the amino proximal 45 amino acid F-box domain targets the protein for association with an E3 ubiquitin ligase complex, by which ubiquitin moieties are then attached to the substrate associated with the carboxy terminal region of the F-box protein. In this way, F-box proteins act as the physical links between target substrates and ligase complexes. Many F-box proteins lack additional amino terminal domains to the F-box, but the ZTL family contains a LOV/PAS domain. The LOV motif was defined based on similarity to a number of prokaryotic and eukaryotic proteins involved in light, oxygen, and voltage sensing (*LOV*[31]) and is a distinct subgroup of the more general PAS domain.[46] The PAS superfamily can be divided into two fundamental classes: those involved in mediating protein–protein interactions and those primarily involved in environmental sensing.[52] In eukaryotes, the former class is a common motif in clock-related proteins, whereas the latter class, which includes the LOV domain, is found largely in photoreceptors. These include the phototropins in plants[31] and WC-1 in *Neurospora*.[29] The ZTL family LOV domains are 40% identical to the LOV domains of the phototropins and WC-1, strongly suggesting a phototransduction role for these proteins.

At least two of the family members affect circadian period. Loss of function mutations in *ZTL* lengthen the free-running period,[47,50] and overexpression of ZTL (Somers, unpublished) and LKP2[49] cause arrhythmicity. ZTL mutations also affect the response of free-running period to light. The significant increase in period with decreasing light intensity evident in WT plants is greatly accentuated in *ztl* mutants. At low-light intensities, *ztl* loss of function mutations causes a 7 to 8 h period lengthening, compared to a 3 h lengthening at high-light intensities.[47] This light-dependent effect coupled with a demonstrated interaction *in vitro* and in yeast between ZTL and phyB and cry1[50] suggests that this member of the ZTL

gene family may play a critical role in bridging the primary light absorption of the photoreceptors with downstream changes in clock protein abundance. One model of ZTL action would involve control of circadian period through a light-dependent proteolysis of key clock components. This could occur via activation of ZTL activity by direct signaling from the light-activated photoreceptors, or through direct blue-light absorption by ZTL via the LOV domain.

Another likely component of the phototransduction pathway is *ELF3*. Loss of function mutations in *ELF3* (*elf3–1*) result in arrhythmicity under all light conditions but have little effect on cycling in the dark.[53,54] Interestingly, although ELF3 promoter activity and mRNA and protein levels cycle, overexpression does not cause arrhythmicity but only lengthens the period.[53,55] This strongly suggests that ELF3 is not an oscillator component. Instead, evidence suggests that ELF3 acts to negatively modulate light input to the clock. Red- and blue-light phase-response curves (PRC) are altered in *ELF3* mutant and overexpression backgrounds. The *elf3–1* accentuates the amplitude of the phase-response curve (PRC), while ELF3 overexpression blunts the effectiveness of phase resetting relative to wild type. Similarly, rapid light-induced gene expression is increased in *elf3–1* and strongly reduced in the overexpressor.[53] These results, and others testing the circadian phase dependence of the effect of light pulses on weaker alleles of ELF3,[56] support ELF3 as an element of the light input pathway.

The ELF3 polypeptide is novel, giving little clue to its molecular function. However, *in vitro* and in yeast, ELF3 interacts specifically with the *C*-terminus of phyB.[55] This appears to link ELF3 directly to phyB signal transduction, and the phenotypes of the *elf3–1 phyB* double mutant and the *phyB* ELF3 OX plants show that *phyB* is largely epistatic to the ELF3 phenotype in both combinations. Although there have been no reports of cry interactions with ELF3, ELF3 overexpression is more effective in lengthening period under constant blue light, as compared to red light.[53] Together with the PRC results (see above), it is clear that blue-light signaling to the clock is also modulated by ELF3.

The photoperception pathway appears to be connected to the molecular components of the plant circadian oscillator by way of a direct binding of a phyB/PIF3 complex to the promoter of two likely oscillator components, *LHY* and *CCA1*. PIF3 is a basic helix-loop-helix transcription factor identified as a phyB and phyA interaction partner by way of a yeast-two hybrid screen. It binds specifically to a G-box DNA-sequence motif present in various light-regulated gene promoters, including the promoter of *CCA1*.[57] Together with the closely related family member, *LHY*, the CCA1 myb transcription factor is a likely oscillator component. Both genes cause arrhythmicity when overexpressed and shortened periods when knocked out or reduced in expression.[58,59] The double mutant displays poor rhythmicity in constant light (LL) and constant dark (DD), implying an additive and partially redundant function for the two genes.[59,60]. The light-dependent association of phyB with PIF3 at the G-box binding site present in the CCA1 and LHY promoters establishes a direct physical connection between a circadian photoreceptor and the transcriptional machinery driving the expression of a clock gene. The potential for rapid, light-induced changes in phase resetting appears great. However, much remains to be determined, as phase shifting in plants (including *Arabidopsis*) is remarkably recalcitrant to the effects of a brief pulse of light. More commonly, a pulse of light (or dark) on the order of an hour or more is required to obtain stable phase resetting.[53]

137.5 Drosophila

The molecular genetic approach to circadian biology began with a period mutant screen in *Drosophila*.[9] Because much of the research in the field was spearheaded using flies, much of the molecular and biochemical specifics of how the clock functions was worked out in this organism. Four core proteins were identified as essential to the function of the oscillator in flies. Loss of any one of the four genes causes arrhythmicity. The first two, CLOCK (CLK) and CYCLE (CYC), are PAS domain-containing bHLH transcription factors that form a heterodimer to activate the transcription of the other two essential genes, *period (per)* and *timeless (tim)*. Three of the four components cycle at the RNA and protein levels; *cycle* transcription is constitutive. PER and TIM proteins accumulate in the cytoplasm, where they dimerize to facilitate their own nuclear transport. In the nucleus, they act to disrupt the CLK-CYC dimer,

thus turning off their own transcription. Eventual nuclear degradation of PER and TIM releases this repression and CLK-CYC-mediated transcription of both genes begins again, renewing the cycle.[8,9] A second, interlocked loop is also part of the process. Here, CLK is cycling in antiphase with PER and TIM and (with CYC) negatively regulates its own transcription, which is derepressed by PER and TIM.[61]

Key steps in this process are the refining elements that help determine period length. These would be the synthesis and degradation rates of these players, as well as the rates of nuclear translocation. Mutant screens turned up three such modifiers of period. A casein kinase Iε (doubletime) is important in controlling the phosphorylation state and half-life of PER, thereby affecting period length. A second kinase (shaggy) regulates the nuclear translocation of the PER/TIM complex through its effect on TIM phosphorylation.[9]

A third modifier of clock function, cryptochrome (CRY), was also identified in a mutant screen, using a period-luciferase reporter in adult flies. Cryptochrome was identified first in plants many years before as a blue-light photoreceptor that mediates light control of stem elongation (see above).[38] As noted earlier, cryptochromes are structurally closely related to blue-light-activated DNA repair enzymes, the photolyases, but lack photolyase activity. Like the photolyases, they bind two blue-light absorbing chromophores, a flavin (usually FAD), and a pterin (methenyltetrahydrofolate), and may function via an intramolecular energy transfer. Photolyases absorb light via the pterin, which transfers the excitation energy to FAD, which in turn, transfers an electron to the DNA photoproduct, effecting pyrimidine restoration.[62] The *C*-terminal regions of the cryptochromes are the most divergent and are the domains most likely to confer specificity among the crys.[38]

Interestingly, although the cryptochrome mutant, cry^{baby} (cry^{b}), fails to entrain PER and TIM to light and dark cycles, locomotor rhythms are little affected.[63] This discrepancy was clarified when it was discovered that *per* and *tim* cycling persists in a subset of lateral neurons in the cry^{b} mutant. Why these cells remain rhythmic is still not clear, but apparently, their function is necessary to maintain whole fly activity rhythms. Entrainment to temperature cycles was also unaffected in this mutant, suggesting that CRY is not an essential component of the central oscillator. Phase resetting by light pulses was also eliminated in the cry^{b} background, though entrainment to 12/12 L/D cycles was normal. This suggested that light responsiveness was diminished but not eliminated. Further tests used the $norpA^{41}$ mutant, deficient in a phospholipase C (PLC) that functions downstream of the rhodopsin-based visual system, in combination with cry^{b}. These double mutant flies entrained poorly to full 12/12 L/D cycles, indicating that the two photoreceptor systems may work in parallel as part of the phototransduction input to the clock in flies.[63] However, unlike WT flies that become arrhythmic with increasing light intensity, cry^{b} flies allowed to free-run at high-light intensities maintain a period similar to WT flies in constant darkness. Entrainment of these flies might occur via the opsin-based visual system, where locomotor activity driven by light and dark cycles feeds back to reset phase nonphotically.[64]

The molecular role for cryptochrome in the phototransduction pathway appears to be direct. CRY protein interacts directly with TIM and PER in yeast two-hybrid assays and transiently transfected *Drosophila* cell culture (S2 cells).[65,66] CRY interaction with TIM is light dependent and appears to disrupt PER–TIM interactions, possibly by hastening the ubiquitination and degradation of TIM.[65,67] Similarly, CRY and PER interact in yeast two-hybrid assays and S2 cells, and as with its interaction with TIM, requires the *C*-terminus of CRY for nuclear localization.[9] The great proportion of CRY is found in the nucleus, independent of light conditions. PER and TIM appear necessary to effect CRY nuclear accumulation, although light is not required for this interaction. CRY is degraded by light, probably through an intramolecular conformational change that is redox dependent.[67] The cry cycles at the mRNA and protein levels in constant darkness, and in light and dark cycles, CRY cycles particularly robustly, with maximum accumulation during the night.[15] The phase of peak CRY accumulation is similar to TIM, making it likely that CRY mediates light-induced phase resetting through its effect on TIM protein levels. This model is consistent with the notion that CRY is not a component of the oscillator but is simply mediating photic input from the environment. One exception lies in a recent examination of rhythms in olfactory responses in fly antenna, which implies a more central role for CRY in this tissue. In this tissue, temperature entrainment in cryb flies failed in constant dark.[68] Hence, recruitment of molecules for clock function may vary among tissue types.

137.6 Mammals

Unsurprisingly, the mammalian clock is the most complex in terms of the number of molecules that were implicated in its composition. The task of sorting out the function of each player was made only slightly simpler in its basic molecular similarity to the *Drosophila* system. Using mouse as the model system, mammals were found to contain three *PER* genes and two *CRY* genes, in addition to *TIM*, *BMAL/MOP3* (fly *cycle*), and *CLK*. Casein kinase 1ε (*CK1ε*) and a BMAL-like protein, MOP9, were also implicated in mammalian clock function.[69,70,71] However, the functions of some of these proteins are surprisingly different from those in flies. The fundamental transcription-translation autoregulatory negative feedback loop is structured the same, but some roles were swapped. A CLK/BMAL bHLH transcription factor heterodimer drives rhythmic transcription of the *cry* and *per* genes, rather than of *timeless* and *per*, as in flies. The PER–TIM pairing, so essential to the *Drosophila* clock, is replaced by PER–CRY interactions in mouse. CRY acts to repress further CLK/BMAL activity, while PER (PER2) promotes BMAL1 transcription.[8–11] Numerous combinations of CRY/CRY, CRY/PER, and PER-PER dimers can form *in vitro*, but PER2 appears to be the critical PER family member, based on the mutant phenotype.[10,11] Unlike in flies, the apparent mammalian homologue to TIMELESS may have little role in the clock.[11] And unlike in flies, both *Cry* genes appear to encode key oscillator components and are less likely to be acting as photoreceptors. This became clear from the phenotypes of *Cry1* and *Cry2* single- and double-knockout mice. Loss of CRY2 lengthens the free-running period in constant darkness and causes an increased responsivity to light during the subjective night. Conversely, *Cry1* mutant mice have a shorter period. Surprisingly, the double mutant is arrhythmic in constant darkness, a result not to be expected from the elimination of components involved only in light perception.[10,11] Since the findings of the cry^b mutant left little doubt of the importance of CRY in circadian photoperception in flies, the *cry1cry2* double mutant put the mammalian field in a quandary over just what mediates phototransduction in mice.

This result came on the heels of a long debate over the role of opsins in mammalian circadian photoperception. Eyeless mice are unable to entrain, clearly localizing the site of primary photoperception to this organ.[17] Retinal degenerate, coneless (*rd/rd cl*) mice, which lack all rod and cone photoreceptors but develop otherwise normal eyes, entrain entirely normally, implying that known opsins, and the retinal-based vision system in general, play no significant role in circadian photoperception. However, the "opsin option" was recently revived through the discovery of a number of novel opsins in vertebrates.[17] Relevant to mammals, melanopsin has become the strongest candidate photopigment for circadian phototransduction. It is localized to a subset of retinal ganglion cells (RGC) that are anatomically distinct from the regions lost in *rd/rd cl* mice and reside in RGC that project into the SCN and can mediate entrainment.[72–76] Melanopsin knockout mice will be key to resolving the question of its role in photoentrainment.

The close association of cryptochromes with the molecular machinery of the mammalian oscillator does not preclude an additional role as photoreceptor. Loss of cycling in the *cry1cry2* double mutant eliminates circadian output, making it difficult to assess a photic role for these proteins. However, *cry1cry2* double-mutant mice still respond behaviorally to light and dark (LD) cycles and *Per2* expression cycles in LD and responds acutely to light pulses in this background.[77] These responses are also present in *rd* mice, but the triple-mutant (*rdcry1cry2*) mice were nearly behaviorally arrhythmic under LD cycles, and light-induced c-*fos* transcription in the suprachiasmatic nucleus (SCN) was also markedly reduced. These results suggest parallel, partially redundant roles for the two classes of molecules and indicate that cryptochrome may function in two anatomically distinct places: in the retina and in the SCN.[78]

137.7 Conclusions

The diversity of components involved in circadian photoperception across the five systems described here appears to reflect the degree of evolutionary distance among these organisms. To the extent that the molecular bases are known, there is no one element that is commonly used across all systems. Clearly, the metazoans (flies and mammals) share a great number of components, and the molecular construction

of the two systems is similar enough to have allowed each to benefit from the most recent discovery of the other. However, even here, the *cry*^{b} mutant in flies misled the field into assuming that *cry* would play the same role in mammals.

What is nearly common, and perhaps surprising, is the extremely close connection between photoperception and the molecular components of the oscillator. Signal transduction cascades do not appear to play a major role in circadian phototransduction. In three of the five systems, photoreceptors physically associate with clock proteins or with the promoters of these proteins. Both in plants and in *Neurospora*, the phyB/PIF3-*CCA1* promoter complex and the WCC-*frequency* promoter interaction, respectively, provide a direct link between light perception and the gene transcription of clock components. In the case of plants, the importance of this interaction to circadian entrainment was not fully tested. For example, does the loss of PIF3 affect circadian period? In addition, other phytochromes are known to affect period, and their ability to signal through PIF3 is unclear. Finally, a direct molecular link between the cryptochromes, the other class of plant circadian photoreceptor, and the clock is still absent. In contrast, the WCC in *Neurospora* appears to be the primary molecular connection between light and the circadian oscillator, despite recent evidence for an additional phototransduction pathway.[33]

In flies, cryptochrome is clearly involved in mediating light-induced disruption of the TIM/PER complex. However, the story may not end here. Interestingly, the recent suggestion that cryptochrome in peripheral oscillators (antenna) may play a nonphotic role in clock function in the fly, is analogous to the clear nonphotic role of CRY as a key oscillator component that normally associates with PER in mammals.

Interestingly, it is the two systems at the opposite ends of complexity, cyanobacteria and mammals, where a molecular bridge between phototransduction and the clock is still unknown. The phytochrome-related *cikA* is a strong candidate as the primary cyanobacterial photoreceptor, but a conclusive molecular partnership with the Kai proteins or other clock component is still absent. In mammals, the physical separation between the primary photoreceptor site, the eye, and the brain-localized central pacemaker in the SCN, dictates that a direct molecular interaction between photoreceptive molecules and the oscillator will not be found. However, the separation is likely based on the necessary consequences derived from the development of a large, highly specialized body plan, where direct light penetration to the master oscillator is not possible. The relative light transparency of the organisms of the other four systems still allows for a direct link between photoperception and the mechanism of the central oscillator. This and the fact that cryptochrome is involved in the molecular machinery of the circadian system in some way in all eukaryotes studied to date, also suggests that the progenitor molecule of circadian photoperception may have been a derivative of an early light-sensitive DNA repair molecule: the cry-like DNA photolyases.[15,79]

Cryptochrome: Discovery of a Circadian Photopigment

138.1 Introduction

Most organisms, from fruit flies to humans, exhibit daily fluctuations in behavioral and molecular processes such as sleep–wake cycles and metabolic rate. These daily fluctuations are governed by an internal circadian clock, which is generated by a transcriptional feedback loop that exists in individual cells as well as in neural tissue, where it coordinates an organism's global rhythms. These rhythms can exist in the absence of light but are adjusted by light exposure in order to coordinate organismal behavior with the solar day. While circadian photoreception is not fully understood and may involve integration of multiple signals from different light input pathways, it appears that cryptochrome, a blue-light photoreceptor, is a major circadian photosensory pigment. Our understanding of the role of cryptochrome in mammalian circadian photoreception evolved from the merging of two distinct fields: plant blue-light photoreception and photoreactivation.

Blue-light responses in plants were first described by Charles Darwin in the 1800s and attributed to an unknown blue-light photoreceptor (cryptochrome). However, no progress was made toward identification of this pigment until 1980, when the HY4 gene locus in Arabidopsis was discovered to be responsible for conferring blue-light sensitivity.[1] When a gene was cloned and sequenced from the HY4 locus in 1993, it was found that the putative protein encoded by HY4 had high sequence homology to photolyase, a blue-light-activated DNA repair protein.[2] The level of sequence identity between the HY4 gene and photolyase was so high that it was unclear whether this protein was a photolyase or a new type of protein. By 1995, we and others demonstrated that this photolyase-homolog lacked DNA repair activity and appeared to represent a new class of blue-light photoreceptor that was called cryptochrome, a name previously used as a universal designation for plant blue-light photoreceptors of unknown (cryptic) identity.[3–6]

The study of photolyase began with the first description of photoreactivation in *S. griseus* in 1949.[7] Photoreactivation is the reversal of the harmful and mutagenic effects of ultraviolet irradiation by blue-light, and in 1958, the enzyme responsible for this phenomenon, photolyase, was discovered.[8] Photolyase uses blue-light energy to repair the two major UV photoproducts in DNA, cyclobutane pyrimidine dimers

and pyrimidine-pyrimidone (6–4) photoproducts, via a cyclic electron transfer mechanism. Although photolyase was found in bacteria, yeast, fruit flies, fish, and even in rattlesnakes and opossums, in 1993, we determined by enzymatic assays that photolyase was absent in humans and all other placental mammals.[9] Therefore, the report of a photolyase-homolog as an EST in the human genome database in 1995 was puzzling.[10] Both this first homolog and a second human homolog we discovered were tested and found to lack photolyase activity, and so in the manner of the plant cryptochromes, we named these proteins CRY1 and CRY2 for Cryptochrome 1 and 2 and hypothesized that they might be circadian photopigments in mammals.[11,12] Later, five groups cloned the sole *Drosophila* homolog, *dCry*.[13–17]

Cryptochromes are 60 to 70 KD proteins that possess a high degree of sequence identity with photolyase throughout the chromophore and DNA-binding regions; therefore, clues to the function and mechanism of mammalian cryptochromes may be gained by modeling upon the α carbon backbone of *E. coli* photolyase crystal structure.[18] Photolyase possesses two main regions, an *N*-terminal α/β domain and a *C*-terminal helical domain. Photolyase family members noncovalently bind two cofactors, which absorb blue light: a pterin, in the form of methenyltetrahydrofolate, which binds along a shallow groove between the two domains; and a flavin, which is bound in a pocket in the α-helical domain. The phosphodiester backbone of DNA interacts with photolyase along a trace of positive electrostatic potential, and during binding, the UV photoproduct is flipped out of the DNA helix into a pocket in the protein (dashed box, Figure 138.1) in a light-independent manner, where it comes into van der Waals contact with the flavin. Photoreactivation is carried out by the following mechanism: the folate absorbs a photon of blue light and transfers energy to the flavin.[19,20] The excited singlet state flavin transfers an electron to the pyrimidine dimer (cyclobutane dimer or [6–4] photoproduct) and thus initiates a cyclic electron transfer, whereby the pyrimidine dimer is reversed to canonical dipyrimidines concomitant with back electron transfer to restore flavin to the catalytically active two-electron reduced form ($FADH^-$). At the end of the repair reaction, there is no net change in the oxidation state of the chromophores.

Molecular modeling of mammalian cryptochromes on the structure of photolyase indicates conservation of the chromophore-binding regions, the DNA binding groove, as well as the damage-binding pocket. However, the functional implications of these structural features for cryptochrome function in circadian photoreception are unknown. The major difference between cryptochrome and photolyase lies in the presence of an extended *C*-terminal tail in cryptochrome, which is absent in photolyase. Based on

evidence from cryptochromes in drosophila and arabidopsis, this tail is believed to be responsible for protein–protein interactions and signal phototransduction.[21,22]

To examine the role of cryptochrome as a photoreceptor in mammals, it is important to understand the anatomy of circadian photoreception. All mammalian photoreception occurs in the retina, including visual and circadian photoreception.[23] While vision is mediated by rod and cone photoreceptors in the outer retina, circadian photoreception does not require the visual photopigments; certain retinal degeneration diseases in mice that result in the loss of the outer retina but leave the inner retina intact do not eliminate circadian photoreception[24–26]; therefore, a circadian photopigment must reside in the inner retina. After a light signal is detected, signal phototransduction is initiated from the retina and transmitted through the optic nerve, and finally to the suprachiasmatic nucleus (SCN) in the hypothalamus, a structure that is located just above the optic chiasm and contains the master circadian clock. In mammals, every cell in the body houses an autonomous circadian clock, but the cellular clocks are coordinated within each organ, and the circadian rhythms of the entire animal are controlled by the master clock in the SCN.[27]

Experiments to determine the photoreceptive function of cryptochrome in mammals have thus far relied on molecular and genetic approaches. While significant strides were made recently in understanding the molecular clock mechanism and the role of cryptochrome in the clockworks, the molecular clock model is becoming ever more complicated and raises new questions. Similarly, while recent intriguing studies concerning circadian photoreception have not yet solved the actual mechanism of signal phototransduction, the genetic data strongly support a major role for cryptochrome in circadian photoreception as well as the integration of photic signals generated by opsins and cryptochromes. In this review, we will detail the current evidence for the role of cryptochrome in circadian photoreception as well as the apparent functional redundancy between the two classes of mammalian photoreceptors.

138.2 Evidence for Cryptochrome as a Circadian Photoreceptor

Historically, circadian photoreception in mammals was attributed to the vitamin A-based opsins, but the discovery of a blue-light absorbing flavoprotein, cryptochrome, introduced new possibilities in understanding clock-resetting by light. To determine whether cryptochrome could be a potential circadian photoreceptor, we examined whether it was expressed appropriately in the inner retina. As shown in Figure 138.2, *Cry2,* and to a lesser extent *Cry1,* were both expressed in the inner retina, specifically in the ganglion cell layer and the inner nuclear layer.[28] The presence of cryptochrome in the ganglion cell layer is especially intriguing in light of the recent discovery of a small subset of ganglion cells that are intrinsically photosensitive.[29] These cells contain a candidate photopigment, melanopsin, that has been postulated as the circadian photoreceptor[30,31]; however, cryptochrome expression in these cells supports a role for cryptochrome in this photoresponse.

Surprisingly, cryptochrome was not found solely in the retina. In addition to low levels found in all tissues, *Cry1* was also expressed in the SCN, and *Cry1* mRNA oscillated with circadian rhythmicity, which indicated an additional role for cryptochrome in circadian clock function.[28] Based on the mRNA expression pattern, we postulated a role for Cry2 in circadian photoreception in the retina as well as a light-independent role for Cry1 in the circadian clock mechanism in the SCN.

The generation of knockout mice for *Cry1* and *Cry2* indicated redundant functions between the two mammalian photolyase-homologs. Both the *Cry1*-/- mouse[32,33] and the *Cry2*-/- mouse[34] exhibited a change in period length, indicating a potential role in clock regulation, as well as a reduction in circadian photosensitivity as measured by circadian gene induction by light in the SCN.[32,34] Based on the hypothesis that the two cryptochromes were the sole circadian photoreceptors in mice, we expected the *Cry1*-/- *Cry2*-/- mice to be "circadian blind." Surprisingly, the double knockout mice responded behaviorally to light–dark cycles (Figure 138.3), and circadian oscillation of the circadian clock gene, *per2* (but not *per1*), as well as acute photoinduction of both *per2*, and *c-fos* was observed in the SCN.[32,33] Therefore, cryptochrome was not absolutely required for circadian responses to light. However, these mice entirely lost

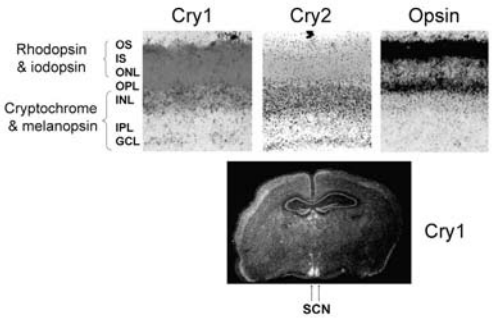

FIGURE 138.2 Expression of cryptochromes in mouse retina and SCN. In situ hybridization for *Cry1* and *Cry2* mRNA in the retina revealed a strong signal in the inner nuclear layer and ganglion cell layer (top, left, and middle). Opsin expression in the outer retina is shown for comparison (top, right). *Cry1* signal is shown in the SCN (bottom). Abbreviations: OS, outer segment; IS, inner segment; ONL, outer nuclear layer; OPL, outer plexiform layer; INL, inner nuclear layer; IPL, inner plexiform layer; GCL, ganglion cell layer. FIGURE 138.3 Wheel-running actograms of cryptochrome and *rd* mutants. Animals were entrained to 12 h light: 12 h dark cycles, followed by constant darkness at Day 19. Numbers on the Y-axis indicate days; numbers on the X-axis indicate time of day. White bars indicate light, black bars indicate dark (top). (From Selby, C.P., et al., *Proc. Natl. Acad. Sci. USA*, 97, 14697, 2000. With permission.)

circadian rhythmicity of behavior and of circadian gene oscillation in the absence of light cues, indicating that cryptochromes were required for circadian clock function.

The light-independent role of cryptochrome in the core circadian clock machinery is now known. Circadian rhythmicity is generated by a transcriptional feedback loop (Figure 138.4). Certain genes, such as circadian clock genes *per1*, *per2*, and *cry1*, as well as output genes like vasopressin, contain an E-box element in the promoter, which governs circadian transcription of these genes.[35–38] The transcriptional activators Bmal and Clock bind the E-box as a heterodimer to drive transcription,[36] and after Per and Cry proteins are made, they reenter the nucleus and negatively regulate transcription from the E-box.[39–41] After light signals are received and transmitted from the retina to the SCN, the clock is reset by activation of the CREB transcription factor, which binds the CRE element in the promoter of *per* genes resulting in acute induction of *per*.[42]

While cryptochrome's role in the circadian clock mechanism is clear, its light-dependent function remains to be elucidated. The evidence for cryptochrome as a blue-light circadian photoreceptor is the following:

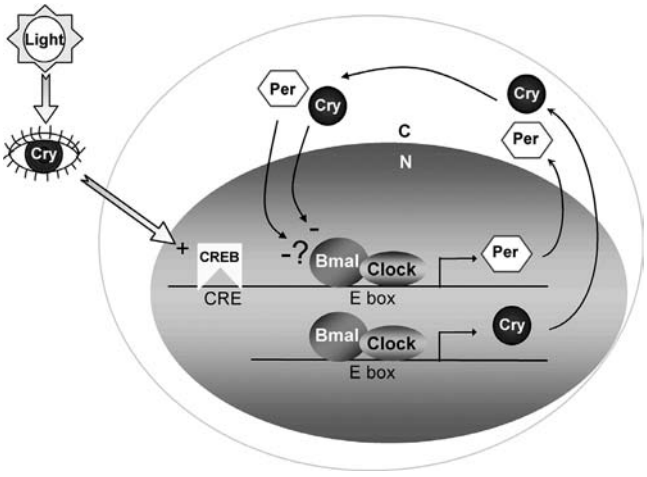

FIGURE 138.4 Molecular mechanism of circadian rhythm. Circadian rhythm is established by a negative feedback loop. This simplified model shows transcriptional activation by the Bmal-Clock heterodimer to drive transcription from E-box containing genes such as Per and Cry. Per and Cry then feed back to inhibit their own transcription. Light input resets the clock by rapid induction of the *per* transcript through the CRE element.

1. Cryptochrome has a high level of sequence identity to the blue-light activated enzyme, photolyase.
2. The homolog of cryptochrome in plants serves as a photoreceptor for a myriad of blue-light responses.[43]
3. Genetic evidence demonstrates that *cry1*-/-*cry2*-/- mice have impaired photoresponses, as shown by reduced gene induction by light in the SCN.[32]

There are two main arguments against cryptochrome as a circadian photoreceptor. The first argument is that the double knockout mice still retain responses to light, both behaviorally and molecularly, indicating the presence of other photoreceptors that can govern these responses. Although this evidence precludes an absolute requirement for cryptochrome in circadian photoreception, it would be consistent with a scenario in which multiple photoreceptors simultaneously contribute to circadian clock resetting, including cryptochromes and opsins.

The second major argument against cryptochrome as a circadian photoreceptor is that the action spectra of circadian photoresponses do not match the absorption spectrum of cryptochrome. Several action spectra were generated for a variety of circadian responses to light. Recently, two groups published similar action spectra for human melatonin suppression by light.[44,45] After testing wavelengths from 420 to 600 nm, they attempted to fit an opsin nomogram to the data (Figure 138.5). They concluded that the best fit of an opsin absorption spectrum to the data was an opsin with peak absorption at 464 nm; however, the peak of the action spectrum clearly did not coincide with the opsin nomogram. The peak of the action spectrum for melatonin suppression was not determined by these experiments, because the maximum effectiveness of light was at the lowest wavelength tested, 420, so it is unclear whether the peak was at 420 or at some even lower wavelength. The preliminary absorption spectrum of cryptochrome revealed a peak at 420 nm, which matches the peak of melatonin suppression, but the shape of the curve does not match.[46] The action spectra appear to indicate to a peak at 420 nm and perhaps a shoulder at 500 nm, but the resolution of the data is insufficient. Therefore, examination of the currently available action spectra support a model in which multiple photoreceptors, such as a cryptochrome and an opsin, contribute to circadian photoresponses.

Action spectra are notoriously difficult to generate, especially in whole animals. Ideally an action spectrum would be generated from a purified enzyme system; however, no such assay exists for cryptochrome or circadian photoreception. A cell-based assay would be a simpler and more favorable system for action spectrum generation. While no such system exists in mammalian cells, a system for circadian

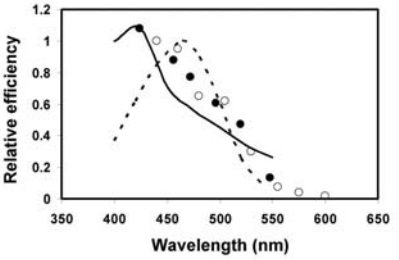

FIGURE 138.5 Combined action spectra of human melatonin suppression. Two separate studies examined the action spectra of melatonin suppression. Dashed line: opsin 464 nomogram. Solid line: hCry2 absorption spectrum (black circles: From Thapan, K., Arendt, J., and Skene, D.J., *J. Physiol.*, 535.1, 261, 2001; white circles: From Brainard, G.C., et al., *J. Neurosci.*, 21, 6405, 2001.)

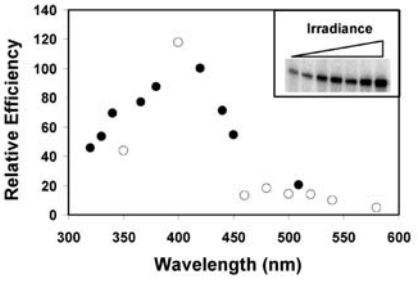

FIGURE 138.6 Action spectrum of photic induction of zebrafish *per2* mRNA. Induction of *per2* occurs in a dose-dependent manner, as shown by RNase protection assay (inset). Relative efficiency of induction was determined as the slope of the dose–response curve for each wavelength (data points from Cermakian et al.[47]).

photoreception was recently established in zebrafish cells. Sassone-Corsi and colleagues established a cell line (Z3) that expresses at least four different cryptochromes.[47] The Z3 cell line not only exhibits circadian oscillation of clock genes, it is the only cell line in which the circadian rhythm can be directly reset by light.[48] A good marker for circadian reception in this line is the acute induction of the *per2* gene by light in a dose-dependent manner (Figure 138.6). Therefore, we generated an action spectrum for *per2* induction by light in the Z3 line (Figure 138.6),[47]

We tested wavelengths of light ranging from 320 to 580 nm and found that wavelengths between 380 and 420 nm were the most effective wavelengths for *per2* induction, and wavelengths above 450 had little effect on *per2* induction. Photolyase family members with folate and FAD chromophores exhibit absorption peaks between 380 to 420 nm,[19,20] so this action spectrum is consistent with a cryptochrome-mediated response. However, zebrafish are known to contain a UV opsin that absorbs blue light as well, but these cells did not contain detectable levels of the opsin cofactor retinaldehyde,[47] so we concluded the response was due to cryptochrome.

138.3 Functional Redundancy of Opsins and Cryptochromes

Although the action spectrum for a circadian photoresponse in zebrafish points to cryptochrome as the responsible photoreceptor in a vertebrate animal, the lack of a similar assay in mammals made elucidation

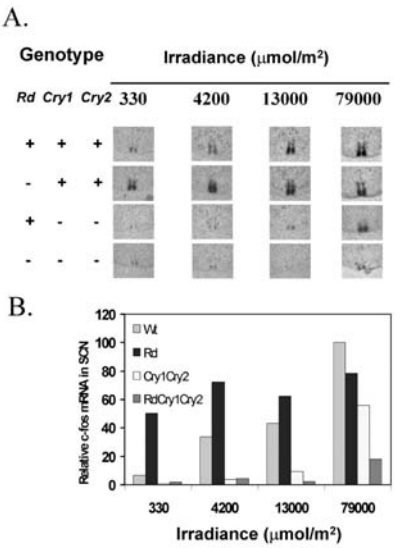

FIGURE 138.7 Acute induction of *fos* mRNA in the SCN by light. Mice lacking rods (*rd*), *Cry1,* or *Cry2* were exposed to four doses of light and examined for *fos* induction after 30 min. (A) Representative SCN images from peak sections. (B) Quantitation of data in A. (From Selby, C.P., et al., *Proc. Natl. Acad. Sci. USA*, 97, 14697, 2000. With permission.)

of mammalian circadian photoreception problematic. Simultaneous input from multiple photoreceptors made interpretation of action spectra in whole animals difficult. There appears to be only two classes of photoreceptors in mammals: cryptochromes and opsins. The contribution of cryptochromes to circadian photoreception can be examined genetically by use of *cry1-/- cry2-/-* mice. The opsin class encompasses the visual opsins (rod and cone opsins) as well as novel opsins, such as the recently discovered melanopsin, expressed in the ganglion cell layer. There are a variety of different genetic mutations in mice that have been used to measure the input of various opsins to this response: *rd/rd* mice, which undergo retinal degeneration and lose all rod photoreceptors as well as the majority of cone photoreceptors[49]; *rdta*/*rdta* mice, which have transgenic expression of a toxin targeted to rod cells, resulting in destruction of rod photoreceptors[50]; and *cl*/*cl* mice, which lack all cone cells.[51] Recently, melanopsin knockouts were also constructed. Thus far, none of these mutations that take out opsins had any significant effects on circadian photoreception. However, in order to examine the input of all opsins to the circadian clock by genetics, it would be necessary to combine at least three mutations to eliminate rods, cones, and melanopsin, and there may be additional novel opsins in the eye.

Cryptochrome knockout mice exhibit reduced circadian photosensitivity, and therefore, we set out to determine whether visual opsins were responsible for the remaining photoresponse. Initially, we compared the circadian responses of the *cry1-/-cry2-/-* mouse with a *rd/rd cry1-/- cry2-/-* mouse to see if the residual response remaining in the cryptochrome-free mouse was mediated by the most abundantly expressed opsin, the rod opsin. We found that most, but not all, of the triple mutant mice were arrhythmic under light–dark cycles, as compared to the *cry1-/- cry2-/-* mice, which responded to light–dark cycles (Figure 138.3).[52] This indicated that visual opsins were primarily responsible for behavioral photoresponses in the absence of cryptochromes. Using induction of *fos* mRNA in the SCN by light, we found that although wild-type and *rd* mice had robust *fos* induction by light, the *cry1-/-cry2-/-* mice had 10- to 100-fold reduced circadian photosensitivity at limiting light fluences and about twofold reduced sensitivity even at the highest light dose given (Figure 138.7). Strikingly, even at the highest light dose, the triple mutant mice had drastically reduced *fos* induction, exhibiting only 15% of wild-type induction

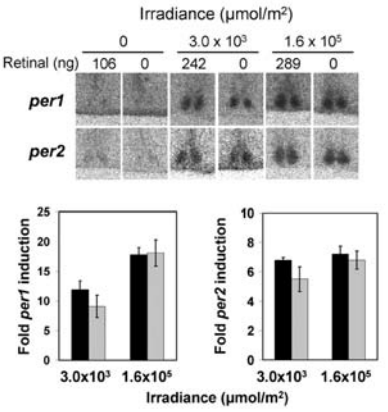

FIGURE 138.8 Opsin-free mice have normal *per* gene induction by light. Mice were exposed to two different doses of light during night phase and were sacrificed after 1.5 h. In situ hybridization for *per1* and *per2* mRNA in the SCN was performed. (A) Representative SCN images from peak sections. (B) Quantitation of data in A. (From Thompson, C.L., et al., *Proc. Natl. Acad. Sci. USA*, 98, 11708, 2001. With permission.)

levels. While this data indicated that visual opsins could allow the *cry1-/-cry2-/-* mice to coordinate their behavior to lighting conditions, the residual *fos* induction in the triple mutant mouse as well as the few triple mice that were not arrhythmic suggested that another photoreceptor may also play a role, and we postulated that a few surviving cone cells or melanopsin may be responsible.

Recently, a new mouse model was developed that allows us to examine photoresponses in an entirely opsin-free mouse model. Opsins require their chromophore, 11-*cis*-retinal, for function, and therefore, one obvious approach to create an opsin-free model would be to deprive mice of dietary vitamin A, rendering all opsins nonfunctional, including rod and cone opsins as well as known and yet to be discovered novel opsins. This approach is not feasible in normal mice, because vitamin A is required during development, and adult mice have stored sufficient vitamin A in their liver to last for the lifetime of the animals, even if they were put on a vitamin-A-free diet. The creation of the plasma retinol-binding protein mutant (*rbp*) enables us to deplete ocular retinal in mice.[53] The Rbp protein transports retinal from storage in the liver to peripheral tissues. With the Rbp mutation, peripheral tissues such as the eye can be vitamin A depleted in 6 to 8 months. Therefore, we used the vitamin-A-depleted *rbp* mouse as an opsin-free model for circadian photoreception.

In Rbp animals maintained on a vitamin-A-free diet and with no detectable retinal, phototransduction from the retina to the SCN was normal, as shown by acute photoinduction of *per* genes[54] (Figure 138.8) as well as *fos*[55] in the SCN. This result is somewhat surprising, because *rd* mice exhibit an increased response to light compared with wild-type mice. In the absence of opsins, the only remaining candidate photoreceptor is cryptochromes, and therefore, these data strongly suggest that cryptochromes are sufficient to mediate photoinduced gene expression in the SCN. Another marker of circadian photoreception is behavioral response to light as measured by wheel running. Because the gene induction by light is normal, we expected behavioral responses to light to be normal. We found that *rbp* -/- mice have circadian behavior coordinated to light–dark cycles and exhibit masking and phase shifting to light, although there are some interesting features of these animals that are consistent with input from opsins to circadian photoreception.[55] This aspect of the mutants remains to be explored.[55] Similarly, like the *rd/rd cry1 -/- cry2-/-* mice which become largely arrhythmic under light–dark cycles, the opsin-free and cryptochrome-free mice, which have lost rod opsins, cone opsins, novel opsins, and cryptochromes, were entirely arrhythmic.[55] This again corroborates that cryptochromes primarily and opsins secondarily contribute to mammalian circadian photoreception. Similar studies in drosophila showed that in that organism as well, cryptochrome and opsin function as redundant circadian photoreceptors.[56]

138.4 Conclusion

The mounting evidence in fruit flies and mammals indicates that circadian photoreception in animals evolved to allow several different light input pathways into resetting the circadian clock. The role of the clock in coordinating behavioral and molecular functions impacts feeding and evading predation, and evolving multiple redundant pathways to circadian photoreception would help ensure survival. The use of multiple photoreceptors, each with different chromophores and separate signaling mechanisms, might allow animals to control a variety of behavioral processes in response to a wide spectrum of light frequencies and intensities, and thereby, allow them to respond appropriately to changing light quality over the course of the day. In mammals, the redundant pathways include signaling by rod opsin and either cone opsin or melanopsin, as well as the blue-light photoreceptor cryptochrome, which appears to be the major contributor to circadian photoreception.

139.1 Introduction

The Green Fluorescent Protein (GFP) appeared on the scientific arena in 1962, when Shimomura et al.[1] first purified the companion protein of the chemiluminescent aequorin from the jellyfish *Aequorea Victoria* and observed its fluorescence in solution. The subsequent spectral characterization[2] showed that GFP absorbs blue light and emits green light, working as the converter of the blue chemoluminescence of aequorin in the greenish bioluminescence of the jellyfish. Evolution and natural selection produced an efficient, highly specialized nano-sized optical device that *Aequorea Victoria* and other organisms have been successfully using for millions of years. This "evolution-driven optimization" is probably at the basis of GFP success in biotechnology. Indeed, the amount of work and publications on GFPs exponentially increased from the 1960s and a vast literature was produced.[3] Cloning[4] and expression[5] of the GFP gene at the beginning of the 1990s were true breakthroughs. They opened the way for the use of GFPs in molecular and cell biology. Nowadays, GFPs are commonly used as markers of gene expression and, genetically fused to other proteins, as fluorescent tags to monitor protein trafficking, localization, and interactions in living cells and organisms.[6] Moreover, in the last decade, the number of available engineered GFP mutants exploded and yielded a whole range of artificial proteins with enhanced fluorescence, different colors, or peculiar sensitivity to external conditions (temperature, pH, etc.).

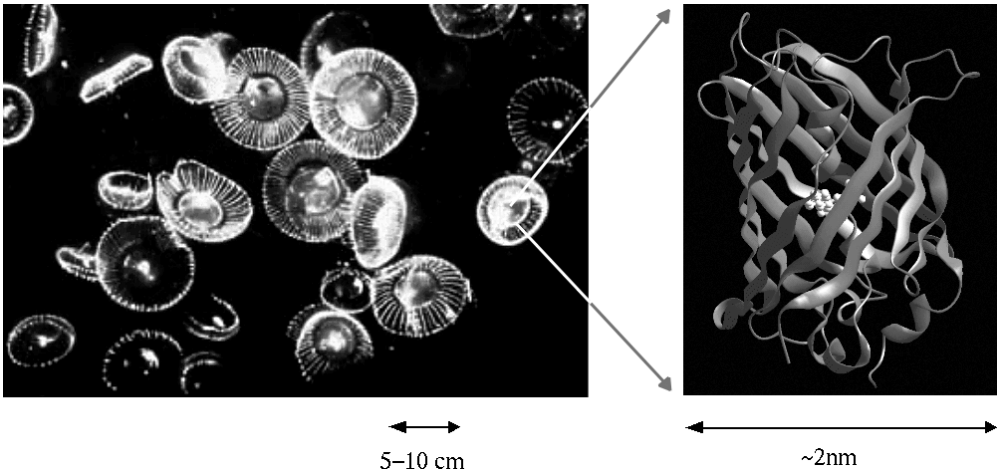

FIGURE 139.1 Specimens of *Aequorea Victoria* (left) and GFP fold (right). The tertiary structure of the protein (β-barrel) is represented in strand style, and the chromophore (represented in *ball and sticks* style) is highlighted in the center of the structure. The approximate size is indicated.

Applications of GFPs are not limited to molecular and cell biology, however. The recent discovery of multistable GFPs acting as optically controllable switches,[7,8] in fact, opens a wide field of new possibilities in bioelectronics. The relatively recent idea of using photoactive proteins to design optical memories was originally associated with another important photoactive protein: rhodopsin. The intrinsic fluorescence of GFPs, however, is a major advantage and allows its use for the implementation of single-molecule optical elements in optobioelectronics.

In this chapter, we review GFP properties and applications. Sections 139.1 through 139.4 are devoted to general and bulk properties, while in Sections 139.5 through 139.7, we focus on single-particle properties that led to the most recent and challenging applications. Other interesting review articles on GFP are listed in the literature.[9]

139.2 GFP Production, Folding, and Structure

Production

The jellyfish *Aequorea* (Figure 139.1), equally named *A. Victoria, A. Aequorea*, or *A. Forskalea*, was the first from which GFP was isolated[1] and the gene cloned[4] and expressed.[5] In the following, we refer to wild-type (WT-)GFP as the protein of *Aequorea*. GFPs with the same core chromophore and fold and similar spectral properties were extracted from other organisms, such as the sea pansy *Renilla* and the hydroid *Obelia*,[9,10] as well as from several other coelenterates of the classes of hydrozoa and anthozoa.[11] The red-fluorescent DsRed protein extracted from the *Discosoma* corallimorpharian and the nonfluorescent purple asCP extracted from *Anemonia sulcata* share the same fold of GFP but have a different chromophore.[12,13]

In the following, we will restrict our discussion to the *Aequorea* protein. We will refer to it simply by GFP. This was first sequenced and cloned in 1992[4] and expressed in heterologous systems in 1994.[14]

Fold and Chromophore Maturation

The WT-GFP was first crystallized and its atomic structure solved by Yang et al. in 1996.[15] The fold (see Figure 139.1) comprises 11 β-sheets arranged in a cylindrical shape. This cylinder is capped by short helical segments. This structure was named "β-can." The chromophore is located in the middle of the can and is bonded to the two α-helix fragments. Crystalline WT-GFP appears in dimeric form, although

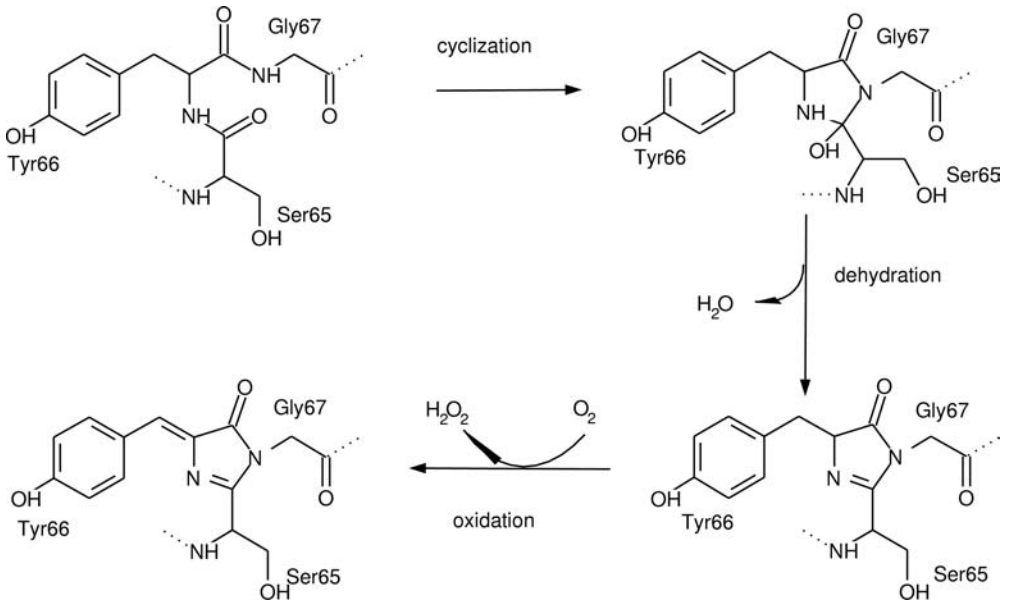

FIGURE 139.2 Chromophore formation, according to the currently accepted mechanism:[21–23] the cyclization occurs via the bonding of the carbonilic carbon of Ser65 to the nitrogen of Gly67; the subsequent dehydration of the C-N bond between Ser65 and Tyr66 with the release of a water molecule is then followed by the oxidation of the C–C bond of Tyr66. The last step is the bottleneck of the process, necessitating more than 1 h to occur. The first two steps occur in a few minutes after the folding of the protein (which necessitates about 10 min).

this characteristic depends on crystallization conditions and is lost in some of the engineered mutants.[16] The whole structure height is about 42 Å, and the diameter is about 24 Å. This unique motif with negligible variations is common to all proteins of the GFP family, including those from *Renilla* and DsRed, in spite of the relatively low sequence homology (about 23% between DsRed and Aequorea GFP).[12] The chromophore autocatalytically forms by the cyclization of the three consecutive amino acids 65, 66, and 67 (Ser, Tyr, and Gly in WT-GFP, see Figure 139.2). It is buried inside a compact, rigid, and chemically protective structure. The latter is thought to be responsible for the high stability and quantum yield of the fluorescence: classical fluorescence quenching agents, such as acrylamide and molecular oxygen, are almost ineffective on GFP fluorescence,[17] and denaturation by heating occurs only at 76°C.[18] Conversely, WT-GFP is sensitive to pH conditions, showing a dramatic decrease in the fluorescence passing from alkaline to acidic conditions.[18] Deletion experiments[19,20] showed that almost all the sequence is necessary for the protein to be functional, indicating a particularly efficient structural optimization of this protein with respect to its function. This, together with the fact that GFPs do not need any external cofactors for the fluorescence, makes these fluorescent proteins unique.

The chromophore formation is the bottleneck of protein folding and requires the presence of oxygen, releasing H_2O_2 at the end of the process. The currently accepted mechanism involving a cyclization followed by an oxidation-dehydration is shown in Figure 139.2 and is supported by the observed kinetics of the phases of the reaction and of the released intermediate by-products,[21–23] although an alternative mechanism, where the oxidation precedes the cyclization, was also proposed on the basis of a theoretical analysis.[24]

The correct folding and configuration of the residues around the chromophore are the main requisite for the fluorescence, because the isolated chromophore is not fluorescent in aqueous solution,[25] and denaturation produces a loss of fluorescence, which is recovered upon correct refolding.[26] Because WT-GFP folds better at temperatures lower than the physiological mammalian cell temperatures, "folding mutations" were designed in order to improve its use as marker in human cell biology. These are, for instance, F64L, F99S, M153T, and V163A, and they are often included in last-generation mutants. The

F64L mutation is widespread: it reduces the average distance between the carbonyl carbon of Ser65 and the amide nitrogen of Gly67 by changing a phenylalanine into the less bulky leucine in proximity of the chromophore. This favors the cyclization and results also in generally brighter mutants at the physiological temperature.[27] Analogously, any mutation of Gly67 produces nonfluorescent proteins,[28–30] indicating the crucial role of a small residue (actually, the smallest) in Position 67 in keeping Residue 65 near Residue 67 during protein maturation. More details on the other folding mutations can be found in the literature.[3,9]

139.3 Steady-State Optical Properties

Wild-Type Fluorescence Mechanism

The fluorescence mechanism of WT-GFP is prototypical of the GFP family. WT-GFP at thermal equilibrium displays two absorption peaks — at 398 nm and at 475 nm.[2,18] It emits at 503 to 509 nm when excited at 398 nm (with quantum yield ~0.7) and at 482 when excited at 475 nm.[21,31] The two absorption peaks were early attributed to structural substates of the protein, where the chromophore takes the phenolic-neutral (A state) form and the phenolate-anionic (B state) form, respectively.[32] The fluorescence mechanism was proposed on the basis of ultrafast excited-state dynamics measurements[31] and rationalized on the basis of the resolved atomic structure of A and B states[32] (Figure 139.3). A and B states are populated with a 3:1 ratio at equilibrium and differ not only in the protonation state of the chromophore but also for the different hydrogen-bond network conformation surrounding the chromophore. According to x-ray structures, a hydrogen-bond network connecting the phenol to E222 is present in the A state. It is interrupted in B state. Also, the T203 residue adopts a different conformation: it is H-bonded to the phenolate in the B state, while it is twisted in the opposite direction in the A state. When GFP is excited in the anionic state at 470 nm, it emits directly from the excited state (B*) at 482 nm and displays the typical Stokes shift and "mirror structure" in the absorption/emission spectra due to the excitation of different vibrational substates. When the neutral state is excited, an excited-state proton transfer (ESPT) occurs from the chromophore to Glu222 in a timescale of the order of picoseconds. ESPT leads to the I* form, which is attributed to an unrelaxed form of the B state. It is characterized by a deprotonated chromophore in an environment similar to that of A for what concerns the conformation of T203 and the H-bond network. The emission of I* peaks at 503 nm. Following radiative relaxation, the system goes back from I to A in the ground state. ESPT is one of the mechanisms competing with the direct fluorescence of A, occurring at 420–470 nm, which is weak in all mutants. The occasional relaxation from I* to B* in the excited state was proposed as the mechanism responsible for the observed A to B photoconversion process occurring on the timescale of minutes/hours when the GFP is excited in the UV,[31] the result of which is a depopulation of A in favor of B. A/B population equilibrium is recovered in 24 h in the dark. Recently, it was proposed that this process is paralleled by an oxidative decarboxilation of residue E222,[33] resulting in a release of CO_2.

This mechanism was supported by most of the subsequent studies. Some controversy was raised on the protonation of the imidazolinone nitrogen on the basis of quantum chemical studies of the absorption energies[34] leading to the cationic and zwitterionic forms (see Figure 139.4). However, up to now, no experimental study provided evidence for these forms in the emitting states of the proteins, as far as for forms protonated on the carbossilic oxygen (quinoid forms, see Figure 139.4). The latter are excluded by calculations in a vast range of pH around the physiological one.[35] Conversely, Raman studies confirm indirectly the attribution of A and B to neutral and anionic states, respectively.[36] The structural changes upon A↔B conversion were addressed by Fourier-transform infrared spectroscopy. No changes linked to a change in Glu protonation and in T203 conformation were observed in the vibrational spectrum.[37] These conclusions were superseded by a subsequent interpretation of the data on the basis of density functional theory (DFT) calculations.[38] We note, however, that the I state was observed also in T203 mutants, which cannot undergo the conformational T203 change.[39] This may indicate that the T203 conformational change is not a main requisite for GFP structural conversions.

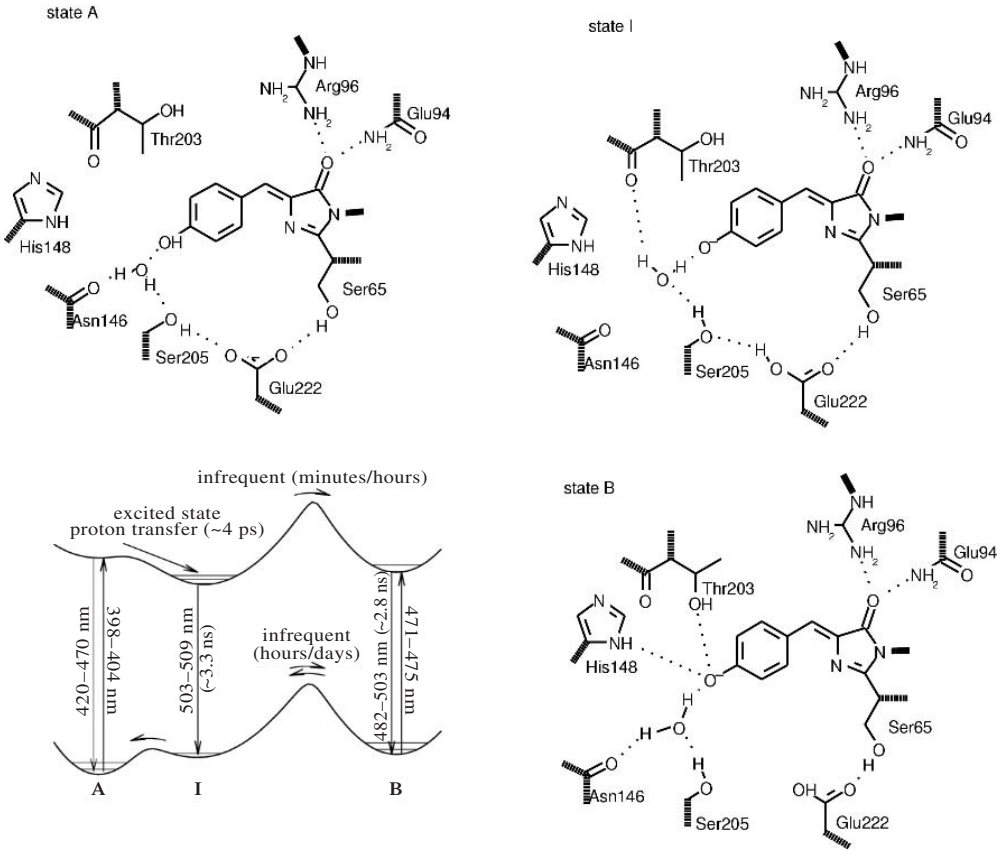

FIGURE 139.3 Structure of the active site of WT-GFP in the bright states and schematic representation of the fluorescence mechanism (bottom-left corner). A state absorbs at 398 to 404 nm (depending on the temperature). The weak direct emission at 420 to 470 nm is competitive with the more favored excited state proton transfer into the excited I state occurring in ~4 ps along the hydrogen bond network connecting the chromophore phenol with Glu222. After emission from I at 503 to 509 nm, the reprotonation of the chromophore occurs in the ground state back from Glu222 to the chromophore penolate along the same hydrogen bond network. State B absorbs at 471–475 nm and emits directly at 482 nm. B and I possess an anionic chromophore but differ in the hydrogen bond configuration, because the network from Glu222 to the chromophore is interrupted in B state.

Phenomenology and Taxonomy of the Mutants: Correlation between Structure and Optical Properties

With the exception of ineffective mutations (such as Q80R appearing in most of the mutants) and the already mentioned folding mutations, mutations occurring in the chromophore or in the chromophore environment can affect one or more steps of the above-described fluorescence mechanisms and change the absorption and emission wavelengths or the equilibrium between A/B/I states.

The large number of engineered mutants makes it necessary to begin this discussion with a classification. In 1998, Tsien[9] divided GFP mutants into seven classes based on the color (blue, cyan, green, and yellow). The green class was, in turn, subdivided into three classes based on the relative population of phenolic and phenolate states: prevalence of phenol (A), prevalence of phenolate (B), and phenol and phenolate mixtures. Here, we extend Tsien's classification also to yellow variants. This has become necessary due to the large amount of yellow mutants investigated in the last years. A list of mutants with some spectral characteristics is given in Table 139.1. For the mutants with atomic structures that are solved, the Protein Data Bank code[40] is also given.

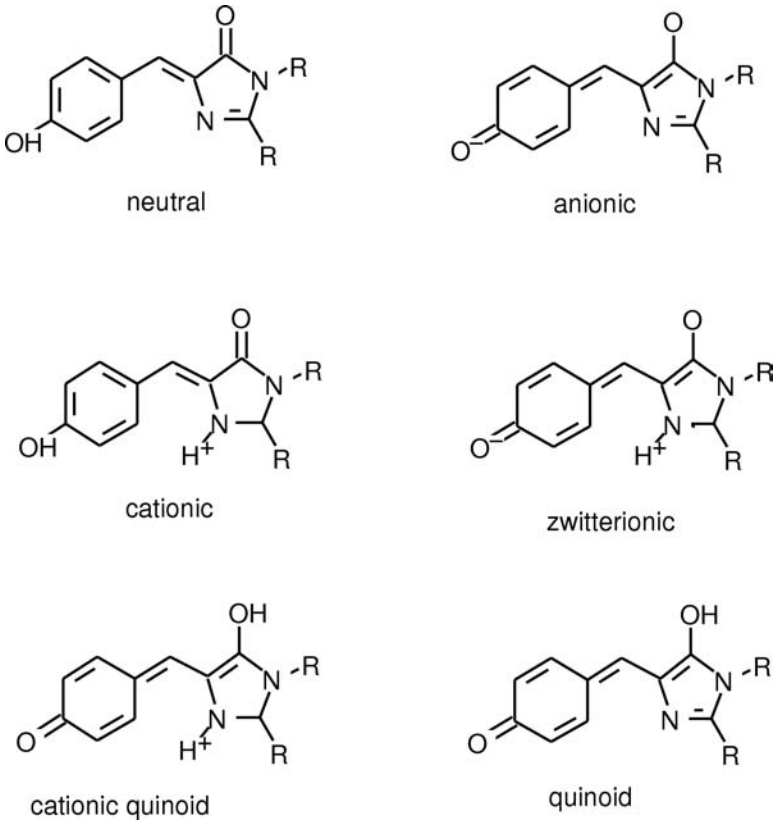

FIGURE 139.4 Possible protonation states of the chromophore. Only the neutral and the anionic forms are thought to be present in the normal state of the protein. The cationic and zwitterionic forms were proposed as candidates for the dark states, while the quinoid forms were proposed to exist in solutions at extremely low pH.[35]

Mutations involving Residues 56 and 66 in the chromophore change the chemical nature of the chromophore and lead to differently colored variants. Chromophore types are reported in Table 139.2. Y66F or Y66H produce blue mutants by reducing the extension of the aromatic system (Classes 6 and 7 in Tsien classification). The same mechanism, to a lesser extent, produces cyan variants for the case of the Y66W mutation (Tsien Class 5). Blue and cyan mutants display only one absorption peak that was associated with state A, because the chromophore is thought to be neutral.[41,43] There is no evidence for ESPT associated to the fluorescence,[44] which is thought to occur by direct A* decay. Even in the presence of folding and enhancing mutations (including Y145F, a specific enhancing mutation for blue variants), cyan and blue mutants present low brightness.

Green and yellow mutants are characterized by a T66 in the chromophore. As already mentioned, these classes are subdivided into three subclasses, i.e., GREEN, GREEN A, and GREEN B (analogous for YELLOW), displaying similar A/B population, prevalent A or B, respectively (see Table 139.1 — these correspond to Classes 1 through 4 in Tsien classification). According to this classification, sgBFP[45] belongs to class GREEN A, although it emits in the cyan.

S65T[32] is the prototype of GREEN B mutants. These are widely used for tagging applications due to their relatively high quantum yield and spectral simplicity (they present a single excitation peak, and ESPT is suppressed). The shift of thermal equilibrium toward B is achieved with different mechanisms. In S65T/C mutants, Thr65 (Cys65) adopts a different conformation with respect to Ser65, forming a less stable hydrogen bond with Glu222 and weakening the hydrogen bond network connecting Glu222 with the chromophore.[32,45] In S65G/A/L mutants, the same effect is produced by eliminating the H-bonding

TABLE 139.1 Classification of GFP Mutants

Class	Mutations	Ref. ([]), Year, Name	PDB Code and Oligomer	Chromophore Type	λ_{exA} (ε 103)	λ_{exB} (ε)	λ_{em} (Q)	A/B Population

Leu (L)				 CLY (510,green)

Note. The names of the chromophore are assigned as follows: C (standing for chromophore) followed by the one-letter notation for amino acids 65 and 66. Residue 67 is always a Gly.

hydroxy group of Residue 65. Mutations of E222 in a residue with opposite polarity (i.e., E222Q) act by disrupting the possibility of donating the proton to the chromophore, again, resulting in a destabilization of A. Finally, I167T, which produces the particularly bright Emerald mutant, adds an additional hydrogen bond donor to the chromophore phenolate, producing additional stabilization of the B state.

Conversely, mutations eliminating a hydrogen donor on the phenolate chromophore, such as T203I and T203V, destabilize State B in favor of A and produce Class GREEN A. These variants emit by ESPT with a relatively high quantum yield and find applications due to their large Stokes shift between absorption and emission.

Mutations of T203 in aromatic residues (F, Y, or H) produce a red shift of 15 to 20 nm in the absorption/emission of State B and of 5 to 10 nm in the absorption of State A, which was attributed to the π-stacking interaction between the chromophore and the aromatic residue.[46] We must note, however, the smaller red shift in A with respect to B and the fact that a slight red shift in B absorption occurs also in the case of T203V. These facts indicate that the elimination of the T203 hydrogen bond in State B must play some role in the red shift of fluorescence. A probable source is the destabilization of the ground state and the consequent reduction of the absorption energy. Accordingly, when only T203Y/F mutations are present, State A tends to be more stable than B, producing the class YELLOW A. In contrast to GREEN A, YELLOW A mutants show relatively lower quantum yields and suppression of ESPT. They were shown to offer some interesting properties at the single molecule level (see next sections). When the typical mutations stabilizing the B state are added (for instance, S65G or the other mentioned above for the green variants), the equilibrium is again restored toward B, and the class YELLOW B is produced, which has similar properties to the class GREEN B.

Acid–Base Equilibria

GFP fluorescence is strongly affected by changes in pH. The chromophore tends to ionize from neutral to anionic in passing from acidic to basic conditions. The population or depopulation of the anionic state is paralleled by an enhancement or quenching of the fluorescence, and thus, the titration curve can be measured with optical techniques, displaying a first titration point (pKa) around pH = 5 (in WT), and a second pKa in basic conditions (around pH = 12[26]). This two-step titration mechanism was interpreted on the basis of force-field-based calculations.[65] In acidic conditions, only the neutral chromophore is present with Glu222 protonated, at basic–intermediate conditions, the protein displays an internal equilibrium between A and B states (shifted on A or B depending on the mutant, see previous section) involving a proton exchange with Glu222. Finally, in basic conditions, the anionic states can only be present with Glu222 deprotonated.

Yellow mutants present particularly high values of the first pKa (~7), which makes them particularly sensitive to pH conditions and not suitable for applications at physiological pH. Q69K reduces the pKa to 6.1, improving folding and thermostability.[62] Mutation Q69M produced the mutant Citrine (pKa = 5.7) that is both less sensitive to pH changes within physiological conditions and more resistant to halide attack.[62] This property stems from the occupation by the Met residue of the halide-binding cavity present in WT-GFP.[62] Conversely, mutation H148G[46] makes the protein more sensitive to the pH conditions (pKa = 8) by producing a "hole" in the β-barrel at position 148 and exposing the chromophore to the solvent. Acidic and halide sensitivity seem to be coupled in YFP-H148Q,[59] where the binding of a halide (I^-) raises the chromophore pKa value.

139.4 Applications to Live-Cell Imaging

Recent experimental results demonstrated that sophisticated optical approaches conjugated with the use of suitable optical tags make it possible to visualize biomolecular events at the surface and in the interior of a living cell, down to the single-molecule level.[6] The application of high-resolution optical spectroscopies to the visualization of proteins labeled with optical tags now offers a series of new tools for the investigation of protein trafficking and interactions inside different cellular compartments. Thanks to the realization of a large set of GFP variants with tunable optical properties, the use of GFPs for live-cell imaging has revolutionized this field in the last years. Particularly relevant is the development and use of suitable GFP markers for the identification of protein–protein interactions *in vivo*. To this end, one of the most powerful optical techniques is based on fluorescence resonant energy transfer (FRET).[66] The development of several pairs of GFP mutants with the required overlap between absorption and emission spectra provided a new arena of FRET applications *in vivo*. In this section, we will mainly concentrate on this application. Before that we recall that FRET exploits radiationless energy transfer driven by dipole–dipole interaction occurring from a fluorophore (the donor) in the excited state to

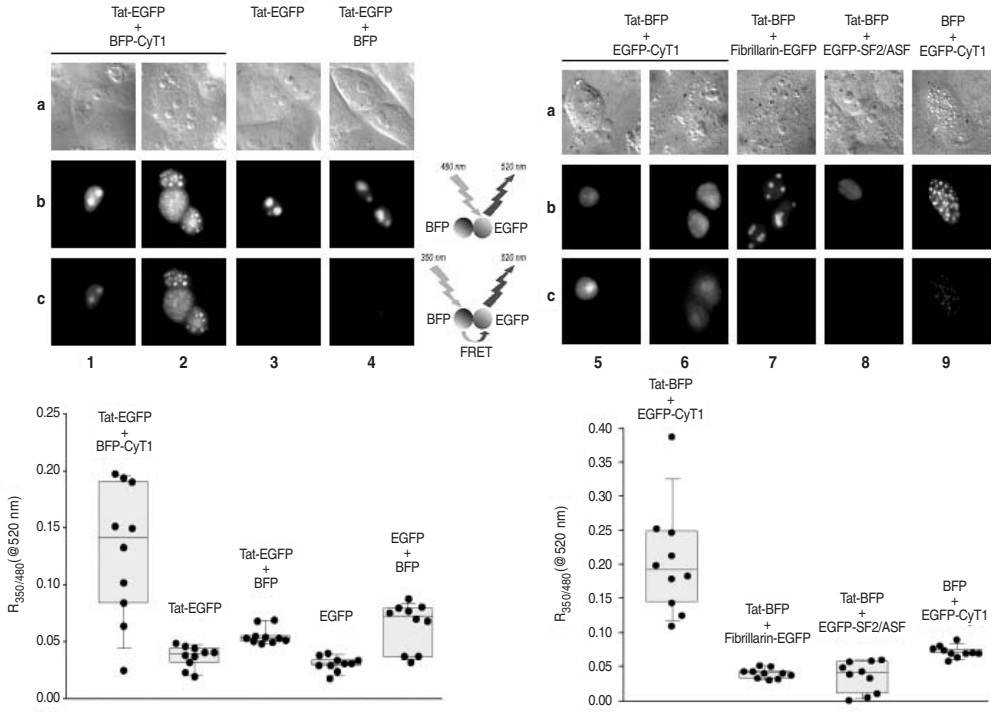

FIGURE 139.5 (Upper) Visualization of FRET in human HL3T1 cells. Transfected cells were visualized by transmitted light in Nomarski configuration (panels in Row a), by excitation at 480 nm, and collection at 520 nm, showing EGFP fluorescence after direct EGFP excitation (panels in Row b), and by excitation at 350 nm and collection at 520 nm, showing EGFP fluorescence after BFP excitation, indicating FRET (panels in Row c). EGFP-SF2/ASF and Fibrillarin-EGFP were generously provided by T. Misteli (National Institute of Health, Bethesda, MD, USA). (Lower left panel) Quantification of FRET between Tat-EGFP and BFP-Cyclin T1. Fluorescent emission at 520 nm from individual cells was recorded after excitation at 350 or 480 nm, and integrated intensities over the whole cell were evaluated. Plotted values (indicated by dots) represent the ratio between these two measurements: higher values indicate more efficient resonant energy transfer between BFP and EGFP. Ten consecutively analyzed cells were considered for each transfection; their individual fluorescence ratios and their percentile box plot distribution are shown. Horizontal lines from top to bottom mark the 10th, 25th, 75th, and 90th percentiles, respectively. (Lower right panel) Quantification of FRET between Tat-BFP and EGFP-Cyclin T1. Graphic representation of FRET is as in the lower left panel. (After Marcello, A., Cinelli, R.A., Ferrari, A., Signorelli, A., Tyagi, M., Pellegrini, V., Beltram, F., and Giacca, M., *J. Biol. Chem.*, 276, 42, 39220–39225, 2001.)

another fluorophore (the acceptor) when in close proximity; energy transfer is followed by acceptor fluorescence. Simple colocalization of two proteins is not sufficient to yield energy transfer. FRET efficiency, in fact, is proportional to $(R/R_o)^{-6}$, where R is the distance between the two fluorophores, and R_o is typically of the order of (or less than) 10 nm: the presence of FRET indicates actual protein–protein interaction at distances of the order of the nanometer for many pairs of optically matched fluorophores.

Shown in Figure 139.5 is an example of FRET observation of protein interaction in human HeLa (HL3T1) cells based on GFP-class tagging.[67] In this experiment, the interaction between two key proteins involved in HIV-1 transcriptional activation, HIV-1 Tat, and human CycT1, was monitored by fusing to them BFP and EGFP mutants. FRET analysis was performed in two steps. First, EGFP fluorescence at 520 nm (this represents the optimum wavelength for EGFP detection) was collected after direct excitation at 480 nm, resonant with EGFP absorption. Second, EGFP emission at 520 nm was measured after excitation at 360 nm, resonant with BFP absorption. In the latter case, EGFP emission mainly originates from the energy transfer. The ratio between the two EGFP emissions provides the FRET efficiency $R_{360/480}$(@520). FRET image analysis of cells transfected with Tat-EGFP and BFP-Cyclin T1 and

controls are shown in Figure 139.5 Panels a1 to c4. Panels (1 through 4) in Row b show the intracellular distribution of fluorescence around 520 nm under excitation at 480 nm. In these conditions, most cells transfected with Tat-EGFP (Panels b1 to b4) showed the characteristic pattern of overexpressed Tat, consisting of diffuse nucleoplasmic fluorescence and intense nucleolar staining. FRET analysis was performed by illuminating the same cells at 360 nm (to excite BFP) and recording at 520 nm (panels in Row c), thus allowing comparison of EGFP emission following BFP excitation with that following direct EGFP excitation. In these conditions, only samples expressing both Tat-EGFP and BFP-Cyclin T1 scored positive for fluorescence (Panels c1 and c2). This result provides strong evidence that the two proteins directly interact inside the cell. Detailed quantitative analysis of several cells transfected with the two proteins or with controls are presented in Figure 139.5(bottom), which shows the experimental FRET signal and its distribution. Most cells transfected with Tat-EGFP plus BFP-Cyclin T1 showed FRET values that were clearly higher than those detected in control transfections. For quantitative analysis based on FRET data, it is often important to eliminate possible artifacts due to different expression efficiencies and quantum yields of the two GFPs. This is particularly relevant for the case of BFP and also for many other EGFP companions in FRET applications. In order to overcome this limitation, one useful additional experiment is to visualize FRET with the reciprocal constructs. In the case of the experiment above described, FRET was analyzed in cells transfected with Tat-BFP and EGFP-Cyclin T1. Also, this protein pair showed intracellular FRET [Figure 139.5, Panels 5 to 9), with acceptor (EGFP) fluorescence in the nucleus (including the nucleolus) after excitation at 350 nm. In contrast, when Tat-BFP was cotransfected with Fibrillarin-EGFP [a protein that specifically localizes in nucleoli, see Figure 139.5, Panels 7] or with EGFP-SF2/ASF [Figure 139.5, Panels 8], which marks sites of mRNA splicing, no FRET was observed. The interaction was also quantitatively analyzed by observing fluorescence in a series of individual cells [see Figure 139.5(lower panels)]. Cells transfected with Tat-BFP plus EGFP-Cyclin T1 showed average FRET values of 0.20 ± 0.08, which were about five times higher than those expressing Tat-BFP and Fibrillarin-EGFP (0.040 ± 0.007) or Tat-BFP and EGFP-SF2/ASF (0.036 ± 0.023; $p < 0.001$ in both cases). FRET values can also be used to address the specific spatial configuration of the two fluorophores. In the case of Tat-CyT1, the observed high FRET signal values imply that the product $n_A \cdot E_T$ between the fraction of EGFPs coupled to a BFP and FRET efficiency is very close to unity.[67] In light of the fact that by definition the two factors have one as an upper bound, this indicates that $E_T \sim 1$. Given the peculiar β-can structure of GFPs, we are led to conclude that the interacting fluorophores are juxtaposed along the β-sheet outer shield with core-to-core distance of approximately 3 nm.

Real-time movement of proteins between different cellular compartments can also be visualized by exploiting GFP optical markers. In these experiments, GFP molecules in a defined area of a living cell are photobleached by an intense laser pulse. The recovery of GFP fluorescence in this area is recorded as a function of time. This technique is called fluorescence recovery after photobleaching (FRAP). Because this recovery is due to movement of GFP-fusion proteins into the bleached area, FRAP analysis allows us to carefully investigate the mobility of proteins in the target area within the cellular environment.[68] Other more sophisticated optical techniques can complement the spectroscopic information with radiative lifetime data, allowing for the development of accurate fingerprints of protein localization and interaction pattern. An important advantage of such lifetime imaging is that the absolute values of lifetimes are independent of the probe concentration, photobleaching, light scattering, and the amount of excitation intensity. Fluorescence lifetime imaging (FLIM) thus offers many additional opportunities for studies of dynamic events in living cells.[69]

139.5 Single-Molecule Photophysics and Applications

Molecular Basis of the ON–OFF Photodynamics

GFP applications are influenced by several photoinduced processes that can drive molecules into states that are dark or have altered fluorescence properties, such as, the already mentioned A → B photoconversion induced by UV illumination of WT-GFP. Another photoinduced process is the conversion to a

red-emitting (~600 nm) species occurring by illumination at 488 nm at low oxygen concentration.[70] However, the more problematic processes are those involving dark states. These affect bulk fluorescence properties but were directly observed and characterized only with the aid of single-molecule techniques. These processes were separated in at least three different classes, based on the different phenomenology: a fast ON–OFF blinking observed during illumination, a photobleaching leading to a long-lived dark state occurring after a certain number of normal photocycles, and, possibly, a recovery of the fluorescence after bleaching induced by illumination at specific wavelengths in the blue-UV range.

Phenomenology

Most of the single molecule experiments were performed on GREEN B and YELLOW class mutants. In general, GREEN B mutants are among the most resistant to photobleaching and blinking, while some yellow mutants revealed an interesting controllable ON–OFF switching behavior. Time-resolved single-molecule spectroscopy and fluorescence correlation experiments were performed on S65T, EGFP, and E222Q,[55,71,72] revealing a common phenomenology: the fluorescence trajectories undergo ON–OFF blinking events until a final long-lived dark state is reached (bleaching). The average ON time during blinking is inversely proportional to the illumination intensity,[71–72] being of the order of tens of ms to s for ordinary illumination intensities. This indicates that turning off is a photoinduced event with a transition yield calculated to be 0.5×10^{-5} in S65T.[73] The average OFF time is of the order of seconds (or tens of seconds[71]) and is not dependent on illumination intensity. Additionally, some experiments[55,71] indicate that more than one process with different timescales may be present in the blinking phenomenology. While single-molecule experiments showed that in EGFP[71] blinking time constants are independent of pH conditions, correlation fluorescence spectroscopy indicates that in EGFP and S65T,[71] the equilibrium time constant between emissive and nonemissive species has two components (both illumination-intensity dependent). One is pH dependent and one is pH independent and is characterized by a much shorter timescale (fraction of ms, *flickering*). Two-color fluorescence correlation spectroscopy on E222Q[72] also revealed a fast dynamics on the order of hundreds of μs. Single-molecule and correlation fluorescence spectroscopy experiments were performed on some YELLOW B class mutants[7,74] displaying almost the same blinking and flickering phenomenology.

In the two YELLOW B mutants S65G/S72A/T203Y(T203F),[7] a controllable switching behavior was observed for the first time. In this work, in addition to blinking (on the timescale of seconds) and photobleaching (after 5 min of illumination), a recovery of the fluorescence was reproducibly observed with 5 min of irradiation at 405 nm. Switching behavior and controllable fluorescence recovery were also observed to occur at a shorter timescale (seconds) in the YELLOW A mutant E^2GFP by illumination in the UV,[60] whereas no fluorescence recovery after bleaching was observed in the same conditions in EGFP.[60]

Photobleaching is usually attributed to a distinct phenomenon with respect to blinking, because it leads to a long-lived dark state after about 10^6 emissive cycles.[7] However, in the literature,[71] the photobleaching observed in bulk experiments for EGFP on timescales dependent on the intensities was associated with the same state transition of blinking, attributed to a bulk manifestation of the latter, and a common transition yield was calculated (3.6 to 8 10^{-6}).

Models

Most of the models for the bright-to-dark dynamics are based on the observation that only B-type states display a significant intrinsic fluorescence. Excitation of State A produces a low fluorescence at about 450 nm, even in mutants with a depressed ESPT. This implies the existence of a nonradiative decay channel for the neutral state, which was identified by some authors[57,70] with a chromophore torsion. According to quantum chemical calculations,[75] the electronic structure of the neutral state allows for the possibility of a nonadiabatic conversion (NAC) between excited and ground state occurring by a torsion of the two bonds connecting the rings. Conversely, owing to the different electronic structure, in anionic species, NAC is not allowed in the restricted volume of the active site, and thus B displays fluorescence. In aqueous

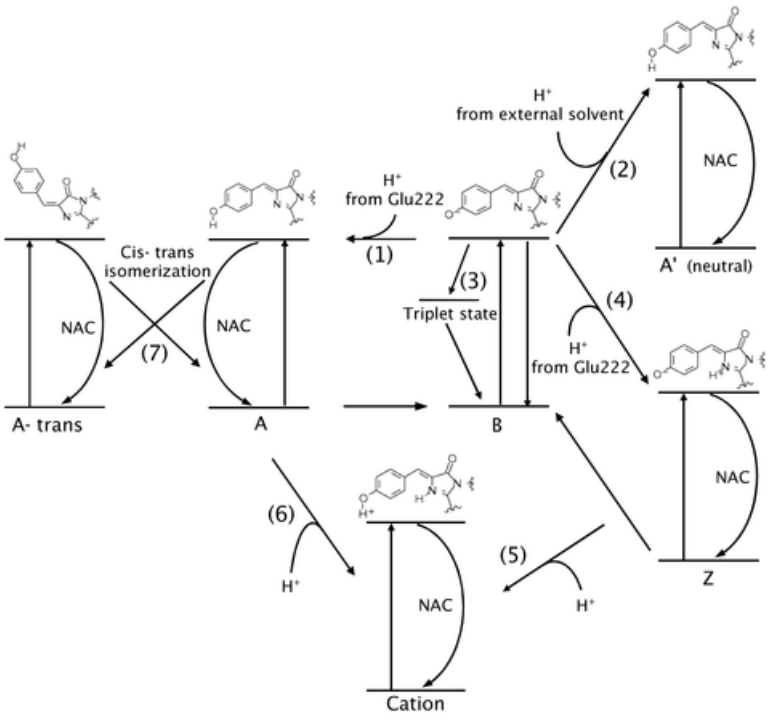

FIGURE 139.6 Hypothetical schemes for blinking, flickering, and photobleaching dynamics. Blinking was attributed to internal (1) or external (2) excited state deprotonation of the chromophore,[56,71–73] or to the zwitterion (Z) formation (4),[70] or the a transient formation to a triplet state (3).[70–71] Process (1) is considered responsible for the photobleaching in mutants where A state is almost dark.[75] The cationic state, reachable by processes (5) or (6) was never seriously considered. Process (7) involving a *cis-trans* isomerization was recently proposed by us as a possible process leading to a reactivable dark state.

solutions, thanks to the absence of the constraints imposed by the protein environment, NAC can always occur, and fluorescence is quenched. Theoretical calculations indicate that the zwitterionic[75] and cationic[76] species are also prone to NAC, and thus can be considered as candidates for the role of dark states.

Following these considerations, several different schemes were proposed to explain the observed phenomenology (Figure 139.6). Several authors[7,71,75] attributed the main blinking component to a B $\rightarrow$ A interconversion with the proton taken from Glu222 (Process 1 in Figure 139.6). The B $\rightarrow$ A process is thought to occur in the excited state, in agreement with the inverse linear dependence of the ON time on light intensity. The inverse process A $\rightarrow$ B is expected to occur in the ground state. The presence of a component dependent on pH in S65T and EGFP was attributed to a different process (Process 2 in Figure 139.6) involving a protonation from the external solvent, leading to a different state (A'), where chromophore and Glu222 are protonated.[71] The fast ms or sub-ms component observed in E222Q and EGFP[77,78] was attributed to a temporary population of the triplet excited state of B (Process 3 in Figure 139.7).

Alternatively, blinking was attributed to the zwitterionic state by several authors, following the scheme suggested in Weber et al.[75] (Process 4 of Figure 139.6). Within the framework proposed by these authors, the B $\rightarrow$ A conversion is responsible for the molecular switching OFF, leading to photobleaching at the bulk level, and lower photostability of yellow mutants reflects the presence of Y203, which yields a larger flexibility in the chromophore environment.

The cationic scheme was discussed by some authors but was not favorably accepted, probably because the two-step process necessary to pass from B to cation is not unique (Processes 5 and 6).

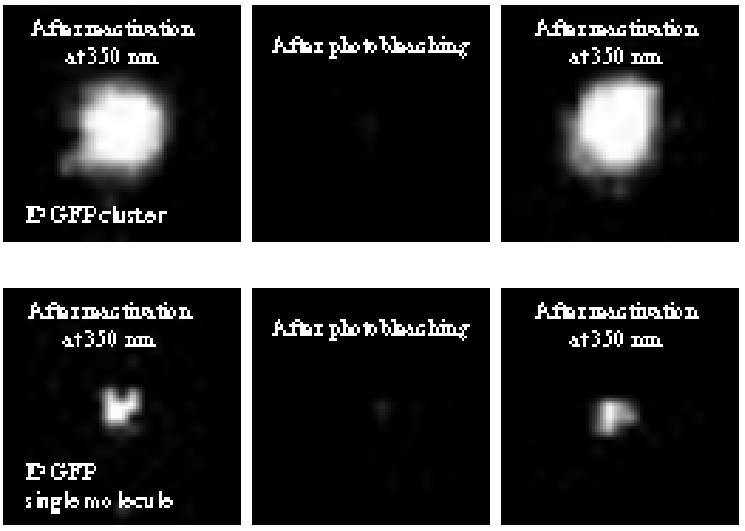

FIGURE 139.7 Typical images (from left to right) of an E²GFP cluster (upper row) and a single E²GFP molecule (lower row) in polyacrylamide (PAA) gels after alternate photobleaching by 10 s excitation at 476 nm and photoconversion by 2 s at 350 nm (0.2 kW/cm² at both wavelengths). Each frame size is 2 μm x μ2 m and integration time 100 ms (After Cinelli, R.A.G., Pellegrini, V., Ferrari, A., Faraci, P., Nifosì, R., Tyagi, M., Giacca, M., and Beltram, F., *Appl. Phys. Lett.*, 79, 3353–3356, 2001.)

As discussed in Section 139.5.1.1, a controllable ON–OFF switching dynamics was recently observed in two different yellow mutants, EYFP[7] and E²GFP.[60] Both of these variants can be reactivated by UV irradiation (400 nm for EYGFP and 350 nm for E²GFP) after bleaching. Notably, E²GFP was reported to require much shorter irradiation times and intensities. In E²GFP, photobleaching was shown to populate a distinct state absorbing at ~365 nm (State C in the following[79]). A theoretical analysis based on *ab initio* calculations indicates that interactions between a chromophore and its environment, such as hydrogen bonds or aromatic stacking, produce a red shift in the chromophore absorption.[34,45,79,80] Consequently, any model for the ON–OFF mechanism should include a neutral chromophore state embedded in an environment forming smaller numbers of or less-stable hydrogen bonds with the chromophore than normal A state. A possibility was suggested[79] for a process of Type 2 in Figure 139.6. Protonation should occur via His148 acting as a proton bridge between the chromophore phenol and the external buffer. At variance with respect to normal A state, Glu222 should be protonated, and this could destabilize some of the hydrogen bonds coordinating the chromophore. An alternative mechanism proposed is based on a *cis-trans* isomerization of the neutral chromophore (Part 7 in Figure 139.6). Nonadiabatic crossing could occasionally convert A* into A-*trans* instead of simply relaxing A* to its ground state. State A-*trans* is dark, because it is prone to NAC, as State A is, and has no possibility of ESPT. This mechanism was supported by Classical Molecular Dynamics simulations that showed that one of the hydrogen bonds on the carbonilic oxygen of the chromophore breaks in the *trans*-neutral state. In this model, the fluorescence recovery can be easily explained as the inverse *trans-cis* isomerization occurring by nonadiabatic crossing (as for the *cis-trans* transition).

The existence of an additional neutral state absorbing at almost the same wavelength as A was previously proposed[81] on the basis of time-resolved single-photon counting spectroscopy, although a role was not assigned to this state in the dark dynamics.

Applications to Bioelectronics

The availability of the distinct photoconvertible ground states in selected GFP variants discussed in the previous paragraph opens the way to the exploitation of these biomolecules for data storage and manipulation

at the single-molecule level, thus expanding the area of GFP applications beyond cell biology. The optical control of the molecular structure as obtained in EYFP and E^{2}GFP represents, in fact, a viable strategy for storing and manipulating data at high density. Among the most remarkable applications, we will mention volumetric memory devices.[82] Prototypes with extremely high capacities, high throughput rates, and fast access times were demonstrated. These concepts, using spectral, spatial, or temporal coordinates, offer attractive alternatives that are compatible with optical interconnection protocols. It is expected that terabits per cubic centimeter storage densities are possible in these volumetric optical memories, with data throughput rates in the range of gigabits/sec and access times of only a few nanoseconds.

Much of the research effort in this direction was directed toward the development of photonic components based on photochromic molecules.[83] Although a number of proteins were explored for device applications,[84] bacteriorhodopsin was the subject of the most intense research effort stimulated by the understanding of the nature of photocycle intermediates and the microscopic pathways connecting them.[85] Following these studies, bacteriorhodopsin-based volumetric optical memories were proposed that exploit photoisomerization between distinct chromophore states populated during the photochemical cycle, and they were shown to offer great improvement in data storage capacity.[86] Bacteriorhodopsin, however, photoisomerizes without fluorescing. This makes it unsuitable for single-molecule detection and use. This ultimate regime represents the most promising strategy toward electronic and photonic detection at the nanoscale level. To this respect, the photochromic GFP variants represent ideal candidates, because their fluorescence can be detected at the single-molecule level.

In the case of the yellow variant E^{2}GFP, in particular, States B and C can be used to encode a (0, 1) bit that can be stored and manipulated in the protein. One possible implementation for the basic operations of writing, reading, and erasing data of a memory device is the following: WRITE corresponds to photoconversion from C to B with irradiation at 350 nm, READ to fluorescence emission following weak excitation at 476 nm, and ERASE to photobleaching (B to C). The latter process can be induced by intense or prolonged excitation at 476 nm. Shown in Figure 139.7 (upper panels) is that controlled photoconversion after irradiation at 350 nm is achieved for a cluster of around 100 E^{2}GFP molecules trapped in polyacrylamide (PAA) gel films. As mentioned above, one important issue for advanced bioelectronic applications concerns the possibility of addressing the protein state at the single-molecule level. This limit was reached in the case of E^{2}GFP optical switching. Individual E^{2}GFP molecules in State B were imaged (Figure 139.7, lower panels) as bright spots at the resolution limit of the optical setup (~0.3 μm). The fluorescence intensity of single spots (~300 CCD counts) was similar to EGFP and displayed the characteristic signatures of single-molecule emission. Most of the molecules blinked and then photobleached within 10 s under excitation at 476 nm. In the lower panels of Figure 139.7, it is shown that the same molecule was repeatedly photobleached by excitation at 476 nm (ERASE), was photoconverted with 350 nm laser irradiation (WRITE), and its fluorescent emission was detected with 100 ms integration time (READ). More recent results demonstrated WRITE processes with irradiation times down to 250 ms.[79]

139.6 Conclusions and Perspectives

Green fluorescent proteins are flexible tools. Their uniqueness stems from the fact that their intrinsically fluorescent chromophore forms autocatalytically during folding, without the need of any external cofactor, and that they can be fused by standard genetic engineering techniques to other proteins. For these reasons, they are considered almost ideal fluorescent markers to monitor protein function and gene expression in living cells. The large quantity of mutants produced in these last decades covers almost all the visible spectrum and this allowed for significant advancements in biotechnology and favorably impacted molecular biology research. In spite of all this, however, the ideal markers do not yet exist. All available mutants suffer from photobleaching and blinking effects that limit their use in biotechnology.

The fluorescence mechanism is known in its general aspects, but the molecular mechanisms underlying the "dark dynamics" are still to be clarified. Detailed knowledge of GFP photophysics would have much impact on single-molecule studies. The development and application of suitable techniques able to probe

protein function down to the ultimate limit of the single-molecule resolution hold the potential to revolutionize modern molecular biology and biomolecular physics. By overcoming the limitation of ensemble averaging, these techniques can address questions that cannot be answered by conventional approaches and can give information on protein function and dynamics with vast impact on biomedicine, diagnostics, and molecular biology.

From another perspective, optical-memory elements that exploit the peculiar photophysics of these proteins show great promise. These molecules are photochemically stable at room temperature; offer photoconnected states addressable to the single-molecule level; and display optical control with wavelength, power, and dynamics suggestive of attractive technological implementations. To this end, further studies aimed at controlling blinking dynamics by appropriate mutant design and at addressing the impact of possible residual blinking events on the ultimate speed of operation of such devices must be carried out. E^2GFP and other mutants that display controllable photochromism can also find new applications in biology, where prolonged monitoring of protein function in living cells is required. Specific mutations that can fine-tune sensitivity to the environments of the optical properties seem to also be at reach. They will lead to highly specialized probes of the cellular milieu that would be of vast interest in cell biology.

Finally, another challenge is the tailoring of the spectral properties of GFP variants, particularly toward the ends of the visible spectrum. Blue variants still suffer from a low quantum yield with respect to green and yellow variants. Furthermore, they display slightly different fluorescence mechanisms, and modeling studies are also lacking for these variants. The other side of the spectrum, the red region, is not covered by GFP mutants, owing to the intrinsic limitations of the chromophore chemical structure. Naturally occurring red proteins have a different chromophore, either modified by a further chemical maturation with respect to the GFP chromophore (such as in DsRed) or produced by a different cyclization process (like in the AsCP). Investigation and tailoring of these variants are at their infancy, and much room for improvement in the photophysics of these molecules is available. It will result only from a detailed understanding and quantitative modeling of their properties.

Acknowledgments

We wish to thank Caterina Arcangeli, Riccardo Cinelli, Aldo Ferrari, Mauro Giacca, Alessandro Marcello, and Riccardo Nifosì, for useful discussions. This work was supported by grants from INFM/B/G (Istituto Nazionale per la Fisica della Materia, Sections B and G).

DNA Damage and Repair

David L. Mitchell
M.D. Anderson Cancer Center

140.1 Introduction

Ultraviolet radiation (UVR) is a primordial and ubiquitous genotoxin. During the earliest stages of molecular evolution as the dynamics of DNA chemistry were being formulated, the surface of the planet was bombarded by extremely high levels of UVR. Any DNA exposed to sunlight during or soon after the genesis of life would require rapid and accurate repair of UVR damage for continued survival and procreation. Hence, it is probable that mechanisms of DNA repair evolved early in the Earth's history and, in fact, may have coevolved with DNA replication and transcription. Today, the amount of UV-B radiation reaching the earth's surface increased due to industrialization and chlorofluorocarbon pollution of the upper atmosphere. The consequences of stratospheric deozonation and increased UV-B exposure to the human population are difficult to predict, but research over the past 40 years suggests that accelerated rates of skin cancer and aging as well as deterioration of the natural environment and major food crops are probable outcomes.

Due to their strong absorbance within the UV-B region of the solar spectrum (290 to 320 nm), certain nucleic and amino acids are considered the primary chromophores of UVR. RNA and proteins are encoded by DNA and are readily replaced by the cellular machinery. DNA, on the other hand, requires an intact copy of itself for replication, and any mistakes made during the replication process can result in mutation, loss of fitness, and cell death. The absorption spectrum of DNA correlates well with photoproduct formation, cell killing, mutation induction, and carcinoma. UVR induces a plethora of structural lesions in DNA that can be detected and measured using a variety of analytical techniques. The sensitive and precise measurement of DNA damage and repair are essential for understanding the lethal and mutagenic effects of UV-induced photoproducts on individual cells and complex organisms. Indeed, over the past 30 years, these techniques were instrumental in revealing the many faces of DNA repair, ranging from the relatively simple photoenzymatic repair system to the elegant interactions of the nucleotide excision repair complex. Our current knowledge of DNA damage and repair derives from a broad range of scientific disciplines, including environmental, evolutionary, cellular, molecular, and structural biology. Indeed, connections between DNA repair and such fundamental cellular processes as transcription and the cell cycle attest to the importance of this ancient and essential biochemical process.

140.2 Biological Significance

The sun emits energies at wavelengths that range through 17 orders of magnitude, from 10^{-4} nm to 10^{12} nm.[1] The vast majority of this energy is biologically irrelevant; short wavelength radiation such as high-energy particles, x-rays, and gamma rays are expended by atomic collisions in the upper atmosphere, and long wavelength far infrared, microwaves, and radiowaves do not have sufficient energy to influence biochemical reactions. Although UVR comprises a minute portion of the total solar output of energy, its biological impact is, by comparison, immense. UVR is divided into three regions: UV-C (240 to 290 nm) is not present in ambient sunlight but is readily produced by low-pressure mercury sterilizing lamps. The peak wavelength of mercury excitation (254 nm) coincides with the peak of DNA absorption (260 nm), and this wavelength has been of major importance in experimental studies. Fortunately, wavelengths below -295 nm are catalytically absorbed by ozone molecules in the stratosphere (i.e., O_3: O_2 + O), and little light shorter than 300 nm reaches the earth's surface. UV-B (290 to 320 nm) overlaps the upper end of the DNA and protein absorption spectra and is the range mainly responsible for environmental and pathological effects through direct photochemical damage to DNA. UV-A (320 to 400 nm) is photocarcinogenic and involved in photoaging but is weakly absorbed in DNA and protein. The relevant chromophores for UV-A probably involve reactive oxygen species (ROS) that secondarily cause damage to DNA.

UV-B is a potent and ubiquitous carcinogen responsible for much of the skin cancer in the human population today.[2,3] Tumor incidence and mortality correlate with exposure: basal and squamous cell carcinomas are most prevalent on the faces and trunks of men and on the faces and legs of women; carcinomas increase with decreasing latitude; tumor incidence is increased in individuals working in occupations with high exposure, such as ranchers or fisherman; and the protective action of skin pigmentation results in lower cancer rates in dark-skinned populations compared to lighter-skinned populations. The importance of UV-B damage and its repair in humans is exemplified by genetic diseases that greatly increase the risk of sunlight-induced skin cancer. In one such disease, xeroderma pigmentosum, a failure in the DNA repair process is associated with a major increase in the rate of squamous and basal cell carcinoma and melanoma. Although UV-B is probably responsible for most of the biological effects of sunlight, lower-energy UV-A comprises the bulk of the solar UVR reaching the earth's surface and, hence, is not without biological importance.

There is now strong evidence that UVR is increasing over many locations on the earth's surface, with the most significant ozone depletion observed over Antarctica and parts of the Southern Ocean, Australia, and New Zealand.[4] Marine plankton comprise the base of oceanic food webs and are sensitive to UV-B stress. There is growing evidence that UV-B and UV-A radiations inhibit primary and heterotrophic production. Ozone thinning, particularly during the austral spring over Antarctica, selectively allows penetration of higher-energy UV-B wavelengths through the upper atmosphere, and the proportion of UV-B relative to UV-A increases. UV penetration in the water column is also selective and wavelength dependent. UV-B is attenuated by water to a greater degree than UV-A, hence, with increasing depth, the proportion of UV-A relative to UV-B increases. Marine organisms are exposed to significant amounts of solar UV-B, even under normal ozone conditions, but organisms living near the surface of the ocean under low ozone conditions are exposed to particularly high levels.

The biological effects of DNA photodamage depend on the type of lesion induced and its genomic location, as well as the nature of the target cell and its developmental state. If the photoproduct is repaired correctly, the DNA is restored to its original state, and after some delay, the cell proceeds with its normal activities. If the damage is not repaired, it may interfere with DNA replication or transcription. Should this occur, cell proliferation will cease or, if the block is situated in a gene required for an essential metabolic function, the cell will die. Alternatively, the damage may not block replication. Bypass of the lesion by a DNA polymerase may produce an incorrect complementary base (i.e., a mutation) that can have several possible outcomes:

1. It may not alter the genetic code and, hence, not affect normal metabolism.
2. It may produce a truncated or partial RNA transcript encoding a dysfunctional protein.
3. It may result in activation of an oncogene or inactivation of a tumor suppressor gene, thereby initiating the carcinogenic process.

140.3 DNA Photoproduct

Photon absorption rapidly converts a pyrimidine base to an excited state.[5] This event promotes an electron in a filled bonding orbital in the singlet ground state into a higher energy, empty * antibonding orbital, thus initiating photoproduct formation. Formation of an excited base occurs within 10^{-12} sec after photon absorption. Various pathways are then available for resolution of this unstable electronic configuration. The major pathway involves rapid dissipation of the energy of the excited singlet base to the ground state (10^{-9} sec) by nonradiative transition or by fluorescence, yielding heat or light in the process. Second, the excited base can react with other molecules to form unstable intermediates (i.e., free radicals) or stable photoproducts. Finally, there is a low probability that intersystem crossing, another nonradiative pathway, can transfer a base from the excited singlet state to the excited triplet state. The lifetime of the triplet state is several orders of magnitude longer than the excited singlet state (10^{-3} sec), increasing the chance of photoproduct formation. Formation of the triplet state can be greatly enhanced in the presence of ketone sensitizers.

Dimerizations between adjacent pyrimidine bases are by far the most prevalent photoreactions resulting from UVC or UV-B irradiation of DNA (Table 140.1), with the relative induction dependent on wavelength, DNA sequence, and protein–DNA interactions.[6] The major photoproducts in DNA are the cyclobutyl pyrimidine dimer (CPD), formed through the excited triplet state, and the pyrimidine-(6–4)pyrimidone dimer [(6–4)PD], formed from a Paterno–Büchi reaction. The (6–4) photoproduct undergoes further UV-B-dependent conversion with its valence photoisomer, the Dewar pyrimidinone. In addition to the major photoproducts, rare dimers may also form, such as the adenine-thymine heterodimer or the 2-imidazolone(5–4)pyrimidone product, another photoisomerization product of the (6–4)PD.

The yield of the individual types of dimers is dependent on the nucleotide composition in and around the potential lesion as well as the wavelengths of UVR used to induce the damage.[7] The induction of both CPDs and (6–4)PDs is greater in the presence of 5′ flanking pyrimidines compared to purines with guanine inhibiting induction more than adenine. UV-B irradiation increases the relative induction of cytosine-containing cyclobutane dimers compared to thymine homodimers.[8] The (6–4)PD is induced primarily at T-C and to a lesser extent at C-C dinucleotides, and its formation is not as wavelength-dependent as the CPD. Although the T-T (6–4)PD is refractory to piperidine digestion and is not detected using conventional sequencing techniques, it may occur at levels comparable to the T-C (6–4)PD in DNA.[6] Cytosine methylation significantly increases the yield of (6–4)PDs after irradiation with UV-C light and of cytosine-containing CPDs and (6–4)PDs after irradiation with UV-B light. The data suggest that CPDs and (6–4)PDs are preferentially induced at 5-methylcytosine bases in DNA of cells exposed to sunlight. And, they comprise a major component of the mutation spectrum leading to the initiation of sunlight-induced skin cancer.[9,10]

The organization of chromatin into nucleosomal particles connected by linker DNA influences sites of dimer induction.[11] Limited flexibility of the DNA helix resulting from histone–DNA interactions inhibits CPD formation and modulates their distribution along DNA with a periodicity of 10.3 bases. Whereas CPDs form with equal efficiencies in core and linker DNA, (6–4)PDs occur with sixfold greater frequency per nucleotide in linker DNA. The preferential formation of the (6–4)PD in "open" chromatin configurations (e.g., transcriptionally active genes and regulatory sequences) may enhance the biological impact of this lesion and partially explain its preferential repair (see below).

In contrast to the direct induction of DNA damage by UV-C and UV-B light, UV-A produces damage indirectly through highly reactive chemical intermediates.[6] Similar to ionizing radiation, UV-A generates

TABLE 140.1 Structures and Relative Induction Frequencies of the Major Photoproducts Induced by UVR

Photoproduct	Structure	Lesions/10^8 Da	J/m^2	% of total photoproducts	
		UV-C	UV-B	UV-C	UV-B
Cyclobutyl pyrimidine dimer		2.3	0.30	77	78
Pyrimidine pyrimidone [6-4]-photoproduct		6 x 10-1	4 x 10-2	20	10
Dewar pyrmidinone		2.3 x 10-2	~4 x 10-2	0.8	10
Adenine-thymine heterodimer		6 x 10-3	nd	0.2	nd
Pyrimidine pyrimidone [5-4]-photoproduct		nd	nd	nd	nd
Cytosine photohydrate		5 x 10-2	6.6 x 10-3	~2	~2
Thymine photohydrates		nd	nd	nd	nd
Single-strand break		~5 x 10-4	~4 x 10-6	<0.1	<0.1
DNA-protein crosslink		~3 x 10-4	~1 x 10-6	<0.1	<0.1

oxygen and hydroxyl radicals, which in turn, react with DNA to form monomeric photoproducts, such as cytosine and thymine photohydrates, photooxidation products (such as 8-oxodeoxyguanine), as well as strand breaks and DNA-protein cross-links (Table 140.1). The relationship between the frequencies of these photoproducts and their biological effects depends on the cytotoxic and mutagenic potentials of the individual lesion. Hence, even though a photoproduct may occur at a low frequency, its structure and location may elicit a potent biological effect.

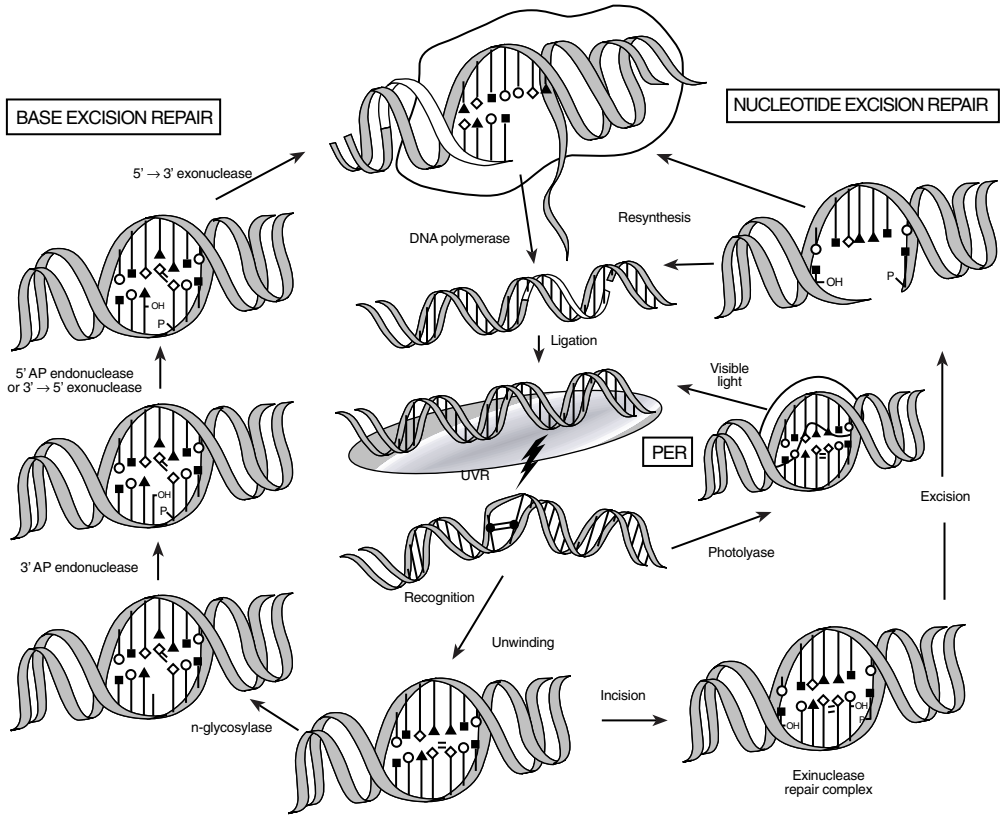

FIGURE 140.1 Enzymatic pathways for the repair of UVR damage in DNA. Shown are photoenzymatic repair (PER), base excision repair, and nucleotide excision repair.

140.4 Detection of DNA Damage

A variety of analytical procedures were developed to measure UVR damage and repair in DNA.[12–14] Many types of photoproducts have been identified and quantified by chromatographic techniques. Since the initial detection of the CPD by two-dimensional paper chromatography, thin-layer chromatography, and high-performance liquid chromatography were adapted to the analysis of this and other types of damage. All of these procedures require DNA that was prelabeled with a radioactive tracer (e.g., ^{3}H-thymidine) and hydrolyzed to free bases or nucleotides by enzymatic digestion or treatment in strong acid at high temperature. Development of ^{32}P-postlabeling procedures obviated the need for prelabeling and expanded the sample repertoire available to chromatographic techniques.

Many types of photodamage can be converted into single-strand breaks in DNA by enzymatic or biochemical treatment. Frank breaks induced directly in DNA by UV and breaks produced at sites of photoproducts by targeted enzymatic or biochemical procedures can be quantified by alkaline gradient centrifugation, alkaline elution, or agarose gel electrophoresis. The sensitivity of these procedures requires maintenance of high-molecular-weight DNA throughout the extraction and analytical procedures. *Uvr*ABC exinuclease, a partial excision repair complex purified from *Escherichia coli*, cleaves DNA on either side of a bulky adduct [e.g., CPD or (6–4)PD; see Figure 140.1, right side]. *Uvr*ABC and the yeast UV DNA damage endonuclease (UCDE) are used to cut sites of CPDs and (6–4)PDs prior to molecular weight analysis. *In vitro* repair by CPD or (6–4)PD photolyase prior to digestion with *uvr*ABC or UVDE focuses the analysis on one or the other photoproduct.

More specific cleavage was achieved by using purified glycosylase-endonucleases from various prokaryotic hosts, primarily *E. coli*. These enzymes combine a glycosylase that cuts the base from the sugar, leaving an apyrimidinic (AP) site, and an AP endonuclease that cleaves the phosphodiester backbone on either side of this site (Figure 140.1, left side). These enzymes range from the CPD-specific T4 phage endonuclease V and 8-oxodeoxyguanine-specific oxoguanine glycosylase (OGG) to more broad-spectrum reagents like endonuclease III (nth) and formamido glycosylase (fpg) that cut a variety of photohydrates and photooxidative products. Nonenzymatic cleavage of alkali-labile sites, such as AP sites or Dewar pyrimidinones, also produces quantifiable strand breaks for analysis of induction and repair.

These techniques were recently adapted to the analysis of UV photoproduct induction and repair at the gene and base sequence levels. Photodamage at the gene level can be mapped as strand breaks in DNA fragments irradiated with high doses of UV-C and UV-B light, and at the gene level using Southern blot hybridization of DNA fragments separated by denaturing agarose gel electrophoresis. Alternatively, gene damage can be measured using quantitative PCR, a technique dependent on the ability of a lesion to block progression of Taq polymerase. Highest resolution is obtained using ligation-mediated polymerase chain reaction, whereby the distribution of photoproducts at the sequence level can be quantified.

In addition to molecular biology techniques, various immunological procedures are available for DNA damage analyses. Polyclonal and monoclonal antibodies recognize and bind a variety of photoproducts, including the CPD, (6–4)PD, Dewar pyrimidinone, and 8-oxodeoxyguanine. Techniques such as immunoprecipitation, enzyme-linked immuoassays, dot and slot-blot assays, radioimmunoassays, quantitative immunofluorescence, and immunoelectron microscopy are powerful analytical tools; each with its own unique attributes and applications. Unlike chromatography, immunological assays do not require chemical or enzymatic degradation of DNA before analysis; unlike assays that require strand scission, sensitivity does not depend on the molecular weight or purity of sample DNA.

140.5 DNA Repair

The total number of photoproducts remaining in cellular DNA at any time depends on the amount of UVR absorbed and the amount of damage repaired. Damage tolerance strategies are complex and vary greatly among organisms and at different times during development.[15,16] Nearly all organisms have behaviors or natural features that mitigate exposure of DNA to solar UVR and reduce the amount of photodamage. In addition to habitat selection, avoidance responses, and physical morphologies that attenuate the transmission of UVR to sensitive, internal areas of cells, many organisms evolved biochemical mechanisms to protect themselves. UVR-absorbing compounds such as melanin and anthocyanin are produced in human skin and in plants; colorless UV-absorbing compounds, such as flavonoids in terrestrial plants, mycosporine amino acids in fungi, and mycosporine-like compounds in marine organisms, were also identified as possible UV-protective chemicals.

Once DNA damage is present, its removal may proceed in whole or in part by at least two well-studied mechanisms, photoenzymatic repair (PER)[17] or excision repair (Figure 140.1). PER involves specific recognition and binding of a small enzyme called a photolyase to a cyclobutane dimer. This enzyme catalyzes the direct reversal of the dimer upon absorption of a photon within the UV-A/visible range of light. Photoreactivation occurs widely throughout the plant and animal kingdoms.[15] Its presence and operation in placental mammals, particularly in human skin, are matters of some controversy.

Organisms that display reduced PER often have a greater capacity for excision repair. The excision repair mechanism utilized by the cell depends on the type of damage encountered and the location of the damage in chromatin. Two major pathways of NER are transcription-coupled repair (TCR) and global genome repair (GGR),[3,18] both of which remove CPDs and (6–4)PDs in DNA and replace the damaged site with a newly synthesized polynucleotide patch ~29 bases in length. TCR removes damage preferentially from transcribing strands.[19] GGR is targeted to nontranscribed regions and is regulated by p53 through expression of the XPE p48 protein. There is considerable difference in the rates of removal of CPDs and (6–4)PDs in the genome overall. In rodent and human fibroblasts, the half-life for (6–4)PD removal is 6 h; the half-life for CPD repair is 24 h in human cells and considerably longer (>72 h) in

rodent cells. The excision of CPDs may be partly delayed, because the strong affinity of the excision system for (6–4)PDs initially sequesters available enzymes. The different rates of excision may also reflect the fact that (6–4)PDs are considerably more distortive in DNA and are preferentially located in internucleosomal regions of DNA.

The differences in excision from active and inactive genes occur because the general transcription factor, TFIIH, regulates basal transcription by RNA polymerase II and plays a major role in repair. Many of the genes that regulate TCR are associated with the human disorders xeroderma pigmentosum (XP), Cockayne syndrome (CS), trichothiodystrophy (TTD), and other disorders.[3] Two of the helicases in TFIIH correspond to the *XPB* and *XPD* genes. TCR also involves the Cockayne syndrome genes, *CSA* and *CSB*, *XPG*, the mismatch repair gene *MLH2*, and the breast cancer susceptibility gene *BRCA1*. The XPC-hHR23B complex is involved in earliest damage recognition, initiates NER in nontranscribed DNA, acting before the XPA protein, and serves to stabilize XPA binding to the damaged site with a high affinity for the (6–4)PD. This complex is specifically involved in GGR but not TCR, where the arrest of RNA polymerase II at a damaged base may function in its place. The core protein factors include the XPA-RPA dimer, the 6 to 9 subunit TFIIH, the XPC-hHR23B complex, the XPG nuclease, and the ERCC1-XPF nuclease. After assembly, the XPC-hHR23B complex dissociates, the XPG protein cuts 3′ to the lesion, and the ERCC1-XPF heterodimer cuts 5′ to the CPD. The nuclease complex plus the 29 to 30 nt single-strand fragment is released by the action of transcription factor TFIIH. The XPG protein is also required for TCR of oxidative damage and is a cofactor for endonuclease III. Once this oligonucleotide is removed, the resulting gap is filled by DNA Pol D, proliferating cell nuclear antigen (PCNA), and single-strand-binding protein and ligase. These processes involve sequential steps of photoproduct recognition, assembly of the excision complex, displacement of the excised fragment, and polymerization of the replacement patch.

Base excision repair is initiated by enzymatic recognition of the lesion and scission of the bond between the damaged base and its associated deoxyribose sugar, a process called aglycosylation (Figure 140.1, left side). Examples of *n*-glycosylases include endonuclease III from *E. coli*, which repairs photohydrates, and endonuclease V from T4 phage, which recognizes CPDs (see above). In the latter case, cleavage of the *n*-glycosyl bond of the 5′ pyrimidine base leaves an abasic site that is subsequently recognized by an AP endonuclease that cleaves the phosphodiester bond 3′ to the abasic site. The remaining abasic site is digested with a 5′ AP endonuclease or 3′6 5′ exonuclease associated with DNA polymerase. The damaged strand is removed and resynthesized by a DNA polymerase complex, and the remaining gap is ligated.

140.6 Summary

The clinical effects of defective DNA repair can include increased risk of skin cancer and accelerated aging, as well as neurological and growth disorders. This phenotypic heterogeneity belies the complexity of the excision repair process and presents a formidable task in defining the functions of the various proteins involved in DNA repair. Advances in cloning the genes involved in DNA repair in mammals, yeast, and *Drosophila melanogaster* have greatly increased our understanding of the DNA repair process. In addition to defining the components of an ancient and essential molecular process, future studies in DNA repair may help direct the prevention and clinical treatment of sunlight-induced skin cancer and lessen the impact of stratospheric deozonation on the human population.

141.1 Biological Background

The harmful wavelengths of sunlight belong to the UV-B/C region between 260 and 320 nm. These wavelengths damage DNA and proteins. They are, to a great extent, filtered out of the solar radiation by the ozone layer, which forms an efficient UV-shield in the upper stratosphere.[1,2] Anthropogenous factors, however, have over the past decade severely reduced the amount of ozone.[3,4] This, in turn, led to a measurable increase in UV radiation, which now reaches the surface of our planet. It is estimated that UV radiation increased by about 10% in Western Europe.[5] The ozone hole, which appears every year during the Antarctic spring, is an area in which the ozone layer is almost completely diminished. It is the most prominent example of how anthropogenic emissions of nitric oxide and other ozone-degrading gases trigger the decrease of the ozone shield, leading to an increase in UV radiation.

UV radiation is harmful for all organisms that live exposed to sunlight. The energy-rich UV-C radiation damages particularly the genome of exposed cells, because the DNA bases exhibit absorption bands around 260 to 280 nm. The light absorption transfers the bases into their excited singlet and triplet states, out of which chemical reactions occur. These lead to severe base modifications[6,7] accompanied by a change of the base pairing properties, which in turn, causes mutations. Herein the most important UV-induced base modifications together with the light-dependent repair processes developed by nature to counteract the harmful effect of base lesions will be covered in this review.

The UV-induced base modifications, generally termed UV-induced DNA lesions, are the fundamental reasons for the development of skin cancer.[8–12] It is today known that every human being has an individual sunlight account. Too much sunlight, and hence too much UV irradiation, which induced too many DNA lesions, particularly during the early years of our life, triggers as the ultimate consequence the development of skin cancer. Skin cancer is today one of the most prevalent forms of cancer. The three most prominent forms are basal cell carcinoma, squamous cell carcinoma, and malignant melanoma. The first two variants contribute about 90 to 95% of all skin cancer incidents. Incidents of 5 to 10% are due to malignant melanoma, which is the most dangerous form of skin cancer because of the rapid

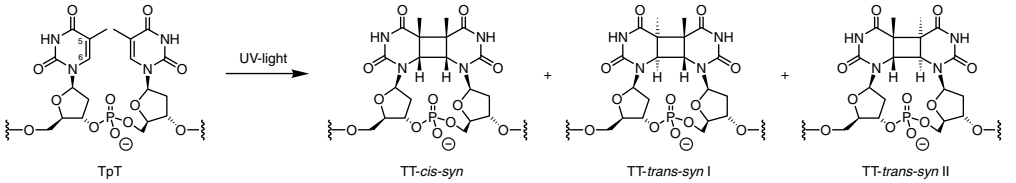


SCHEME 1 Three cyclobutane thymidine dimer DNA lesions (*cis-syn*, *trans-syn* I, *trans-syn* II) formed after UV irradiation of TT sequences in DNA.

formation of metastases.[13,14] In 1980, about 1600 people died from malignant melanoma in Germany. In the year 2000, the death toll rose to about 2100, which represents a 30% increase. Worldwide, the number of new skin cancer incidents was estimated by the World Health Organization (WHO) to be around 130,000 cases, with about 35,000 deaths directly linked to skin cancer.[15,16]

What is our key hint in linking these skin cancer cases to UV irradiation? Analysis of the *p53* tumor suppressor gene from basal and squamous cell carcinomas showed in more than 30% of all investigated cases deleterious mutations in this critical gene, which is the guardian of the cell.[17] Approximately 68% of the detected mutations are C → T transitions, which in over 90% of cases, are present at dipyrimidine sites.[18–20] Tandem-transition mutations CC → TT make up about 14% of all detected *p53* mutations.[13,14,21,22] These C to T transitions, particularly at dipyrimidine sites, are so-called fingerprint mutations. They are formed due to DNA replication mistakes made by the cell in the presence of UV-induced DNA lesions. The main mechanisms believed to be responsible for these mutations are also covered in this review.

141.2 The Chemistry of Lesion Formation

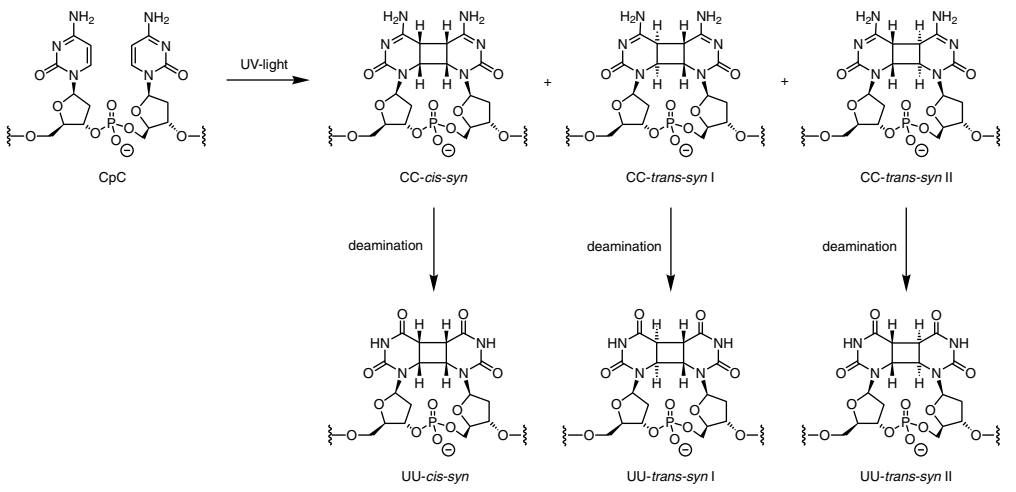
Cyclobutane Pyrimidine Dimers

Lesion Formation

Absorption of light around 260 nm by the DNA bases, particularly by the pyrimidine bases thymine and cytosine, results in the formation of cyclobutane pyrimidines dimers at dipyrimidine sites. The reaction depicted in Scheme 1 for thymidine is a [2π + 2π] cycloaddition reaction between the two C(5) = C(6) double bonds. The reaction furnishes three isomers: *cis-syn*, *trans-syn* I, and *trans-syn* II. Due to the constrains imposed by the DNA double strand, the *cis-syn* dimer is the major photoproduct.[18,23–25] It is formed when both pyrimidines adopt a *syn*-conformation around the glycosidic bond, which is the case in the double-strand environment. For both *trans-syn* photoproducts, one of the pyrimidines has to react out of the *anti*-conformation. This conformation is energetically more costly, and consequently, the reaction is less likely. Cyclobutane pyrimidine dimers are formed predominantly at TT sites, but cytosines can react as well (Scheme 2). The cyclobutane thymine dimer reaction products show only a weak absorption in the UV-C regime. Because the dimer formation is reversible (irradiation of cyclobutane pyrimidine dimers with UV light splits the dimer), this absorption characteristic drives the photostationary state toward dimer formation. The cyclobutane cytosine dimers feature residual absorption in the UV-C region and, therefore, give a photostationary state with a much smaller photoproduct content.[26] HPLC-MS/MS investigations provided detailed information about the relative yields of the various cyclobutane pyrimidine dimers after UV irradiation of DNA.[27] The relative ratios of all *cis-syn* dimer reaction products are: 5′-TT-3′, 5′-TC-3′, 5′-CT-3′, 5′-CC-3′ (2:1:0.4:0.1).

Structural Effects and Repair by the Nucleotide Excision Repair System

All of these cyclobutane pyrimidine dimers cause a structural distortion of the DNA double helix and a significant destabilization of the duplex around the lesion. The destabilizing effects are, however, different for the *cis-syn* and the *trans-syn* dimers. Detailed melting point studies,[28] theoretical calculations,[29–31]



SCHEME 2 Formation of the cyclobutane cytosine dimers and of their deamination products, which are uridine-containing dimer lesions.

and NMR structural investigations[28,32–34] showed that the predominantly formed *cis-syn* lesions induce relatively small structural changes. The DNA double helix is bent by about 7 to 10°. The 3′-T of the T = T dimer remains well paired in the double strand, whereas almost no pairing occurs at the 5′-side of the DNA lesion. Overall, one T = T dimer destabilizes a DNA duplex approximately like one mismatch. Interestingly, the destabilization of a DNA:RNA double strand by a *cis-syn* dimer, which exists in the A conformation, is much less pronounced.[35,36] This could indicate that the dimer lesion is much better at accommodating in duplexes that have more A-like conformations. The destabilization effects of *trans-syn* dimers are significantly stronger, as are the structural distortions.[37] None of the two *trans-syn* dimers fit into a DNA double helix.

The amount of destabilization caused by a lesion is of paramount importance. All DNA lesions have to be removed from the genome in order to avoid cell death and mutagenesis. This is performed by a series of repair proteins and repair factors.[38] Some are believed to recognize DNA lesions based on their destabilization effect.[39,40] The UV lesions are generally repaired by the nucleotide excision repair pathway (NER), where a small piece of DNA around the lesion is excised.[38] It is known that this repair system recognizes DNA lesions predominantly based on their disturbing effect on the duplex structure. Based on our knowledge of how lesions destabilize the duplex, it can now be rationalized why repair of the *cis-syn* cyclobutane thymidine dimer is, in general, so sluggish, and in certain sequence contexts, almost not measurable.[18] These lesions cause simply only a small destabilization, which is readily overlooked by the nucleotide excision repair system. The large destabilization induced by the *trans-syn* dimers makes them, in contrast, excellent substrates for the nucleotide excision repair machinery.

The Mutagenic Potential of the Cyclobutane Cytosine Dimer Lesions

Particularly mutagenic are the cytosine-containing cyclobutane pyrimidine dimers depicted in Scheme 2.[41] The cytosine unit within a cyclobutane pyrimidine dimer rapidly hydrolyzes under physiological conditions.[42] In fact, the half-life time of a dihydrocytosine in a cyclobutane-type UV lesion was estimated to be just around 1.5 h for CpT *in vitro* and 5 h *in vivo*.[43,44] The hydrolysis furnishes uridine-containing lesions, as shown in Scheme 2 and Figure 141.1(a). These lesions instruct polymerases to incorporate an adenine as the counterbase if the polymerase reads over the lesion (Figure 141.1) upon copying the DNA strand.[41] This gives a U = U:AA double mismatch sequences which will subsequently force any repair system to replace the U = U lesion with two thymidines. This mechanism could be one main reason for the observed C → T and CC → TT transitions in the genes of skin cancer cells.[42] Another

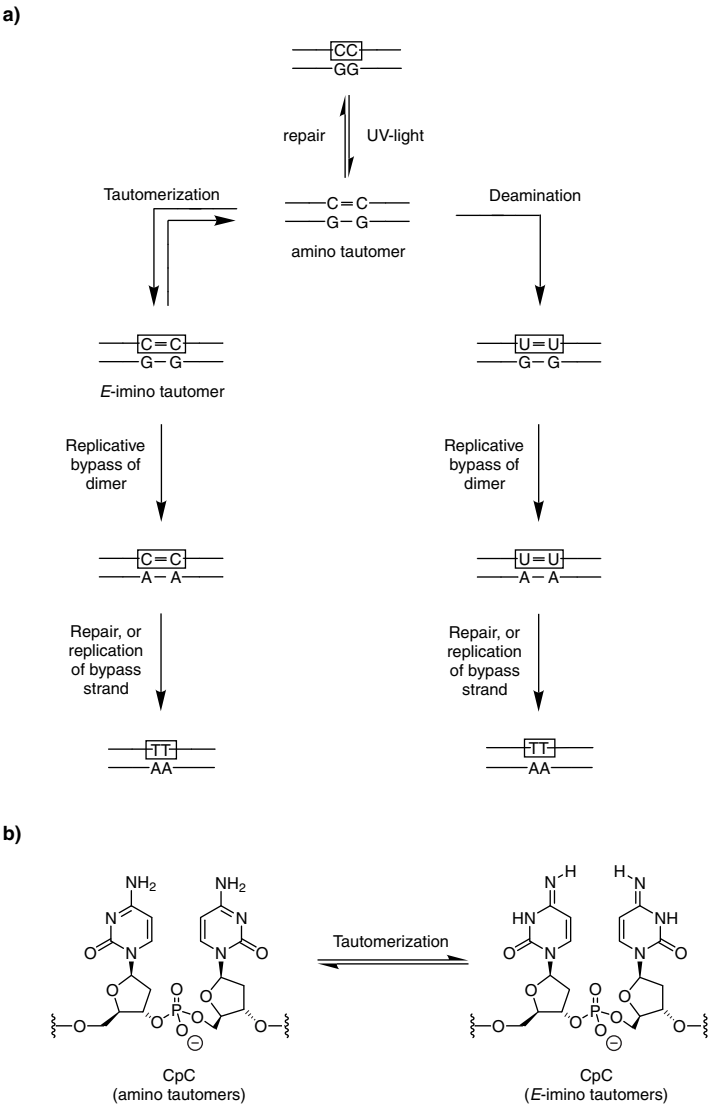


FIGURE 141.1 (a) The tautomer bypass and the deamination mechanism of CC-dimer mutagenicity, used to explain C → T transitions and CC → TT tandem transition mutations. (b) A cytidylyl–cytidine sequence and a situation in which both cytidins are present in their *E*-imino tautomeric forms.

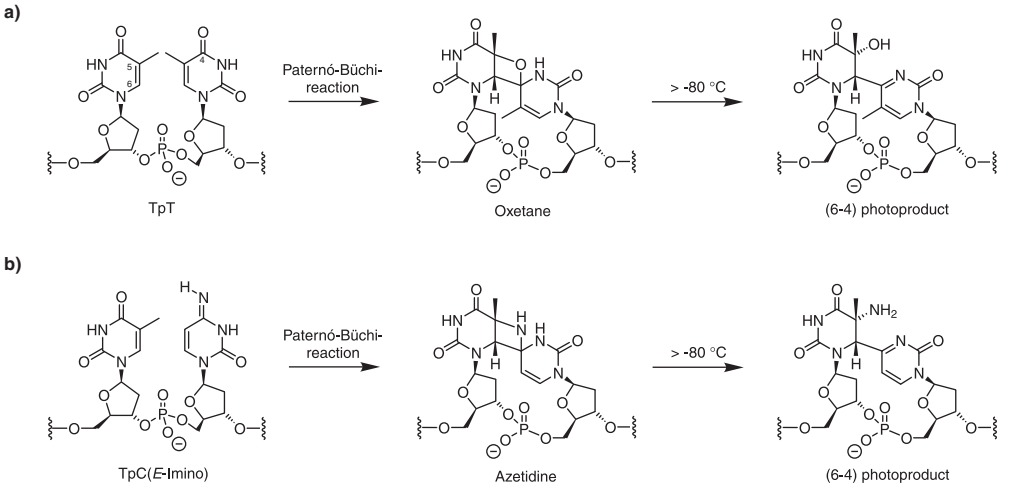
explanation for the observed mutations invokes tautomerization of the cytosine in a cyclobutane pyrimidine dimer into the (*E*)-imino tautomeric form [Figure 141.1(b)]. This tautomeric form would also instruct polymerases to pair the lesion with one or two adenines. Both mechanisms provide plausible explanation for the observed UV-fingerprint mutations.[10]

⟨6–4⟩ Photolesions

Another main photoreaction that occurs upon UV-light absorption of pyrimidine bases is the Paternó–Büchi reaction between the C(5) = C(6) double bond of the first pyrimidine and the C(4) = O carbonyl group of the second base. This reaction furnishes initially an oxetane intermediate at TT dipyrimidine sites.[9] The cytosine can react out of its (*E*)-imino tautomeric form with its C(4) = NH. The formed reaction product is an azetidine intermediate.



SCHEME 3 Reaction of a dipyrimidine site in a Paternó–Büchi reaction to give first an oxetane or azetidine reaction intermediate, which rearranges to give the stable (6–4) photolesions. (a) Reaction at a TT bis-pyrimidine site. (b) Reaction at a TC bis-pyrimidine sequence to give a cytidine-derived (6–4) photoproduct.

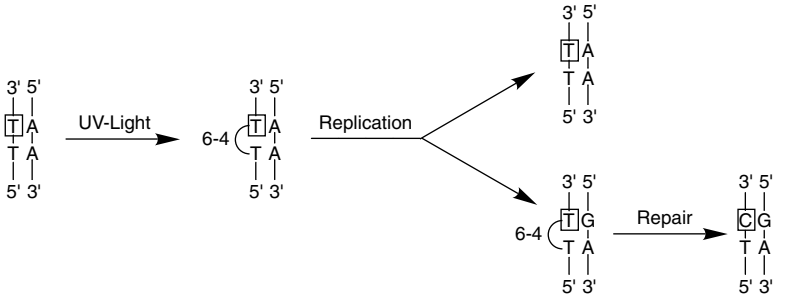


FIGURE 141.2 Modified pairing properties of the (6–4) lesion induce a T → C transition mutation. The mispairing 3′-T of the (6–4) lesion is shown in a box.

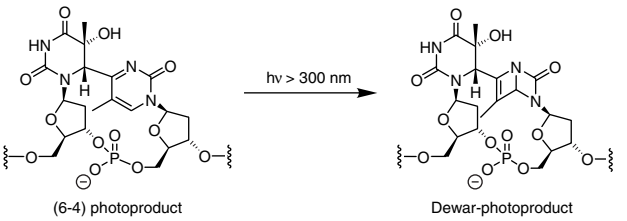
The oxetane and azetidine reaction products formed at 5′-TC-3′, 5′-CC-3′, 5′-TT-3′, and 5′-CT-3′ sites are not stable above -80°C. They rapidly undergo a ring-opening reaction to the corresponding (6–4) photolesions depicted in Scheme 3.[9,45,46] The stereochemistry of the pyrimidine–pyrimidine reaction products is again determined by the chiral DNA environment. The relative ratios of (6–4) lesions at different dipyrimidine sites were determined by HPLC-MS/MS[27] as follows: 5′-TC-3′ > 5′-TT-3′ > 5′-CC-3′ > 5′-CT-3′ (1:0.2:0.1:0.01).

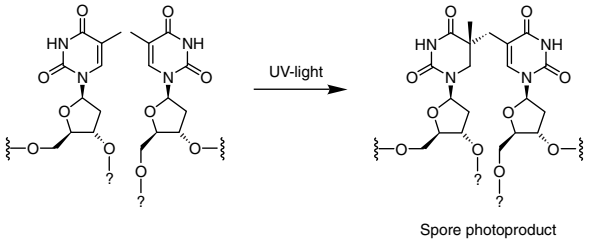
Detailed NMR investigations show that the (6–4) lesions strongly change the B conformation of the DNA duplex.[47] The NMR studies suggest that the DNA duplex is bent at the lesion site by about 44°.[48,49] FRET experiments[50] and calculations,[31] however, point to a much smaller bend of just 5°. The 5′-T of a T-T (6–4) lesion is still paired in the Watson–Crick modus. The 3′-T, however, pairs preferentially with a guanine.[48,51,52] This observation offers an explanation for T → C transition mutations in UV-irradiated cells (depicted in Figure 141.2).[53,54]

The Dewar Valence Isomer

Irradiation of DNA containing the (6–4) photoadduct with wavelength above 300 nm induces a rearrangement of this (6–4) lesion into a Dewar valence isomer (Scheme 4).[55]



SCHEME 4 Rearrangement of the (6–4) photoproduct to the Dewar valence isomer upon irradiation with light >300 nm (UV-B).



SCHEME 5 UV-light-induced formation of the spore photoproduct in spore DNA by an intrastrand or interstrand reaction of two thymidines.

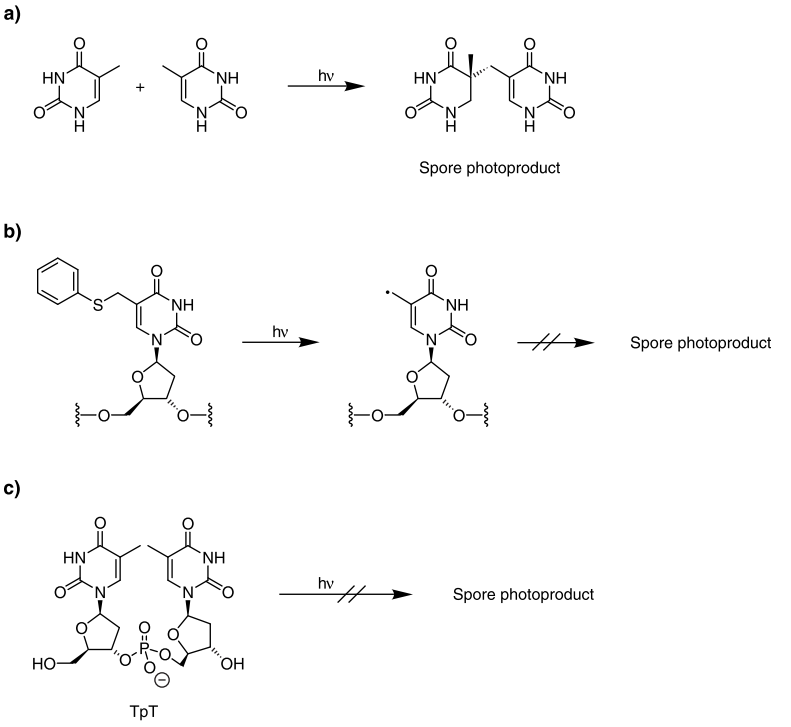
J.-S. Taylor[46,56,57] could clarify that the pyrimidone substructure of the (6–4) lesion is the rearranging unit. So far, formation of this Dewar lesion was detected by HPLC-MS/MS only at CC-sites upon irradiation of isolated or cellular DNA with UV-B and UV-C light.[27] Our understanding of its biological impact is still rudimentary. Information of how this lesion influences the structure and stability of DNA duplexes is, at this point, consequently limited.[47] From the available information, however, one can conclude that the structural effect on the DNA duplex is substantially different compared to the (6–4) adduct.[47,58] DNA repair enzymes seem to recognize this lesion like an abasic site.[59] Whereas the cyclobutane pyrimidine dimers, and to a lesser extent, also the (6–4) adducts, can still instruct polymerases (misinstruction), the Dewar valence isomer seems to be fully noninstructional. Polymerases, however, which are forced to read through a noninstructional site preferentially incorporates an adenine. This feature of polymerases is known as the A rule. This A rule seems to govern the mutagenicity of the Dewar valence isomer.

To summarize, at our current level of understanding, the mutagenic effect of UV light is clearly dominated by the formation of the cyclobutane pyrimidine dimers and (6–4) photoadducts. Among them, the cytosine-containing lesions are the most mutagenic lesions due to their sensitivity to hydrolytic deamination.

The Spore Photoproduct

DNA in spores is densely packed and covered by small acid-soluble spore proteins.[60,61] The DNA is strongly dehydrated and exits in a more A-like conformation.[62] This dense packing enables spores to "survive" even extreme conditions like extreme cold and heat or severe dryness. Irradiation of spores with UV light causes formation of yet another photolesion, which is exclusively formed in spores, possibly due to the unusual A-like conformation of the DNA.[63,64] The formation of this lesion (Scheme 5) can be mimicked by irradiation of a thin film of dry thymine or of a frozen thymidine solution with a UV-C light source (254 nm), as depicted in Scheme 6(a).[65–68]

The mechanism of formation is still unclear. Attempts to simulate the formation of the spore lesion with thiophenyl substituted thymidine [Scheme 6(b)], which produces a 5-centered radical upon irradiation, failed.[69] This failure indicates that the lesion may not form via a 5-(2′-deoxyuridilyl)methyl



SCHEME 6 Attempt to prepare the spore photoproduct by irradiation of chemically synthesized precursors. (a) Irradiation of thymine in a thin dry film. (b) Irradiation of a thiophenyl-substituted thymidine, which yields an intermediate 5-(2′-deoxyuridilyl)methyl radical. (c) Irradiation of a thymidylyl-thymidine dinucleotide.

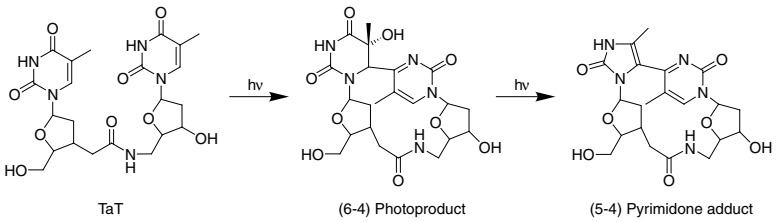
radical intermediate that could attack a second thymine. Alternatively, a precise geometrical rearrangement of the two involved thymines may be required, which is not accessible by the thymines if one bears the 5-thiophenyl modification. In our opinion, it is also unclear whether the lesion is formed in an intrastrand or in an interstrand reaction. So far, all attempts to create the lesion through irradiation of a TpT dinucleotide [Scheme 6(c)] failed,[70] which indicates that the lesion could be, in fact, an interstrand cross-link.

Other DNA Photoproducts

The described UV photolesions are the best-studied photoproducts so far. We can, however, be sure that many more UV-induced lesions exist, which await structural characterization. Recently, Clivio et al.[71] isolated a new photoproduct after UV irradiation of an amide-linked thymidyl-thymidine. The UV photoproduct is an interesting 2-imidazolone-(5–4)-pyrimidone adduct, shown in Scheme 7. It is yet unclear if similar photoproducts are also formed in DNA.

141.3 Photoinduced DNA Repair

DNA photorepair is one of the most fascinating enzymatic activities that nature invented to remove UV-induced DNA lesions from the cellular genome. In general, cells need to remove DNA lesions with high efficiency in order to avoid cell death or the development of mutations, which may result in carcinogenic cell growth. The UV lesions are prominent DNA alterations formed in DNA, because life exists in exposure to sunlight. Already, the earliest photosynthetic cyanobacteria, about 2 to 3 billion years ago, required an efficient repair pathway for UV lesions.[72] Due to the lack of any ozone shield, this must have been of paramount importance for survival. The fascinating creativity of nature is manifested in the development



SCHEME 7 Irradiation of an amide-linked thymidylyl-thymidine (TaT) furnished a novel (5–4) photoproduct via the (6–4) photolesion.

of enzymes that use the harmless long-wavelength part of sunlight as an energy source to drive the repair of the UV-induced lesions. These enzymes are the DNA-photolyases.[73–75] Although repair of UV lesions in many higher organisms, like humans, is achieved by the nucleotide excision pathway (see above), photolyases still represent a major defense shield against UV-induced lesions in many plants, bacteria, reptiles, fish, and marsupials.

Cyclobutane Pyrimidine Dimer DNA Photolyases

Cyclobutane pyrimidine dimer DNA-photolyases (CPD-photolyases) are monomeric DNA repair proteins (~55 kDa) that directly repair cyclobutane containing UV-light-induced DNA lesions.[73,74] Another type of photolyases repairs (6–4) lesions. They will be discussed later. The CPD-photolyases are mechanistically the best understood, and three crystal structures of CPD-photolyases from *E. coli*,[76] *A. nidulans*,[77] and *T. thermophilus*[78] provide detailed information about the structural requirements for efficient genome repair.

Structures and Lesion Recognition

The crystal structures of all photolyases revealed a globular shape and the presence of two coenzymes at a distance of 16.8 Å and 17.5 Å to each other, respectively.[76,77] Every photolyase known today contains one FAD-cofactor bound in a cavity with the right dimension and polarity to also accommodate the DNA lesion. The architecture suggests that photolyases recognize the lesion substrate in a flipped out conformation. The second coenzyme, either a methenyltetrahydrofolate (MTHF) (Type-I photolyases) or a 5-deazaflavin (5-DF) (Type-II photolyase), depending on the type of photolyase, is bound in a shallow groove close to the surface of the protein (Figure 141.3).

In accordance with x-ray crystal structures obtained from other repair enzymes in complex with lesioned DNA,[79–82] photolyase seems to trigger, upon binding to damaged DNA, a major conformational rearrangement.[83] Atomic force microscopy studies suggest that photolyases induce upon binding to DNA a bend of about 36°, which possibly leads to the extrusion of the dimer lesion into the putative lesion binding site.[84,85] A recent crystal structure of the photolyase from *T. thermophilus*,[78] together with a thymine, shows the thymine inside this putative active site in close van der Waals contact to the isoalloxazine ring of the FAD coenzyme. Additional stacking interactions of the thymine with the Trp_{353} and van der Waals contacts with Trp_{247}, Met_{314}, and Gln_{349} fix the thymine in the active site. This "cocrystal" structure provides compelling evidence that the dimer is bound in a flipped-out conformation.

Although the enzyme binds to the DNA lesion in a light-independent process, it, however, requires long wavelength light (350 to 450 nm) as the energy source to repair the lesion. Photolyases are, hence, only operative in tissues exposed to daylight. Biochemical investigations and model compound studies showed that the light energy is initially absorbed by the second cofactor like the MTHF.[73] This antenna chromophore funnels the energy to the $FADH^-$ which must exist in the two-electron reduced and deprotonated state. The excited, fully reduced flavin subsequently injects one electron into the dimer, which undergoes spontaneous splitting into two thymidine monomers (Scheme 8).

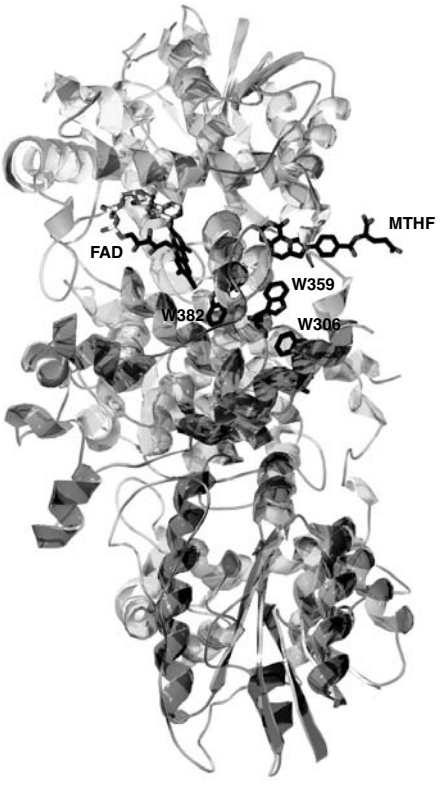


FIGURE 141.3 DNA photolyase from *E. coli*, with the two cofactors FAD and MTHF.

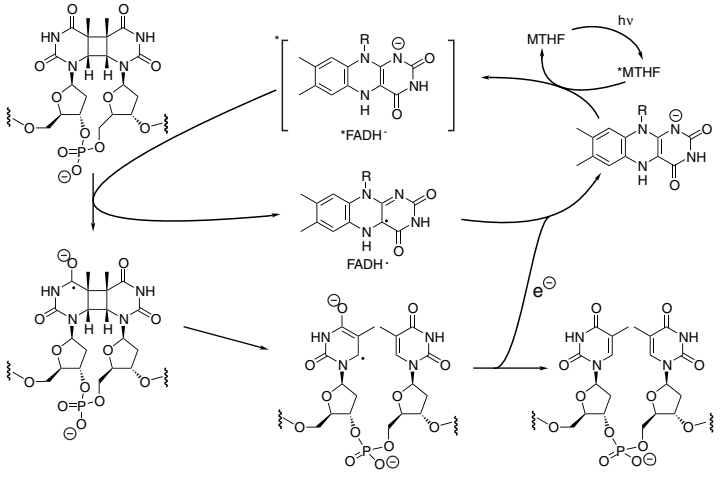

SCHEME 8 Reaction mechanism of CPD-photolyases (Type-I) with a methenyltetrahydrofolate (MTHF) as the second cofactor.

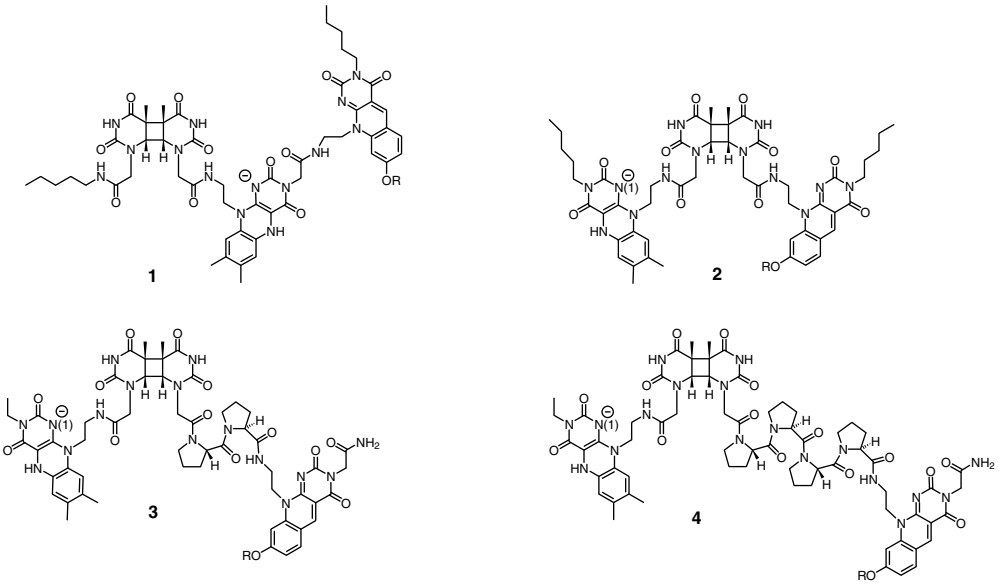

FIGURE 141.4 Covalent flavin-deazaflavin-thymine dimer model compounds **1** to **4** for the investigation of the photolyase-catalyzed repair reaction. The flavin-dimer distance is kept constant, while the distance between the deazaflavin and the dimer is systematically increased from **1** over **2** and **3** to **4**.

Electron Transfer to the Dimer Lesion in CPD-Photolyases

Recently, the structure of the DNA-lesion-photolyase complex and the electron-transfer pathway from the flavin to the dimer was investigated theoretically.[86,87] Applying the DOCK 4.0 program to model a hypothetical dimer–DNA complex, it was shown that the distance between the FAD and the dimer lesion could be around 3 Å. Other studies point, however, to a much larger distance.[88] Regardless of the distance, theory predicts that the electron is transferred indirectly from the $FADH^{\cdot}$ via the adenine to the dimer. The adenine moiety of the FAD closely approaches the dimer lesion due to the U-type conformation of the FAD (Figure 141.3). Model compound studies recently revealed further details about the critical electron transfer process.[75,89] Using model compounds like **1** to **4** (Figure 141.4), which contain a cyclobutane thymine dimer covalently connected to a flavin, it was shown that the deprotonation at N(1) (pK_a = 6.5) is critical for the repair reaction.[90] Protonation of N(1) stops the cleavage reaction immediately. The strict necessity of deprotonating the reduced flavin indicates that the system has to avoid a zwitterionic $FADH_2^{+}$-$Dimer^{-}$ state, which would form soon after electron transfer from the neutral $FADH_2$. Instead, photolyases seem to favor a charge shift reaction intermediate $FADH^{\cdot}$-$Dimer^{-}$, may be in order to reduce the rate of an unproductive charge recombination process, which competes with the dimer-splitting reaction ($k_{split} = 2 \cdot 10^6\ s^{-1}$). Protonation of the dimer radical anion or H-bonding was suggested to accelerate the cleavage process.[89,91]

Energy Transfer between the Two Coenzymes

Investigations of model compounds **1** to **4** also allowed us to get deeper insight into the energy transfer event from a deazaflavin, as the second cofactor in Type-II photolyases, to the flavin.[92,93] Of particular interest was to study how the cofactor–cofactor distance affects the dimer-splitting process. It was noted by Deisenhofer[76] that the large separation between the two cofactors in the protein structures is difficult to rationalize in light of the energy-transfer mechanism. The rate for such a dipole–dipole energy transfer (k_{EET}), as described by the Förster theory, depends strongly on the distance ($k_{EET} \propto r^{-6}$). This distance

dependence argues for a preferred short cofactor separation, in order to increase the light-transfer efficiency.

The model compounds **1** to **4** feature constant flavin–dimer arrangements and systematically increased flavin–deazaflavin separation. Monochromatic and selective irradiation of the deazaflavins in each model compound proved that fastest dimer cleavage occurs in Compound **4**. Model Compound **4** features, however, the largest cofactor–cofactor separation and, hence, the worst energy-transfer efficiency. A systematic decrease of the cofactor–cofactor distances from Compound **3** to model system **1**, furnished a surprisingly systematic decreased splitting rate, although increasing energy-transfer efficiencies were noted. Short cofactor distances, therefore, allow efficient energy transfer but inefficient dimer splitting. This unexpected result was explained with a "short-circuit" reaction, which interferes with the dimer-splitting process. We now believe that this short-circuit process is an alternative electron transfer from the reduced flavin FlH^- to the deazaflavin. The deazaflavin has the more positive reduction potential compared to the thymine dimer and should be the preferred electron acceptor. The large distance between the antenna-chromophore and the flavin reduces the rate for this short-circuit reaction, while the short $FADH^-$ dimer separation favors electron transfer to the lesion.

The Photoactivation Process

In the model Compounds **1** to **4**, an efficient energy transfer was observed from the deazaflavin to flavin, when both chromophores were present in their oxidized redox states. This energy transfer strongly accelerated any photoreduction of the flavin-chromophore in the presence of external photo reductants like EDTA. A similar photoreduction is also needed in photolyases in order to transform the semireduced $FADH^{\cdot}$ cofactor, present in the resting state of many enzymes, into the fully reduced $FADH^-$ redox state needed for catalysis. This one-electron photoreduction process was recently investigated by time-resolved absorption and EPR spectroscopy (Figure 141.5).[94,95] In the *A. nidulans* photolyase [Figure 141.5(a)], without the deazaflavin coenzyme, it was found that after a 7 ns laser flash pulse, which excitated the $FADH^{\cdot}$, a fast electron transfer from a nearby tryptophan occurs. This electron transfer leads to the formation of the fully reduced state $FADH^-$, and gives a tryptophanyl radical in less than 500 ns. Surprisingly, a tyrosine residue subsequently donates an electron to the tryptophanyl radical forming a deprotonated neutral tyrosyl radical ($TyrO^{\cdot}$) with $t_{1/2} = 50\ \mu s$. The $TyrO^{\cdot}$ is subsequently reduced by an external electron donor in a bimolecular reaction. Further evidence for the formation of the $TyrO^{\cdot}$ was obtained by time-resolved EPR spectroscopy.[95]

The photoactivation process in Type-I photolyases involves even more tryptophan units [Figure 141.5(b)]. Short time spectroscopic studies of the *E. coli* enzyme revealed an intraprotein multistep radical transfer cascade. Approximately 30 ps after the laser flash pulse exciting the FADH; formation of a first tryptophanyl radical ($Trp^{\cdot+}_{382}$) was observed, followed by two additional fast (<10 ns) electron-transfer events from Trp_{359} to $Trp^{\cdot+}_{382}$ and Trp_{306} to $Trp^{\cdot+}_{359}$, respectively. Final deprotonation of the radical $Trp_{306}^{\cdot+}$ to $Trp_{306}^{\cdot}$ in about 300 ns seems to trap the radical at Trp_{306}, which is located close to the surface of the protein. Here, reduction of $Trp_{306}^{\cdot}$ can occur by an external reducing agent. The energies for the individual electron-transfer steps in these cascades were recently calculated.[96] The first electron transfer between Trp_{359} and $Trp^{\cdot+}_{382}$ is almost isoenergetic. The second electron transfer from Trp_{306} to $Trp^{\cdot+}_{359}$ is, however, exothermic with 200 meV, which stabilizes the $Trp^{\cdot+}_{306}$ radical cation. Another 214 meV are gained by the deprotonation. All the tryptophan residues involved in this radical transfer cascade are precisely aligned. The distances between the tryptophan "stepping stones" are 4.2 Å, 5.2 Å, and 3.9 Å, which is optimal for electron transfer. The function of Trp_{306} as an essential partner in the photoactivation cascade was also supported by side-directed mutagenesis studies. Replacement of the Trp amino acids by alanine fully diminished the ability of the *E. coli* photolyase to activate the $FADH^{\cdot}$ cofactor.[73] From these studies, it became clear that photolyases use the transfer of radicals along amino acid side chains to photoreduce the FAD. Photolyases seem to share this property with class I ribonucleotide reductases, in which a radical transfer occurs over 35 Å from a tyrosyl radical to a cysteine in the active site.[97]

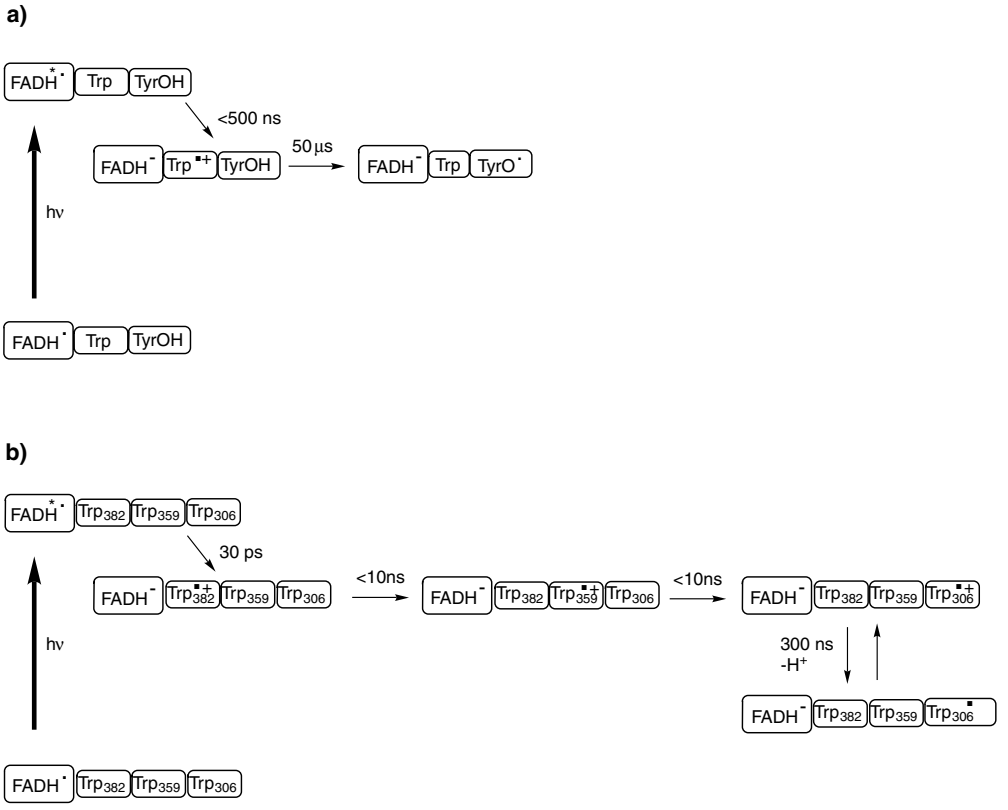

FIGURE 141.5 Trp- and Tyr-mediated electron-transfer cascades in Type-II DNA photolyases (a) and in Type-I DNA photolyases (b). The electron-transfer cascade is responsible for the photoreduction of the FAD-coenzyme to give the active $FADH^-$.

The Mechanism of Action of (6–4) Photolyase

Photoactivation of the Enzyme

The (6–4) photoadducts and the Dewar valence isomers are repaired by a special class of (6–4) photolyases.[98] The strong sequence homology between the (6–4) and the "classical" CPD-photolyases fuels the belief that both enzymes utilize a similar mechanism, which includes binding of the substrate, absorption of a photon, and restoration of the normal bases via electron transfer. Support for this assumption stems from the observation that (6–4) photolyases contain an FAD cofactor and presumably a folate as the second cofactor. The FAD is again needed in the two-electron reduced form ($FADH^-$). A recent EPR study of the (6–4) photolyase from *X. laevis* showed clearly that the FAD is reduced to the $FADH^-$ in two successive, light-induced electron-transfer steps via an intermediate that was assigned to be the neutral $FADH^•$ radical, formed after protonation of an initially formed $FAD^{•-}$.[99] Similar to CPD-photolyases, a Trp seems to function as the electron donor in question. Due to the lack of a crystal structure of a (6–4) photolyase, the structural requirements for this electron transfer are yet unclear. Based on the observed structural similarity between CPD and (6–4) photolyases, Kim et al.[100] suggested a repair mechanism for (6–4) photolyases shown in Figure 141.6. He proposed that the (6–4) lesion is first converted back into the oxetane within the active site of the enzyme. This rearrangement could be followed by a retro-Paternó–Büchi reaction, triggered by a single-electron donation from the reduced $FADH^-$ (Figure 141.6).

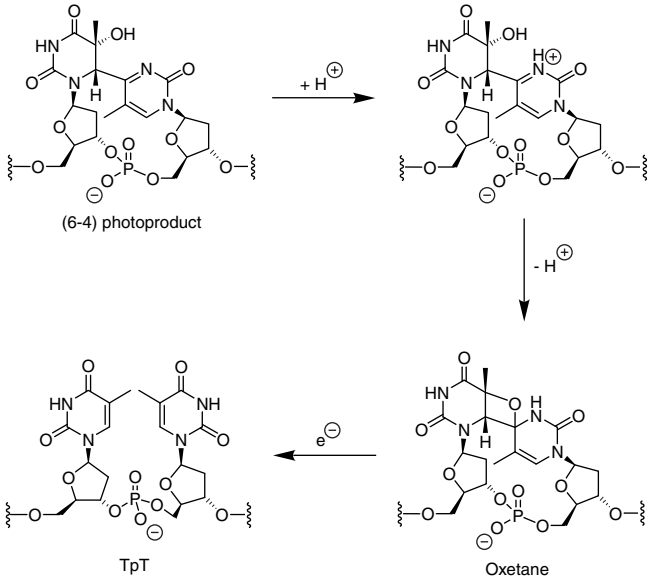

FIGURE 141.6 Proposed mechanism for the repair of (6–4) lesions by the (6–4) photolyase. Protonation gives an *N*-acyliminium ion, which is attacked by the *tert*-OH group to form the oxetane intermediate. This is split by single-electron reduction.

Enzymatic Studies with (6–4) Photolyases

Recent enzymatic investigation of the (6–4) photolyases from *D. melanogaster*[101] and *X. laevis*[102] provided the basis for our current understanding of the light-induced (6–4) repair process. (6–4) photolyases bind strongly ($K_D \approx 10^{-9}$ M – 10^{-10} M) and with high specificity to the (6–4) lesion. DNase I footprinting studies show that (6–4) photolyases protect an 11 (*X. laevis*) to 20 (*D. melanogaster*) base pair long patch around the lesion-containing site.

The quantum yield for the repair of the (6–4) lesion is smaller ($\phi = 0.1$) compared to the repair of cyclobutane pyrimidine dimer (CPD) lesions ($\phi = 0.7$) by CPD photolyases. (6–4) photolyases also bind and repair the Dewar photoproduct, although binding is not as tight ($K_D = 10^{-8}$ M – 10^{-9} M), and the relative quantum yield for repair $\phi_{rel} = 0.5$ is two orders of magnitude smaller compared to the (6–4) lesion ($\phi_{rel} = 100$).

Semiempirical AM1 and PM3 calculations suggest that a hypothetical oxetan intermediate would efficiently split after single-electron reduction or oxidation.[103] The reductive pathway was found to be more exothermic and should proceed over lower rate-determining barriers, which supports the assumption that the (6–4) repair is based on a reductive electron transfer from the $FADH^-$ to the lesion.[103] It was also calculated that the Dewar valence isomer could be transformed into the (6–4) lesion by a single-electron reduction, which could explain the ability of (6–4) photolyases to repair this lesion as well, although with much lower efficiency.[103]

Investigation of the (6–4) Repair Mechanism with Model Compounds

The key step in the proposed oxetane repair mechanism is the rapid fragmentation of the oxetane radical anion. This ring-opening reaction was recently studied with model compounds. Falvey and coworkers[104,105] prepared stable oxetane adducts from dimethylthymine and various benzaldehyde derivatives. Laser flash photolysis investigations in the presence of external electron donors like dimethyl aniline showed efficient oxetane splitting, which allowed investigation of the radical intermediates. The radical cations of the various sensitizers and the radical anions of the carbonyl products formed after

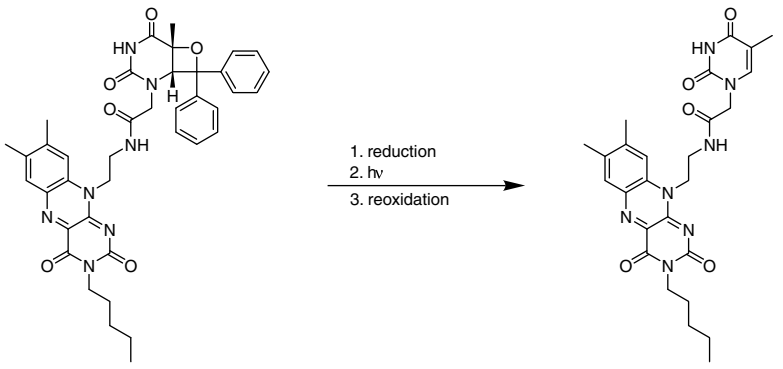

FIGURE 141.7 Model compound for the (6–4) photolyase, used to study the reductive flavin (FlH^-)-induced oxetane cleavage.

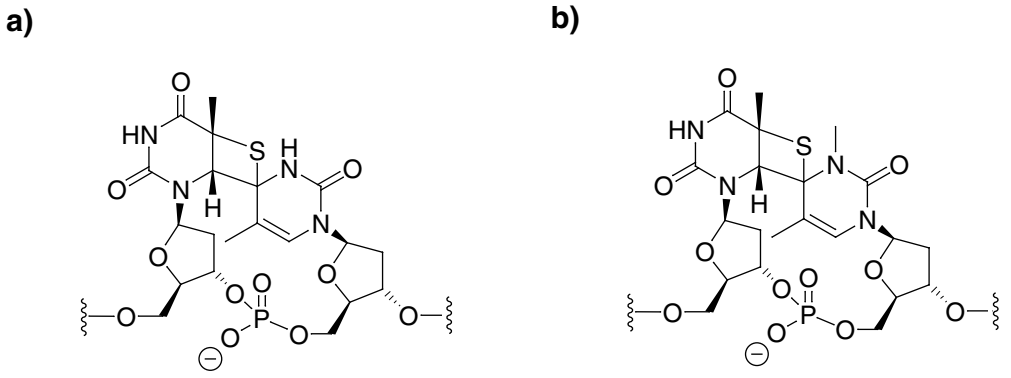

FIGURE 141.8 Two stable thietane analogs used to study the binding of the (6–4) photolyase to an assumed oxetane intermediate.

oxetane cleavage were both detected. Estimation of the oxetane–anion cleavage rate provided a value of $k_d \approx 5 \cdot 10^7\ s^{-1}$. This value is significantly larger than the rate measured for the splitting of cyclobutane pyrimidine dimers ($k_d \approx 2 \cdot 10^6\ s^{-1}$), indicating that the model oxetane anions, generated in this study, cleave about 10 times faster.[105] Recently, the first model compound containing a stable oxetane covalently connected to a flavin derivative was prepared.[106] With these compounds, it was shown that only the reduced and deprotonated flavin is able to cleave the oxetane. This result supports the assumption that the repair is triggered by an electron transfer from the $FADH^-$ to the dimer (Figure 141.7).

The alternative oxidative ring opening of oxetanes after electron abstraction is currently under intensive investigation in the Miranda group.[107,108] Although this process is, at this point, biologically not relevant, it provides currently, detailed information about the chemical properties of oxetanes.

Although reductive splitting of a hypothetical oxetane is now established as the most plausible biologically relevant mechanism, direct evidence for the formation of an oxetane intermediate during enzymatic (6–4) repair is yet to be determined. In this context, it was found that binding and repairing the thietane compounds [Figure 141.8(a,b)],[101,109–111] which closely resemble the structure of the hypothetical oxetane intermediate, by (6–4) DNA photolyases, failed. In addition, density functional calculations and semiempirical studies revealed free energy difference between 14.5 to 16.5 kcal/mol for the rearrangement of the (6–4) into the oxetane species.[112] This suggested that shifting the (6–4)/oxetane equilibrium toward the oxetane compound is energetically costly. Even though the calculated values might be too large, as recently speculated, the rearrangement of the (6–4) lesion to the oxetane intermediate is

difficult to explain, and it therefore remains an open question. The rearrangement would require reaction of the 5-OH group of the (6–4) adduct with the enamide substructure. This attack could be accelerated if the corresponding nitrogen is protonated to give an *N*-acyliminium ion (Figure 141.6). Recently, two histidine residues were identified by side-directed mutagenesis, which could be responsible for this protonation.[113] *N*-acyliminium ions possess a highly electrophilic reactivity. This high reactivity allows even weak nucleophiles to attack. The addition of oxygen nucleophiles to *N*-acyliminium ions was observed and yields *N,O*-acetals. The rate-determining step in this reaction is thought to be the formation of the *N*-acyliminium ion. The rearrangement of the (6–4) adduct to the oxetane could therefore depend on the efficiency of protonation in the lesion-binding pocket, which could explain the low quantum yield of the enzymatic (6–4) repair.

The Spore Photoproduct Lyase

Although the spore photoproduct lyase is not a light-dependent enzyme,[114] we are, nevertheless, covering the recently gained mechanistic insights, mainly because this enzyme repairs one of the major UV lesions. The spore photoproduct lyase is only able to repair the special UV-irradiation products in spores. Other UV lesions like the cyclobutane-containing photoproducts are not substrates for this unusual enzyme. The enzyme is only expressed during sporulation and then stored inside the spore. If the spore starts to develop (germination), the spore photoproduct lyase becomes active.[114–116] Today, it is known that the enzyme, e.g., from *Bacillus subtilis*, is made from 342 amino acid. The protein has a molecular weight of about 40 kDa and shows some sequence homology with the *C*-terminus of other photolyases.[116,117] The spore photoproduct lyase reverts the spore UV lesions directly back into the original thymine bases, similar to the other photolyases. Light, however, is not required. In contrast, the repair mechanism involves *C*-centered radicals. The enzyme contains four cysteins in close contact to a Fe in a [4Fe + 4S] cluster.[118,119] This cluster is oxygen sensitive, so that efficient repair requires anaerobic conditions. The enzyme also needs one molecule of *S*-adenosyl-methionine (SAM) as an additional cofactor. Strong sequence homology of the spore photoproduct lyase with other adenosyl methionine radical enzymes and recent mechanistic studies led to the formulation of the mechanism shown in Figure 141.9.[119–122] The initial step in the reaction mechanism could be the formation of an adenosyl radical, which abstracts an H-atom from the 6-position of the spore photoproduct. The formed lesion radical could then rearrange to give a thymine and a 5-(2′-deoxyuridilyl)methyl radical. Back transfer of the H-atom from adenosine would furnish a restored second thymine base under regeneration of the radical coenzyme. Our current understanding of the spore photoproduct lyase indicates therefore that the enzyme belongs to the family of SAM-dependent radical enzymes. The protein is the first DNA repair protein, which utilizes a radical mechanism for repair.

141.4 Conclusions

In the past decades, much knowledge was gained about UV-light-induced DNA lesions. The structures of the main lesions, e.g., the CPD lesions, the (6–4) lesions, and of the spore photoproduct, were elucidated. Plausible mechanisms of how these lesions induce mutations were proposed. Although still awaiting rigorous proof, these mechanisms explain why UV-induced lesions induce mutations and cancerogenous cell growth.

The repair of these lesions in higher organisms is performed mainly by nucleotide excision repair. However, light is also used as an energy source to remove these lesions from the genome in many organisms. DNA photolyases convert sunlight into DNA repair activity. They repair cyclobutane pyrimidine dimer lesions (CPD photolyases) and (6–4) lesions [(6–4)-photolyases] using a unique electron-transfer-driven mechanism. A similar mechanism is used by the spore photoproduct lyase to repair spore photoproducts. The spore photoproduct lyase is an interesting radical enzyme, which, however, operates light independently. The mechanism of action of CPD photolyase is well understood. For (6–4) photolyases,

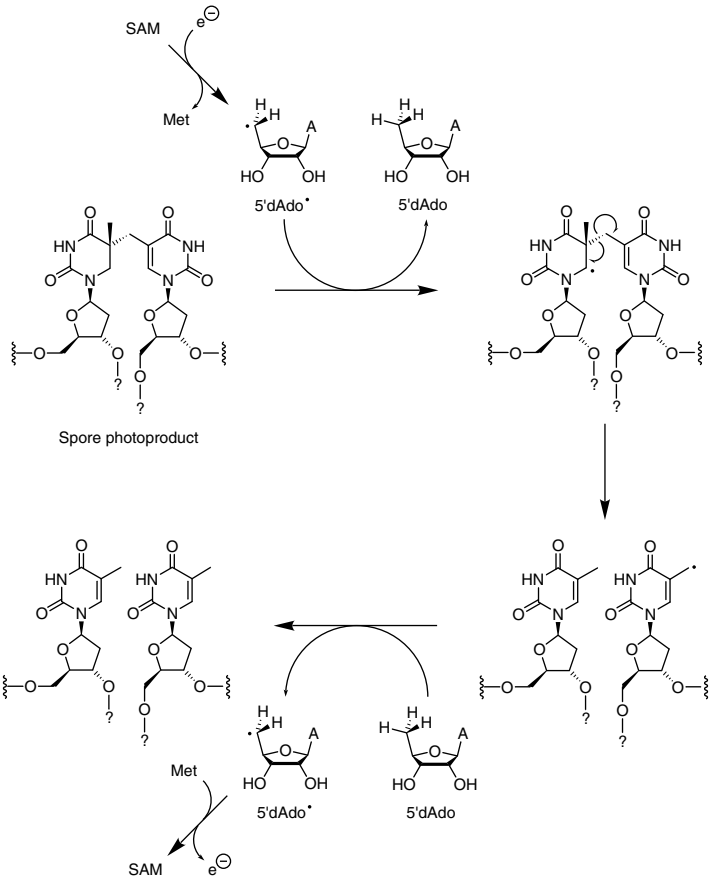

FIGURE 141.9 Proposed mechanism of action of the spore photoproduct lyase, which specifically repairs UV-induced spore DNA lesions.

a solid mechanistic theory was developed, but many steps still wait for scientific proof. The mechanism of action of the spore photoproduct lyase is still rather unknown.

Future developments must also address the question of what happens inside the cell. We clearly need a better understanding of how photolesions promote the development of cancer.

142.1 Introduction

Psoralens, also known as furocoumarins, are naturally occurring or synthetic tricyclic aromatic compounds (Figure 142.1), deriving from the condensation of a coumarine nucleus with a furan ring. They exhibit interesting photobiological and phototherapeutical activities, such as skin photosensitization characterized by the onset of erythema followed by dark pigmentation. The related angular isomers, angelicins and allopsoralens, are also present in the vegetal world; namely, angelicin is present in *Angelica archangelica*, and a derivative of allopsoralen is present in *Mammea americana*.[1]

The ancient Hindus, Turks, Egyptians, and other Orientals exploited this property in popular medicine. In fact, the use of *Psoralea corylifolia* extracts to treat vitiligo is mentioned in the Indian sacred book "*Atharva Veda*" and in the old Buddhist Bower manuscript. Another plant, *Amni Majus* that grows in the Nile valley, was used for centuries as a cure for leukoderma.[1,2]

Psoralens have a toxic effect on the skin, which manifests itself in the summer as phytophotodermatitis. It results from contact with certain plants or herbs that contain psoralens and then from exposure to sunlight. However, it was also recognized that this may be a beneficial effect that, because it allows modulation of skin pigmentation, can be used for medicinal purposes or in cosmetics.[1,2]

An important application of psoralens and UV-A light (PUVA therapy) was introduced into clinical practice by Parrish et al.[3] A treatment consisting of the oral administration of 8-methoxypsoralen (8-MOP), followed by artificial ultraviolet illumination (UV-A) of patients' skin was used for the first time to cure psoriasis, a disease characterized by hyperproliferation of skin cells. It is now recognized that psoriasis is an autoimmune disorder, and hyperproliferation is only one aspect of its manifestation.

In 1982, an extracorporeal form of 8-MOP photochemotherapy (photopheresis) was developed by Edelson et al.[4] for the treatment of cutaneous T-cell lymphoma, a CD4-positive T-cell malignancy. Photopheresis was also found to be effective in a number of other T-cell-mediated diseases. Clinical trials demonstrated beneficial effects in *pemphigo vulgaris*,[5] severe atopic dermatitis,[6] AIDS-related complex,[7] rheumatoid arthritis,[8] and systemic lupus erythematosus.[9]

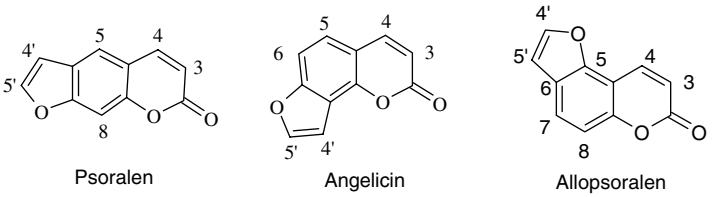

FIGURE 142.1 Molecular structures of psoralen, angelicin, and allopsoralen.

Some psoralens are also used in the photosterilization of blood products, in particular, platelet concentrate.[10] Different psoralen derivatives, such as 8-MOP and 4′-aminomethyl-4,5′,8-trimethylpsoralen (AMT) combined with UV-A are useful for sterilizing platelet concentrate, because of its capacity to target nucleic acids.[10,11] Lipid-enveloped viruses such as the model-virus vesicular stomatitis virus,[12] as well as immunodeficiency virus[13] and duck hepatitis B virus,[14] are sensitive to this photochemical treatment. On the other hand, platelets are well preserved, especially in the presence of rutin, which prevents damage to the platelet membrane by reactive oxygen species.[13] The newly synthesized psoralen derivative S-59, with a structure that is covered by patent, is claimed to have a high nucleic acid binding affinity and would, therefore, be an efficient inactivating agent, while preserving platelet quality. Interestingly, S-59 in combination with UV-A was shown to inactivate not only different lipid-enveloped viruses but also gram-positive and most gram-negative bacteria.[10] Non-lipid enveloped viruses are not inactivated, probably because their protein coating prevents the psoralen derivative from reaching the cellular target.

A completely different and unusual application of psoralens, without light activation, is to exploit the ability of some derivatives to interact with ionic channels. It was recently shown that 5-methoxypsoralen (5-MOP)[15] and 5,8-disubstituted psoralens,[16] can block voltage-dependent K^+ channels (K_v). In addition, they are able to alleviate functional deficits in certain multiple sclerosis patients in a manner similar to 4-aminopyridine.

Some new photobiological and pharmacological aspects of psoralen compounds are reported in this chapter.

142.2 Properties of Psoralens

Photophysical and Photochemical Properties of Psoralens

The absorption spectra of the most common psoralen derivatives exhibit two bands centered at about 250 and 300 nm and a shoulder at 330 to 340 nm, extending to about 400 nm. Absorption is due to two main transitions in the 320 to 400 nm (UV-A) range: an n,π^* transition resulting from the excitation of a nonbonding electron on the C_2 carbonyl group to the π^* orbital and a π,π^* transition occurring when a π^* electron in the psoralen ring system is excited to the π^* orbital. The lowest singlet and triplet states are the (π,π) states.[17] The intrinsic photoreactivity of psoralens is determined by the electronic structure of the lowest excited states (S_1 and T_1). Intersystem quantum yields for various psoralen derivatives fall within the range of 0.1 to 0.4, with the exception of 5-MOP, which has $\phi_t < 0.01$.[18] The UV-A absorption bands of all psoralen derivatives derive from their benzopyrone moiety. Their extinction coefficients, however, differ appreciably from one compound to another in the UV region.

The photosensitizing effects of psoralens may involve oxygen-dependent and oxygen-independent mechanisms that are summarized in Figure 142.2. Types I and II are oxygen dependent, whereas Type III is an anoxic pathway. Energy transfer to thymine bases was also shown to occur with pyridopsoralens leading to the formation of thymine dimer.[19,20]

In particular, the Type I mechanism may involve one-electron oxidation of targets like guanine[21] and the generation of reactive oxygen species ($O_2^{\cdot-}$ and ·OH), which may further react with substrates. The Type II mechanism implies generating singlet oxygen by energy transfer, which, in turn, may induce

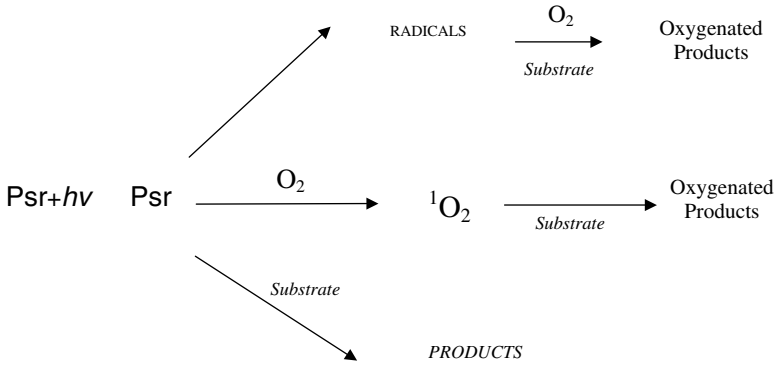

FIGURE 142.2 Pathways of the photosensitizing actions of psoralens.

oxidation of guanine,[22] histidine, cysteine, or tryptophan. The Type III mechanism consists of photoreactions between psoralens and a substrate that do not involve oxygen, which are favored by polar solvents. At the molecular level, the first photoreaction investigated concerning coumarins and furocoumarins was dimerization.[23]

Under the action of UV-A light, a [2 + 2] cycloaddition occurs between one of the double bonds of each monomer. In general, both double bonds of psoralen are potentially photoreactive, but which one is involved in a particular reaction depends on the reactivity of the excited states. In solution, only the pyrone 3,4-double bond is involved, showing that the triplet states make this site particularly reactive. In order to elicit the reactivity of the furan 4′,5′-double bond, the psoralen derivative has to be excited in the vicinity of the substrate, which may be achieved by freezing the solution.

Recently, detailed studies have thrown new light on these aspects, in particular the photophysical features of angelicins and methylated thioangelicins.[24,25] Lifetimes and quantum yields were measured for the different excited states of these compounds in different solvents, and the results were compared to semiempirical quantum mechanical calculations. It may be concluded that the polarity of the solvent in which the radiative excitation occurs, plays a major role in photoreactivity. In fact, methylthioangelicin derivatives show more singlet states at increasing energy, the most important being S_1 and S_2. The first excited state is a π,π^* transition, whereas the second is an n,π^* transition, known as a forbidden transition.

The deactivation of the excited molecule in hydrophobic solvents occurs almost totally by internal conversion. On the other hand, the internal conversion quantum yields decrease progressively in polar solvents, while the fluorescence and triplet quantum yields increase. In conclusion, polar solvents favor the triplet formation. This leads to an increase in its half-life, indicating that the photophysical properties are strongly solvent dependent.

The question remains whether the chemical reactivity of this class of compounds is correlated to biological activity.[26] For example, 1-thiopsoralen was studied, and it was calculated that the quantum yield of intersystem crossing and fluorescence of photoexcited 1-thiopsoralen is very low, and practically the only excited state is the triplet. It should be noted that 1-thiopsoralen undergoes intercalation into DNA. Subsequent UV-A irradiation of the latter complex is found to promote [2 + 2] photocycloaddition of the furan ring with the thymine. In this regard, it is interesting to note the different behavior manifested by visnagin and khellin,[27] two compounds with similar chemical structures but that exhibit different biological activities. The former is more active, and studies performed in dioxane–water mixtures demonstrate that the triplet quantum yields of visnagin are higher than khellin. These facts account for the greater photobiological activity of visnagin with respect to khellin in some biological models.[27]

Psoralen Photolysis

It is generally accepted that photosensitizing agents act toward biological substrates through the three main mechanisms mentioned above.

Some of these pathways are also useful for explaining photolysis of furocoumarins in solution. When a furocoumarin is UV-A-excited in solution in the absence of any substrate, its target may be another furocoumarin molecule (in its ground state) or a solvent molecule. In both cases, a Type III (oxygen-independent) addition reaction occurs. When the solution is aerated, the Type II pathway is also involved, and singlet oxygen may oxidize a psoralen molecule.[28]

[2 + 2] Photocycloadditions are the most common psoralen photoaddition reactions. Ciamician and Silber[23] first proposed a cyclobutane structure for a photodimer of coumarin. Von Wessely and Dinjaski[29] and von Wessely and Plaichinger[30] found that the same reaction occurs with UV-irradiated psoralens. They obtained dimers in which the pyrone rings of both monomers are joined through a cyclobutane ring (pyrone–pyrone dimer).

Von Wessely and Plaichinger[30] reported some data on pimpinellin (5,6-dimethoxyangelicin) and 8-MOP photodimers; however, the data concerning two isomeric compounds are not clear in terms of structure assignment. Successively, Krauch and Farid,[31] working with 8-MOP, reported that only a single pyrone–pyrone is formed, having a *trans-anti* configuration.

In any case, taking into account that both the double bonds of psoralens are photoreactive (furan side and pyrone side), cyclodimerization not only yields pyrone–pyrone dimers but also pyrone–furan dimers, as shown by Caffieri and Dall'Acqua.[32]

A third type of dimerization involving the furan ring of each monomer was observed, and a furan–furan dimer was found, although only in particular experimental conditions, such as with a thin layer of the solid compound.[32]

Oxidative processes were studied by Rodighiero et al.[33] and Musajo et al.[34] that showed that photolysis of psoralen and 5-methoxypsoralen (5-MOP), in water–methanol solution in the presence of flavin-mono nucleotide, leads to the formation of 6-formyl-7-hydroxycoumarin (from psoralen) and 6-formyl-7-hydroxy-5-methoxycoumarin, derived from 5-MOP. The corresponding aldehyde deriving from 8-methoxypsoralen (8-MOP) was isolated by Rodighiero et al.[35]

The same 6-formyl-7-hydroxy-8-methoxycoumarin was later characterized as a direct photolysis product of 8-MOP with the involvement of singlet oxygen, generated by the psoralen.[36]

The same hydroxyaldehyde was obtained from 8-methoxypsoralen (8-MOP) producing singlet oxygen with methylene blue and visible light.[37] On this basis, a mechanism in which an excited oxygen molecule binds to the furan side of 8-MOP giving rise to a dioxetane, was proposed. The C4′-C5′ bond of this intermediate is broken, followed by the loss of formic acid forming hydroxyaldehyde. Similar products were obtained as products of photolysis of 4,5′,8-trimethylpsoralen (TMP).[38]

The same mechanism should also lead to fission of the pyrone ring, according to Marley and Larson.[39] These authors for the first time isolated the unstable 5-formyl-6-hydroxybenzofuran by UV irradiation of 8-methoxypsoralen.

From the dioxetane intermediate described above, other compounds can be formed, which in turn, may have biological effects. Dioxetane intermediate may be opened by nucleophilic compounds (e.g., a solvent molecule) in a way different from that leading to the aldehyde; that is, it leaves the C–C bond unaffected, therefore avoiding fission of the furan ring.

This mechanism was further supported by Adam et al.,[40] who studied the chemical reaction of 2,3-dimethylbenzofuran dioxetane derivatives.

Biological Effects of Photolysis and Metabolic Products

It was shown that some products of photolysis of psoralen may exhibit interesting biological effects in the dark.[28]

In this connection, Potapenko et al.[41] suggested that the photobiological activity of psoralens derives from its photooxidized products formed during preirradiation (POP). These authors analyzed the efficacy of crude preirradiated solutions of psoralen in a variety of biological models. First, they proved that the solutions are active only when irradiation is carried out in the presence of oxygen, and they concluded that the activity should be ascribed to photooxidized psoralen species (POP).

POP is active in inducing hemolysis in erythrocytes, in oxidizing unsaturated fatty acids and altering cell membrane lipids. POP is generally stable at room temperature and in organic solvents, while heat and water decompose them, as do ferrous ions.[41]

It was found that POP induces hemolysis of erythrocyte,[42] modifies the "respiratory burst" of phagocytes, and increases the permeability of their membranes.[43] Chemically oxidized or photooxidized psoralens inhibit chemotactic activity of polymorphonucleate cells,[44] and induce mutagenic and lethal effects in the microorganism.[45]

The products of photooxidation of psoralens administered to mice were shown to induce modulation of the T-cell-mediated immune response and inhibit growth of grafted EL-4 lymphoma.[46] Administration of POP to eczema patients induced therapeutic effects with remission of more than 1 year.[47] The above-mentioned effects were produced in the dark.

A final remark concerns the immune-suppressive effects of psoralens. A possible mechanism of action concerns modulation of the major histocompatibility complex (MHC) located in antigen-presenting cells.[48]

The immune functions of these MHC peptides depend on the interaction of carbonyls and amino groups present on the surface of antigen-presenting cells and T-cells.

Small molecules able to form Shiff bases were proven to interfere with this mechanism and modulate the profile of cytokine release. The most potent among the set of molecules tested is tucaresol,[48] an *O*-hydroxybenzaldehyde, closely correlated chemically to various photoproducts deriving from psoralen photolysis. Thus, it is reasonable to expect that some photoproducts of psoralen, formed *in vivo*, may play a role in regulating the immune system.

Recently in this connection, Koenig and Trager[49] observed that psoralen and 8-MOP are potent inhibitors of P450 2A6 and 2B1 reductase activity in human hepatic microsomes in the dark. 5-MOP is also active, while trimethylpsoralen (TMP) is not. P450 inactivation, however, was induced not by intact psoralen but by its metabolite formed in liver microsomes. This metabolite is able to bind covalently to an amino acid of the active site of the enzyme, forming a product with molecular weight that corresponds to that of the enzyme plus 8-MPO plus one oxygen atom. Similar behavior was observed when exogenous nucleophiles were added (reduced glutatione, *N*-acethylcysteine, methoxamine), suggesting that the photobinding to the enzyme takes place at the nucleophilic site. Moreover, a dihydrodiol formed by the saturation of the furan ring, which is strictly similar to the dihydrodiols isolated from UV-A irradiation of khellin, was found in the medium. The occurrence of these metabolic products can be accounted for by hypothesizing the formation of an epoxide, as an instable intermediate, which is attacked by amines, thiols, or water to yield the observed dihydrodiols. These compounds were identified in the case of psoralens, 5-MOP, and 8-MOP, but not in the case of TMP.

To summarize, the mechanism of inactivation of this enzyme takes place through the initial oxidation of the furan ring to generate a furan epoxide that then reacts with a nucleophilic amino acid at the active site of P450 2A6, leading to the inactivation of the enzyme, or it reacts with H_2O to form dihydrodiol (Figure 142.3).

Photoadduct Formation with Biomolecules

According to the different mechanisms involved in photosensitization, psoralens may affect various cellular components and involve precise molecular targets. These are summarized in Table 142.1 and are discussed later in the text.

The main psoralen photosensitizing effect used in the treatment of certain skin diseases involves stimulating the pigmentation of melanocytes, increasing melanin synthesis on one hand and antiproliferative activity of psoriatic plaques on the other. The effects may, therefore, appear to be contradictory. However, recent findings explain that the two activities are likely to be connected to distinct cellular targets that are photomodified by psoralens in different ways.

TABLE 142.1 Target of Psoralen at Cellular Level

Membranes	C_4-cycloaddition to unsaturated fatty acids and phospholipids, lipid peroxidation, formation of cross-links in membrane proteins. Interaction of psoralen photolysis products with proteins
Receptors	Dark and photointeractions with membrane and cytoplasm receptors

Photoreactions with DNA

The photochemical reactions of psoralens with DNA are well characterized, having been studied for a considerable amount of time.[50,51] The photoreaction between psoralens and DNA takes place in two steps:

1. A molecular complex is formed in the ground state, in which the psoralen derivative intercalates inside the nucleic acid duplex.[52] This step is critical for the subsequent reaction.
2. Upon photoactivation of the intercalated psoralen molecule, the excited molecule reacts with the 5,6-double bond of thymine, and to a lesser extent with those of cytosine, giving a C_4-cycloadduct.

A psoralen photoadduct to adenine was also isolated and characterized upon irradiation of a mixture of adenine and psoralen derivative,[53] however, the latter photoadduct does not appear to be generated in cellular DNA.[53] The psoralen adducts within nuclear DNA are formed primarily by a [2 + 2] photocycloaddition reaction between the 4′,5′-furan double bond of the psoralen molecule and the 5,6-double bond of thymine. Monoadducts involving the 3,4-pyrone double bond of the psoralen and the pyrimidine 5,6-double bond are also formed, but to a lesser extent (Figure 142.4). Photoisomerization can lead to 4′,5′-monoadducts being converted into 3,4-monoadducts, at least in isolated DNA.[54] Interstrand cross-links can be generated as the result of photoexcitation of the 4′,5′-monoadduct and its subsequent cycloaddition with the pyrone 3,4 double bond. The structures of the monoadducts and cross-links are shown in Figure 142.4. The cross-linking process depends on the structure of the psoralen derivative. Linear psoralens form cross-links efficiently with a yield, which may reach up to 50% of the overall adducts formed.

It is likely that substituting the psoralen molecule with alkyl groups like methyls, which increase lipophilicity of the compound and, within certain limits the intercalation capacity, can modify this picture. In particular, the photoreaction of 4-methyl psoralen derivatives with DNA yields a lower percentage of pyrone-side monoadducts.[55] This may be rationalized in terms of a hindering effect partly due to the methyl group of thymine, although the cross-linking capacity is not affected. The photoreactivity of one of the double bonds of the furan and pyrone moieties may be reduced or completely canceled if the substituting groups are bulkier or exhibit electron-withdrawing properties. This could also be achieved by introducing a fourth aromatic ring, fused at the 4′,5′ or 3,4 position. As a result, linear monofunctional compounds, including carbetoxy-, pyrido-, and benzopsoralen are available.[56,57,58]

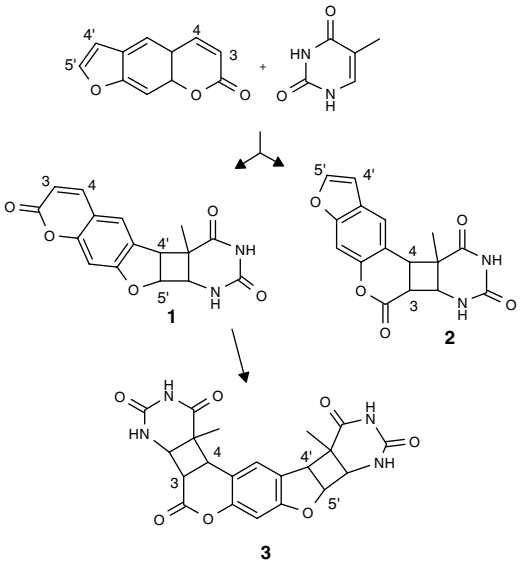

FIGURE 142.4 Molecular structure of mono- and diadducts between psoralen and thymidine. 1: furan-side monoadduct involving the 4′,5′ double bond of psoralen and the 5,6 double bond of thymidine; 2: Pyrone-side monoadduct involving the 3,4 double bond of psoralen and the 5,6 double bond of thymidine; 3: diadduct involving the cross-link by two thymidines by a psoralen molecule.

The regio- and stereochemistry of the resulting monoadducts formed in isolated DNA were found to exhibit a *cis-syn* configuration. This was recently confirmed by an x-ray diffraction analysis of the furan-side 4,6-dimethyl tetrahydrobenzoangelicin monocycloadduct to thymine generated within naked DNA.[59,60]

Angular psoralens, also called angelicins, are designed to obtain monofunctional agents toward DNA. In fact, both double bonds of the furan and pyrone moieties are photoreactive. However, the intercalation geometry within DNA base pairs does not favor cross-link formation, although some angelicins induce the generation number of cross-links. It was shown that photoexcited 4,6,4′-trimethylangelicin is able to induce cross-links.[61] Thus, the extent and nature of adduct formation, together with the distribution of monoadducts and cross-links, depends on the psoralen derivative and the DNA sequence.

Photoreactions with Proteins

Yoshikawa et al.[62] observed that adding a preirradiated solution of tritiated 8-MOP (POP) to an aqueous solution of serum albumin leads to covalent binding between the protein and psoralen. The structure of the product was not clarified, but the observation that photobinding proceeds faster in oxygen-saturated solution suggests that it should derive from an oxic pathway. Moreover, the higher photobinding rate in D_2O strongly suggests that singlet oxygen is involved in its formation in the protein-binding photoproduct. Other authors studied the photoreactions between 8-MOP and protein, evidencing the formation of a covalent binding between the two molecules.[63,64,65]

The structural basis of the chemical adducts between psoralen on the one hand, and proteins and amino acids on the other, was only recently elucidated, and not yet completely.

Interestingly, studies on the subcellular fractions of rat epidermis after treatment with 8-MOP and UV-A, showed that 17% of 8-MOP was bound to DNA, while a substantial amount was tethered to proteins (57%) and lipids (26%).[66]

Photobinding of 8-MOP was quantified, but no specific photoproduct could be isolated by Schmitt et al.[65] Nevertheless, there is evidence of photobinding to protein. Psoralen covalently photobinds *in vitro* to several proteins, such as bovine serum albumin[17] and lysozyme.[63] Inactivation of enzymes and cross-linking of their subunits were also observed. 8-MOP can photobind *in vivo* to proteins even more than to lipids and DNA of epidermal cells of rats; the more lipophilic 4,6,4′-trimethylangelicin has lipid as its

main target.[66] In addition, it was observed that lysozyme and ovalbumin exhibit different enzymatic processing patterns after *in vitro* treatment with 8-MOP and UV-A. The photomodification of these proteins also alters the ability of endopeptidases (trypsin and chymotrypsin) to recognize the usual sites of incision.[65] When PUVA effects on proteins were measured, it was commonly found that much greater doses of 8-MOP and UV-A are required, compared with the doses necessary to induce DNA damage. Recently, Sastry[67] characterized a photoadduct formed between 8-MOP and tyrosine from the acid hydrolysate of 8-MOP-treated T7RNA polymerase. Spectroscopic analyses suggest that the pyrone moiety of the original 8-MOP is modified in the isolated photoadduct, and that the adduct probably contains a benzofuran. Mass spectrometry analysis was consistent with the photoaddition of tyrosine to 8-MOP, although low yields of the adduct prevented confirmation of the proposed structure by NMR analysis.

Formation of DNA-Protein Cross-Links

It was shown that psoralen can photoinduce, in mammalian cells, a covalent linkage between a DNA molecule and a protein forming DNA-protein cross-links,[68] and this photodamage provokes evident biological effects. In particular, the formation of these photocompounds in mammalian cells by psoralen and UV-A light was evidenced by alkaline elution, protein precipitation, and isopycnic sedimentation.[68,69] It was observed that psoralens are more effective in inducing this photochemical event than are angular angelicins.[68] The induction of DNA-protein cross-links (DPC) was obtained by using the *double irradiation* method, previously used by Ashwood-Smith and Grant,[70] to study the formation of interstrands cross-links in DNA in *E. coli in vivo*. Psoralens form DNA-protein cross-links (DPC) by a two-step reaction that requires the sequential absorption of two photons.[69,71] This method was applied in whole mammalian cells and *in vitro* on a chromatin-like complex formed by mixing purified DNA and histones from calf thymus.[71,72] The results of these studies, together with similar data independently obtained by Sastry et al.,[73] suggest that in a first-step furan-side, monoadducts are formed, which in a second step, further react with proteins, forming DNA-protein cross-links (DPC). These data support that these lesions are bifunctional adducts, in which the psoralen moiety is a physical part of the bridge linking the two macromolecules; therewith, they must be defined DPC *at length greater than zero* ($DPC_{L>0}$), differently from DNA-protein cross-links induced by UVC light ($DPC_{L=0}$), in which DNA and proteins are connected without any intermediate molecule.[74] Some angelicin isosters [angular furoquinolinones (FQ)] induce DNA-protein cross-links, in a similar way as do psoralens, by means of the double irradiation method. Surprisingly, biological consequences produced by these compounds, in spite of their inability to cross-link DNA, are more pronounced than those induced by 4,5′,8-trimethylpsoralen (TMP).[72,75] To explain these results, and the difference emerging by the comparison with that obtained by TMP, Marzano et al.[76] suggested that DNA-protein cross-links induced by FQ could be repaired by topoisomerase II, which cuts DNA, but similar to what happens with topoisomerase poisons, cannot conclude its enzymatic functions, thus leading to an extensive DNA fragmentation and to cell death.

Photoreactions with Lipids

The possible photointeractions between psoralens and membrane constituents (phospholipids and unsaturated fatty acids) were suggested by Kittler and Lober.[84] Preliminary experimental evidence of the covalent photobinding between psoralen and unsaturated fatty acids was obtained by Caffieri et al.[85] and by Specht et al.,[86] and phospholipids by Antony et al.[87]

It was also shown that UV irradiation activates phospholipase A_2 in human skin and cultured human keratinocytes, thereby giving rise to the release of arachidonic acid, the fatty acid precursor of proinflammatory eicosanoids.[88]

Moreover, a further class of second messengers released from the plasma membrane, as illustrated by 1,2-diacylglycerols (DAG), may play major roles in melanogenesis. Gordon and Gilchrest[89] demonstrated that the exogenous addition of synthetic DAG 1-oleoyl-2-acetylglycerol to cultured human melanocytes increases the basal melanin content and the melanogenic responses of the cells to UV irradiation.

In this context, the formation of covalent adducts between unsaturated fatty acids of membrane phospholipids and psoralens may affect the regulation of some cell processes.

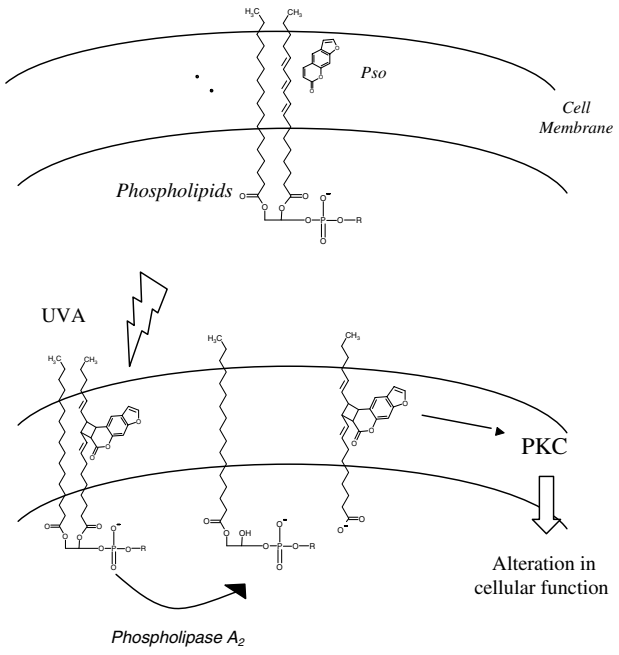

FIGURE 142.5 Proposed mechanism of psoralen-fatty-acid adduct action on protein kinase C (PKC). UV-A irradiation induces a covalent adduct between psoralen and phospholipids that stimulates phospholipase A_2. The enzyme hydrolizes the photocompound, producing psoralen-fatty-acid adduct, which in turn, activates protein kinase C. The activation of this phosphorylating enzyme can modulate cell function and metabolism, i.e., stimulating melanogenesis in melanocytes.

In fact, the cycloadducts between psoralen and unsaturated fatty acid of a phospholipid once formed inside the cell, undergo hydrolysis by phospholypases A_2, generating photocompounds that play the role of second messenger, exhibiting behavior similar to that of DAG (Figure 142.5). To study this photochemical event *in vitro*, studies of the photoreactions between unsaturated fatty acid and psoralen were carried out; it consists of a [2 + 2] photocycloaddition between the 3,4 double bond of the psoralen and one of the olefin bonds of the fatty acid. Some adducts were isolated and their structures elucidated. This concerned several psoralen derivatives and unsaturated fatty acids, including oleic, elaidic, linoleic, and linolenic acid and their methyl esters.[83,84] It was shown that the latter adducts are produced in the skin of rats[66] and in human lymphocytes.[85]

Recently, the structure of psoralen–oleic-acid adducts was assigned in detail.[83] The photocycloadducts were isolated, and it was shown that the photoreaction between psoralen and oleic acid gives rise to four main photoproducts: two exhibit a *cis,cis* structure, whereas the two others have a *trans,cis* stereochemistry (Figure 142.6).

On the other hand, Caffieri et al.[86] showed that fatty–fatty acids cycloadducts in platelets, stimulate the activity of protein kinase C, promoting, in particular, the process of melanogenesis in human epidermis.

The study was extended to a synthetic lecithin bearing an oleyl moiety esterified at position 2 of the glycerol backbone.[87] Structural analysis indicates the similarity of the isomeric forms of cycloadducts involving lecithin and those formed with oleic acid. Moreover, the four diastereomeric oleic–oleic acid photoadducts were tested for their ability to activate protein kinase C in platelets: all were active in a dose-dependent manner, but a significant difference between them could not be noted.

More recently, Anthony et al.[80] showed that 8-MOP-fatty-acid adduct plays the same role of DAG in terms of melanocyte protein kinase C activation. Interestingly, they showed that radiolabeled 8-MOP binds to cell phospholipids specifically in the PI/PS fraction. PI, which is a source of arachidonate, is the

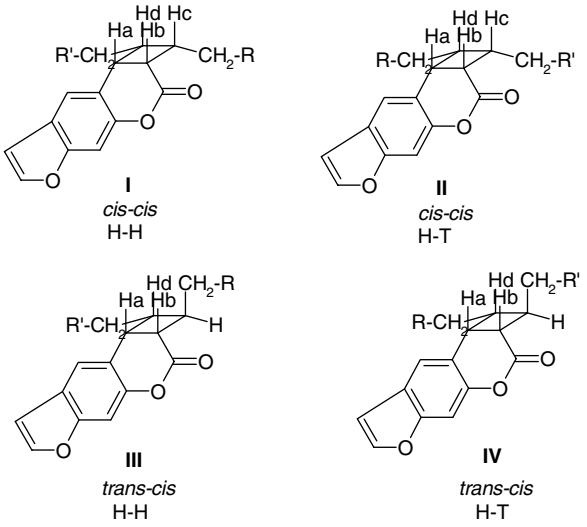

FIGURE 142.6 Molecular structure of isolated cycloadducts between psoralen and oleic acid. R' = $(CH_2)_6$-CH_3 and R = $(CH_2)_6$-COOH. (Adapted from Frank, S., Caffieri, S., Raffaelli, A., Vedaldi, D., and Dall'Acqua, F., *J. Photochem. Photobiol., B: Biol.*, 44, 39, 1998. With permission.)

principal substrate of phospholipase C.[88] In this regard, it was shown that the β-isoform of protein kinase C activates cytoplasmic tyrosinase directly by phosphorylating its serine residues in the melanocytes.[89]

Also, PUVA modulates nonmelanogenic cell functions; thus, 8-MOP fatty acid adducts may influence PKC-mediated pathways in other types of cells.[97] Interestingly, Zarebska et al.[98] showed that acid–fatty-acid adducts are able to induce apoptosis of human lymphocytes in culture.

Apoptosis

In the 1990s, some authors demonstrated that apoptosis was involved in PUVA and psoralen photopheresis treatments.[92] Early studies were carried out essentially by nick translation analysis of DNA fragmentation.[93] The literature of that time does not report indications concerning the action mechanism of apoptosis.[92,93] Only recently have some authors suggested a possible correlation between apoptosis and DNA damage.[94] A recent paper gives experimental evidence that DNA damage by extracorporeal photochemotherapy and psoralen induces apoptosis in mononuclear cells of patients suffering from Sezary syndrome, mycosis fungoides, systemic sclerosis, pemphigus vulgaris, and Hodgkin's disease.[94] Subcellular structures, moreover, other than nucleic acids, may be involved. In particular, considering that mitochondria[95,96] may play a vital role in terms of cell vitality, and that the role of these organelles in the apoptotic event was shown in photodynamic therapy, studies are now being developed to highlight a possible role of mitochondria damage in terms of psoralen apoptosis.[95,96] A recent study carried out on Jurkat cells gives experimental evidence that this is the prevailing form of cell death in Jurkat cells treated with PUVA. In particular, the apoptotic event is due to mitochondrial disfunction caused by mitochondrial alterations of the pore opening,[97] supporting that PUVA damage induced in mitochondria triggers the apoptotic event.[98]

142.3 Dark Effects of Psoralens

Psoralen Receptors

Laskin et al.[99] identified cellular protein as a target for the psoralen molecules linked to cell growth regulation. Subcellular fractionation studies revealed that this receptor is located in membranes and the cytoplasmic fractions of various cell types, in particular, melanocytes and keratinocytes.[99,100]

This receptor was characterized by SDS-PAGE electrophoresis and was found to be a protein with a molecular weight of 22.000. Psoralens bind reversibly to this receptor and with high affinity in a dark reaction.[99] Laskin et al. also found that a number of structurally related psoralen analogues that are active as cutaneous photosensitizers also bind to this receptor. However, 5-methyl angelicin, which is a poor photosensitizer, only binds weakly, indicating that the receptor can readily discriminate between structurally related analogues of psoralens. In addition, a psoralen binds specifically to its receptors, because structurally unrelated compounds fail to compete with psoralens in receptor-binding assay.

It is not necessary to expose a psoralen to UV light in order for the molecule to bind to its receptor. However, once bound to its receptor, the psoralen molecule is photoactivated, producing photoalkylation of the receptor.[99] This event appears to be necessary in order to initiate a biological response.[101] Extensive studies suggest that the ability of psoralens to induce sensitization reactions, including alteration of epidermal cell growth and differentiation, is highly specific and due to interaction with the epidermal growth factor receptor.[102]

Interestingly, the presence of a specific saturable high affinity [^{3}H]8-methoxypsoralen binding protein in cultured S-91 mouse melanoma cells is reported, similar to that mentioned above.[103]

Interaction with Ionic Channels

Recently, it was observed that psoralens, by blocking voltage-dependent K^+ channels (K_v), may alleviate functional deficits in certain multiple sclerosis patients in a manner similar to 4-aminopyridine.[15,16]

In voltage clamp experiments on amphibian nodes of Ranvier, 5-MOP was found to selectively block delayed rectifier K currents. In this line, single trials showed that 5-MOP can alleviate functional deficits in certain patients affected by multiple sclerosis.[104]

A series of psoralens and structurally related 5,7-disubstituted coumarins were synthesized and investigated for their K^+ channel-blocking activity and their phototoxicity. After screening the compounds on Ranvier nodes of the Xenopus Laevis toad, the affinities of the most promising compounds, which proved to be psoralens bearing alkoxy substituents in the 5-position or alkoxymethyl substituents in the neighboring 4- or 4′-positions, to a number of homomeric K^+ channels were characterized. All compounds exhibited the highest affinity to $K_v1.2$. 5,8-Diethoxypsoralen was found to be an equally potent inhibitor of $K_v1.2$ and $K_v1.3$, while lacking the phototoxicity normally inherent in psoralens. These compounds represent a novel series of nonpeptide blockers of Shaker-type K^+ channels that could be developed further into selective inhibitors of $K_v1.2$ or $K_v1.3$.

Because K_v channel blockers are known to inhibit T-cell-mediated immune responses *in vitro* and *in vivo*, subsequent studies investigated *in vivo* the effects of three psoralen derivatives, 5-methoxypsoralen, 8-methoxypsoralen, and 5,8-diethoxypsoralen, in Lewis rats challenged for experimental autoimmune encephalomyelitis (EAE). The derivatives examined exhibited suppressive effects on the parameters measured with the same sequence of efficacy: 5,8-diethoxypsoralen > 5-MOP > 8-MOP. The authors suggest that K_v channel-blocking psoralens interfere with voltage-controlled signal transduction in lymphocytes and might thereby suppress immune responses in autoimmune diseases of the central nervous system and probably also in other autoimmune disorders. These derivatives, especially the nonphototoxic 5,8-diethoxypsoralen, are, therefore, new candidates for further studies on K^+ channel-blocking immunosuppressive drugs. The agents may exert a dual beneficial effect on demyelinating diseases like multiple sclerosis, because they could attenuate the inflammatory process and improve axonal conductivity.

Another interesting report suggests that psoralens open cystic fibrosis transmembrane conductance regulator Cl^- channels in T84 cell monolayer. Similar results with psoralens in rat colon and primary cultures of murine tracheal epithelium were obtained. On the basis of these observations, it was suggested that psoralens represent a novel class of Cl^- channel openers that can be used to probe mechanisms underlying Ca^{2+}-mediated Cl^- secretion.

142.4 Future Perspectives

The basic mechanisms responsible for the photosensitizing effects of psoralens were clarified, although some aspects require additional research in order to be able to give a more complete picture of the various processes.

Demonstrating that fatty–fatty-acid adducts are formed in cells stimulated studies of the biological role of these adducts. In this regard, these photocompounds may play the role of second messenger that stimulates protein kinase C. This may lead to stimulation of melanin synthesis in melanocytes, thus explaining one of the mechanisms of the melanogenic effect of psoralen. A proposed mechanism is depicted in Figure 142.6. Because photoactivated psoralens have a wide range of biological effects, it is likely that their ability to generate signals, e.g., by modulating protein kinase C activity, is dependent on cell type.

Besides their application in PUVA therapy to treat diseases characterized by hyperproliferation or the lack of pigmenting ability of some regions of the skin, in the last years, psoralens were also used in photopheresis, a therapeutic approach useful in treating immune disorders.

An important application, recently developed, is represented by sterilizing blood components, in particular, platelet concentrate. Recently, clinical trials carried out with a novel psoralen S-59 derivative demonstrated the efficacy of the photochemical treatment, thus offering the potential to reduce transfusion-related viral and antibacterial diseases.

In the last decade, the involvement of apoptosis in PUVA and in photopheresis strongly stimulated research in this field. A recent paper reports that mitochondria represent an important target psoralen photoinduced apoptosis.[98]

The important finding that some psoralen molecules, in particular 5,8 disubstituted derivatives, have significant *in vitro* and *in vivo* activity as potassium channel blockers, although lacking the phototoxicity normally inherent in psoralen, opened a new field of research toward an innovative application of this class of molecule in many important diseases, such as multiple sclerosis, in which the capacity to block voltage-gated potassium channels improves conduction in demyelinated fibers. It is also important to point out that potassium channels are involved in the control of membrane potential, production of lymphokine, and proliferation of human T-lymphocytes. Therefore, 5,8 disubstituted psoralens represent a novel series of compounds able to block potassium channels that could be developed further into more selective inhibitors.

143.1 Introduction

As the field of photosensitization enters its second century of intensive scientific study, it has matured into an area of science that has broad applicability in a variety of settings, many of them health related.[1] Since the turn of the 20th century when Oscar Raab and his mentor Hermann von Tappeiner published their observations on the effects of dyes on paramecia,[2,3] photosensitization of molecules, organelles, cells, tissues, plants, and animals has been investigated using a wide array of photosensitizers, including xanthenes, porphyrins, phenothiazines, and flavins.

In contrast to the descriptive studies of photosensitization effects that were the subject of so many publications 100 years ago, current work capitalizes on a better understanding of the underlying mechanism of photosensitization. For example, therapeutic applications in photodynamic therapy currently in use to treat malignant tumors as well as other conditions, are increasingly exploring two-photon excitation processes to improve localization of the effects. Because two-photon excitation requires a high-energy density of illumination for activation of the photosensitizer, the intensity of a convergent beam can be adjusted so that this critical energy density is only reached near the focal point of the beam, providing excellent spatial resolution. This approach also allows control of the depth of the photodynamic effect (Figure 143.1). In two-photon excitation, each absorbed photon carries only half of the excitation energy, exciting the photosensitizer through a virtual excited state.[4] Planck's Law dictates that these lower-energy

0-8493-1348-1/04/$0.00+$1.50

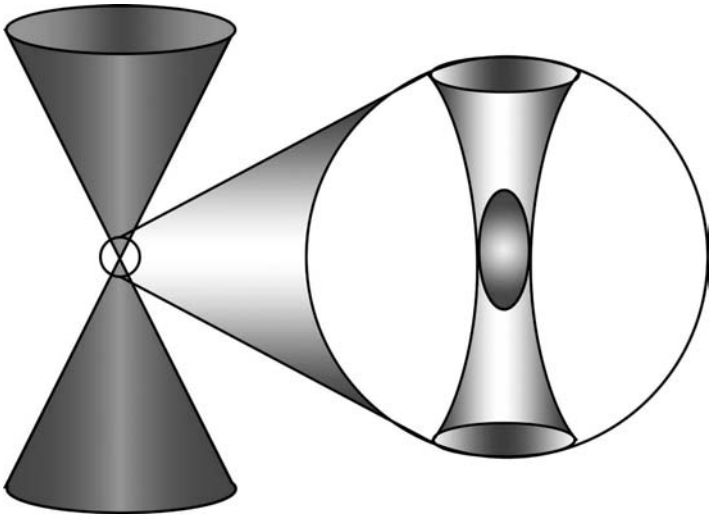

FIGURE 143.1 Two-photon excitation allows activation of photosensitizers at deeper tissue depths, because it uses longer wavelength illumination. In addition, the energy density required for near simultaneous absorption of two photons can be manipulated to restrict the volume of excitation to a small region near the focal point of a convergent beam.

photons will have a longer wavelength. Because longer wavelength illumination has much greater tissue penetration compared to shorter wavelengths, two-photon techniques can produce effects at much greater depths than previously possible. While the high-energy requirement is still a problem for clinical applications, this may well become less critical as laser technology improves.

Better understanding of the localization of different chemical species of photosensitizers allowed better targeting of photosensitization effects. For example, using aluminum phthalocyanine disulfonate as photosensitizer, Selbo et al.[5] demonstrated localization of the photosensitizer in endocytic vesicles in tumor-bearing mice. They subsequently administered a membrane-impermeable chemotherapeutic agent, gelonin, which is normally taken up by endocytic vesicles. Illumination of the tumors of these mice, reduced tumor cell survival while producing complete remission in six of nine treated animals.

Like the examples cited above, there are several current hot topics of research in photosensitization, including the use of photodynamic therapy for malignancies,[6] the use of photosensitizers as model systems for studying physiological and pathological processes involving reactive oxygen species,[7] the development of model systems to produce cerebral ischemia,[8] the use as antimicrobials and to treat blood and blood products,[9] and photosensitization in the cardiovascular system, the main topic area of this review.

143.2 Photosensitization of the Microcirculation

Reactive Oxygen Effects in the Microcirculation

Because photosensitization effects are thought to occur via the intermediacy of reactive oxygen species (ROS), an understanding of the considerable literature in this field of study is useful in understanding photosensitization effects in the microcirculation. ROS are molecules that have an unpaired electron in their outer orbit, and as a result, they are highly reactive.[10] Addition of an electron to molecular oxygen forms superoxide, with approximately 5% of oxygen converted to ROS under normal conditions. Cells contain several enzymatic free-radical scavengers (i.e., superoxide dismutase, catalase, and glutathione peroxidase) as well as antioxidants (i.e., glutathione, lipoic acid) that protect against ROS-induced damage under normal conditions. In situations associated with increased ROS production, however, the antioxidant defenses are not sufficient to detoxify ROS, with higher ROS levels resulting in irreversible changes in lipids and proteins.

ROS can be produced in a variety of cells, with endothelial cells and leukocytes of particular significance to the cardiovascular system. Endothelial cells form a single cell layer along the inner surface of all blood vessels and play a critical role in regulating microvascular function, the nature of which is dependent on the particular vascular segment:[11]

1. *Arterioles*: These vessels, consisting largely of vascular smooth muscle, regulate organ blood flow via changes in vessel diameter and, thereby, vascular resistance to blood flow. The endothelial cell layer produces a variety of vasoactive mediators that cause relaxation or constriction of vascular smooth muscle. One of these mediators, nitric oxide (NO), is of particular importance, as it is continuously produced under normal conditions and, therefore, plays an important role in regulating vascular tone. In addition, NO mediates the effects of certain vasoactive agents; for example, increased blood flow in response to acetylcholine is dependent on increased NO formation by endothelial cells.
2. *Capillaries*: These vessels consist of a single cell layer of endothelial cells. The absence of overlying vascular smooth muscle cells permits exchange of fluid and nutrients between blood and tissue. NO produced by capillary endothelial cells appears to maintain low vascular permeability under normal conditions.
3. *Venules*: Postcapillary venules play an important role in regulating leukocyte recruitment into tissues. Circulating leukocytes interact with venular endothelial cells through a highly coordinated process.[11] The first step involves a leukocyte rolling along the endothelium, which is mediated through interaction of specific adhesion molecules with their corresponding ligands. Leukocyte rolling reduces the forward velocity of leukocytes sufficiently to allow interaction between different types of adhesion molecules on each cell, leading to firm adherence of leukocytes within the venule. The final step, leukocyte emigration, involves movement of leukocytes out of the circulation into the tissue.

To illustrate the effects of ROS on microvascular function, ischemia–reperfusion (I/R) will be briefly discussed. A prolonged reduction or absence of blood flow (i.e., ischemia) results in a series of biochemical changes within endothelial cells that will initiate a microvascular inflammatory response upon reintroduction of blood flow to the tissue (i.e., reperfusion).[12,13] Clinical situations involving I/R-induced microvascular dysfunction include organ transplantation, coronary angioplasty, thrombolytic therapy, and cardiopulmonary bypass.[13]

During prolonged ischemia, calcium levels within endothelial cells rise, resulting in conversion of xanthine dehydrogenase to xanthine oxidase.[11,14] Upon reintroduction of oxygen to tissue upon reperfusion, a marked increase in ROS generation occurs primarily via xanthine oxidase. The resulting oxidant stress will have site-specific effects within the microcirculation:

1. *Arterioles*: The primary effect of I/R on arterioles is impaired endothelium-dependent relaxation of vascular smooth muscle. The net result is arteriolar constriction and reduced blood flow, which may promote organ injury. ROS generation during reperfusion appears to be the underlying cause of this response, as antioxidants attenuate I/R-induced arteriolar constriction. The specific oxidant involved is superoxide, which interacts with NO, such that levels of this endothelial-derived dilator are reduced during reperfusion.
2. *Capillaries*: I/R results in increased filtration of fluid across capillaries as well as a decrease in the number of perfused capillaries. The mechanisms underlying these responses are still not clearly defined but may be related to decreased NO levels in capillary endothelial cells as a result of oxidant stress, as described above. Lower NO levels may increase capillary permeability, and increase the rate of filtration of fluid into the tissue. The resulting edema was proposed to compress the capillaries sufficiently to impede blood flow through these vessels.
3. *Venules*: ROS generation during reperfusion has several effects on postcapillary venules: increased leukocyte adherence to venular endothelium, with subsequent emigration of some leukocytes into the tissue; platelet aggregation; and increased vascular permeability. These responses are dependent

on reduced levels of the anti-inflammatory agent NO within endothelial cells (via inactivation of NO by superoxide), generation of lipid inflammatory mediators (such as platelet activating factor and leukotriene B_4), and activation of perivascular mast cells, resulting in local release of proinflammatory mediators.

Microcirculatory Effects of Photodynamic Therapy for Tumors

Much of what is known about photosensitization effects on microcirculation comes from studies related to photodynamic therapy of tumors. Photodynamic therapy of tumors will be covered more fully in subsequent chapters. Nonetheless, a brief synopsis of the vascular effects is appropriate here to allow comparison with other results in the vasculature.[15]

It is now well established that, depending on the photosensitizer used and the route of administration, the effects on tumors can be predominantly at the cellular level, on the vasculature, or on both. Observations made on tumor microcirculation must be interpreted carefully, because it differs morphologically and functionally from normal microcirculation. Tumor microcirculation is characterized by spatial and temporal heterogeneity in structure and function. This includes increased leakiness, incomplete basement membranes, and overexpression of glycoproteins. There is an increased proliferative rate of endothelial cells. Tumors can have areas that are relatively hypoxic, such that its microcirculation is similar in many ways to embryonic vascular beds.

Photodynamic therapy of tumor microvasculature damages sensitive sites on endothelial cells, largely their surface membranes or mitochondria. Tight junctions between the cells separate, exposing basement membrane. The exposed basement membrane serves as a thrombogenic site causing platelet aggregation, release of vasoactive substances such as thromboxane and the leukotrienes, and leukocyte adhesion leading to increased vascular permeability and vessel constriction. Mediators such as VEGF/VPF and EDRF/NO are thought to be important intermediates, as are LDL receptors.

Because photodynamic therapy is an oxygen-dependent process, typically thought to occur via a Type II singlet oxygen mechanism, it is often combined with hyperbaric oxygen or hyperthermia to augment tumor destruction, particularly in hypoxic areas of the tumor.

Effects of Hypoxia on the Microcirculation

In the next section, we will briefly discuss the acute and chronic effects of hypoxia (i.e., reduced oxygen levels) on microcirculation. As indicated previously, the efficacy of photosensitizers in the treatment of cancer may be limited in part by the development of tissue hypoxia within rapidly growing tumors.

In contrast to ischemia–reperfusion, relatively few studies examined the effect of hypoxia on microvascular function, despite clinical evidence of a microvascular inflammatory response in this setting. For example, systemic hypoxia occurs in people at high altitudes and may result in high-altitude cerebral edema (HACE). Although the underlying cause of this serious condition is not yet known, microcirculatory alterations were proposed to play a major role. For example, increased leukocyte–endothelial interactions are frequently associated with the pathological features of environmental hypoxia.[16,17]

A growing body of evidence implicates ROS as an underlying cause of hypoxia-induced microvascular inflammatory responses. As described above, the initiating cause of microvascular injury following I/R is generation of reactive oxygen species (ROS) upon reintroduction of oxygen after prolonged ischemia.[11,12] It is now known that a reduction in the PO_2 of the culture media increases ROS levels within isolated endothelial cells, cardiomyocytes, and hepatocytes.[18,19] The view that hypoxia promotes ROS generation is also consistent with studies showing reduced antioxidant levels in cultured endothelial cells,[20] as well as in the liver *in vivo*.[21] Recent observations implicate alterations in the electron transport system within mitochondria as the major site of ROS formation during hypoxia.[22]

Under *in vivo* conditions, an acute reduction of the inspired PO_2 initiates a rapid microvascular response characterized by increased leukocyte–endothelial interactions,[23] followed by leukocyte emigration into the interstitium and increased vascular permeability.[24] An alteration in the balance between

ROS and NO appears to play a critical role in this phenomenon.[25] In support, microvascular ROS levels (as assessed using oxidant-sensitive fluorescent probes) increased during hypoxia.[26] Antioxidants attenuated the hypoxia-induced increase in ROS formation, leukocyte adherence, vascular permeability, and leukocyte emigration. Interventions designed to increase tissue levels of NO also attenuated these microvascular inflammatory responses during hypoxia.[23]

A potential consequence of oxidant stress during hypoxia due to alterations in the ROS/NO balance is local formation of lipid inflammatory mediators, such as platelet activating factor and leukotriene B_4.[27] These mediators promote leukocyte and platelet adhesiveness to venular endothelium and may contribute to enhanced thrombosis reported during hypoxia.[28,29]

If hypoxia is maintained, the initial microvascular responses described previously eventually resolve. In the mesenteric and cremasteric microcirculations of rats exposed to a hypoxic environment for 3 weeks, measurements of leukocyte adherence, leukocyte emigration, and vascular permeability are not significantly different from values obtained in animals maintained in a normal oxygen environment (i.e., normoxic animals). The mechanisms responsible for the acclimatization of vascular endothelial function during sustained hypoxia are not yet clear. However, it is well known that chronic hypoxia leads to an increase in red blood cell mass in response to increased erythropoietin secretion. It is possible that the elevated hemoglobin concentration resulting from the increased red blood cells could improve oxygen delivery to tissues and attenuate the severity of hypoxia at the venular level. However, systemic hypoxia did not result in leukocyte adherence to mesenteric venules of acclimatized rats, even after the red blood cell concentration was reduced to normal values.[23]

Because the initial microvascular inflammatory response to hypoxia is dependent on an increase in the ROS/NO balance, microvascular acclimatization may be associated with a restoration of this balance. Two observations support this possibility: microvascular ROS levels in the mesenteric microcirculation do not increase when acclimatized rats are exposed to hypoxia; and inhibition of inducible NO synthase (iNOS) results in an increase in leukocyte rolling and adherence, and in ROS generation, during hypoxia in acclimatized rats.

These effects of iNOS inhibition suggest that the microvascular acclimatization involves upregulation of iNOS. Under normal conditions, NO is formed by eNOS, an enzyme that is constitutively expressed in endothelial cells. However, the inducible form can be expressed in various situations, and it is capable of generating higher amounts of NO than eNOS. It is possible, therefore, that the rate of NO formation in the vascular endothelium of acclimatized rats is markedly increased over normal levels. Because NO is an anti-inflammatory agent, increased microvascular NO levels could inhibit leukocyte–endothelial interactions and may contribute to acclimatization of vascular endothelial function during sustained hypoxia.

The upregulation of iNOS in acclimatized animals may be secondary to induction of hypoxia-inducible factor-1 (HIF-1). Recent studies showed that increased intracellular ROS generation promotes HIF-1 expression.[30,31] HIF-1 activates gene transcription and results in multiple cellular changes, including expression of iNOS, vascular endothelial growth factor (VEGF), and heme oxygenase-1. The latter two factors may also contribute to microvascular acclimatization to hypoxia. Interestingly, VEGF is an important mediator of angiogenesis and appears to play a major role in sustaining tumor growth. It is possible that the increased ROS generation may participate in initiating the events that eventually lead to acclimatization of the vascular endothelium during sustained hypoxia. Further knowledge of the mechanisms underlying microvascular acclimatization to hypoxia may potentially be relevant to studies of the efficacy of photosensitizers in limiting tumor growth.

In summary, exposure to environmental hypoxia promotes increased leukocyte–endothelial interactions characterized by increased leukocyte rolling and adherence to the vascular endothelium, followed by leukocyte emigration and increased vascular permeability. This response is observed in several microcirculatory beds, suggesting that it represents a generalized response to systemic hypoxia. After 3 weeks of continuous hypoxic exposure, the microvascular inflammatory response resolves, and the vascular endothelium is resistant to even lower PO_2 levels. The initial microvascular response to hypoxia is

characterized by an increase in the ROS/NO balance, while the acclimatization process features a restoration of this balance, in part due to upregulation of iNOS.

Photodynamic Therapy for Macular Degeneration

Roughly 1.7 million Americans are afflicted with age-related macular degeneration (AMD). Although the form of the disease known as wet AMD accounts for only about 10% of these cases, it accounts for 90% of blindness from AMD. Approximately 100,000 people in the United States are blind from the disease. The major cause of visual problems in wet AMD is choroidal neovascularization, growth of new blood vessels in the choroidal layer beneath the macular region of the retina.[32]

Photodynamic occlusion of vessels was investigated in the 1980s using various photosensitizers, including Rose Bengal and aluminum sulfonated phthalocyanine, but the main focus gravitated to benzoporphyrin derivatives by the 1990s.[33,34] One such lipophilic derivative known as Vertoporfin with an absorption peak at 690 nm underwent a clinical trial involving more than 400 patients, with promising results.[35] In a single case report using the same photosensitizer, fluorescein angiography, 2 weeks posttreatment, revealed a 60% decrease in the area of neovascularization with evidence of endothelial cell degeneration, platelet aggregation, and thrombus formation. Macrophages were sometimes seen in the treated area. However, at 3 weeks posttreatment, the fluorescein leakage area returned to the same size as before treatment.[36] The changes induced by treatment are not permanent. In the larger case study, patients had an average of five treatments over the course of 24 months, and it was only during the last 12 months of the regimen that visual acuity began to differ significantly from sham-treated controls. In April 2000, the FDA (US) approved Vertoporfin for treatment of choroidal neovascularization from AMD,[37] and in August 2001, the approval was extended to include choroidal neovascularization from pathologic myopia and from presumed ocular histoplasmosis.[38]

143.3 Photosensitization of the Macrocirculation

Heart disease was the leading cause of death in the United States in 1999, and the preliminary data for 2000 are similar,[39] with atherosclerotic changes contributing to many of the categories included in this broad grouping. In the past, therapeutic protocols were aimed at enlarging narrowed vessels using interventions such as balloon angioplasty of stenotic (narrowed) regions of arteries. Restenosis often occurred, which limited the efficacy of such procedures and led to intensive efforts to minimize this process. An alternate treatment involves grafting a segment of vein to replace affected arterial segments. These grafts also show structural changes that often lead to their failure. Recent studies focused on arterial plaque development, aiming to intervene before stenosis recurs. Photosensitizers used in photoangioplasty are promising candidates for treatment of atherosclerosis and prevention of restenosis.[40]

Photodynamic Therapy for Vascular Plaques

Interest recently focused on so-called vulnerable plaque as an initiator of serious cardiac and vascular events. These plaques begin as cholesterol is deposited in fatty streaks within arterial walls. The intima, the inner layer of the arterial wall, thickens, and monocytes infiltrate, becoming tissue macrophages. In vulnerable plaque, macrophages release lytic enzymes, including colagenase and elastase.[41] These enzymes degrade the fibrous cap separating the plaque from the arterial lumen that can then rupture, exposing thrombogenic connective tissue and lipids. This event initiates a cascade of platelet and clotting factor activations producing intravascular thrombosis and occlusion. Such vulnerable plaque can contribute to myocardial ischemia, unstable angina, and myocardial infarction.[42]

Vulnerable plaque is often not easily detectable by angiography, because the luminal area may not be compromised until late in the disease process. Recently, fluorescent photosensitizers were used to localize vulnerable plaque.[43] Specific targeting of some photosensitizers to macrophages of vulnerable plaque may depend on scavenger receptors.[44,45] Photosensitizers were also used to treat vulnerable plaque and are

particularly valuable, because they are able to reduce the number of resident macrophages. Using Lu-Tex, a water-soluble, expanded porphyrin that absorbs at 732 nm, a wavelength in the red end of the visible spectrum with good tissue penetration, Hayase et al.[42] demonstrated a small but statistically significant reduction in plaque volume but a dramatic reduction in macrophages within the intima and the media. Lu-Tex was previously shown to localize within macrophages in plaque and to cause plaque regression over a period of days following endovascular illumination.

Photodynamic Therapy to Create Nonthrombogenic Vessel Grafts

Coronary artery bypass surgery, as well as bypass of other arteries, is often accomplished using a vein graft, most often, the saphenous vein. The major complication is occlusion of the graft, typically as a result of intimal hyperplasia.[46] Within 2 months of implantation, the transplanted vein becomes little more than a "stiff, fibrous-tissue conduit." Thickening of the intima of veins implanted into the arterial system was recognized since the early 1900s.[47] It is now recognized that vein grafts demonstrate rapid infiltration of inflammatory cells and development of a fibrous coating. As in arterial plaques, there is infiltration of macrophages. Within a month, there is subendothelial proliferation of smooth muscle cells and fibroblasts, producing intimal thickening. This is followed by gradual loss of smooth muscle cells and their replacement by fibrous tissue, as elastic tissue disappears.

In vitro treatment of excised segments of vein with chloroaluminum sulfonated phthalocyanine and light prior to their implantation as arterial grafts significantly reduced the processes that lead to graft occlusion.[46] When compared to untreated control arterial grafts, intimal and medial cross-sectional areas were reduced in the treated grafts. However, in this study, there was no difference in the intimal hyperplasia at the junctions between the carotid artery and its venous graft. This may reflect proliferation of untreated arterial cells adjacent to the graft and may indicate a problem associated with the *in vitro* graft treatment used here.

The photosensitizer Lu-Tex was shown to localize in smooth muscle cells of vein grafts and to produce apoptotic death of these cells following illumination. Intimal thickening was significantly reduced by treatment but was strongly dependent on the interval between graft implantation and treatment — 4 weeks was effective, while 12 weeks was not.[48] The authors interpreted this dependence to indicate an important role for macrophages in the process, because macrophages are strongly active at 4 weeks. Prevention of monocyte recruitment (the precursors of tissue macrophages) may prevent much of the venous remodeling that normally occurs in grafts.[49]

Similarly encouraging results were obtained in a rat heart transplant model. A second heart was transplanted into the abdomen to study graft coronary artery disease. Photosensitizer and light treatment significantly reduced the percent of vessels affected and reduced intimal hyperplasia in those that were.[50]

Photodynamic Inhibition of Restenosis

Restenosis following procedures such as balloon angioplasty was reported to occur in 30 to 50% of cases within 6 months.[51] Intimal hyperplasia from smooth muscle cell proliferation is a major cause of restenosis, but there are contributions from changes in elastic recoil, extracellular matrix, and constrictive arterial remodeling. The use of stents has obviated the problems associated with changes in elastic recoil but may actually augment intimal hyperplasia.[52,53]

Photosensitizers and light were shown to kill human vein endothelial cells and cultured vascular smooth muscle cells via apoptosis *in vitro*. Treatment of extracellular matrix results in reduced attachment of smooth muscle cells[54] and cross-linking of collagen that inhibits smooth muscle cell migration.[55]

In normal arteries, photosensitizers and light denude the endothelial cell lining and reduce smooth muscle cell numbers without generating an inflammatory response.[56,57] Endothelial repopulation occurs with time after treatment, and there are no problems with late thrombotic occlusion of treated vessels, as there are with radiation treatments to prevent restenosis.[58] Importantly, the mechanical responses of normal arteries are not altered by photosensitizers and light treatment.[59]

Reduction of arterial intimal hyperplasia following balloon injury was demonstrated a decade ago using chloraluminum sulfonated phthalocyanine.[60] A variety of photosensitizers are now known to produce similar effects, including Photofrin, texaphyrins, and the porphyrin precursor that is converted to an active form *in vivo*, 5-aminolevulinic acid. As seen in normal arteries, endothelial denudation occurs, but there is rapid repopulation. Medial smooth muscle cell repopulation is relatively delayed,[57,61] Injured pig femoral arteries treated with Photofrin and light showed a reduced media/intima thickness ratio 3 weeks after treatment compared to injured, untreated controls.[62] Another study using 5-ALA in pig arteries found improvement that could be attributed to inhibition of constrictive arterial remodeling in the treated arteries. Limited clinical results are promising,[51] but the number of patients treated is still small.

143.4 Cardiac Effects of Photosensitization

It is well established that not only is the ischemic myocardium susceptible to arrhythmias, the myocardium that is reperfused following ischemia (e.g., after successful angioplasty) is also susceptible,[63–65] Ventricular tachycardia, accelerated idioventricular rhythms, ventricular premature beats, and rate-dependent fibrillation occur within minutes of reperfusion after an ischemic episode. In a series of studies using isolated, aerobically perfused rat hearts, Hearse and colleagues[66–68] demonstrated that photosensitization leads to rapid development of electrocardiographic (ECG) abnormalities and arrhythmias similar to those that occur during reperfusion of the ischemic myocardium. To induce photosensitization, the perfusion fluid contained rose bengal, and the heart was uniformly illuminated with green light via 200 fiber optic cables placed in a manner that illuminated the entire heart surface. The initial ECG changes, induced within 12 sec of photosensitization onset, consisted of inversion of the terminal portion of the T wave and of an increase in the Q–T interval indicative of increased duration of the ventricular action potential. This was followed by production of ventricular premature beats (within 2 min), ventricular tachycardia (within 3 min), and complete atrioventricular block (within 6 min). Light intensity and rose bengal concentration affected the time to onset and severity of the arrhythmias. Arrhythmia production was attenuated by adding histidine (a $^1O_2$ quencher) to the perfusion fluid, but other antioxidants such as ascorbate, dimethylthiourea, glutathione, superoxide dismutase, and methionine did not provide protection. The ability of a $^1O_2$ quencher, but not other antioxidants, to protect the heart against photosensitization-induced arrhythmias implicates $^1O_2$ as the mediator of the electrophysiological events. This is of interest, because there is now a variety of evidence indicating that $^1O_2$ plays a role in cardiac ischemic–reperfusion (I/R) injury. For example, Kukreja et al.[69] demonstrated that histidine provided better protection against cardiac I/R injury than did a mixture of superoxide dismutase, catalase, and mannitol. Zhai and Ashraf[70] demonstrated that $^1O_2$ is detectable in postischemic reperfused isolated rat hearts. More recently, Lee et al.[71] demonstrated that improvement in functional recovery of ischemic rat hearts correlated with the effectiveness with which agents quenched $^1O_2$.

Photosensitization studies using isolated cardiac tissue (muscle fibers or the isolated single cell) provided insights into the mechanisms responsible for the ECG changes and arrhythmia production discussed above. Increased and decreased duration of the cardiac action potential were reported,[72–74] and duration and intensity of photosensitization can affect the outcome. Continuous, low-level photosensitization first prolongs the action potential and then shortens it.[72,73] However, brief (<10 s), high-intensity photosensitization can shorten the action potential without first prolonging it.[75] Accordingly, regional differences in the level of $^1O_2$ exposure could produce refractory period inhomogeneity; a condition that plays an important role in production of reentrant arrhythmias. These arrhythmias are also favored by a decrease in action potential duration. Shortening of the action potential favors reentrant conduction by reducing the length of tissue occupied by the action potential (a product of conduction velocity and action potential duration). It was demonstrated that reperfusion of ischemic myocardial tissue can transiently produce conditions that favor reentrant conduction.[63] In addition to modifying action potential duration, photosensitization can initiate abnormal spontaneous electrical activity and aftercontractions related to production of early and delayed afterdepolarizations.[74,76] Early afterdepolarizations

(EADs) occur during the plateau or rapid repolarization phase of the action potential, and these can lead to tachycardias independent of reentrant conduction. It was reported that about 75% of tachycardias initiated early during reperfusion are initiated by a nonreentrant mechanism.[65] It is also well established that fibrillation can be initiated by EADs. By comparison, delayed afterdepolarizations (DADs) occur following action potential repolarization, and these can trigger premature action potentials and contractions.

Photosensitization effects on cardiac ionic currents provided insights into mechanisms responsible for alterations in action potential waveform and conduction in different cardiac regions. A wide variety of cardiac voltage-gated ionic currents are suppressed or completely blocked by photosensitization.[72,73,77–80] These include the sodium current (I_{Na}), L-type calcium current (I_{CaL}), transient outward potassium current (I_{to}), slow-activating delayed rectifier potassium current (I_{Ks}), and inward rectifier potassium current (I_{K1}). Suppression of I_{Na} slows action potential conduction in atrial and ventricular tissue and enhances the probability of production of reentrant arrhythmias. Suppression of I_{CaL} would act to decrease action potential duration and reduce the probability of EAD production related to the so-called calcium window current. It would also suppress production of the calcium-dependent action potential in AV-node cells and produce AV-block. Suppression of I_{to} and I_{Ks} acts to prolong the action potential and enhance the probability of EAD production. Suppression of I_{K1} depolarizes the resting potential of atrial and ventricular cells, an event that occurs late during continuous photosensitization.

Calcium overload is a ubiquitous phenomena associated with cellular oxidant stress, including photosensitization-induced stress. Ver Donck et al.[81] were the first to demonstrate that photosensitization causes calcium overload-induced hypercontracture of the isolated cardiac cell. Subsequent studies provided evidence that a variety of mechanisms play a role in photosensitization-induced calcium overload. These include inhibition of the sodium-potassium pump,[82] the sodium–calcium exchanger,[83] and calcium uptake by the sarcoplasmic reticulum.[84] Inhibition of the sodium–potassium pump leads to increased intracellular sodium and subsequent reduction of calcium efflux via the sodium–calcium exchanger. Suppression of sodium–calcium exchange also reduces calcium efflux. Inhibition of calcium uptake by the sarcoplasmic reticulum increases free-ionized intracellular calcium concentration. Calcium influx also plays an important role in photosensitization-induced calcium overload. Photosensitization increases membrane permeability and produces an associated leak current.[85,86] The membrane conductance related to this leak current increases with time during photosensitization, does not require a rise in intracellular calcium for its activation, and provides a path for sodium and calcium influx and potassium efflux. Calcium influx via the membrane permeability pathway created by photosensitization produces a calcium-dependent hypercontracture of the isolated cardiac cell at membrane conductances indicative of an intact membrane.[87] It also plays a role in cell killing.[88,89]

It is well established that calcium overload can be arrhythmogenic by enhancing two calcium-sensitive, inward currents that play a role in DAD production. One is a nonselective cation current, and the other is the sodium–calcium exchange current. Matsuura and Shattock[73,78] presented evidence that photosensitization enhances both of these currents. In the mammalian cardiac cell, photosensitization-induced calcium overload produces oscillatory release of calcium from the sarcoplasmic reticulum that is arrhythmogenic via production of EADs.[76] This finding indicates that inward current via the sodium–calcium exchanger, rather than the L-type calcium channel, accounts for photosensitization-induced EAD production.

143.5 Other Photosensitization Effects in the Cardiovascular System

Sterilization of Blood and Blood Products

The risk of disease transmission through blood transfusion improved considerably thanks to donor counseling and much improved blood-screening procedures. Nonetheless, a risk remains that is thought to be primarily associated with a "window period," the interval of time between infection and development of detectable antigen, antibody, or nucleic acid.[90] Photosensitization was shown to inactivate a

broad range of pathogens. Its selectivity relative to photosensitization of normal blood components is the basis for the treatment of whole blood and blood products, such as plasma, platelets, or pack cells, by this means.

Phenothiazines, such as methylene blue, were used as virucidal agents for more than 70 years, and they were investigated as agents to prevent the transfusion-mediated spread of hepatitis during the Korean War.[9] In plasma, 5 to 6 log virus inactivation can be obtained. Further treatment inactivates clotting factors, particularly fibrinogen and C1 inactivator.

Successful treatment of packed red cells can be more difficult than plasma treatment because of the need to inactivate extracellular and intracellular viruses. The choice of photosensitizer is critical in this regard. For example, uncharged phenothiazines are more effective at inactivating intracellular virus than are charged species.[91] Other promising candidates include merocyanine-540, tetrasulfonated aluminum phthalocyanine,[92] and hypericin.[93] Manipulation of the composition and pH of the medium can shift the selectivity of the method for virus versus red cells. Strong treatment can damage red cell membranes, inducing potassium leakage and enhanced hemolysis.

Another interesting possibility in blood product treatment stems from the high sensitivity of T cells to photosensitized inactivation. T cells were shown to be more sensitive than viruses using phenothiazines as photosensitizers,[94] and this may provide a means by which to inhibit transfusion-associated graft-versus-host disease, because T cells play an important role in this disease process.

Inhibition of Clotting by $^1O_2$

Treatment of blood with photosensitizers and light *in vitro* does not produce the same effect as treatment *in vivo*. Due to the inhibition of clotting factors, treatment of blood inhibits clotting,[95–98] but *in vivo* treatment may produce thrombosis and vessel occlusion. The difference *in vivo* is the simultaneous treatment of the vasculature along with the blood. Effects on the vasculature, as described above, can initiate microvascular responses that lead to thrombogenic foci. This effect was often observed in studies related to photodynamic therapy for malignancies. With careful selection of the photosensitizer, its concentration, and its illumination intensity, thrombosis may be avoided, as discussed previously.

143.6 Summary and Conclusions

Clinical applications of photosensitization hold considerable promise. Unlike alternative therapies, such as ionizing radiation, photodynamic therapy can be repeated with no known limits. It poses considerably less risk to administering personnel. The photon energy is not sufficient to produce DNA damage directly, and most photosensitizers in use do not penetrate to the nucleus or interact with nuclear DNA, so mutation is not as significant a concern. With the current protocols, an apoptotic response appears to be dominant, with no inflammatory response at the treatment site.

Synthetic Strategies in Designing Porphyrin-Based Photosensitizers for Photodynamic Therapy

Ravindra K. Pandey
Roswell Park Cancer Institute

144.1 Introduction

Photodynamic therapy (PDT) is a promising cancer treatment that involves the combination of visible light and a photosensitizer.[1] Each factor is harmless by itself, but when combined with oxygen, they can produce lethal cytotoxic agents, initially singlet oxygen, that inactivate tumor cells.[2] This enables greater selectivity toward diseased tissue, as only those cells that are simultaneously exposed to the photosensitizer, light, and oxygen are exposed to the cytotoxic effect. The dual selectivity of PDT is produced by a preferential uptake of the photosensitizer by the diseased tissue and the ability to confine activation of the photosensitizer to this diseased tissue by restricting illumination to the specific site.

The porphyrins and related tetrapyrrolic systems are among the most widely studied compounds for use as photosensitizers in PDT.[3] Porphyrins are 18π-electron aromatic macrocycles that exhibit characteristic optical spectra with a strong π–π^* transition around 400 nm (Soret band) and usually four Q

0-8493-1348-1/04/$0.00+$1.50

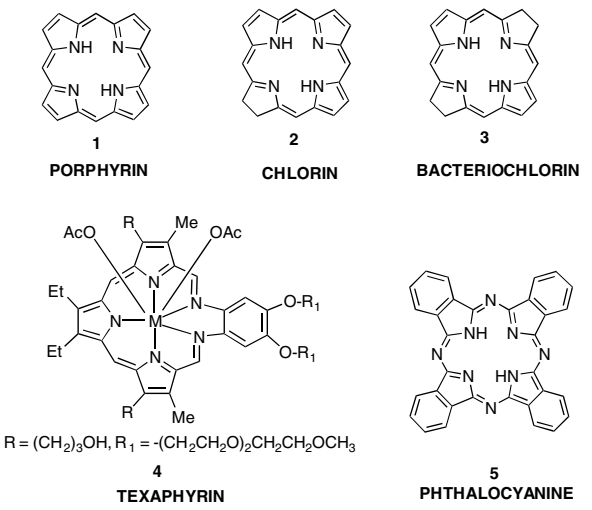

FIGURE 144.1

bands in the visible region. As can be seen in Figure 144.1, two of the peripheral double bonds in opposite pyrrolic rings are cross-conjugated and are not required to maintain aromaticity. Thus, reduction of one or both of these cross-conjugated double bonds (to give chlorins and bacteriochlorins, respectively) maintains much of the aromaticity, but the change in symmetry results in bathochromically shifted Q bands with high extinction coefficients.[4] Nature uses these optical properties of the reduced porphyrins to harvest solar energy for photosynthesis with chlorophylls and bacteriochlorophylls as both antenna and reaction-center pigments.[5] The long wavelength absorption of these natural chromophores led to explorations of their use as photosensitizers in PDT.

As indicated previously, PDT is based on the interaction of a photosensitizer retained in tumors with photons of visible light, resulting in the formation of singlet oxygen ($^1O_2$), the putative lethal agent.[6] To achieve an effective destruction of tumor cells, a high quantum yield of singlet oxygen is required. Even in the absence of heavy atom substitution and coordination of transition-metal ions, porphyrin systems generally satisfy these criteria, which is why most of the sensitizers currently under clinical evaluation for PDT are porphyrins or porphyrin-based molecules.

At present, Photofrin®* , a hematoporphyrin derivative,[7] is the only photosensitizer that has been approved worldwide for the treatment of various types of cancer by PDT. It fits some of the criteria for ideal photosensitizers, but it also suffers from several drawbacks. First, it is a complex mixture of various monomeric, dimeric, and oligomeric forms.[7b–d] Second, its long wavelength absorption falls at 630 nm, which lies well below the wavelength necessary for maximum tissue penetration. Finally, it induces prolonged cutaneous phototoxicity, a major adverse effect associated with most of the porphyrin-based photosensitizers.

It is well established that absorption and scattering of light by tissue increases as the wavelength decreases, and that most efficient sensitizers are those that have strong absorption bands from 700 to 800 nm.[8] Light transmission by tissues drops rapidly below 550 nm; however, it doubles from 550 to 630 nm and doubles again from 630 to 700 nm. This is followed by an additional 10% increase in tissue penetration as the wavelength increases toward 800 nm.[3] Another reason to set the ideal wavelength for PDT at 700 to 800 nm is due to the availability of easy-to-use diode lasers. Although diode lasers are now available at 630 nm (where clinically approved Photofrin absorbs), photosensitizers with absorptions between 700 to 800 nm, in conjunction with diode lasers, are still desirable for treating deeply seated

tumors. Therefore, in recent years, a variety of photosensitizers related to chlorins, bacteriochlorins, porphycenes, phthalocyanines, naphthalocyanines, and expanded porphyrins were synthesized and evaluated for PDT efficacy. However, for designing improved photosensitizers for PDT, it becomes necessary to consider several other factors, such as overall lipophilicity (i.e., a proper balance between hydrophobicity and hydrophibicity), pH, lymphatic drainage, and lipoprotein binding, which could influence the biodistribution and localization of sensitizers in tissue and tumors.[9]

The main focus of this chapter is to summarize the various synthetic strategies followed by several research groups in designing long-wavelength-absorbing photosensitizers related to chlorins, bacteriochlorins, expanded porphyrins, and phthalocyanines. An ongoing interest on developing target-specific photosensitizers is also briefly reviewed. The majority of chlorins and bacteriochlorins were generated through three different approaches. One method involves modification of a preformed porphyrin. The second approach utilizes the use of chlorophyll *a* as the starting material for the synthesis of other chlorins and bacteriochlorins. The third approach utilizes the unstable bacteriochlorophyll *a* as a substrate for the synthesis of stable bacteriochlorins. Each procedure was used successfully for preparing sensitizers that show promise in photodynamic therapy and is discussed in terms of synthetic methodology and biological significance.

144.2 Chlorins and Bacteriochlorins from Porphyrins

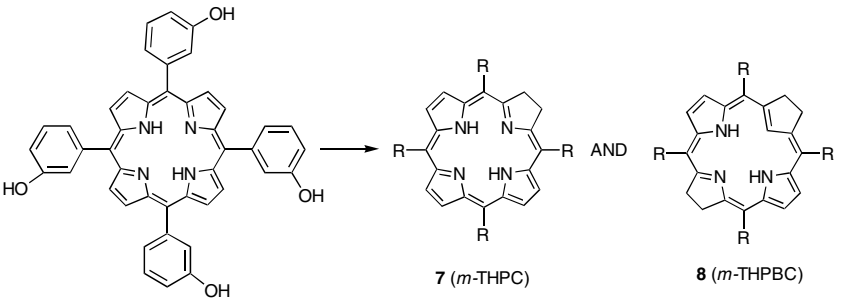
Chlorins and Bacteriochlorins by Diimide Reduction

Almost 30 years ago, Whitlock et al.[10] developed an efficient diimide reduction method for the synthesis of bacteriochlorins and isobacteriochlorins from porphyrins. Diimide reduction of metal-free tetraphenyl chlorin afforded tetraphenyl bacteriochlorin, while reduction of the corresponding zinc analog produced the related tetraphenylisobacteriochlorin. It is now accepted that the reduced double bond in chlorins induces a pathway for the delocalized π electrons that "isolates" the diagonal crossing-conjugated pyrrolic double bond, such that reduction of this double bond is favored due to minimal loss of π energy over the double bond present in the adjacent ring. The presence of a metal changes the delocalization of the π electrons, which makes the adjacent pyrrolic ring more reactive, and diimide reduction produces mainly the corresponding isobacteriochlorin. In order to avoid the formation of an isomeric mixture, this approach is useful only for reduction of symmetrical porphyrins. This diimide-reduction approach was later employed by Bonnett et al.[11] for preparing the *meso*-tetra (*m*-hydroxyphenyl)-chlorin (*m*-THPC) **7** (650 nm) and the bacteriochlorin (*m*-THPBC) **8**. The formation of these components was found to depend on the amount of reductant used.

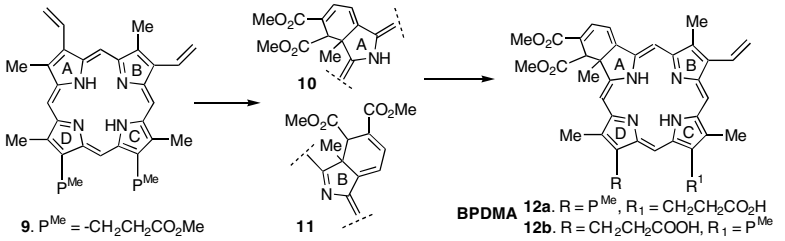
Although the formation of a bacteriochlorin resulted in further red shift in the electronic absorption spectrum, with long-wavelength absorption near 750 nm, these molecules were generally found to be air sensitive. Among various chlorin analogs, *m*-THPC (Foscan®) 7 (Scheme 1) appears to be quite effective and is currently under Phase III human clinical trials (see Chapter 147).

Chlorins and Bacteriochlorins by Diels–Alder Reaction

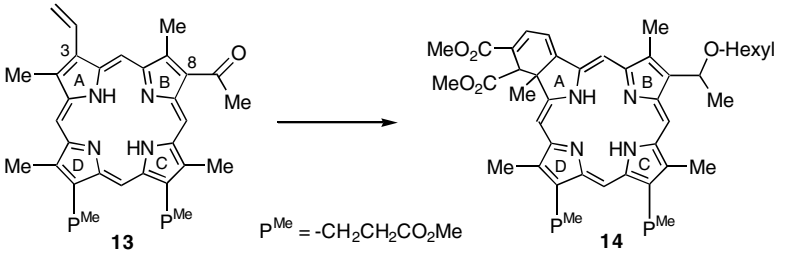
Cycloaddition reactions are among the most powerful reactions available to organic chemists.[12] The ability to simultaneously form and break several bonds, with a wide variety of atomic substitution patterns, and often with high degree of stereocontrol, has made cycloaddition reactions the subject of intense study. In porphyrin chemistry, the [4 + 2] Diels–Alder reactions were used by various investigators for converting porphyrins into chlorin systems. Callot et al. were the first to show that protoporphyrin IX dimethyl ester 9 can undergo cycloaddition reactions with various dienophiles[13] (Scheme 2). A few years later, Dolphin and coworkers discovered the utility of one such analog named benzoporphyrin derivative monocarboxylic acid (BPDMA) 12a and 12b for treating age-related macular degeneration (AMD) when activated with light at 690 nm.[14] This treatment has already received approval worldwide. BPDMA has also been used for the treatment of cancer by photodynamic therapy (see Chapter 147). However, due



SCHEME 1



SCHEME 2

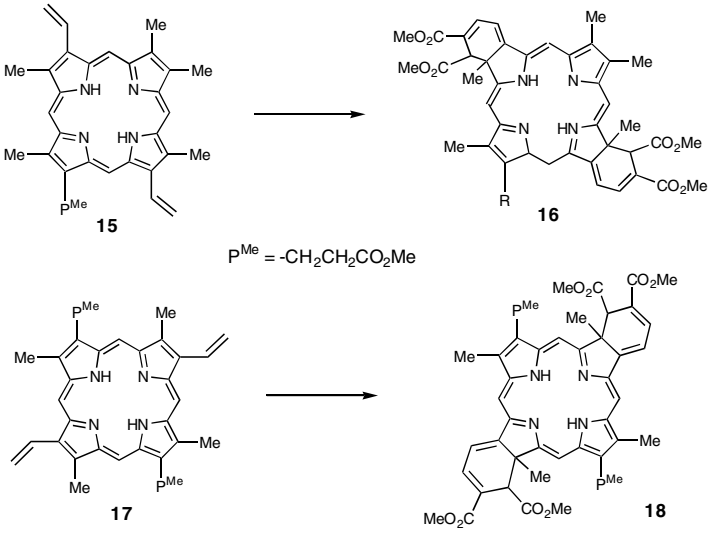


SCHEME 3

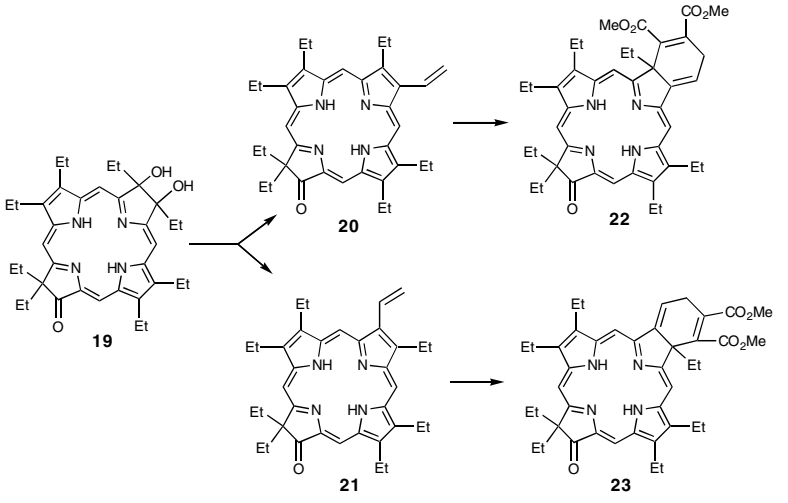
to its rapid clearance, it was found to be effective only if the tumors were treated with light at 3 h post injection of the drug. Pandey et al.[15] developed another approach for preparing these analogs, starting from 8-acetyl-3-vinyl deuteroporphyrin IX dimethyl ester (Scheme 3).

The vinyl group was replaced with various alkyl ether functionalities. Among these analogs, the related 8-(1-hexyloxy ethyl)-derivative 14 was found to be more effective than BPDMA in eradicating tumors in mice bearing SMT-F tumors.[15] This methodology was further extended independently by Pandey et al.[16] and Yon-Hin et al.[17] for the synthesis of novel bacteriochlorins, which involved a double Diels–Alder reaction on divinylporphyrins 15 and 17 (Scheme 4). These bacteriochlorins 16 and 18 exhibit long-wavelength absorption maxima near 800 nm with limited PDT efficacy.

Morgan et al.[18] showed that bacteriochlorin-like macrocycles can also be generated by cyclization of either 5,10- or 5,15-bis[(ethoxycarbonyl)vinyl]-porphyrins. However, the resulting products rapidly decomposed upon exposure to air, thus precluding their use as photosensitizers for PDT. For developing a general synthesis of stable bacteriochlorins, the same authors[19] followed the pinacol-pinacolone approach in preparing ketochlorins 22 and 23. In brief, dehydration of 19 produced a mixture of 20 and



SCHEME 4

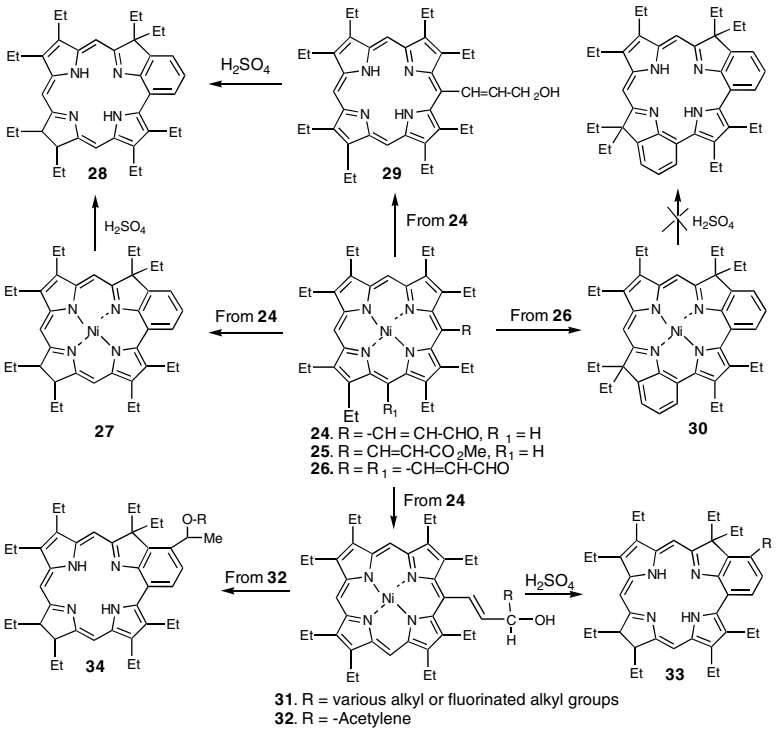


SCHEME 5

21, which on reaction with dimethylacetylenedicarboxylate (DMAD) produced the corresponding bacteriochlorins 22 and 23 as an isomeric mixture. This isomeric mixture showed some photodynamic activity in a mouse tumor model: 75% of the mice treated at a dose of 1 mg/kg were found to be free from palpable tumor 12 days after the light treatment. However, in this class of compounds, the spectroscopic properties of 22 and 23 resemble those of porphyrinones (long-wavelength absorption near 700 nm) rather than bacteriochlorins (Scheme 5).

Benzochlorins and Benzobacteriochlorins

Benzochlorin consists of a benzene ring fused between the *meso*- and the adjacent β-position of the pyrrole ring. In a sequence of reactions, this class of compounds was first reported by Arnold et al. from



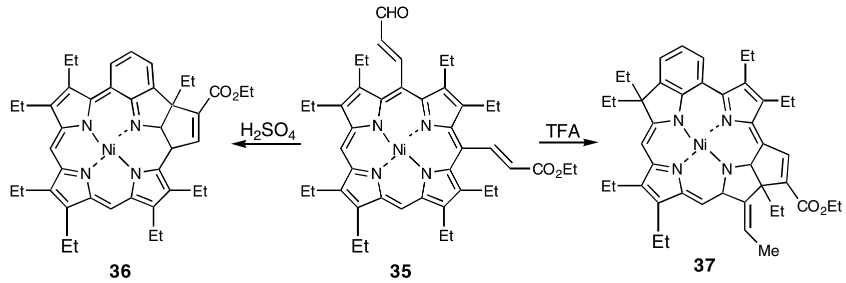
SCHEME 6

octaethylporphyrin.[20] Morgan et al.[21] were the first to demonstrate the photosensitizing efficacy of these analogs (e.g., 28). One of the major problems associated with this preparation is the difficulty in demetalation at the final step of the synthesis, and it is also difficult to chemically modify these benzochlorins. Therefore, this procedure has limited application in preparing a series of analogs with variable lipophilicity. This problem can be avoided by following the method recently reported by Li et al.[22,23] (Scheme 6). In their approach, Ni(II)meso-(2-formylvinyl)octaethylporphyrin 26 was reacted with the Grignard's reagent of various fluorinated or nonfluorinated alkyl halides or Ruppert's reagent. The corresponding intermediates via intramolecular cyclization under acidic conditions afforded the related free-base benzochlorins **34.** In this series of compounds, compared to the free-base analogs, the related Zn(II) complexes (671 to 677 nm) were found to be more effective both *in vitro* and *in vivo*. In preliminary screening, the fluorinated analogs showed better efficacy than the corresponding nonfluorinated derivatives.[22b]

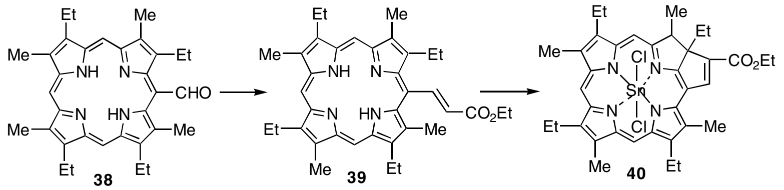
This methodology was later extended by Vicente et al.[24] for the preparation of octaethylporphyrin-based benzochlorin 30 by intramolecular cyclization of Ni(II)5,10 bis-(2-formylvinyl) porphyrin 21 (Scheme 7). Unfortunately, attempts to remove the Ni(II) metal were unsuccessful. When Ni(II)5-(2-formyl-vinyl)-10-(2-ethoxycarbonyl-vinyl)octaethyl porphyrin was used as a substrate, the formation of the reaction product was found to depend on the strength of the acid used.[25] For example, reaction of **35** with sulfuric acid produced a chlorin containing six- and five-member rings fused at the same pyrrole unit **36**. Replacing sulfuric acid with trifluoroacetic acid (TFA) produced **37**, the Ni (II) complex of bacteriochlorin containing an ethylidine group at the peripheral position (λ_{max} 895 nm). Attempts to prepare the desired free-base analogs for investigating their application as photosensitizers were unsuccessful.

Purpurins (Tin Etiopurpurin Dichloride)

Purpurins have been known as degradation products of chlorophyll for quite some time.



SCHEME 7



SCHEME 8

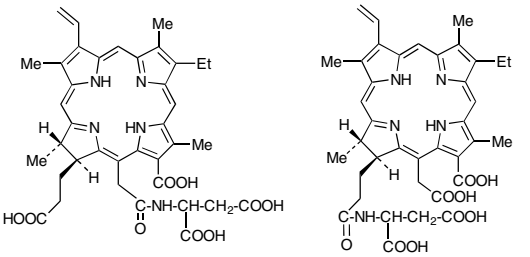
The first synthesis of this class of compounds was reported by Woodward[26] during the synthesis of chlorophyll *a* by intramolecular cyclization of a *meso*-acrylate functionality to a β-pyrrolic position. This methodology was later followed by Morgan et al.[27] and others[28] to synthesize a series of octaetylporphyrin, etioporphyrin, 5,10-diphenyl- and 5,10-dipyridylporphyrin-based purpurin analogs. Among all the purpurins evaluated for PDT efficacy, the Sn etiopurpurin ($SnEt_2$) 40 (Scheme 8) is considered to be the most effective *in vivo*.[27] Its long wavelength absorption falls at 650 nm and produces a high singlet oxygen quantum yield. This product is currently in Phase III clinical trials for the treatment of age-related macular degeneration (AMD), a major cause of blindness among people over 50 years of age.

144.3 Chlorins and Bacteriochlorins from Chlorophyll

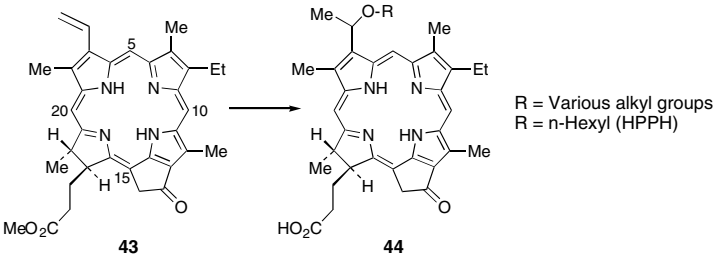
Chlorophyll *a*, the green photosynthetic pigment, is one of the prototypes of the chlorin class of natural product. Because it is readily available, a large amount of work was done by several investigators to modify and to synthesize other chlorin-like chromophores. The photosensitizers derived from chlorophyll *a* can be divided into three categories in which the five-member isocyclic ring was cleaved or kept intact or was replaced with other ring systems. Some of the photosensitizers in these series attracted enormous attention; their description follows.

Aspartic Acid Derivative of Chlorin e_6 (Npe_6)

Chlorophyllin, a water-soluble degradation product of chlorophyll *a*, can be obtained by cleavage of the isocyclic ring of chlorophyll.[29] Removal of magnesium resulted in chlorin e_6 with limited *in vivo* photosensitizing efficacy. It was shown that replacing the vinyl group with alkyl ether groups of variable carbon units generally enhances the photosensitizing efficacy.[30] However, in this series, better results were obtained with the monoaspartyl derivative known as Npe_6.[31] This photosensitizer appears to clear rapidly from skin, and good tumor response was obtained only after irradiation within 3 to 4 h of sensitizer administration. Npe_6 is in human clinical trials in Japan for treatment of endobronchial lung cancer. The recent extensive NMR studies of Npe_6 confirmed that in Npe_6, the aspartic acid functionality is linked



SCHEME 9

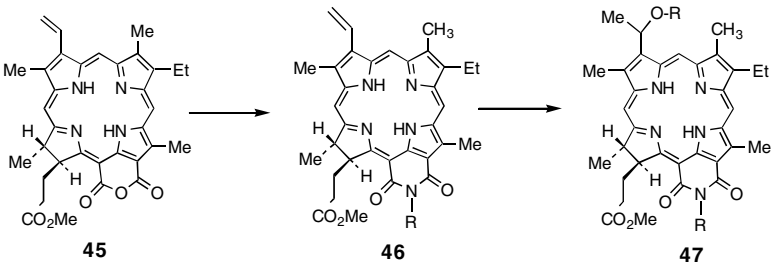


SCHEME 10

with an amide bond at Position-15 (41) of chlorin e_6,[32] instead of at Position-17 (42) as reported in several publications[33] (Scheme 9).

Alkyl Ether Derivatives of Pyropheophorbide *a*

To understand the effect of various substituents on photosensitizing efficacy, the Roswell Park group synthesized and evaluated a series of pyropheophorbide *a* analogs with variable lipophilicity. In their effort to establish a structure–activity relationship (QSAR), a congeneric series of the primary and secondary alkyl ether derivatives of pyropheophorbide *a* was synthesized (the isocyclic ring was kept intact). For the preparation of these analogs, methylpheophorbide *a* obtained from *Spirulina Pacifica* was converted into more stable pyropheophorbide *a* 43, which on reacting with HBr/AcOH and then the appropriate alcohol, produced the corresponding ether analogs in excellent yield[34] (Scheme 10). At the final step, the methyl ester functionality was hydrolyzed into the corresponding carboxylic acid 44 (HPPH: R = *n*-hexyl). These analogs exhibit long-wavelength absorption near 665 nm *(in vivo)* and show excellent singlet-oxygen-producing efficiency (45%). The results obtained from *in vivo* studies in mice demonstrated that the photodynamic efficacy of these photosensitizers increased by increasing the length of the carbon chain, reaching a maximum in compounds with *n*-hexyl and *n*-heptyl chains at Position-3. Interestingly, the PDT efficacy decreased by further increasing the length of alkylether carbon units. When compensated for differences in tumor photosensitizer concentration, the *n*-hexyl derivative (HPPH) (optimal lipophilicity) was fivefold more potent than the *n*-dodecyl derivative (more lipophilic) and threefold more potent than the *n*-pentyl analog (less lipophilic). Interestingly, the introduction of the hexyl ether side chain at other positions of the macrocycle (Position-8 or Position-20) significantly reduced the *in vivo* efficacy.[35] These data suggest that besides the lipophilicity, the presence and position of the substituent possibly play an important role in drug efficacy. HPPH is currently at Phase I/II human clinical trials for the treatment of a variety of cancers. Among the patients treated so far, no long-term skin phototoxicity was observed.[36]



R = Various Alkyl groups

SCHEME 11

Alkyl Ether Analogs of Purpurinimides

Having developed a QSAR for the alkyl ether analogs of pyropheophorbide series, the Roswell Park group extended their approach to photosensitizers with longer wavelength absorption. For this study, the purpurin-18 methyl ester obtained from methylpheophorbide *a*[37] was converted into purpurin-18-*N*-alkyl imides **46**.[38] The vinyl group at Position-3 was then replaced with a variety of alkyl ether analogs **47** (Scheme 11) with variable carbon units with log *P* values ranging from 5.32 to 16.44 and exhibiting long-wavelength absorption near 700 nm.[39]

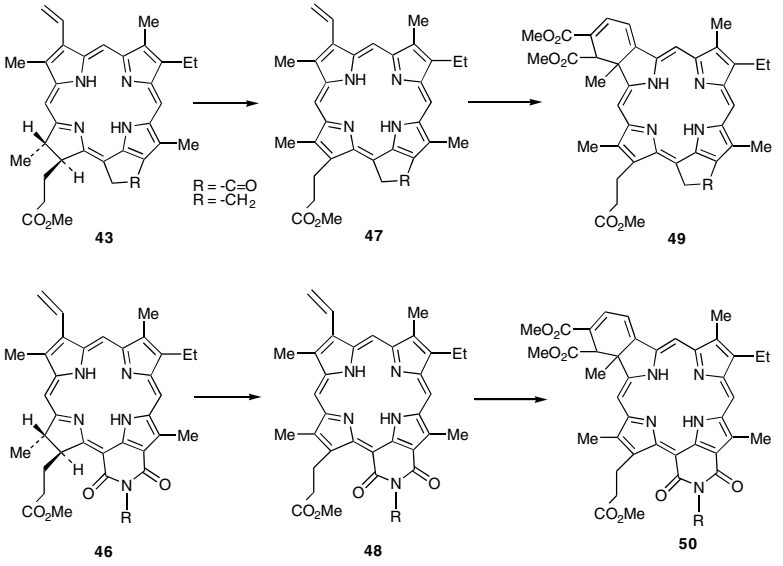
In animal studies, this class of compounds was found to be effective *in vivo*. The results obtained from a set of photosensitizers with similar lipophilicity (log *P* 10.68 to 10.88) indicate that similar to the pyropheophorbide series, in addition to the overall lipophilicity, the presence and position of the alkyl groups (*O*-alkyl versus *N*-alkyl) in a molecule also play an important role in tumor uptake, tumor selectivity, and *in vivo* PDT efficacy.[39,40]

Benzoporphyrin Derivatives from Pyropheophorbide *A* and Purpurinimides

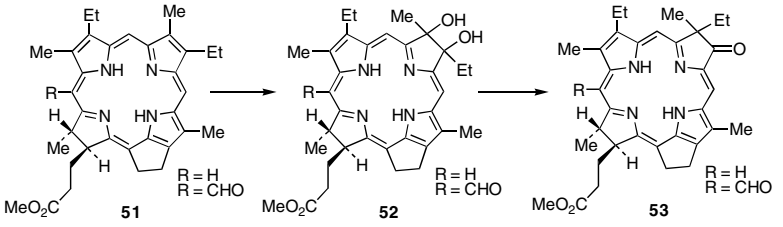
One of the main synthetic problems associated with PP-IX-based benzoporphyrin derivatives is to isolate the most effective analog (ring-A reduced, monocarboxylic acid) from the complex reaction mixture. In order to solve this problem, the Roswell Park and Vancouver groups[41,42] reported the preparation of various BPD analogs (e.g., 49) from phylloerythrrin and methyl 9-deoxypyropheophorbide (Scheme 12). Among these compounds, the benzoporphyrin derivative (*cis*- isomer) obtained from rhodoporphyrin XV di-*tert*-butyl aspartate was found to have PDT efficacy similar to BPDMA. This methodology was also extended in the purpurinimide series, and the lipophilicity was altered by introducing *N*-alkyl groups with variable carbon units at the imide ring system 50.[43] In preliminary *in vivo* testing, the corresponding *N*-hexyl and *N*-dodecyl analogs were found to be effective at a dose of 0.5 μM/kg when treated with light (135 J/cm^2, 75 mW/cm^2) at 728 nm and 24 h postinjection. Under similar treatment conditions (treated with light at 690 nm), the BPDMA obtained from protoporphyrin IX dimethyl ester did not produce any photosensitizing efficacy.[44] Therefore, the Diels–Alder approach in a purpurinimide system provides a simple approach for generating effective photosensitizers with variable lipophilicity.

vic-Dihydroxy- and Ketobacteriochlorins

Osmium tetroxide was frequently used for the conversion of porphyrins to the corresponding *vic*-dihydroxy chlorins and tetrahydroxy bacteriochlorins as a mixture of isomers.[45] The overall lipophilicity of these analogs can be altered by subjecting them to pinacolpinacolone reaction conditions. The formation of the corresponding keto- analog is not straightforward and depends not only on the intrinsic nature of the migratory group but also of the electronic and steric factors elsewhere on the porphyrin nuclues.[46] Therefore, the concept of designing chlorin and bacteriochlorin analogs from porphyrins by following this approach was not successful. A few years ago, Chang et al.[47] showed that chlorins under



SCHEME 12

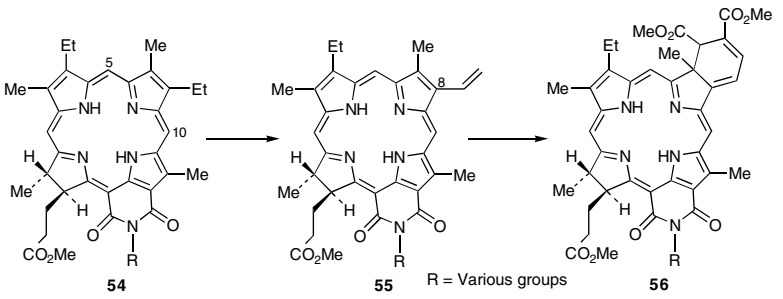


SCHEME 13

certain conditions can be converted into *vic*-dihydroxybacteriochlorins upon reaction with osmium tetroxide. The Roswell Park group extended this methodology to the pheophorbide, chlorin e_6, and a series of *vic*-hydroxy- and ketobacteriochlorins were synthesized. The stable ketobacteriochlorins had strong absorptions in the 710 to 760 nm region but did not show any significant photosensitizing activity in mice (DBA/2) transplanted with SMT-F tumors.[48] However, the ketobacteriochlorins obtained from 9-deoxypyropheophorbide *a* 51 and the related *meso*-formyl derivative with long-wavelength absorption showed long-wavelength absorptions at 734 and 758 nm, respectively (Scheme 13). Among these bacteriochlorins, the triplet states were quenched by ground-state molecular oxygen in a relatively similar manner, yielding comparative singlet oxygen quantum yields. In preliminary *in vivo* screening, the ketochlorins 53 (R = CHO) were found to be more photodynamically active than the related *vic*-dihydroxy analogs. Replacement of the methyl ester functionalities with di-*tert*-butylaspartic acids enhanced the *in vivo* efficacy.[49] It appears to be cleared rapidly from skin, and good tumor responses can be obtained after irradiation within 3 to 4 h of sensitizer administration.

Bacteriochlorins Derived from 8-Vinyl Chlorins

The Roswell Park group combined the use of osmium tetroxide and Diels–Alder approach to construct stable bacteriochlorins. In their approach, mesopurpurin-18 methyl ester 54, obtained from methylpheophorbide *a*, was reacted with osmium tetroxide. The resulting *vic*-dihydroxy bacteriochlorin on



SCHEME 14

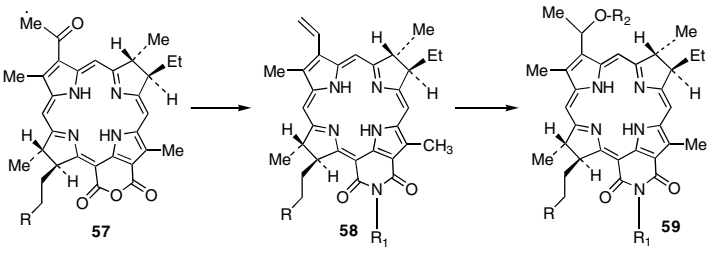
reacting with *p*-toluenesulfonic acid in refluxing benzene produced the 8-vinyl derivative 55, which on reacting with dimethylacetylene dicarboxylate (DMAD) under Diels–Alder reaction conditions produced bacteriochlorin 56 with long-wavelength absorption near 800 nm.[50] Unfortunately, the utility of this compound for use in PDT was diminished due to the unstable nature of the six-member anhydride ring system (Scheme 14). In their recent approach, the anhydride ring is replaced with an *N*-hexyl-imide ring system, and these compounds were found to be stable *in vivo*.[51] The preliminary *in vitro* photosensitizing results obtained from this compound are promising. This system also possesses a unique opportunity to prepare a series of *N*-alkyl ether derivatives with variable carbon units and to establish the structure and activity relationship in a particular series of compounds.

Bacteriochlorins from Bacteriochlorophyll

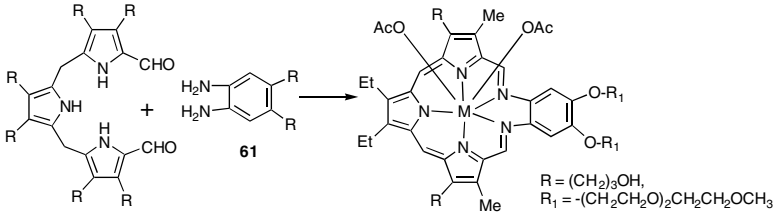
Most of the naturally occurring bacteriochlorins have absorptions between 760 to 780 nm and were studied by various investigators for their use as photosensitizers for PDT.[52] They were found to be extremely sensitive to oxidation, resulting in a rapid transformation into the chlorin state, which generally has an absorption maximum at or below 660 nm.[53] Furthermore, if a laser is used to excite the bacteriochlorin *in vivo*, oxidation may result in the formation of a new chromophore absorbing outside the laser window, reducing the photodynamic efficacy. Due to the desirable photophysical properties and promising *in vitro*/*in vivo* photosensitizing efficacy of bacteriochlorins, there is increasing interest in the synthesis of stable bacteriochlorins, either from bacteriochlorophyll *a* or from the other related tetrapyrrolic systems.

In general, for designing improved photosensitizers, overall lipophilicity was proven to be one of the important factors. For example, among porphyrin-based photosensitizers, the hydrophobic porphyrins are preferentially accumulated and partitioned into corresponding hydrophobic loci *in vivo*. Moan and coworkers[54] showed that among diether derivatives of hematoporphyrin, retention in cells increases with decreasing polarity. The Roswell Park group studied the uptake of a series of alkyl ether derivatives of pyropheophorbide *a* and found that a strong correlation exists between uptake and hydrophobicity, although each correlation cannot be extended to the *in vivo* PDT efficacy. On the other hand, photosensitizers with high partition coefficient values (increased hydrophobicity) induce sensitizer insolubility, thus preventing drugs from entering the circulation. Therefore, a proper balance between hydrophobicity and hydrophilicity is probably the most important factor that influences tumor localization of sensitizers.

A simple approach used by the Roswell Park group was to vary the overall lipophilicity of various types of photosensitizers, such as pyropheophorbide *a*, benzoporphyrin derivatives, benzochlorins, and purpurinimides by altering the length of carbon units in alkyl ether substituents; an approach that was successful. It was demonstrated that replacing an anhydride ring system in purpurin-18 (a chlorophyll *a* analog) with a six-member imide ring substantially enhanced its *in vivo* stability and retained effective *in vivo* photodynamic activity.[55] Therefore, in order to investigate the effect of such substitutions in the bacteriochlorin series, bacteriochlorophyll *a,* present in *Rb. Sphaeroides*, was first converted (*in situ*) into bacteriopurpurin-18 (**57**),[56] which in a sequence of reactions, was transformed into a series of related



SCHEME 15

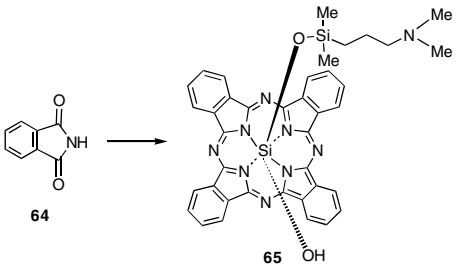


SCHEME 16

N-alkyl derivatives **58**[57] (Scheme 15). To determine the effect of the presence of these alkyl substituents with variable carbon units, the acetyl group was first reduced with sodium borohydride that on reacting with HBr gas and an appropriate alcohol produced the corresponding alkyl ether derivatives of bacteriochlorin **59** in high yield. These compounds are stable *in vitro* and *in vivo*, exhibit long-wavelength absorption near 790 nm, and show high tumor uptake. In preliminary *in vitro* and *in vivo* studies, some of these compounds were found to be effective at low injected doses.[58]

144.4 Expanded Porphyrins

The texaphyrins are aromatic tripyrrolic, pentaaza, Schiff-base macrocycles that bear a strong, but "expanded" resemblance to the porphyrins and other naturally occurring tetrapyrrolic prosthetic groups.[59] Similar to porphyrins, the texaphyrins are fully aromatic and colored compounds (Scheme 16). However, they are 22 π-electron electron systems rather than 18 π-electron ones. This class of compounds exhibits long-wavelength absorption >700 nm, depending on the nature of substituents present at the peripheral position. Also, in contrast to porphyrins, the texaphyrins are monoanionic ligands that contain five, rather than four, coordinating nitrogen atoms within the central core that is roughly 20% larger than that of the porphyrins. High-yield production of long-lived triplet states and their remarkable singlet-oxygen-producing efficiency are important features of this class of photosensitizers. Currently, two different water-solubilized lanthanide(III)texaphyrin complexes, namely, the gadolinium(III) (62)[60] and lutetium(III) (63)[61] derivatives (Gd-Tex and Lu-Tex, respectively), are being tested clinically. The first of these, XCYTRIN™, is in a pivotal Phase III clinical trial as a potential enhancer of radiation therapy for patients with metastatic cancers of the brain receiving whole-brain radiation therapy. The second, in various formulations, is being tested as a photosensitizer for use in the treatment of recurrent breast cancer (LUTRIN), in Phase II clinical trials; photoangioplastic reduction of atherosclerosis involving peripheral arteries (ANTRIN); and light-based treatment of age-related macular degeneration (OPRTIN), currently in Phase I clinical trials.[59]

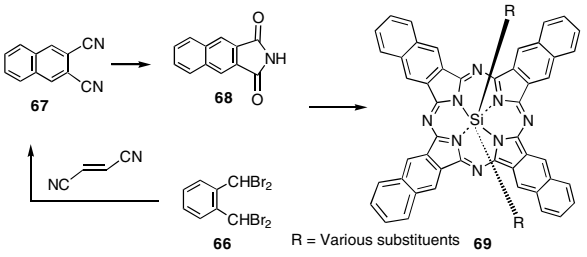


SCHEME 17

144.5 Phthalocyanines and Naphthalocyanines

Phthalocyanines (Pc) and naphthalocyanines (Nc) can be regarded as azaporphyrins containing four isoindoles linked by nitrogen atoms[62] (Scheme 17). Compared to porphyrins, Pc and Nc offer high molar-extinction coefficients and red shift maximums at 680 nm for Pc and 780 nm for Nc, resulting from the benzene or naphthalene rings condensed at the periphery of the porphyrin-like macrocycle. They possess high-singlet-oxygen-producing efficiency, and interestingly, chelation of metal ions such as zinc or aluminum increases the singlet-oxygen yield to nearly 100%. Therefore, metal complexes of the Pc and Nc attracted attention for their use as photosensitizers in PDT. In recent years, a large number of metalated or nonmetalated phthalocyanine-based photosensitizers were synthesized by introducing a variety of substituents at the peripheral positions. If the valency of the central metal is higher than two, it binds various axial ligands. All of these chemical changes of the Pc and Nc skeletons alter their PDT efficacy. Aggregated Pc and Nc are inactive photochemically because of a greatly enhanced rate of excited singlet-state deactivation by internal conversion of the ground state. In the phthalocyanine series, Olenick and coworkers in collaboration with Kenney[63] synthesized and evaluated four silicon analogs with variable lipophilicity to learn more about the structural features that silicon phthalocyanine must have in order to be a good PDT photosensitizer. All of these analogs produced similar photophysical properties; however, the photosensitizer denoted as Pc4, bearing a long-chain amino axial ligand 65, showed promising results *in vitro* and *in vivo* and is presently entering clinical trials.[64] Further, it was concluded that the presence of structural features leading to improvement in the association between photosensitizers and important cellular targets is more useful than the presence of those leading to improvements in their already acceptable photophysical and photochemical characteristics. A series of benzyl-substituted phthalonitriles, substituted at the 3,4 and 4,5 positions were converted into a series of Zn(II) hydroxyphthalocyanines phthalocyanine phenol analogs). Their efficacy as sensitizers for PDT was evaluated on the EMT-B mammary tumor cell line. The most active *in vitro* was the 2-hydroxy Zn Pc, followed by 2,3- and 2,9-dihydroxy ZnPc, with the 2,9,16-trihydroxy ZnPc exhibiting the least activity. In inducing tumor necrosis, *in vivo*, the monohydroxy derivative and the 2,3-dihydroxy analog were efficient, but complete tumor regression was poor even at high doses. In contrast, the 2,9-dihydroxy isomer at 2 μM/Kg induced tumor necrosis in all animals treated, with 75% complete regression. These results underline the importance of the position of the substituents on the Pc macrocycle to optimize tumor response and confirm the PDT potential of the unsymmetrical Pcs bearing functional groups on adjacent benzene rings.[65]

Rodgers et al. in collaboration with Kenney and collaborators[66] developed a new route to silicon-substituted phthalocyanines and phthalocyanines-like compounds that is robust and flexible. One of the siloxysilicon compounds, that with the ligand 5,9,12,16,23,28,32-octabutoxy-33H, 35H[b,g]dinaphtho[2,3–1:2′,3′-q]porphyrazine **69**, has a q band at a wavelength of 804 nm and an extinction coefficient of 1.9×10^5 M-1 cm^{-1} (Scheme 18). These compounds showed promising *in vitro* photosensitizing efficacy *in vitro*, however, in animal studies, compared to phthalocyanine (Pc 4) were found to be less effective. A first photophysical study of a member of the family of subnaphthalocyanones is described.[67] The cone-shaped unsubstituted subnaphthalocyanines, synthesized in 35% yield, showed distinctive photophysical



SCHEME 18

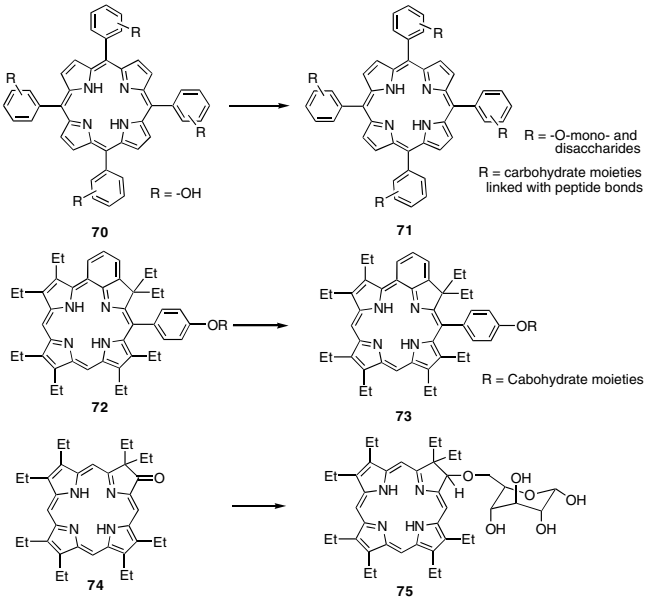
properties that are better than those of the related planar phthalo- and naphthalocyanines. SubNc absorbs in the red part of the spectrum and has substantial fluorescence. Triplet and singlet oxygen quantum yield are substantially higher than that of the related phthalo- and naphthalocyanines. These results, together with their synthetic availability, high solubility, and low tendency to aggregate, make this class of sensitizers interesting for further study, with a view to investigate their photodynamic therapy applications.

144.6 Target-Specific Photosensitizers

Since the introduction of the first PDT drug Photofrin, there has not been much success on improving the photosensitizer's tumor selectivity and specificity, because tumor cells in general have nonspecific affinity to porphyrins.[68] Although the mechanism of porphyrin retention by tumors is not well understood, the balance between lipophilicity and hydrophilicity is recognized as an important factor.[69] Some attempts were made to direct photosensitizers to known cellular targets by creating a photosensitizer conjugate, where the other molecule is a ligand that is specific for the target. For example, to improve localization to cell membranes, cholesterol[70] and antibody conjugates were also prepared to direct photosensitizers to specific tumor antigens.[71–73] Certain chemotherapeutic agents were also attached to porphyrin chromophores to increase the lethality of the PDT treatment.[74] Certain protein and microsphere conjugates were made to improve the pharmacology of the compounds.[75] These strategies seldom work well, because the pharmacological properties of both compounds are drastically altered.[76]

Recently, the bovine serum albumin conjugate of a sulfonated phthalocyanine (BSA-AlPcS_4) prepared by Brasseur et al. was shown to target the scavenger receptor of macrophages.[77] Relative photocytotoxicities were reported using a receptor-positive and a receptor-negative cell line, where their lethal effects correlated with its receptor affinity. Also, certain adenoviral proteins were employed to target lung cancer cells rich in the appropriate class integrin receptor.[78] Using the EMT-6 murine model, *in vivo* results were encouraging, with Pc-adenoviral protein conjugates. Further, AlPc and CoPc were covalently labeled with epidermal growth factor (EGF), and this conjugate produced a fivefold increase in photocytotoxicity as compared to nonconjugated phthalocyanine.[79]

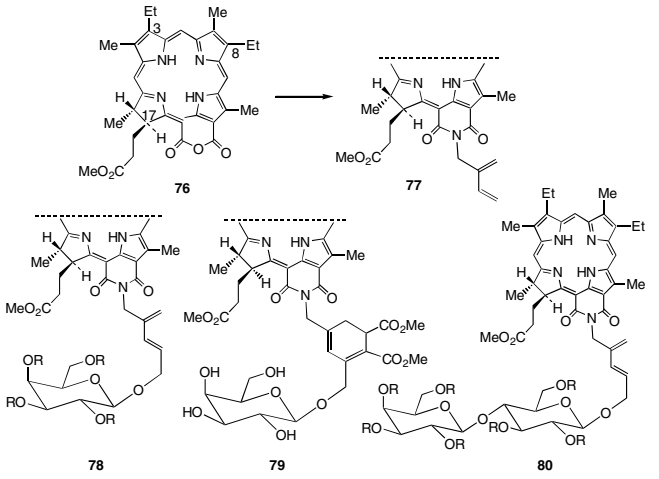
Because oligosaccharides play essential roles in molecular recognition,[80] porphyrins with sugar moieties should not only have good aqueous solubility but also possible specific membrane interaction. In addition to providing the molecule with polar hydroxy groups, it is possible that the sugar moiety might lead the conjugate to a cell surface target through specific binding to its receptor. Oligosaccharides play essential roles in various cellular activities, as antigens, growth signals, targets of bacterial and viral infections, and glues in cell adhesion and metastasis, where the saccharide–receptor interactions are usually specific and multivalent.[81] This specificity suggests a potential utility of synthetic saccharide derivatives as carriers in directed drug delivery. Therefore, in recent years, a number of carbohydrate derivatives of various photosensitizers were synthesized. Hombrecher and Schell[82] reported the preparation of a galactopyranosyl-cholesteryloxy-substituted porphyrin by following the McDonald approach. Several tetra- and octaglycoconjugated tetraphenylporphyrins were also reported by Yano and coworkers,[83] Cornia et al.,[84]



SCHEME 19

Momemteau and coworkers,[85] and Ono et al.[86] A glycosylated peptide porphyrin synthesized by Krausz and coworkers[87] showed promising *in vitro* PDT efficacy. Millard and Momemteau[88] reported the synthesis of a glycoconjugated *meso*- monoarylbenzochlorin (related to 71 and 73) (see Scheme 19). This compound displayed good *in vitro* PDT efficacy in tumor cell lines. A few years ago, Bonnett and coworkers[89] showed that compared to β-hydroxy-octaethylchlorin 75, the related glycosylated analog was more effective as a photosensitizing agent *in vitro* as well as *in vivo*. Montforts et al.[90] further explored this approach by attaching hydrophilic carbohydrate structural units to certain chlorins. Such conjugation increased the water solubility of the parent chlorins by introducing an estradiol with a diethyl spacer. The chlorin–estrogen conjugate was then prepared with the hope that it would bind to an estrogen receptor, which could induce destruction of a mammalian carcinoma. In a recent report, Aoyama and coworkers[91] reported the synthesis of certain tetraphenylporphyrin-based saccharide-functionalized porphyrins and demonstrated the importance of hydrophobicity masking for the saccharide-directed cell recognition. Because the saccharide–receptor interactions are ubiquitous, well-defined and well-designed synthetic saccharides clusters may serve as a new tool in glycoscience and glycotechnology.

It is known that galectins are involved in the modulation of cell adhesion, cell growth, immune response, and angiogenesis, therefore, there is a good possibility that their expression might have a critical role in tumor progression.[92] Gal-1 mRNA levels increase 20-fold in low tumorigenic and up to 100-fold in highly tumorigenic cells.[93] The Roswell Park group recently reported the synthesis and biological significance of certain β-galactose-conjugated purpurinimides (a class of chlorins containing a six-member fused imide ring system) **78–90** (Scheme 20) as Gal-1 recognized photosensitizer via enyne metathesis.[94] Molecular modeling analysis utilizing model photosensitizers and the available crystal structures of galectin-carbohydrate moiety indicates that when placed at an appropriate position, the photosensitizer does not interfere with the galectin-carbohydrate recognition. The intracellular studies with known cell surface counterstains confirmed the cell surface recognition of the conjugates. Under similar drug and light doses, compared to the free purpurinimide analog, the galactose and lactose conjugated analog showed a considerable increase in *in vitro* and *in vivo* photosensitizing efficacy. These results, therefore, indicate the possibility of development of a new class of tumor-specific photosensitizers for PDT based on recognition of a cellular receptor.[94]



SCHEME 20

144.7 Summary

The focus in this chapter is largely on chemical rather than biological aspects of various porphyrin-based photosensitizers for their use in photodynamic therapy. It is important to note that porphyrin-based compounds, in addition to their use in cancer, also show potential for application in other areas: treatment of age-related macular degeneration (AMD), tumor imaging by MRI, psoriasis, bone marrow purging, and purification of blood infected with various viruses, including HIV. Since the discovery of Photofrin, enormous progress has been made in the development of various porphyrin-based compounds with improved photophysical characteristics. In recent years, a number of pharmaceutical companies, such as QLT Pharmaceuticals, Vancouver, B.C.; Miravant, California; Scotia Pharmaceuticals, U.K.; Ciba Vision, New Jersey; Pharmacia, Sweden; DUSA, New Jersey; Pharmacyclics, California; and Light Sciences Corp., Washington, have shown major interest in PDT. However, given the possible implications for the use of porphyrin-based compounds (porphyrins, chlorins, bacteriochlorins, expanded porphyrins, phthalocyanines) for the treatment of cancer by photodynamic therapy, future design strategies for new agents should be directed toward tumor-specific drug molecules. Such compounds might show greater tumor selectivity with reduced skin phototoxicity, a major problem associated with most of the porphyrin-based compounds.

145.1 Introduction

Photodynamic therapy (PDT) exploits the biological consequences of localized oxidative damage inflicted by photodynamic processes. Three critical elements are required for the initial photodynamic processes to occur: a drug that can be activated by light (a photosensitizer), light, and oxygen.[1] Interaction of light at the appropriate wavelength with a photosensitizer produces an excited triplet-state photosensitizer that can interact with ground-state oxygen via two different pathways, designated as Type I and Type II. The Type II reaction that gives rise to singlet oxygen ($^1O_2$) is believed to be the dominant pathway, because elimination of oxygen or scavenging of $^1O_2$ from the system essentially eliminates the cytocidal effects of PDT.[2–4] Type I reactions, however, may become important under hypoxic conditions or where photosensitizers are highly concentrated.[5] The highly reactive $^1O_2$ has a short lifetime (<0.04 μsec) in the biological milieu and, therefore, a short radius of action (<0.02 μm).[6] Consequently, $^1O_2$-mediated oxidative damage will occur in the immediate vicinity of the subcellular site of photosensitizer localization. Depending on photosensitizer pharmacokinetics, these sites can be varied and numerous, resulting in a large and complex array of cellular effects. Similarly, on a tissue level, tumor cells as well as various normal cells can take up photosensitizer, which, upon activation by light, can lead to effects upon such targets as the tumor cells proper, the tumor and normal microvasculature, and the inflammatory and immune host system. PDT effects on all of these targets may influence each other, producing a plethora of responses; the relative importance of each has yet to be fully defined. It seems clear, however, that the combination of all these components is required for long-term tumor control.

145.2 Subcellular Targets for Photosensitization

The cellular targets of PDT depend on the specific pharmacokinetic characteristics, such as lipophilicity, amphiphilicity, aggregation, and serum protein interactions (reviewed in MacDonald and Dougherty[1]) of the photosensitizer, but appear to be largely independent of cell type. Localization studies were generally carried out in *in vitro* cell systems, where exposure conditions to the photosensitizer can be easily controlled or varied. Such studies revealed that cellular photosensitizer distribution can be a dynamic process, influenced by such parameters as length of exposure and drug concentration.[7–9] Photosensitizers may even relocalize after photodamage to an initial site of accumulation, such as from lysosomes to other, possibly more sensitive, cellular locations, where they will then be available for activation.[10,11] That subcellular localization of a photosensitizer, and consequently the target of PDT, may influence *in vivo* treatment outcome was demonstrated in a series of studies that could relate structure and activity of a congeneric series of pyropheophorbide-*a* ether derivatives to their subcellular localization.[9,12] The most and least active compounds in the series revealed mitochondrial localization for the former and lysosomal localization for the latter. Nevertheless, such less-active compounds can be effective photosensitizers, because the lack of sensitivity can be compensated by higher dosing, given that treatment selectivity is maintained.

Mitochondria

Although the first-generation photosensitizer Photofrin®* and its forerunners are chemically heterogeneous and, therefore, exhibit heterogeneous subcellular distributions,[8] the major target also appears to be the mitochondria.[13–16] The development of chemically pure and well-defined photosensitizers, and the use of 5-aminolevulinic acid (ALA) for the intramitochondrial generation of photosensitizing protoporphyrin IX (PpIX),[17] allowed for the targeting of specific subcellular sites and the analysis of the relative sensitivity to photodamage of these sites.[18–21] Again, the mitochondria emerged as especially sensitive targets. Recent interest focused on the mitochondrial permeability transition pore, a protein complex consisting of hexokinase, the peripheral benzodiazepine receptor (PBR), the voltage-dependent

*Registered trademark of Axcan Scandipharm Inc., Birmingham, AL.

anion channel (VDAC), creatinin kinase, the adenine nucleotide translocator (ANT), and cyclophyllin D. Several of its components were implicated as PDT targets.[22–32]

Lysosomes

Hydrophilic or highly aggregated sensitizers may be taken up by pinocytosis and endocytosis and therefore accumulate in cytoplasmic vesicles.[9,10,18,33] While PDT-induced rupture of lysosomes and release of damaging hydrolytic enzymes into the cytoplasm were described,[33,34] it appears now that lysosomes per se are not effective targets for PDT.[9,18] In a recent study, selective lysosomal photodamage that was associated with release of cathepsin B was followed by a gradual loss of mitochondrial membrane potential, release of cytochrome *c* into the cytosol, caspase 3 activation, and a limited apoptotic response.[35] Thus, lysosomal damage may secondarily mediate mitochondrial damage. It was also suggested that lysosomes might serve as reservoirs, from which photosensitizers might be released after vesicle rupture and migrate to more sensitive sites.[10] All of these studies assume that initial sensitizer accumulation is restricted to the lysosomes, but the possibility cannot be entirely excluded that high lysosomal concentration may mask small but highly effective sensitizer accumulations at other sites.[9] An innovative approach to intracellular delivery of macromolecules from endocytic vesicles, such as, for example, immunotoxins or protein encoding DNA, to the cytosol uses lysosome-targeted PDT to rupture the vesicles that entrapped these agents.[36]

Nucleus

Photosensitizers used in PDT generally do not accumulate in the cell nucleus. Therefore, frank DNA damage, such as strand breaks, sister–chromatid exchanges, and chromatid aberrations, are much less frequently observed in PDT than in ionizing or UV irradiation.[37–39] Consistent with these findings, the mutation potential of PDT was found to be significantly less than that of ionizing radiation or UV.[40]

Plasma Membrane

The plasma membrane may become a target of PDT, especially if the sensitizer is highly lipophilic and the incubation time of cells *in vitro* is brief. Membrane damage manifests itself rapidly through blebbing,[20,41] as well as leakage of cytosolic enzymes[42,43] and chromium.[44] Leakage of lactate dehydrogenase (LDH) showed the same kinetics as generation of prostaglandin E_2 from tumor cells *in vitro*, directly relating membrane disruption to production of eicosanoids.[43] The biosynthesis of eicosanoids, which play an important role in mediating the PDT tissue response (discussed below), is set in motion when phospholipases catalyze the liberation of free fatty acids from membrane phospholipids. Unsaturated phospholipids and cholesterol are important membrane targets of photodamage, and lipid peroxidation by PDT was extensively studied and linked with cell lethality.[45,46] Oxidation of intrinsic membrane proteins[47] and protein cross-linking[48] was also observed. PDT can inhibit the plasma membrane enzymes Na^+K^+-adenosine triphosphate (ATPase) and Mg^{2+}-ATPase.[49] Ca^{2+} flux may be affected, and the plasma membrane may become depolarized.[50]

Certain membrane-localized photosensitizers, such as mesotetraphenylporphines (TPPS), can destroy microtubules in interphase cells and lead to arrest of cells in mitosis.[34,51]

145.3 Mode of Cell Death

PDT can induce cell death via the apoptotic or necrotic pathways.[52] Necrosis is metabolism independent and a result of massive insult. In contrast, the apoptotic pathway is an intrinsic physiological process dependent upon active cellular metabolism and characterized by chromatin condensation, DNA fragmentation, and the formation of apoptotic bodies.[53] The dominant mode of cell death is dependent upon the photosensitizer used, the localization of the photosensitizer, and the treatment protocol.[1] Dellinger[54] demonstrated that increasing the drug incubation time, prior to administration of light, altered the mode

of cell death induced by Photofrin-PDT; longer incubation times (1 day) resulted in apoptosis, while shorter incubation times (1 h) induced necrosis. The cellular localization of Photofrin changes with time of incubation, moving from the cell membrane to the intracellular sites as the incubation time increases.[9] Similar results were recently published for zinc II phthalocyanine (Pc).[55] Studies by Kessel and Luo[19] demonstrated that photosensitizers that localize to the mitochondria (porphycenes PcM and PcD) resulted in apoptotic cell death, while those that localize to the lysosome (chlorin LCP) or cell membrane (cationic porphyrin, MCP) do not. Kessel et al.[56] also demonstrated that photodamage of the cell membrane can inhibit the induction of apoptosis by photodamage to the mitochondria. These results were confirmed by Luo and Kessel,[57] and this study also demonstrated that the mode of cell death shifts in response to the photodynamic dose, such that high doses result in a necrotic cell death, while lower doses result in an apoptotic mode of death. Similar results were recently obtained for the photosensitizer hypericin.[58]

The kinetics and extent of PDT-induced apoptosis also varies with photosensitizer and cell type treated.[56,57,59–62] Photodynamic treatment of L5178Y murine lymphoma cells with ClAlPc resulted in apoptosis within 30 min of treatment.[62] Treatment of the lymphoma line P388 with ClAlPc or tin etiopurpurin ($SnEt_2$), which localize to the lysosome and the mitochondria, induced apoptotic nuclei within 1 h.[56,57] However, treatment of the same cell line with tin octaethylpurpurin amidine, which localizes to the mitochondria, the lysosome, and the cell membranes, did not result in apoptotic nuclei until 24 h after treatment.

The rapid induction of apoptosis suggests that PDT triggers late-stage apoptotic processes directly. Release of cytochrome *c* from the mitochondria triggers caspase 3 activation and results in initiation of apoptosis at a late stage in the pathway.[63] Cytochrome *c* release is associated with a loss of mitochondrial potential. PDT results in the loss of mitochondrial potential and the rapid release of cytochrome *c*.[64–71] Several studies demonstrated that PDT also induces rapid activation of caspases 3, 6, 7, and 8 and cleavage of poly(ADP-ribose) polymerase (PARP).[61,64] Kessel and Luo showed that PDT-induced release of cytochrome *c* is sufficient to directly initiate a caspase-dependent apoptotic cell death.[72] However, a recent study by Xue et al.[73,74] indicates that while caspase 3 is required for the late stages of apoptosis, it is not the critical lethal event in PDT-induced apoptosis.

Bcl-2 was shown to block the release of cytochrome *c* from the mitochondria and thus to prevent apoptosis.[63] Several groups altered the expression of bcl-2, through overexpression or antisense technology, and demonstrated that increasing the levels of bcl-2 enhances cellular resistance to PDT-induced apoptotic cell death.[75–78] Xue et al.[79] demonstrated that Pc 4-PDT results in photochemical destruction of bcl-2. Similar results were reported for AlPc-PDT.[80] Interestingly, a study by Kim et al.[80] reported that overexpression of bcl-2 enhanced the apoptotic response. In these studies, overexpression of bcl-2 was accompanied by an increase in bax, a proapoptotic member of the bcl-2 family. PDT resulted in the selective destruction of bcl-2 but had no effect on bax. The greater apoptotic response in the cells overexpressing bcl-2 was attributed to a higher bax:bcl-2 ratio after PDT. A PDT-induced shift in the bax:bcl-2 ratio toward apoptosis was also reported.[75,81] Bcl-2 was implicated in the release of Ca^{2+} from endoplasmic reticulum and mitochondrial stores during PDT-induced apoptosis.[82]

PDT also affects other proteins implicated in apoptosis. Phospholipases C and A2, which are involved in the transient increases in intracellular calcium levels and DNA fragmentation, are activated by Photofrin-PDT.[83] The apoptotic associated proto-oncogenes c-jun and c-fos are also activated by PII-PDT.[84] Ceramide, which was linked to apoptosis in several malignant cell lines, accumulates following PDT and was associated with PDT-induced apoptosis and cytotoxicity.[85] Gupta et al.[86] demonstrated that Pc 4-PDT induces expression of nitric oxide and suggested that it may be involved in PDT-induced apoptosis. The tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) was implicated in apoptosis mediated by hypericin PDT of Jurkat cells.[87] The tumor suppressor gene p53, which is able to force damaged cells into the apoptotic pathway, was found to be associated with Photofrin-PDT resistance,[88,89] although there were dichotomous reports on the role of p53 in PDT sensitivity.[90] Finally, similarly diverse effects on apoptosis were described for IL-6, a cytokine strongly induced by PDT,[91,92] when it was transduced into cells *in vitro*. While one report described increased PDT-induced apoptosis in IL-6 overexpressing

cells due to an increased bax/bcl-2 ratio,[81] another reports enhanced resistance to PDT-induced apoptosis and tumorigenic potential.[93]

145.4 Molecular Mechanisms

Alterations in gene expression are generally due to changes in the molecular mediators present in the cell. PDT was shown to alter the expression of several molecular mediators, including the redox-regulated transcription factor, AP-1.[91,94] AP-1 is induced by changes in the redox potential[95–97] and hypoxia.[98] It is composed of homodimers of the products of the c-jun gene family or heterodimeric combinations of c-jun and c-fos family members. PDT induces prolonged expression of c-fos and c-jun as a result of oxidative stress.[84,99] Therefore, modulation of AP-1 activity by PDT might be mediated by changes in oxidative potential as a result of the generation of singlet oxygen or PDT-induced hypoxia.

NF-κB plays a critical role in the expression of immunomodulatory and proinflammatory genes.[100] Activated NF-κB is a heterodimeric protein most commonly comprised of the p50 and p65 (Rel A) species. It is also activated in response to cellular oxidative stress.[101] NF-κB is sequestered in the cytoplasm by IκB proteins; phosphorylation of IκB results in its proteosomal degradation and release of NF-κB.[102,103] NF-κB binding activity was found to be induced by PDT[104–106] and was proposed to play a role in determining the cellular response to PDT.[107] Granville et al.[104] demonstrated that cellular levels of IκB were transiently depressed following Verteporfrin®-PDT. Pyropheophorbide — a methyl ester — PDT also leads to IκB degradation.[106] In contrast to these studies, other groups failed to demonstrate NF-κB activation following Photofrin-PDT.[91,94] Thus, NF-κB activation may be photosensitizer specific. It was also suggested that activation is related to PDT dose in that higher doses do not result in decreases in IκB.[104]

In addition to AP-1 and NF-κB activation, PDT was been shown to stimulate stress kinase signaling pathways (SAPK/JNK, p38/HOG1)[108,109] and HS1 phosphorylation,[110] as well as stress response transcriptional activators. HIF-1 (hypoxia inducible factor-1) is a key regulator of the cellular response to hypoxia and is induced in response to PDT.[111,112] PDT also enhanced the expression of the HIF-1 target gene, vascular endothelial growth factor (VEGF),[112] and it was proposed that HIF-1 expression may act as a predictor of PDT responsiveness.[111] Cyclooxygenase (COX)-2 expression was found upregulated by PDT in preclinical tumor models, and combined PDT and COX-2 inhibitor treatment proved beneficial for tumor control.[113] Finally, PDT activates the heat shock protein (HSP) family promoters[114] and induces the expression of HSPs and the related glucose regulated proteins,[115–119] as well as heme oxygenase (HSP 32).[120] Luna et al.[121] used the PDT-induced activation of the GRP-78 promoter as a molecular switch to drive the expression of the herpes simplex virus-thymidine kinase (HSV-tk) suicide gene in murine tumor cells *in vitro* and *in vivo*. HSPs 27 and 60 were implicated in the resistance of cells to PDT-mediated oxidative damage.[122,123] Finally, Ahmad et al.[124] demonstrated that PDT can result in a downmodulation of the protein expression and phosphorylation of the epidermal growth factor receptor (EGFR) that may have important consequences for PDT surviving tumor cells.

145.5 Tissue Targets of Photosensitization

Tumor Cells

The capacity of PDT to eliminate tumor cells through direct photodamage was most effectively studied by *in vivo–in vitro* tumor explant methodology.[125] Such in-depth analysis revealed that the full potential of direct photodynamic tumor cell kill, provided by the gross tumor photosensitizer concentration and absorbed light dose, is generally not realized by *in vivo* PDT treatment.[126] Clonogenic assays carried out with a number of different photosensitizers and tumor systems immediately after potentially curative PDT exposures *in vivo* revealed that at most, 1 to 2 logs of direct tumor cell kill were achieved,[127–132] far less than the 7 to 8 logs required for tumor cure. Clearly, limitations to direct tumor cell kill exist *in vivo*, the most important of which may be the following:

1. Inhomogeneous photosensitizer distribution within the tumor, including a gradual decrease of photosensitizer concentration with distance from blood vessels.[133]
2. Insufficient light penetration through the tissue (light is attenuated exponentially with depth of tissue penetration).[134,135]
3. Insufficient oxygen availability (discussed below).

That intrinsic tumor cell sensitivity contributes to the overall PDT response was suggested by studies using tumor cells selected to be resistant to PDT.[136] Tumors of resistant phenotype were less responsive to PDT than sensitive tumors, while exhibiting equal vascular responses. The studies did not exclude the possibility, however, that tumor immunogenicity might have differed in the two tumor lines, thus affecting the response. On the other hand, tumors expressing a multidrug-resistance phenotype that prevented the uptake of a cationic photosensitizer were, nevertheless, found responsive to PDT carried out with that agent, the antitumor effect being attributed to vascular disruption.[137] Studies like these illustrate the capacity of PDT to exert its antitumor action through several different tissue targets.

Initial studies trying to establish a pattern of selectivity of photosensitizer uptake in malignant versus normal cells *in vitro* were largely unsuccessful.[138] *In vivo*, moderately favorable tumor-to-normal-tissue ratios can be found for almost all photosensitizers, with establishment of these ratios depending on the specific pharmacokinetics of the compound as well as the pathophysiology of the tumor (for detailed reviews see the literature[1,139,140]). Mechanisms invoked for this "selectivity" range from leaky vasculature and impaired lymphatic drainage in tumors, to low tumor pH and an increase in low-density lipoprotein and other membrane receptors on tumor cells.[141,142] Carrier systems, such as photosensitizer (immuno) conjugates, were designed to direct the photosensitizer directly to the tumor cells. Such conjugates were directed against epitopes on ovarian[143–145] and colon cancer cells,[146] as well as against the epidermal growth factor receptor (EGFR) that is overexpressed in oral precancer.[147]

Microvasculature

The microvasculature was one of the earliest tissue targets identified, because vascular PDT effects are rapid and dramatic, especially with the use of the sensitizer Photofrin and its forerunners. Reduction and cessation of tumor microcirculation following *in vivo* PDT exposure employing a variety of photosensitizers were demonstrated in preclinical models through numerous different techniques, including window chamber observation,[148,149] radiobiological assay,[150] tracers,[151,152] contrast-enhanced MRI,[153] oxygen microelectrodes,[151,154] laser Doppler,[155] and hypoxia markers.[156] Because the kinetics of vascular shutdown and tumor cell death coincide[128,157] and inhibition of shutdown retards tumor response,[158] it was argued that disruption of the tumor microcirculation is a major factor contributing to tumor control by PDT. Differences in response between tumor and normal microvasculature are subtle and difficult to discern.[159] Careful dose-ranging studies revealed that the tumor vasculature is slightly more susceptible to shutdown than its normal counterpart.[160,161] It was also demonstrated that Photofrin-PDT at high fluence rate can protect the normal skin microvasculature, but the same treatment fails to protect tumor vessels.[151,162] Occlusion of the tumor-surrounding vasculature can contribute to tumor control, at least in preclinical models, presumably by adding to the nutrient deprivation and retardation of vascular resupply of the tumor.[160,163] Another approach toward retardation of vessel regrowth after PDT is the use of antiangiogenic agents in combination with PDT, which was shown to enhance long-term tumor control.[112,164] PDT-mediated ischaemia may be transient, and the oxidative stress following tissue reperfusion may contribute to tumor control.[165,166]

The acute manifestations of PDT-induced vascular damage greatly depend on the type and dose of photosensitizer used. On the microscopic level, vascular changes in a rat cremaster muscle preparation after Photofrin PDT included vessel constriction, occlusive platelet thrombi in arteries, arterioles, veins and venules, edema, and neutrophil margination and migration.[148,167,168] Ultrastructural features included damage to numerous endothelial cell organelles, as well as perivascular changes, such as degranulation of perivascular mast cells and damage to myocytes.[167] Npe_6 (mono-L-aspartyl chlorin e_6)-PDT in a rat chondrosarcoma model resulted in obstructive platelet thrombi but no vasoconstriction.[169] PDT with

variously substituted zinc Pcs, tested in the same tumor model, showed a spectrum of effects, including vessel constriction and leakage, with one compound (disulfonated zinc Pc) exhibiting no apparent effects.[149]

Numerous vascular response mediators seem to be involved in these processes, including histamine,[170] serotonin,[171] clotting factors,[172] and most prominently, eicosanoids.[43,173,174] The latter are products of the release from the cell membrane of arachidonic acid that is subsequently metabolized by cyclooxygenase to generate prostaglandins and thromboxanes, and by lipoxygenase to form leukotrienes and hydroxy acids. The generation of a wide spectrum of arachidonic acid metabolites by PDT was described in mast cells, macrophages, endothelial cells, platelets and tumor cells, as well as in animals. Interestingly, *in vitro* PDT exposure of platelets blocks their capacity to aggregate,[175,176] and *in vitro* exposure of endothelial cells is dominated by the release of prostacyclin (PGI_2) that inhibits platelet aggregation.[176] These *in vitro* findings contradict the well-established, proaggregating mechanisms observed *in vivo* and demonstrate the difficulty of translating *in vitro* data to the *in vivo* situation. The latter represents a much more complex interplay of mechanistic components that likely involves platelets, endothelial cells, leukocytes, macrophages, and other stromal cells. Thromboxane appears to play a major role in mediating the observed vascular effects, at least in rat models.[174] Anti-inflammatory drugs, such as indomethacine or aspirin, can block the release of eicosanoids *in vitro*[43,176] and *in vivo*.[149,174,177,178] Rats made thrombocytopenic and thus deprived of a source for thromboxane generation also showed a diminished vascular response.[179] Eicosanoids, as well as serotonin, appear to also be involved in changes of tumor interstitial pressure observed after Photofrin-PDT, a consequence of fluid leakage from the vasculature, possibly contributing to occlusion of the tumor microvasculature.[180]

145.6 Tumor Oxygenation and PDT

Any restriction of tissue oxygen supply *during* PDT light delivery will reduce $^1O_2$ production and, therefore, have negative consequences for treatment outcome. Such restrictions can arise from numerous sources, including preexisting tumor hypoxia, acute vascular damage, and photochemical oxygen depletion. All of these can interact, and the dynamics of these interactions may determine treatment success.

Preexisting Tumor Hypoxia

Preexisting tumor hypoxia, a therapeutic problem still grappled with by radiation oncologists because of the oxygen dependence of sparsely ionizing radiation treatment, may limit the oxygen supply for PDT as well. Solid tumors are prone to develop hypoxic tumor regions due to deteriorating diffusion geometry, structural abnormalities of tumor microvessels, and disturbed microcirculation.[181] Hypoxic, but viable, tumor cells located in these areas may be protected from PDT-induced photodamage. In a preclinical study, Fingar et al.[182] manipulated tumors pharmacologically and physically to induce a wide range of hypoxic tumor fractions (~2% to ~40%) and followed this by aggressive Photofrin-PDT. It was found that hypoxic fractions below 5% did not adversely affect tumor control, hypoxic fractions of ~10% slightly diminished tumor control, and hypoxic fractions of ~40% totally blocked tumor control. Vascular shutdown and nutrient deprivation following PDT were believed to be responsible for the elimination of small numbers of initially surviving hypoxic tumor cells. Early preclinical attempts to raise tumor oxygenation prior to PDT through the administration of a perfluorochemical emulsion and carbogen breathing were highly successful in increasing tumor oxygen levels (~10-fold) up to 1 h after PDT. The intervention did not alter long-term tumor control,[183] probably because the vascular damage induced by the aggressive PDT regime overwhelmed any subtle improvement in treatment outcome that might have been attributed to increased tumor oxygenation. More recent studies, preclinical and clinical, demonstrated significantly improved PDT efficiency with adjuvant administration of hyperbaric oxygen or carbogen.[77,184,185]

The factor, however, that probably influences preexisting tumor hypoxia most profoundly is one that accompanies most PDT treatments, namely, changes in tumor temperature. Temperature increases due

to PDT light delivery were analyzed by Svaasand et al.[186] and recorded in preclinical models[187] and in patient's tumors.[188] Measurements of baseline intratumoral temperature and pO_2 in nodular basal cell carcinomas demonstrated a linear relationship between increasing tumor pO_2 and lesion temperature in the ranges between 0 to 20 mm Hg and 30 to 35°C.[188] Upon laser illumination during Photofrin-PDT, the temperature in these lesions increased further in a fluence-rate-dependent manner. Surprisingly, even low-fluence-rate light produced significant temperature rises (150 mW/cm^2: median temperature change +1.°9C [range 1.0 to 6.2], 30 mW/cm^2: median temperature change +1.5°C [range -1.3 to 3.6]), and these correlated with increased tumor pO_2. Whether these relationships hold true for tumors other than skin tumors remains to be seen.

Oxygen Limitation through Vascular Damage

With photosensitizers that can acutely constrict and occlude vessels, blood flow obstruction can be marked, rapidly limiting the oxygen supply to the tumor. Photofrin-PDT in mouse models, for example, rendered up to 10% of tumor cells hypoxic within a moderate light exposure (45 J/cm^2, 10 min).[126] This hypoxia was persistent and progressive with time, 50% of tumor cells being hypoxic within 1 h of such light exposure. Similar observations were reported for a rabbit skin tumor model, where a series of brief light exposures resulted in induction of irreversible tumor hypoxia that was cumulative with the number of exposures, i.e., fluence.[189] Hypoxia induction by PDT depends greatly on the vascular supply of a given tumor, and even on the site of tumor implantation in rodent models.[190] Transient reoxygenation may occur, depending on PDT dose.[190] With certain second-generation sensitizers, many of which exert less severe acute effects on the vasculature than Photofrin,[149] and a tendency toward the use of lower drug doses, such acute vascular effects are less likely to occur. As discussed above, the extent and timing of vascular damage, and therefore induction of tumor hypoxia, are of significant importance for treatment outcome. Vascular occlusion can be detrimental when occurring during treatment but beneficial when occurring *after* completion of the PDT tumor treatment.

Oxygen Limitation through Photochemical Oxygen Depletion

Photochemical oxygen depletion is roughly characterized by instantaneous or near instantaneous development of tumor hypoxia upon light exposure of a photosensitized tumor or tissue and equally rapid reoxygenation upon cessation of light. The theoretical basis for this phenomenon was provided through mathematical modeling of the dynamic changes to be expected in tissue when oxygen is consumed in the process of $^1O_2$ generation.[191,192] Photochemical oxygen depletion will occur in tissue if the rate of photodynamic oxygen consumption is faster than the rate of oxygen resupply from the vasculature. The major parameters that determine whether or not photochemical oxygen depletion will occur are as follows:

1. Absorption coefficient of the photosensitizer
2. Tissue concentration of the photosensitizer
3. Fluence rate of light
4. Vascular supply of the tissue.[191,193,194]

If the first three parameters are high, $^1O_2$ production will be rapid, and oxygen depletion will be favored; if the vascular supply of the tissue is poor, oxygen depletion will also be favored. The mathematical predictions were validated in tightly defined *in vitro* systems,[195,196] in tumor models,[151,156,189,197] and in humans.[188] Light fluence rate is the most easily controlled parameter, one that can be readily modulated during light delivery. Therefore, much attention is paid to the effects of fluence rate on PDT oxygen consumption. It is clear that lowering of the fluence rate can diminish or eliminate photochemical oxygen consumption through lowering the $^1O_2$ generation rate. However, the optimal fluence rate will depend on the other parameters listed above, and will therefore vary from situation to situation. In human tumors, the variability is great, among patients and among lesions in the same patient.[188]

The Role of Photobleaching in Photochemical Oxygen Depletion

Photobleaching is the destruction of the photosensitizer by light-mediated processes.[198–201] Because photosensitizer concentration is one of the major determinants for photochemical oxygen depletion, it stands to reason that the destruction of photosensitizer through photobleaching during PDT will reduce the likelihood that oxygen depletion will occur. The most detailed studies of photobleaching were carried out in an *in vitro* multicell tumor spheroid model.[202] It was shown that sustained illumination of Photofrin photosensitized spheroids led to a progressive decrease of photochemical oxygen depletion, implying reduction of photosensitizer levels, and being consistent with a theoretical model in which bleaching occurs via a self-sensitized singlet oxygen reaction with the photosensitizer ground state. Similarly, protoporphyrin IX was degraded by $^1O_2$-mediated mechanisms, while another photosensitizer (Nile blue selenium) was degraded by $^1O_2$-independent mechanisms.[203] Oxygen measurements in rodent tumor models and human basal cell carcinomas also implicated photobleaching in influencing photochemical oxygen depletion.[151,188] In these studies, significant oxygen depletion was observed during the early time periods of illumination at high fluence rates of Photofrin-photosensitized lesions, but less or no oxygen depletion was detected toward the end of illumination, implying that the Photofrin concentration was reduced through photobleaching below the threshold needed for oxygen depletion.

Enhancement of PDT Efficiency through Modified Light Delivery Schemes

It is evident that any means by which the well-oxygenated tumor volume can be increased during light exposure should have beneficial effects on treatment outcome. Downward adjustment of treatment fluence rate is one such means, fractionation of light delivery is another.[151,204–207] While the former allows for continuous maintenance of oxygen levels sufficient for $^1O_2$ production, the latter facilitates reoxygenation of the tissue between light exposures. Significant enhancements of tumor response were observed with these alternatives for PDT with Photofrin, ALA/protoporphyrin IX and mTHPC. In part, this may be due to a significant but moderate increase in direct photodamage to tumor cells. Direct tumor cell death increased with low fluence rate PDT by ~1/2–1 log in the RIF mouse model.[132] However, the microvasculature, especially the normal, tumor-surrounding microvasculature, can also be affected by modification of fluence rate.[162] One practical drawback of low-fluence-rate treatment, as compared to high fluence rate, is the increase in exposure time required to deliver a given fluence. Due to the higher treatment efficiency, this can be somewhat, but not entirely, compensated for by a reduction of the total fluence delivered. In fact, a reduction of the total fluence may be necessary with low-fluence-rate treatment, because the PDT efficiency for causing vascular and normal tissue effects will also increase, thus decreasing treatment selectivity.[162,207]

Enhanced responses to light dose fractionation in ALA-PDT of murine tumors and normal rat colon may involve relocalization or resupply of protoporphyrin IX during dark periods, in addition to reoxygenation.[208,209]

145.7 Immune Effects of PDT

Immune Suppression

The effect of PDT on the host immune system is dichotomous, resulting in immune suppression or immune activation. Although the mechanism leading to immune activation or suppression is unclear, recent studies indicated that the nature and extent of the tissue treated and the dose play a major role.[210,211] Cutaneous PDT suppresses allograft rejection[212–214] and contact hypersensitivity (CHS) reactions.[210,215–218] PDT suppression of CHS in murine models was demonstrated with a number of different photosensitizers[215–217,219–222] and is antigen specific.[215,216] The kinetics of CHS suppression is photosensitizer dependent.[216] $TPPS_4$ and HpD-PDT induce immediate CHS suppression, while *m*-THPC and Photofrin-PDT suppression require 72 h to develop. Kinetic differences were linked to photosensitizer

localization.[216] The mechanism of PDT-induced suppression appears to be associated with the induction of immunosuppressive cytokines. PDT induces tumor necrosis factor (TNF)-α,[218,223] which is involved in some aspects of UV-mediated immunosuppression.[224] However, it is not responsible for PDT-induced CHS suppression.[218] PDT also induces interleukin (IL)-10,[92,210,220] which was shown to inhibit cell-mediated immune responses, including CHS.[220,225,226] Gollnick et al.[210] showed that *in vitro* PDT induces IL-10 expression from keratinocytes as a result of activation of the IL-10 gene promoter by enhanced expression of AP-1 and prolonged IL-10 mRNA half-life. IL-10 is thought to mediate its suppressive activity through inhibition of the ability of antigen-presenting cells (APCs) to stimulate $CD4^+$ T-helper (Th) 1 cells.[225] Th1 cells, which secrete IL-2 and interferon (IFN)-γ, are necessary for induction of cell-mediated immune responses. The duration and strength of CHS reactions are increased in the presence of Th1 cells.[220] Th1 cells are dependent upon the presence of IL-12, secreted from APCs such as macrophages and dendritic cells, for their development.[227,228] Cytotoxic T-cell (Tc) 1 cells are the major effector cells in the CHS response[226] and are also dependent upon IL-12 for their development. IL-12 secretion from APCs is inhibited by IL-10.[225,226] Interestingly, Lynch et al.[217] demonstrated that adoptive transfer of macrophages from mice treated with peritoneal Photofrin-PDT, which involves treatment of the entire peritoneal cavity, suppressed the CHS response to dinitrofluorobenzene (DNFB) in the adoptively transferred animals, suggesting that this PDT regime altered the ability of the macrophages to induce Th1 and Tc1 cells. Direct mechanistic studies into the role of IL-10 in PDT-induced suppression of CHS yielded contradictory results that can be explained, at least in part, by the treatment regime and dose of PDT. Treatment with cutaneous PDT, using Photofrin and blue light centered at 430 nm, results in irradiation that is mostly limited to the skin. In contrast, transdermal PDT, with BPD-MA and illumination with 690 nm light, involves whole-body irradiation. Also, due to the greater depth of light penetration of this wavelength, some irradiation of internal sites may occur. Both transdermal and cutaneous PDT result in CHS suppression and induce IL-10 expression in the skin.[92,210,220] Simkin et al.[220] implicated IL-10 as the active mediator in transdermal PDT-induced suppression of CHS by demonstrating that IL-10 knockout (KO) mice did not undergo transdermal PDT-induced CHS suppression. In contrast, cutaneous PDT treatment of IL-10 KO mice induced CHS suppression.[210] The lack of involvement of IL-10 in suppression of CHS by cutaneous PDT was further confirmed when studies using neutralizing anti-IL-10 antibodies failed to inhibit cutaneous PDT-induced CHS suppression.[210,222] Thus, it appears as though the mechanism of PDT-induced suppression of CHS is dependent upon the treatment regime. Regimes that result in large treatment fields and internal exposure, i.e., transdermal and potentially peritoneal PDT, mediate CHS suppression via IL-10. PDT regimes that employ lower doses and superficial cutaneous exposure suppress CHS reactions via an IL-10 independent mechanism.

Interestingly, CHS suppression by transdermal and cutaneous PDT was reversed by administration of exogenous IL-12,[210,220] suggesting that these processes share a common regulatory point, perhaps in the development of Th1 or Tc1 cells. A second potential suppressor of Th1 and Tc1 development, and thus CHS, is IL-4. IL-4 was shown to directly inhibit Th1 cell proliferation[229] and to induce anergy in Tc1 cells.[230] Th2 cells, which are critical for the development of humoral immunity[229] and secrete IL-4, were shown to negatively regulate CHS responses.[89] Induction of systemic IL-4 by cutaneous PD may result in direct inhibition of Th1/Tc1 cells and suppression of CHS responses. Preliminary data from our group suggest that cutaneous PDT results in the induction of systemic IL-4 and a recent study demonstrated that cutaneous PDT suppression could be transferred by a $CD4^+$ T-cell population.[211]

In addition to the effects of cytokines on PDT-induced suppression of immune responses, it is important to consider the effect of PDT on the expression of immune molecules critical to immune system activation. Transdermal PDT was shown to inhibit the ability of Langerhans cells (LC) to stimulate alloreactive T-cells[212] and LC treated *ex vivo* expressed lower levels of major histocompatibility (MHC) antigens and CD80 and CD86 costimulatory molecules, which are needed for T-cell activation. Additionally, *in vitro* PDT-treated murine DC had a reduced ability to stimulate alloreactive T-cells and exhibited lower levels of MHC molecules, costimulatory molecules, and adhesion molecules.[231] Thus, in addition to altering the function of APCs, PDT has the ability to disrupt the APC-T-cell cognate, which is needed for T-cell activation.

Immune Potentiation

In contrast to the immunosuppressive effects of transdermal or cutaneous PDT, tumor-directed PDT was shown by a number of preclinical studies to trigger an inflammatory response and, depending on the treatment regimen, enhance a specific antitumor response.[140,232,233] PDT is characterized by the onset of an inflammatory reaction that is dominated by an influx of neutrophils.[92,234] The strength of the inflammatory response varies with photosensitizer; Photofrin-PDT induces a strong inflammatory response and a rapid influx of neutrophils, which appear to be critical to long-term tumor control.[235–240] HPPH-PDT induces a mild inflammatory response that is associated with reduced neutrophil infiltration,[241] which is not critical to long-term tumor control following HPPH-PDT.[241] The influx of neutrophils into the treatment site is preceded by an induction of chemokines and adhesion molecules critical to neutrophil migrations.[241] Neutrophil infiltration is followed by an influx of mast cells and macrophages.[92,234] PDT enhances macrophage tumoricidal activity[242–244] and stimulates macrophage release of TNF-α and tumor cell recognition.[84] It was suggested that nonspecific killing of tumor cells by inflammatory cells, potentially through the release of reactive oxygen species, contributes to the overall tumor kill by PDT.[237] This hypothesis is supported by studies showing that if the PDT-induced inflammatory response is further stimulated by addition of adjuvants or macrophage-activating factors, the overall tumor response to PDT is greater.[245–247] The role of the innate immune response in overall tumor kill by PDT was also shown to involve NK (natural killer) cells. Depletion of NK cells reduced the long-term tumor control by PDT,[232] and augmentation of NK activity enhanced PDT tumor control.[248]

PDT was also shown to enhance the adaptive or specific host antitumor response.[140,237] Tumor-draining lymph node cells isolated from PDT-treated mice are able to suppress subsequent tumor challenges when transferred to a naïve host.[249,250] Canti et al.[250] showed that PDT-treated mice that remain tumor free for 100 days post-PDT are resistant to subsequent tumor challenges, suggesting the presence of immune memory cells. The establishment of immune memory by PDT was recently confirmed by studies of Korbelik and Dougherty,[232] showing that immune cells isolated at protracted times post-PDT could transfer tumor immunity. The importance of the immune response in PDT was definitively shown by a series of experiments in *scid* (severe combined immunodeficient) and nude mice.[232,235] PDT treatment, at a dose that was curative in immunocompetent BALB/c mice, provided only short-term cures of EMT6 tumors in *scid* and nude mice. The ability to provide long-term cures was restored when immunodeficient animals were reconstituted with bone marrow cells from BALB/c mice. Depletion studies showed that the critical cells involved in the PDT-induced immune response were $CD8^+$ cells, although $CD4^+$ cells played a supportive role.[232,238] Interestingly, a recent clinical study demonstrated an infiltration of $CD8^+$ cells into PDT-treated tumor tissue.[251] These studies suggest that a functional immune system is necessary for long-term tumor control by PDT; however, the mechanism behind the potentiation of the immune response by PDT is unknown.

Several factors were postulated to contribute to the ability of PDT to enhance the host antitumor immune response, including release of tumor antigens and stimulation of various proinflammatory cytokines and other immunologically important genes via activation of stress response factors such as AP-1 and NF-κB.[92] PDT was shown to enhance the expression of a number of cytokines, including IL-6, TNF-α, IL-1β, IL-2, and granulocyte macrophage colony-stimulating factor (GM-CSF).[92,218,223,252,253] PDT modulation of IL-6 is the result of increased AP-1 activity.[91] The release of tumor antigens by PDT is also likely to play a role in the initiation of the antitumor immune response. The mechanism by which tumor cells are killed and the environment into which tumor antigens are released were shown to dictate the ensuing immune response.[254,255] Release of tumor antigens into an inflammatory milieu is thought to promote an effective antitumor immune response,[254] and the presence of apoptotic and necrotic tissue acts to stimulate dendritic cells,[255] which are necessary for initiation of the immune response.[256] Thus, PDT, by stimulating inflammation and by generating apoptotic and necrotic tissue, provides an ideal environment for initiation of an antitumor immune response. Preliminary evidence demonstrating that PDT-generated tumor cell lysates are able to activate DC in the absence of cofactors[257] supports this hypothesis. An understanding of the mechanisms leading to PDT enhancement of the host antitumor

immune response may allow for amplification of the response, thereby enhancing the effectiveness of PDT and potentially providing protection against metastases outside the treatment field. Information regarding the impact of PDT on metastasis formation is at present inconclusive. While several publications describe a reduction in metastases following PDT, invoking changes in adhesion molecule expression[244] or innate immune responses[258] as mechanisms for the observed effects, other work suggests that PDT enhances lung metastases in an orthotopic prostate tumor model.[259]

145.8 Conclusion

The scientific effort that supports this new cancer therapy led to numerous significant advances. The development of new photosensitizers is essentially eliminating the problem of prolonged cutaneous photosensitivity and is extending treatment depth, an issue dealt with in detail elsewhere in this volume. The complex dynamics of tumor oxygenation in response to PDT are now largely understood. The oxidative stress effects of PDT on redox-sensitive transcription factors and the genes they control are being uncovered. The complex interplay of biological mechanisms governing the PDT tumor response was realized. Given these accomplishments, it remains for them to be translated into actual patient benefit. Noninvasive probes need to be perfected that will allow for monitoring photosensitizer levels, oxygen status, or ideally, singlet oxygen, the cytotoxic agent. New light delivery regimes need to be devised for clinical use that will minimize oxygen limitations. The ways in which such regimes might influence redox-sensitive gene regulation and how these genes might affect treatment outcome need to be explored. Finally, our expanding understanding of the complex effects of PDT on host immunity needs to be exploited to modulate the PDT response.

Photodynamic Therapy: Basic and Preclinical Aspects

Giulio Jori
University of Padova

146.1 Introduction

Photodynamic therapy (PDT) represents an increasingly accepted modality for the curative or palliative treatment of cancer and some noncancerous conditions that are generally characterized by overgrowth of transformed cells.[1] Interest in this technique was promoted by the recent approval of PDT with Photofrin® (a complex mixture of hematoporphyrin derivatives[2]) by regulatory health authorities in several countries for the treatment of lung, gastric, esophageal, bladder, and cervical tumors, in addition to cervical dysplasia and actinic keratosis.[3] At the same time, a more detailed understanding of the mechanisms involved in the photosensitized damage of cells and tissues, as well as a definition of the correlation between chemical structure and photodynamic activity for various classes of porphyrin derivatives,[4] led to the development of second-generation photosensitizers with improved phototherapeutic properties and the extension of PDT outside the oncological field; a typical example is represented by the approval of PDT with benzoporphyrin derivative for the treatment of the wet form of age-related macular degeneration.[5] As known, the successful outcome of PDT depends on the optimal interaction among three elements: light, photosensitizer, and oxygen. In general, light wavelengths in the red/near-infrared region of the visible spectrum are endowed with good penetration power into most human tissues, ranging from 4 to 5 mm for the 630 nm wavelength (which is used to activate Photofrin *in vivo*) to about 1.5 cm for wavelengths around 800 nm.[6] As a consequence, porphyrins and their analogues (such as chlorins, bacteriochlorins, phthalocyanines) are most frequently used as PDT agents: such compounds exhibit absorption bands in selected intervals within the 600 to 800 nm range and show no detectable cytotoxicity at the doses that are photochemically active. Red light has an additional advantage in that it undergoes no appreciable absorption by the chromophores commonly present in mammalian tissues, with the exception of melanin; therefore, there is a minimal risk to initiate photoprocesses in areas different from those containing the exogenously introduced photosensitizer that might induce generalized and undesired side effects. Last, several noncoherent and coherent light sources specifically suitable for PDT applications for different diseases and different anatomical sites were developed in the

0-8493-1348-1/04/$0.00+$1.50

TABLE 146.1 Physicochemical Properties of an Efficient PDT Agent in the Ground and Electronically Excited States

Property	Typical Values	Related Features
Absorption range	700–800 nm	Large tissue transmittance; sufficient triplet energy to generate singlet oxygen
Molar extinction coefficient	$>10^5$ M^{-1} cm^{-1}	Extensive π electron delocalization; use of low photosensitizer dosages
Fluorescence quantum yield	≥0.2	Useful for diagnostic applications; not too large to compete with intersystem crossing to the triplet state
Triplet quantum yield	>0.7–0.8	Essential for efficient photosensitization
Triplet lifetime	Longer than 100 μs	Typical of monomeric photosensitizers, allows a major role in diffusion-controlled processes
Singlet oxygen quantum yield	>0.5	Easy accessibility to oxygen for the triplet photosensitizer
Photobleaching quantum yield	$<10^{-5}$	Prevents a decrease that is too fast in the photosensitizer concentration during irradiation

last few years.[7] Notable is the availability of typically low-cost and compact red-emitting diode lasers that can be efficiently coupled with optical fibers, thus allowing for irradiation of lesions in internal organs, which has been useful for broadening the utilization of this technique. Recent findings[8] also suggest that less tissue-penetrating light wavelengths (e.g., green or even blue light) might be preferable in specific cases to avoid the photoinduced damage of deeper tissue layers not involved in the disease (for example, the treatment of neoplastic lesions of the gastric mucosa) or the perforation of tissues (for example, in the removal of atherosclerotic plaques). Thus, it is likely that the final PDT protocol needs to be tailored to any given disease.

In general, the successful outcome of PDT largely depends on the choice of a photosensitizer with optimal properties for any specific application. Such properties can be subdivided into photophysical/photochemical, photobiological, and pharmacokinetic/phototherapeutic properties.

146.2 Photophysical and Photochemical Processes in PDT

A synthetic list of the photophysical and photochemical properties, which are typical of an efficient PDT photosensitizer, is shown in Table 146.1. Apparently, the first requirement is represented by the presence of intense absorption bands in the 700 to 800 nm wavelength region, which guarantees the uniform illumination of relatively large tissue volumes. To achieve this goal, selected modifications of the porphyrin-type tetrapyrrolic macrocycle were devised, [9] including the following:

1. Expansion of the macrocycle through condensation of a benzene or naphthalene moiety with each pyrrole ring — as a result, the 18 π electron cloud of porphyrins increases to 24 or 26 π electrons with a consequent shift of the longest wavelength absorption maximum to ca. 680 to 720 nm (phthalocyanines) and, respectively, 780 to 820 nm (naphthalocyanines); the latter wavelength is considered a kind of energy threshold for the triplet state of the photosensitizer to be phototherapeutically active[10]
2. Hydrogenation of a carbon–carbon double bond in one or two pyrrole rings to generate chlorins and, respectively, bacteriochlorins — this modification results in a shift of the red absorption to around 690 to 700 nm and around 780 nm, as well as in a marked increase in the molar extinction coefficient
3. Synthesis of a porphyrin isomer, the porphycene, differing from traditional porphyrins in the number of carbon–carbon bonds between the individual pyrrole rings — even though the total number of resonating π electrons is still 18, such an alteration of the overall molecular geometry is accompanied by an about 50 nm red shift of the lowest-energy absorption band and a simultaneous ca. 10-fold enhancement of the molar extinction coefficient; a similar pattern of structural changes is typical of texaphyrins, which also display a maximum absorption at 680 to 700 nm

TABLE 146.2 Main Targets of Photodynamic Processes in Biological Systems

Cell Constituent	Photosensitive Targets	Main Photoproduct	
		Type I	Type II
Proteins	Tryptophan	Hydroxy-indoles	Kynurenines
	Histidine	Keto derivatives	Keto derivatives
	Methionine	Methional	Methionine sulfoside
	Cysteine	Cysteic acid	Cystine
Unsaturated lipids	Oleic, linoleic, linolenic, arachidonic acids	Polymeric derivatives	Endoperoxides, hydroperoxides
Steroids	Cholesterol	5α-Hydroperoxide	7α-Hydroperoxide
Nucleosides	Guanosine	Various	Various

Further modifications of the absorbance properties of PDT photosensitizers, including a fine-tuning of the position and intensity of the absorption maxima, can be obtained by a careful choice of other structural elements, such as the following:

1. The nature of the substituents protruding from the peripheral positions of the macrocycle or appended to the meso-carbon or nitrogen atoms — Alkoxy-type substituents are particularly effective in bathochromically shifting the absorption.
2. The insertion of a metal ion at the center of the macrocycle, the ion being coordinated with the four pyrrole nitrogen atoms — Such ions should be diamagnetic or have filled *d* orbitals; paramagnetic ions are known to cause drastic shortening of the photosensitizer triplet lifetime, with a consequent inhibition of the PDT activity. Typical ions successfully introduced into the tetrapyrrolic macrocycle include Zn(II), Al(III), Pd(II), Si(IV), and Ge(IV) ions.[11]
3. The addition of axial ligands in the fifth or sixth coordinative position of the centrally located metal ion[12] — This approach offers large flexibility in the choice of the auxochromic or bathochromic functional groups, allowing for precise control of the photosensitizer physicochemical properties in both ground and electronically excited states.

In spite of the broad number of photosensitizers so far tested as PDT agents and the variety of their microenvironments in biological systems, the photophysical pathways involved in the early steps of photodynamic processes are of fairly general occurrence. Thus, it is now widely accepted[13,14] that the main cytotoxic intermediate is represented by singlet oxygen ($^1\Delta g\ O_2$) generated via electronic energy transfer from the photoexcited sensitizer in its long-lived (a few hundred microseconds) lowest triplet state. A minor contribution to the photoprocess is given by radical species originated through redox reactions that are based on electron–hydrogen transfer steps between the triplet photosensitizer and nearby substrates (including ground-state oxygen). The latter step may give rise to the superoxide anion ($O_2\cdot^-$), which is intrinsically characterized by a low reactivity; however, under specific circumstances, the superoxide anion can undergo the Fenton reaction originating the OH· radical, which is extremely reactive.

In any case, the photochemically produced transients are characterized by a high level of electrophilicity, hence, only electron-rich sites of molecules located in the immediate surroundings (a few nanometers) of the photosensitizer are modified, at least in the initial stages of the photoprocess. Therefore, the PDT action is most frequently characterized by a high spatial selectivity. As shown in Table 146.2, typical targets of photodynamic processes occurring in biological systems include aromatic and sulfur-containing amino acids, unsaturated lipids, steroids, and guanosine nucleotides.[15–17] In several cases, the end-products of the photoprocess are dependent on the prevailing mechanism; this circumstance can be utilized as a diagnostic tool between Type I and Type II photosensitization pathways.

One factor that strongly influences the photophysical properties of porphyrin derivatives is represented by the tendency of these compounds to undergo aggregation in aqueous media.[18] Dimers and higher oligomers are readily formed as a result of π–π and hydrophobic interactions between the flat tetrapyrrolic macrocycles with an aim to minimize the contact area with the polar milieu. In such aggregates, the excitation energy is largely dissipated through nonradiative channels, thus drastically shortening the

lifetime of the photosensitizer triplet state. As a consequence, oligomeric porphyrins are generally inefficient photodynamic agents.[18,19] The tendency to aggregate can be counteracted by various strategies, such as the presence of charged peripheral substituents (e.g., carboxylate or ammonium functions), the introduction of bulky axial substituents, or the localization of the porphyrin in hydrophobic niches of cells and tissues.

Last, it is important to underline that the energy–electron transfer process from the triplet photosensitizer is usually competitive with one or more photochemical reactions, causing an irreversible modification of the photosensitizer molecule. The latter process is also known as "photobleaching," because it is accompanied by a cleavage of the tetrapyrrolic macrocycle and a consequent disappearance of the visible absorption bands. The efficiency of the photoprocess is strongly dependent on the nature of the coordinated metal ion and the side chains attached to the macrocycle: quantum yields typically are in the 10^{-4} to 10^{-6} range.[20] From the point of view of phototherapeutic applications, the occurrence of photobleaching may have positive effects, because it avoids the persistence of significant photosensitizer concentrations in the irradiated site that could induce some long-lasting photosensitivity.

146.3 Photobiology of PDT

It is now established[21] that the photosensitizing agent must be bound to a cell for the photodynamic process to proceed with high efficiency. As a consequence, a large variety of mechanisms are involved in the response of cells to photodynamic action. Such responses usually vary with the cell type and its metabolic characteristics, such as the mitotic index, the presence of pigmented endocellular constituents, and the development of photoprotective factors. At the same time, cell responses are modulated by the interplay among several experimental variables,[22,23] including the following:

- Subcellular distribution of the photosensitizer (this is, in turn, influenced by the chemical structure of the photosensitizer and the cell-photosensitizer incubation time prior to irradiation)
- Photosensitizer concentration in the incubation medium
- Irradiation fluence-rate (mW/cm^2), which may particularly control the onset of repair processes
- Total delivered light dose (J/cm^2)

In general, porphyrins and their derivatives, which are most frequently used as PDT agents, localize at the level of cell membranes, including the cytoplasmic, mitochondrial and lysosomal membranes, the Golgi apparatus, and the rough endoplasmic reticulum.[18] Relative partitioning of the porphyrin-type photosensitizers among these subcellular compartments is at least partially dependent on the degree of hydrophilicity or hydrophobicity. Thus, highly water-soluble derivatives, such as tetrasulfonate or tetracarboxylate porphyrinoids, preferentially localize in lysosomes; on the other hand, appreciably lipophilic compounds (e.g., porphyrins having *n*-octanol/water partition coefficient greater than ca. 20) are almost exclusively associated with the lipid domains of the cytoplasmic membrane, at least for short incubation times, while binding to mitochondria is favored by the presence of positively charged functional groups in the porphyrin molecule.[24]

In spite of such a large variety of possible situations, three levels of cell response to PDT treatment can be identified (see Table 146.3). Thus, when mild irradiation regimes are used, cells are sublethally damaged. As a result, a variety of signaling pathways are activated that can counteract the photoinduced damage (e.g., expression of stress proteins) or promote the development of repair processes. Frequently, the action of photodynamic sensitizers causes a transient increase in the intracellular Ca^{2+} ions, due to an influx of extracellular Ca^{2+} and a release of Ca^{2+} from intracellular stores (e.g., the endoplasmic reticulum).[24] Photosensitization of cells by porphyrinoids often produces an oxidative stress that can lead to the upregulation of specific factors, such as tumor necrosis factor (TNF) and nuclear factor-kB (NF-kB), as well as the inactivation of sphingomyelinase with the consequent generation of ceramide.[25,26]

These processes may play an important stimulatory or inhibitory role in the photosensitized induction of apoptosis. There are several modes by which photodynamic reactions can promote the activation of processes eventually leading to programmed cell death (for an excellent review, see Oleinick et al.[27]). The

TABLE 146.3 Cell Response to Visible Light Irradiation in the Presence of Photodynamic Sensitizers

Response	Typical Features	Irradiation Protocol
Signaling events	Formation of cytokines; expression of surface receptors; increase in intracellular Ca^{2+}; activation of second messengers (e.g., ceramide)	**Mild** (low light and sensitizer doses; short incubation times)
Cell death via apoptotic pathways	Chromatin condensation; membrane blebbing; release of cytochrome *c* through the permeability transition pore complex; activation of caspases	**Intermediate** (fluence rates in the 10–20 mW/cm^2 range; short irradiation times; sensitizer binding mainly to mitochondria)
Cell death via random necrosis	Disruption of cytoplasmic membrane and other organelles (e.g., lysosomes, Golgi apparatus); drastic alteration of transmembrane transport processes; inhibition of protein synthesis	**Intensive** (prolonged irradiation at fluence rates as high as 50 $mW/cm;^2$ photosensitizer distribution in several membranous districts)

relative importance of the different mechanisms appears to be determined by a multiplicity of factors, such as the cell type, the nature of the photosensitizer, and the irradiation protocol. In any case, a central pathway for the induction of cell apoptosis by photosensitization involves the oxidative damage of mitochondrial components. In particular, photomodification of the Bcl-2 protein, which performs an important antiapoptotic role, certainly gives a major contribution to the promotion of apoptosis.[28,29] Other important targets of mitochondria-localized photosensitizers are represented by some constituents of the permeability transition pore complex; this results in the release of cytochrome *c* into the cytosol, where it binds to the so-called apoptosis-activating Factor-1 and activates the cascade of caspases, a family of proteins responsible for the final stages of apoptosis.[30] Recent findings suggest that apoptosis can also be initiated by photodynamic processes occurring at the level of the cytoplasmic membrane or lysosomes.[29]

Most often, when drastic irradiation regimes are adopted, apoptotic processes become less frequent (partly because of the irreversible photodamage of proapoptotic proteins), and cell death takes place mainly via a less-controlled mechanism, which is designated as random necrosis. This type of process is characterized by an early disruption of various membranous systems and is clearly favored by a heterogeneous distribution of the photosensitizer in the cell. As a consequence, multiple sites are almost simultaneously damaged.[29,31,32] Typical effects can be summarized as follows:

- *Plasma membrane*: Increased permeability, enzyme inactivation, extensive loss of membrane potential
- *Lysosomes*: Release of hydrolases into the cytosol, inactivation of specific enzymes, reduction of cytosolic pH
- *Mitochondria*: Inhibition of ATP production; inactivation of ATPase, the ADP/ATP translocator, and the enzymes associated with the inner membrane; uncoupling of oxidative phosphorylation
- *Endoplasmic reticulum (ER) and Golgi apparatus*: Inactivation of the ER-specific enzyme acyl coenzyme A; cholesterol-*O*-acyl transferase; extensive swelling; decreased synthesis and transport of plasma membrane proteins (which occurs in rough ER and Golgi apparatus)
- *Cytosol*: Damage of tubulin and other microtubule-associated proteins, increase in the intracellular concentration of free Ca^{2+}

Finally, it must be underlined that a photosensitizer can undergo an extensive relocalization within the cell owing to the disruption or modification of the initial binding sites, as documented by time-resolved fluorescence microscopic studies.[33] This can significantly amplify the overall photoinduced damage.

146.4 Experimental PDT of Tumors

As mentioned in Section 2, the most efficient and selective targeting of tumor tissues is achieved by using hydrophobic photosensitizers. The low water-solubility of such compounds requires the utilization of

TABLE 146.4 Delivery Systems Used for the *in vivo* Administration of Tumor Photosensitizer

Delivery System	Photosensitizer	Observed Behavior of the Photosensitizer
Liposomes made by		
DPPC	Hp, ZnPc, $SnET_2$	Highly preferential delivery to serum lipoproteins
DMPC	ZnPc, $SnET_2$	Delivery to albumin and lipoproteins
POPC, OOPS	ZnPc	Selective release to lipoproteins
Cremophor EL emulsions	$SnET_2$, ZnPc	Preferential delivery to serum LDL as compared to liposome-delivered photosensitizers
LDL	Hp, ZnPc, BPD	Fast redistribution among all members of the lipoprotein family
Albumin	Photofrin	Exchange with lipoproteins in serum; large amounts recovered in the vascular stroma
Epidermal growth factor (EGF)	Hp, Photofrin	Efficient binding to the EGF receptor
Monoclonal antibodies	Chlorin e_6, BPD	Highly selective targeting of tumor cells (encouraging results with cell cultures)

Note: Abbreviations are as follows: DPPC, diplamitoyl-phosphatidylcholine; DMPC, dimiristoyl-phosphatidylcholine; POPC, monooleyl-monopalmitoyl-phosphatidylcholine; OOPS, dioleyl-phosphatidylserine; LDL, low-density lipoproteins; Hp, hematoporphyrin; ZnPc, Zn(II)-phthalocyanine; $SnET_2$, Sn(IV)-etiopurpurin; and BPD, benzoporphyrin derivative.

suitable delivery systems for their intravenous administration. The main delivery systems, which have so far been tested in experimental or clinical PDT, are listed in Table 146.4 (see Jori and Reddi[34] for a more detailed discussion of this topic). In this connection, a few photosensitizers presently involved in clinical trials, such as $SnET_2$ and BPD, are formulated in liposomal vesicles. The choice of the delivery system affects the distribution of the incorporated photosensitizer among serum proteins, which are the actual carriers of the photosensitizer *in vivo*. As shown in Table 146.4, albumin-bound photosensitizers are largely released in the vascular stroma, whereas LDL-carried photosensitizers are preferentially released to malignant cells: it is well known that LDL express a specific interaction with rapidly proliferating cells through a process of receptor-mediated endocytosis.[35,36]

As a consequence, the use of delivery systems is useful for controlling the partitioning of the photosensitizer among the various compartments of the tumor tissue and enhancing the selectivity of tumor loading. Therefore, there are two possible targets of tumor PDT:

1. Direct killing of malignant cells — Three main parameters determine the efficiency of the phototoxic effect: the photosensitizer concentration (which in turn determines the dose of absorbed light), the subcellular distribution of the photosensitizer, and the oxygen level. The lack of vascular occlusion when the photoprocess is focused on tumor cells guarantees a steady supply of oxygen throughout the irradiation procedure, thereby reducing the risk of oxygen depletion that would limit the progress of the photoinduced damage. On the other hand, attempts at improving the oxygenation of the tumor tissue by using oxygen-rich prefluorochemical emulsions as blood substituents yielded no appreciable results.
2. Damage of blood vessels in the tumor leading to vascular occlusion — The consequent development of ischemia provokes the inactivation of neoplastic cells that are spared from direct killing. This process normally induces the onset of a strong inflammatory reaction, which typically triggers the appearance of gross edema and erythema. The release of powerful inflammatory mediators, induced by PDT, such as metabolites of arachidonic acid, histamine, components of the complement cascade clotting system, nitric oxide, and various cytokines, was repeatedly documented.[37,38]

The marked inflammatory reaction induced by PDT elicits an important additional consequence, namely, directing immune cells into the site of injury.[39–41] Massive invasion of neutrophils, mast cells, and macrophages provides a significant contribution to the photodestruction of cancerous cells. Furthermore, the PDT-induced tumor immune reaction may be important in attaining long-term tumor control. It was shown that tumor-associated macrophages can phagocytize cancer cells that were killed

TABLE 146.5 Main Pharmacological Properties of an Efficient Photodynamic Agent

Property	Related Structural and Biological Features
Efficient and selective targeting of the tumor tissue	Hydrophobic or amphiphilic properties; association with suitable delivery systems
Degree of hydrophobicity	Partition coefficient *n*-octanol/water greater than 10
Fast clearance from serum and healthy tissues	High affinity for serum proteins (e.g., high-density lipoproteins) responsible for transport of photosensitizers from peripheral tissues to liver
Low systemic toxicity	Lethal dose (LD-50) higher than ca. 100 mg/kg body weight

or extensively damaged by the photodynamic treatment, thus mediating the initial step of tumor-specific immune development. The mechanisms regulating this process were clearly discussed by Korbelik and Krosl.[42] The induction of immunity against a weakly immunogenic murine fibrosarcoma by PDT with Al(III)-phthalocyanine was detected by Canti et al.[41] These findings open challenging new perspectives for achieving long-term tumor control, e.g., by combining PDT with other immunotherapy protocols.

On the basis of the considerations developed so far, it is possible to outline at least some optimal pharmacological properties of an efficient PDT agent for tumors (see Table 146.5). The basically hydrophobic character imported by the flat aromatic macrocycle, which is present in porphyrinoid derivatives, can be adequately modulated by inserting suitable peripheral substituents; in particular, the presence of two polar moieties on two adjacent pyrrole rings generates an amphiphilic molecule with a lipophilic and a hydrophilic matrix. The need for fast clearance of the systemically injected photosensitizer from nontumor tissues is motivated by two aims: to obtain a high selectivity of tumor labeling, and to avoid the onset of a persistent cutaneous or ocular photosensitivity, which represents one main undesired side effect of PDT.[43] Because porphyrins and their analogues (with the exception of a few highly water-soluble derivatives, such as uroporphyrin) are eliminated from the organism via the bile–gut pathway, it is essential that the adopted photosensitizer display a high affinity for those serum proteins (e.g., high-density lipoproteins) that are deputed to the transport of lipophilic substances from peripheral tissues to liver. This circumstance further stresses the importance of hydrophobicity as a peculiar feature of PDT agents.

146.5 Novel Perspectives

A large variety of solid tumors were shown to be positively responsive to PDT, independent of their histological type or the nature of the anatomical site from which the tumor originates or into which the neoplastic lesion grows.[44,45] One notable exception is represented by malignant melanotic melanoma, where the large concentration of melanin-type pigments acts as an optical filter and prevents the in-depth penetration of sufficient light intensity. Because the absorption of UV and visible light by melanin decreases in an exponential fashion with increasing wavelength, the possibility exists to circumvent its optical filtering by using photosensitizers with intense absorbance above 800 nm.[46] However, such photosensitizers usually have no sufficient energy in their lowest triplet state to generate singlet oxygen. Recent findings[47–49] indicate that such a limitation can be overcome through photothermal sensitization, i.e., by using ns-pulsed laser sources emitting in the 800 to 1000 nm range to photoexcite phthalocyanine or naphthalocyanine complexes with paramagnetic metal ions, such as Ni(II), Fe(II), and Cu(II). These derivatives are characterized by short-lived triplet states and can efficiently convert electronic energy into heat. Under suitable irradiation conditions, temperature increases as large as 100°C are achieved in a sphere of a few nanometers diameter surrounding the photosensitizer binding site. Photothermal sensitization proved to be effective toward cultured neoplastic cells and subcutaneously transplanted tumors in mice.[48] Because the mechanisms of action of photothermal and photodynamic sensitization are substantially different, one can envisage a new phototherapeutic modality, named photothermal therapy (PTT), as well as a combination therapy involving the sequential application of PTT and PDT.

Clinical Applications of Photodynamic Therapy

Thomas J. Dougherty

Julia G. Levy
QLT Inc.

147.1 Introduction: Photodynamic Therapy

Photodynamic therapy refers to photodynamic action *in vivo* to destroy or modify tissue. Originally developed for treatment of various solid cancers, applications of it expanded to include treatment of precancerous conditions, e.g., actinic keratoses, high-grade dysplasia in Barrett's esophagus, and noncancerous conditions, e.g., various eye diseases, including age-related macular degeneration (AMD).

Photodynamic therapy (PDT) is currently approved for commercialization worldwide for various cancers (lung, esophagus) and for AMD.

PDT requires a drug (photosensitizer), light corresponding to an absorption band of the photosensitizer, and endogenous oxygen. The absence of any of these agents precludes the photodynamic effect.

0-8493-1348-1/04/$0.00+$1.50

The putative cytotoxic agent is singlet oxygen,[1] an electronically excited state of ground-state triplet oxygen formed according to the Type II photochemical process, as follows:

$P + h\nu \rightarrow P^* (S)$	Absorption
$P^* (S) \rightarrow P^* (T)$	Intersystem crossing
$P^* (T) + O_2 \rightarrow {}^1O^*_2 + P$	Energy transfer

where P = photosensitizer; $P^*(S)$ = excited singlet state; $P^*(T)$ = excited triplet state; and ${}^1O^*_2$ = singlet excited state of oxygen.

The Photosensitizer

Only photosensitizers that undergo efficient intersystem crossing to the excited triplet state and that possess a triplet state that is relatively long lived (to allow time for collision with oxygen) and have few other competing pathways will produce high yields of singlet oxygen. Most photosensitizers in clinical use have triplet quantum yields in the range of 40 to 60%, with the singlet oxygen yield being slightly lower. Competing processes include loss of energy by deactivation to ground state by fluorescence or internal conversion (loss of energy to the environment). However, while a high yield of singlet oxygen is desirable, it is by no means sufficient for a photosensitizer to be clinically useful. Pharmacokinetics, pharmacodynamics, stability *in vivo*, and acceptable toxicity play critical roles as well. For example, it is desirable to have relatively selective uptake in the tumor or other tissue being treated relative to the normal tissue that necessarily will be exposed to the exciting light as well. Pharmacodynamic issues, such as the subcellular localization of the photosensitizer, may be important, as certain organelles appear to be more sensitive to PDT damage than others (e.g., the mitochondria). Toxicity can become an issue if high doses of photosensitizer are necessary in order to obtain a complete response to treatment. For example, although PDT is rarely carried out on the liver, dark toxicity to the liver is often the main limiting toxicity seen in animal toxicity studies. Along the same lines, lack of *in vivo* stability would be a further issue relating to toxicity, as the toxicity profile of the breakdown products may need to be evaluated as well. In spite of all these impediments, there are large numbers of photosensitizers potentially useful in PDT, several of which are currently in various stages of clinical trials for FDA approval. Additional information on photosensitizers and mechanisms involved in PDT is discussed in Chapter 145.

Light

A limiting factor in PDT is the penetration of the activating light into tissue. Visible light in the red region of the spectrum (the most penetrating) generally has a penetration depth ($1/\varepsilon$) in the range of 2 to 6 mm, depending on the wavelength and the tissue. However, the depth of the biological effect of PDT (necrosis, apoptosis, vascular collapse) is generally found to occur at approximately twice this depth, i.e., 4 to 12 mm, meaning that approximately 10% of the incident light, i.e., the intensity drop-off at two penetration depths, is sufficient to elicit the photodynamic effect in tissue. As would be expected, the liver is one of the most opaque of tissues (due to pigmentation) and the muscle one of the most transparent. Most solid cancers originate in epithelial tissue (carcinomas) and have optical penetration depths of 3 to 5 mm (at ~600 nm) to approximately 6 to 10 mm (at 800 nm, where an optical window exists between absorption by blood and that of water).

Light sources are generally gas vapor lasers, e.g., argon pumped, wavelength tunable dye lasers, or solid-state lasers, such as frequency doubled Nd-YAG pumped dye lasers, or, now more frequently being used, diode lasers. However, appropriate lamps can be used as well, as was the case in the early days of PDT and is currently the case for treatment of actinic keratoses. Light from the laser is generally coupled into quartz fibers of various configurations. For lesions involving the skin and in certain other instances, a lens fiber is used that has a microlens on the tip to produce a homogeneous spot. For treatment of esophageal and lung tumors as well as for interstitial placement, a fiber is used that has a diffuser on the

end of the fiber, allowing for scattering of the light laterally from the fiber over a distance of 1 to 5 cm generally. For bladder treatment, a bulb-type tip is used to produce isotropic distribution over the entire bladder wall. Details of the light dosimetry for particular types of treatments will be described below.

147.2 Methodology of Clinical PDT

The following refers to the photosensitizer Photofrin®* (as used in PDT, for which the most information is available, and with only some differences, applies to the use of most photosensitizers.

Photosensitizer Injection

Patients receive an intravenous bolus injection of Photofrin in doses ranging from 1 to 2 mg/kg body weight. With Photofrin as well as certain other photosensitizers taken up by the skin, this immediately renders the patient susceptible to severe burns from bright light exposure (sunlight being the most likely source), a condition which generally lasts 4 to 6 weeks and possibly longer. Therefore, the patient, family, and others are educated prior to injection to take appropriate precautions, e.g., wearing clothing to cover the body completely, wearing a broad-brimmed hat, etc. However, it is important to point out that patients should not remain in darkened rooms during the day, as photobleaching by low-level light enhances clearance of the drug from the skin. Patients are asked to expose a small area on the back of their hand to bright sunlight for 10 min beginning about 4 weeks after injection, before slowly beginning to go into the sun. Should a reaction occur, they are advised to wait an additional week and retest their sun sensitivity. While cutaneous photosensitivity is a bothersome side effect of certain photosensitizers, it is our experience that patients rarely refuse PDT treatment for this reason.

Injection-Light Treatment Time Interval

The amount of time between injection and light exposure varies considerably between photosensitizers, ranging from 1 to 2 days for Photofrin to 15 min for AMD treatment. In general for solid tumor treatment, it is best (but not always necessary) to allow for photosensitizer clearance from normal tissue that may also be exposed to the activating light during treatment in order to minimize damage as much as possible. Some photosensitizers, however, demonstrate little retention in tumors and are therefore generally activated shortly after injection. While this could present some risks to normal tissue, in some cases, the dosimetry can be adjusted to minimize the damage to normal tissue. Selectivity can also be increased by using a minimum amount of photosensitizer and increasing the light dose to compensate because photobleaching of the lower amount of photosensitizer generally found in the normal tissue can lead to protection. Interstitial placement of the fibers into the tumor also tends to protect surrounding normal tissue but is not always feasible or desirable, e.g., attempts to insert fibers into obstructing esophageal tumors can result in perforations; in this case they are generally placed within the lumen adjacent to the tumor, while in the case of endobronchial tumors, insertion into the tumor can often be done without risking perforation.

Light Dosimetry

This is probably the most difficult variable to define in PDT because the optimum light dose in one organ may be ineffective or toxic in another. Time-consuming light dose ranging protocols must be carried out to define this parameter for each indication. (Recently, it was recognized that the light dose rate may also be important, see Chapter 145.) Summarized in Table 147.1 is the general range of PDT variables used for various photosensitizers, showing the large range of time interval, drug doses, and

TABLE 147.1TABLE 147.1 Photosensitizers in Clinical Trials

Photosensitizer[a]	Photosensitizer Dose (mg/kg)	Interval (hours)	Energy Dose[b] J/cm^2(1) or J/cm (2)	Wavelength (nm)	Indications
Photofrin®	1–2	24–48	15–215 (1) 100–300 (2)	630	Esophageal, lung, skin, bladder, head and neck, brain, and certain other sites
ALA (Levulan)	Topical ALA (20% in vehicle)	14–18	10 (1)	Blue (peak at 417 nm)	Actinic keratosis
mTHPc (Foscan)	0.15	72–96	10–20 (1)	650	Oral (approved in Europe)
$SnET_2$* (Purlytin)	1.2	4	200 (1)	660	Breast metastases
Lutetium Texaphyrin*+	1.5–3	3	100–150	732	Prostate, photoangioplasty, AMD
BPD-MA (Visudyne)	6 mg/m^2 (~0.15 mg/kg)	0.25	50 (1)	699	AMD (also in Phase III trial for skin cancer)
HPPH (Photochlor)	3–6 mg/m^2 (~0.08–0.15 mg/kg)	24–48	50–150 (1) 150 (2)	665	Skin, lung, esophagus
PC4	—	—	—	—	Cutaneous cancers (no further information available)

[a] Chemical structures can be found in Chapter 144.

[b] J = Joules; J/cm^2 refers to surface dose; J/cm refers to the Joules delivered/cm from a diffusing fiber.

Note: Photosensitizers are as follows: Photofrin®, polyhematoporphyrin ethers; ALA, aminolevulinic acid; mTHPc, meta-tetetrahydroxyphenylchlorin; SnET2, tin etiopurpurin,; Lutetium Texaphyrin, a pendadentate aromatic metalloporphyrin; BPD-MA, benzoporphyrin derivative mono acid; HPPH, 2-[1-hexyloxyethyl]-devinylpyropheophorbide-a; PC4, a silicon phthalocyanine; AMD, age-related macular degeneration.

light fluence. However, even for a single photosensitizer, Photofrin, light doses range from 15 J/cm^2 in bladder to over 200 J/cm^2 for skin lesions.

PDT with Photofrin®

Photofrin® (polyhematoporphyrin ethers), the first and so far only photosensitizer approved by health agencies worldwide for treatment of cancer, remains the most widely used in routine clinical practice for treatment of esophageal and lung cancers (approved), as well as in a host of off-label indications (e.g., skin cancer, bladder cancer, brain tumors, head and neck cancers, etc.).

The following describes the methods of treatment and outcomes for the various indications, beginning with those approved by various health agencies worldwide.

147.3 Health Agency Approved Indications for Photofrin®-PDT

Obstructive Esophageal Cancer

This indication is for palliation of partially or totally obstructing tumors in the esophagus. Photofrin, obtained as lyophilized powder, is dissolved in 5% dextrose for injection shortly before a single bolus injection of 2 mg/kg body weight. Because this photosensitizer is accumulated and retained in the skin (as well as in most other tissues and tumors), patients are immediately rendered photosensitive and must take precautions against exposure to bright lights (e.g., in a dental office) and especially sunlight. While the supplier of Photofrin suggests that precautions continue for 90 days, it is our experience that clearance occurs within 30 to 60 days, although there are some reported cases of up to 90 days. We ask our patients to expose a small patch of skin on the hand to bright sunlight for 10 min at 30 days postinjection, and if redness and swelling occur, to continue to take precautions for another week, and continue this until reaction no longer occurs, at which time they can then slowly increase exposure. It should be noted that patients should not remain in the dark, as low-level light aids clearance by photobleaching the drug. It should also be noted that because Photofrin is activated by visible light, sunscreens and window glass are not protective. As a further precaution, we supply sunglasses to wear when outside. This cutaneous photosensitivity is an annoyance, but rarely has a patient refused treatment because of it.

Approximately 48 h postinjection, the photosensitizer localized to the tumor is activated by light at 630 nm (generally derived from a laser) that is directed via a single quartz fiber optic and delivered to the tumor through the biopsy channel of an endoscope. The distal end of the fiber is fitted with a diffusing surface, generally 2.5 to 5.0 cm in length, that allows the light to scatter laterally to the tumor on the wall of the esophagus. In some instances, the fiber may be inserted directly into the tumor, although care must be taken to avoid perforation of the esophageal wall. This can be problematical because obstructing tumors may cause distortion of the esophagus, making insertion of the fiber somewhat blind. In most instances, the fiber is placed in the remaining lumen adjacent to the tumor. Some physicians place patients under general anesthesia, but this is generally not necessary, and conscious sedation is used most often. The light dose is 300 J/cm of diffuser length, with a power density of 400 mW/cm diffuser length, requiring 12.5 min to deliver the prescribed dose. Patients will often experience mild to severe chest pain (due to edema induced by treatment) controlled with analgesics. Other adverse reactions include fever, abdominal pain, constipation, and substernal pain. Two days following treatment, patients are examined endoscopically to judge initial response, to obtain biopsies, and to remove necrotic debris (not generally necessary). Also, if necessary, a second light treatment can be administered at this time (an advantage of long tumor retention of Photofrin). The treated tumor becomes blanched, and noninvolved areas in the light field are generally found to be edematous and erythemic. Summarized in Table 147.2 is the outcome of the randomized clinical trial of PDT versus Nd-YAG laser thermal ablation, carried out for the FDA and other health agency approvals.[2]

Only at 1 month was the advantage of PDT evident, a similar outcome seen for PDT treatment of obstructive endobronchial tumors versus Nd-YAG ablation (see below). This may reflect the ability of

TABLE 147.2 Objective Tumor Response — PDT versus Nd-YAG Laser in Partially Obstructing Esophageal Cancer

	Week 1		Month 1	
	PDT	Nd-YAG	PDT	Nd-YAG
Complete + partial response	45	40	32[a]	20
Stable disease	24	22	15	14
Progressive disease	3	1	11	14

the light to reach more of the tumor than is possible with the Nd-YAG laser, which must be aimed at the tumor, where care must be taken to avoid perforation. (In the clinical trial noted above, there were seven perforations in the Nd-YAG group versus one in the PDT group.)

Obstructing Endobronchial Tumors (Nonsmall-Cell Lung Cancer)

Also approved by the U.S. FDA and other health agencies is the palliative treatment of obstructive endobronchial tumors. The treatment approach is similar to that for the obstructing esophageal tumors (2.0 mg/kg body weight Photofrin and 630 nm light treatment approximately 48 h later), with certain notable differences. The light dose is 200 J/cm diffuser (8.3 min), generally delivered interstitially, when feasible, with 1.0 or 2.5 cm diffuser fibers. Also, 2 days following treatment, patients are reendoscoped and all necrotic tumor debris and exudates must be removed because this can further obstruct the airway. This step is especially critical when the treatment is near the carina, and debris and exudates can extend into both main-stem bronchi, presenting a potentially life-threatening outcome.[3]

As in the esophageal study, patients in this multicenter Phase III trial were randomized to PDT or thermal ablation with the Nd-YAG laser. Also, as was seen in the esophageal trial, there was no statistical difference in outcome until after 1 week.[4] (See Table 147.3.)

For example, at 1 month, 40% of PDT-treated patients demonstrated improvement in symptoms (dyspnea, cough, hemoptysis) versus 27% of Nd-YAG patients. Adverse reactions included photosensitivity reaction (20% in PDT arm only), hemoptysis, cough, dyspnea, chest pain, and fever, which occurred with similar frequency in both arms.

Early-Stage Endobronchial Tumors

Treatment of microinvasive, nonsmall-cell endobronchial tumors using Photofrin-PDT is the only indication so far approved by the FDA and other health agencies, where the intent is not palliation but cure. Also, unlike the above palliative approval, this study was approved based on several studies not specifically designed and carried out by the sponsoring company but carried out independently in three noncomparative studies. Patients in this study included those with CIS (carcinoma-*in situ*) or microinvasive tumors. Also included were patients not considered candidates for surgery (or radiation therapy in some cases).

Patients received Photofrin, 2 mg/kg, and 2 days later were treated endoscopically using a diffuser fiber (usually 1 to 2.5 cm) delivering 200 J/cm diffuser length at 630 nm. As these lesions are very thin, the

TABLE 147.4 Outcome of Patients with Microinvasive Lung Cancer

	11 Patients	62 Patients
CR (3 month) (biopsy proven)	3/11	31/62
Recurrence	1	11
Median time to recurrence		>2.7 years
Median survival		2.9 years
Median disease-specific survival		4.1 years

fiber was held in the lumen adjacent to the lesion. Two days following treatment, patients were rescoped, and the treated area was debrided.

Results with 102 patients indicated biopsy-proven complete response in 79% of patients (initial follow-up) with more than half continuing to be complete responders, often more than 2 years posttreatment. The median survival was 3.5 years, and disease-specific survival was 5.7 years. In a smaller segment of this trial population with microinvasive lung cancer (the actual approved indication), 62 inoperable patients were treated, 11 of whom were considered not to be candidates for surgery or radiation therapy. Indicated in Table 147.4 are the outcomes in this group.[5,6]

Early-Stage Esophageal Cancer

Although not yet approved by the U.S. FDA, a Phase III randomized, controlled, multicenter trial of Photofrin-PDT in patients with high-grade dysplasia (HGD) in Barrett's esophagus was recently completed for filing with the FDA. This study randomized patients to receive an acid suppressor, Omeprazole (Prilosec) or PDT plus Omeprazole. Endoscopic PDT was applied using a specially designed balloon light applicator with windows of 3, 5, or 7 cm in lengths produced from diffuser fibers of 5, 7, or 9 cm in length. The last 1 cm on each end is blocked off because the power at the ends of the diffuser is less than that emitted in the center of these fibers. The balloon was inserted deflated and then inflated in place to an appropriate pressure to allow "unfolding" of the esophageal wall without shutting down the blood flow. The Photofrin dose was 2.0 mg/kg injected approximately 2 days prior to light delivery of 130 J/cm of diffuser length. A preliminary report[7] at 6 months follow-up indicated that HGD was eliminated in 72% of patients in the PDT group but only in 31% of patients in the control group (Omeprazole alone). Moreover, at 2 years, 70% of responders in the PDT group continued to be complete responders, while none of the patients in the Omeprazole alone group were without HGD. Significantly, only 10% of patients in the PDT group progressed from HGD to esophageal cancer, compared to 19% of patients receiving only Omeprazole.

Overholt et al. reported on 100 patients treated for this indication with Photofrin and the balloon light emitter. Fifty-six of 73 patients with HGD were complete responders, and 32 had complete elimination of the Barrett's.[8]

The current practice in patients with HGD is to subject them to an esophagectomy, a surgical procedure associated with high mortality (5 to 10%) and morbidity.

It should be noted that Barrett's esophagus also is eliminated by the PDT treatment to the extent of 70 to 100% in most patients, being replaced with normal squamous mucosa. While not a specific endpoint in the trial, PDT appears to be one of the few methods currently available to remove this acid-reflux-induced inflammatory process, a risk factor for developing esophageal cancer (from 0.5 to 1.9% of patients with Barrett's esophagus will progress to HGD, and up to 50% of patients with HGD will go on to esophageal cancer over a 3-year period.[9]

147.4 Other Indications for Photofrin®-PDT

In addition to the approved or soon-to-be-approved indications of PDT using Photofrin, numerous other types of cancers were treated, including those of the head and neck, especially early-stage,[10] skin,[11,12]

brain,[13,14] bladder,[15] intrathoracic cavity (especially as an adjunct to surgery for mesothelioma),[16,17] and intraperitoneal tumors, such as ovarian studding[18] and cholangiocarcinoma.[19] Several of these are discussed below.

Cholangiocarcinoma

A potentially useful application of PDT is in the treatment of cholangiocarcinoma cancer. These tumors are generally diagnosed late, when surgery is rarely curative. In nonresectable cases, drainage or biliary bypass is used for palliation. Radiation therapy and chemotherapy appear to be of little benefit. In a series of 21 patients reported by Ortner et al.,[19] nonresectable patients were treated with Photofrin (2 mg/kg) 2 days prior to endoscopic fiber placement in the lumen (630 nm, diffuser fibers, 2.5 or 4.0 cm of diffuser length delivering 180 J/cm at a constant power output of 800 mW total). There was a dramatic drop in bilirubin in the PDT group (69 μmol/L) compared to stenting alone (20 μmol/L) and the Karnofsky score improved from 49 to 73 in the PDT arm. Eight patients were alive at 82 to 739 days posttreatment, and median survival was about 1 year. A small randomized trial was reported[20] with 35 patients, 20 to PDT + endoprostheses insertion (EP) and 15 to EP alone. An additional 34 patients who refused randomization received compassionate PDT + EP and were analyzed separately. The PDT treatment was as above. The median survival for the PDT + ES was 493 days, compared to the EP alone group of 98 days. The compassionate PDT + EP group had median survival of 406 days. All patients in the control arm (EP alone) are dead; six are alive in the PDT + EP compassionate group and two in the PDT + EP group. Significant improvement in bilirubin levels was seen in both groups receiving PDT + ED, but none was seen in the EP alone group. The Karnofsky scale score improved only in the PDT + EP compassionate group. It was concluded that addition of PDT to EP was a valuable improvement in palliation treatment because of significantly increased survival and improvement in quality of life. Because of this outcome, the randomized trial was stopped for ethical considerations.

Head and Neck Cancers

Application of PDT to treatment of head and neck cancers was initially limited to treatment of patients with advanced disease who failed or recurred on standard therapy. These patients rarely benefited from PDT. However, more recently, Biel[10] showed a high success rate in PDT treatment of early-stage disease of the oral cavity and larynx. Twenty-five patients who failed radiation therapy for early laryngeal cancers (carcinoma-*in situ* or T1) received Photofrin (2 mg/kg) followed 2 days later by 630 nm light at an energy dose of 80 J/cm^2. All patients received a complete response and remain free of disease, with a mean follow-up of 27 months. An additional 23 patients with early carcinomas (carcinoma-*in situ*, T1, T2) of the oral cavity, nasal cavity, and nasopharynx were treated similarly, and all were initially complete responders, with a mean follow-up of 26 months. One patient with recurrent leukoplakia of the tongue recurred at 12 months, one with recurrent cancer of the tongue and floor of the mouth recurred at 8 months, one patient developed regional metastases at 2 months, and another patient with recurrent nasal ala cancer recurred at 3 months post-PDT.

Skin Cancers

At this institution, we completed an extensive dose ranging study of Photofrin-PDT in patients with basal cell carcinoma (BCC). This represents the largest dose ranging clinical trial of PDT ever undertaken (80 patients, over 2000 lesions, three different Photofrin doses). We found that 1.0 mg/kg (215 J/cm^2 48 h postinjection, 630 nm) was more effective than 0.75 or 0.875 mg/kg Photofrin. Some 20 of these patients had nevoid basal cell carcinoma syndrome (NBCCS), an autosomal dominant mutation with loss of function of one copy of the PTCH tumor suppressor gene, resulting in these patients having a high susceptibility to frequently develop large numbers of BCC lesions over their lifetime. Some NBCCS patients in the study presented with 50 or more lesions, no longer susceptible to surgery without extensive scarring. PDT was of particular benefit to these patients because 30 to 40 lesions could be treated in a

single day with high and long-lasting complete response rates (>92%, 1.0 mg/kg Photofrin, 215 J/cm^2 48 h postinjection). Several of these patients were treated 4 to 5 times over several years as new lesions appeared. Taking into account all patients (NBCCS and non-NBCCS patients), the overall complete response rate was over 90%, comparable to other methods for treatment of BCC. Within this group, we found that larger lesions (>2 cm) responded slightly less than smaller lesions, and that those on the scalp were somewhat less responsive to PDT.

Treatment was accomplished using a laser beam splitter system that allowed treatment of up to eight lesions simultaneously. The delivery fibers were directly attached to the patient with special tripod holders,[21] allowing for some movement of the patient without diverting the beam from the lesion. At 150 mW/cm^2, treatment time to deliver 215 J/cm^2 was 23.9 min. Thus, in four such sessions, 32 lesions could be treated. This was easily accomplished in a single day. Without this capability, adequate treatment of the NBCCS patients would have been impossible.

147.5 PDT as Adjuvant Treatment

Head and Neck Cancers

PDT has been used frequently as an adjuvant to surgery in an attempt to "clean up" the remaining cancer cells in the operative bed. Biel reported on five patients with recurrent infiltrating squamous cell carcinoma — all who had failed previous surgery, radiation therapy, and chemotherapy. Patients received 2 mg/kg Photofrin followed 2 days later by surgery and PDT at 50 J/cm^2. He reported no postoperative complications. With a follow-up of 18 to 30 months, only one patient had recurred in an area outside the surgical and PDT field.

Brain Tumors

Muller treated over 100 patients with surgery and PDT.[13] Most had glioblastoma or astrocytoma, newly diagnosed or recurrent. These tumors are rarely curable by surgery, radiation therapy, or chemotherapy. The adjuvant studies were undertaken to determine the safety and feasibility of adding PDT to the surgical resection. Photofrin (2 mg/kg) was injected 12 to 36 h prior to light treatment using a specially designed expandable balloon applicator that fit within the surgical cavity and was filled with a light scattering material (1:1000 dilution of lipid). The delivered light at 630 nm was measured using a "pick-up" fiber placed adjacent to the balloon. Total energy doses ranged from 440 to 4500 J, with an energy density of 8 to 110 J/cm^2. The mortality rate was 3%, with a combined serious mortality and morbidity rate of 8%. Eight patients with recurrent gliomas who received greater than 60 J/cm^2 had a median survival of 58 weeks, while 24 who received less than 60 J/cm^2 had a median survival of 29 weeks.

Twenty patients with all types of brain tumors who received PDT at first operation had median survival of 44 weeks, with a 1-year survival of 40% and 2-year survival of 15%. Again, a light dose effect was found, with those patients receiving less than a total light dose of 1200 J having a median survival of 39 weeks and those with light doses greater than 1200 J having a median survival of 52 weeks. Patient characteristics in the two groups were similar. Patients with high Karnofsky score (>70) and who received light doses over 1260 J had a median survival of 92 weeks, with 1- and 2-year survival rates of 83 and 33%, respectively. The authors conclude that PDT with Photofrin is safe and appears to increase survival, especially at higher light doses. There is currently a multicenter, randomized (high- or low-light dose) trial ongoing to verify this conclusion.

Mesothelioma

This asbestos-induced disease of the mesothelium can be advanced before becoming symptomatic, and like the brain tumors discussed above, it is rarely curable by surgery and radiation therapy or chemotherapy. Moskal et al. reported on a series of 40 patients treated by a combination of surgery and PDT.[17]

Patients received Photofrin, 2 mg/kg, and 2 days later, as much tumor was removed as possible or debulked to 5 mm or less. PDT was then carried out by delivering 630 nm light to the entire thoracic cavity via 4 to 6 diffuser-type delivery fibers (2.5 to 5.0 cm in diffuser length), placed so as to deliver 20 to 30 J/cm^2 as evenly as possible. This was done in two placements of the fibers, posteriorly and anteriorly. Because of the large area to be treated (estimated from the CT scans), total light treatment time can range up to 4 h at a power density of approximately 10 J/cm^2. Postoperative staging indicated 12 patients with Stage I disease, 10 being completely resected; 11 patients with Stage II disease, with complete resection; 25 patients with Stage III disease, only five of whom could be completely resected (three died); and two patients with Stage IV disease. Morbidity and mortality rates for patients with Stage I or II disease were 38 and 0%, respectively, and for Stage III or IV disease were 48 and 11%, respectively. Patients requiring extrapleural pneumonectomy did not benefit from the combined treatment, as 43% of these patients had a bronchopleural fistula, much higher than the 1 to 4% reported in the literature. However, patients with disease in Stages I and II not requiring pneumonectomy appear to have increased survival rates (41% at 2 years) compared to those receiving surgery alone.

147.6 Other Photosensitizers

Because of prolonged cutaneous photosensitivity induced by Photofrin (30 to 60 days) and less than optimum absorption in the red region of the spectrum, a host of newer photosensitizers are undergoing clinical trials.

ALA (δ-Aminolevulinic acid)

δ-Aminolevulinic acid (ALA) is involved in the heme pathway, in which the final metal insertion step can be obviated with a large excess of ALA, thus causing the buildup of protoporphyrin IX (PPIX), a porphyrin photosensitizer. Injectable PPIX is not a useful photosensitizer because it is not well retained by tumors or other tissues and clears the system rapidly. However, the intracellular accumulation of PPIX through excess ALA can be effective. In fact, topically applied ALA is approved by the U.S. FDA for the treatment of actinic keratosis, a precancerous lesion that can lead to squamous cell carcinoma. The sponsor also developed a special blue light source that can be fitted on the patient's head to allow treatment of the entire face for patients with numerous lesions. In the Phase III trials,[22] patients were treated topically with 20% ALA in a proprietary vehicle (Levulan®, registered trademark of DUSA Pharma Inc., Wilmington, MA), and the next day received the blue light treatment (approximately 15 min exposure). In one study of 117 patients, 80% of lesions had a complete response that increased to 94% with a second treatment, while in the placebo group (placebo + light), only 32% of lesions responded completely after two treatments. Adverse reactions included a stinging, burning sensation that was well tolerated.

Topical ALA was also applied to the treatment of superficial skin cancers with excellent results. It is less effective for nodular lesions.[12] In this treatment, the ALA (10 to 40%) was applied topically in leucerin cream for various periods (usually 4 or 24 h) and then activated at 635 nm derived from a dye laser delivering light doses up to 200 J/cm^2. In this treatment, the pain is sufficient to require local injection of an anesthetic prior to treatment. Most patients tolerate this well.

ALA is currently being investigated as a fluorescent localizing agent in bladder cancer (see below) and for treatment of low-grade dysplasia in Barrett's esophagus.[23]

mTHPc (Foscan)

This chlorin-type photosensitizer was approved in Europe for treatment of oral cancers. Fan et al. reported preliminary clinical results.[24] Nineteen patients with various stages of disease (eight with field change disease) were injected with mTHPc (0.15 mg/kg), and 72 to 96 h later were treated with varying light doses at 652 nm. Three patients with single T3 lesions received a complete response, as did three of six T4 tumors. Field change disease responded less well, with nine of 14 T1 and T2 lesions responding

completely. Adverse reactions included one patient with tongue tethering and necrosis of normal tissue in another. However, while approved in Europe for this indication, the U.S. FDA chose not to approve it for use in the United States, although as of this writing, this is under review.

SnET2 (Purlytin, Tin Etiopurpurin)

While trials were completed with this photosensitizer in cutaneous breast cancer metastasis, the sponsoring company chose not to file for approval for the indication. However, they completed two placebo-controlled clinical trials with 933 patients in 59 centers for AMD (age-related macular degeneration).[25] These trials concluded in December 2001 (a two-year follow-up period is required).

Lutetium Texaphrin (Lutex)

This is an example of so-called expanded metalloporphyrin system resulting in a strong shift in the red absorption band from near 620 nm to 732 nm, where nearly optimum tissue penetration occurs. Current clinical trials are in locally recurrent prostate cancer, and noncancerous indications, AMD and photoangioplasty.[26] Details are not available. Moderate to severe pain during treatment hampered studies of treatment of various cutaneous malignancies.

HPPH (Photochlor)

Three clinical trials (Phases I and II) of PDT with this new chlorin-type photosensitizer are underway at Roswell Park Cancer Institute: partially obstructing esophageal cancer, early-stage lung cancer, and basal cell carcinoma.

In obstructing esophageal cancer, eight patients were treated at 6 mg/m^2 (0.15 to 0.19 mg/kg body weight) and 150 J/cm of 665 nm light delivered at approximately 48 h postinfusion of HPPH. All patients achieved partial or complete opening of the esophageal obstruction, and most had improvement in dysphagia. In these trials, patients are tested daily for cutaneous photosensitivity for 3 to 4 days using a solar simulator (1 cm spot on the underside of the wrist) at doses up to 133 J/cm^2. Only two patients had a mild erythemic reaction. Although the in-house solar simulator indicates little cutaneous photosensitivity, patients are still advised to test their reaction to sunlight by exposing a small area on the back of their hand for 10 to 30 min daily until no HPPH-induced reaction is found before ceasing precautions.

PC4

This silicon phthalocyanine with two axial ligands on silicon, a hydroxy group, and a dimethylaminopropyl siloxy group, recently entered Phase I dose escalation clinical studies with cutaneous lesions. No information is available as of this writing.

147.7 Treatment of Age-Related Macular Degeneration by PDT with BPD-MA (Verteporfin)

Background

The macula constitutes a small, highly specialized region of the human retina. The central part is rich in photoreceptor cells and is the area responsible for high visual acuity in humans. The end result of macular degeneration is the ultimate destruction of photoreceptor cells in the macula as well as the underlying cells of the retinal pigmented epithelium (RPE). Macular degeneration is the leading cause of blindness in the developed world and is most prevalent in people over the age of 60. There are two principal forms of age-related macular degeneration (AMD), dry or nonexudative AMD and wet or exudative AMD. While wet AMD constitutes only about 10% of all cases of AMD, it is responsible for most of the vision loss associated with the disease. There are approximately 500,000 new cases of wet

AMD every year worldwide. As this is a disease predominantly of Caucasians, the main areas of disease incidence are North America and Europe. Wet AMD occurs when rapidly growing abnormal blood vessels develop under the macula in a process described as subretinal neovascularization. The newly formed vessels do not mature properly and leak into the subretinal space, effecting detachment of the RPE and the ultimate degeneration and destruction of the photoreceptor cells in the region of the lesion.

The underlying causes of wet or dry AMD are not well understood, but there is evidence for genetic tendencies because there are familial as well as racial propensities in disease occurrence. While there is strong circumstantial evidence for a genetic base for the disease, the genes relating to susceptibility are clearly complex and are not well understood at this time. Familial studies on patients with Stargardt's disease clearly identified a specific gene mutation associated with this severe macular disorder. The gene identified is a photoreceptor cell-specific ATP-binding cassette transporter gene (ABCA4), and patients with Stargardt's disease as well as a number of other disorders associated with the retina express mutations in this gene, which is polymorphic.[27] A recent study showed that patients who express particular mutations in at least one allele of this same gene are at a threefold or fivefold greater risk of developing wet AMD.[28] These studies support the genetic basis for susceptibility to AMD and demonstrate that the genetic basis is complex and no doubt involves additional gene loci. A functional role for the ABCA4 gene was suggested in the eye. Most ABC transporters act as "flippases," i.e., as transporters of the protonated complex of all-*trans* retinal and phosphatidylethanolamine (*N*-retinylidene-PE). In knockout mice lacking the ABCA4 gene, phosphatidylethanolamine accumulates with resulting deposition of a major lipofuscin fluorophore (A2-E or a pyridium *bis*-retinoid, which is derived from two molecules of vitamin A aldehyde and one molecule of ethanolamine) in the retina. Accumulation of lipofuscin in the macular region of aging eyes is characteristic of AMD.[29]

The exudative or wet form of AMD is diagnosed using standard fluorescein angiography. Serial fluorescent photography of the macular area can readily identify where areas of vessel leakage are occurring because fluorescein will pool in the area of neovasculature. Exudative AMD is subdivided into two categories on the basis of the speed of visible leakage on angiographs. The "classic" form of AMD is considered the most aggressive form of the disease, and leakage occurs rapidly during the angiography. This form of AMD is characterized by rapid progression and concurrent vision loss. Lesions that leak slowly and show up on angiograms late are defined as "occult" wet AMD. These lesions lead to vision loss at a slower rate than with the classic form.

Although the overwhelming majority of research and clinical testing with PDT addressed the application of this technology in the treatment of solid tumors, during the past decade and a half, possible applications in other disease areas were investigated. Because many photosensitizers accumulate or are retained somewhat selectively in rapidly dividing cells as well as neovascular endothelial cells, the PDT effect, at least on solid tumors, was elegantly demonstrated, using Photofrin, to effect the tumor cells and the neovascular bed underlying rapidly growing tumors.[30,31]

Ocular conditions involving neoplasias or hypervascularity lend themselves to PDT because of the accessibility to light of all parts of the eye. Early investigator-sponsored studies using Photofrin for the treatment of ocular tumors demonstrated the effectiveness of this therapy in destroying local tumors as well as the neovascular bed surrounding them. The Verteporfin molecule (also termed BPD-MA or Visudyne) is a hydrophobic photosensitizer with pharmacokinetic properties that make it a desirable drug to use in indications such as AMD. It is formulated as a liposome in order to render it soluble in water. However, once in association with plasma, the drug demonstrates an affinity for lipoproteins much greater than its affinity for the liposomal constituents. Consequently, it is almost instantaneously released from the liposome and transferred to LDL and HDL in blood. This somewhat unusual characteristic results in rapid uptake of the drug by neovascular endothelia and a treatment window for selective accumulation at between 15 and 30 min following intravenous administration. Therefore, unlike most photosensitizers, which rely on selective retention by target cells, Verteporfin achieves selectivity by differential uptake by target tissue.[32] Verteporfin has the additional advantage of having a very short half-life (4 to 5 h in humans). Thus, treatment at an early time interval permits use of relatively low drug doses, and with the rapid half life, patients are only photosensitive for 24 h.

Research was undertaken in 1992 to investigate the feasibility of using Verteporfin for the treatment of AMD. Initially, two models in the rabbit were used: induced corneal neovasculature and implanted ocular tumors. Results from these studies were encouraging and showed in both instances that the expected thrombotic closure of neovasculature was seen in PDT-treated eyes. These studies also suggested a window of selectivity in which normal vasculature might be preserved.[33] Final proof of concept work involved the primate model for AMD, in which thermal laser damage to the retina induces a neovascular lesion on the choroid. Although self-limiting, this model is considered the most reliable for testing treatments for AMD. Results from these studies were encouraging and continued to demonstrate effective closure of neovascular vessels at time intervals from 10 to 60 min following intravenous administration.[34]

AMD Clinical Trials

Clinical work with Verteporfin for Phases I and II was initiated in 1996, where patients with AMD received a single treatment with Verteporfin and were followed for 12 weeks by angiographic examination and visual acuity evaluation. A variety of regimens were tested, involving two different drug doses, five different light doses, and two different times of treatment. These studies revealed that at 7 days post-PDT, all lesions treated showed complete closure of neovasculature, with no accompanying vision loss or closure of normal retinal blood vessels, with the exception of two patients who received the highest light dose (150 J/cm^2 at 690 nm and 600 mW/cm). In these patients, closure of normal retinal vessels was observed, thus demonstrating the level at which selectivity was lost. It was of interest to note that while patients on average did not lose significant visual acuity at either 4 weeks or 12 weeks following treatment, a majority showed the presence of vascular leakage at the 12-week time point, indicating that repeat treatment would likely be necessary if a sustained benefit of PDT were to be maintained.[35]

These preliminary clinical trials in which approximately 150 patients participated, led to development of a protocol for two pivotal Phase III trials for treatment of patients with AMD with lesions that contained a classic component. The study design involved randomization of patients in a 2:1 ratio to Verteporfin treatment versus placebo. A total of 609 patients were accrued in the two trials — approximately 400 received treatment, while 200 received placebo. Patients were tested for baseline visual acuity and lesion assessment by angiography. They received Verteporfin intravenously at a dose of 6 mg/m^2 or placebo. At 15 min after drug administration, light treatment of 50 J/cm^2 at 600 mW/cm^2 was administered to the lesion using a diode laser emitting at 690 nm. Patients returned every 3 months, at which time, they were tested by angiography for evidence of vessel leakage. If leakage was present, they received another treatment. Visual acuity was tested at each visit. The primary endpoint was designated as showing a significant difference between treatment versus placebo in a loss of three lines of vision (approximately 15 letters on a standard eye chart) at 12 months. Secondary endpoints included serious vision loss (six lines), lesion size and progression, contrast sensitivity (a measure of reading ability), and actual visual acuity. Although the study was a 2-year study, agreement with regulatory bodies permitted filing for approval if the 12 month primary endpoint was achieved. All primary endpoints achieved significance at the 12 month time point.[36] These patients have now been followed for nearly 4 years. After 2 years, all patients, including placebo patients, have been receiving treatment if needed. Visual acuity in treated patients stabilized within the first year, and no loss of vision was observed in years two and three.[37]

Visudyne (Verteporfin) therapy was approved for wet, predominantly classic AMD in more than 50 countries, and over 50,000 patients have been treated.

Further clinical trials were carried out to test the ability of PDT to arrest progression of the occult form of AMD. A placebo-controlled study of similar design to that used for the classic containing lesions was carried out, with similar endpoints. In this study, significance of the primary endpoint was not reached at 12 months, but patients on treatment stabilized during the second year, and all endpoints were significant at 2 years. Because occult disease progresses slower than the classic form, it is not surprising that the difference between placebo and treatment arms took longer to show a significant difference.[38]

In addition to AMD, other ocular conditions were treated with Visudyne therapy. These diseases include conditions that cause choroidal neovasculature similar to that seen in AMD. Among these are pathologic

myopia, a complication of extreme nearsightedness, and ocular histoplasmosis syndrome, a complication of a parasitic infection. Regulatory approval for these conditions was also granted in North America and Europe.[39]

These studies established PDT as first-line therapy for AMD and other conditions. The safety of repeated treatments was established with few side effects noted. In the occult trial, it was noted that about 4% of patients experienced severe vision loss within the first week after treatment. A majority of these patients had recovery from this event, but further treatment is not recommended.

Two other photosensitizers were tested clinically for their effect on choroidal neovasculature. These are tin ethyl etiopurpurin (Purlytin) and texaphrin. Phases I and II studies with Purlytin showed similar vessel closure to that seen with Visudyne.[40] A Phase III placebo-controlled trial is almost completed, with 2 years of follow-up, and results should be made available early in 2002. Since this also is a hydrophobic photosensitizer, one would assume that vessel closure similar to that seen with Visudyne should be achieved. Texaphrin was tested in Phases I and II clinical trials in approximately 70 patients. These results, reported at various ophthalmology meetings, suggested that vessel closure was difficult to achieve, even at high drug doses. It is possible that the relative water solubility of this drug in comparison to Visudyne and Purlytin to some extent does not lend itself to rapid cell uptake.

PDT is now established as part of the ophthalmologist's armamentarium for the treatment of abnormal vascular conditions in the eye. The therapy is proven to be safe and efficacious. In addition to the diseases mentioned above, there are a number of other ocular conditions in which PDT could play a role. These include diabetic macular edema, diabetic retinopathy, corneal neovasculature, and ocular tumors. While there are alternative therapies for these conditions, unlike AMD where there was no treatment, it is possible that PDT may offer some advantages over existing therapies.

147.8 Photodetection

Photosensitizer fluorescence as a marker of early-stage cancers was studied in several indications. Protoporphyrin IX fluorescence derived *in situ* from ALA was shown to be capable of detecting lesions in the bladder not detectable by ordinary cystoscopy.[41] Riedl et al. recently demonstrated the clinical significance of this increased detection rate.[26] In a prospective, randomized study of 102 bladder cancer patients with tumors ranging from TaG1 to T1G3, 51 received transurethral resection under white light cystoscopy, and 51 received ALA-induced fluorescence-guided transurethral resection. Fluorescence detection was carried out by instilling into the bladder 1.5 g ALA in 50 cc sodium bicarbonate (to achieve a pH of 6.5) and left in place 1 to 4 h (the time did not appear to affect the outcome). A white light source coupled with a bandpass filter to produce blue light was used to excite the red fluorescence of protoporphyrin IX. Six weeks later, all patients underwent ALA-assisted transurethral resection. Tumor was detected in 39% (20/51) of patients who initially received the standard method and 16% (8/51) in the ALA group, a reduction in tumor recurrence of 59% ($p = 0.005$). The authors conclude that ALA-assisted transurethral resection is an inexpensive and effective method for significantly increased tumor detection in the bladder.

Detection of Early-Stage Lung Cancer

As is well known, early-stage lung cancer is difficult to detect, and earlier screening studies of high-risk patients, using chest x-ray and sputum cytology, show no survival benefit. Recently, however, spiral CT and fluorescence bronchoscopy were investigated for detection of early lung lesions: the former to detect peripheral lesions and the latter mainly for centrally located lesions. At this institution, we initiated a screening program of high-risk patients (previous history of lung cancer or head and neck cancers or exposure to asbestos) using an FDA-approved fluorescence endoscopic method, LIFE (Light-Induced Fluorescence Excitation), from Xillix Technologies Corp. (Richmond, British Columbia,
Canada), for examination of the central airways. This system was shown to be nearly three times as likely to detect an early lesion when used with white light bronchoscopy as white light bronchoscopy alone. It is based on the principle that even early dysplasia or carcinoma-*in situ* tend to accumulate endogenous

chromophores (e.g., porphyrins), thus presenting a reddish-brown fluorescence compared to normal bronchial mucosa, which is seen as greenish in color.[42] The suspicious areas are confirmed by biopsy. In addition, each patient will be screened using spiral CT for detection of peripheral lesions. Appropriate patients will be treated by PDT. While this is a relatively modest trial of 500 patients, the intention is not only to investigate these techniques for efficacy in detection of early lesions but also to determine the effect on survival after appropriate treatment, and not incidentally, to assist in convincing third-party payers to reimburse for screening.

147.9 Future Directions for Photodynamic Therapy

While PDT has mainly been used as a cancer therapy, it is clear that its applications are extending to many noncancerous conditions, as is evident from some of the foregoing. Other areas currently being investigated are prevention of restenosis after balloon angioplasty for cardiac artery disease, treatment of rheumatoid arthritis (inflammatory cells are particularly prone to photosensitizer uptake), and certain early detection indications.
