Preface to the Second Edition

When this book first appeared in 1984 it rapidly established itself as one of the foremost textbooks and references on the subject. It was enthusiastically adopted by both students and teachers and has already been translated into several European and Asian languages. The novel features which it adopted (see Preface to the First Edition) were clearly much appreciated and we have been pressed for some time now to bring out a second edition. Accordingly we have completely revised and updated the text and have incorporated over 2000 new literature references to work which has appeared since the first edition was published. In addition, innumerable modifications and extensions incorporating recent advances have been made throughout the text and, indeed, no single page has been left unaltered. However, by judicious editing we have ensured that all the features which made the first edition so attractive to its readers have been retained.

The main plan of the book has been left unchanged except that the general section on organometallic chemistry has been removed from Chapter 8 (Carbon) and has been incorporated, together with a summary of other aspects of coordination chemistry, in a restyled Chapter 19. However, the chemistry of even the simplest elements has been considerably enriched during the past few years, sometimes by quite dramatic advances. Thus the chemistry of the alkali metals has a complexity that was undreamt of one or two decades ago and lithium, for example, is now known in at least 20 coordination geometries having coordination numbers from 1 to 12. Compounds of alkali metal *anions* and even electrides are known. Likewise, there is expanding interest in the organometallic chemistry of the heavier congeners of magnesium, particularly those with bulky ligands. Boron continues to amaze and confound, and its cluster chemistry continues to expand, as does sulfur–nitrogen chemistry, heteropolyacid chemistry, bioinorganic aspects of the chemistry of many of the elements, lower-valent lanthanide element chemistry, and so on through each of the chapters, up to the synthesis and characterization of the heaviest trans-actinide element, $Z = 112$. It is salutory to reflect that there are now 49 more elements known than the 63 known to Mendeleev when he devised the periodic table of the elements.

A further indication of the rapid advances that have occurred in the chemistry of the elements during the past 15 years can be gauged from the several completely new sections which have been added to review work in what were previously both nonexistent and unsuspected areas. These include (a) coordination compounds of dihapto-dihydrogen, (b) the fullerenes and their many derivatives, (c) the metcars, and (d) high-temperature oxide superconductors.

We hope that this new edition of *Chemistry of the Elements* will continue to stimulate and inform its readers, and that they will experience something of the excitement and fascination which we ourselves feel for this burgeoning subject. We should also like to thank our many correspondents who have kept us informed of their work and the School of Chemistry in the University of Leeds for providing us with facilities.

Preface to the First Edition

IN this book we have tried to give a balanced, coherent and comprehensive account of the chemistry of the elements for both undergraduate and postgraduate students. This crucial central area of chemistry is full of ingenious experiments, intriguing compounds and exciting new discoveries. We have specifically avoided the term *inorganic chemistry* since this emphasizes an outmoded view of chemistry which is no longer appropriate in the closing decades of the 20th century. Accordingly, we deal not only with inorganic chemistry but also with those aspects which might be called analytical, theoretical, industrial, organometallic, bio-inorganic or any other of the numerous branches of the subject currently in vogue.

We make no apology for giving pride of place to the phenomena of chemistry and to the factual basis of the subject. Of course the chemistry of the elements is discussed within the context of an underlying theoretical framework that gives cohesion and structure to the text, but at all times it is the chemical chemistry that is emphasized. There are several reasons for this. First, theories change whereas facts do so less often — a greater permanency and value therefore attaches to a treatment based on a knowledge and understanding of the factual basis of the subject. We recognize, of course, that though the facts may not change dramatically, their significance frequently does. It is therefore important to learn how to assess observations and to analyse information reliably. Numerous examples are provided throughout the text. Moreover, it is scientifically unsound to present a theory and then describe experiments which purport to prove it. It is essential to distinguish between facts and theories and to recognize that, by their nature, theories are ephemeral and continually changing. Science advances by removing error, not by establishing truth, and no amount of experimentation can "prove" a theory, only that the theory is consistent with the facts as known *so far*. (At a more subtle level we also recognize that all facts are theory-laden.)

It is also important to realize that chemistry is not a static body of knowledge as defined by the contents of a textbook. Chemistry came from somewhere and is at present heading in various specific directions. It is a living self-stimulating discipline, and we have tried to transmit this sense of growth and excitement by reference to the historical development of the subject when appropriate. The chemistry of the elements is presented in a logical and academically consistent way but is interspersed with additional material which illuminates, exemplifies, extends or otherwise enhances the chemistry being discussed.

Chemistry is a human activity and its results have a substantial impact on our daily lives. However, we have not allowed ourselves to become obsessed by "relevance". Today's relevance is tomorrow's obsolescence. On the other hand, it would be obtuse in the modern world not to recognize that chemistry, in addition to being academically stimulating and aesthetically satisfying, is frequently also useful. This gives added point to much of the chemistry of the elements and indeed a great deal of that chemistry has been specifically developed because of society's needs. To many this is one of the most attractive aspects of the subject — its potential usefulness. We therefore wrote to over 500 chemically based firms throughout the world asking for information about the chemicals they manufactured or used, in what

quantities and for what purposes. This produced an immense wealth of technical information which has proved to be an invaluable resource in discussing the chemistry of the elements. Our own experience as teachers had already alerted us to the difficulty of acquiring such topical information and we have incorporated much of this material where appropriate throughout the text. We believe it is important to know whether a given compound was made perhaps once in milligram amounts, or is produced annually in tonne quantities, and for what purpose.

In a textbook devoted to the chemistry of the elements it seemed logical to begin with such questions as: where do the elements come from, how were they made, why do they have their observed terrestrial abundances, what determines their atomic weights, and so on. Such questions, through usually ignored in textbooks and certainly difficult to answer, are ones which are currently being actively pursued, and some tentative answers and suggestions are given in the opening chapter. This followed by a brief description of chemical periodicity and the periodic table before the chemistry of the individual elements and their group relationships are discussed on a systematic basis.

We have been much encouraged by the careful assessment and comments on individual chapters by numerous colleagues not only throughout the U.K. but also in Australia, Canada, Denmark, the Federal Republic of Germany, Japan, the U.S.A and several other countries. We believe that this new approach will be widely welcomed as a basis for discussing the very diverse behaviour of the chemical elements and their compounds.

It is a pleasure to record our gratitude to the staff of the Edward Boyle Library in the University of Leeds for their unfailing help over many years during the writing of this book. We should also like to express our deep appreciation to Mrs Jean Thomas for her perseverance and outstanding skill in preparing the manuscript for the publishers. Without her generous help and the understanding of our families this work could not have been completed.

Origin of the Elements. Isotopes and Atomic Weights

1.1 Introduction

This book presents a unified treatment of the chemistry of the elements. At present 112 elements are known, though not all occur in nature: of the 92 elements from hydrogen to uranium all except technetium and promethium are found on earth and technetium has been detected in some stars. To these elements a further 20 have been added by artificial nuclear syntheses in the laboratory. Why are there only 90 elements in nature? Why do they have their observed abundances and why do their individual isotopes occur with the particular relative abundances observed? Indeed, we must also ask to what extent these isotopic abundances commonly vary in nature, thus causing variability in atomic weights and possibly jeopardizing the classical means of determining chemical composition and structure by chemical analysis.

Theories abound, and it is important at all times to distinguish carefully between what has been experimentally established, what is a useful model for suggesting further experiments, and what is a currently acceptable theory which interprets the known facts. The tentative nature of our knowledge is perhaps nowhere more evident than in the first few sections of this chapter dealing with the origin of the chemical elements and their present isotopic composition. This is not surprising, for it is only in the last few decades that progress in this enormous enterprise has been made possible by discoveries in nuclear physics, astrophysics, relativity and quantum theory.

1.2 Origin of the Universe

At present, the most widely accepted theory for the origin and evolution of the universe to its present form is the "hot big bang".[1] It is supposed that all the matter in the universe

[1] J. SILK, *The Big Bang: The Creation and Evolution of the Universe*, 2nd edn., W. H. Freeman, New York, 1989, 485 pp. J. D. BARROW and J. SILK, *The Left Hand of Creation: The Origin and Evolution of the Expanding Universe*, Heinemann, London, 1984, 256 pp. E. W. KOLB and M. S. TURNER, *The Early Universe*, Addison-Wesley, Redwood City, CA, 1990, 547 pp.

was once contained in a primeval nucleus of immense density ($\sim 10^{96}$ g cm^{-3}) and temperature ($\sim 10^{32}$ K) which, for some reason, exploded and distributed radiation and matter uniformly throughout space. As the universe expanded it cooled; this allowed the four main types of force to become progressively differentiated, and permitted the formation of various types of particle to occur. Nothing scientific can be said about the conditions obtaining at times shorter than the Planck time, t_P [$(Gh/c^5)^{1/2} = 1.33 \times 10^{-43}$ s] at which moment the forces of gravity and electromagnetism, and the weak and strong nuclear forces were all undifferentiated and equally powerful. At 10^{-43} s after the big bang ($T = 10^{31}$ K) gravity separated as a distinct force, and at 10^{-35} s (10^{28} K) the strong nuclear force separated from the still combined electroweak force. These are, of course, inconceivably short times and unimaginably high temperatures: for example, it takes as long as 10^{-24} s for a photon (travelling at the speed of light) to traverse a distance equal to the diameter of an atomic nucleus. When a time interval of 10^{-10} s had elapsed from the big bang the temperature is calculated to have fallen to 10^{15} K and this enabled the electromagnetic and weak nuclear forces to separate. By 6×10^{-6} s (1.4×10^{12} K) protons and neutrons had been formed from quarks, and this was followed by stabilization of electrons. One second after the big bang, after a period of extensive particle–antiparticle annihilation to form electromagnetic photons, the universe was populated by particles which sound familiar to chemists — protons, neutrons and electrons.

Shortly thereafter, the strong nuclear force ensured that large numbers of protons and neutrons rapidly combined to form deuterium nuclei (p + n), then helium (2p + 2n). *The process of element building had begun.* During this small niche of cosmic history, from about 10–500 s after the big bang, the entire universe is thought to have behaved as a colossal homogeneous fusion reactor converting hydrogen into helium. Previously no helium nuclei could exist — the temperature was so high that the sea of radiation would have immediately decomposed them back to protons and neutrons. Subsequently, the continuing expansion of the universe was such that the particle density was too low for these strong (but short-range) interactions to occur. Thus, within the time slot of about eight minutes, it has been calculated that about one-quarter of the mass of the universe was converted to helium nuclei and about three-quarters remained as hydrogen. Simultaneously, a minute 10^{-3}% was converted to deuterons and about 10^{-6}% to lithium nuclei. These remarkable predictions of the big bang cosmological theory are borne out by experimental observations. Wherever one looks in the universe — the oldest stars in our own galaxy, or the "more recent" stars in remote galaxies — the universal abundance of helium is about 25%. Even more remarkably, the expected concentration of deuterium has been detected in interstellar clouds. Yet, as we shall shortly see, stars can only destroy deuterium as soon as it is formed; they cannot create any appreciable equilibrium concentration of deuterium nuclei because of the high temperature of the stellar environment. The sole source of deuterium in the universe seems to be the big bang. At present no other cosmological theory can explain this observed ratio of H:He:D.

Two other features of the universe find ready interpretation in terms of the big bang theory. First, as observed originally by E. Hubble in 1929, the light received on earth from distant galaxies is shifted increasingly towards the red end of the spectrum as the distance of the source increases. This implies that the universe is continually expanding and, on certain assumptions, extrapolation backwards in time indicates that the big bang occurred some 15 billion years ago. Estimates from several other independent lines of evidence give reassuringly similar values for the age of the universe. Secondly, the theory convincingly explains (indeed predicted) the existence of an all-pervading isotropic cosmic black-body radiation. This radiation (which corresponds to a temperature of 2.735 ± 0.06 K according to the most recent measurements) was discovered in

1965 by A. A. Penzias and R. W. Wilson[2] and is seen as the dying remnants of the big bang. No other comological theory yet proposed is able to interpret all these diverse observations.

1.3 Abundances of the Elements in the Universe

Information on the abundances of at least some of the elements in the sun, stars, gaseous nebulae and the interstellar regions has been obtained from detailed spectroscopic analysis using various regions of the electromagnetic spectrum. This data can be supplemented by direct analysis of samples from the earth, from meteorites, and increasingly from comets, the moon, and the surfaces of other planets and satellites in the solar system. The results indicate extensive differentiation in the solar system and in some stars, but the overall picture is one of astonishing uniformity of composition. Hydrogen is by far the most abundant element in the universe, accounting for some 88.6% of all atoms (or nuclei). Helium is about eightfold less abundant (11.3%), but these two elements together account for over 99.9% of the atoms and nearly 99% of the mass of the universe. Clearly nucleosynthesis of the heavier elements from hydrogen and helium has not yet proceeded very far.

Various estimates of the universal abundances of the elements have been made and, although these sometimes differ in detail for particular elements, they rarely do so by more than a factor of 3 ($10^{0.5}$) on a scale that spans more than 12 orders of magnitude. Representative values are plotted in Fig. 1.1, which shows a number of features that must be explained by any satisfactory theory of the origin of the elements. For example:

(i) Abundances decrease approximately exponentially with increase in atomic mass number A until $A \sim 100$ (i.e. $Z \sim 42$); thereafter the decrease is more gradual and is sometimes masked by local fluctuations.

(ii) There is a pronounced peak between $Z = 23$–28 including V, Cr, Mn, Fe, Co and Ni, and rising to a maximum at Fe which is $\sim 10^3$ more abundant than expected from the general trend.

(iii) Deuterium (D), Li, Be and B are rare compared with the neighbouring H, He, C and N.

(iv) Among the lighter nuclei (up to Sc, $Z = 21$), those having an atomic mass number A divisible by 4 are more abundant than their neighbours, e.g. ^{16}O, ^{20}Ne, ^{24}Mg, ^{28}Si, ^{32}S, ^{36}Ar and ^{40}Ca (rule of G. Oddo, 1914).

(v) Atoms with A even are more abundant than those with A odd. (This is seen in Fig. 1.1 as an upward displacement of the curve for Z even, the exception at beryllium being due to the non-existence of $^{8}_{4}Be$, the isotope $^{9}_{4}Be$ being the stable species.)

Two further features become apparent when abundances are plotted against A rather than Z:

(vi) Atoms of heavy elements tend to be neutron rich; heavy proton-rich nuclides are rare.

(vii) Double-peaked abundance maxima occur at $A = 80$, 90; $A = 130$, 138; and $A = 196$, 208 (see Fig. 1.5 on p. 11).

It is also necessary to explain the existence of naturally occurring radioactive elements whose half-lives (or those of their precursors) are substantially less than the presumed age of the universe.

As a result of extensive studies over the past four decades it is now possible to give a detailed and convincing explanation of the experimental abundance data summarized above. The historical sequence of events which led to our present

[2] R. W. Wilson, The cosmic microwave background radiation, pp. 113–33 in *Les Prix Nobel 1978*, Almqvist & Wiksell International, Stockholm 1979. A. A. Penzias, The origin of the elements, pp. 93–106 in *Les Prix Nobel 1978* (also in *Science* **105**, 549–54 (1979)).

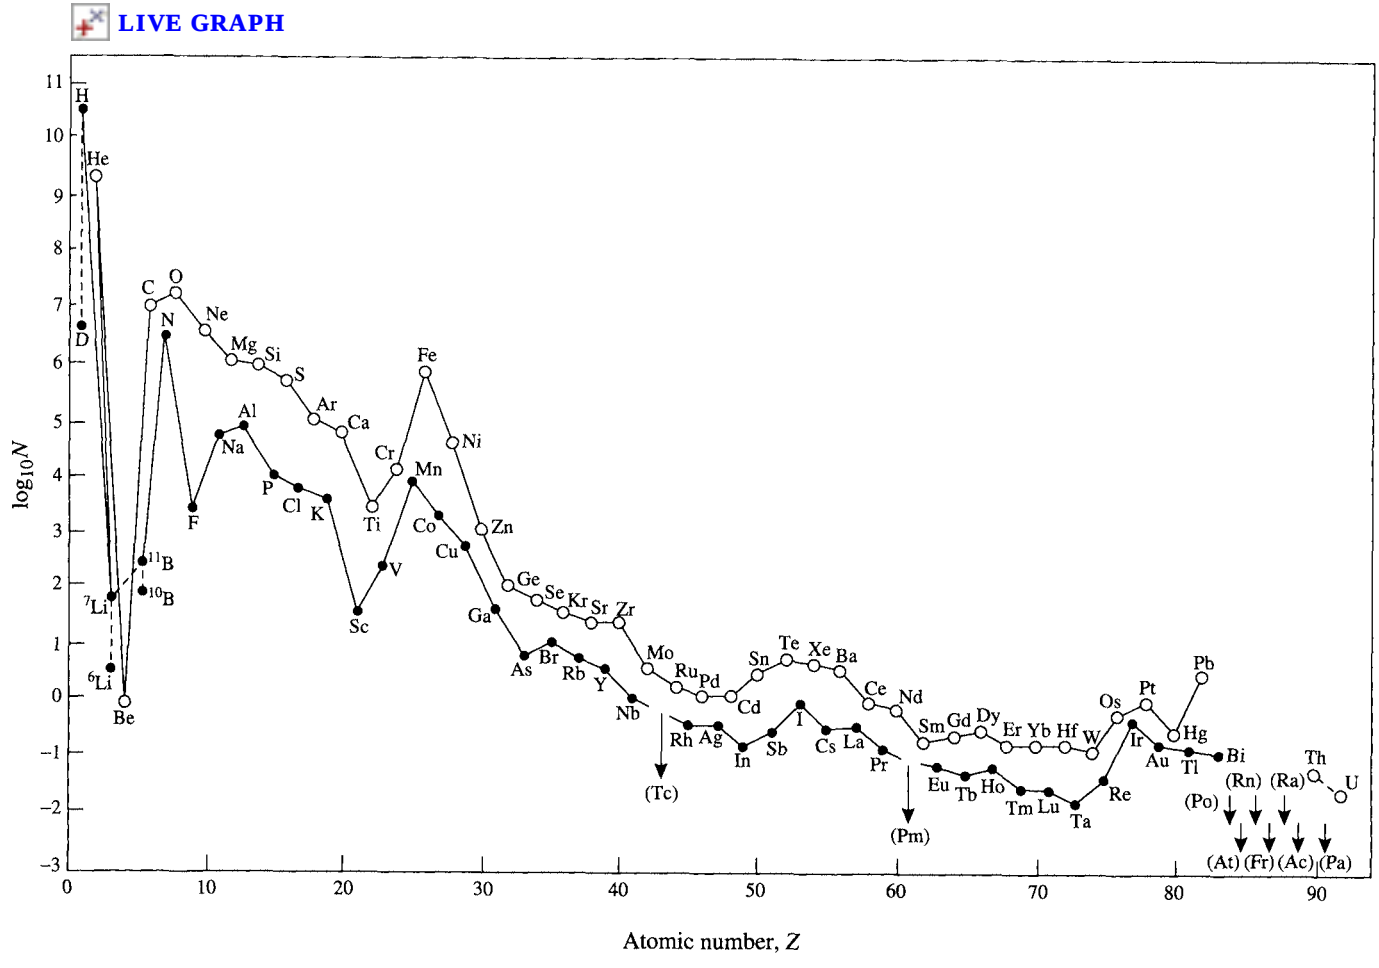

Figure 1.1 Cosmic abundances of the elements as a function of atomic number Z. Abundances are expressed as numbers of atoms per 10^6 atoms of Si and are plotted on a logarithmic scale. (From A. G. W. Cameron, *Space Sci. Rev.* **15**, 121–46 (1973), with some updating.)

understanding is briefly summarized in the Panel. As the genesis of the elements is closely linked with theories of stellar evolution, a short description of the various types of star is given in the next section and this is then followed by a fuller discussion of the various processes by which the chemical elements are synthesized.

1.4 Stellar Evolution and the Spectral Classes of Stars[3,4]

In broad outline stars are thought to evolve by the following sequence of events. First, there is self-gravitational accretion from the cooled primordial hydrogen and helium. For a star the size and mean density of the sun (mass = 1.991×10^{30} kg = 1 $M_\odot$) this might take ~20 y. This gravitational contraction releases heat energy, some of which is lost by radiation; however, the continued contraction results in a steady rise in temperature until at $\sim 10^7$ K the core can sustain nuclear reactions. These reactions release enough additional energy to compensate for radiational losses and a temporary equilibrium or steady state is established.

When ~10% of the hydrogen in the core has been consumed gravitational contraction again occurs until at a temperature of $\sim 2 \times 10^8$ K helium burning (fusion) can occur. This is followed by a similar depletion, contraction and temperature rise until nuclear reactions involving

Genesis of the Elements — Historical Landmarks

1890s	First systematic studies on the terrestrial abundances of the elements	F. W. Clarke; H. S. Washington and others
1905	Special relativity theory: $E = mc^2$	A. Einstein
1911	Nuclear model of the atom	E. Rutherford
1913	First observation of isotopes in a stable element (Ne)	J. J. Thompson
1919	First artificial transmutation of an element $^{14}_{7}N(\alpha,p)^{17}_{8}O$	E. Rutherford
1925–8	First abundance data on stars (spectroscopy)	Cecilia H. Payne; H. N. Russell
1929	First proposal of stellar nucleosynthesis by proton fusion to helium and heavier nuclides	R. D'E. Atkinson and F. G. Houtermans
1937	The "missing element" $Z = 43$ (technetium) synthesized by $^{99}_{42}Mo(d,n)^{99}_{43}Tc$	C. Perrier and E. G. Segré
1938	Catalytic CNO process independently proposed to assist nuclear synthesis in stars	H. A. Bethe; C. F. von Weizsäcker
1938	Uranium fission discovered experimentally	O. Hahn and F. Strassmann
1940	First transuranium element $^{239}_{93}Np$ synthesized	E. M. McMillan and P. Abelson
1947	The last "missing element" $Z = 61$ (Pm) discovered among uranium fission products	J. A. Marinsky, L. E. Glendenin and C. D. Coryell
1948	Hot big-bang theory of expanding universe includes an (incorrect) theory of nucleogenesis	R. A. Alpher, H. A. Bethe and G. Gamow
1952–4	Helium burning as additional process for nucleogenesis	E. E. Salpeter; F. Hoyle
1954	Slow neutron absorption added to stellar reactions	A. G. W. Cameron
1955–7	Comprehensive theory of stellar synthesis of all elements in observed cosmic abundances	E. M. Burbidge, G. R. Burbidge, W. A. Fowler and F. Hoyle
1965	2.7 K radiation detected	A. P. Penzias and R. W. Wilson

still heavier nuclei ($Z = 8-22$) can occur at $\sim 10^9$ K. The time scale of these processes depends sensitively on the mass of the star, taking perhaps 10^{12} y for a star of mass 0.2 $M_\odot$, 10^{10} y for a star of 1 solar mass, 10^7 y for mass 10 $M_\odot$, and only 8×10^4 y for a star of 50 $M_\odot$; i.e. the more massive the star, the more rapidly it consumes its nuclear fuel. Further catastrophic changes may then occur which result in much of the stellar material being ejected into space, where it becomes incorporated together with further hydrogen and helium in the next generation of stars. It should be noted, however, that, as iron is at the maximum of the nuclear binding energy curve, only those elements up to iron ($Z = 26$) can be produced by exothermic processes of the type just considered, which occur automatically if the temperature rises sufficiently. Beyond iron, an input of energy is required to promote further element building.

The evidence on which this theory of stellar evolution is based comes not only from known nuclear reactions and the relativistic equivalence of mass and energy, but also from the spectroscopic analysis of the light reaching us from the stars. This leads to the spectral classification of stars, which is the cornerstone of modern experimental astrophysics. The spectroscopic analysis of starlight reveals much information about the chemical composition of stars — the identity of the elements present and their relative concentrations. In addition, the "red shift" or Doppler effect can be used to gauge the relative motions of the stars and their distance from the earth. More subtly, the surface temperature of stars can be determined from the spectral characteristics of their "blackbody" radiation, the higher the temperature the shorter the wavelength of maximum emission. Thus cooler stars appear red, and successively hotter stars appear progressively yellow, white, and blue. Differences in colour are also associated with differences in chemical composition as indicated in Table 1.1.

If the spectral classes (or temperatures) of stars are plotted against their absolute magnitudes (or luminosities) the resulting diagram shows several preferred regions into which most of the stars fall. Such diagrams were first made, independently, by E. Hertzsprung and H. N. Russell about 1913 and are now called HR diagrams (Fig. 1.2). More than 90% of all stars fall on a broad band called the main sequence, which covers the full range of spectral classes and magnitudes from the large, hot, massive O stars at the top to the small, dense, reddish M stars at the bottom. However, it should be emphasized that the terms "large" and "small" are purely relative since all stars within the main sequence are classified as dwarfs.

Table 1.1 Spectral classes of stars

Class[a]	Colour	Surface (T/K)	Spectral characterization	Examples
O	Blue	>25 000	Lines of ionized He and other elements; H lines weak	10 Lacertae
B	Blue-white	11 000–25 000	H and He prominent	Rigel, Spica
A	White	7500–11 000	H lines very strong	Sirius, Vega
F	Yellow-white	6000–7000	H weaker; lines of ionized metals becoming prominent	Canopus, Procyon
G	Yellow	5000–6000	Lines of ionized and neutral metals prominent (especially Ca)	Sun, Capella
K	Orange	3500–5000	Lines of neutral metals and band spectra of simple radicals (e.g. CN, OH, CH)	Arcturus, Aldebaran
M	Red	2000–3500	Band spectra of many simple compounds prominent (e.g. TiO)	Betelgeuse, Antares

[a]Further division of each class into 10 subclasses is possible, e.g. ... F8, F9, G0, G1, G2, ... The sun is G2 with a surface temperature of 5780 K. This curious alphabetical sequence of classes arose historically and can perhaps best be remembered by the mnemonic "Oh Be A Fine Girl (Guy), Kiss Me".

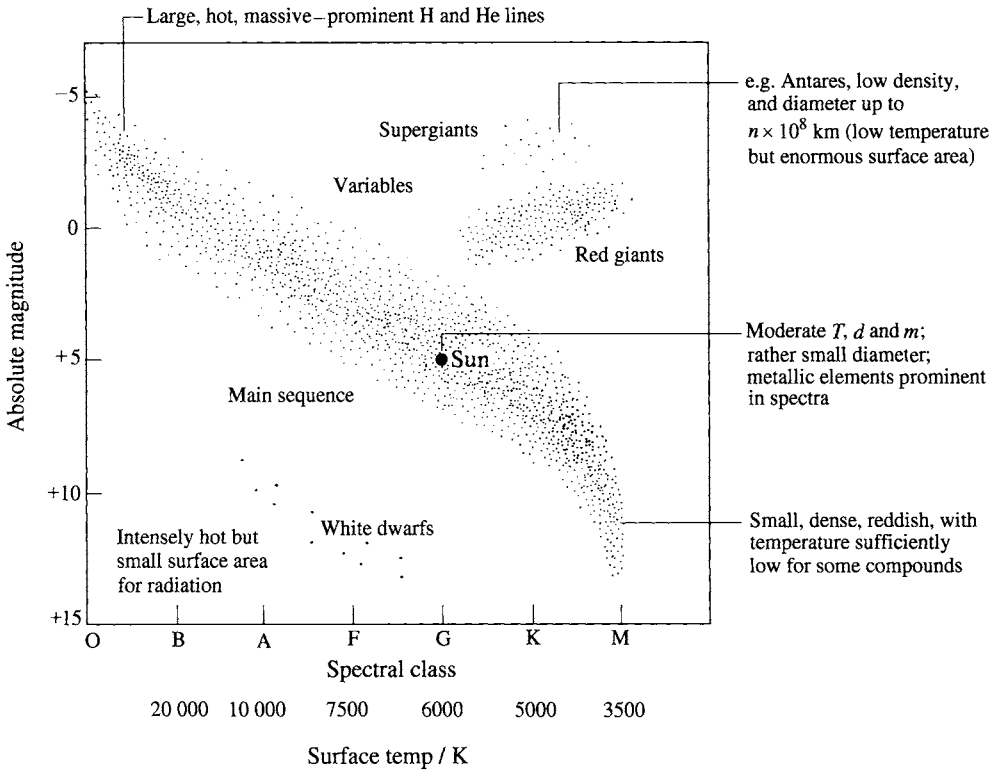

Figure 1.2 The Hertzsprung-Russell diagram for stars with known luminosities and spectra.

The next most numerous group of stars lie above and to the right of the main sequence and are called red giants. For example, Capella and the sun are both G-type stars yet Capella is 100 times more luminous than the sun; since they both have the same temperature it is concluded that Capella must have a radiating surface 100 times larger than the sun and thus has about 10 times its radius. Lying above the red giants are the supergiants such as Antares (Fig. 1.3), which has a surface temperature only half that of the sun but is 10 000 times more luminous: it is concluded that its radius is 100 times that of the sun. By contrast, the lower left-hand corner of the HR diagram is populated with relatively hot stars of low luminosity which implies that they are very small. These are the white dwarfs such as Sirius B which is only about the size of the earth though its mass is that of the sun: the implied density

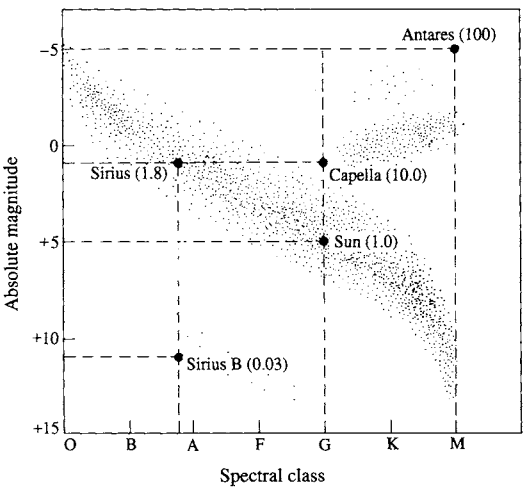

Figure 1.3 The comparison of various stars on the HR diagram. The number in parentheses indicates the approximate diameter of the star (sun = 1.0).

of $\sim 5 \times 10^4$ g cm^{-3} indicates the extraordinarily compact nature of these bodies.

It is now possible to connect this description of stellar types with the discussion of the thermonuclear processes and the synthesis of the elements to be given in the next section. When a protostar begins to form by gravitational contraction from interstellar hydrogen and helium, its temperature rises until the temperature in its core can sustain proton burning (p. 9). A star of approximately the mass of the sun joins the main sequence at this point and spends perhaps 90% of its life there, losing little mass but generating colossal amounts of energy. Subsequent exhaustion of the hydrogen in the core (but not in the outer layers of the star) leads to further contraction to form a helium-burning core which forces much of the remaining hydrogen into a vast tenuous outer envelope — the star has become a red giant since its enormous radiating surface area can no longer be maintained at such a high temperature as previously despite the higher core temperature. Typical red giants have surface temperatures in the range 3500–5500 K; their luminosities are about 10^2–10^4 times that of the sun and diameters about 10–100 times that of the sun. Carbon burning (p. 10) can follow in older red giants followed by the α-process (p. 11) during its final demise to white dwarf status.

Many stars are in fact partners in a binary system of two stars revolving around each other. If, as frequently occurs, the two stars have different masses, the more massive one will evolve faster and reach the white-dwarf stage before its partner. Then, as the second star expands to become a red giant its extended atmosphere encompasses the neighbouring white dwarf and induces instabilities which result in an outburst of energy and transfer of matter to the more massive partner. During this process the luminosity of the white dwarf increases perhaps ten-thousandfold and the event is witnessed as a nova (since the preceding binary was previously invisible to the naked eye).

As we shall see in the description of the e-process and the γ-process (p. 12), even more spectacular instabilities can develop in larger main sequence stars. If the initial mass is greater than about 3.5 solar masses, current theories suggest that gravitational collapse may be so catastrophic that the system implodes beyond nuclear densities to become a black hole. For main sequence stars in the mass range 1.4–3.5 $M_\odot$, implosion probably halts at nuclear densities to give a rapidly rotating neutron star (density $\sim 10^{14}$ g cm^{-3}) which may be observable as a pulsar emitting electromagnetic radiation over a wide range of frequencies in pulses at intervals of a fraction of a second. During this process of star implosion the sudden arrest of the collapsing core at nuclear densities yields an enormous temperature ($\sim 10^{12}$ K) and high pressure which produces an outward-moving shock wave. This strikes the star's outer envelope with resulting rapid compression, a dramatic rise in temperature, the onset of many new nuclear reactions, and explosive ejection of a significant fraction of the star's mass. The overall result is a supernova up to 10^8 times as bright as the original star. At this point a single supernova is comparable in brightness to the whole of the rest of the galaxy in which it is formed, after which the brightness decays exponentially, often with a half-life of about two months. Supernovae, novae, and unstable variables from dying red giants are thus all candidates for the synthesis of heavier elements and their ejection into interstellar regions for subsequent processing in later generations of condensing main sequence stars such as the sun. It should be stressed, however, that these various theories of the origin of the chemical elements are all very recent and the detailed processes are by no means all fully understood. Since this is at present a very active area of research, some of the conclusions given in this chapter are correspondingly tentative, and will undoubtedly be modified and refined in the light of future experimental and theoretical studies. With this caveat we now turn to a more detailed description of the individual nuclear processes thought to be involved in the synthesis of the elements.

1.5 Synthesis of the Elements[5-9]

The following types of nuclear reactions have been proposed to account for the various types of stars and the observed abundances of the elements:

(i) Exothermic processes in stellar interiors: these include (successively) hydrogen burning, helium burning, carbon burning, the α-process, and the equilibrium or e-process.
(ii) Neutron capture processes: these include the s-process (slow neutron capture) and the r-process (rapid neutron capture).
(iii) Miscellaneous processes: these include the p-process (proton capture) and spallation within the stars, and the x-process which involves spallation (p. 14) by galactic cosmic rays in interstellar regions.

1.5.1 Hydrogen burning

When the temperature of a contracting mass of hydrogen and helium atoms reaches about 10^7 K, a sequence of thermonuclear reactions is possible of which the most important are as shown in Table 1.2.

The overall reaction thus converts 4 protons into 1 helium nucleus plus 2 positrons and 2 neutrinos:

$$4\,^1\mathrm{H} \longrightarrow {}^4\mathrm{He} + 2\mathrm{e}^+ + 2\nu_\mathrm{e}; \quad Q = 26.72 \text{ MeV}$$

Table 1.2 Thermonuclear consumption of protons

Reaction	Energy evolved, Q	Reaction time[(a)]
$^1\mathrm{H} + {}^1\mathrm{H} \rightarrow {}^2\mathrm{H} + \mathrm{e}^+ + \nu_\mathrm{e}$	1.44 MeV	1.4×10^{10} y
$^2\mathrm{H} + {}^1\mathrm{H} \rightarrow {}^3\mathrm{He} + \gamma$	5.49 MeV	0.6 s
$^3\mathrm{He} + {}^3\mathrm{He} \rightarrow {}^4\mathrm{He} + 2\,{}^1\mathrm{H}$	12.86 MeV	10^6 y

[(a)]The reaction time quoted is the time required for half the constituents involved to undergo reaction — this is sensitively dependent on both temperature and density; the figures given are appropriate for the centre of the sun, i.e. 1.3×10^7 K and 200 g cm^{-3}.
1 MeV per atom $\equiv 96.485 \times 10^6$ kJ mol^{-1}.

Making allowance for the energy carried away by the 2 neutrinos (2×0.25 MeV) this leaves a total of 26.22 MeV for radiation, i.e. 4.20 pJ per atom of helium or 2.53×10^9 kJ mol^{-1}. This vast release of energy arises mainly from the difference between the rest mass of the helium-4 nucleus and the 4 protons from which it was formed (0.028 atomic mass units). There are several other peripheral reactions between the protons, deuterons and ^{3}He nuclei, but these need not detain us. It should be noted, however, that only 0.7% of the mass is lost during this transformation, so that the star remains approximately constant in mass. For example, in the sun during each second, some 600×10^6 tonnes (600×10^9 kg) of hydrogen are processed into 595.5×10^6 tonnes of helium, the remaining 4.5×10^6 tonnes of matter being transformed into energy. This energy is released deep in the sun's interior as high-energy γ-rays which interact with stellar material and are gradually transformed into photons with longer wavelengths; these work their way to the surface taking perhaps 10^6 y to emerge.

In fact, the sun is not a first-generation main-sequence star since spectroscopic evidence shows the presence of many heavier elements thought to be formed in other types of stars and subsequently distributed throughout the galaxy for eventual accretion into later generations of main-sequence stars. In the presence of heavier elements, particularly carbon and nitrogen, a catalytic sequence of nuclear reactions aids the fusion of protons to helium (H. A. Bethe

and C. F. von Weizsäcker, 1938) (Fig. 1.4). The overall reaction is precisely as before with the evolution of 26.72 MeV, but the 2 neutrinos now carry away 0.7 and 1.0 MeV respectively, leaving 25.0 MeV (4.01 pJ) per cycle for radiation. The coulombic energy barriers in the C–N–O cycle are some 6–7 times greater than for the direct proton–proton reaction and hence the catalytic cycle does not predominate until about 1.6×10^{7} K. In the sun, for example, it is estimated that about 10% of the energy comes from this process and most of the rest comes from the straightforward proton–proton reaction.

When approximately 10% of the hydrogen in a main-sequence star like the sun has been consumed in making helium, the outward thermal pressure of radiation is insufficient to counteract the gravitational attraction and a further stage of contraction ensues. During this process the helium concentrates in a dense central core ($\rho \sim 10^{5}$ g cm^{-3}) and the temperature rises to perhaps 2×10^{8} K. This is sufficient to overcome the coulombic potential energy barriers surrounding the helium nuclei, and helium burning (fusion) can occur. The hydrogen forms a vast tenuous envelope around this core with the result that the star evolves rapidly from the main sequence to become a red giant (p. 7). It is salutory to note that hydrogen burning in main-sequence stars has so far contributed an amount of helium to the universe which is only about 20% of that which was formed in the few minutes directly following the big bang (p. 2).

1.5.2 Helium burning and carbon burning

The main nuclear reactions occurring in helium burning are:

$$^{4}\mathrm{He} + {}^{4}\mathrm{He} \rightleftharpoons {}^{8}\mathrm{Be}$$

and

$$^{8}\mathrm{Be} + {}^{4}\mathrm{He} \rightleftharpoons {}^{12}\mathrm{C}^{*} \longrightarrow {}^{12}\mathrm{C} + \gamma$$

The nucleus ^{8}Be is unstable to α-particle emission ($t_{1/2} \sim 2 \times 10^{-16}$ s) being 0.094 MeV less stable than its constituent helium nuclei; under the conditions obtaining in the core of a red giant the calculated equilibrium ratio of ^{8}Be to ^{4}He is $\sim 10^{-9}$. Though small, this enables the otherwise improbable 3-body collision to occur. It is noteworthy that, from consideration of stellar nucleogenesis, F. Hoyle predicted in 1954 that the nucleus of ^{12}C would have a radioactive excited state ^{12}C* 7.70 MeV above its ground state, some three years before this activity was observed experimentally at 7.653 MeV. Experiments also indicate that the energy difference $Q(^{12}\mathrm{C}^{*} - 3\,^{4}\mathrm{He})$ is 0.373 MeV, thus leading to the overall reaction energy

$$3\,^{4}\mathrm{He} \longrightarrow {}^{12}\mathrm{C} + \gamma; \quad Q = 7.281 \text{ MeV}$$

Further helium-burning reactions can now follow during which even heavier nuclei are synthesized:

$$^{12}\mathrm{C} + {}^{4}\mathrm{He} \longrightarrow {}^{16}\mathrm{O} + \gamma; \quad Q = 7.148 \text{ MeV}$$

$$^{16}\mathrm{O} + {}^{4}\mathrm{He} \longrightarrow {}^{20}\mathrm{Ne} + \gamma; \quad Q = 4.75 \text{ MeV}$$

$$^{20}\mathrm{Ne} + {}^{4}\mathrm{He} \longrightarrow {}^{24}\mathrm{Mg} + \gamma; \quad Q = 9.31 \text{ MeV}$$

These reactions result in the exhaustion of helium previously produced in the hydrogen-burning process and an inner core of carbon, oxygen and neon develops which eventually undergoes gravitational contraction and heating as before. At a temperature of $\sim 5 \times 10^8$ K carbon burning becomes possible in addition to other processes which must be considered. Thus, ageing red giant stars are now thought to be capable of generating a carbon-rich nuclear reactor core at densities of the order of 10^4 g cm^{-3}. Typical initial reactions would be:

$$^{12}C + {}^{12}C \longrightarrow {}^{24}Mg + \gamma; \qquad Q = 13.85 \text{ MeV}$$

$$^{12}C + {}^{12}C \longrightarrow {}^{23}Na + {}^{1}H; \qquad Q = 2.23 \text{ MeV}$$

$$^{12}C + {}^{12}C \longrightarrow {}^{20}Ne + {}^{4}He; \qquad Q = 4.62 \text{ MeV}$$

The time scale of such reactions is calculated to be $\sim 10^5$ y at 6×10^8 K and ~ 1 y at 8.5×10^8 K. It will be noticed that hydrogen and helium nuclei are regenerated in these processes and numerous subsequent reactions become possible, generating numerous nuclides in this mass range.

1.5.3 The α-process

The evolution of a star after it leaves the red-giant phase depends to some extent on its mass. If it is not more than about 1.4 $M_\odot$ it may contract appreciably again and then enter an oscillatory phase of its life before becoming a white dwarf (p. 7). When core contraction following helium and carbon depletion raises the temperature above $\sim 10^9$ K the γ-rays in the stellar assembly become sufficiently energetic to promote the (endothermic) reaction $^{20}Ne(\gamma,\alpha)^{16}O$. The α-particle released can penetrate the coulomb barrier of other neon nuclei to form ^{24}Mg in a strongly exothermic reaction:

$$^{20}Ne + \gamma \longrightarrow {}^{16}O + {}^{4}He; \qquad Q = -4.75 \text{ MeV}$$

$$^{20}Ne + {}^{4}He \longrightarrow {}^{24}Mg + \gamma; \qquad Q = +9.31 \text{ MeV}$$

$$\text{i.e.} \quad 2\,{}^{20}Ne \longrightarrow {}^{16}O + {}^{24}Mg + \gamma; \qquad Q = +4.56 \text{ MeV}$$

Some of the released α-particles can also scour out ^{12}C to give more ^{16}O and the ^{24}Mg formed can react further by $^{24}Mg(\alpha,\gamma)^{28}Si$. Likewise for ^{32}S, ^{36}Ar and ^{40}Ca. It is this process that is considered to be responsible for building up the decreasing proportion of these so-called α-particle nuclei (Figs. 1.1 and 1.5). The relevant numerical data (including for comparison those for ^{20}Ne which is produced in helium and carbon burning) are as follows:

Nuclide	(^{20}Ne)	^{24}Mg	^{28}Si	^{32}S	^{36}Ar	^{40}Ca	^{44}Ca	^{48}Ti
Q_α/MeV	(9.31)	10.00	6.94	6.66	7.04	5.28	9.40	9.32
Relative abundance (as observed)	(8.4)	0.78	1.00	0.39	0.14	0.052	0.0011	0.0019

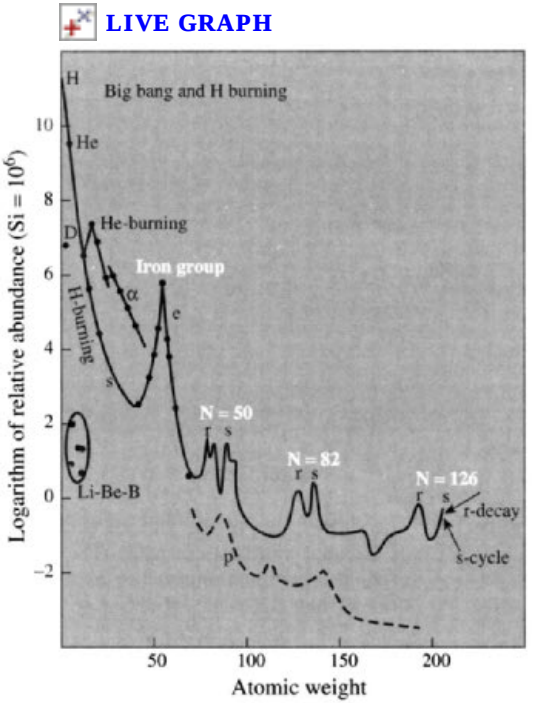

Figure 1.5 Schematic representation of the main features of the curve of cosmic abundances shown in Fig. 1.1, labelled according to the various stellar reactions considered to be responsible for the synthesis of the elements. (After E. M. Burbidge *et al.*[6].)

In a sense the α-process resembles helium burning but is distinguished from it by the quite

different source of the α-particles consumed. The straightforward α-process stops at ^{40}Ca since ^{44}Ti* is unstable to electron-capture decay. Hence (and including atomic numbers Z as subscripts for clarity):

$$^{40}_{20}\mathrm{Ca} + {}^{4}_{2}\mathrm{He} \longrightarrow {}^{44}_{22}\mathrm{Ti}^{*} + \gamma$$

$$^{44}_{22}\mathrm{Ti}^{*} + \mathrm{e}^{-} \longrightarrow {}^{44}_{21}\mathrm{Sc}^{*} + \nu_{+}; \quad t_{1/2} \sim 49\ \mathrm{y}$$

$$^{44}_{21}\mathrm{Sc}^{*} \longrightarrow {}^{44}_{20}\mathrm{Ca} + \beta^{+} + \nu_{+}; \quad t_{1/2}\ 3.93\ \mathrm{h}$$

Then $^{44}_{20}\mathrm{Ca} + {}^{4}_{2}\mathrm{He} \longrightarrow {}^{48}_{22}\mathrm{Ti} + \gamma$

The total time spent by a star in this α-phase may be $\sim 10^2 - 10^4$ y (Fig. 1.6).

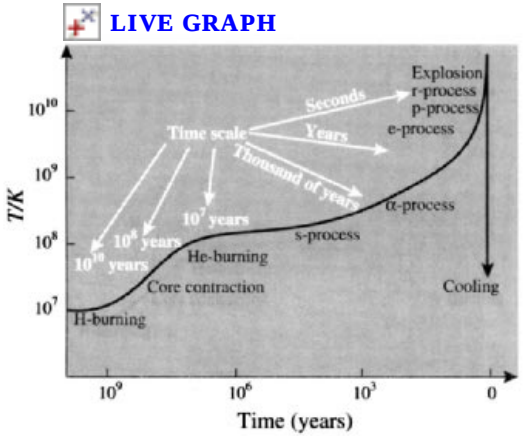

Figure 1.6 The time-scales of the various processes of element synthesis in stars. The curve gives the central temperature as a function of time for a star of about one solar mass. The curve is schematic.[6]

1.5.4 The e-process (equilibrium process)

More massive stars in the upper part of the main-sequence diagram (i.e. stars with masses in the range 1.4–3.5 $M_\odot$) have a somewhat different history to that considered in the preceding sections. We have seen (p. 6) that such stars consume their hydrogen much more rapidly than do smaller stars and hence spend less time in the main sequence. Helium reactions begin in their interiors long before the hydrogen is exhausted, and in the middle part of their life they may expand only slightly. Eventually they become unstable and explode violently, emitting enormous amounts of material into interstellar space. Such explosions are seen on earth as supernovae, perhaps 10 000 times more luminous than ordinary novae. In the seconds (or minutes) preceding this catastrophic outburst, at temperatures above $\sim 3 \times 10^9$ K, many types of nuclear reactions can occur in great profusion, e.g. (γ,α), (γ,p), (γ,n), (α,n), (p,γ), (n,γ), (p,n), etc. (Fig. 1.6). This enables numerous interconversions to occur with the rapid establishment of a statistical equilibrium between the various nuclei and the free protons and neutrons. This is believed to explain the cosmic abundances of elements from $_{22}$Ti to $_{29}$Cu. Specifically, since $^{56}_{26}$Fe is at the peak of the nuclear binding-energy curve, this element is considerably more abundant than those further removed from the most stable state.

1.5.5 The s- and r-processes (slow and rapid neutron absorption)

Slow neutron capture with emission of γ-rays is thought to be responsible for synthesizing most of the isotopes in the mass range $A = 63-209$ and also the majority of non-α-process nuclei in the range $A = 23-46$. These processes probably occur in pulsating red giants over a time span of $\sim 10^7$ y, and production loops for individual isotopes are typically in the range $10^2 - 10^5$ y. Several stellar neutron sources have been proposed, but the most likely candidates are the exothermic reactions $^{13}\mathrm{C}(\alpha,\mathrm{n})^{16}\mathrm{O}$ (2.20 MeV) and $^{21}\mathrm{Ne}(\alpha,\mathrm{n})^{24}\mathrm{Mg}$ (2.58 MeV). In both cases the target nuclei ($A = 4n + 1$) would be produced by a (p,γ) reaction on the more stable $4n$ nucleus followed by positron emission.

Because of the long time scale involved in the s-process, unstable nuclides formed by (n,γ) reactions have time to decay subsequently by β^- decay (electron emission). The crucial factor in determining the relative abundance of elements

formed by this process is thus the neutron capture cross-section of the precursor nuclide. In this way the process provides an ingenious explanation of the local peaks in abundance that occur near $A =$ 90, 138 and 208, since these occur near unusually stable nuclei (neutron "magic numbers" 50, 82 and 126) which have very low capture cross-sections (Fig. 1.5). Their concentration therefore builds up by resisting further reaction. In this way the relatively high abundances of specific isotopes such as $^{89}_{39}$Y and $^{90}_{40}$Zr, $^{138}_{56}$Ba and $^{140}_{58}$Ce, $^{208}_{82}$Pb and $^{209}_{83}$Bi can be understood.

In contrast to the more leisured processes considered in preceding paragraphs, conditions can arise (e.g. at $\sim 10^9$ K in supernovae outbursts) where many neutrons are rapidly added successively to a nucleus before subsequent β-decay becomes possible. The time scale for the r-process is envisaged as $\sim$0.01–10 s, so that, for example, some 200 neutrons might be added to an iron nucleus in 10–100 s. Only when β^- instability of the excessively neutron-rich product nuclei becomes extreme and the cross-section for further neutron absorption diminishes near the "magic numbers", does a cascade of some 8–10 β^- emissions bring the product back into the region of stable isotopes. This gives a convincing interpretation of the local abundance peaks near $A = 80$, 130 and 194, i.e. some 8–10 mass units below the nuclides associated with the s-process maxima (Fig. 1.5). It has also been suggested that neutron-rich isotopes of several of the lighter elements might also be the products of an r-process, e.g. ^{36}S, ^{46}Ca, ^{48}Ca and perhaps ^{47}Ti, ^{49}Ti and ^{50}Ti. These isotopes, though not as abundant as others of these elements, nevertheless do exist as stable species and cannot be so readily synthesized by other potential routes.

The problem of the existence of the heavy elements must also be considered. The short half-lives of all isotopes of technetium and promethium adequately accounts for their absence on earth. However, no element with atomic number greater than $_{83}$Bi has any stable isotope. Many of these (notably $_{84}$Po, $_{85}$At, $_{86}$Rn, $_{87}$Fr, $_{88}$Ra, $_{89}$Ac and $_{91}$Pa) can be understood on the basis of secular equilibria with radioactive precursors, and their relative concentrations are determined by the various half-lives of the isotopes in the radioactive series which produce them. The problem then devolves on explaining the cosmic presence of thorium and uranium, the longest lived of whose isotopes are ^{232}Th ($t_{1/2}1.4 \times 10^{10}$ y), ^{238}U ($t_{1/2}4.5 \times 10^9$ y) and ^{235}U ($t_{1/2}7.0 \times 10^8$ y). The half-life of thorium is commensurate with the age of the universe ($\sim 1.5 \times 10^{10}$ y) and so causes no difficulty. If all the present terrestrial uranium was produced by an r-process in a single supernova event then this occurred 6.6×10^9 y ago (p. 1257). If, as seems more probable, many supernovae contributed to this process, then such events, distributed uniformly in time, must have started $\sim 10^{10}$ y ago. In either case the uranium appears to have been formed long before the formation of the solar system $(4.6–5.0) \times 10^9$ y ago. More recent considerations of the formation and decay of ^{232}Th, ^{235}U and ^{238}U suggest that our own galaxy is $(1.2–2.0) \times 10^{10}$ y old.

1.5.6 The p-process (proton capture)

Proton capture processes by heavy nuclei have already been briefly mentioned in several of the preceding sections. The (p,γ) reaction can also be invoked to explain the presence of a number of proton-rich isotopes of lower abundance than those of nearby normal and neutron-rich isotopes (Fig. 1.5). Such isotopes would also result from expulsion of a neutron by a γ-ray, i.e. (γ,n). Such processes may again be associated with supernovae activity on a very short time scale. With the exceptions of ^{113}In and ^{115}Sn, all of the 36 isotopes thought to be produced in this way have even atomic mass numbers; the lightest is $^{74}_{34}$Se and the heaviest $^{196}_{80}$Hg.

1.5.7 The x-process

One of the most obvious features of Figs. 1.1 and 1.5 is the very low cosmic abundance of the stable isotopes of lithium, beryllium and

boron.[10] Paradoxically, the problem is not to explain why these abundances are so low but why these elements exist at all since their isotopes are bypassed by the normal chain of thermonuclear reactions described on the preceding pages. Again, deuterium and ^{3}He, though part of the hydrogen-burning process, are also virtually completely consumed by it, so that their existence in the universe, even at relatively low abundances, is very surprising. Moreover, even if these various isotopes were produced in stars, they would not survive the intense internal heat since their bonding energies imply that deuterium would be destroyed above 0.5×10^6 K, Li above 2×10^6 K, Be above 3.5×10^6 and B above 5×10^6. Deuterium and ^{3}He are absent from the spectra of almost all stars and are now generally thought to have been formed by nucleosynthesis during the last few seconds of the original big bang; their main agent of destruction is stellar processing.

It now seems likely that the 5 stable isotopes ^{6}Li, ^{7}Li, ^{9}Be, ^{10}B and ^{11}B are formed predominantly by spallation reactions (i.e. fragmentation) effected by galactic cosmic-ray bombardment (the x-process). Cosmic rays consist of a wide variety of atomic particles moving through the galaxy at relativistic velocities. Nuclei ranging from hydrogen to uranium have been detected in cosmic rays though ^{1}H and ^{4}He are by far the most abundant components [^{1}H: 500; ^{4}He: 40; all particles with atomic numbers from 3 to 9: 5; all particles with $Z \geq 10$: ~1]. However, there is a striking deviation from stellar abundances since Li, Be and B are vastly over abundant as are Sc, Ti, V and Cr (immediately preceding the abundance peak near iron). The simplest interpretation of these facts is that the (heavier) particles comprising cosmic rays, travelling as they do great distances in the galaxy, occasionally collide with atoms of the interstellar gas (predominantly ^{1}H and ^{4}He) and thereby fragment. This fragmentation, or spallation as it is called, produces lighter nuclei from heavier ones. Conversely, high-speed ^{4}He particles may occasionally collide with interstellar iron-group elements and other heavy nuclei, thus inducing spallation and forming Li, Be and B (and possibly even some ^{2}H and ^{3}He), on the one hand, and elements in the range Sc–Cr, on the other. As we have seen, the lighter transition elements are also formed in various stellar processes, but the presence of elements in the mass range 6–12 suggest the need for a low-temperature low-density extra-stellar process. In addition to spallation, interstellar (p,α) reactions in the wake of supernova shock waves may contribute to the synthesis of boron isotopes:

$$^{13}\mathrm{C(p,\alpha)}^{10}\mathrm{B} \quad \text{and} \quad ^{14}\mathrm{N(p,\alpha)}^{11}\mathrm{C} \xrightarrow{\beta^+} {}^{11}\mathrm{B}.$$

A further intriguing possibility has recently been mooted.[11] If the universe were not completely isotropic and uniform in density during the first few minutes after the big bang, then the high-density regions would have a greater concentration of protons than expected and the low-density regions would have more neutrons; this is because the diffusion of protons from high to low density regions would be inhibited by the presence of oppositely charged electrons whereas the electrically neutral neutrons can diffuse more readily. In the neutron-abundant lower-density regions certain neutron-rich species can then be synthesized. For example, in the homogeneous big bang, most of the ^{7}Li formed is rapidly destroyed by proton bombardment ($^7\mathrm{Li} + \mathrm{p} \rightarrow 2\,^4\mathrm{He}$) but in a neutron-rich region the radioactive isotope ^{8}Li* can be formed:

$$^7\mathrm{Li} + \mathrm{n} \longrightarrow {}^8\mathrm{Li}^* \ (t_{1/2}\ 0.84\,\mathrm{s} \longrightarrow \beta^- + 2\,^4\mathrm{He})$$

If, before it decays, ^{8}Li* is struck by a prevalent ^{4}He nucleus then ^{11}B can be formed ($^8\mathrm{Li}^* + {}^4\mathrm{He} \rightarrow {}^{11}\mathrm{B} + \mathrm{n}$) and this will survive longer than in a proton-rich environment ($^{11}\mathrm{B} + \mathrm{p} \rightarrow 3\,^4\mathrm{He}$). Other neutron-rich species could also be synthesized and survive in greater numbers than would

[10] H. Reeves, Origin of the light elements, *A. Rev. Astron. Astrophys.* **12**. 437–69 (1974).

[11] K. Crosswell, *New Scientist*, 9 Nov. 1991, 42–8.

be possible with higher concentrations of protons, e.g.:

$$^{7}Li + {}^{3}H \longrightarrow {}^{9}Be + n$$

$$^{9}Be + {}^{3}H \longrightarrow {}^{11}B + n$$

The relative abundances of the various isotopes of the light elements Li, Be and B therefore depend to some extent on which detailed model of the big bang is adopted, and experimentally determined abundances may in time permit conclusions to be drawn as to the relative importance of these processes as compared to x-process spallation reactions.

In overall summary, using a variety of nuclear syntheses it is now possible to account for the presence of the 270 known stable isotopes of the elements up to $^{209}_{83}Bi$ and to understand, at least in broad outline, their relative concentrations in the universe. The tremendous number of hypothetically possible internuclear conversions and reactions makes detailed computation extremely difficult. Energy changes are readily calculated from the known relative atomic masses of the various nuclides, but the cross-sections (probabilities) of many of the reactions are unknown and this prevents precise calculation of reaction rates and equilibrium concentrations in the extreme conditions occurring even in stable stars. Conditions and reactions occurring during supernova outbursts are even more difficult to define precisely. However, it is clear that substantial progress has been made in the last few decades in interpreting the bewildering variety of isotopic abundances which comprise the elements used by chemists. The approximate constancy of the isotopic composition of the individual elements is a fortunate result of the quasi-steady-state conditions obtaining in the universe during the time required to form the solar system. It is tempting to speculate whether chemistry could ever have emerged as a quantitative science if the elements had had widely varying isotopic composition, since gravimetric analysis would then have been impossible and the great developments of the nineteenth century could hardly have occurred. Equally, it should no longer cause surprise that the atomic weights of the elements are not necessarily always "constants of nature", and variations are to be expected, particularly among the lighter elements, which can have appreciable effects on physicochemical measurements and quantitative analysis.

1.6 Atomic Weights[12]

The concept of "atomic weight" or "mean relative atomic mass" is fundamental to the development of chemistry. Dalton originally supposed that all atoms of a given element had the same unalterable weight but, after the discovery of isotopes earlier this century, this property was transferred to them. Today the possibility of variable isotopic composition of an element (whether natural or artificially induced) precludes the possibility of defining *the* atomic weight of most elements, and the tendency nowadays is to define *an* atomic weight of an element as "the ratio of the average mass per atom of an element to one-twelfth of the mass of an atom of ^{12}C". It is important to stress that atomic weights (mean relative atomic masses) of the elements are dimensionless numbers (ratios) and therefore have no units.

Because of their central importance in chemistry, atomic weights have been continually refined and improved since the first tabulations by Dalton (1803–5). By 1808 Dalton had included 20 elements in his list and these results were substantially extended and improved by Berzelius during the following decades. An illustration of the dramatic and continuing improvement in accuracy and precision during the past 100 y is given in Table 1.3. In 1874 no atomic weight was quoted to better than one part in 200, but by 1903 33 elements had values quoted to one part in 10^3 and 2 of these (silver and

[12] N. N. GREENWOOD, Atomic weights, Ch. 8 in Part I, Vol. 1, Section C, of Kolthoff and Elving's *Treatise on Analytical Chemistry*, pp. 453–78, Interscience, New York, 1978. This gives a fuller account of the history and techniques of atomic weight determinations and their significance, and incorporates a full bibliographical list of Reports on Atomic Weights.

iodine) were quoted to 1 in 10^4. Today the majority of values are known to 1 in 10^4 and 26 elements have an accuracy exceeding 1 in 10^6. This improvement was first due to improved chemical methods, particularly between 1900 and 1935 when increasing use of fused silica ware and electric furnaces reduced the possibility of contamination. More recently the use of mass spectrometry has effected a further improvement in precision. Mass spectrometric data were first used in a confirmatory role in the 1935 table of atomic weights, and by 1938 mass spectrometric values were preferred to chemical determinations for hydrogen and osmium and to gas-density values for helium. In 1959 the atomic weight values of over 50 elements were still based on classical chemical methods, but by 1973 this number had dwindled to 9 (Ti, Ge, Se, Mo, Sn, Sb, Te, Hg and Tl) or to 10 if the coulometric determination for Zn is counted as chemical. The values for a further 8 elements were based on a judicious blend of chemical and mass-spectrometric data, but the values quoted for all other elements were based entirely on mass-spectrometric data.

Accurate atomic weight values do not automatically follow from precise measurements of relative atomic masses, however, since the relative abundance of the various isotopes must also be determined. That this can be a limiting factor is readily seen from Table 1.3: the value for praseodymium (which has only 1 stable naturally occurring isotope) has two more significant figures than the value for the neighbouring element cerium which has 4 such isotopes. In the twelve years since the first edition of this book was published the atomic weight values of no fewer than 55 elements have been improved, sometimes spectacularly, e.g. Ni from 58.69(1) to 58.6934(2).

1.6.1 Uncertainty in atomic weights

Numerical values for the atomic weights of the elements are now reviewed every 2 y by the Commission on Atomic Weights and Isotopic

Table 1.3 Evolution of atomic weight values for selected elements[a]; (the dates selected were chosen for the reasons given below)

Element	1873–5	1903	1925	1959	1961	1997

[a]The annotations g, m and r appended to some values in the final column have the same meanings as those in the definitive table (facing inside front cover). The numbers in parentheses are the uncertainties in the last digit of the quoted value.
[b]The value for rhenium was first listed in 1929.
Note on dates:
1874 Foundation of the American Chemical Society (64 elements listed).
1903 First international table of atomic weights (78 elements listed).
1925 Major review of table (83 elements listed).
1959 Last table to be based on oxygen = 16 (83 elements listed).
1961 Complete reassessment of data and revision to $^{12}C = 12$ (83 elements).
1997 Latest available IUPAC values (84 + 28 elements listed).

Abundances of IUPAC (the International Union of Pure and Applied Chemistry). Their most recent recommendations[13] are tabulated on the inside front fly sheet. From this it is clear that there is still a wide variation in the reliability of the data. The most accurately quoted value is that for fluorine which is known to better than 1 part in 38 million; the least accurate is for boron (1 part in 1500, i.e. 7 parts in 10^4). Apart from boron all values are reliable to better than 5 parts in 10^4 and the majority are reliable to better than 1 part in 10^4. For some elements (such as boron) the rather large uncertainty arises not because of experimental error, since the use of mass-spectrometric measurements has yielded results of very high precision, but because the natural variation in the relative abundance of the 2 isotopes ^{10}B and ^{11}B results in a range of values of at least ± 0.003 about the quoted value of 10.811. By contrast, there is no known variation in isotopic abundances for elements such as selenium and osmium, but calibrated mass-spectrometric data are not available, and the existence of 6 and 7 stable isotopes respectively for these elements makes high precision difficult to obtain: they are thus prime candidates for improvement.

Atomic weights are known most accurately for elements which have only 1 stable isotope; the relative atomic mass of this isotope can be determined to at least 1 ppm and there is no possibility of variability in nature. There are 20 such elements: Be, F, Na, Al, P, Sc, Mn, Co, As, Y, Nb, Rh, I, Cs, Pr, Tb, Ho, Tm, Au and Bi. (Note that all of these elements except beryllium have odd atomic numbers — why?)

Elements with 1 predominant isotope can also, potentially, permit very precise atomic weight determinations since variations in isotopic composition or errors in its determination have a correspondingly small effect on the mass-spectrometrically determined value of the atomic weight. Nine elements have 1 isotope that is more than 99% abundant (H, He, N, O, Ar, V, La, Ta and U) and carbon also approaches this category (^{13}C 1.11% abundant).

Known variations in the isotopic composition of normal terrestrial material prevent a more accurate atomic weight being given for 13 elements and these carry the footnote r in the Table of Atomic Weights. For each of these elements (H, He, Li, B, C, N, O, Si, S, Ar, Cu, Sr and Pb) the accuracy attainable in an atomic weight determination on a given sample is greater than that implied by the recommended value since this must be applicable to any sample and so must embrace all known variations in isotopic composition from commercial terrestrial sources. For example, for hydrogen the present attainable accuracy of calibrated mass-spectrometric atomic weight determinations is about ± 1 in the sixth significant figure, but the recommended value of 1.007 94(± 7) is so given because of the natural terrestrial variation in the deuterium content. The most likely value relevant to laboratory chemicals (e.g. H_2O) is 1.007 97, but it should be noted that hydrogen gas used in laboratories is often inadvertently depleted during its preparation by electrolysis, and for such samples the atomic weight is close to 1.007 90. By contrast, intentional fractionation to yield heavy water (thousands of tonnes annually) or deuterated chemicals implies an atomic weight approaching 2.014, and great care should be taken to avoid contamination of "normal" samples when working with or disposing of such enriched materials.

Fascinating stories of natural variability could be told for each of the 13 elements having the footnote r and, indeed, determinations of such variations in isotopic composition are now an essential tool in unravelling the geochemical history of various ore bodies. For example, the atomic weight of sulfur obtained from virgin Texas sulfur is detectably different from that obtained from sulfate ores, and an overall range approaching ± 0.01 is found for terrestrial samples; this limits the value quoted to 32.066(6) though the accuracy of atomic weight determinations on individual samples is $\pm 0.000\,15$. Boron is even more adversely

[13] IUPAC Inorganic Chemistry Division, Atomic Weights of the Elements 1995, *Pure Appl. Chem.* **68**, 2339–59 (1996).

affected, as previously noted, and the actual atomic weight can vary from 10.809 to 10.812 depending on whether the mineral source is Turkey or the USA.

Even more disconcerting are the substantial deviations in atomic weight that can occur in commercially available material because of inadvertent or undisclosed changes in isotopic composition (footnote m in the Table of Atomic Weights). This situation at present obtains for 8 elements (H, Li, B, Ne, Cl, Kr, Xe and U) and may well also soon affect others (such as C, N and O). The separated or partially enriched isotopes of Li, B and U are now extensively used in nuclear reactor technology and weaponry, and the unwanted residues, depleted in the desired isotopes, are sometimes dumped on the market and sold as "normal" material. Thus lithium salts may unsuspectingly be purchased which have been severely depleted in ^{6}Li (natural abundance 7.5%), and a major commercial supplier has marketed lithium containing as little as 3.75% of this isotope, thereby inducing an atomic weight change of 0.53%. For this reason practically all lithium compounds now obtainable in the USA are suspect and quantitative data obtained on them are potentially unreliable. Again, the practice of "milking" fission-product rare gases from reactor fuels and marketing these materials, produces samples with anomalous isotopic compositions. The effect, particularly on physicochemical computations, can be serious and, whilst not wishing to strike an alarmist note, the possibility of such deviations must continually be borne in mind for elements carrying the footnote m in the Table of Atomic Weights.

The related problem arising from radioactive elements is considered in the next section.

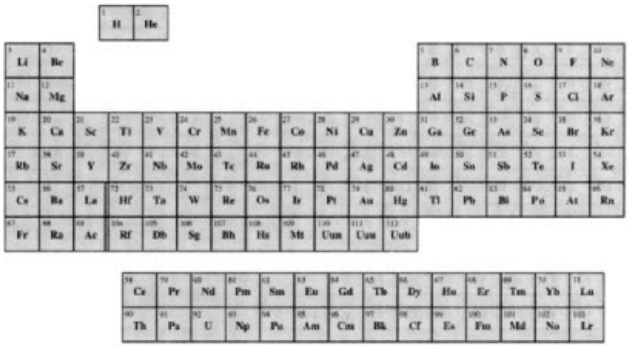
1.6.2 The problem of radioactive elements

Elements with radioactive nuclides amongst their naturally occurring isotopes have a built-in time variation of the relative concentration of their isotopes and hence a continually varying atomic weight. Whether this variation is chemically significant depends on the half-life of the transition and the relative abundance of the various isotopes. Similarly, the actual concentration of stable isotopes of several elements (e.g. Ar, Ca and Pb) may be influenced by association of those elements with radioactive precursors (i.e. ^{40}K, ^{238}U, etc.) which generate potentially variable amounts of the stable isotopes concerned. Again, some elements (such as technetium, promethium and the transuranium elements) are synthesized by nuclear reactions which produce a single isotope of the element. The "atomic weight" therefore depends on which particular isotope is being synthesized, and the concept of a "normal" atomic weight is irrelevant. For example, cyclotron production of technetium yields ^{97}Tc ($t_{1/2}$ 2.6×10^{6} y) with an atomic weight of 96.9064, whereas fission product technetium is ^{99}Tc ($t_{1/2}$ 2.11×10^{5} y), atomic weight 98.9063, and the isotope of longest half-life is ^{98}Tc ($t_{1/2}$ 4.2×10^{6} y), atomic weight 97.9072.

At least 19 elements not usually considered to be radioactive do in fact have naturally occurring unstable isotopes. The minute traces of naturally occurring ^{3}H ($t_{1/2}$ 12.33 y) and ^{14}C ($t_{1/2}$ 5730 y) have no influence on the atomic weights of these elements though, of course, they are of crucial importance in other areas of study. The radioactivity of ^{40}K ($t_{1/2}$ 1.28×10^{9} y) influences the atomic weights of its daughter elements argon (by electron capture) and calcium (by β^{-} emission) but fortunately does not significantly affect the atomic weight of potassium itself because of the low absolute abundance of this particular isotope (0.0117%). The half-lives of the radioactive isotopes of the 16 other "stable" elements are all greater than 10^{10} y and so normally have little influence on the atomic weight of these elements even when, as in the case of ^{115}In ($t_{1/2}$ 4.41×10^{14} y, 95.7% abundant) and ^{187}Re ($t_{1/2}$ 4.35×10^{10} y, 62.6% abundant), they are the most abundant isotopes. Note, however, that on a geological time scale it has been possible to build up significant concentrations of ^{187}Os in rhenium-containing

ores (by β^- decay of ^{187}Re), thereby generating samples of osmium with an anomalous atomic weight nearer to 187 than to the published value of 190.23(3). Lead was the first element known to be subject to such isotopic disturbances and, indeed, the discovery and interpretation of the significance of isotopes was itself hastened by the reluctant conclusion of T. W. Richards at the turn of the century that a group of lead samples of differing geological origins were identical chemically but differed in atomic weight — the possible variation is now known to span almost the complete range from 204 to 208. Such elements, for which geological specimens are known in which the element has an anomalous isotopic composition, are given the footnote g in the Table of Atomic Weights. In addition to Ar, Ca, Os and Pb just discussed, such variability affects at least 38 other elements, including Sr (resulting from the β^- decay of ^{87}Rb), Ra, Th and U. A spectacular example, which affects virtually every element in the central third of the periodic table, has recently come to light with the discovery of prehistoric natural nuclear reactors at Oklo in Africa (see p. 1257). Fortunately this mine is a source of uranium ore only and so will not affect commercially available samples of the other elements involved.

In summary, as a consequence of the factors considered in this and the preceding section, the atomic weights of only the 20 mononuclidic elements can be regarded as "constants of nature". For all other elements variability in atomic weight is potentially possible and in several instances is known to occur to an extent which affects the reliability of quantitative results of even modest precision.



2

Chemical Periodicity and the Periodic Table

2.1 Introduction

The concept of chemical periodicity is central to the study of inorganic chemistry. No other generalization rivals the periodic table of the elements in its ability to systematize and rationalize known chemical facts or to predict new ones and suggest fruitful areas for further study. Chemical periodicity and the periodic table now find their natural interpretation in the detailed electronic structure of the atom; indeed, they played a major role at the turn of the century in elucidating the mysterious phenomena of radioactivity and the quantum effects which led ultimately to Bohr's theory of the hydrogen atom. Because of this central position it is perhaps not surprising that innumerable articles and books have been written on the subject since the seminal papers by Mendeleev in 1869, and some 700 forms of the periodic table (classified into 146 different types or subtypes) have been proposed.[1-3] A brief historical survey of these developments is summarized in the Panel opposite.

There is no single *best* form of the periodic table since the choice depends on the purpose for which the table is used. Some forms emphasize chemical relations and valence, whereas others stress the electronic configuration of the elements or the dependence of the periods on the shells and subshells of the atomic structure. The most convenient form for our purpose is the so-called "long form" with separate panels for the lanthanide and actinide elements (see inside front cover). There has been a lively debate during the past decade as to the best numbering system to be used for the individual

[1] F. P. VENABLE, *The Development of the Periodic Law*, Chemical Publishing Co., Easton, Pa., 1896. This is the first general review of periodic tables and has an almost complete collection of those published to that time. J. W. VAN SPRONSEN, *The Periodic System of the Chemical Elements*, Elsevier, Amsterdam, 1969, 368 pp. An excellent modern account of the historical developments leading up to Mendeleev's table.

groups in the table; we will adopt the 1–18 numbering scheme recommended by IUPAC.[3] The following sections of this chapter summarize:

(a) the interpretation of the periodic law in terms of the electronic structure of atoms;
(b) the use of the periodic table and graphs to systematize trends in physical and chemical properties and to detect possible errors, anomalies, and inconsistencies;
(c) the use of the periodic table to predict new elements and compounds, and to suggest new areas of research.

2.2 The Electronic Structure of Atoms[4]

The ubiquitous electron was discovered by J. J. Thompson in 1897 some 25 y after the original work on chemical periodicity by D. I. Mendeleev and Lothar Meyer; however, a further 20 y were to pass before G. N. Lewis and then I. Langmuir connected the electron with valency and chemical bonding. Refinements continued via wave mechanics and molecular orbital theory, and the symbiotic relation between experiment and theory still continues

Mendeleev's Periodic Table

Precursors and Successors

1772	L. B. G. de Morveau made the first table of "chemically simple" substances. A. L. Lavoisier used this in his *Traité Elémentaire de Chimie* published in 1789.
1817–29	J. W. Döbereiner discovered many triads of elements and compounds, the combining weight of the central component being the average of its partners (e.g. CaO, SrO, BaO, and NiO, CuO, ZnO).
1843	L. Gmelin included a V-shaped arrangement of 16 triads in the 4th edition of his *Handbuch der Chemie*.
1857	J. B. Dumas published a rudimentary table of 32 elements in 8 columns indicating their relationships.
1862	A. E. B. de Chancourtois first arranged the elements in order of increasing atomic weight; he located similar elements in this way and published a helical form in 1863.
1864	L. Meyer published a table of valences for 49 elements.
1864	W. Odling drew up an almost correct table with 17 vertical columns and including 57 elements.
1865	J. A. R. Newlands propounded his law of octaves after several partial classifications during the preceding 2 y; he also correctly predicted the atomic weight of the undiscovered element germanium.
1868–9	L. Meyer drew up an atomic volume curve and a periodic table, but this latter was not published until 1895.
1869	D. I. Mendeleev enunciated his periodic law that "the properties of the elements are a periodic function of their atomic weights". He published several forms of periodic table, one containing 63 elements.
1871	D. I. Mendeleev modified and improved his tables and predicted the discovery of 10 elements (now known as Sc, Ga, Ge, Tc, Re, Po, Fr, Ra, Ac and Pa). He fully described with amazing prescience the properties of 4 of these (Sc, Ga, Ge, Po). Note, however, that it was not possible to predict the existence of the noble gases or the number of lanthanide elements.
1894–8	Lord Rayleigh, W. Ramsay and M. W. Travers detected and then isolated the noble gases (He), Ne, Ar, Kr, Xe.
1913	N. Bohr explained the form of the periodic table on the basis of his theory of atomic structure and showed that there could be only 14 lanthanide elements.
1913	H. G. J. Moseley observed regularities in the characteristic X-ray spectra of the elements; he thereby discovered atomic numbers Z and provided justification for the ordinal sequence of the elements.
1940	E. McMillan and P. Abelson synthesized the first transuranium element $_{93}$Np. Others were synthesized by G. T. Seaborg and his colleagues during the next 15 y.
1944	G. T. Seaborg proposed the actinide hypothesis and predicted 14 elements (up to Z = 103) in this group.

today. It should always be remembered, however, that it is incorrect to "deduce" known chemical phenomena from theoretical models; the proper relationship is that the currently accepted theoretical models interpret the facts and suggest new experiments — they will be modified (or discarded and replaced) when new results demand it. Theories can never be proved by experiment — only refuted, the best that can be said of a theory is that it is consistent with a wide range of information which it interprets logically and that it is a fruitful source of predictions and new experiments.

Our present views on the electronic structure of atoms are based on a variety of experimental results and theoretical models which are fully discussed in many elementary texts. In summary, an atom comprises a central, massive, positively charged nucleus surrounded by a more tenuous envelope of negative electrons. The nucleus is composed of neutrons ($^1_0$n) and protons ($^1_1$p, i.e. $^1_1$H$^+$) of approximately equal mass tightly bound by the force field of mesons. The number of protons (Z) is called the atomic number and this, together with the number of neutrons (N), gives the atomic mass number of the nuclide ($A = N + Z$). An element consists of atoms all of which have the same number of protons (Z) and this number determines the position of the element in the periodic table (H. G. J. Moseley, 1913). Isotopes of an element all have the same value of Z but differ in the number of neutrons in their nuclei. The charge on the electron (e^-) is equal in size but opposite in sign to that of the proton and the ratio of their masses is 1/1836.1527.

The arrangement of electrons in an atom is described by means of four quantum numbers which determine the spatial distribution, energy, and other properties, see Appendix 1 (p. 1285). The principal quantum number n defines the general energy level or "shell" to which the electron belongs. Electrons with $n = 1, 2, 3, 4, \ldots$, are sometimes referred to as K, L, M, N, ..., electrons. The orbital quantum number l defines both the shape of the electron charge distribution and its orbital angular momentum. The number of possible values for l for a given electron depends on its principal quantum number n; it can have n values running from 0 to $n - 1$, and electrons with $l = 0, 1, 2, 3, \ldots$, are designated s, p, d, f, ..., electrons. Whereas n is the prime determinant of an electron's energy this also depends to some extent on l (for atoms or ions containing more than one electron). It is found that the sequence of increasing electron energy levels in an atom follows the sequence of values $n + l$; if 2 electrons have the same value of $n + l$ then the one with smaller n is the more tightly bound.

The third quantum number m is called the magnetic quantum number for it is only in an applied magnetic field that it is possible to define a direction within the atom with respect to which the orbital can be directed. In general, the magnetic quantum number can take up $2l + 1$ values (i.e. $0, \pm 1, \ldots, \pm l$); thus an s electron (which is spherically symmetrical and has zero orbital angular momentum) can have only one orientation, but a p electron can have three (frequently chosen to be the x, y, and z directions in Cartesian coordinates). Likewise there are five possibilities for d orbitals and seven for f orbitals.

The fourth quantum number m_s is called the spin angular momentum quantum number for historical reasons. In relativistic (four-dimensional) quantum mechanics this quantum number is associated with the property of symmetry of the wave function and it can take on one of two values designated as $+\frac{1}{2}$ and $-\frac{1}{2}$, or simply α and β. All electrons in atoms can be described by means of these four quantum numbers and, as first enumerated by W. Pauli in his *Exclusion Principle* (1926), each electron in an atom must have a unique set of the four quantum numbers.

It can now be seen that there is a direct and simple correspondence between this description of electronic structure and the form of the periodic table. Hydrogen, with 1 proton and 1 electron, is the first element, and, in the ground state (i.e. the state of lowest energy) it has the electronic configuration $1s^1$ with zero orbital angular momentum. Helium, $Z = 2$, has the configuration $1s^2$, and this completes the first period since no

other unique combination of $n = 1$, $l = m = 0$, $m_s = \pm\frac{1}{2}$ exists. The second period begins with lithium ($Z = 3$), the least tightly bound electron having the configuration $2s^1$. The same situation obtains for each of the other periods in the table, the number of the period being the principal quantum number of the least tightly bound electron of the first element in the period. It will also be seen that there is a direct relation between the various blocks of elements in the periodic table and the electronic configuration of the atoms it contains; the s block is 2 elements wide, the p block 6 elements wide, the d block 10, and the f block 14, i.e. $2(2l + 1)$, the factor 2 appearing because of the spins.

In so far as the chemical (and physical) properties of an element derive from its electronic configuration, and especially the configuration of its least tightly bound electrons, it follows that chemical periodicity and the form of the periodic table can be elegantly interpreted in terms of electronic structure.

2.3 Periodic Trends in Properties[5,6]

General similarities and trends in the *chemical* properties of the elements had been noticed increasingly since the end of the eighteenth century and predated the observation of periodic variations in *physical* properties which were not noted until about 1868. However, it is more convenient to invert this order and to look at trends in atomic and physical properties first.

2.3.1 Trends in atomic and physical properties

Figure 2.1 shows a modern version of Lothar Meyer's atomic volume curve: the alkali metals

[5] R. RICH, *Periodic Correlations*, W. A. Benjamin, New York, 1965, 159 pp.

[6] R. T. SANDERSON, *Inorganic Chemistry*, Reinhold Publishing Corp., New York, 1967, 430 pp.

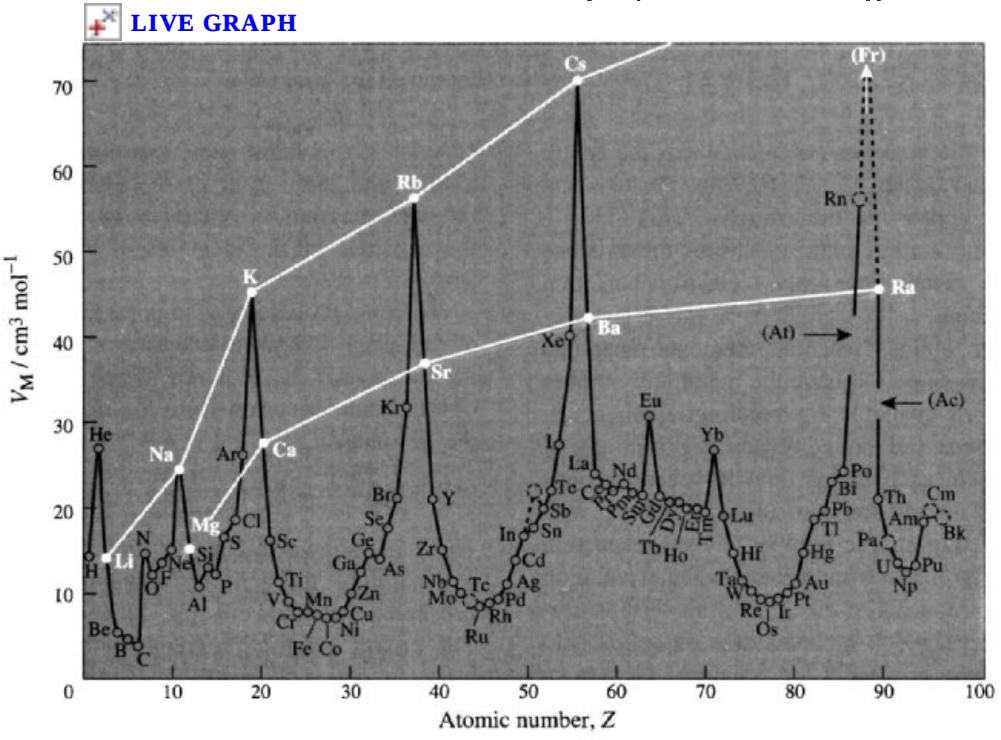

Figure 2.1 Atomic volumes (molar volumes) of the elements in the solid state.

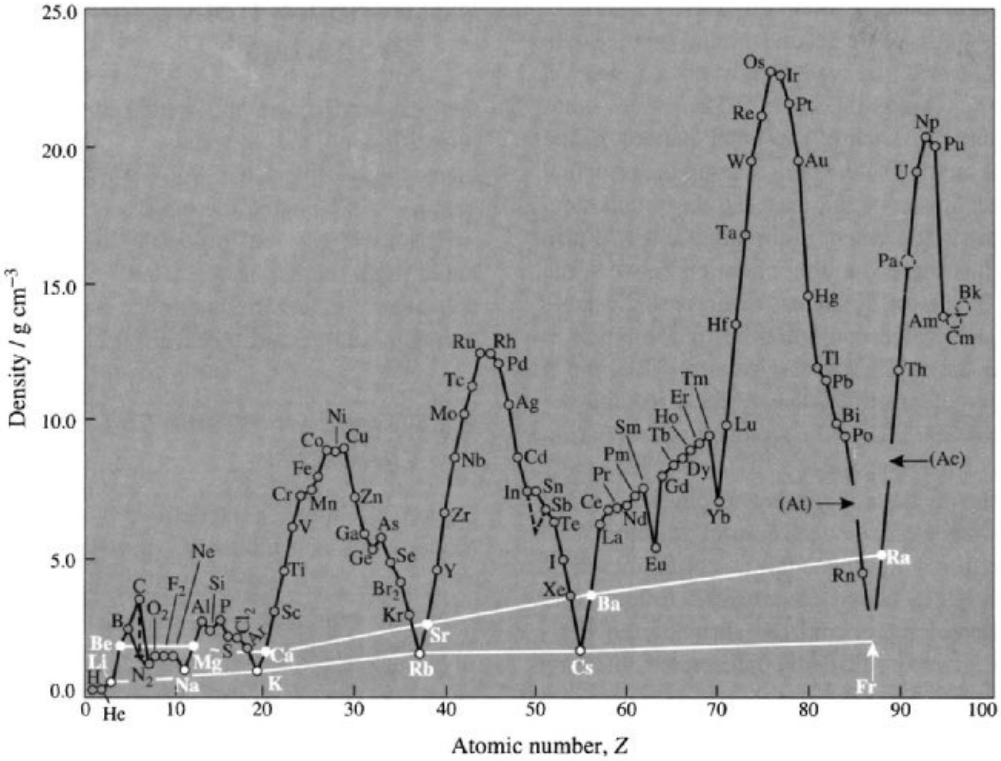

Figure 2.2 Densities of the elements in the solid state.

appear at the peaks and elements near the centre of each period (B, C; Al, Si; Mn, Fe, Co; Ru; and Os) appear in the troughs. This finds a ready interpretation on the electronic theory since the alkali metals have only 1 electron per atom to contribute to the binding of the 8 nearest-neighbour atoms, whereas elements near the centre of each period have the maximum number of electrons available for bonding. Elements in other groups fall on corresponding sections of the curve in each period, and in several groups there is a steady trend to higher volumes with the increasing atomic number. Closer inspection reveals that a much more detailed interpretation would be required to encompass all the features of the curve which includes data on solids held by very diverse types of bonding. Note also that the position of helium is anomalous (why?), and that there are local anomalies at europium and ytterbium in the lanthanide elements (see Chapter 30). Similar plots are obtained for the atomic and ionic radii of the elements and an inverted diagram is obtained, as expected, for the densities of the elements in the solid state (Fig. 2.2).

Of more fundamental importance is the plot of first-stage ionization energies of the elements, i.e. the energy I_M required to remove the least tightly bound electron from the neutral atom in the gas phase:

$$M(g) \longrightarrow M^+(g) + e^-; \quad \Delta H^\circ = I_M$$

These are shown in Fig. 2.3 and illustrate most convincingly the various quantum shells and subshells described in the preceding section. The energy required to remove the 1 electron from an atom of hydrogen is 13.606 eV (i.e. 1312 kJ per mole of H atoms). This rises to 2372 kJ mol^{-1} for He ($1s^2$) since the positive charge on the helium nucleus is twice that of the

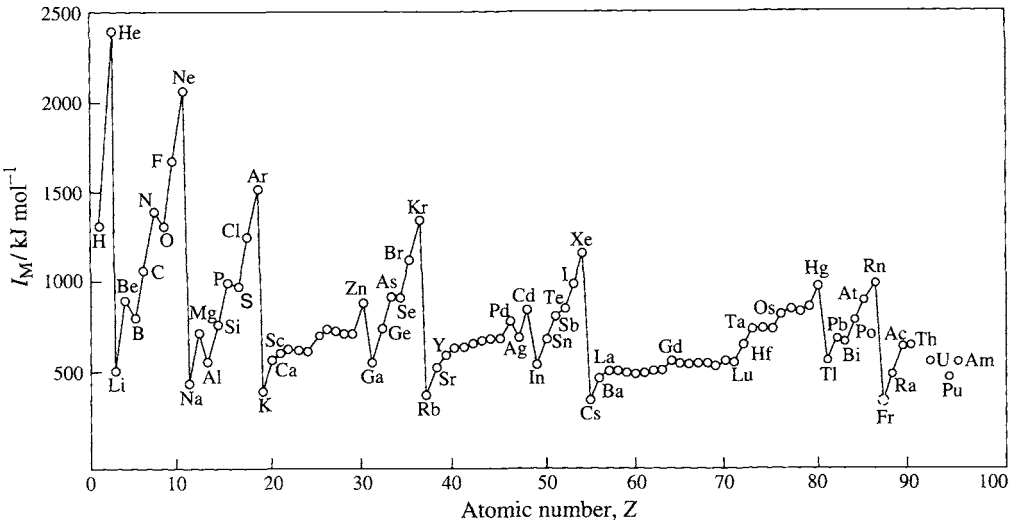

Figure 2.3 First-stage ionization energies of the elements.

proton and the additional charge is not completely shielded by the second electron. There is a large drop in ionization energy between helium and lithium ($1s^2 2s^1$) because the principal quantum number n increases from 1 to 2, after which the ionization energy rises somewhat for beryllium ($1s^2 2s^2$), though not to a value which is so high that beryllium would be expected to be an inert gas. The interpretation that is placed on the other values in Fig. 2.3 is as follows. The slight decrease at boron ($1s^2 2s^2 2p^1$) is due to the increase in orbital quantum number l from 0 to 1 and the similar decrease between nitrogen and oxygen is due to increased interelectronic coulomb repulsion as the fourth p electron is added to the 3 already occupying $2p_x$, $2p_y$, and $2p_z$. The ionization energy then continues to increase with increasing Z until the second quantum shell is filled at neon ($2s^2 sp^6$). The process is precisely repeated from sodium ($3s^1$) to argon ($3s^2 3p^6$) which again occurs at a peak in the curve, although at this point the third quantum shell is not yet completed (3d). This is because the next added electron for the next element potassium ($Z = 19$) enters the 4s shell ($n + l = 4$) rather than the 3d ($n + l = 5$). After calcium ($Z = 20$) the 3d shell fills and then the 4p ($n + l = 5$, but n higher than for 3d). The implications of this and of the subsequent filling of later s, p, d, and f levels will be elaborated in considerable detail in later chapters. Suffice it to note for the moment that the chemical inertness of the lighter noble gases correlates with their high ionization energies whereas the extreme reactivity of the alkali metals (and their prominent flame tests) finds a ready interpretation in their much lower ionization energies.

Electronegativities also show well-developed periodic trends though the concept of electronegativity itself, as introduced by L. Pauling,[7] is rather qualitative: "Electronegativity is the power of an atom *in a molecule* to attract electrons to itself." It is to be expected that the electronegativity of an element will depend to some extent not only on the other atoms to which it is bonded but also on its coordination number and oxidation state; for example, the electronegativity of a given atom increases with increase in its oxidation state. Fortunately, however, these effects do not obscure the main trends. Various measures of electronegativity have been proposed by L. Pauling, by R. S. Mulliken, by A. L. Allred

[7] L. PAULING, *J. Am. Chem. Soc.* **54**, 3570 (1932); *The Nature of the Chemical Bond*, 3rd edn., pp. 88–107. Cornell University Press, Ithaca, NY, 1960.

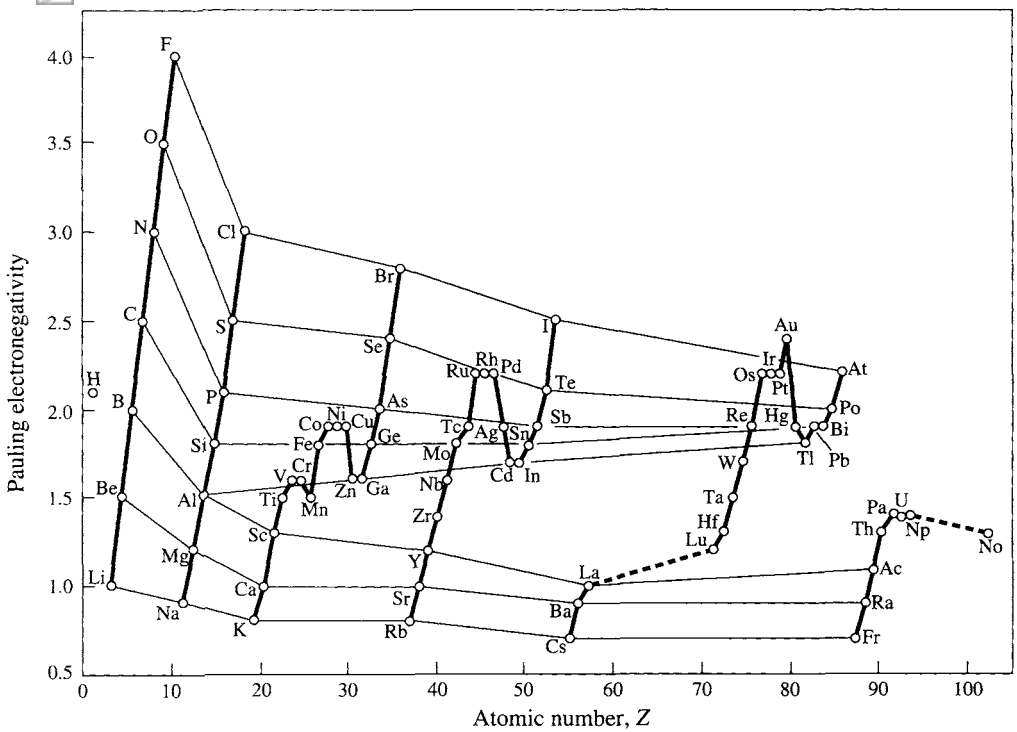

Figure 2.4 Values of electronegativity of the elements.

and E. Rochow, and by R. T. Sanderson, and all give roughly parallel scales. Figure 2.4, which incorporates Pauling's values, illustrates the trends observed; electronegativities tend to increase with increasing atomic number within a given period (e.g. Li to F, or K to Br) and to decrease with increasing atomic number within a given group (e.g. F to At, or O to Po). Numerous reviews are available.[8]

Many other properties have been found to show periodic variations and these can be displayed graphically or by circles of varying size on a periodic table, e.g. melting points of the elements, boiling points, heats of fusion, heats of vaporization, energies of atomization, etc.[6] Similarly, the properties of simple binary compounds of the elements can be plotted, e.g. heats of formation, melting points and boiling points of hydrides, fluorides, chlorides, bromides, iodides, oxides, sulfides, etc.[6] Trends immediately become apparent, and the selection of compounds with specific values for particular properties is facilitated. Such trends also permit interpolation to give estimates of undetermined values of properties for a given compound though such a procedure can be misleading and should only be used as a first rough guide. Extrapolation has also frequently been used, and to good effect, though it too can be hazardous and unreliable particularly when new or unsuspected effects are involved. Perhaps the classic example concerns the dissociation energy of the fluorine molecule which is difficult to measure experimentally: for many years this was taken to be ~265 kJ mol^{-1} by extrapolation of the values for iodine, bromine, and chlorine (151, 193, and 243 kJ mol^{-1}), whereas the

[8] K. D. SEN and C. K. JØRGENSEN (eds.), *Structure and Bonding* **66** *Electronegativity*, Springer-Verlag, Berlin, 1987, 198 pp. J. Mullay, *J. Am. Chem. Soc.* **106**, 5842–7 (1984). R. T. Sanderson, *Inorg. Chem.* **25**, 1856–8 (1986). R. G. Pearson, *Inorg. Chem.* **27**, 734–40 (1988).

most recent experimental values are close to 159 kJ mol^{-1} (see Chapter 17). The detection of such anomalous data from periodic plots thus serves to identify either inaccurate experimental observations or inadequate theories (or both).

2.3.2 Trends in chemical properties

These, though more difficult to describe quantitatively than the trends in atomic and physical properties described in the preceding subsection, also become apparent when the elements are compared in each group and along each period. Such trends will be discussed in detail in later chapters and it is only necessary here to enumerate briefly the various types of behaviour that frequently recur.

The most characteristic chemical property of an element is its valence. There are numerous measures of valency each with its own area of usefulness and applicability. Simple definitions refer to the number of hydrogen atoms that can combine with an element in a binary hydride or to twice the number of oxygen atoms combining with an element in its oxide(s). It was noticed from the beginning that there was a close relation between the position of an element in the periodic table and the stoichiometry of its simple compounds. Hydrides of main group elements have the formula MH_n where n was related to the group number N by the equations $n = N$ $(N \leq 4)$, and $n = 18 - N$ for $N > 14$. By contrast, oxygen elicited an increasing valence in the highest normal oxide of each element and this was directly related to the group number, i.e. M_2O, MO, M_2O_3, ..., M_2O_7. These periodic regularities find a ready explanation in terms of the electronic configuration of the elements and simple theories of chemical bonding. In more complicated chemical formulae involving more than 2 elements, it is convenient to define the "oxidation state" of an element as the formal charge remaining on the element when all other atoms have been removed as their normal ions. For example, nitrogen has an oxidation state of -3 in ammonium chloride $[NH_4Cl - (4H^+ + Cl^-) = N^{3-}]$ and manganese has an oxidation state of +7 in potassium permanganate {tetraoxomanganate(1−)} $[KMnO_4 - (K^+ + 4O^{2-}) = Mn^{7+}]$. For a compound such as Fe_3O_4 iron has an average oxidation state of +2.67 [i.e. $(4 \times 2)/3$] which may be thought of as comprising $1Fe^{2+}$ and $2Fe^{3+}$. It should be emphasized that these charges are formal, not actual, and that the concept of oxidation state is not particularly helpful when considering predominantly covalent compounds (such as organic compounds) or highly catenated inorganic compounds such as S_7NH.

The periodicity in the oxidation state or valence shown by the elements was forcefully illustrated by Mendeleev in one of his early forms of the periodic system and this is shown in an extended form in Fig. 2.5 which incorporates more recent information. The predictive and interpolative powers of such a plot are obvious and have been a fruitful source of chemical experimentation for over a century.

Other periodic trends which occur in the chemical properties of the elements and which are discussed in more detail throughout later chapters are:

(i) The "anomalous" properties of elements in the first short period (from lithium to fluorine) — see Chapters 4, 5, 6, 8, 11, 14 and 17.
(ii) The "anomalies" in the post-transition element series (from gallium to bromine) related to the d-block contraction — see Chapters 7, 10, 13, 16 and 17.
(iii) The effects of the lanthanide contraction — see Chapters 21–30.
(iv) Diagonal relationships between lithium and magnesium, beryllium and aluminium, boron and silicon.
(v) The so-called inert pair effect (see Chapters 7, 10 and 13) and the variation of oxidation state in the main group elements in steps of 2 (e.g. IF, IF_3, IF_5, IF_7).
(vi) Variability in the oxidation state of transition elements in steps of 1.
(vii) Trends in the basicity and electropositivity of elements — both vertical trends

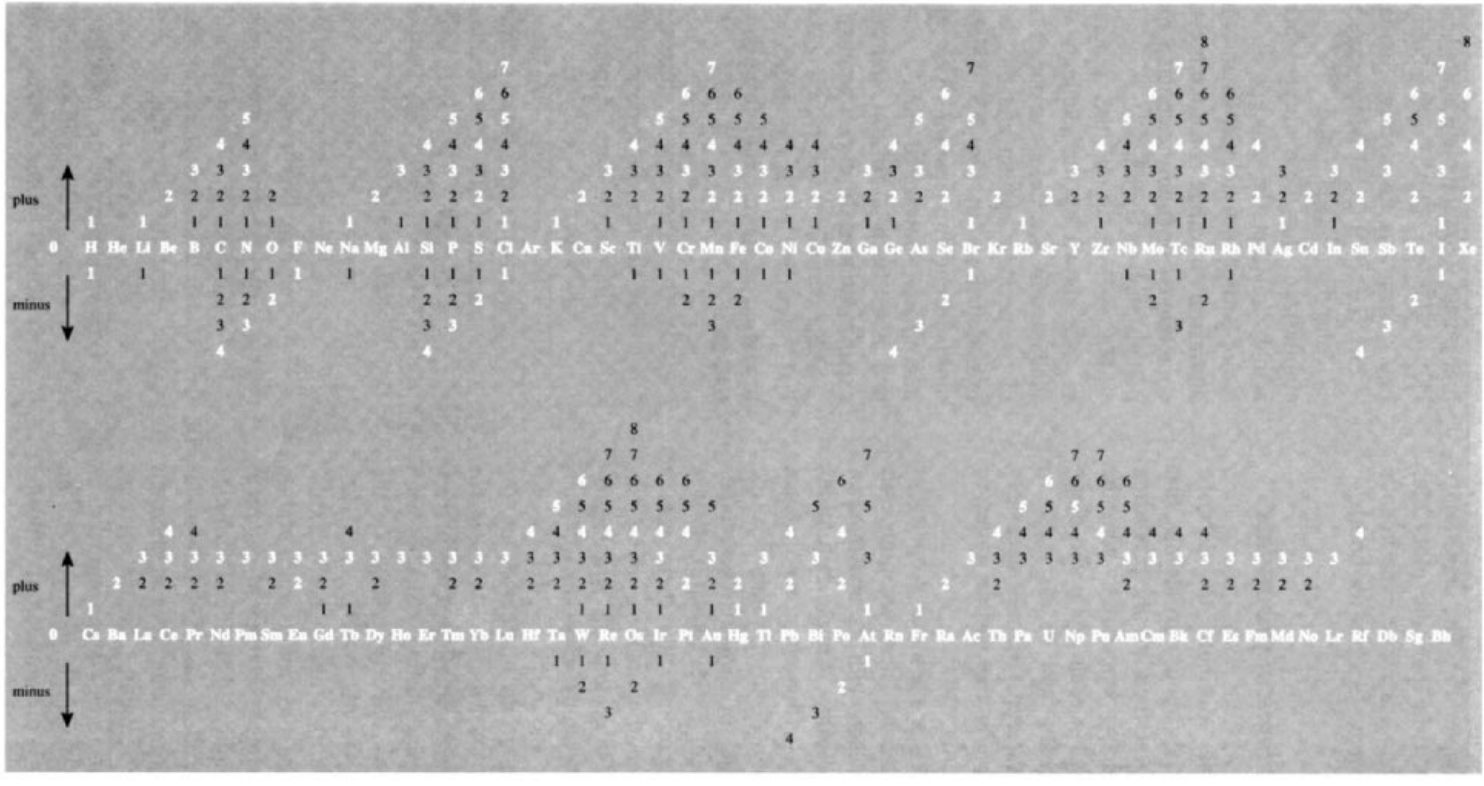

Figure 2.5 Formal oxidation states of the elements displayed in a format originally devised by Mendeleev in 1889. The more common oxidation states (including zero) are shown in white. Nonintegral values, as in B_5H_9, C_3H_8, HN_3, S_8^{2+}, etc., are not included.

within groups and horizontal trends along periods.

(viii) Trends in bond type with position of the elements in the table and with oxidation state for a given element.

(ix) Trends in stability of compounds and regularities in the methods used to extract the elements from their compounds.

(x) Trends in the stability of coordination complexes and the electron-donor power of various series of ligands.

2.4 Prediction of New Elements and Compounds

Newlands (1864) was the first to predict correctly the existence of a "missing element" when he calculated an atomic weight of 73 for an element between silicon and tin, close to the present value of 72.61 for germanium (discovered by C. A. Winkler in 1886). However, his method of detecting potential triads was unreliable and he predicted (non-existent) elements between rhodium and iridium, and between palladium and platinum. Mendeleev's predictions 1869–71 were much more extensive and reliable, as indicated in the historical panel on p. 21. The depth of his insight and the power of his method remain impressive even today, but in the state of development of the subject in 1869 they were monumental. A comparison of the properties of eka-silicon predicted by Mendeleev and those determined experimentally for germanium is shown in Table 2.1. Similarly accurate predictions were made for eka-aluminium and gallium and for eka-boron and scandium.

Of the remaining 26 undiscovered elements between hydrogen and uranium, 11 were lanthanoids which Mendeleev's system was unable to characterize because of their great chemical similarity and the new numerological feature dictated by the filling of the 4f orbitals. Only cerium, terbium and erbium were established with certainty in 1871, and the others (except promethium, 1945) were separated and identified in the period 1879–1907. The isolation of the (unpredicted) noble gases also occurred at this time (1894–8).

Table 2.1

Mendeleev's predictions (1871) for eka-silicon, M		Observed properties (1995) of germanium (discovered 1886)	
Atomic weight	72	Atomic weight	72.61(2)
Density/g cm^{-3}	5.5	Density/g cm^{-3}	5.323
Molar volume/cm^3 mol^{-1}	13.1	Molar volume/cm^3 mol^{-1}	13.64
MP/°C	high	MP/°C	945
Specific heat/J g^{-1} K^{-1}	0.305	Specific heat/J g^{-1} K^{-1}	0.309
Valence	4	Valence	4
Colour	dark grey	Colour	greyish-white
M will be obtained from MO_2 or K_2MF_6 by reaction with Na		Ge is obtained by reaction of K_2GeF_6 with Na	
M will be slightly attacked by acids such as HCl and will resist alkalis such as NaOH		Ge is not dissolved by HCl or dilute NaOH but reacts with hot conc HNO_3	
M, on being heated, will form MO_2 with high mp, and d 4.7 g cm^{-3}		Ge reacts with oxygen to give GeO_2, mp 1086°, d 4.228 g cm^{-3}	
M will give a hydrated MO_2 soluble in acid and easily reprecipitated		"$Ge(OH)_4$" dissolves in conc acid and is reprecipitated on dilution or addition of base	
MS_2 will be insoluble in water but soluble in ammonium sulfide		GeS_2 is insoluble in water and dilute acid but readily soluble in ammonium sulfide	
MCl_4 will be a volatile liquid with bp a little under 100°C and d 1.9 g cm^{-3}		$GeCl_4$ is a volatile liquid with bp 83°C and d 1.8443 g cm^{-3}	
M will form MEt_4 bp 160°C		$GeEt_4$ bp 185°C	

The isolation and identification of 4 radioactive elements in minute amounts took place at the turn of the century, and in each case the insight provided by the periodic classification into the predicted chemical properties of these elements proved invaluable. Marie Curie identified polonium in 1898 and, later in the same year working with Pierre Curie, isolated radium. Actinium followed in 1899 (A. Debierne) and the heaviest noble gas, radon, in 1900 (F. E. Dorn). Details will be found in later chapters which also recount the discoveries made in the present century of protactinium (O. Hahn and Lise Meitner, 1917), hafnium (D. Coster and G. von Hevesey, 1923), rhenium (W. Noddack, Ida Tacke and O. Berg, 1925), technetium (C. Perrier and E. Segré, 1937), francium (Marguerite Perey, 1939) and promethium (J. A. Marinsky, L. E. Glendenin and C. D. Coryell, 1945).

A further group of elements, the transuranium elements, has been synthesized by artificial nuclear reactions in the period from 1940 onwards; their relation to the periodic table is discussed fully in Chapter 31 and need not be repeated here. Perhaps even more striking today are the predictions, as yet unverified, for the properties of the currently non-existent superheavy elements.[9] Elements up to lawrencium ($Z = 103$) are actinides (5f) and the 6d transition series starts with element 104. So far only elements 104–112 have been synthesized,[10] and, because there is as yet no agreement on trivial names for some of these elements (see pp. 1280–1), they are here referred to by their atomic numbers. A systematic naming scheme was approved by IUPAC in 1977 but is not widely used by researchers in the field. It involves the use of three-letter symbols derived directly from the atomic number by using the following numerical roots:

0	1	2	3	4	5	6	7	8	9
nil	un	bi	tri	quad	pent	hex	sept	oct	enn

These names and symbols can be used for elements 110 and beyond until agreed trivial names have been internationally approved. Hence, 110 is un-un-nilium (Uun), 111 is un-un-unium (Uuu), and 112 is un-un-bium, (Uub). These elements are increasingly unstable with respect to α-decay or spontaneous fission with half-lives of less than 1 s. It is therefore unlikely that much chemistry will ever be carried out on them though their ionization energies, mps, bps, densities, atomic and metallic radii, etc., have all been predicted. Element 112 is expected to be eka-mercury at the end of the 6d transition series, and should be, followed by the 7p and 8s configurations $Z = 113–120$. On the basis of present theories of nuclear structure an "island of stability" is expected near element 114 with half-lives in the region of years. Much effort is being concentrated on attempts to make these elements, and oxidation states are expected to follow the main group trends (e.g. 113: eka-thallium mainly + 1). Other physical properties have been predicted by extrapolation of known periodic trends. Still heavier elements have been postulated, though it is unlikely (on present theories) that their chemistry will ever be studied because of their very short predicted half-lives. Calculated energy levels for the range $Z = 121–154$ lead to the expectation of an unprecedented 5g series of 18 elements followed by fourteen 6f elements.

In addition to the prediction of new elements and their probable properties, the periodic table has proved invaluable in suggesting fruitful lines of research in the preparation of new compounds. Indeed, this mode of thinking is now so ingrained in the minds of chemists that they rarely pause to reflect how extraordinarily difficult their task would be if periodic trends were unknown. It is the ability to anticipate the effect of changing an element or a group in a compound which enables work to be planned effectively, though the prudent chemist is always alert to the possibility of

[9] B. FRICKE, Superheavy elements, *Structure and Bonding* **21**, 89 (1975). A full account of the predicted stabilities and chemical properties of elements with atomic numbers in the range $Z = 104–184$.

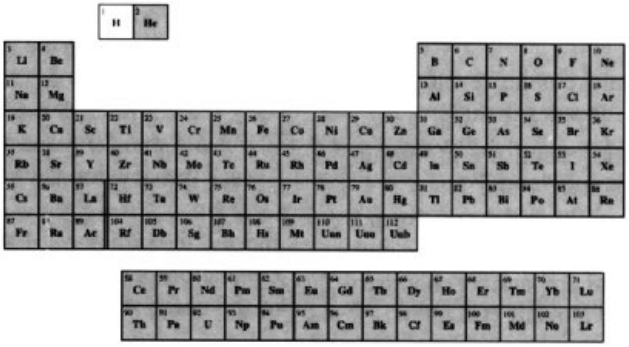
[10] R. C. BARBER, N. N. GREENWOOD, A. Z. HRYNKIEWICZ, M. LEFORT, M. SAKAI, I. ULEHLA, A. H. WAPSTRA and D. H. WILKINSON, *Progr. in Particle and Nuclear Physics*, **29**, 453–530 (1992); also published in *Pure Appl. Chem.* **65**, 1757–824 (1993). See also §31.4.

new effects or unsuspected factors which might surprisingly intervene.

Typical examples taken from the developments of the past two or three decades include:

(i) the organometallic chemistry of lithium and thallium (Chapters 4 and 7);
(ii) the use of boron hydrides as ligands (Chapter 6);
(iii) solvent systems and preparative chemistry based on the interhalogens (Chapter 17);
(iv) the development of the chemistry of xenon (Chapter 18);
(v) ferrocene — leading to ruthenocene and dibenzene chromium, etc. (Chapters 19, 25 and 23 respectively);
(vi) the development of solid-state chemistry.

Indeed, the influence of Mendeleev's fruitful generalization pervades the whole modern approach to the chemistry of the elements.



3

Hydrogen

3.1 Introduction

Hydrogen is the most abundant element in the universe and is also common on earth, being the third most abundant element (after oxygen and silicon) on the surface of the globe. Hydrogen in combined form accounts for about 15.4% of the atoms in the earth's crust and oceans and is the ninth element in order of abundance by weight (0.9%). In the crustal rocks alone it is tenth in order of abundance (0.15 wt%). The gradual recognition of hydrogen as an element during the sixteenth and seventeenth centuries forms part of the obscure and tangled web of experiments that were carried out as chemistry emerged from alchemy to become a modern science.[1] Until almost the end of the eighteenth century the element was inextricably entwined with the concept of phlogiston and H. Cavendish, who is generally regarded as having finally isolated and identified the gas in 1766, and who established conclusively that water was a compound of oxygen and hydrogen, actually communicated his findings to the Royal Society in January 1784 in the following words: "There seems to be the utmost reason to think that dephlogisticated air is only water deprived of its phlogiston" and that "water consists of dephlogisticated air united with phlogiston".

The continued importance of hydrogen in the development of experimental and theoretical chemistry is further illustrated by some of the dates listed in the Panel on the page opposite.

Hydrogen was recognized as the essential element in acids by H. Davy after his work on the hydrohalic acids, and theories of acids and bases have played an important role ever since. The electrolytic dissociation theory of S. A. Arrhenius and W. Ostwald in the 1880s, the introduction of the pH scale for hydrogen-ion concentrations by S. P. L. Sørensen in 1909, the theory of acid–base titrations and indicators, and J. N. Brønsted's fruitful concept of acids and conjugate bases as proton donors and acceptors (1923) are other land marks (see p. 48). The discovery of *ortho-* and *para-*hydrogen in 1924, closely followed by the discovery of heavy hydrogen (deuterium) and

[1] J. W. MELLOR, *A Comprehensive Treatise on Inorganic and Theoretical Chemistry*, Vol. 1, Chap. 3, Longmans, Green & Co., London, 1922.

tritium in the 1930s, added a further range of phenomena that could be studied by means of this element (pp. 34–43). In more recent times, the technique of nmr spectroscopy, which was first demonstrated in 1946 using the hydrogen nucleus, has revolutionized the study of structural chemistry and permitted previously unsuspected phenomena such as fluxionality to be studied. Simultaneously, the discovery of complex metal hydrides such as $LiAlH_4$ has had a major impact on synthetic chemistry and enabled new classes of compound to be readily prepared in high yield (p. 229). The most important compound of hydrogen is, of course, water,

Hydrogen — Some Significant Dates

1671	R. Boyle showed that dilute sulfuric acid acting on iron gave a flammable gas; several other seventeenth-century scientists made similar observations.
1766	H. Cavendish established the true properties of hydrogen by reacting several acids with iron, zinc and tin; he showed that it was much lighter than air.
1781	H. Cavendish showed quantitatively that water was formed when hydrogen was exploded with oxygen, and that water was therefore not an element as had previously been supposed.
1783	A. L. Lavoisier proposed the name "hydrogen" (Greek ὕδωρ γείνομαι, water former).
1800	W. Nicholson and A. Carlisle decomposed water electrolytically into hydrogen and oxygen which were then recombined by explosion to resynthesize water.
1810–15	Hydrogen recognized as the essential element in acids by H. Davy (contrary to Lavoisier who originally considered oxygen to be essential — hence Greek ὀξύς γείνομαι, acid former).
1866	The remarkable solubility of hydrogen in palladium discovered by T. Graham following the observation of hydrogen diffusion through red-hot platinum and iron by H. St. C. Deville and L. Troost, 1863.
1878	Hydrogen detected spectroscopically in the sun's chromosphere (J. N. Lockyer).
1895	Hydrogen first liquefied in sufficient quantity to show a meniscus (J. Dewar) following earlier observations of mists and droplets by others, 1877–85.
1909	The pH scale for hydrogen-ion concentration introduced by S. P. L. Sørensen.
1912	H_3^+ discovered mass-spectrometrically by J. J. Thompson.
1920	The concept of hydrogen bonding introduced by W. M. Latimer and W. H. Rodebush (and by M. L. Huggins, 1921).
1923	J. N. Brønsted defined an acid as a species that tended to lose a proton: $A \rightleftharpoons B + H^+$.
1924	*Ortho-* and *para*-hydrogen discovered spectroscopically by R. Mecke and interpreted quantum-mechanically by W. Heisenberg, 1927.
1929–30	Concept of quantum-mechanical tunnelling in proton-transfer reactions introduced (without experimental evidence) by several authors.
1931	First hydrido complex of a transition metal prepared by W. Hieber and F. Leutert.
1932	Deuterium discovered spectroscopically and enriched by gaseous diffusion of hydrogen and by electrolysis of water (H. C. Urey, F. G. Brickwedde and G. M. Murphy).
1932	Acidity function H_0 proposed by L. P. Hammett for assessing the strength of very strong acids.
1934	Tritium first made by deuteron bombardment of D_3PO_4 and $(ND_4)_2SO_4$ (i.e. $^2D + {}^2D = {}^3T + {}^1H$); M. L. E. Oliphant, P. Harteck and E. Rutherford.
1939	Tritium found to be radioactive by L. W. Alvarez and R. Cornog after a prediction by T. W. Bonner in 1938.
1946	Proton nmr first detected in bulk matter by E. M. Purcell, H. C. Torrey and R. V. Pound; and by F. Bloch, W. W. Hansen and M. E. Packard.
1947	$LiAlH_4$ first prepared and subsequently shown to be a versatile reducing agent; A. E. Finholt, A. C. Bond and H. I. Schlesinger.
1950	Tritium first detected in atmospheric hydrogen (V. Faltings and P. Harteck) and later shown to be present in rain water (W. F. Libby *et al.*, 1951).
1954	Detonation of the first hydrogen bomb on Bikini Atoll.
1960s	"Superacids" (10^7–10^{19} times stronger than sulfuric acid) studied systematically by G. A. Olah's group and by R. J. Gillespie's group.
1966	The term "magic acid" coined in G. A. Olah's laboratory for the non-aqueous system HSO_3F/SbF_5.
1976–79	Encapsulated H atom detected and located in octahedral polynuclear carbonyls such as $[HRu_6(CO)_{18}]^-$ and $[HCo_6(CO)_{15}]^-$ following A. Simon's characterization of interstitial H in HNb_6I_{11}.
1984	Stable transition-metal complexes of dihapto-dihydrogen (η^2-H_2) discovered by G. Kubas.

and a detailed discussion of this compound is given on pp. 620–33 in the chapter on oxygen. In fact, hydrogen forms more chemical compounds than any other element, including carbon, and a survey of its chemistry therefore encompasses virtually the whole periodic table. However, before embarking on such a review in Sections 3.4–3.7 it is convenient to summarize the atomic and physical properties of the various forms of hydrogen (Section 3.2), to enumerate the various methods used for its preparation and industrial production, and to indicate some of its many applications and uses (Section 3.3).

3.2 Atomic and Physical Properties of Hydrogen[2]

Despite its very simple electronic configuration ($1s^1$) hydrogen can, paradoxically, exist in over 50 different forms most of which have been well characterized. This multiplicity of forms arises firstly from the existence of atomic, molecular and ionized species in the gas phase: H, H_2, H^+, H^-, H_2^+, H_3^+ ..., H_{11}^+; secondly, from the existence of three isotopes, $^1_1$H, $^2_1$H(D) and $^3_1$H(T), and correspondingly of D, D_2, HD, DT, etc.; and, finally, from the existence of nuclear spin isomers for the homonuclear diatomic species, i.e. *ortho*- and *para*-dihydrogen, -dideuterium and -ditritium.†

3.2.1 Isotopes of hydrogen

Hydrogen as it occurs in nature is predominantly composed of atoms in which the nucleus is a single proton. In addition, terrestrial hydrogen contains about 0.0156% of deuterium atoms in which the nucleus also contains a neutron, and this is the reason for its variable atomic weight (p. 17). Addition of a second neutron induces instability and tritium is radioactive, emitting low-energy β^- particles with a half-life of 12.33 y. Some characteristic properties of these 3 atoms are given in Table 3.1, and their implications for stable isotope studies, radioactive tracer studies, and nmr spectroscopy are obvious.

In the molecular form, dihydrogen is a stable, colourless, odourless, tasteless gas with a very low mp and bp. Data are in Table 3.2 from which it is clear that the values for deuterium and tritium are substantially higher.

[2] K. M. MACKAY, The element hydrogen, *Comprehensive Inorganic Chemistry*, Vol. 1, Chap. 1. K. M. MACKAY and M. F. A. DOVE, Deuterium and tritium, *ibid.*, Vol. 1, Chap. 3, Pergamon Press, Oxford, 1973.

† The term dihydrogen (like dinitrogen, dioxygen, etc.) is used when it is necessary to refer unambiguously to the molecule H_2 (or N_2, O_2, etc.) rather than to the element as a substance or to an atom of the element. Strictly, one should use "diprotium" when referring specifically to the species H_2 and "dihydrogen" when referring to an undifferentiated isotopic mixture such as would be obtained from materials having the natural isotopic abundances of H and D; likewise "proton" only when referring specifically to H^+, but "hydron" when referring to an undifferentiated isotopic mixture.

Table 3.1 Atomic properties of hydrogen (protium), deuterium, and tritium

Property	H	D	T
Relative atomic mass	1.007 825	2.014 102	3.016 049
Nuclear spin quantum number	$\frac{1}{2}$	1	$\frac{1}{2}$
Nuclear magnetic moment/(nuclear magnetons)[a]	2.792 70	0.857 38	2.978 8
NMR frequency (at 2.35 tesla)/MHz	100.56	15.360	104.68
NMR relative sensitivity (constant field)	1.000	0.009 64	1.21
Nuclear quadrupole moment/(10^{-28} m^2)	0	2.766×10^{-3}	0
Radioactive stability	Stable	Stable	β^- $t_{\frac{1}{2}}$ 12.33 y[b]

[a] Nuclear magneton $\mu_N = e\hbar/2m_p = 5.0508 \times 10^{-27}$ J T^{-1}.

[b] E_{max} 18.6 keV; E_{mean} 5.7 keV; range in air ~6 mm; range in water ~6 μm.

Table 3.2 Physical properties of hydrogen, deuterium and tritium

Property[a]	H_2	D_2	T_2
MP/K	13.957	18.73	20.62
BP/K	20.39	23.67	25.04
Heat of fusion/kJ mol^{-1}	0.117	0.197	0.250
Heat of vaporization/kJ mol^{-1}	0.904	1.226	1.393
Critical temperature/K	33.19	38.35	40.6 (calc)
Critical pressure/atm[b]	12.98	16.43	18.1 (calc)
Heat of dissociation/kJ mol^{-1} (at 298.2 K)	435.88	443.35	446.9
Zero point energy/kJ mol^{-1}	25.9	18.5	15.1
Internuclear distance/pm	74.14	74.14	(74.14)

[a]Data refer to H_2 of normal isotopic composition (i.e. containing 0.0156 atom % of deuterium, predominantly as HD). All data refer to the mixture of *ortho*- and *para*-forms that are in equilibrium at room temperature.
[b]1 atm = 101.325 kN m^{-2} = 101.325 kPa.

For example, the mp of T_2 is above the bp of H_2. Other forms such as HD and DT tend to have properties intermediate between those of their components. Thus HD has mp 16.60 K, bp 22.13 K, ΔH_{fus} 0.159 kJ mol^{-1}, ΔH_{vap} 1.075 kJ mol^{-1}, T_c 35.91 K, P_c 14.64 atm and ΔH_{dissoc} 439.3 kJ mol^{-1}. The critical temperature T_c is the temperature above which a gas cannot be liquefied simply by application of pressure, and the critical pressure P_c is the pressure required for liquefaction at this point.

Table 3.2 also indicates that the heat of dissociation of the hydrogen molecule is extremely high, the H–H bond energy being larger than for almost all other single bonds. This contributes to the relative unreactivity of hydrogen at room temperature. Significant thermal decomposition into hydrogen atoms occurs only above 2000 K: the percentage of atomic H is 0.081 at this temperature, and this rises to 7.85% at 3000 K and 95.5% at 5000 K. Atomic hydrogen can, however, be conveniently prepared in low-pressure glow discharges, and the study of its reactions forms an important branch of chemical gas kinetics. The high heat of recombination of hydrogen atoms finds application in the atomic hydrogen torch — dihydrogen is dissociated in an arc and the atoms then recombine on the surface of a metal, generating temperatures in the region of 4000 K which can be used to weld very high melting metals such as tantalum and tungsten.

3.2.2 Ortho- *and* para-*hydrogen*

All homonuclear diatomic molecules having nuclides with non-zero spin are expected to show nuclear spin isomers. The effect was first detected in dihydrogen where it is particularly noticeable, and it has also been established for D_2, T_2, $^{14}N_2$, $^{15}N_2$, $^{17}O_2$, etc. When the two nuclear spins are parallel (*ortho*-hydrogen) the resultant nuclear spin quantum number is 1 (i.e. $\frac{1}{2} + \frac{1}{2}$) and the state is threefold degenerate ($2S + 1$). When the two proton spins are antiparallel, however, the resultant nuclear spin is zero and the state is non-degenerate. Conversion between the two states involves a forbidden triplet–singlet transition and is normally slow unless catalysed by interaction with solids or paramagnetic species which either break the H–H bond, weaken it, or allow magnetic perturbations. Typical catalysts are Pd, Pt, active Fe_2O_3 and NO. *Para*-hydrogen (spins antiparallel) has the lower energy and this state is favoured at low temperatures. Above 0 K (100% *para*) the equilibrium concentration of *ortho*-hydrogen gradually increases until, above room temperature, the statistically weighted proportion of 3 *ortho*:1 *para* is obtained, i.e. 25% *para*. Typical equilibrium concentrations of *para*-hydrogen are 99.8% at 20 K, 65.4% at 60 K, 38.5% at 100 K, 25.7% at 210 K, and 25.1% at 273 K (Fig. 3.1). It follows that, whereas essentially pure *para*-hydrogen can be obtained, it is never possible to obtain a sample

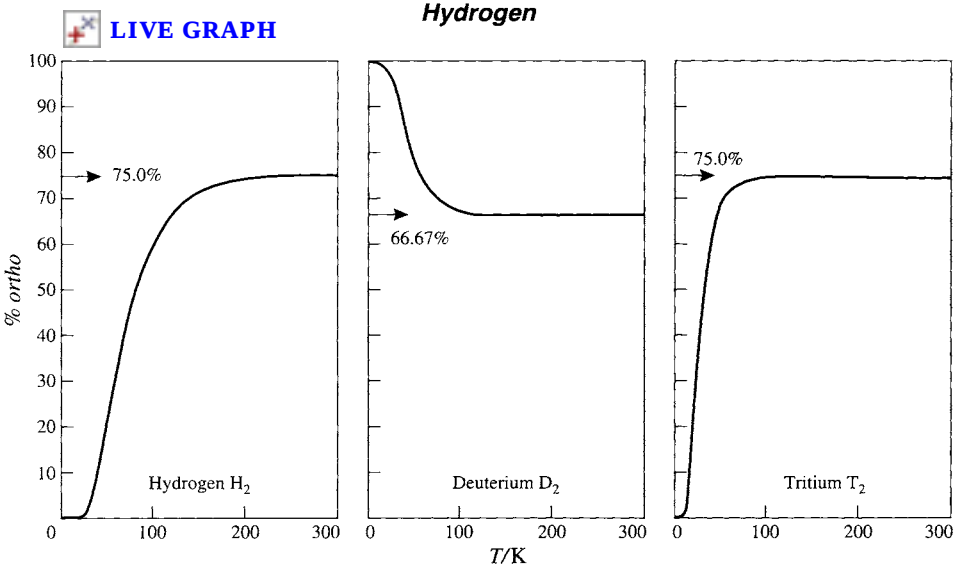


Figure 3.1 *Ortho-para* equilibria for H_2, D_2 and T_2.

containing more than 75% of *ortho*-hydrogen. Experimentally, the presence of both *o*-H_2 and *p*-H_2 is seen as an alternation in the intensities of successive rotational lines in the fine structure of the electronic band spectrum of H_2. It also explains the curious temperature dependence of the heat capacity of hydrogen gas.

Similar principles apply to *ortho*- and *para*-deuterium except that, as the nuclear spin quantum number of the deuteron is 1 rather than $\frac{1}{2}$ as for the proton, the system is described by Bose–Einstein statistics rather than the more familiar Fermi–Dirac statistics. For this reason, the stable low-temperature form is *ortho*-deuterium and at high temperatures the statistical weights are 6 *ortho*:3 *para* leading to an upper equilibrium concentration of 33.3% *para*-deuterium above about 190 K as shown in Fig. 3.1. Tritium (spin $\frac{1}{2}$) resembles H_2 rather than D_2.

Most physical properties are but little affected by nuclear-spin isomerism though the thermal conductivity of *p*-H_2 is more than 50% greater than that of *o*-H_2, and this forms a ready means of analysing mixtures. The mp of *p*-H_2 (containing only 0.21% *o*-H_2) is 0.15 K below that of "normal" hydrogen (containing 75% *o*-H_2), and by extrapolation the mp of (unobtainable) pure *o*-H_2 is calculated to be 0.24 K above that of *p*-H_2. Similar differences are found for the bps which occur at the following temperatures: normal-H_2 20.39 K, *o*-H_2 20.45 K. For deuterium the converse relation holds, *o*-D_2 melting some 0.03 K below "normal"-D_2 (66.7% *ortho*) and boiling some 0.04 K below. The effects for other elements are even smaller.

3.2.3 Ionized forms of hydrogen

This section briefly considers the proton H^+, the hydride ion H^-, the hydrogen molecule ion H_2^+, the triatomic 2-electron species H_3^+ and the recently established cluster species H_n^+,[3,4].

The hydrogen atom has a high ionization energy (1312 kJ mol^{-1}) and in this it resembles the halogens rather than the alkali metals. Removal of the 1s electron leaves a bare proton which, having a radius of only about 1.5×10^{-3} pm, is not a stable chemical entity in the condensed phase. However, when bonded to other species it is well known in solution and in

[3] N. J. Kirchner and M. T. Bowers, *J. Chem. Phys.* **86**, 1301–10 (1987).

[4] M. Okumura, L. I. Yeh and Y. T. Lee, *J. Chem. Phys.* **88**, 79–91 (1988), and references cited therein.

solids, e.g. H_3O^+, NH_4^+, etc. The proton affinity of water and the enthalpy of solution of H^+ in water have been estimated by several authors and typical values that are currently accepted are:

$$H^+(g) + H_2O(g) \longrightarrow H_3O^+(g); \quad -\Delta H \sim 710\,kJ\,mol^{-1}$$

$$H^+(g) \longrightarrow H_3O^+(aq); \quad -\Delta H \sim 1090\,kJ\,mol^{-1}$$

It follows that the heat of solution of the oxonium ion in water is $\sim 380\,kJ\,mol^{-1}$, intermediate between the values calculated for Na^+ ($405\,kJ\,mol^{-1}$) and K^+ ($325\,kJ\,mol^{-1}$). Reactions involving proton transfer will be considered in more detail in Section 3.5.

The hydrogen atom, like the alkali metals (ns^1) and halogens (ns^2np^5), has an affinity for the electron and heat is evolved in the following process:

$$H(g) + e^- \longrightarrow H^-(g); \quad -\Delta H_{calc} = 72\,kJ\,mol^{-1}$$

This is larger than the corresponding value for Li ($57\,kJ\,mol^{-1}$) but substantially smaller than the value for F ($333\,kJ\,mol^{-1}$). The hydride ion H^- has the same electron configuration as helium but is much less stable because the single positive charge on the proton must now control the 2 electrons. The hydride ion is thus readily deformable and this constitutes a characteristic feature of its structural chemistry (see p. 66).

The species H_2^+ and H_3^+ are important as model systems for chemical bonding theory. The hydrogen molecule ion H_2^+ comprises 2 protons and 1 electron and is extremely unstable even in a low-pressure gas discharge system; the energy of dissociation and the internuclear distance (with the corresponding values for H_2 in parentheses) are:

$$\Delta H_{dissoc}\ 255(436)\,kJ\,mol^{-1};$$

$$r(H{-}H)\ 106(74.2)\,pm$$

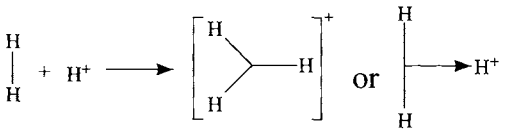
The triatomic hydrogen molecule ion H_3^+ was first detected by J. J. Thomson in gas discharges and later fully characterized by mass spectrometry; its relative atomic mass, 3.0235, clearly distinguishes it from HD (3.0219) and from tritium (3.0160). The "observed" equilateral triangular 3-centre, 2-electron structure is more stable than the hypothetical linear structure, and the comparative stability of the species is shown by the following gas-phase enthalpies:

$$H + H + H^+ = H_3^+; \quad -\Delta H\ 855.9\,kJ\,mol^{-1}$$

$$H_2 + H^+ = H_3^+; \quad -\Delta H\ 423.8\,kJ\,mol^{-1}$$

$$H + H_2^+ = H_3^+; \quad -\Delta H\ 600.2\,kJ\,mol^{-1}$$

The H_3^+ ion is the simplest possible example of a three-centre two-electron bond (see discussion of bonding in boranes on p. 157) and is also a model for the dihapto bonding mode of the ligand η^2-H_2 (pp. 44–7):



A series of ions H_n^+ with n-odd up to 15 and n-even up to 10 have recently been observed mass-spectrometrically and characterized for the first time.[3,4] The odd-numbered species are much more stable than the even-numbered members, as shown in the subjoined table which gives the relative intensities, I, as a function of n (in H_n^+) obtained in a particular experiment with a high-pressure ion source, relative to H_3^+:[3].

n	1	2	3	4	5	6
10^4I	160	50	**10 000**	4.2	4200	210
n	7		8	9	10	11
10^4I	3200		7.4	2600	18	34

The structures of H_5^+, H_7^+ and H_9^+ are related to that of H_3^+ with H_2 molecules added perpendicularly at the corners, whereas those of H_4^+, H_6^+ and H_8^+ feature an added H atom at the first corner. Typical structures are shown below. The structures of higher members of the series, with $n \geq 10$ are unknown but may involve further loosely bonded H_2 molecules above and below the H_3^+ plane. Enthalpies of dissociation are ΔH°_{300} ($H_5^+ \rightleftharpoons H_3^+ + H_2$) $28\,kJ\,mol^{-1}$ and ΔH°_{300} ($H_7^+ \rightleftharpoons H_5^+ + H_2$) $13\,kJ\,mol^{-1}$.[4]

3.3 Preparation, Production and Uses[5,6]

3.3.1 Hydrogen

Hydrogen can be prepared by the reaction of water or dilute acids on electropositive metals such as the alkali metals, alkaline earth metals, the metals of Groups 3, 4 and the lanthanoids. The reaction can be explosively violent. Convenient laboratory methods employ sodium amalgam or calcium with water, or zinc with hydrochloric acid. The reaction of aluminium or ferrosilicon with aqueous sodium hydroxide has also been used. For small-scale preparations the hydrolysis of metal hydrides is convenient, and this generates twice the amount of hydrogen as contained in the hydride, e.g.:

$$CaH_2 + 2H_2O \longrightarrow Ca(OH)_2 + 2H_2$$

Electrolysis of acidified water using platinum electrodes is a convenient source of hydrogen (and oxygen) and, on a larger scale, very pure hydrogen (>99.95%) can be obtained from the electrolysis of warm aqueous solutions of barium hydroxide between nickel electrodes. The method is expensive but becomes economical on an industrial scale when integrated with the chloralkali industry (p. 798). Other bulk processes involve the (endothermic) reaction of steam on hydrocarbons or coke:

$$CH_4 + H_2O \xrightarrow{1100°C} CO + 3H_2$$

$$C + H_2O \xrightarrow{1000°C} CO + H_2 \quad \text{(water gas)}$$

In both processes the CO can be converted to CO_2 by passing the gases and steam over an iron oxide or cobalt oxide catalyst at 400°C, thereby generating more hydrogen:

$$CO + H_2O \xrightarrow[\text{catalyst}]{400°C} CO_2 + H_2$$

This is the so-called water–gas shift reaction ($-\Delta G^\circ_{298}$ 19.9 kJ mol^{-1}) and it can also be effected by low-temperature homogeneous catalysts in aqueous acid solutions.[7] The extent of subsequent purification of the hydrogen depends on the use to which it will be put.

The industrial production of hydrogen is considered in more detail in the Panel. The largest single use of hydrogen is in ammonia synthesis (p. 421) but other major applications are in the catalytic hydrogenation of unsaturated liquid vegetable oils to solid, edible fats (margarine), and in the manufacture of bulk organic chemicals, particularly methanol (by the "oxo" or hydroformylation process):

$$CO + 2H_2 \xrightarrow[\text{catalyst}]{\text{cobalt}} MeOH$$

Direct reaction of hydrogen with chlorine is a major source of hydrogen chloride (p. 811), and a smaller, though still substantial use is in the manufacture of metal hydrides and complex metal hydrides (p. 64). Hydrogen is used in metallurgy to reduce oxides to metals (e.g. Mo, W) and to produce a reducing atmosphere. Direct reduction of iron ores in steelmaking is also now becoming technically and economically feasible.

[7] C.-H. Cheng and R. Eisenberg, *J. Am. Chem. Soc.* **100**, 5969–70 (1978).

Industrial Production of Hydrogen

Many reactions are available for the preparation of hydrogen and the one chosen depends on the amount needed, the purity required, and the availability of raw materials. Most (~97%) of the hydrogen produced in industry is consumed in integrated plants on site (e.g. ammonia synthesis, petrochemical works, etc.). Even so, vast amounts of the gas are produced for the general market, e.g. $\sim 6.5 \times 10^{10}\ m^3$ or 5.4 million tonnes yearly in the USA alone. Small generators may have a capacity of $100-4000\ m^3\ h^{-1}$, medium-sized plants $4000-10\,000\ m^3\ h^{-1}$, and large plants can produce $10^4-10^5\ m^3\ h^{-1}$. The dominant large-scale process in integrated plants is the catalytic steam–hydrocarbon reforming process using natural gas or oil-refinery feedstock. After desulfurization (to protect catalysts) the feedstock is mixed with process steam and passed over a nickel-based catalyst at 700–1000°C to convert it irreversibly to CO and H_2, e.g.

$$C_3H_8 + 3H_2O \xrightarrow[\text{catalyst}]{900°C} 3CO + 7H_2$$

Two reversible reactions also occur to give an equilibrium mixture of H_2, CO, CO_2 and H_2O:

$$CO + H_2O \rightleftharpoons CO_2 + H_2$$

$$CO + 3H_2 \rightleftharpoons CH_4 + H_2O$$

The mixture is cooled to ~350°C before entering a high-temperature shift convertor where the major portion of the CO is catalytically and exothermically converted to CO_2 and hydrogen by reaction with H_2O. The issuing gas is further cooled to 200° before entering the low-temperature shift convertor which reduces the CO content to 0.2 vol%. The product is further cooled and CO_2 absorbed in a liquid contacter. Further removal of residual CO and CO_2 can be effected by methanation at 350°C to a maximum of 10 ppm. Provided that the feedstock contains no nitrogen the product purity is about 98%. Alternatively the low-temperature shift process and methanation stage can be replaced by a single pressure-swing absorption (PSA) system in which the hydrogen is purified by molecular sieves. The sieves are regenerated by adiabatic depressurization at ambient temperature (hence the name) and the product has a purity of ≥99.9%.

At present about 77% of the industrial hydrogen produced is from petrochemicals, 18% from coal, 4% by electrolysis of aqueous solutions and at most 1% from other sources. Thus, hydrogen is produced as a byproduct of the brine electrolysis process for the manufacture of chlorine and sodium hydroxide (p. 798). The ratio of H_2:Cl_2:NaOH is, of course, fixed by stoichiometry and this is an economic determinant since bulk transport of the byproduct hydrogen is expensive. To illustrate the scale of the problem: the total world chlorine production capacity is about 38 million tonnes per year which corresponds to 105 000 tonnes of hydrogen ($1.3 \times 10^{10}\ m^3$). Plants designed specifically for the electrolytic manufacture of hydrogen as the main product, use steel cells and aqueous potassium hydroxide as electrolyte. The cells may be operated at atmospheric pressure (Knowles cells) or at 30 atm (Lonza cells).

When relatively small amounts of hydrogen are required, perhaps in remote locations such as weather stations, then small transportable generators can be used which can produce $1-17\ m^3\ h^{-1}$. During production a 1:1 molar mixture of methanol and water is vaporized and passed over a "base-metal chromite" type catalyst at 400°C where it is cracked into hydrogen and carbon monoxide; subsequently steam reacts with the carbon monoxide to produce the dioxide and more hydrogen:

$$MeOH \xrightarrow[\text{catalyst}]{400°C} CO + 2H_2$$

$$CO + H_2O \longrightarrow CO_2 + H_2$$

All the gases are then passed through a diffuser separator comprising a large number of small-diameter thin-walled tubes of palladium-silver alloy tightly packed in a stainless steel case. The solubility of hydrogen in palladium is well known (p. 1150) and the alloy with silver is used to prolong the life of the diffuser by avoiding troublesome changes in dimensions during the passage of hydrogen. The hydrogen which emerges is cool, pure, dry and ready for use via a metering device.

Another medium-scale use is in oxyhydrogen torches and atomic hydrogen torches for welding and cutting. Liquid hydrogen is used in bubble chambers for studying high-energy particles and as a rocket fuel (with oxygen) in the space programme. Hydrogen gas is potentially a large-scale fuel for use in internal combustion engines and fuel cells if the notional "hydrogen economy" (see Panel on p. 40) is ever developed.

3.3.2 Deuterium

Deuterium is invariably prepared from heavy water, D_2O, which is itself now manufactured

The Hydrogen Economy[6,8–11]

The growing recognition during the past decades that world reserves of coal and oil are finite and that nuclear power cannot supply all our energy requirements, particularly for small mobile units such as cars, has prompted an active search for alternatives. One solution which has many attractive features is the "hydrogen economy" whereby energy is transported and stored in the form of liquid or gaseous hydrogen. Enthusiasts point out that such a major change in the source of energy, though apparently dramatic, is not unprecedented and has in fact occurred twice during the past 100 y. In 1880 wood was overtaken by coal as the main world supplier of energy and now it accounts for only about 2% of the total. Likewise in 1960 coal was itself overtaken by oil and now accounts for only 15% of the total. (Note, however, that this does not imply a decrease in the total amount of coal used: in 1930 this was 14.5×10^6 barrels per day of oil equivalent and was 75% of the then total energy supply whereas in 1975 coal had increased in absolute terms by 11% to 16.2×10^6 b/d oe, but this was only 18% of the total energy supply which had itself increased 4.6-fold in the interim.) Another change may well be in the offing since nuclear power, which was effectively non-existent as an industrial source of energy in 1950, now accounts for 16% of the world supply of electricity; it has already overtaken coal as a source of energy and may well overtake oil during the next century. The aim of the "hydrogen economy" is to transmit this energy, not as electric power but in the form of hydrogen; this overcomes the great problem of electricity — that it cannot be stored — and also reduces the costs of power transmission.

The technology already exists for producing hydrogen electrically and storing it in bulk. For example huge quantities of liquid hydrogen are routinely stored in vacuum insulated cryogenic tanks for the US space programme, one such tank alone holding over 3400 m^3 (900 000 US gallons). Liquid hydrogen can be transported by road or by rail tankers of 75.7 m^3 capacity (20 000 US gallons). Underground storage of the type currently used for hydrogen — natural gas mixtures and transmission through large pipes is also feasible, and pipelines carrying hydrogen up to 80 km in the USA and South Africa and 200 km in Europe have been in operation for many years. Smaller storage units based on metal alloy systems have also been suggested, e.g. $LaNi_5$ can absorb up to 7 moles of H atoms per mole of $LaNi_5$ at room temperature and 2.5 atm, the density of contained hydrogen being twice that in the liquid element itself. Other systems include $Mg–MgH_2$, $Mg_2Ni–Mg_2NiH_4$, $Ti–TiH_2$ and $TiFe–TiFeH_{1.95}$.

The advantages claimed for hydrogen as an automobile fuel are the greater energy release per unit weight of fuel and the absence of polluting emissions such as CO, CO_2, NO_x, SO_2, hydrocarbons, aldehydes and lead compounds. The product of combustion is water with only traces of nitrogen oxides. Several conventional internal-combustion petrol engines have already been simply and effectively modified to run on hydrogen. Fuel cells for the regeneration of electric power have also been successfully operated commercially with a conversion efficiency of 70%, and test cells at higher pressures have achieved 85% efficiency.

Non-electrolytic sources of hydrogen have also been studied. The chemical problem is how to transfer the correct amount of free energy to a water molecule in order to decompose it. In the last few years about 10 000 such thermochemical water-splitting cycles have been identified, most of them with the help of computers, though it is significant that the most promising ones were discovered first by the intuition of chemists.

The stage is thus set, and further work to establish safe and economically viable sources of hydrogen for general energy usage seems destined to flourish as an active area of research for some while.

on the multitonne scale by the electrolytic enrichment of normal water.[12,13] The enrichment is expressed as a separation factor between the gaseous and liquid phases:

$$s = (H/D)_g/(H/D)_l$$

The equilibrium constant for the exchange reaction

$$H_2O + HD \rightleftharpoons HDO + H_2$$

is about 3 at room temperature and this would lead to a value of $s = 3$ if this were the only effect. However, the choice of the metal used for the electrodes can also affect the various electrode processes, and this increases the separation still further. Using alkaline solutions s values in

the range 5–7.6 are obtained for many metals, rising to 13.9 for platinum cathodes and even higher for gold. By operating a large number of cells in cascade, and burning the evolved H_2/D_2 mixture to replenish the electrolyte of earlier cells in the sequence, any desired degree of enrichment can ultimately be attained. Thus, starting with normal water (0.0156% of hydrogen as deuterium) and a separation factor of 5, the deuterium content rises to 10% after the original volume has been reduced by a factor of 2400. Reduction by 66 000 is required for 90% deuterium and by 130 000 for 99% deuterium. If, however, the separation factor is 10, then 99% deuterium can be obtained by a volume reduction on electrolysis of 22 000. Prior enrichment of the electrolyte to 15% deuterium can be achieved by a chemical exchange between H_2S and H_2O after which a fortyfold volume reduction produces heavy water with 99% deuterium content. Other enrichment processes are now rarely used but include fractional distillation of water (which also enriches ^{18}O), thermal diffusion of gaseous hydrogen, and diffusion of H_2/D_2 through palladium metal.

Many methods have been used to determine the deuterium content of hydrogen gas or water. For H_2/D_2 mixtures mass spectroscopy and thermal conductivity can be used together with gas chromatography (alumina activated with manganese chloride at 77 K). For heavy water the deuterium content can be determined by density measurements, refractive index change, or infrared spectroscopy.

The main uses of deuterium are in tracer studies to follow reaction paths and in kinetic studies to determine isotope effects.[14] A good discussion with appropriate references is in *Comprehensive Inorganic Chemistry*, Vol. 1, pp. 99–116. The use of deuterated solvents is widespread in proton nmr studies to avoid interference from solvent hydrogen atoms, and deuteriated compounds are also valuable in structural studies involving neutron diffraction techniques.

[14] L. MELANDER and W. H. SAUNDERS, *Reaction Rates of Isotopic Molecules*, Wiley, New York, 1980, 331 pp.

3.3.3 Tritium[15]

Tritium differs from the other two isotopes of hydrogen in being radioactive and this immediately indicates its potential uses and its method of detection. Tritium occurs naturally to the extent of about 1 atom per 10^{18} hydrogen atoms as a result of nuclear reactions induced by cosmic rays in the upper atmosphere:

$$^{14}_{7}N + ^{1}_{0}n = ^{3}_{1}H + ^{12}_{6}C$$

$$^{14}_{7}N + ^{1}_{1}H = ^{3}_{1}H + \text{fragments}$$

$$^{2}_{1}H + ^{2}_{1}H = ^{3}_{1}H + ^{1}_{1}H$$

The concentration of tritium increased by over a hundredfold when thermonuclear weapon testing began on Bikini Atoll in March 1954 but has now subsided as a result of the ban on atmospheric weapon testing and the natural radioactivity of the isotope ($t_{\frac{1}{2}}$ 12.33 y).

Numerous reactions are available for the artificial production of tritium and it is now made on a large scale by neutron irradiation of enriched ^{6}Li in a nuclear reactor:

$$^{6}_{3}Li + ^{1}_{0}n = ^{4}_{2}He + ^{3}_{1}H$$

The lithium is in the form of an alloy with magnesium or aluminium which retains much of the tritium until it is released by treatment with acid. Alternatively the tritium can be produced by neutron irradiation of enriched LiF at 450° in a vacuum and then recovered from the gaseous products by diffusion through a palladium barrier. As a result of the massive production of tritium for thermonuclear devices and research into energy production by fusion reactions, tritium is available cheaply on the megacurie scale for peaceful purposes.† The most convenient way of storing the gas is to react it with finely divided uranium

[15] E. A. EVANS, *Tritium and its Compounds*, 2nd edn., Butterworths, London, 1974, 840 pp. E. A. EVANS, D. C. WARRELL, J. A. ELVIDGE and J. R. JONES, *Handbook of Tritium NMR Spectroscopy and Applications*, Wiley, Chichester, 1985, 249 pp.

† See also p. 18 for the influence on the atomic weight of commercially available lithium in some countries.

to give UT_3 from which it can be released by heating above 400°C.

Besides being one of the least expensive radioisotopes, tritium has certain unique advantages as a tracer. Like ^{14}C it is a pure low-energy β^- emitter with no associated γ-rays. The radiation is stopped by ~6 mm of air or ~6 μm of material of density 1 g cm^{-3} (e.g. water). As the range is inversely proportional to the density, this is reduced to only ~1 μm in photographic emulsion (ρ ~3.5 g cm^{-3}) thus making tritium ideal for high-resolution autoradiography. Moreover, tritium has a high specific activity. The weight of tritium equal to an activity of 1 Ci is 0.103 mg and 1 mmol T_2 has an activity of 58.25 Ci. [Note: 1 Ci (curie) = 3.7×10^{10} Bq (becquerel); 1 Bq = 1 s^{-1}.] Tritium is one of the least toxic of radioisotopes and shielding is unnecessary; however, precautions must be taken against ingestion, and no work should be carried out without appropriate statutory authorization and adequate radiochemical facilities.

Tritium has been used extensively in hydrological studies to follow the movement of ground waters and to determine the age of various bodies of water. It has also been used to study the adsorption of hydrogen and the hydrogenation of ethylene on a nickel catalyst and to study the absorption of hydrogen in metals. Autoradiography has been used extensively to study the distribution of tritium in multiphase alloys, though care must be taken to correct for the photographic darkening caused by emanated tritium gas. Increasing use is also being made of tritium as a tracer for hydrogen in the study of reaction mechanisms and kinetics and in work on homogeneous catalysis.

The production of tritium-labelled organic compounds was enormously facilitated by K. E. Wilzbach's discovery in 1956 that tritium could be introduced merely by storing a compound under tritium gas for a few days or weeks: the β^- radiation induces exchange reactions between the hydrogen atoms in the compound and the tritium gas. The excess of gas is recovered for further use and the tritiated compound is purified chromatographically. Another widely used method of general applicability is catalytic exchange in solution using either a tritiated solution or tritium gas. This is valuable for the routine production of tritium compounds in high radiochemical yield and at high specific activity (>50 mCi mmol^{-1}). For example, although ammonium ions exchange relatively slowly with D_2O, tritium exchange equilibria are established virtually instantaneously: tritiated ammonium salts can therefore be readily prepared by dissolving the salt in tritiated water and then removing the water by evaporation:

$$(NH_4)_2SO_4 + HTO \rightleftharpoons (NH_3T)_2SO_4 + H_2O, \text{ etc.}$$

For exchange of non-labile organic hydrogen atoms, acid–base catalysis (or some other catalytic hydrogen-transfer agent such as palladium or platinum) is required. The method routinely gives tritiated products having a specific activity almost 1000 times that obtained by the Wilzbach method; shorter times are required (2–12 h) and subsequent purification is easier.

When specifically labelled compounds are required, direct chemical synthesis may be necessary. The standard techniques of preparative chemistry are used, suitably modified for small-scale work with radioactive materials. The starting material is tritium gas which can be obtained at greater than 98% isotopic abundance. Tritiated water can be made either by catalytic oxidation over palladium or by reduction of a metal oxide:

$$2T_2 + O_2 \xrightarrow{Pd} 2T_2O$$

$$T_2 + CuO \longrightarrow T_2O + Cu$$

Note, however, that pure tritiated water is virtually never used since 1 ml would contain 2650 Ci; it is self-luminescent, irradiates itself at the rate of 6×10^{17} eV ml^{-1} s^{-1} (~10^9 rad day^{-1}), undergoes rapid self-radiolysis, and also causes considerable radiation damage to dissolved species. In chemical syntheses or exchange reactions tritiated water of 1% tritium abundance (580 mCi mmol^{-1}) is usually sufficient to produce compounds having a specific activity of at least 100 mCi mmol^{-1}. Other useful

synthetic reagents are NaT, $LiAlH_3T$, $NaBH_3T$, $NaBT_4$, B_2T_6 and tritiated Grignard reagents. Typical preparations are as follows:

$$LiH + T_2 \xrightarrow{350°C} LiT + HT$$

$$LiBH_4 + T_2 \xrightarrow{200°C} LiBH_3T + HT$$

$$4LiT + AlBr_3 \xrightarrow{\text{ether}} LiAlT_4 + 3LiBr$$

$$B_2H_6 + T_2 \xrightarrow{55°C} B_2H_5T + HT$$

$$3NaBT_4 + 4BF_3.OEt_2 \longrightarrow 2B_2T_6 + 3NaBF_4$$

$$3T_2O(g) + P(CN)_3 \longrightarrow 3TCN + T_3PO_3$$

$$2AgCl + T_2 \xrightarrow{700°C} 2TCl + 2Ag$$

$$Br_2 + T_2 \xrightarrow{\text{uv}} 2TBr$$

$$P(red) + I_2 + HTO \longrightarrow TI + HI + \ldots$$

$$NH_3 + T_2 \longrightarrow NH_2T + TH$$

$$Mg_3N_2 + 6T_2O \xrightarrow{100°C} 2NT_3 + 3Mg(OT)_2$$

$$M + \frac{x}{2}T_2 \xrightarrow{\text{heat}} MT_x$$

The preparation and use of $LiEt_3BT$ and $LiAlT_4$ at maximum specific activity ($57.5\,Ci\,mmol^{-1}$) has also been described.[16]

3.4 Chemical Properties and Trends

Hydrogen is a colourless, tasteless, odourless gas which has only low solubility in liquid solvents. It is comparatively unreactive at room temperature though it combines with fluorine even in the dark and readily reduces aqueous solutions of palladium(II) chloride:

$$PdCl_2(aq) + H_2 \longrightarrow Pd(s) + 2HCl(aq)$$

This reaction can be used as a sensitive test for the presence of hydrogen. At higher temperatures hydrogen reacts vigorously, even explosively, with many metals and non-metals to give the corresponding hydrides. Activation can also be induced photolytically, by heterogeneous catalysts (Raney nickel, Pd, Pt, etc.), or by means of homogeneous hydrogenation catalysts. Industrially important processes include the hydrogenation of many organic compounds and the use of cobalt compounds as catalysts in the hydroformylation of olefins to aldehydes and alcohols at high temperatures and pressures (p. 1140):

$$RCH{=}CH_2 + H_2 + CO \longrightarrow RCH_2CH_2CHO$$

$$RCH_2CH_2CHO + H_2 \longrightarrow RCH_2CH_2CH_2OH$$

An even more effective homogeneous hydrogenation catalyst is the complex $[RhCl(PPh_3)_3]$ which permits rapid reduction of alkenes, alkynes and other unsaturated compounds in benzene solution at 25°C and 1 atm pressure (p. 1134). The Haber process, which uses iron metal catalysts for the direct synthesis of ammonia from nitrogen and hydrogen at high temperatures and pressures, is a further example (p. 421).

The hydrogen atom has a unique electronic configuration $1s^1$: accordingly it can gain an electron to give H^- with the helium configuration $1s^2$ or it can lose an electron to give the proton H^+ (p. 36). There are thus superficial resemblances both to the halogens which can gain an electron to give an inert-gas configuration ns^2np^6, and to the alkali metals which can lose an electron to give M^+ (ns^2np^6). However, because hydrogen has no other electrons in its structure there are sufficient differences from each of these two groups to justify placing hydrogen outside either. For example, the proton is so small ($r \sim 1.5 \times 10^{-3}$ pm compared with normal atomic and ionic sizes of ~50–220 pm) that it cannot exist in condensed systems unless associated with other atoms or molecules. The transfer of protons between chemical species constitutes the basis of acid–base phenomena (see Section 3.5). The hydrogen atom is also frequently found in close association with 2

[16] H. ANDRES, H. MORIMOTO and P. G. WILLIAMS, *J. Chem. Soc., Chem. Commun.*, 627–8 (1990).

other atoms in linear array; this particularly important type of interaction is called hydrogen bonding (see Section 3.6). Again, the ability to penetrate metals to form nonstoichiometric metallic hydrides, though not unique to hydrogen, is one of its more characteristic properties as is its ability to form nonlinear hydrogen bridge bonds in many of its compounds. These properties will be further discussed during the general classification of the hydrides of the elements in section 3.7. The most important compound of hydrogen is, of course, water and a detailed discussion of this compound is given on pp. 620–33 in the chapter on oxygen.

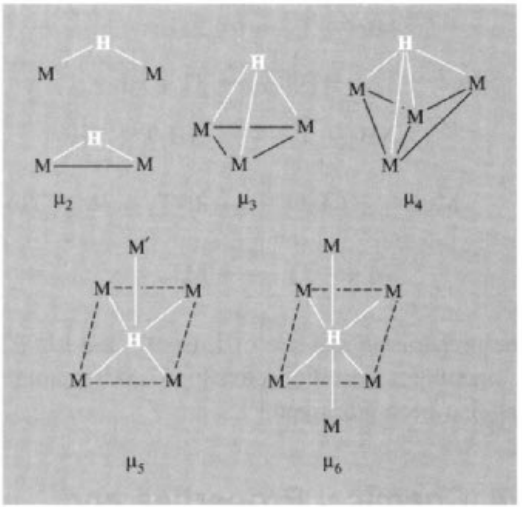
3.4.1 The coordination chemistry of hydrogen

Perhaps the most exciting recent development in the chemistry of hydrogen is the discovery that, in transition metal polyhydrides, the molecule H_2 can act as a dihapto ligand, η^2-H_2 (see below). Even the H atom itself can form compounds in which its coordination number (CN) is not just 1 (as expected) but also 2, 3, 4, 5 or even 6. A rich and unexpectedly varied coordination chemistry is thus emerging. We shall deal with the H atom first and then with the H_2 molecule.

By far the most common CN of hydrogen is 1, as in HCl, H_2S, PH_3, CH_4 and most other covalent hydrides and organic compounds. Bridging modes in which the H atom has a higher CN are shown schematically in the next column — in these structures M is typically a transition metal but, particularly in the μ_2-mode and to some extent in the μ_3-mode, one or more of the M can represent a main-group element such as B, Al; C, Si; N etc. Typical examples are in Table 3.3.[17–19] Fuller discussion and references, when appropriate, will be found in later chapters dealing with the individual elements concerned.

Table 3.3 Stereochemistry of hydrogen

CN	Examples
1	HCl, H_2S, PH_3, NH_4^+, BH_4^-, etc.; $[HMn(CO)_5]$, $[H_2Fe(CO)_4]$, $[H_3Ta(C_5H_5)_2]$, $[H_4Cr(dmpe)_2]$, $[CoH_5]^{4-}$, $[H_6W(PR_3)_3]$, $[\{H_7Re(PR_3)_2\}_2Ag]^+$, $[H_8Re(PR_3)]^-$, $[ReH_9]^{2-}$
2	B_2H_6, $[Me_2NAlH_2]_3$, $[H_3BHCu(PMePh_2)_3]$, $[nido\text{-}Ir(B_5H_8)(CO)(PPh_3)_2]$, $[(CO)_5WHW(CO)_5]^-$, $[(C_5Me_5)Ir(\mu_2\text{-}H)_3Ir(C_5Me_5)$
3	$[closo\text{-}B_6H_6(\mu_3\text{-}H)]^-$, $[(\mu_3\text{-}H)Rh_3(C_5H_5)_4]$, $[(\mu_3\text{-}H)_4Co_4(C_5H_5)_4]$
4	$[(\mu_4\text{-}H)Ru_8(CO)_{21}H]^{2-}$
5	β-$Mg_2NiH_4(d_4)$ (1 "covalent" Ni–D 149 pm plus 4 "ionic" Mg–D 230 pm)
6	$[HNb_6I_{11}]$, $[HRu_6(CO)_{18}]^-$, $[HCo_6(CO)_{15}]^-$, $[(\mu_6\text{-}H)_2Ni_{12}(CO)_{21}]^{2-}$, $[(\mu_6\text{-}H)Ni_{12}(CO)_{21}]^{3-}$



The crucial experiment suggesting that the H_2 molecule might act as a dihapto ligand to transition metals was the dramatic observation[20] that toluene solutions of the deep purple coordinatively unsaturated 16-electron complexes $[Mo(CO)_3(PCy_3)_2]$ and $[W(CO)_3(PCy_3)_2]$ (where Cy = cyclohexyl) react readily and cleanly with H_2 (1 atm) at low temperatures to precipitate yellow crystals of $[M(CO)_3H_2(PCy_3)_2]$ in 85–95% yield. The

H_2 could be quantitatively removed at room temperature either by partial evacuation or by sparging the solution with argon. Definitive confirmation that the complexes did indeed contain η^2-H_2 came from X-ray and neutron diffraction studies on the bis(tri *i*-propylphosphine) analogue at $-100°$, which revealed the side-on coordination of H_2 as shown in Fig. 3.2.[21] During the past decade many other such compounds have been prepared and studied in great detail, and the field has been well reviewed.[22–24]

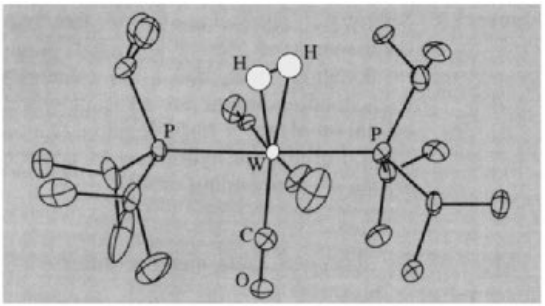

Figure 3.2 The geometry of *mer-trans*-$[W(CO)_3(\eta^2\text{-}H_2)(PPr^i_3)_2]$ from X-ray and neutron diffraction data: r(H–H) 84 pm (compared with 74.14 pm for free H_2), r(W–H) 175 pm. Infrared vibration spectroscopy gives ν(H–H) 2690 cm^{-1} compared with 4159 cm^{-1} (Raman) for free H_2.

There are two general routes to η^2-H_2 complexes. The first involves direct addition of molecular H_2 either to an unoccupied coordination site in a 16-electron complex (as above) or by displacement of a ligand such as CO, Cl, H_2O in the coordination sphere of an 18-electron complex; in this latter case ultraviolet irradiation may be required to assist in the substitution reaction. Examples are:

$$[W(CO)_3(PPr^i_3)_2] + H_2 \longrightarrow [W(CO)_3(\eta^2\text{-}H_2)(PPr^i_3)_2]$$

$$[FeClH(R_2PCH_2CH_2PR_2)_2] + H_2 + NaBPh_4 \longrightarrow [FeH(\eta^2\text{-}H_2)(R_2PCH_2CH_2PR_2)_2]^+ + BPh_4^- + NaCl$$

$$\textit{trans}\text{-}[IrH(H_2O)(PPh_3)_2(Bq)]^+ + H_2 \longrightarrow \textit{trans}\text{-}[IrH(\eta^2\text{-}H_2)(PPh_3)_2(Bq)]^+$$

$$[Cr(CO)_6] + H_2 \xrightarrow[\text{liq. Xe}]{h\nu} [Cr(CO)_5(\eta^2\text{-}H_2)] + CO$$

$$Co(CO)_3(NO) + H_2 \xrightarrow[\text{liq. Xe}]{h\nu} [Co(CO)_2(\eta^2\text{-}H_2)(NO)] + CO$$

The second general method involves the protonation of a polyhydrido complex using a strong acid such as $HBF_4.Et_2O$. Typical examples involving d^2, d^4, d^6 or d^8 metal centres are:

(d^2) $[MoH_4(dppe)_2] + 2H^+ \longrightarrow [MoH_4(\eta^2\text{-}H_2)(dppe)_2]^{2+}$

(d^4) $[IrH_5(PCy_3)_2] \underset{NEt_3}{\overset{H^+}{\rightleftharpoons}} [IrH_2(\eta^2\text{-}H_2)_2(PCy_3)_2]^+$

(d^6) $[RuH_2(dppe)_2] + H^+ \longrightarrow [RuH(\eta^2\text{-}H_2)(dppe)_2]^+$

(d^8) $[RhH\{P(CH_2CH_2PPh_2)_3\}] + H^+ \longrightarrow [Rh(\eta^2\text{-}H_2)\{P(CH_2CH_2PPh_2)_3\}]^+$

There is even a rare example involving a d^0 polyhydride:[25]

(d^0) $[ReH_7(PCy_3)_2] \underset{NEt_3}{\overset{H^+(-80°)}{\rightleftharpoons}} [ReH_{8-2x}(\eta^2\text{-}H_2)_x(PCy_3)_2]^+$

If deuterio acids are used then η^2-HD complexes are formed; these are particularly useful in establishing the retention of substantive H–H bonding in the coordinated ligand by observation of a 1:1:1 triplet in the proton nmr spectrum (the proton signal being split by coupling to deuterium with nuclear spin $J = 1$).

The stability of η^2-H_2 complexes varies considerably, from those which can be observed only in low-temperature matrix-isolation experiments to those which are moderately robust even at room temperature and above. Stability depends on the electron configuration of the metal centre, the electronic and steric nature of the co-ligands, the overall charge on the complex, the state of aggregation and, of course, the temperature. Most η^2-H_2 complexes involve transition metals in Groups 6–8, in oxidation states having a formal d^6 electron configuration. No η^2-H_2 complexes are yet known for transition metals in Groups 3 or 4 of the periodic table, although examples involving Group 5 metals have recently been reported, e.g. the d^4 species $[V(\eta^5\text{-}C_5H_5)(CO)_3(\eta^2\text{-}H_2)]$[26] and $[Nb(\eta^5\text{-}C_5H_5)(CO)_3(\eta^2\text{-}H_2)]$.[27] Within a given Group, the first and second members more readily form η^2-H_2 complexes while the third member tends to form polyhydrido species, e.g. $[Fe(H)_2(\eta^2\text{-}H_2)(PEtPh_2)_3]$ and $[Ru(H)_2(\eta^2\text{-}H_2)(PPh_3)_3]$ but $[Os(H)_4(P(o\text{-tol})_3)_3]$.[28] Stability is also enhanced by an overall cationic charge on the complex (remember protonation as a route to η^2-H_2 complexes). In such cases, however, stability of the resulting compound depends on the presence of a non-coordinating anion such as BF_4^-, otherwise there is a risk of decomposition by displacement of the more weakly coordinating (η^2-H_2). Neutral complexes are also well known, but no examples of anionic η^2-H_2 complexes have been reported.

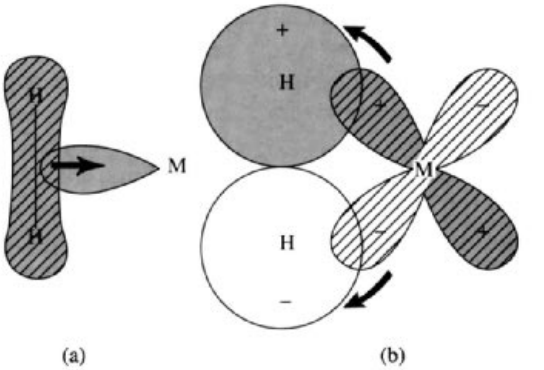

Figure 3.3 Schematic representation of the two components of the η^2-H_2-metal bond: (a) donation from the filled (hatched) σ-H_2 bonding orbital into a vacant hybrid orbital on M; (b) π-back donation from a filled d orbital (or hybrid) on M into the vacant σ^* antibonding orbital of H_2.

Most of the observed facts can be understood in terms of a bonding scheme which envisages donation of electron density from the σ bond of H_2 into a vacant hybrid orbital on the metal, plus a certain amount of synergic back donation from an occupied d orbital on the metal into the σ^* antibonding orbital of H_2 (see Fig. 3.3). This is reminiscent of the bonding in the well known metal–alkene complexes (to be discussed in more detail on p. 931) but with two significant differences: (a) the electron density being donated from the H_2 ligand is in the single-bond σ orbital whereas for alkenes such as $H_2C{=}CH_2$ it is in the π component of the double bond; and (b) the H_2 antibonding orbital involved in accepting back-donated electron density has σ^* symmetry rather than π^* as in alkenes. It is clear from this description that an overall positive charge on the metal centre encourages forward donation to form the 3-centre  bond, but diminishes the extent of back donation. By contrast, an overall negative charge might be expected to enhance back donation into the σ^* antibonding orbital and thus promote rupture of the H_2 single bond, with concommitant formation of two new hydrido M–H bonds.

[28] R. H. Crabtree and D. G. Hamilton, *J. Am. Chem. Soc.* **108** 3124–5 (1986).

The bonding scheme is also consistent with the observed lengthening of the H–H distance to about 84–90 pm in the η^2-H_2 complexes (as compared with 74 pm in free molecular H_2), and with the lowering of the ν(H–H) vibration frequency from 4159 cm^{-1} in free H_2 to values typically in the range 2650–3250 cm^{-1} in the complexes.

There is evidently a very fine balance between the two options {M(η^2-H_2)} and {M$(H)_2$}; indeed, examples of an equilibrium between the two forms have recently been discovered:[27,29,30]

$$[Nb(\eta^5\text{-}C_5H_5)(CO)_3(\eta^2\text{-}H_2)] \overset{-78^\circ \text{ to } +25^\circ}{\rightleftharpoons} [Nb(\eta^5\text{-}C_5H_5)(CO)_3(H)_2]$$

$$[Re(CO)(\eta^2\text{-}H_2)(H)_2(PMe_2Ph)_3]^+ \overset{-85^\circ \text{ to } -65^\circ}{\rightleftharpoons} [Re(CO)(H)_4(PMe_2Ph)_3]^+$$

$$[Ru(\eta^2\text{-}H_2)(\eta^2\text{-}O_2CCF_3)(PCy_3)_2] \overset{\text{hexane/r.t.}}{\rightleftharpoons} [Ru(H)_2(\eta^2\text{-}O_2CCF_3)(PCy_3)_2]$$

In the niobium system[27] the η^2-H_2 form is marginally the more stable, with $\Delta H = 2.0\,kJ\,mol^{-1}$, whereas in the rhenium system,[29] it is the tetrahydrido form which is the more stable, with $-\Delta G_{208} = 2.5\,kJ\,mol^{-1}$ and $-\Delta H = 4.6\,kJ\,mol^{-1}$.

In a sense the formation of η^2-H_2 complexes can be thought of as an intermediate stage in the oxidative addition of H_2 to form two M–H bonds and, as such, the complexes might serve as a model for this process and for catalytic hydrogenation reactions by metal hydrides.[31] Indeed, intermediate cases between η^2-H_2 and (σ-H)$_2$ coordination are occasionally observed, as in [$ReH_7(P(p\text{-tol})_3)_2$], where neutron-diffraction studies[32] have revealed one H···H contact of 137.7(7) pm whereas all other H···H distances in the complex are greater than 174 pm. (This distance of 137.7 pm is seen to be intermediate between values of *ca.* 80 pm typical of η^2-H_2 complexes and values greater than *ca.* 160 pm which are found in classical hydrido complexes.) Likewise, some trihydrogen complexes, such as [$Ir(\eta^5\text{-}C_5H_5)H_3(PMe_3)$],[33] have nmr behaviour which suggests the presence of a bent (or possibly triangular) η^3-H_3 ligand which is bonded "side-on" rather like an allylic group (pp. 933–5).

The possibility of η^1-H_2 "end-on" coordination has also been mooted. For example, deposition of Pd atoms onto a krypton matrix doped with H_2 at 12 K apparently yields both Pd(η^1-H_2) and Pd(η^2-H_2) species, whereas with a Xe/H_2 matrix only Pd(η^2-H_2) was obtained.[34] Again, the complex [$ReCl(H_2)(PMePh_2)_4$] appears to feature an asymmetrically-bonded H_2 ligand which may well be (η^1-H_2).[35]

Nearly one hundred η^2-H_2 complexes have so far been prepared and the crystal and molecular structure of about half a dozen have been determined by X-ray/neutron diffraction. Some are dinuclear, such as the homobimetallic [(P–N)($\boldsymbol{\eta^2}$-$\mathbf{H_2}$)**Ru**(μ-Cl)$_2$(μ-H)**Ru**(H)$(PPh_3)_2$][36] and the heterobimetallic [$(PPh_3)_2$**HRe**(μ-H)(μ-Cl)$_2$(μ-CO)**Ru**($\boldsymbol{\eta^2}$-$\mathbf{H_2}$)$(PPh_3)_2]^+$.[37]

The coordination chemistry of hydrogen is still being intensively studied and new developments are continually being reported.

3.5 Protonic acids and bases[38]

Many compounds that contain hydrogen can donate protons to a solvent such as water and so behave as acids. Water itself undergoes ionic dissociation to a small extent by means of autoprotolysis; the process is usually represented formally by the equilibrium

$$H_2O + H_2O \rightleftharpoons H_3O^+ + OH^-$$

though it should be remembered that both ions are further solvated and that the time a proton spends in close association with any one water molecule is probably only about 10^{-13} s. (See also pp. 630–2 for structural studies on $[H(OH_2)_n]^+$ $n = 1$–6.) Depending on what aspect of the process is being emphasized, the species $H_3O^+(aq)$ can be called an oxonium ion, a hydrogen ion, or simply a solvated (hydrated) proton. The equilibrium constant for autoprotolysis is

$$K_1 = [H_3O^+][OH^-]/[H_2O]^2$$

and, since the concentration of water is essentially constant, the ionic product of water can be written as

$$K_w = [H_3O^+][OH^-] \text{ mol}^2\,l^{-2}$$

The value of K_w depends on the temperature, being 0.69×10^{-14} mol^2 l^{-2} at 0°C, 1.00×10^{-14} at 25°C and 47.6×10^{-14} at 100°C. It follows that the hydrogen-ion concentration in pure water at 25°C is 10^{-7} mol l^{-1}. Acids increase this concentration by means of the reaction

$$HA + H_2O \rightleftharpoons H_3O^+ + A^-;$$

$$K = \frac{[H_3O^+][A^-]}{[HA][H_2O]}$$

It is to be understood that all the species are in aqueous solution and the symbol HA implies only that the (aquated) species can act as a proton donor: it can be a neutral species (e.g. H_2S), an anion (e.g. $H_2PO_4^-$) or a cation such as $[Fe(H_2O)_6]^{3+}$. The hydrogen-ion concentration is usually expressed as pH (see Panel). In dilute solution the concentration of water molecules is constant at 25°C (55.345 mol l^{-1}), and the dissociation of the acid is often rewritten as

$$HA \rightleftharpoons H^+ + A^-;$$

$$K_a = [H^+][A^-]/[HA] \text{ mol}\,l^{-1}$$

The acid constant K_a can also be expressed by the relation

$$pK_a = -\log K_a. \quad \text{Hence, as } K_a = 55.345\,K$$

$$pK_a = pK - 1.734$$

Further, as the free energy of dissociation is given by

$$\Delta G^\circ = -RT \ln K = -2.3026RT \log K,$$

the standard free energy of dissociation is

$$\Delta G^\circ_{298.15} = 5.708pK$$

$$= 5.708(pK_a + 1.734) \text{ kJ mol}^{-1}$$

Textbooks of analytical chemistry should be consulted for further details concerning the ionization of weak acids and bases and the theory of indicators, buffer solutions, and acid–alkali titrations.[39–41]

Various trends have long been noted in the acid strengths of many binary hydrides and oxoacids.[38] Values for some simple hydrides are given in Table 3.4 from which it is clear that acid strength increases with atomic number both in any one horizontal period and in any

ELVING (eds.), *Treatise on Analytical Chemistry*, 2nd edn., Vol. 2, Part 1, 1979, pp. 157–236. Succeeding chapters (pp. 237–440) deal with acid–base equilibria and titrations in non-aqueous solvents.

The Concept of pH

The now universally used measure of the hydrogen-ion concentration was introduced in 1909 by the Danish biochemist S. P. L. Sørensen during his work at the Carlsberg Breweries (*Biochem. Z.* **21**, 131, 1909):

$$\mathrm{pH} = -\log[\mathrm{H}^+]$$

The symbol pH derives from the French *puissance d'hydrogéne*, referring to the exponent or "power of ten" used to express the concentration. Thus a hydrogen-ion concentration of 10^{-7} mol l^{-1} is designated pH 7, whilst acid solutions with higher hydrogen-ion concentrations have a lower pH. For example, a strong acid of concentration 1 mmol l^{-1} has pH 3, whereas a strong alkali of the same concentration has pH 11 since $[\mathrm{H_3O^+}] = 10^{-14}/[\mathrm{OH^-}] = 10^{-11}$.

Unfortunately, it is far simpler to define pH than to measure it, despite the commercial availability of instruments that purport to do this. Most instruments use an electrochemical cell such as

$$\text{glass electrode}|\text{test solution}|3.5\ \text{M KCl(aq)}|\mathrm{Hg_2Cl_2}|\mathrm{Hg}$$

Assuming that the glass electrode shows an ideal hydrogen electrode response, the emf of the cell still depends on the magnitude of the liquid junction potential E_j and the activity coefficients γ of the ionic species:

$$E = E^\circ - \frac{RT}{F}\ln \gamma_{\mathrm{Cl}}[\mathrm{Cl^-}] + E_j - \frac{RT}{F}\ln \gamma_{\mathrm{H}}[\mathrm{H^+}]$$

For this reason, the pH as measured by any of the existing national standards is an operational quantity which has no simple fundamental significance. It is defined by the equation

$$\mathrm{pH(X)} = \mathrm{pH(S)} + \frac{(E_x - E_s)F}{RT\ln 10}$$

where pH(S) is the *assigned* pH of a standard buffer solution such as those supplied with pH meters.

Only in the case of dilute aqueous solutions (<0.1 mol l^{-1}) which are neither strongly acid or alkaline ($2 < \mathrm{pH} < 12$) is pH(X) such that

$$\mathrm{pH(X)} = -\log[\mathrm{H^+}]\gamma_\pm \pm 0.02$$

where $\gamma_\pm$, the mean ionic activity coefficient of a typical uni-univalent electrolyte, is given by

$$-\log \gamma_\pm = AI^{\frac{1}{2}}(1 + I)^{-\frac{1}{2}}$$

In this expression I is the ionic strength of the solution and A is a temperature-dependent constant ($0.511\frac{1}{2}$ $\mathrm{mol}^{-\frac{1}{2}}$ at 25°C; $0.501\frac{1}{2}$ $\mathrm{mol}^{-\frac{1}{2}}$ at 15°C). It is clearly unwise to associate a pH meter reading too closely with pH unless under very controlled conditions, and still less sensible to relate the reading to the actual hydrogen-ion concentration in solution. For further discussion of pH measurements, see *Pure Appl. Chem.* **57**, 531–42 (1985): Definition of pH Scales, Standard Reference Values, Measurement of pH and Related Terminology. Also *C&E News*, Oct. 20, 1997, p. 6.

Table 3.4 Approximate values of pK_a for simple hydrides

CH_4	46	NH_3	35	OH_2	16	FH	3
		PH_3	27	SH_2	7	ClH	−7
				SeH_2	4	BrH	−9
				TeH_2	3	IH	−10

vertical group. Several attempts have been made to interpret these trends, at least qualitatively, but the situation is complex. The trend to increasing acidity from left to right in the periodic table could be ascribed to the increasing electronegativity of the elements which would favour release of the proton, but this is clearly not the dominant effect within any one group since the trend there is in precisely the opposite direction. Within a group it is the diminution in bond strength with increasing atomic number that prevails, and entropies of solvation are also important. It should, perhaps, also be emphasized that thermodynamic computations do not "explain" the observed acid strengths; they merely allocate the overall values of ΔG,

ΔH and ΔS to various notional subprocesses such as bond dissociation energies, ionization energies, electron affinities, heats and entropies of hydration, etc., which themselves have empirically observed values that are difficult to compute *ab initio*.

Regularities in the observed strengths of oxoacids have been formulated in terms of two rules by L. Pauling and others:

(i) for polybasic mononuclear oxoacids, successive acid dissociation constants diminish approximately in the ratios $1{:}10^{-5}{:}10^{-10}{:}\ldots$;

(ii) the value of the first ionization constant for acids of formula $XO_m(OH)_n$ depends sensitively on m but is approximately independent of n and X for constant m, being $\leq 10^{-8}$ for $m = 0$, $\sim 10^{-2}$ for $m = 1$, $\sim 10^{3}$ for $m = 2$, and $> 10^{8}$ for $m = 3$.

Thus to illustrate the first rule:

$$H_3PO_4 \rightleftharpoons H^+ + H_2PO_4^-;$$

$$K_1 = \frac{[H^+][H_2PO_4^-]}{[H_3PO_4]} = 7.11 \times 10^{-3}\,\text{mol}\,l^{-1};$$

$$pK_1 = 2.15$$

$$H_2PO_4^- \rightleftharpoons H^+ + HPO_4^{2-};$$

$$K_2 = \frac{[H^+][HPO_4^{2-}]}{[H_2PO_4^-]} = 6.31 \times 10^{-8}\,\text{mol}\,l^{-1};$$

$$pK_2 = 7.20$$

$$HPO_4^{2-} \rightleftharpoons H^+ + PO_4^{3-};$$

$$K_3 = \frac{[H^+][PO_4^{3-}]}{[HPO_4^{2-}]} = 4.22 \times 10^{-13}\,\text{mol}\,l^{-1};$$

$$pK_3 = 12.37$$

Qualitatively, a reduction in pK_a for each successive stage of ionization is to be expected since the proton must separate from an anion of increasingly negative charge, though the approximately constant reduction factor of 10^5 is more difficult to rationalize quantitatively.

Acids which illustrate the second rule are summarized in Table 3.5. The qualitative explanation for this regularity is that, with increasing numbers of oxygen atoms the single negative charge on the anion can be spread more widely, thereby reducing the electrostatic energy attracting the proton and facilitating the ionization. On this basis one might expect an even more dramatic effect if the anion were monoatomic (e.g. S^{2-}, Se^{2-}, Te^{2-}) since the attraction of these dianions for protons will be very strong and the acid dissociation constant of SH^-, SeH^- and TeH^- correspondingly small; this is indeed observed and the ratio of

Table 3.5 Values of pK_a for some mononuclear oxoacids $XO_m(OH)_n$ ($pK_a \approx 8-5n$)

$X(OH)_n$ (very weak)		$XO(OH)_n$ (weak)		$XO_2(OH)_n$ (strong)		$XO_3(OH)_n$ (very strong)	
$Cl(OH)$	7.2	$NO(OH)$	3.3	$NO_2(OH)$	−1.4	$ClO_3(OH)$	(−10)
$Br(OH)$	8.7	$ClO(OH)$	2.0	$ClO_2(OH)$	−1	$MnO_3(OH)$	—
$I(OH)$	10.0	$CO(OH)_2$	3.9[a]	$IO_2(OH)$	0.8		
$B(OH)_3$	9.2	$SO(OH)_2$	1.9	$SO_2(OH)_2$	<0		
$As(OH)_3$	9.2	$SeO(OH)_2$	2.6	$SeO_2(OH)_2$	<0		
$Sb(OH)_3$	11.0	$TeO(OH)_2$	2.7				
$Si(OH)_4$	10.0	$PO(OH)_3$	2.1				
$Ge(OH)_4$	8.6	$AsO(OH)_3$	2.3				
$Te(OH)_6$	8.8	$IO(OH)_5$	1.6				
		$HPO(OH)_2$	1.8[b]				
		$H_2PO(OH)$	2.0[b]				

[a]Corrected for the fact that only 0.4% of dissolved CO_2 is in the form of H_2CO_3; the conventional value is pK_a 6.5.

[b]Note that the value of pK_a for hypophosphorous acid H_3PO_3 is consistent with its (correct) formulation as $HPO(OH)_2$ rather than as $P(OH)_3$, which would be expected to have $pK_a > 8$. Similarly for H_3PO_2, which is $H_2PO(OH)$ rather than $HP(OH)_2$.

Table 3.6 First and second ionization constants for H_2S, H_2Se and H_2Te

	pK_1	pK_2	ΔpK
H_2S	7	14	7
H_2Se	4	12	8
H_2Te	3	11	8

the first and second dissociation constants is $\sim 10^8$ rather than 10^5 (Table 3.6).

The results for dinuclear and polynuclear oxoacids are also consistent with this interpretation. Thus for phosphoric acid, $H_4P_2O_7$, the successive pK_a values are 1.5, 2.4, 6.6 and 9.2; the ~10-fold decrease between pK_1 and pK_2 (instead of a decrease of 10^5) is related to the fact that ionization occurs from two different PO_4 units. The third stage ionization, however, is $\sim 10^5$ less than the first stage and the difference between the mean of the first two and the last two ionization constants is $\sim 5 \times 10^5$.

Another phenomenon that is closely associated with acid–base equilibria is the so-called hydrolysis of metal cations in aqueous solution, which is probably better considered as the protolysis of hydrated cations, e.g.:

"hydrolysis":

$$Fe^{3+} + H_2O \rightleftharpoons [Fe(OH)]^{2+} + H^+$$

protolysis:

$$[Fe(H_2O)_6]^{3+} + H_2O \rightleftharpoons [Fe(H_2O)_5(OH)]^{2+} + H_3O^+; \quad pK_a\ 3.05$$

$$[Fe(H_2O)_5(OH)]^{2+} + H_2O \rightleftharpoons [Fe(H_2O)_4(OH)_2]^{+} + H_3O^+; \quad pK_a\ 3.26$$

It is these reactions that impart the characteristic yellow to reddish-brown coloration of the hydroxoaquo species to aqueous solutions of iron(III) salts, whereas the undissociated ion $[Fe(H_2O)_6]^{3+}$ is pale mauve, as seen in crystals of iron(III) alum $\{[Fe(H_2O)_6][K(H_2O)_6](SO_4)_2\}$ and iron(III) nitrate $\{[Fe(H_2O)_6](NO_3)_3.3H_2O\}$. Such reactions may proceed to the stage where the diminished charge on the hydrated cation permits the formation of oxobridged, or hydroxobridged polynuclear species that eventually precipitate as hydrous oxides (see discussion of the chemistry of many elements in later chapters). A useful summary is in Fig. 3.4. By contrast, extensive studies of the pK_a values of hydrated metal ions in solution has generated a wealth of numerical data but no generalizations such as those just discussed for the hydrides and oxoacids of the non-metals.[42] Typical pK_a values fall in the range 3–14 and, as expected, there is a general tendency for protolysis to be greater (pK_a values to be lower) the higher the cationic charge. For example, aqueous solutions of iron(III) salts are more acidic than solutions of the corresponding iron(II) salts. However, it is difficult to discern any regularities in pK_a for series of cations of the same ionic charge, and it is clear that specific "chemical" effects must also be considered.

Brønsted acidity is not confined to dilute aqueous solutions and the ideas developed in the preceding pages can be extended to proton donors in nonaqueous solutions.[43,44] In organic solvents and anhydrous protonic liquids the concepts of hydrogen-ion concentration and pH, if not actually meaningless, are certainly operationally inapplicable and acidity must be defined on some other scale. The one most frequently used is the Hammett acidity function H_0 which enables various acids to be compared in a given solvent and a given acid to be compared in various solvents. For the equilibrium between a base and its conjugate acid (frequently a coloured indicator)

$$B + H^+ \rightleftharpoons BH^+$$

the acidity function is defined as

$$H_0 = pK_{BH^+} - \log\{[BH^+]/[B]\}$$

In very dilute solutions

$$K_{BH^+} = [B][H^+]/[BH^+]$$

so that in water H_0 becomes the same as pH. Some values for typical anhydrous acids are in Table 3.7 and these are discussed in more detail in appropriate sections of later chapters.

Table 3.7 Hammett acidity functions for some anhydrous acids

Acid	$-H_0$	Acid	$-H_0$
$HSO_3F + SbF_5$	15–27	HF	~11
$HF + SbF_5$ (1M)	20.4	H_3PO_4	5.0
HSO_3F	15.0	H_2SO_4 (63% in H_2O)	4.9
H_2SO_4	12.0	HCO_2H	2.2

It will be noted that addition of SbF_5 to HF considerably enhances its acidity and the same effect can be achieved by other fluoride acceptors such as BF_3 and TaF_5:

$$2HF + MF_n \rightleftharpoons H_2F^+ + MF_{n+1}^-$$

The enhancement of the acidity of HSO_3F by the addition of SbF_5 is more complex and the equilibria involved are discussed on p. 570.

3.6 The Hydrogen Bond[45-7]

The properties of many substances suggest that, in addition to the "normal" chemical bonding between the atoms and ions, there exists some further interaction involving a hydrogen atom placed between two or more other groups of atoms. Such interaction is called hydrogen bonding and, though normally weak (10–60 kJ per mol of H-bonded H), it frequently has a decisive influence on the structure and properties of the substance. A hydrogen bond can be said to exist between 2 atoms A and B when these atoms approach more closely than would otherwise be expected in the absence of the hydrogen atom and when, as a result, the system has a lower total energy. The bond is represented

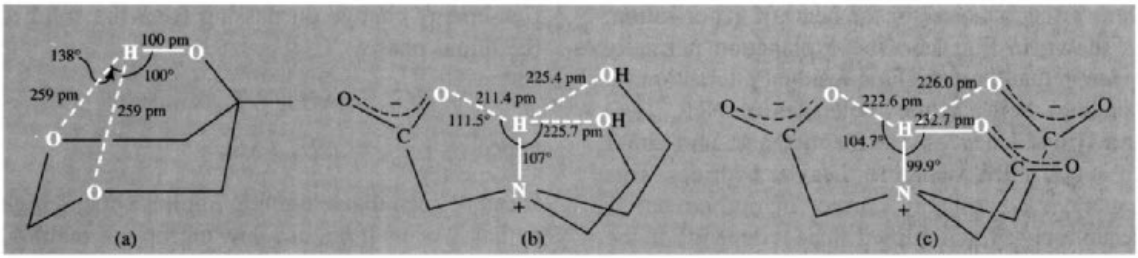

Figure 3.5 Some examples of branched H bonds: (a) the bifurcated bond in 1,3-dioxanol-5[49]; and trifurcated bonds in (b) *N,N*-bis(2-hydroxyethyl)glycine[50] and (c) the nitrilotriacetate dianion.[51]

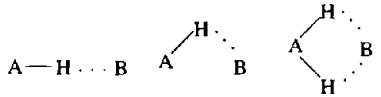
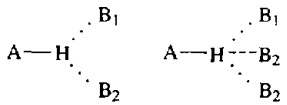
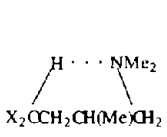
as A–H···B and usually occurs when A is sufficiently electronegative to enhance the acidic nature of H (proton donor) and where the acceptor B has a region of high electron density (such as a lone pair of electrons) which can interact strongly with the acidic hydrogen. In fact, the H bond in A–H···B can be either linear as in schematic structure (1) or significantly non-linear as in structures (1b) and (1c). H-bonds can also join three adjacent atoms (bifurcated) as in structure (2) or even four atoms (trifurcated) as in structure (3).

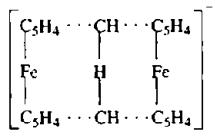




Thus, in a recent survey of 1509 N–H···O=C hydrogen bonds in organic carbonyls or carboxylates, nearly 80% (1199) were unbranched, some 20% (304) were bifurcated, but only 0.4% (6) were trifurcated.[48] Some examples are in Fig. 3.5.

It will be convenient first to indicate the range of phenomena which are influenced by H bonding and then to discuss more specifically the nature of the bond itself according to current theories. The experimental evidence suggests that strong H bonds can be formed when A is F, O or N; weaker H bonds are sometimes formed when A is C or a second row element, P, S, Cl or even Br, I. Strong H bonds are favoured when the atom B is F, O or N; the other halogens Cl, Br, I are less effective unless negatively charged and the atoms C, S and P can also sometimes act as B in weak H bonds. Recent examples of C–H···N and C–H···C bonds are in bis(phenylsulfonyl)trimethylbutylamine (4)[52] and the carbanion of [1.1]ferrocenophane (5).[53]





3.6.1 Influence on properties

It is well known that the mps and bps of NH_3, H_2O and HF are anomalously high when compared with the mps and bps of the hydrides of other elements in Groups 15, 16 and 17, and the

same effect is noted for the heats of vaporization, as shown in Fig. 3.6. The explanation normally given is that there is some residual interaction (H bonding) between the molecules of NH_3, H_2O and HF which is absent for methane, and either absent or much weaker for heavier hydrides. This argument is probably correct in outline but is deceptively oversimplified since it depends on the assumption that only some of the H bonds in solid HF (for example) are broken during the melting process and that others are broken on vaporization, though not all, since HF is known to be substantially polymerized even in the gas phase. The mp is the temperature at which there is zero free-energy change on passing from the solid to the liquid phase:

$$\Delta G_m = \Delta H_m - T_m \Delta S_m = 0;$$

hence $$T_m = \Delta H_m / \Delta S_m$$

It can be seen that a high mp implies either a high enthalpy of melting, or a low entropy of melting, or both. Similar arguments apply to vaporization and the bp, and indicate the difficulties in quantifying the discussion.

Other properties that are influenced by H bonding are solubility and miscibility, heats of mixing, phase-partitioning properties, the

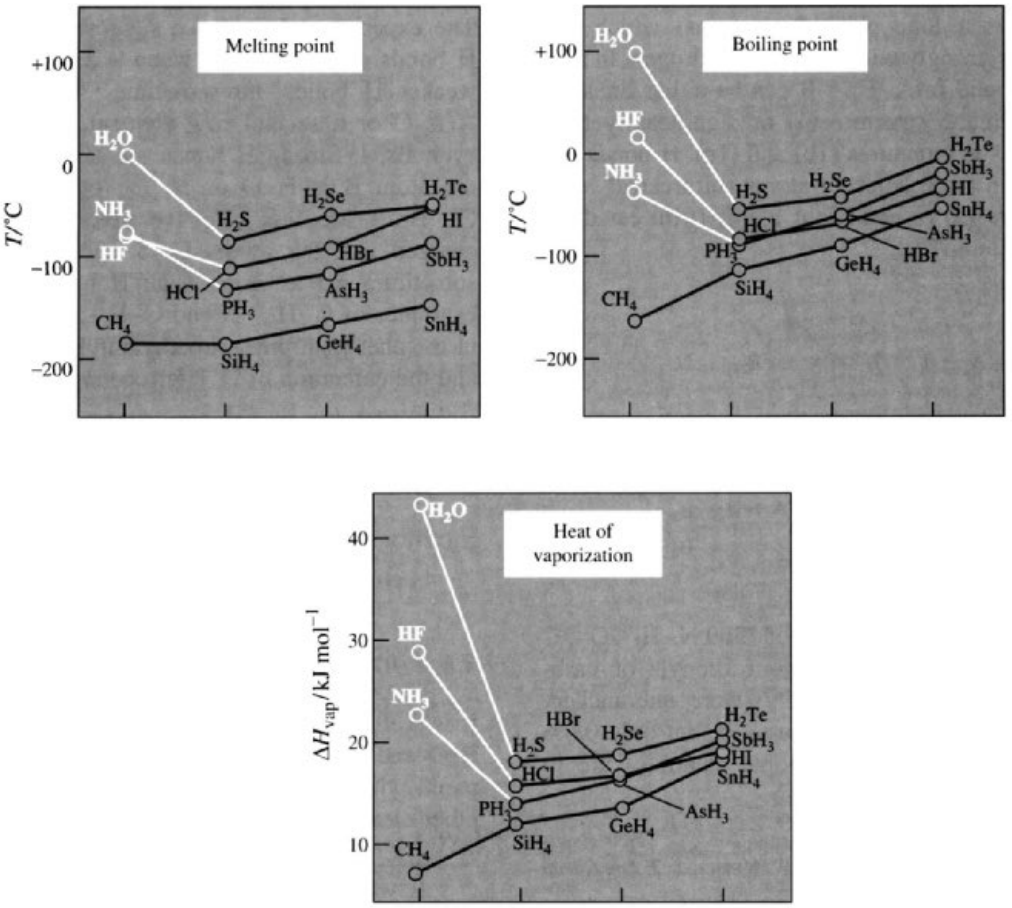

Figure 3.6 Plots showing the high values of mp, bp and heat of vaporization of NH_3, H_2O and HF when compared with other hydrides. Note also that the mp of CH_4 (−182.5°C) is slightly higher than that of SiH_4 (−185°C).

existence of azeotropes, and the sensitivity of chromatographic separation. Liquid crystals (or mesophases) which can be regarded as "partly melted" solids also frequently involve molecules that have H-bonded groups (e.g. cholesterols, polypeptides, etc.). Again, H bonding frequently results in liquids having a higher density and lower molar volume than would otherwise have been expected, and viscosity is also affected (e.g. glycerol, anhydrous H_2SO_4, H_3PO_4, etc.).

Electrical properties of liquids and solids are sometimes crucially influenced by H bonding. The ionic mobility and conductance of H_3O^+ and OH^- in aqueous solutions are substantially greater than those of other univalent ions due to a proton-switch mechanism in the H-bonded associated solvent, water. For example, at 25°C the conductance of H_3O^+ and OH^- are 350 and 192 $ohm^{-1}\,cm^2\,mol^{-1}$, whereas for other (viscosity-controlled) ions the values fall mainly in the range 50–75 $ohm^{-1}\,cm^2\,mol^{-1}$. (To convert to mobility, $v\,cm^2\,s^{-1}\,V^{-1}$, divide by 96 485 $C\,mol^{-1}$.) It is also notable that the dielectric constant is not linearly related to molecular dipole moments for H-bonded liquids being much higher due to the orientating effect of the H bonds: large domains are able to align in an applied electric field so that the molecular dipoles reinforce one another rather than cancelling each other due to random thermal motion. Some examples are given in Fig. 3.7, which also illustrates the substantial influence of temperature on the dielectric constant of H-bonded liquids presumably due to the progressive thermal dissociation of the H bonds. Even more dramatic are the properties of ferroelectric crystals where there is a stable permanent electric polarization (see Fig. 3.8). Hydrogen bonding is one of the important ordering mechanisms

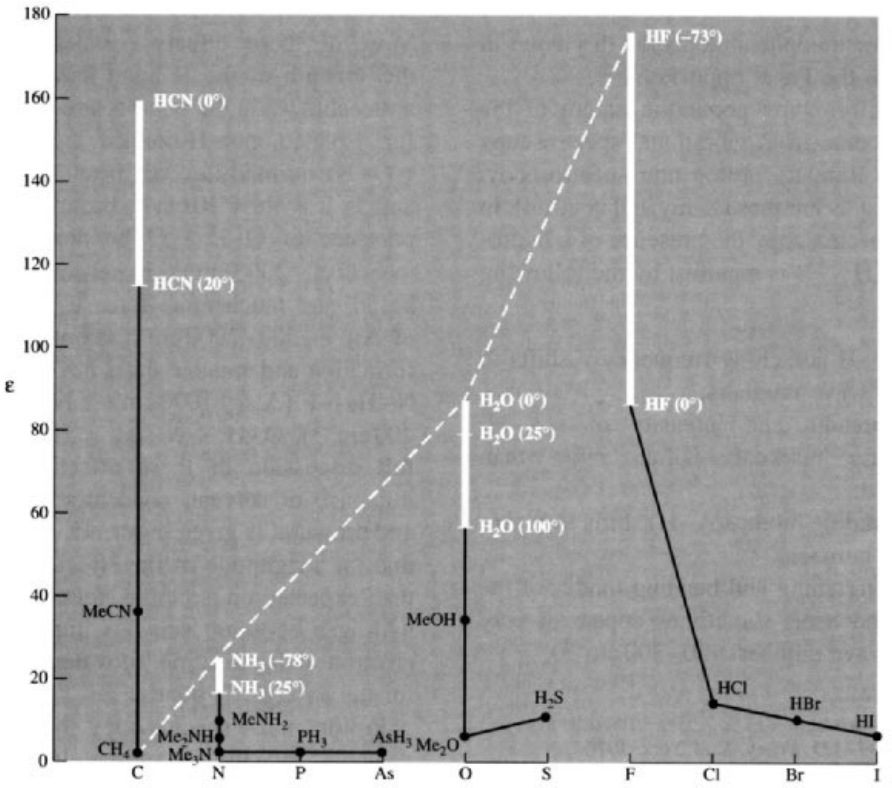

Figure 3.7 Dielectric constant of selected liquids.

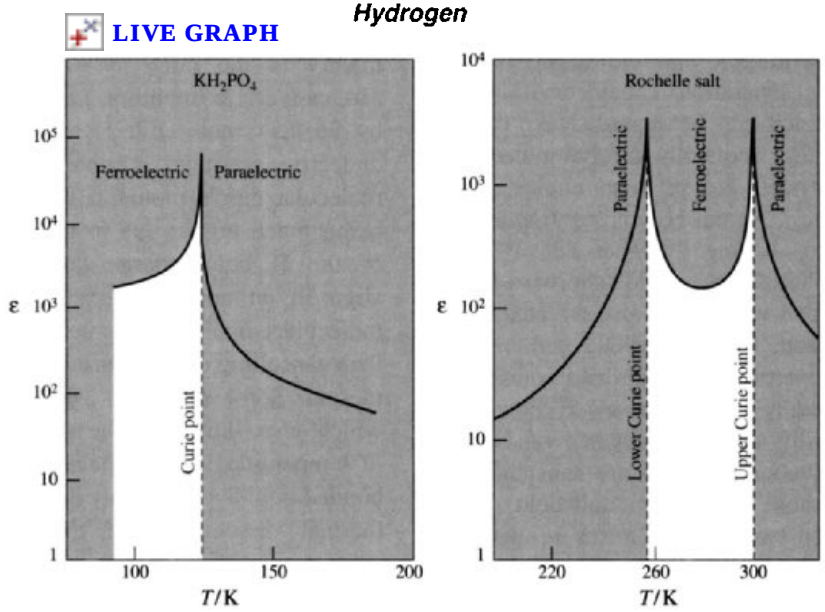

Figure 3.8 Anomalous temperature dependence of relative dielectric constant of ferroelectric crystals at the transition temperature (Curie point).

responsible for this phenomenon as discussed in more detail in the Panel opposite.[54,55]

Intimate information about the nature of the H bond has come from vibrational spectroscopy (infrared and Raman), proton nmr spectroscopy, and diffraction techniques (X-ray and neutron). In vibrational spectroscopy the presence of a hydrogen bond A–H···B is manifest by the following effects:

(i) the A–H stretching frequency ν shifts to lower wave numbers;
(ii) the breadth and intensity of ν(A–H) increase markedly, often more than tenfold;
(iii) the bending mode δ(A–H) shifts to higher wave numbers;
(iv) new stretching and bending modes of the H bond itself sometimes appear at very low wave numbers (20–200 cm^{-1}).

Most of these effects correlate roughly with the strength of the H bond and are particularly noticeable when the bond is strong. For example, for isolated non-H-bonded hydrogen groups, ν(O–H) normally occurs near 3500–3600 cm^{-1} and is less than 10 cm^{-1} broad whereas in the presence of O–H···O bonding $\nu_{antisym}$ drops to ~1700–2000 cm^{-1}, is several hundred cm^{-1} broad, and much more intense. A similar effect of $\Delta\nu \sim$ 1500–2000 cm^{-1} is noted on F–H···F formation and smaller shifts have been found for N–H···F ($\Delta\nu \leq$ 1000 cm^{-1}), N–H···O ($\Delta\nu \leq$ 400 cm^{-1}), O–H···N ($\Delta\nu \leq$ 100 cm^{-1}), etc. A full discussion of these effects, including the influence of solvent, concentration, temperature and pressure, is given in ref. 45. Suffice it to note that the magnitude of the effect is much greater than expected on a simple electrostatic theory of hydrogen bonding, and this implies appreciable electron delocalization (covalency) particularly for the stronger H bonds.

Proton nmr spectroscopy has also proved valuable in studying H-bonded systems. As might be expected, substantial chemical shifts are observed and information can be obtained

Ferroelectric Crystals[54,55]

A ferroelectric crystal is one that has an electric dipole moment even in the absence of an external electric field. This arises because the centre of positive charge in the crystal does not coincide with the centre of negative charge. The phenomenon was discovered in 1920 by J. Valasek in Rochelle salt, which is the H-bonded hydrated d-tartrate $NaKC_4H_4O_6.4H_2O$. In such compounds the dielectric constant can rise to enormous values of 10^3 or more due to presence of a stable permanent electric polarization. Before considering the effect further, it will be helpful to recall various definitions and SI units:

electric polarization $P = D - \varepsilon_0 E (\mathrm{C\,m^{-2}})$
where D is the electric displacement ($\mathrm{C\,m^{-2}}$)
E is the electric field strength ($\mathrm{V\,m^{-1}}$)
ε_0 is the permittivity of vacuum ($\mathrm{F\,m^{-1}} = \mathrm{A\ s\ V^{-1}\,m^{-1}}$)

dielectric constant $\varepsilon = \dfrac{\varepsilon_0 E + P}{\varepsilon_0 E} = 1 + \chi$ (dimensionless)

where $\chi = \varepsilon - 1 = P/\varepsilon_0 E$ is the dielectric susceptibility.
There are two main types of ferroelectric crystal:

(a) those in which the polarization arises from an ordering process typically by H bonding;
(b) those in which the polarization arises by a displacement of one sublattice with respect to another, as in perovskite-type structures like barium titanate (p. 963).

The ferroelectricity usually disappears above a certain transition temperature (often called a Curie temperature) above which the crystal is said to be paraelectric; this is because thermal motion has destroyed the ferroelectric order. Occasionally the crystal melts or decomposes before the paraelectric state is reached. There are thus some analogies to ferromagnetic and paramagnetic compounds though it should be noted that there is no iron in ferroelectric compounds. Some typical examples, together with their transition temperatures and spontaneous permanent electric polarization P_s, are given in the Table.

Table Properties of some ferroelectric compounds

Compound	T_c/K	$P_s/\mu\mathrm{C\,cm^{-2}}$[a]	(at T/K)
KH_2PO_4	123	5.3	(96)
KD_2PO_4	213	4.5	—
KH_2AsO_4	96	3.0	(80)
KD_2AsO_4	162		
RbH_2PO_4	147	5.6	(90)
$(NH_2CH_2CO_2H)_3.H_2SO_4$[b]	322	2.8	(293)
$(NH_2CH_2CO_2H)_3.H_2SeO_4$[b]	295	3.2	(273)
$BaTiO_3$	393	26.0	(296)
$KNbO_3$	712	30.0	(523)
$PbTiO_3$	763	>50.0	(300)
$LiTaO_3$	890	23.0	(720)
$LiNbO_3$	1470	300.0	—

[a] To convert to the basic SI unit of $\mathrm{C\,m^{-2}}$ divide the tabulated values of P_s by 10^2; to convert to the CGS unit of esu $\mathrm{cm^{-2}}$ multiply by 3×10^3. For a full compilation see E. C. Subbarao, *Ferroelectrics* **5**, 267 (1973).
[b] Triglycinesulfate and selenate.

In KH_2PO_4 and related compounds each tetrahedral $[PO_2(OH)_2]^-$ group is joined by H bonds to neighbouring $[PO_2(OH)_2]^-$ groups; below the transition temperature all the short O–H bonds are ordered on the same side of the PO_4 units, and by appropriate application of an electric field, the polarization of the H bonds can be reversed. The dramatic effect of deuterium substitution in raising the transition temperature of such compounds can be seen from the Table: this has been ascribed to a quantum-mechanical effect involving the mass dependence of the de Broglie wavelength of hydrogen. Other examples of H-bonded ferroelectrics are $(NH_4)H_2PO_4$, $(NH_4)H_2AsO_4$, $Ag_2H_3IO_6$, $(NH_4)Al(SO_4)_2.6H_2O$ and $(NH_4)_2SO_4$. Rochelle salt is unusual in having both an upper and a lower critical temperature between which the compound is ferroelectric.

Panel continues

The closely related phenomenon of antiferroelectric behaviour is also known, in which there is an ordered, self-cancelling arrangement of permanent electric dipole moments below a certain transition temperature; H bonding is again implicated in the ordering mechanism for several ammonium salts of this type, e.g. $(NH_4)H_2PO_4$ 148 K, $(NH_4)D_2PO_4$ 242 K, $(NH_4)H_2AsO_4$ 216 K, $(NH_4)D_2AsO_4$ 304 K and $(NH_4)_2H_3IO_6$ 254 K. As with ferroelectrics, antiferroelectrics can also arise by a displacive mechanism in perovskite-type structures, and typical examples, with their transition temperatures, are:

$PbZrO_3$ 506 K, $PbHfO_3$ 488 K, $NaNbO_3$ 793, 911 K, WO_3 1010 K.

Ferroelectrics have many practical applications: they can be used as miniature ceramic capacitors because of their large capacitance, and their electro-optical characteristics enable them to modulate and deflect laser beams. The temperature dependence of spontaneous polarization induces a strong pyroelectric effect which can be exploited in thermal and infrared detection. Many applications depend on the fact that all ferroelectrics are also piezoelectrics. Piezoelectricity is the property of acquiring (or altering) an electric polarization P under external mechanical stress, or conversely, the property of changing size (or shape) when subjected to an external electric field E. Thus ferroelectrics have been used as transducers to convert mechanical pulses into electrical ones and vice versa, and find extensive application in ultrasonic generators, microphones, and gramophone pickups; they can also be used as frequency controllers, electric filters, modulating devices, frequency multipliers, and as switches, counters and other bistable elements in computer circuits. A further ingeneous application is in delay lines by means of which an electric signal is transformed piezoelectrically into an acoustic signal which passes down the piezoelectric rod at the velocity of sound until, at the other end, it is reconverted into a (delayed) electric signal.

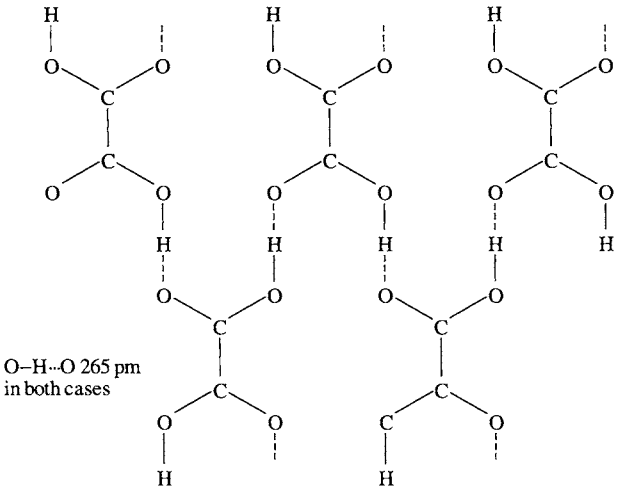
It should be noted that, whereas ferroelectrics are necessarily piezoelectrics, the converse need not apply. The necessary condition for a crystal to be piezoelectric is that it must lack a centre of inversion symmetry. Of the 32 point groups, 20 qualify for piezoelectricity on this criterion, but for ferroelectric behaviour a further criterion is required (the possession of a single non-equivalent direction) and only 10 space groups meet this additional requirement. An example of a crystal that is piezoelectric but not ferroelectric is quartz, and indeed this is a particularly important example since the use of quartz for oscillator stabilization has permitted the development of extremely accurate clocks (1 in 10^8) and has also made possible the whole of modern radio and television broadcasting including mobile radio communications with aircraft and ground vehicles.

concerning H-bond dissociation, proton exchange times, and other relaxation processes. The chemical shift always occurs to low field and some typical values are tabulated below for the shifts which occur between the gas and liquid phases or on dilution in an inert solvent:

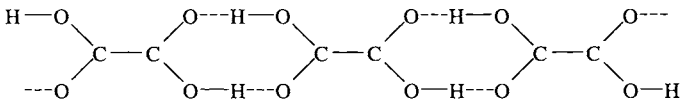
Compound	CH_4	C_2H_6	$CHCl_3$	HCN	NH_3	PH_3
δ ppm	0	0	0.30	1.65	1.05	0.78
Compound	H_2O	H_2S	HF	HCl	HBr	HI
δ ppm	4.58	1.50	6.65	2.05	1.78	2.55

The low-field shift is generally interpreted, at least qualitatively, in terms of a decrease in diamagnetic shielding of the proton: the formation of A–H···B tends to draw H towards B and to repel the bonding electrons in A–H towards A thus reducing the electron density about H and reducing the shielding. The strong electric field due to B also inhibits the diamagnetic circulation within the H atom and this further reduces the shielding. In addition, there is a magnetic anisotropy effect due to B; this will be positive (upfield shift) if the principal symmetry axis of B is towards the H bond, but the effect is presumably small since the overall shift is always downfield.

Ultraviolet and visible spectra are also influenced by H bonding, but the effects are more difficult to quantify and have been rather less used than ir and nmr. It has been found that the $n \rightarrow \pi^*$ transition of the base B always moves to high frequency (blue shift) on H-bond formation, the magnitude of $\Delta\nu$ being $\sim 300-4000\,cm^{-1}$ for bands in the region $15\,000-35\,000\,cm^{-1}$. By contrast $\pi \rightarrow \pi^*$ transitions on the base B usually move to lower frequencies (red shift) and shifts are in the range -500 to $-2300\,cm^{-1}$ for bands in the region $30\,000-47\,000\,cm^{-1}$. Detailed interpretations of these data are somewhat complex and obscure, but it will be noted that the shifts are approximately of the same magnitude as the enthalpy of formation of many H bonds ($83.59\,cm^{-1}$ per atom $\equiv 1\,kJ\,mol^{-1}$).



α-form : layer structure with easy cleavage (H bonds remain intact)



β-form : long chains giving crystals that cleave into laths parallel to the chain

Figure 3.9 Schematic representation of the two forms of oxalic acid, $(-CO_2H)_2$.

3.6.2 Influence on structure [56,57]

The crystal structure of many compounds is dominated by the effect of H bonds, and numerous examples will emerge in ensuing chapters. Ice (p. 624) is perhaps the classic example, but the layer lattice structure of $B(OH)_3$ (p. 203) and the striking difference between the α- and β-forms of oxalic and other dicarboxylic acids is notable (Fig. 3.9). The more subtle distortions that lead to ferroelectric phenomena in KH_2PO_4 and other crystals have already been noted (p. 57). Hydrogen bonds between fluorine atoms result in the formation of infinite zigzag chains in crystalline hydrogen fluoride with F–H···F distance 249 pm and the angle HFH 120.1°. Likewise, the crystal structure of NH_4HF_2 is completely determined by H bonds, each nitrogen atom being surrounded by 8 fluorines, 4 in tetrahedral array at 280 pm due to the formation of N–H···F bonds, and 4 further away at about 310 pm; the two sets of fluorine atoms are themselves bonded pairwise at 232 pm by F–H–F interactions. Ammonium azide NH_4N_3 has the same structure as NH_4HF_2, with N–H···N 298 pm. Hydrogen bonding also leads NH_4F to crystallize with a structure different from that of the other ammonium (and alkali) halides: NH_4Cl, NH_4Br and NH_4I each have a low-temperature CsCl-type structure and a high-temperature NaCl-type structure, but NH_4F adopts the wurtzite (ZnS) structure in which each NH_4^+ group is surrounded tetrahedrally by 4 F to which it is bonded by 4 N–H···F bonds at 271 pm. This is very similar to the structure

[a] Σ = sum of van der Waals' radii (in pm) of A and B (ignoring H which has a value of ~120 pm) and using the values F 135, Cl 180, Br 195, I 215; O 140, S 185; N 150, P 190.

of ordinary ice. Typical values of A–H···B distances found in crystals are given in Table 3.8.

The precise position of the H atom in crystalline compounds containing H bonds has excited considerable experimental and theoretical interest. In situations where a symmetric H bond is possible in principle, it is frequently difficult to decide whether the proton is vibrating with a large amplitude about a single potential minimum or whether it is vibrating with a smaller amplitude but is also statistically disordered between two close sites, the potential energy barrier between the two sites being small.[46,47] It now seems well established that the F–H–F bond is symmetrical in $NaHF_2$ and KHF_2, and that the O–H–O bond is symmetrical in $HCrO_2$. Other examples are the intra-molecular H bonds in potassium hydrogen maleate, $K^+[cis\text{-}\overline{CH{=}CHC(O)O{-}H{-}OC(O)}]^-$ and its monochloro derivative: Numerous other examples of H bonding will be found in later chapters.

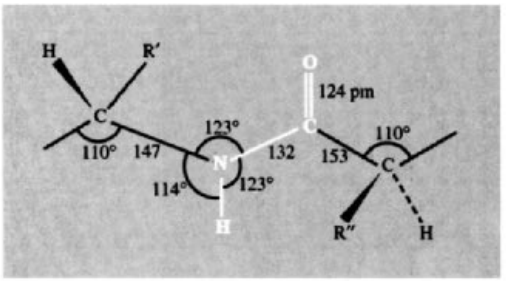
In summary, we can see that H bonding influences crystal structure by linking atoms or groups into larger structural units. These may be:

finite groups: HF_2^-; $[O_2CO{-}H{\cdot\cdot}OCO_2]^{3-}$ in $Na_3H(CO_3)_2.2H_2O$ dimers of carboxylic acids, etc.;
infinite chains: HF, HCN, HCO_3^-, HSO_4^-, etc.;
infinite layers: $N_2H_6F_2$, $B(OH)_3$, $B_3O_3(OH)_3$, H_2SO_4, etc.;
three-dimensional nets: NH_4F, H_2O, H_2O_2, $Te(OH)_6$, $H_2PO_4^-$ in KH_2PO_4, etc.

H bonding also vitally influences the conformation and detailed structure of the polypeptide chains of protein molecules and the complementary intertwined polynucleotide chains which form the double helix in nucleic acids.[56,58] Thus, proteins are built up from polypeptide chains of the type shown at the top of the next column.

These chains are coiled in a precise way which is determined to a large extent by N–H···O hydrogen bonds of length 279 ±

[58] G. A. JEFFREY and W. SAENGER, *Hydrogen Bonding in Biological Structures*, Springer Verlag, Berlin, 1991, 567 pp.



12 pm depending on the amino–acid residue involved. Each amide group is attached by such a hydrogen bond to the third amide group from it in both directions along the chain, resulting in an α-helix of pitch (total rise of helix per turn) of about 538 pm, corresponding to 3.60 amino–acid residues per turn. These helical chains can, in turn, become stretched and form hydrogen bonds with neighbouring chains to generate either parallel-chain pleated sheets (repeat distances 650 pm) or antiparallel-chain pleated sheets (700 pm).

Nucleic acids, which control the synthesis of proteins in the cells of living organisms and which transfer heredity information via genes, are also dominated by H bonding. Their structure involves two polynucleotide chains intertwined to form a double helix. The complimentariness in the structure of the two chains is ascribed to the formation of H bonds between the pyrimidine residue (thymine or cytosine) in one chain and the purine residue (adenine or guanine) in the other as illustrated in Fig. 3.10. Whilst there is still some uncertainty as to the precise configuration of the N–H···O and N–H···N hydrogen bonds in particular cases, the extraordinary fruitfulness of these basic ideas has led to a profusion of developments of fundamental importance in biochemistry.[58]

3.6.3 Strength of hydrogen bonds and theoretical description[59]

Measurement of the properties of H-bonded systems over a range of temperatures leads to experimental values of ΔG, ΔH and ΔS for H-bond formation, and these data have been supplemented in recent years by increasingly reliable *ab initio* quantum-mechanical calculations.[60] Some typical values for the enthalpy of dissociation of H-bonded pairs in the gas phase are in Table 3.9.

The uncertainty in these values varies between ± 1 and $\pm 6\,\text{kJ mol}^{-1}$. In general, H bonds of energy $<25\,\text{kJ mol}^{-1}$ are classified as weak; those in the range $25–40\,\text{kJ mol}^{-1}$ are medium; and those having $\Delta H > 40\,\text{kJ mol}^{-1}$ are strong. Until recently, it was thought that the strongest H bond was that in the hydrogendifluoride ion $[F–H–F]^-$; this is difficult to determine experimentally and values in the range $150–250\,\text{kJ mol}^{-1}$ have been reported. A recent theoretically computed value is $169\,\text{kJ mol}^{-1}$ which agrees well with the value of $163 \pm 4\,\text{kJ mol}^{-1}$ from ion cyclotron resonance studies.[61] In fact, it now seems that the H bond between formic acid and the fluoride ion,

$[HCO_2H\cdots F^-]$, is some $30\,kJ\,mol^{-1}$ stronger than that calculated on the same basis for HF_2^-.[62]

Early discussions on the nature of the hydrogen bond tended to adopt an electrostatic approach in order to avoid the implication of a covalency greater than one for hydrogen. Indeed, such calculations can reproduce the experimental H-bond energies and dipole moments, but this is not a particularly severe test because of the parametric freedom in positioning the charges. However, the purely electrostatic theory is unable to account for the substantial increase in intensity of the stretching vibration ν(A–H) on H bonding or for the lowered intensity of the bending mode δ(A–H). More seriously, such a theory does not account for the absence of correlation between H-bond strength and dipole moment of the base, and it leaves the frequency shifts in the electronic transitions unexplained. Nonlinear A–H···B bonds would also be unexpected, though numerous examples of angles in the range 150–180° are known.[46]

Valence-bond descriptions envisage up to five contributions to the total bond wave function,[45] but these are now considered to be merely computational devices for approximating to the true wave function. Perturbation theory has also been employed and apportions the resultant bond energy between (1) the electrostatic energy of interaction between the fixed nuclei and the electron distribution of the component molecules, (2) Pauli exchange repulsion energy between electrons of like spin, (3) polarization energy resulting from the attraction between the polarizable charge cloud of one molecule and the permanent multipoles of the other molecule, (4) quantum-mechanical charge-transfer energy, and (5) dispersion energy, resulting from second-order induced dipole-induced dipole attraction. The results suggest that electrostatic effects predominate, particularly for weak bonds, but that covalency effects increase in importance as the strength of the bond increases. It is also possible to apportion the energy obtained from *ab initio* SCF-MO calculations in this way.[63] For example, in one particular calculation for the water dimer $HOH\cdots OH_2$, the five energy terms enumerated above were calculated to be: $E_{\text{elec stat}} - 26.5$, $E_{\text{Pauli}} + 18$, $E_{\text{polar}} - 2$, $E_{\text{ch tr}} - 7.5$, E_{disp} $0\,kJ\,mol^{-1}$. There was also a coupling interaction $E_{\text{mix}} - 0.5$, making in all a total attractive force $\Delta E_0 = E_{\text{dimer}} - E_{\text{monomers}} = -18.5\,kJ\,mol^{-1}$. To calculate the enthalpy change ΔH_{298} as listed on p. 61, it is also necessary to consider the work of expansion and the various spectroscopic degrees of freedom:

$$\Delta H_{298} = E_0 + \Delta(PV) + \Delta E_{\text{trans}} + \Delta E_{\text{vib}} + \Delta E_{\text{rot}}$$

Such calculations can also give an indication of the influence of H-bond formation on the detailed electron distribution within the interacting components. There is general agreement that in the system X–A–H···B–Y as compared with the isolated species XAH and BY, there is a net gain of electron density by X, A and B and a net loss of electrons by H and Y. There is also a small transfer of electronic charge (~0.05 electrons) from BY to XAH in moderately strong H bonds ($20–40\,kJ\,mol^{-1}$). In virtually all neutral dimers, the increase in the A–H bond length on H-bond formation is quite small (<5 pm), the one exception so far studied theoretically being $ClH\cdots NH_3$, where the proton position in the H bond is half-way between completely transferred to NH_3 and completely fixed on HCl.

It follows from the preceding discussion that the unbranched H bond can be regarded as a 3-centre 4-electron bond A–H···B in which the 2 pairs of electrons involved are the bond pair in A–H and the lone pair on B. The degree of charge separation on bond formation will depend on the nature of the proton-donor group AH and the Lewis base B. The relation between this 3-centre bond formalism and the 3-centre bond descriptions frequently used for boranes, polyhalides and compounds of xenon is particularly instructive and is elaborated in

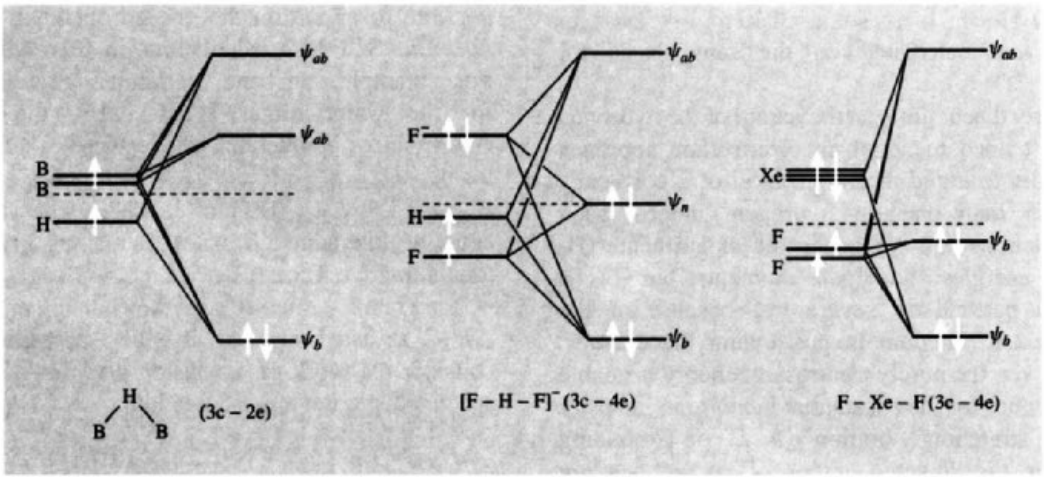

Figure 3.11 Schematic representation of the energy levels in various types of 3-centre bond. The B–H–B ("electron deficient") bond is non-linear, the ("electron excess") F–Xe–F bond is linear, and the A–H···B hydrogen bond can be either linear or non-linear depending on the compound.

Fig. 3.11. Numerous examples are also known in which hydrogen acts as a bridge between metallic elements in binary and more complex hydrides, and some of these will be mentioned in the following section which considers the general question of the hydrides of the elements.

3.7 Hydrides of the Elements[64-6]

Hydrogen combines with many elements to form binary hydrides MH_x (or M_mH_n). All the main-group elements except the noble gases and perhaps indium and thallium form hydrides, as do all the lanthanoids and actinoids that have been studied. Hydrides are also formed by the more electropositive transition elements, notably Sc, Y, La, Ac; Ti, Zr, Hf; and to a lesser extent V, Nb, Ta; Cr; Cu; and Zn. Hydrides of other transition elements are either non-existent or poorly characterized, with the spectacular exception of palladium which has been more studied than any other metal hydride system.[67] The situation is summarized in Fig. 3.12; this indicates the idealized formulae of the known hydrides though many of the d-block and f-block elements form phases of variable compositions.

It has been customary to group the binary hydrides of the elements into various classes according to the presumed nature of their bonding: ionic, metallic, covalent, polymeric, and "intermediate" or "borderline". However, this is unsatisfactory because the nature of the bonding is but poorly understood in many cases and the classification obscures the important point that there is an almost continuous gradation in properties — and bond types(?) — between members of the various classes. It is also somewhat misleading in implying that the various bond types are mutually exclusive whereas it seems likely that more than one type of bonding is present in many cases. The situation is not unique to hydrides but is also well known for

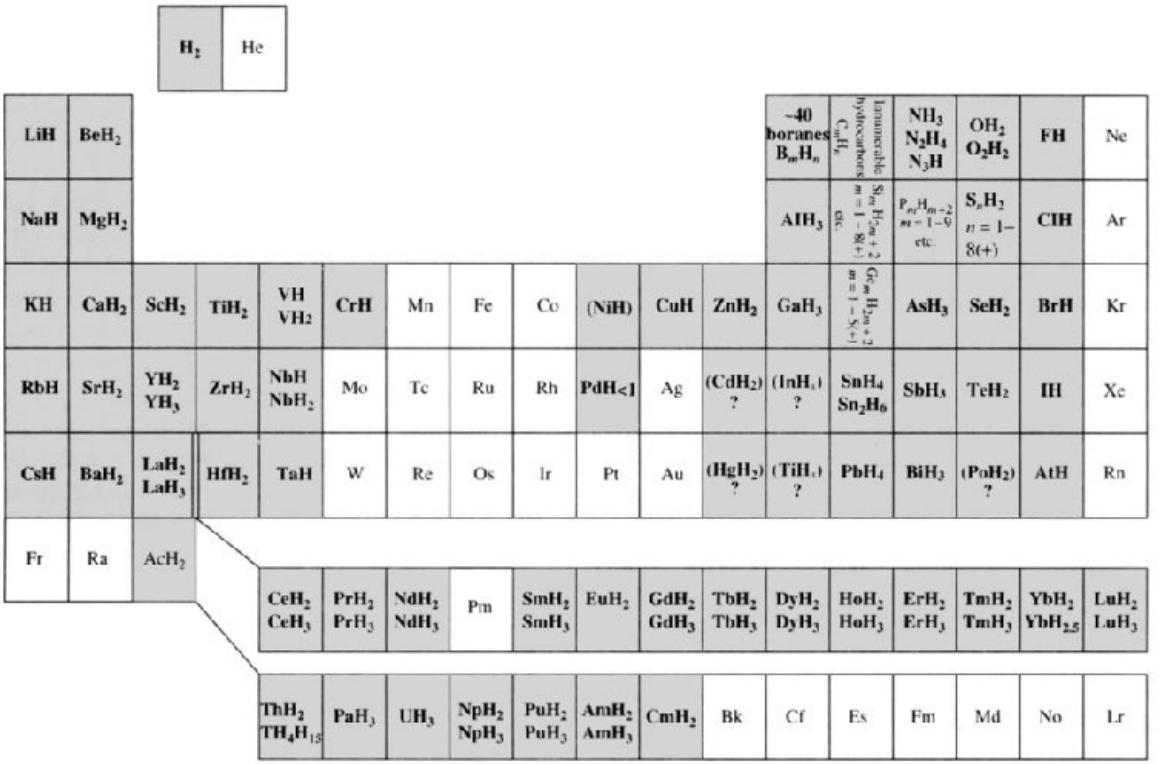

Figure 3.12 The hydrides of the elements.

binary halides, oxides, sulfides, etc.: this serves to remind us that the various bond models represent grossly oversimplified limiting cases and that in most actual systems the position is more complex. For example, oxides might be classed as ionic (MgO), metallic (TiO, ReO_3), covalent (CO_2), polymeric (SiO_2), or as intermediate between these various classes, though any adequate bonding theory would recognize the arbitrary nature of these distinctions which merely emphasize particular features of the overall assembly of molecular orbitals and electron populations.

The metals in Groups 1 and 2 of the periodic table react directly with hydrogen to form white, crystalline, stoichiometric hydrides of formula MX and MX_2 respectively. The salt-like character of these compounds was recognized by G. N. Lewis in 1916 and he suggested that they contained the hydride ion H^-. Shortly thereafter (1920) K. Moers showed that electrolysis of molten LiH (mp 692°C) gave the appropriate amount of hydrogen at the anode; the other hydrides tended to decompose before they could be melted. As expected, the ionic-bond model is most satisfactory for the later (larger) members of each group, and the tendency towards covalency becomes more marked for the smaller elements LiH, MgH_2, and particularly BeH_2, which is best described in terms of polymeric covalent bridge bonds. X-ray and neutron diffraction studies show that the alkali metal hydrides adopt the cubic NaCl structure (p. 242) whereas MgH_2 has the tetragonal TiO_2 (rutile type) structure (p. 961) and CaH_2, SrH_2 and BaH_2 adopt the orthorhombic $PbCl_2$-type structure (p. 382). The implied radius of the hydride ion H^- ($1s^2$) varies considerably with the nature of the metal because of the ready deformability of the pair of electrons surrounding a single proton. Typical values are

given below and these can be compared with $r(F^-) \sim 133$ pm and $r(Cl^-) \sim 184$ pm.

Compound	MgH_2	LiH	NaH	KH	RbH	CsH	Free H^- (calculated)
$r(H^-)$/pm	130	137	146	152	154	152	208

The closest M–M approach in these compounds is often less than for the metal itself: this should occasion no surprise since this is a common feature of many compounds in which there is substantial separation of charge. For example, the shortest Ca–Ca interatomic distance is 393 pm in calcium metal, 360 pm in CaH_2, 380 pm in CaF_2, and only 340 pm in CaO (why?).

The thermal stability of the alkali metal hydrides decreases from lithium to caesium, the temperature at which the reversible dissociation pressure of hydrogen reaches 10 mmHg being ~550°C for LiH, ~210°C for NaH and KH, and ~170°C for RbH and CsH. The corresponding figures for the alkaline earth metal hydrides are CaH_2 885°C, SrH_2 585°C and BaH_2 230°C, though for MgH_2 it is only 85°C. Chemical reactivity depends markedly on both the purity and the state of subdivision but increases from lithium to caesium and from calcium to barium with CaH_2 being rather less reactive than LiH. The reaction of water with these latter two compounds forms a convenient portable source of hydrogen, but with NaH the reaction is more violent than with sodium itself. RbH and CsH actually ignite spontaneously in dry air.

Turning next to Group 3, Fig. 3.12 indicates that hydrides of limiting stoichiometry MH_2 are also formed by Sc, Y, La, Ac and by most of the lanthanoids and actinoids. In the special case of EuH_2 (Eu^{II} $4f^7$) and YbH_2 ($Yb^{II}4f^{14}$) the hydrides are isostructural with CaH_2 and the ionic bonding model gives a reasonable description of the observed properties; however, YbH_2 can absorb more hydrogen up to about $YbH_{2.5}$. The other hydrides adopt the fluorite (CaF_2) crystal structure (p. 118) and the supernumerary valence electron is delocalized, thereby conferring considerable metallic conductivity. For example, LaH_2 is a dark-coloured, brittle compound with a conductivity of about 10 $ohm^{-1}\,cm^{-1}$ (~1% of that of La metal). Further uptake of hydrogen progressively diminishes this conductivity to $<10^{-1}$ $ohm^{-1}\,cm^{-1}$ for the cubic phase LaH_3 (cf. $\sim 3 \times 10^{-5}$ $ohm^{-1}\,cm^{-1}$ for YbH_2). The other Group 3 elements and the lanthanoids and actinoids are similar.

There is a lively controversy concerning the interpretation of these and other properties, and cogent arguments have been advanced both for the presence of hydride ions H^- and for the presence of protons H^+ in the d-block and f-block hydride phases.[64,66] These difficulties emphasize again the problems attending any classification based on presumed bond type, and a phenomenological approach which describes the observed properties is a sounder initial basis for discussion. Thus the predominantly ionic nature of a phase cannot safely be inferred either from crystal structure or from calculated lattice energies since many metallic alloys adopt the NaCl-type or CsCl-type structures (e.g. LaBi, β-brass) and enthalpy calculations are notoriously insensitive to bond type.

The hydrides of limiting composition MH_3 have complex structures and there is evidence that the third hydrogen is sometimes less strongly bound in the crystal. For the earlier (larger) lanthanoids La, Ce, Pr and Nd, hydrogen enters octahedral sites and LnH_3 has the cubic Li_3Bi structure.[57] For Y and the smaller lanthanoids Sm, Gd, Tb, Dy, Ho, Er, Tm and Lu, as well as for the actinoids Np, Pu and Am, the hexagonal HoH_3 structure is adopted. This is a rather complex structure based on an extended unit cell containing 6 Ho and 18 H atoms.[68] The idealized structure has hcp Ho atoms with 12 tetrahedrally coordinated H atoms and 6 octahedrally coordinated H atoms; however, to make room for the bulky Ho atoms, close pairs of tetrahedral H atoms are slightly displaced and there is a more substantial movement of the "octahedral" H atoms towards the planes of the Ho atoms so that 2 of the H atoms are actually in the Ho planes and are trigonal 3-coordinate. The

[68] M. MANSMANN and W. E. WALLACE *J. de Physique* **25**, 454–9 (1964).

hydrogen atoms are thus of three types having respectively 14, 11, and 9 H neighbours for the distorted trigonal, octahedral and tetrahedral sites. Each H atom has 3 Ho neighbours at either 210 or 217 or 224–299 pm respectively, and each Ho has 11 hydrogen neighbours, 9 at 210–229 pm and 2 somewhat further away at 248 pm. The 3-coordinate hydrogen is most unusual, the only other hydride in which it occurs being the complex cubic phase Th_4H_{15}.

Uranium forms two hydrides of stoichiometric composition UH_3. The normal β-form has a complex cubic structure and is the only one formed when the preparation is carried out above 200°C. Below this temperature increasing amounts of the slightly denser cubic α-form occur and this can be transformed to the β-phase by warming to 250°C. Both phases have ferromagnetic and metallic properties. Uranium hydride is commonly used as a starting material for the preparation of uranium compounds as it is finely powdered and extremely reactive. It is also used for purifying and regenerating hydrogen (or deuterium) gas.

The hydrides of Ti, Zr and Hf are characterized by considerable variability in composition and structure. When pure, the limiting phases MH_2 form massive, metallic crystals of fluorite structure (TiH_2) or body-centred tetragonal structure (ZrH_2, HfH_2, ThH_2), but there are also several hydrogen-deficient phases of variable composition and complex structure in which several M–H distances occur.[57,64,66] These phases (and others based on Y, Ce and Nb) have been extensively investigated in recent years because of their potential applications as moderators, reflectors, or shield components for high-temperature, mobile nuclear reactors.

Other hydrides with interstitial or metallic properties are formed by V, Nb and Ta; they are, however, very much less stable than the compounds we have been considering and have extensive ranges of composition. Chromium also forms a hydride, CrH, though this must be prepared electrolytically rather than by direct reaction of the metal with hydrogen. It has the anti-NiAs structure (p. 555). Most other elements in this area of the periodic table have little or no affinity for hydrogen and this has given rise to the phrase "hydrogen gap". The notable exception is the palladium–hydrogen system which is discussed on p. 1150.

The hydrides of the later main-group elements present few problems of classification and are best discussed during the detailed treatment of the individual elements. Many of these hydrides are covalent, molecular species, though association via H bonding sometimes occurs, as already noted (p. 53). Catenation flourishes in Group 14 and the complexities of the boron hydrides merit special attention (p. 151). The hydrides of aluminium, gallium, zinc (and beryllium) tend to be more extensively associated via M–H–M bonds, but their characterization and detailed structural elucidation has proved extremely difficult.

Two further important groups of hydride compounds should be mentioned and will receive detailed attention in later chapters. One is the group of complex metal hydrides of which notable examples are $LiBH_4$, $NaBH_4$, $LiAlH_4$, $Al(BH_4)_3$, etc.[69] The other is the growing number of compounds in which the hydrogen atom is a monodentate or bidentate (bridging) ligand to a transition element:[70–73] these date from the early 1930s when W. Hieber discovered $[Fe(CO)_4H_2]$ and $[Co(CO)_4H]$ and now cover an astonishing variety of structural types. The modest steric requirements of the H atom enable complexes such as $[ReH_9]^{2-}$ to be synthesized, and bridged complexes such as the linear $[Cr_2(CO)_{10}H]^-$ and bent $[W_2(CO)_9H(NO)]$, are known. For η^2-H_2 complexes see pp. 44–7. The role of hydrido complexes in homogeneous catalysis is also exciting considerable attention.

4

Lithium, Sodium, Potassium, Rubidium, Caesium and Francium

4.1 Introduction

The alkali metals form a homogeneous group of extremely reactive elements which illustrate well the similarities and trends to be expected from the periodic classification, as discussed in Chapter 2. Their physical and chemical properties are readily interpreted in terms of their simple electronic configuration, ns^1, and for this reason they have been extensively studied by the full range of experimental and theoretical techniques. Compounds of sodium and potassium have been known from ancient times and both elements are essential for animal life. They are also major items of trade, commerce and chemical industry. Lithium was first recognized as a separate element at the beginning of the nineteenth century but did not assume major industrial importance until about 40 y ago. Rubidium and caesium are of considerable academic interest but so far have few industrial applications. Francium, the elusive element 87, has only fleeting existence in nature due to its very short radioactive half-life, and this delayed its discovery until 1939.

4.2 The Elements

4.2.1 Discovery and isolation

The spectacular success (in 1807) of Humphry Davy, then aged 29 y, in isolating metallic potassium by electrolysis of molten caustic potash (KOH) is too well known to need repeating in detail.[1] Globules of molten sodium were similarly prepared by him a few days later from molten caustic soda. Earlier experiments with aqueous solutions had been unsuccessful because of the great reactivity of these new elements. The names chosen by Davy reflect the sources of the elements.

Lithium was recognized as a new alkali metal by J. A. Arfvedson in 1817 whilst he was working as a young assistant in J. J. Berzelius's laboratory. He noted that Li compounds were similar to those of Na and K but that the carbonate and hydroxide were much less soluble

[1] M. E. Weeks, *Discovery of the Elements*, Journal of Chemical Education, Easton, 6th edn., 1956, 910 pp.

in water. Lithium was first isolated from the sheet silicate mineral petalite, $LiAlSi_4O_{10}$, and Arfvedson also showed it was present in the pyroxene silicate spodumene, $LiAlSi_2O_6$, and in the mica lepidolite, which has an approximate composition $K_2Li_3Al_4Si_7O_{21}(OH,F)_3$. He chose the name lithium (Greek λιθος, stone) to contrast it with the vegetable origin of Davy's sodium and potassium. Davy isolated the metal in 1818 by electrolysing molten Li_2O.

Rubidium was discovered as a minor constituent of lepidolite by R. W. Bunsen and G. R. Kirchhoff in 1861 only a few months after their discovery of caesium (1860) in mineral spa waters. These two elements were the first to be discovered by means of the spectroscope, which Bunsen and Kirchhoff had invented the previous year (1859); accordingly their names refer to the colour of the most prominent lines in their spectra (Latin *rubidus*, deepest red; *caesius*, sky blue).

Francium was first identified in 1939 by the elegant radiochemical work of Marguerite Perey who named the element in honour of her native country. It occurs in minute traces in nature as a result of the rare (1.38%) branching decay of ^{227}Ac in the ^{235}U series:

$$^{227}_{89}\mathrm{Ac} \xrightarrow[t_{1/2}\ 21.77\ \mathrm{y}]{\alpha\ (1.38\%)} {}^{223}_{87}\mathbf{Fr} \xrightarrow[\mathbf{21.8\ min}]{\beta^-} {}^{223}_{88}\mathrm{Ra} \xrightarrow[11.43\ \mathrm{d}]{\alpha}$$

Its terrestrial abundance has been estimated as 2×10^{-18} ppm, which corresponds to a total of only 15 g in the top 1 km of the earth's crust. Other isotopes have since been produced by nuclear reactions but all have shorter half-lives than ^{223}Fr, which decays by energetic β^- emission, $t_{1/2}$ 21.8 min. Because of this intense radioactivity it is only possible to work with tracer amounts of the element.

4.2.2 Terrestrial abundance and distribution

Despite their chemical similarity, Li, Na and K are not closely associated in their occurrence, mainly because of differences in size (see Table on p. 75). Lithium tends to occur in ferromagnesian minerals where it partly replaces magnesium; it occurs to the extent of about 18 ppm by weight in crustal rocks, and this reflects its relatively low abundance in the cosmos (Chapter 1). It is about as abundant as gallium (19 ppm) and niobium (20 ppm). The most important mineral commercially is spodumene, $LiAlSi_2O_6$, and large deposits occur in the USA, Canada, Brazil, Argentina, the former USSR, Spain, China, Zimbabwe and the Congo. An indication of the industrial uses of lithium and its compounds is given in the Panel. World production of lithium compounds in 1994 corresponded to some 5700 tonnes of contained lithium (equivalent to 30 000 tonnes of lithium carbonate) of which over 70% was in the USA.

Sodium, 22 700 ppm (2.27%) is the seventh most abundant element in crustal rocks and the fifth most abundant metal, after Al, Fe, Ca and Mg. Potassium (18 400 ppm) is the next most abundant element after sodium. Vast deposits of both Na and K salts occur in relatively pure form on all continents as a result of evaporation of ancient seas, and this process still continues today in the Great Salt Lake (Utah), the Dead Sea and elsewhere. Sodium occurs as rock-salt (NaCl) and as the carbonate (trona), nitrate (saltpetre), sulfate (mirabilite), borate (borax, kernite), etc. Potassium occurs principally as the simple chloride (sylvite), as the double chloride $KCl.MgCl_2.6H_2O$ (carnallite) and the anhydrous sulfate $K_2Mg_2(SO_4)_3$ (langbeinite). There are also unlimited supplies of NaCl in natural brines and oceanic waters ($\sim$30 kg m^{-3}). Thus, it has been calculated that rock-salt equivalent to the NaCl in the oceans of the world would occupy 19 million cubic km (i.e. 50% more than the total volume of the North American continent above sea-level). Alternatively stated, a one-km square prism would stretch from the earth to the moon 47 times. Note also that, although Na and K are almost equally abundant in the crustal rocks of the earth, Na is some 30 times as abundant as K in the oceans. This is partly because K salts with the larger anions tend to be less soluble than the Na salts and, likewise, K is more strongly bound to

Lithium and its Compounds[2–4]

The dramatic transformation of Li from a small-scale specialist commodity to a multikilotonne industry during the past three decades is due to the many valuable properties of its compounds. About 35 compounds of Li are currently available in bulk, and a similar number again can be obtained in developmental or research quantities. A major industrial use of Li is in the form of **lithium stearate** which is used as a thickener and gelling agent to transform oils into lubricating greases. These "all-purpose" greases combine high water resistance with good low-temperature properties (−20°C) and excellent high-temperature stability (>150°C); they are readily prepared from $LiOH.H_2O$ and tallow or other natural fats and have captured nearly half the total market for automotive greases in the USA.

Lithium carbonate is the most important industrial compound of lithium and is the starting point for the production of most other lithium compounds. It is also used as a flux in porcelain enamel formulations and in the production of special toughened glasses (by replacement of the larger Na ions): Li can either be incorporated within the glass itself or the preformed Na-glass can be dipped in a molten-salt bath containing Li ions to effect a surface cation exchange. In another application, the use of Li_2CO_3 by primary aluminium producers has risen sharply in recent years since it increases production capacity by 7–10% by lowering the mp of the cell content and permitting larger current flow: in addition, troublesome fluorine emissions are reduced by 25–50% and production costs are appreciably lowered. In 1987 the price for bulk quantities of Li_2CO_3 in the USA was $3.30 per kg.

The first commercial use of **Li metal** (in the 1920s) was as an alloying agent with lead to give toughened bearings; currently it is used to produce high-strength, low-density aluminium alloys for aircraft construction. With magnesium it forms an extremely tough low-density alloy which is used for armour plate and for aerospace components (e.g. LA 141, d 1.35 g cm^{-3}, contains 14% Li, 1% Al, 85% Mg). Other metallurgical applications employ **LiCl** as an invaluable brazing flux for Al automobile parts.

LiOH is used in the manufacture of lithium stearate greases (see above) and for CO_2 absorption in closed environments such as space capsules (light weight) and submarines. **LiH** is used to generate hydrogen in military, meteorological, and other applications, and the use of LiD in thermonuclear weaponry and research has been mentioned (p. 18). Likewise, the important applications of **$LiAlH_4$**, **Li/NH_3** and **organolithium reagents** in synthetic organic chemistry are well known, though these account for only a small percentage of the lithium produced. Other specialist uses include the growing market for ferroelectrics such as **$LiTaO_3$** to modulate laser beams (p. 57), and increasing use of thermoluminescent LiF in X-ray dosimetry.

Perhaps one of the most exciting new applications stems from the discovery in 1949 that small daily doses (1–2 g) of **Li_2CO_3** taken orally provide an effective treatment for manic-depressive psychoses. The mode of action is not well understood but there appear to be no undesirable side effects. The dosage maintains the level of Li in the blood at about 1 mmol l^{-1} and its action may be related to the influence of Li on the Na/K balance and (or) the Mg/Ca balance since Li is related chemically to both pairs of elements.

Looking to the future, Li/FeS_x battery systems are emerging as a potentially viable energy storage system for off-peak electricity and as a non-polluting silent source of power for electric cars. The battery resembles the conventional lead–acid battery in having solid electrodes (Li/Si alloy, negative; FeS_x positive) and a liquid electrolyte (molten LiCl/KCl at 400°C). Other battery systems which have reached the prototype stage include the Li/S and Na/S cells (see p. 678).

the complex silicates and alumino silicates in the soils (ion exchange in clays). Again, K leached from rocks is preferentially absorbed and used by plants whereas Na can proceed to the sea. Potassium is an essential element for plant life and the growth of wild plants is often limited by the supply of K available to them.

The vital importance of NaCl in the heavy chemical industry is indicated in the Panel opposite, and information on potassium salts is given in the Panel on p. 73.

Rubidium (78 ppm, similar to Ni, Cu, Zn) and caesium (2.6 ppm, similar to Br, Hf, U) are much less abundant than Na and K and have only recently become available in quantity. No purely Rb-containing mineral is known and much of the commercially available material is obtained as a byproduct of lepidolite processing for Li. Caesium occurs as the hydrated aluminosilicate pollucite, $Cs_4Al_4Si_9O_{26}.H_2O$, but the world's only commercial source is at Bernic Lake,

Production and Uses of Salt[5–7]

More NaCl is used for inorganic chemical manufacture than is any other material. It is approached only by phosphate rock, and world consumption of each exceeds 150 million tonnes annually, the figure for NaCl in 1982 being 168.7 million tonnes. Production is dominated by Europe (39%), North America (34%) and Asia (20%), whilst South America and Oceania have only 3% each and Africa 1%. Rock-salt occurs as vast subterranean deposits often hundreds of metres thick and containing >90% NaCl. The Cheshire salt field (which is the principal UK source of NaCl) is typical, occupying an area of 60 km × 24 km and being some 400 m thick: this field alone corresponds to reserves of $>10^{11}$ tonnes. Similar deposits occur near Carlsbad New Mexico, in Saskachewan Canada and in many other places. Production methods vary with locality and with the use to be made of the salt. For example, in the UK 82% is extracted as brine for direct use in the chemical industry and 18% is mined as rock-salt, mainly for use on roads; less than 1% is obtained by solar evaporation. By contrast, in the USA only 55% comes from brine, whereas 32% is mined as rock salt, 8% is obtained by vacuum pan evaporation, 4% by solar evaporation and 1% by the open pan process.

Major sections of the inorganic heavy chemicals industry are based on salt and, indeed, this compound was the very starting point of the chemical industry. Nicolas Leblanc (1742–1806), physician to the Duke of Orleans, devised a satisfactory process for making NaOH from NaCl in 1787 (Patent 1791) and this achieved enormous technological significance in Europe during most of the nineteenth century as the first industrial chemical process to be worked on a really large scale. It was, however, never important in the USA since it was initially cheaper to import from Europe and, by the time the US chemical industry began to develop in the last quarter of the century, the Leblanc process had been superseded by the electrolytic process. Thus in 1874 world production of NaOH was 525 000 tonnes of which 495 000 were by the Leblanc process; by 1902 production had risen to 1 800 000 tonnes, but only 150 000 tonnes of this was Leblanc. Despite its long history, there is still great scope for innovation and development in the chlor-alkali and related industries. For example, in recent years there has been a steady switch from mercury electrolysis cells to diaphragm and membrane cells for environmental and economic reasons.[7] Similarly, the ammonia-soda (Solvay) process for Na_2CO_3 is being phased out because of the difficulty of disposing of embarrassing byproducts such as NH_4Cl and $CaCl_2$, coupled with the increasing cost of NH_3 and the possibility of direct mining for trona, $Na_2CO_3.NaHCO_3.2H_2O$. The closely interlocking chemical processes based on salt are set out in the flow sheet (Fig. 4.1). The detailed balance of the processes differs somewhat in the various industrial nations but data for the usage of salt in the USA are typical: of the 34.8 million tonnes consumed in 1982, 48% was used for chlor-alkali production and Na_2CO_3, 24% for the salting of roads, 6% for food and food processing, 5% for animal feeds, 5% for various industries such as paper pulp, textiles, metal manufacturing and the rubber and oil industries, 2% for all other chemical manufacturing, and the remaining 10% for a wide variety of other purposes. Further discussion on the industrial production and uses of many of these chemicals (e.g. NaOH, Na_2CO_3, Na_2SO_4) is given on p. 89.

Current industrial prices are ~$5 per tonne for salt in brine and ~$55 per tonne for solid salt, depending on quality.

Manitoba and Cs (like Rb) is mainly obtained as a byproduct of the Li industry. The intense interest in Li for thermonuclear purposes since about 1958, coupled with its extensive use in automotive greases (p. 70), has consequently made Rb and Cs compounds much more available than formerly: annual production is in the region of 5 tonnes for each.

4.2.3 Production and uses of the metals

Most commercial Li ores have 1–3% Li and this is increased by flotation to 4–6%. Spodumene, $LiAlSi_2O_6$, is heated to ~1100° to convert the α-form into the less-dense, more friable β-form, which is then washed with H_2SO_4 at 250°C and water-leached to give $Li_2SO_4.H_2O$. Successive treatment with Na_2CO_3 and HCl gives Li_2CO_3 (insol) and LiCl. Alternatively, the chloride can be obtained by calcining the washed ore with limestone ($CaCO_3$) at 1000° followed by water leaching to give LiOH and then treatment with HCl. Recovery from natural brines is also extensively used in the USA (Searles Lake, California and Clayton Valley, Nevada).

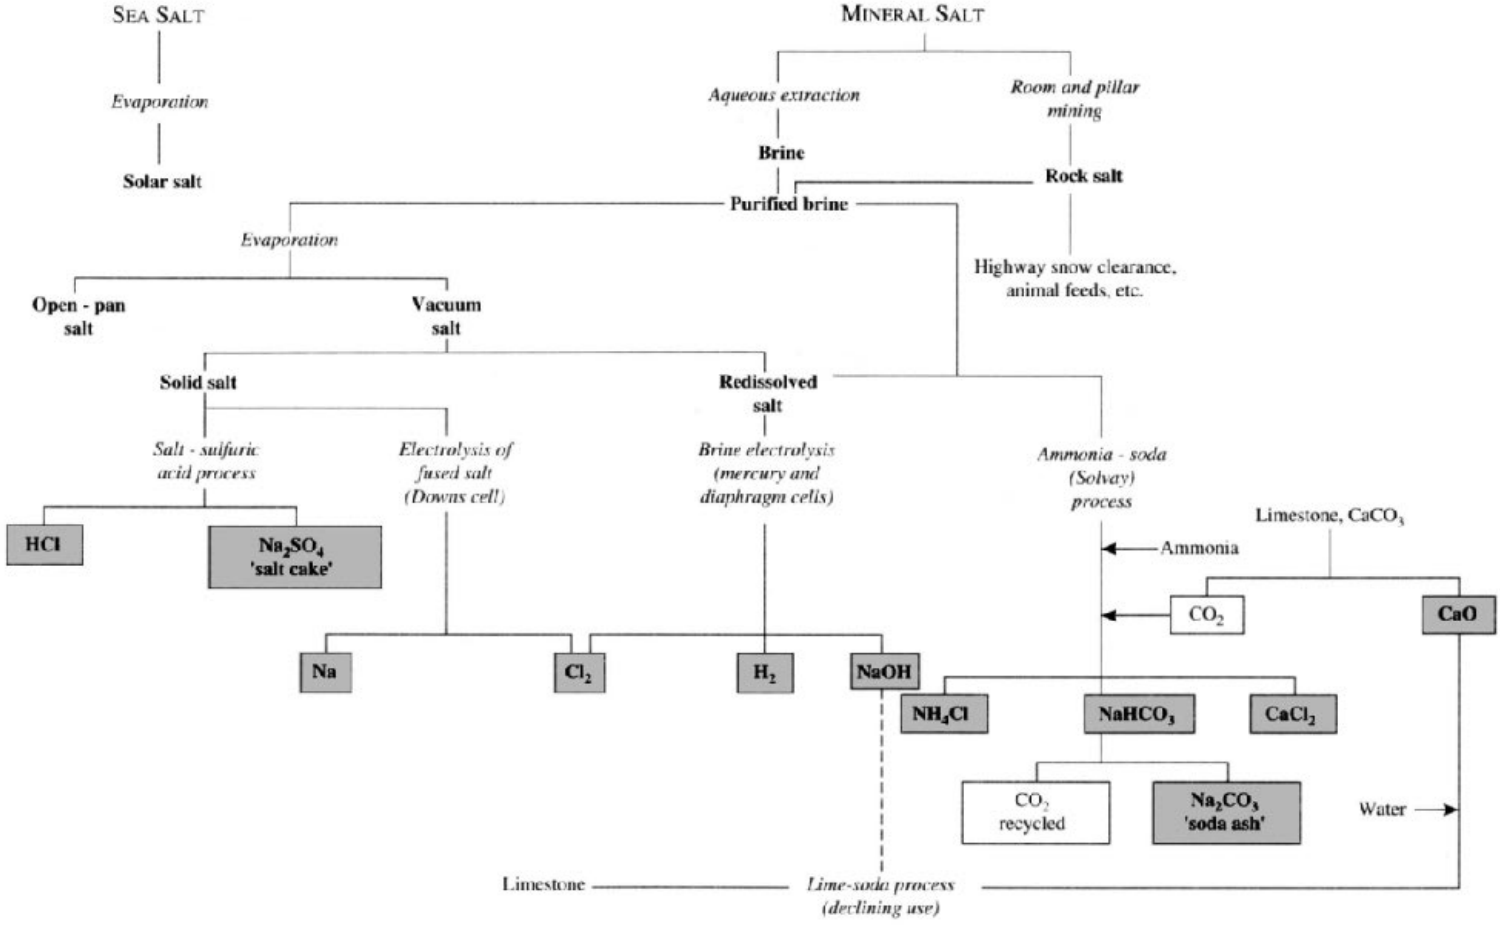

Figure 4.1 Flow sheet on chemical processes based on salt.

Production of Potassium Salts[8–10]

Sylvite (KCl) and sylvinite (mixed NaCl, KCl) are the most important K minerals for chemical industry; carnallite is also mined. Ocean waters contain only about 0.06% KCl, though this can rise to as high as 1.5% in some inland marshes and seas such as Searle's Lake, the Great Salt Lake, or the Dead Sea, thereby making recovery economically feasible. Soluble minerals of K are generally referred to (incorrectly) as potash, and production figures are always expressed as the weight of K_2O equivalent. Massive evaporite beds of soluble K salts were first discovered at Stassfurt, Germany, in 1856 and were worked there for potash and rock-salt from 1861 until 1972. World production was 28.6 million tonnes K_2O equivalent in 1986 of which 35% was produced in the USSR and 24% Canada.

In the UK workable potash deposits are confined to the Cleveland–North Yorkshire bed which is ~11 m thick and has reserves of >500 million tonnes. Massive recovery is also possible from brines; e.g. Jordan has a huge plant capable of recovering up to a million tonnes pa from the Dead Sea and the annual production by this country and by Israel now matches that of the USA and France.

Potassium is a major essential element for plant growth and potassic fertilizers account for the overwhelming proportion of production (95%). Again KCl is dominant, accounting for more than 90% of the K used in fertilizers; K_2SO_4 is also used. KNO_3, though an excellent fertilizer, is now of only minor importance because of production costs. In addition to its dominant use in fertilizers, KCl is used mainly to manufacture KOH by electrolysis using the mercury and membrane processes (about 0.7 million tonnes of KOH worldwide in 1985). This in turn is used to make a variety of other compounds and materials such as those listed below (the figures referring to the percentage usage of KOH in the USA in 1984): K_2CO_3 25%, liquid fertilizers 15%, soaps 10%, liquid detergents ($K_4P_2O_7$) 9%, synthetic rubber 5%, crop protection agents 3%, $KMnO_4$ 2%, other chemicals 26% and export 5%. The manufacture of metallic K is relatively minor, the world production in 1994 amounting only to about 500 tonnes. Prices in 1994 were $30–40 per kg for bulk K and $16–22 per kg for NaK (78% K).

The main industrial uses of potassium compounds other than KCl and KOH are:

- K_2CO_3 (from KOH and CO_2), used chiefly in high-quality decorative glassware, in optical lenses, colour TV tubes and fluorescent lamps; it is also used in china ware, textile dyes and pigments.
- KNO_3, a powerful oxidizing agent now used mainly in gunpowders and pyrotechnics, and in fertilizers.
- $KMnO_4$, an oxidizer, decolorizer, bleacher and purification agent; its major application is in the manufacture of saccharin.
- KO_2, used in breathing apparatus (p. 74).
- $KClO_3$, used in small amounts in matches and explosives (pp. 509, 862).
- KBr, used extensively in photography and as the usual source of bromine in organic syntheses; formerly used as a sedative.

It is interesting to note the effect of varying the alkali metal cation on the properties of various compounds and industrial materials. For example, a soap is an alkali metal salt formed by neutralizing a long-chain organic acid such as stearic acid, $CH_3(CH_2)_{16}CO_2H$, with MOH. Potassium soaps are soft and low melting, and are therefore used in liquid detergents. Sodium soaps have higher mps and are the basis for the familiar domestic "hard soaps" or bar soaps. Lithium soaps have still higher mps and are therefore used as thickening agents for high-temperature lubricating oils and greases — their job is to hold the oil in contact with the metal under conditions when the oil by itself would run off.

The metal is obtained by electrolysis of a fused mixture of 55% LiCl, 45% KCl at ~450°C, the first commercial production being by Metallgeselleschaft AG, in Germany, 1923. Current world production of Li metal is about 1000 tonnes pa. Far greater tonnages of Li compounds are, of course, produced and their major commercial applications have already been noted (p. 70).

Sodium metal is produced commercially on the kilotonne scale by the electrolysis of a fused eutectic mixture of 40% NaCl, 60% $CaCl_2$ at ~580°C in a Downs cell (introduced by du Pont, Niagara Falls, 1921). Metallic Na and Ca are liberated at the cylindrical steel cathode and rise through a cooled collecting pipe which allows the calcium to solidify and fall back into the melt. Chlorine liberated at the central graphite anode is collected in a nickel dome and subsequently purified. Potassium cannot be produced in this way because it is too soluble in the molten chloride to float on top of the cell for collection and because it vaporizes readily

[10] Ref. 7 pp. 228–31.

at the operating temperatures, creating hazardous conditions. Superoxide formation is an added difficulty since this reacts explosively with K metal. Consequently, commercial production of K relies on reduction of molten KCl with metallic Na at 850°C.† A similar process using Ca metal at 750°C under reduced pressure is used to produce metallic Rb and Cs.

Industrial uses of Na metal reflect its strong reducing properties. Much of the world production was used to make $PbEt_4$ (or $PbMe_4$) for gasoline antiknocks via the high-pressure reaction of alkyl chlorides with Na/Pb alloy, though this use is declining rapidly for environmental reasons. A further major use is to produce Ti, Zr and other metals by reduction of their chlorides, and a smaller amount is used to make compounds such as NaH, NaOR and Na_2O_2. Sodium dispersions are also a valuable catalyst for the production of some artificial rubbers and elastomers. A growing use is as a heat-exchange liquid in fast breeder nuclear reactors where sodium's low mp, low viscosity and low neutron absorption cross-section combine with its exceptionally high heat capacity and thermal conductivity to make it (and its alloys with K) the most-favoured material.[11] The annual production of metallic Na in the USA fell steadily from 170 000 tonnes in 1974 to 86 000 tonnes in 1985 and is still falling. Potassium metal, being more difficult and expensive to produce, is manufactured on a much smaller scale. One of its main uses is to make the superoxide KO_2 by direct combustion; this compound is used in breathing masks as an auxiliary supply of O_2 in mines, submarines and space vehicles:

$$4KO_2 + 2CO_2 \longrightarrow 2K_2CO_3 + 3O_2$$

$$4KO_2 + 4CO_2 + 2H_2O \longrightarrow 4KHCO_3 + 3O_2$$

An indication of the relative cost of the alkali metals in bulk at 1980–82 prices (USA) is:

Metal	Li	Na	K	Rb	Cs
Price/\$ kg^{-1}	36.3	1.50	34.4	827	716
Relative cost (per kg)	24	1	23	550	477
Relative cost (per mol)	7.3	1	39	2050	2760

4.2.4 Properties of the alkali metals

The Group 1 elements are soft, low-melting metals which crystallize with bcc lattices. All are silvery-white except caesium which is golden yellow;[12] in fact, caesium is one of only three metallic elements which are intensely coloured, the other two being copper and gold (see also pp. 112, 1177, 1232). Lithium is harder than sodium but softer than lead. Atomic properties are summarized in Table 4.1 and general physical properties are in Table 4.2. Further physical properties of the alkali metals, together with a review of the chemical properties and industrial applications of the metals in the molten state are in ref. 11.

Lithium has a variable atomic weight (p. 18) whereas sodium and caesium, being mononuclidic, have very precisely known and invariant atomic weights. Potassium and rubidium are both radioactive but the half-lives of their radioisotopes are so long that the atomic weight does not vary significantly from this cause. The large size and low ionization energies of the alkali metals compared with all other elements have already been noted (pp. 23–5) and this confers on the elements their characteristic properties. The group usually shows smooth trends in properties, and the weak bonding of the single valence electron leads to low mp, bp and density, and low heats of sublimation, vaporization and dissociation. Conversely, the elements have large atomic and ionic radii and extremely high thermal and electrical conductivity. Lithium is the smallest element in the group and has the highest ionization energy, mp and heat

† This reduction of KCl by Na appears to be contrary to the normal order of reactivity (K > Na). However, at 850–880° an equilibrium is set up: $Na(g) + K^+(l) \rightleftharpoons Na^+(l) + K(g)$. Since K is the more volatile (p. 75), it distils off more readily, thus displacing the equilibrium and allowing the reaction to proceed. By fractional distillation through a packed tower, K of 99.5% purity can be obtained but usually an Na/K mixture is drawn off because alloys with 15–55% Na are liquid at room temperature and therefore easier to transport.

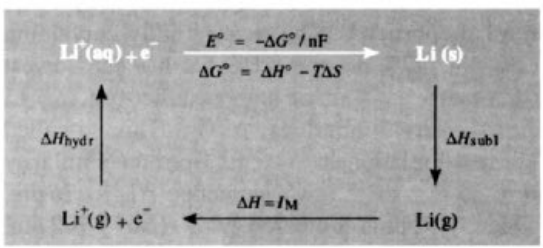
of atomization; it also has the lowest density of any solid at room temperature.

All the alkali metals have characteristic flame colorations due to the ready excitation of the outermost electron, and this is the basis of their analytical determination by flame photometry or atomic absorption spectroscopy. The colours and principal emission (or absorption) wavelengths, λ, are given below but it should be noted that these lines do not all refer to the same transition; for example, the Na D-line doublet at 589.0, 589.6 nm arises from the $3s^1 - 3p^1$ transition in Na atoms formed by reduction of Na^+ in the flame, whereas the red line for lithium is associated with the short-lived species LiOH.

Element	Li	Na	K	Rb	Cs
Colour	Crimson	Yellow	Violet	Red-violet	Blue
λ/nm	670.8	589.2	766.5	780.0	455.5

The reduction potential for lithium appears at first sight to be anomalous and is one of the few properties that does not show a smooth trend with increasing atomic number in the group. This arises from the small size and very large hydration energy of the free gaseous lithium ion. The standard reduction potential E° refers to the reaction $Li^+(aq) + e^- \longrightarrow Li(s)$ and is related to the free-energy change: $\Delta G^\circ = -nFE^\circ$. The ionization energy I_M, which is the enthalpy change of the gas-phase reaction $Li(g) \longrightarrow Li^+(g) + e^-$, is only one component of this, as can be seen from the following cycle:



Estimates of the heat of hydration of $Li^+(g)$ give values near 520 kJ mol^{-1} compared with

405 kJ mol^{-1} for $Na^+(g)$ and only 265 kJ mol^{-1} for $Cs^+(g)$. This factor, although opposed by the much larger entropy change for the lithium electrode reaction (due to the more severe disruption of the water structure by the lithium ion), is sufficient to reverse the position of lithium and make it the most electropositive of the alkali metals (as measured by electrode potential) despite the fact that it is the most difficult element of the group to ionize in the gas phase.

4.2.5 Chemical reactivity and trends

The ease of involving the outermost ns^1 electron in bonding, coupled with the very high second-stage ionization energy of the alkali metals, immediately explains both the great chemical reactivity of these elements and the fact that their oxidation state in compounds never exceeds +1. The metals have a high lustre when freshly cut but tarnish rapidly in air due to reaction with O_2 and moisture. Reaction with the halogens is vigorous; even explosive in some cases. All the alkali metals react with hydrogen (p. 65) and with proton donors such as alcohols, gaseous ammonia and even alkynes. They also act as powerful reducing agents towards many oxides and halides and so can be used to prepare many metallic elements or their alloys.

The small size of lithium frequently confers special properties on its compounds and for this reason the element is sometimes termed "anomalous". For example, it is miscible with Na only above 380° and is immiscible with molten K, Rb and Cs, whereas all other pairs of alkali metals are miscible with each other in all proportions. (The ternary alloy containing 12% Na, 47% K and 41% Cs has the lowest known mp, −78°C, of any metallic system.) Li shows many similarities to Mg. This so-called "diagonal relationship" stems from the similarity in ionic size of the two elements: $r(Li^+)$ 76 pm, $r(Mg^{2+})$ 72 pm, compared with $r(Na^+)$ 102 pm. Thus, as first noted by Arfvedson in establishing lithium as a new element, LiOH and Li_2CO_3 are much less soluble than the corresponding Na and K compounds and the carbonate (like $MgCO_3$) decomposes more readily on being heated. Similarly, LiF (like MgF_2) is much less soluble in water than are the other alkali metal fluorides because of the large lattice energy associated with the small size of both the cation and the anion. By contrast, lithium salts of large, non-polarizable anions such as ClO_4^- are much more soluble than those of the other alkali metals, presumably because of the high energy of solvation of Li^+. For the same reason many simple lithium salts are normally hydrated (p. 88) and the anhydrous salts are extremely hygroscopic: this great affinity for water forms the basis of the widespread use of LiCl and LiBr brines in dehumidifying and air-conditioning units. More subtly there is also a close structural relation between the hydrogen-bonded structures of $LiClO_4.3H_2O$ and $Mg(ClO_4)_2.6H_2O$ in which the face-shared octahedral groups of $[Li(H_2O)_6]^+$ are replaced alternately by half the number of discrete $[Mg(H_2O)_6]^{2+}$ groups.[13] Lithium sulfate, unlike the other alkali metal sulfates, does not form alums $[M(H_2O)_6]^+[Al(H_2O)_6]^{3+}$-$[SO_4]^{2-}{}_2$ because the hydrated lithium cation is too small to fill the appropriate site in the alum structure.

Lithium is unusual in reacting directly with N_2 to form the nitride Li_3N; no other alkali metal has this property, which lithium shares with magnesium (which readily forms Mg_3N_2). On the basis of size, it would be expected that Li would be tetrahedrally coordinated by N but, as pointed out by A. F. Wells,[13] this would require 12 tetrahedra to meet at a point which is a geometrical impossibility, 8 being the maximum number theoretically possible; accordingly Li_3N has a unique structure (see p. 92) in which one-third of the Li have 2 N atoms as nearest neighbours (at 194 pm) and the remainder have 3 N atoms as neighbours (at 213 pm); each N is surrounded by 2 Li at 194 pm and 6 more at 213 pm.

[13] A. F. WELLS, *Structural Inorganic Chemistry*, 5th edn., Oxford University Press, Oxford, 1984, 1382 pp.

4.2.6 Solutions in liquid ammonia and other solvents [14]

One of the most remarkable features of the alkali metals is their ready solubility in liquid ammonia to give bright blue, metastable solutions with unusual properties. Such solutions have been extensively studied since they were first observed by T. Weyl in 1863,† and it is now known that similar solutions are formed by the heavier alkaline earth metals (Ca, Sr and Ba) and the divalent lanthanoids europium and ytterbium in liquid ammonia. Many amines share with ammonia this ability though to a much lesser extent. It is clear that solubility is favoured by low metal lattice energy, low ionization energies and high cation solvation energy. The most striking physical properties of the solutions are their colour, electrical conductivity and magnetic susceptibility. The solutions all have the same blue colour when dilute, suggesting the presence of a common coloured species, and they become bronze-coloured and metallic at higher concentrations. The conductivity of the dilute solutions is an order of magnitude higher than that of completely ionized salts in water; as the solutions become more concentrated the conductivity at first diminishes to a minimum value at about 0.04 M and then increases dramatically to approach values typical of liquid metals. Dilute solutions are paramagnetic with a susceptibility appropriate to the presence of 1 free electron per metal atom; this susceptibility diminishes with increase in concentration, the solutions becoming diamagnetic in the region of the conductivity minimum and then weakly paramagnetic again at still higher concentrations.

The interpretation of these remarkable properties has excited considerable interest: whilst there is still some uncertainty as to detail, it is now generally agreed that in dilute solution the alkali metals ionize to give a cation M^+ and a quasi-free electron which is distributed over a cavity in the solvent of radius 300–340 pm formed by displacement of 2–3 NH_3 molecules. This species has a broad absorption band extending into the infrared with a maximum at ~1500 nm and it is the short wavelength tail of this band which gives rise to the deep-blue colour of the solutions. The cavity model also interprets the fact that dissolution occurs with considerable expansion of volume so that the solutions have densities that are appreciably lower than that of liquid ammonia itself. The variation of properties with concentration can best be explained in terms of three equilibria between five solute species M, M_2, M^+, M^- and e^-:

$$M_{am} \rightleftharpoons M^+_{am} + e^-_{am}; \quad K \sim 10^{-2}\,\text{mol}\,l^{-1}$$

$$M^-_{am} \rightleftharpoons M_{am} + e^-_{am}; \quad K \sim 10^{-3}\,\text{mol}\,l^{-1}$$

$$(M_2)_{am} \rightleftharpoons 2M_{am}; \quad K \sim 2 \times 10^{-4}\,\text{mol}\,l^{-1}$$

The subscript am indicates that the species are dissolved in liquid ammonia and may be solvated. At very low concentrations the first equilibrium predominates and the high ionic conductivity stems from the high mobility of the electron which is some 280 times that of the cation. The species M_{am} can be thought of as an ion pair in which M^+_{am} and e^-_{am} are held together by coulombic forces. As the concentration is raised the second equilibrium begins to remove mobile electrons e^-_{am} as the complex M^-_{am} and the conductivity drops. Concurrently M_{am} begins to dimerize to give $(M_2)_{am}$ in which the interaction between the 2 electrons is sufficiently strong to lead to spin-pairing and diamagnetism. At still higher concentrations the system behaves as a molten metal in which the metal cations are ammoniated. Saturated solutions are indeed extremely concentrated as indicated by the following table:

[14] W. L. JOLLY and C. J. HALLADA, Liquid ammonia, Chap. 1 in T. C. WADDINGTON (ed.), *Non-aqueous Solvent Systems*, pp. 1–45, Academic Press, London, 1965. J. C. THOMPSON, The physical properties of metal solutions in non-aqueous solvents, Chap. 6 in J. LAGOWSKI (ed.), *The Chemistry of Non-aqueous Solvents*, Vol. 2, pp. 265–317, Academic Press, New York, 1967. J. JANDER (ed.), *Chemistry in Anhydrous Liquid Ammonia*, Wiley, Interscience, New York, 1966, 561 pp.

† Actually, the first observation was probably made by Sir Humphry Davy some 55 years earlier: an unpublished observation in his Notebook for November 1807 reads "When 8 grains of potassium were heated in ammoniacal gas it assumed a beautiful metallic appearance and gradually became of a pure blue colour".

Solute	Li	Na	K	Rb	Cs
T/°C	−33.2°	−33.5°	−33.2°	–	−50°
g(M)/kg(NH_3)	108.7	251.4	463.7	–	3335
mol(NH_3)/ mol(M)	3.75	5.37	4.95	–	2.34

The lower solubility of Li on a wt/wt basis reflects its lower atomic weight and, when compared on a molar basis, it is nearly 50% more soluble than Na (15.66 mol/kg NH_3 compared to 10.93 mol/kg NH_3). Note that it requires only 2.34 mol NH_3 (39.8 g) to dissolve 1 mol Cs (132.9 g).

Solutions of alkali metals in liquid ammonia are valuable as powerful and selective reducing agents. The solutions are themselves unstable with respect to amide formation:

$$M + NH_3 \longrightarrow MNH_2 + \tfrac{1}{2}H_2$$

However, under anhydrous conditions and in the absence of catalytic impurities such as transition metal ions, solutions can be stored for several days with only a few per cent decomposition. Some reductions occur without bond cleavage as in the formation of alkali metal superoxides and peroxide (p. 84).

$$O_2 \xrightarrow{e^-_{am}} O_2^- \xrightarrow{e^-_{am}} O_2^{2-}$$

Transition metal complexes can be reduced to unusually low oxidation states either with or without bond cleavage, e.g.:

$$K_2[Ni(CN)_4] + 2K \xrightarrow{NH_3/-33°} K_4[Ni(CN)_4];$$

i.e. Ni(0)

$$[Pt(NH_3)_4]Br_2 + 2K \xrightarrow{NH_3/-33°} [Pt(NH_3)_4] + 2KBr;$$

i.e. Pt(0)

$$Mn_2(CO)_{10} + 2K \xrightarrow{NH_3/-33°} 2K[Mn(CO)_5];$$

i.e. Mn(−1)

$$Fe(CO)_5 + 2Na \xrightarrow{NH_3/-33°} Na_2[Fe(CO)_4] + CO;$$

i.e. Fe(−2)

Salts of several heavy main-group elements can be reduced to form polyanions such as $Na_4[Sn_9]$, $Na_3[Sb_3]$ and $Na_3[Sb_7]$ (p. 588).

Many protonic species react with liberation of hydrogen:

$$RC{\equiv}CH + e^-_{am} \longrightarrow RC{\equiv}C^- + \tfrac{1}{2}H_2$$

$$GeH_4 + e^-_{am} \longrightarrow GeH_3^- + \tfrac{1}{2}H_2$$

$$NH_4^+ + e^-_{am} \longrightarrow NH_3 + \tfrac{1}{2}H_2$$

$$AsH_3 + e^-_{am} \longrightarrow AsH_2^- + \tfrac{1}{2}H_2$$

$$EtOH + e^-_{am} \longrightarrow EtO^- + \tfrac{1}{2}H_2$$

These and similar reactions have considerable synthetic utility. Other reactions which result in bond cleavage by the addition of one electron are:

$$R_2S + e^-_{am} \longrightarrow RS^- + \tfrac{1}{2}R_2$$

$$Et_3SnBr + e^-_{am} \longrightarrow Et_3Sn^\bullet + Br^-$$

When a bond is broken by addition of 2 electrons, either 2 anions or a dianion is formed:

$$Ge_2H_6 + 2e^-_{am} \longrightarrow 2GeH_3^-$$

$$PhNHNH_2 + 2e^-_{am} \longrightarrow PhNH^- + NH_2^-$$

$$PhN{=}O + 2e^-_{am} \longrightarrow PhN^-{-}O^-$$

$$S_8 + 2e^-_{am} \longrightarrow S_8^{2-}$$

Subsequent ammonolysis may also occur:

$$RCH{=}CH_2 + 2e^-_{am} \longrightarrow \{RCH{-}CH_2^{2-}\}$$

$$\xrightarrow{2NH_3} RCH_2CH_3 + 2NH_2^-$$

$$N_2O + 2e^-_{am} \longrightarrow \{N_2 + O^{2-}\}$$

$$\xrightarrow{NH_3} N_2 + OH^- + NH_2^-$$

Next Page

Previous Page

$$NCO^- + 2e^-_{am} \longrightarrow \{CN^- + O^{2-}\}$$

$$\xrightarrow{NH_3} CN^- + OH^- + NH_2^-$$

$$EtBr + 2e^-_{am} \longrightarrow \{Br^- + Et^-\}$$

$$\xrightarrow{NH_3} Br^- + C_2H_6 + NH_2^-$$

Solutions of alkali metals in liquid ammonia have been developed as versatile reducing agents which effect reactions with organic compounds that are otherwise difficult or impossible.[15] Aromatic systems are reduced smoothly to cyclic mono- or di-olefins and alkynes are reduced stereospecifically to *trans*-alkenes (in contrast to Pd/H_2 which gives *cis*-alkenes).

The alkali metals are also soluble in aliphatic amines and hexamethylphosphoramide, $P(NMe_2)_3$ to give coloured solutions which are strong reducing agents. These solutions appear to be similar in many respects to the dilute solutions in liquid ammonia though they are less stable with respect to decomposition into amide and H_2. Likewise, fairly stable solutions of the larger alkali metals K, Rb and Cs have been obtained in tetrahydrofuran, ethylene glycol dimethyl ether and other polyethers. These and similar solutions have been successfully used as strong reducing agents in situations where protonic solvents would have caused solvolysis. For example, naphthalene reacts with Na in tetrahydrofuran to form deep-green solutions of the paramagnetic sodium naphthenide, $NaC_{10}H_8$, which can be used directly in the presence of a bis(tertiary phosphine) ligand to reduce the anhydrous chlorides VCl_3, $CrCl_3$, $MoCl_5$ and WCl_6 to the zerovalent octahedral complexes $[M(Me_2PCH_2CH_2PMe_2)_3]$, where M = V, Cr, Mo, W. Similarly the planar complex $[Fe(Me_2PCH_2CH_2PMe_2)_2]$ was obtained from *trans*-$[Fe(Me_2PCH_2CH_2PMe_2)_2Cl_2]$, and the corresponding tetrahedral Co(0) compound from $CoCl_2$.[16]

4.3 Compounds[17]

4.3.1 Introduction: the ionic-bond model[18]

The alkali metals form a complete range of compounds with all the common anions and have long been used to illustrate group similarities and trends. It has been customary to discuss the simple binary compounds in terms of the ionic bond model and there is little doubt that there is substantial separation of charge between the cationic and anionic components of the crystal lattice. On this model the ions are considered as hard, undeformable spheres carrying charges which are integral multiples of the electronic charge z_1e^+. Corrections can be incorporated for zero-point energies, London dispersion energies, ligand-field stabilization energies and non-spherical ions (such as NO_3^-, etc.). The attractive simplicity of this model, and its considerable success during the past 70 y in interpreting many of the properties of simple salts, should not, however, be allowed to obscure the growing realization of its inadequacy.[18,19] In particular, as already noted, success in calculating lattice energies and hence enthalpy of formation via the Born–Haber cycle, does not establish the correctness of the model but merely indicates that it is consistent with these particular observations. For example, the ionic model is quite successful in reproducing the enthalpy of formation of BF_3, SiF_4, PF_5 and even SF_6 on the assumption that they are assemblies of point charges at the known interatomic distance, i.e. $B^{3+}(F^-)_3$, etc.,[20] but this is not a sound reason

Next Page

for considering these molecular compounds as ionic. Likewise, the known lattice energy of lithium metal can be reproduced quite well by assuming that the observed bcc arrangement of atoms is made up from alternating ions Li^+Li^- in the CsCl structure;[21] the discrepancy is no worse than that obtained using the same model for AgCl (which has the NaCl structure). It appears that the ionic-bond model is self compensating and that the decrease in the hypothetical binding energy which accompanies the diminution of formal charges on the atoms is accompanied by an equivalent increase in binding energy which could be described as "covalent" (BF_3) or "metallic" (Li metal).

Indeed, the inherent improbability of the ionic bond model can be appreciated when it is realized that all simple cations have a positive charge and several vacant orbitals (and are therefore potentially electron pair acceptors) whereas all simple anions have a negative charge and several lone pairs of electrons (and are therefore potentially electron pair donors). The close juxtaposition of these electron-pair donor and acceptor species is thus likely to result in the transfer of at least some charge density by coordination, thereby introducing a substantial measure of covalency into the bonding of the alkali metal halides and related compounds. A more satisfactory procedure, at least conceptually, would be to describe crystalline salts and other solid compounds in terms of molecular orbitals. Quantitative calculations are difficult to carry out but the model allows flexibility in placing "partial ionic charges" on atoms by modifying orbital coefficients and populations, and it can also incorporate metallic behaviour by modifying the extent to which partly filled individual molecular orbitals are either separated by energy gaps or overlap.

The compounds which most nearly fit the classicial conception of ionic bonding are the alkali metal halides. However, even here, one must ask to what extent it is reasonable to maintain that positively charged cations M^+ with favourably directed vacant p orbitals remain uncoordinated by the surrounding anionic ligands X^- to form extended (bridged) complexes. Such interaction would be expected to increase from Cs^+ to Li^+ and from F^- to I^- (why?) and would place some electron density between the cation and anion. Some evidence on this comes from very precise electron density plots obtained by X-ray diffraction experiments on LiF, NaCl, KCl, MgO and CaF_2.[22] Data for LiF are shown in Fig. 4.2a from which it is clear that the Li^+ ion is no longer spherical and that the electron density, while it falls to a low value between the ions, does not become zero. Even more significantly, as shown in Fig. 4.2b, the minimum does not occur at the position to be expected from the conventional ionic radii: whatever set of tabulated values is used the cation is always larger than expected and the anion smaller. This is consistent with a transfer of some electronic density from anion to cation since the smaller resultant positive charge on the cation exerts smaller coulombic attraction for the electrons and the ion expands. The opposite holds for the anion. These results also call into question the use of radius-ratio rules to calculate the coordination number of cations and leave undecided the numerical value of the ionic radii to be used (see also p. 66, hydrides). In fact, the radius-ratio rules are particularly unhelpful for the alkali halides, since they predict (incorrectly) that LiCl, LiBr and LiI should have tetrahedral coordination and that NaF, KF, KCl, RbF, RbCl, RbBr and CsF should all have the CsCl structure. It may be significant that adoption of the NaCl structure by all these compounds maximizes the p orbital overlap along the orthogonal *x*-, *y*- and *z*-directions, and so favours molecular orbital formation in these directions. Further information on the variation in apparent radius of the hydride, halide and other anions in compounds with the alkali metals and other cations is in ref. 23.

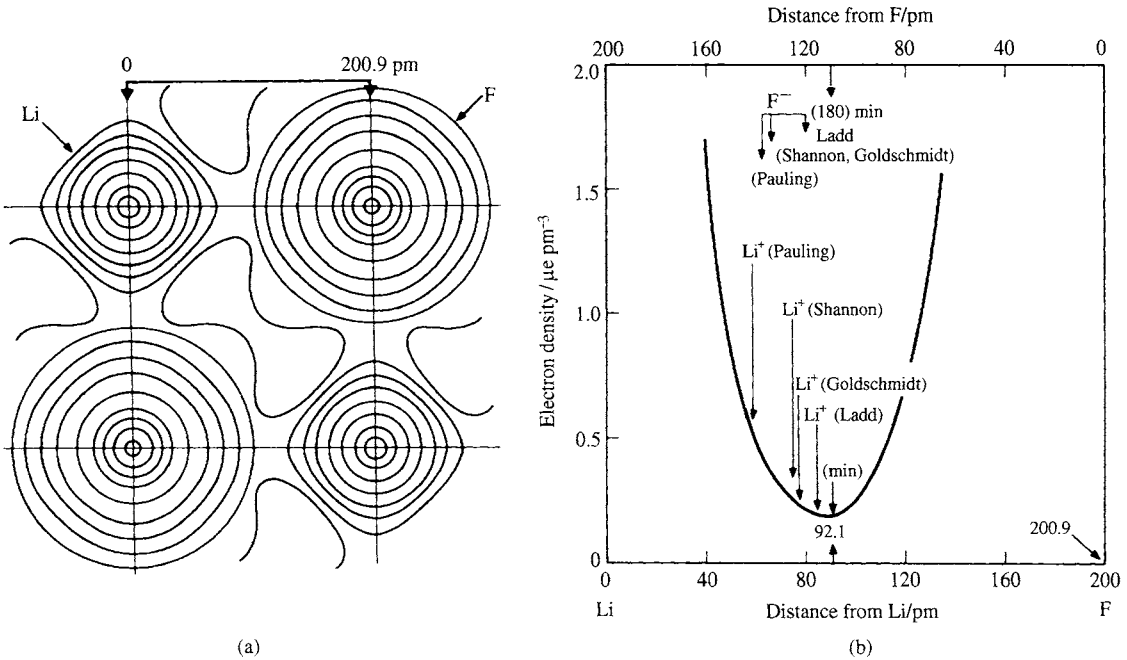

Figure 4.2 (a) Distribution of electron density ($\mu e/pm^3$) in the *xyo* plane of LiF, and (b) variation of electron density along the Li–F direction near the minimum. The electron density rises to 17.99 $\mu e\,pm^{-3}$ at Li and to 115.63 $\mu e\,pm^{-3}$ at F. (The unit $\mu e\,pm^{-3}$ is numerically identical to e $Å^{-3}$.)

Deviations from the simple ionic model are expected to increase with increasing formal charge on the cation or anion and with increasing size and ease of distortion of the anion. Again, deviations tend to be greater for smaller cations and for those (such as Cu^+, Ag^+, etc.) which do not have an inert-gas configuration.[18] The gradual transition from predominantly ionic to covalent is illustrated by the "isoelectronic" series:

$$NaF, MgF_2, AlF_3, SiF_4, PF_5, SF_6, IF_7, F_2$$

A similar transition towards metallic bonding is illustrated by the series:

$$NaCl, Na_2O, Na_2S, Na_3P, Na_3As, Na_3Sb, Na_3Bi, Na$$

Alkali metal alloys with gold have the CsCl structure and, whilst NaAu and KAu are essentially metallic, RbAu and CsAu have partial ionic bonding and are n-type semiconductors. These factors should constantly be borne in mind during the discussion of compounds in later chapters.

The extent to which charge is transferred back from the anion towards the cation in the alkali metal halides themselves is difficult to determine precisely. Calculations indicate that it is probably only a few percent for some salts such as NaCl, whereas for others (e.g. LiI) it may amount to more than 0.33 e^- per atom. Direct experimental evidence on these matters is available for some other elements from techniques such as Mössbauer spectroscopy,[24] electron spin resonance spectroscopy,[25] and neutron scattering form factors.[26]

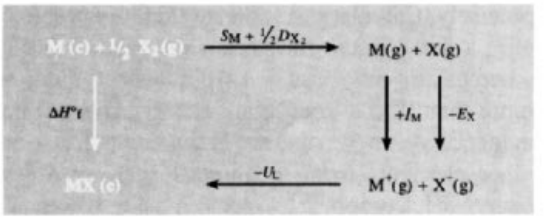
4.3.2 Halides and hydrides

The alkali metal halides are all high-melting, colourless crystalline solids which can be conveniently prepared by reaction of the appropriate hydroxide (MOH) or carbonate (M_2CO_3) with aqueous hydrohalic acid (HX), followed by recrystallization. Vast quantities of NaCl and KCl are available in nature and can be purified if necessary by simple crystallization. The hydrides have already been discussed (p. 65).

Trends in the properties of MX have been much studied and typical examples are illustrated in Figs. 4.3 and 4.4. The mp and bp always follow the trend F > Cl > Br > I except perhaps for some of the Cs salts where the data are uncertain. Figure 4.3 also shows that the mp and bp of LiX are always below those of NaX and that (with the exception of the mp of KI) the values for NaX are the maximum for each series. Trends in enthalpy of formation ΔH_f° and lattice energy U_L are even more regular (Fig. 4.4) and can readily be interpreted in terms of the Born–Haber cycle, providing one assumes an invariant charge corresponding to loss or gain of one complete electron per ion, M^+X^-. The Born–Haber cycle considers two possible routes to the formation of MX and equates the corresponding enthalpy changes by applying Hess's law:[18]



Hence

$$\Delta H_f^\circ(MX) = S_M + \tfrac{1}{2}D_{X_2} + I_M - E_X - U_L$$

where S_M is the heat of sublimation of M(c) to a monatomic gas (Table 4.2), D_{x_2} is the dissociation energy of X_2(g) (Table 4.2), I_M is the ionization energy of M(g) (Table 4.2), and E_x the electron affinity of X(g) (Table 17.3, p. 800). The

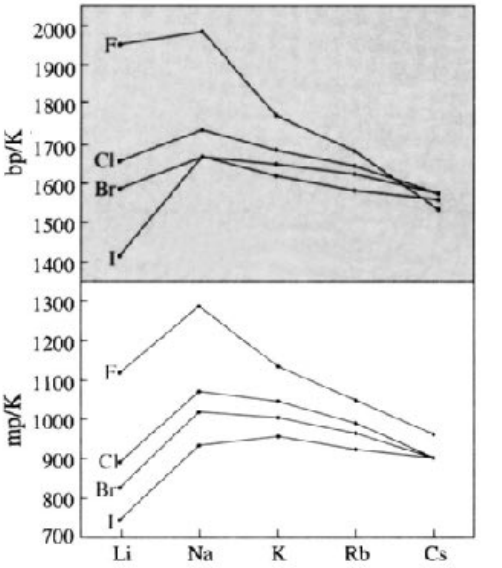


Figure 4.3 Melting point and boiling point of alkali metal halides.

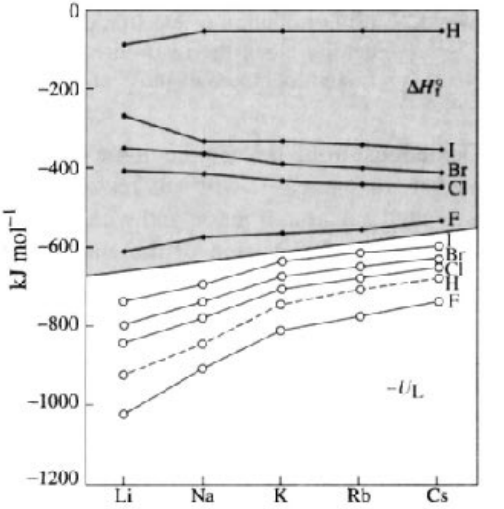

Figure 4.4 Standard enthalpies of formation (ΔH_f°) and lattice energies (plotted as $-U_L$) for alkali metal halides and hydrides.

lattice energy U_L is given approximately by the expression

$$U_L = \frac{N_0 A e^2}{4\pi\varepsilon_0 r_0}\left(1 - \frac{\rho}{r_0}\right)$$

where N_0 is the Avogadro constant, A is a geometrical factor, the Madelung constant (which has the value of 1.7627 for the CsCl structure and 1.7476 for the NaCl structure), r_0 is the shortest internuclear distance between M^+ and X^- in the crystal, and ρ is a measure of the close-range repulsion force which resists mutual interpenetration of the ions. It is clear that the sequence of lattice energies is determined primarily by r_0, so that the lattice energy is greatest for LiF and smallest for CsI, as shown in Fig. 4.4. In the Born–Haber expression for ΔH_f° this factor predominates for the fluorides and there is a trend to smaller enthalpies of formation from LiF to CsF (Fig. 4.4). The same incipient trend is noted for the hydrides MH, though here the numerical values of ΔH_f° are all much smaller than those for MX because of the much higher heat of dissociation of H_2 compared to X_2. By contrast with the fluorides, the lattice energy for the larger halides is smaller and less dominant, and the resultant trend of ΔH_f° is to larger values, thus reflecting the greater ease of subliming and ionizing the heavier alkali metals.

The Born–Haber cycle is also useful in examining the possibility of forming alkali–metal halides of stoichiometry MX_2. The dominant term will clearly be the very large second-stage ionization energy for the process $M^+(g) \longrightarrow M^{2+}(g) + e^-$; this is 7297 kJ mol^{-1} for Li but drops to 2255 kJ mol^{-1} for Cs. The largest possible lattice energy to compensate for this would be obtained with the smallest halogen F and (making plausible assumptions on lattice structure and ionic radius) calculations indicate that CsF_2 could indeed be formed exothermically from its elements:

$$Cs(s) + F_2(g) = CsF_2(s); \quad \Delta H_f^\circ \simeq -125\,kJ\,mol^{-1}$$

However, the compound cannot be prepared because of the much greater enthalpy of formation of CsF which makes CsF_2 unstable with respect to decomposition:

$$Cs(s) + \tfrac{1}{2}F_2(g) = CsF(s); \quad \Delta H_f^\circ = -530\,kJ\,mol^{-1}$$

whence

$$CsF_2(s) = CsF(s) + \tfrac{1}{2}F_2; \quad \Delta H_{disprop} \simeq -405\,kJ\,mol^{-1}$$

There is some evidence that Cs^{3+} can be formed by cyclic voltammetry of $Cs^+[OTeF_5]^-$ in pure MeCN at the extremely high oxidizing potential of 3 V, and that Cs^{3+} might be stabilized by 18-crown-6 and cryptand (see pp. 96 and 97 for nomenclature).[27] However, the isolation of pure compounds containing Cs^{3+} has so far not been reported.

Ternary alkali-metal halide oxides are known and have the expected structures. Thus Na_3ClO and the yellow K_3BrO have the anti-perovskite structure (p. 963) whereas Na_4Br_2O, Na_4I_2O and K_4Br_2O have the tetragonal anti-K_2NiF_4 structure.[28]

The alkali metal halides, particularly NaCl and KCl, find extensive application in industry (pp. 71 and 73). The hydrides are frequently used as reducing agents, the product being a hydride or complex metal hydride depending on the conditions used, or the free element if the hydride is unstable. Illustrative examples using NaH are:

$$2BF_3 + 6NaH \xrightarrow{200^\circ} B_2H_6 + 6NaF$$

$$BF_3 + 4NaH \xrightarrow{Et_2O/125^\circ} NaBH_4 + 3NaF$$

$$B(OMe)_3 + NaH \xrightarrow{\text{reflux}} Na[BH(OMe)_3]$$

$$B(OMe)_3 + 4NaH \xrightarrow{225-275^\circ} NaBH_4 + 3NaOMe$$

$$AlBr_3 + 4NaH \xrightarrow{Me_2O} NaAlH_4 + 3NaBr$$

$$TiCl_4 + 4NaH \xrightarrow{400^\circ} Ti + 4NaCl + 2H_2$$

Sulfur dioxide is uniquely reduced to dithionite (a process useful in bleaching paper pulp, p. 720). CO_2 gives the formate:

$$2SO_2(l) + 2NaH \longrightarrow Na_2S_2O_4 + H_2$$

$$CO_2(g) + NaH \longrightarrow HCO_2Na$$

Particularly reactive (pyrophoric) forms of LiH, NaH and KH can be prepared simply and in high yield by the direct hydrogenation of

[27] K. Moock and K. Seppelt, *Angew. Chem. Int. Edn. Engl.* **28**, 1676–8 (1989).

[28] S. Sitta, K. Hippler, P. Vogt and H. Sabrowsky, *Z. anorg. allg. Chem.* **597**, 197–200 (1991).

hexane solutions of MBu^n in the presence of tetramethylethylenediamine (tmeda) and these have proved extremely useful reagents for the metalation of organic compounds which have an active hydrogen site.[29]

4.3.3 Oxides, peroxides, superoxides and suboxides

The alkali metals form a fascinating variety of binary compounds with oxygen, the most versatile being Cs which forms 9 compounds with stoichiometries ranging from Cs_7O to CsO_3. When the metals are burned in a free supply of air the predominant product depends on the metal: Li forms the oxide Li_2O (plus some Li_2O_2), Na forms the peroxide Na_2O_2 (plus some Na_2O) whilst K, Rb and Cs form the superoxide MO_2. Under the appropriate conditions pure compounds M_2O, M_2O_2 and MO_2 can be prepared for all five metals.

The "normal" oxides M_2O (Li, Na, K, Rb) have the antifluorite structure as do many of the corresponding sulfides, selenides and tellurides. This structure is related to the CaF_2 structure (p. 118) but with the sites occupied by the cations and anions interchanged so that M replaces F and O replaces Ca in the structure. Cs_2O has the anti-$CdCl_2$ layer structure (p. 1211). There is a trend to increasing coloration with increasing atomic number, Li_2O and Na_2O being pure white, K_2O yellowish white, Rb_2O bright yellow and Cs_2O orange. The compounds are fairly stable towards heat, and thermal decomposition is not extensive below about 500°. Pure Li_2O is best prepared by thermal decomposition of Li_2O_2 (see below) at 450°C. Na_2O is obtained by reaction of Na_2O_2, NaOH or preferably $NaNO_2$ with the Na metal:

$$Na_2O_2 + 2Na \longrightarrow 2Na_2O$$

$$NaOH + Na \longrightarrow Na_2O + \tfrac{1}{2}H_2$$

$$NaNO_2 + 3Na \longrightarrow 2Na_2O + \tfrac{1}{2}N_2$$

In this last reaction Na can be replaced by the azide NaN_3 to give the same products. The normal oxides of the other alkali metals can be prepared similarly.

The peroxides M_2O_2 contain the peroxide ion O_2^{2-} which is isoelectronic with F_2. Li_2O_2 is prepared industrially by the reaction of $LiOH.H_2O$ with hydrogen peroxide, followed by dehydration of the hydroperoxide by gentle heating under reduced pressure:

$$LiOH.H_2O + H_2O_2 \longrightarrow LiOOH.H_2O + H_2O$$

$$2LiOOH.H_2O \xrightarrow{\text{heat}} Li_2O_2 + H_2O_2 + 2H_2O$$

It is a thermodynamically stable, white, crystalline solid which decomposes to Li_2O on being heated above 195°C.

Na_2O_2, is prepared as pale-yellow powder by first oxidizing Na to Na_2O in a limited supply of dry oxygen (air) and then reacting this further to give Na_2O_2:

$$2Na + \tfrac{1}{2}O_2 \xrightarrow{\text{heat}} Na_2O \xrightarrow{\frac{1}{2}O_2} Na_2O_2$$

Preparation of pure K_2O_2, Rb_2O_2 and Cs_2O_2 by this route is difficult because of the ease with which they oxidize further to the superoxides MO_2. Oxidation of the metals with NO has been used but the best method is the quantitative oxidation of the metals in liquid ammonia solution (p. 78). The peroxides can be regarded as salts of the dibasic acid H_2O_2. Thus reaction with acids or water quantitatively liberates H_2O_2:

$$M_2O_2 + H_2SO_4 \longrightarrow M_2SO_4 + H_2O_2;$$

$$M_2O_2 + H_2O \longrightarrow 2MOH + H_2O_2$$

Sodium peroxide finds widespread use industrially as a bleaching agent for fabrics, paper pulp, wood, etc., and as a powerful oxidant; it explodes with powdered aluminium or charcoal, reacts with sulfur with incandescence and ignites many organic liquids. Carbon monoxide forms the carbonate, and CO_2 liberates oxygen (an important application in breathing apparatus for divers, firemen, and in submarines — space capsules use the lighter Li_2O_2):

$$Na_2O_2 + CO \longrightarrow Na_2CO_3$$

[29] P. A. A. KLUSENER, L. BRANDSMA, H. D. VERKRUIJSSE, P. v. R. SCHLEYER, T. FRIEDL and R. PI, *Angew. Chem. Int. Edn. Engl.* **25**, 465 (1986).

$$Na_2O_2 + CO_2 \longrightarrow Na_2CO_3 + \tfrac{1}{2}O_2$$

In the absence of oxygen or oxidizable material, the peroxides (except Li_2O_2) are stable towards thermal decomposition up to quite high temperatures, e.g. $Na_2O_2 \sim 675°C$, $Cs_2O_2 \sim 590°C$.

The superoxides MO_2 contain the paramagnetic ion O_2^- which is stable only in the presence of large cations such as K, Rb, Cs (and Sr, Ba, etc.). LiO_2 has only been prepared by matrix isolation experiments at 15 K and positive evidence for NaO_2 was first obtained by reaction of O_2 with Na dissolved in liquid NH_3; it can be obtained pure by reacting Na with O_2 at 450°C and 150 atm pressure. By contrast, the normal products of combustion of the heavier alkali metals in air are KO_2 (orange), mp 380°C, RbO_2 (dark brown), mp 412°C and CsO_2 (orange), mp 432°C. NaO_2 is trimorphic, having the marcasite structure (p. 680) at low temperatures, the pyrite structure (p. 680) between −77° and −50°C and a pseudo-NaCl structure above this, due to disordering of the O_2^- ions by rotation. The heavier congeners adopt the tetragonal CaC_2 structure (p. 298) at room temperature and the pseudo-NaCl structure at high temperature.

Sesquoxides "M_2O_3" have been prepared as dark-coloured paramagnetic powders by careful thermal decomposition of MO_2 (K, Rb, Cs). They can also be obtained by oxidation of liquid ammonia solutions of the metals or by controlled oxidation of the peroxides, and are considered to be peroxide disuperoxides $[(M^+)_4(O_2^{2-})(O_2^-)_2]$. Indeed, pure Rb_4O_6, prepared by solid-state reaction between Rb_2O_2 and $2RbO_2$, has recently been shown to be $[Rb_4(O_2^{2-})(O_2^-)_2]$ by single-crystal diffractometry, although the two types of diatomic anion could not be distinguished in the cubic unit cell even at −60°C; the compound is thermodynamically stable and melts at 461°C[30]

Ozonides MO_3 have been prepared for Na, K, Rb and Cs by the reaction of O_3 on powdered anhydrous MOH at low temperature and extraction of the red MO_3 by liquid NH_3:

$$3MOH(c) + 2O_3(g) \longrightarrow 2MO_3(c) + MOH.H_2O(c) + \tfrac{1}{2}O_2(g)$$

Under similar conditions Li gives $[Li(NH_3)_4]O_3$ which decomposes on attempted removal of the coordinated NH_3, again emphasizing the important role of cation size in stabilizing catenated oxygen anions. Improved techniques involving the reaction of oxygen/ozone mixtures on the preformed peroxide, followed by extraction with liquid ammonia, now permit gram amounts of the pure crystalline ozonides of K, Rb and Cs to be prepared.[31] (See also p. 98, p. 610.) The ozonides, on standing, slowly decompose to oxygen and the superoxide MO_2, but on hydrolysis they appear to go directly to the hydroxide:

$$MO_3 \longrightarrow MO_2 + \tfrac{1}{2}O_2$$

$$4MO_3 + 2H_2O \longrightarrow 4MOH + 5O_2$$

In addition to the above oxides M_2O, M_2O_2, M_4O_6, MO_2 and MO_3 in which the alkali metal has the constant oxidation state +1, rubidium and caesium also form suboxides in which the formal oxidation state of the metal is considerably lower. Some of these intriguing compounds have been known since the turn of the century but only recently have their structures been elucidated by single crystal X-ray analysis.[32] Partial oxidation of Rb at low temperatures gives Rb_6O which decomposes above −7.3°C to give copper-coloured metallic crystals of Rb_9O_2:

$$2Rb_6O \xrightarrow{-7.3°} Rb_9O_2 + 3Rb$$

Rb_9O_2 inflames with H_2O and melts incongruently at 40.2° to give $2Rb_2O + 5Rb$. The structure of Rb_9O_2 comprises two ORb_6 octahedra sharing a common face (Fig. 4.5). It thus has the anti-$[Tl_2Cl_9]^{3-}$ structure. The Rb–Rb distance within this unit is only 352 pm (compared with 485 pm in Rb metal) and the nearest Rb–Rb distance

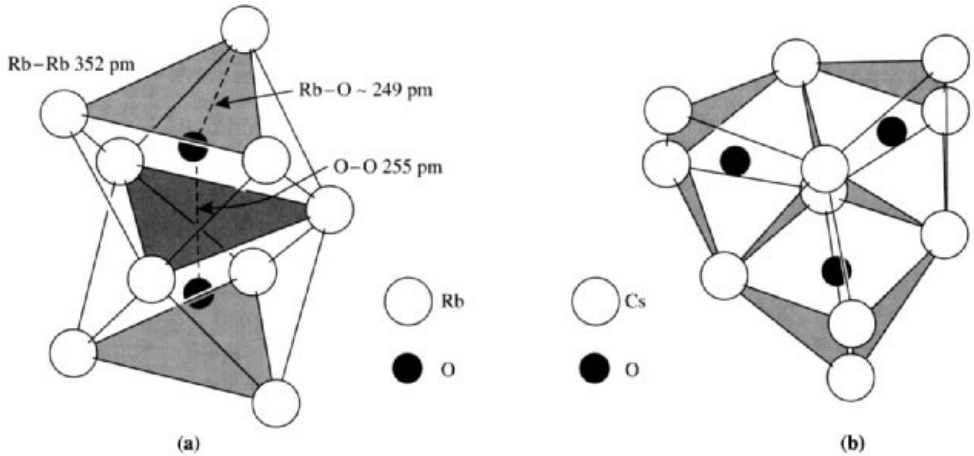

Figure 4.5 (a) The confacial bioctahedral Rb_9O_2 group in Rb_9O_2 and Rb_6O, and (b) the confacial trioctahedral $Cs_{11}O_3$ group in Cs_7O.

between groups is 511 pm. The Rb–O distance is ~249 pm, much less than the sum of the conventional ionic radii (289 pm) and the metallic character of the oxide comes from the excess of at least 5 electrons above that required for simple bookkeeping. Crystalline Rb_6O has a unit cell containing 4 formula units, i.e. $Rb_{24}O_4$, and the structure consists of alternating layers of Rb_9O_2 and close-packed metal atoms parallel to (001) to give the structural formula $[(Rb_9O_2)Rb_3]$.

Caesium forms an even more extensive series of suboxides:[32] Cs_7O, bronze-coloured, mp +4.3°C; Cs_4O, red-violet, decomposes >10.5°; $Cs_{11}O_3$, violet crystals, mp (incongruent) 52.5°C; and $Cs_{3+x}O$, a nonstoichiometric phase up to Cs_4O, which decomposes at 166°C. Cs_7O reacts vigorously with O_2 and H_2O and the unit cell is found to be $Cs_{21}O_3$, i.e. $[(Cs_{11}O_3)Cs_{10}]$. The unit $Cs_{11}O_3$ comprises 3 octahedral OCs_6 groups each sharing 2 adjacent faces to form the trigonal group shown in Fig. 4.5b. These groups form chains along (001) and are also surrounded by the other Cs atoms. The Cs–Cs distance within the $Cs_{11}O_3$ group is only 376 pm, whereas between groups it is 527 pm; this latter distance is also the shortest distance between Cs in a group and the other 10 Cs atoms, and is similar to the interatomic distance in Cs metal. The structures of the other 3 suboxides are more complex but it is salutory to realize that Cs forms at least 9 crystalline oxides whose structures can be rationalized in terms of general bonding systematics.

4.3.4 Hydroxides

Evaporation of aqueous solutions of LiOH under normal conditions produces the monohydrate, and this can be readily dehydrated by heating in an inert atmosphere or under reduced pressure. $LiOH.H_2O$ has a crystal structure built up of double chains in which both Li and H_2O have 4 nearest neighbours (Fig. 4.6a); Li is tetrahedrally coordinated by 2OH and $2H_2O$, and each tetrahedron shares an edge (2OH) and two corners ($2H_2O$) to produce double chains which are held laterally by H bonds. Each H_2O molecule is tetrahedrally coordinated by 2Li from the same chain and 2OH from other chains. Anhydrous LiOH has a layer lattice of edge-shared $Li(OH)_4$ tetrahedra (Fig. 4.6b) in which each Li in a plane is surrounded tetrahedrally by 4OH, and each OH has 4Li neighbours all lying on one side; neutron diffraction shows that the OH bonds are normal to the layer plane and there is no H bonding between layers.

Numerous hydrates have been prepared from aqueous solutions of the heavier alkali metal

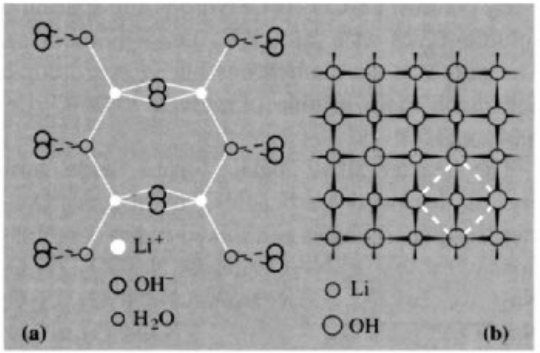

Figure 4.6 (a) The double-chain structure of $LiOH.H_2O$, and (b) the layer structure of anhydrous LiOH (see text).

hydroxides (e.g. $NaOH.nH_2O$, where $n = 1$, 2, 2.5, 3.5, 4, 5.25 and 7) but little detailed structural information is available.[33] The anhydrous compounds all show the influence of oriented OH groups on the structure,[13] and there is evidence of weak O—H···O bonding for KOH and RbOH. Melting points are substantially lower than those of the halides, decreasing from 471°C for LiOH to 272° for CsOH, and the mp of the hydrates is even lower, e.g. 2.5°C (incongr.) for $CsOH.2H_2O$ and −5.5°C for the trihydrate.

The alkali metal hydroxides are the most basic of all hydroxides. They react with acids to form salts and with alcohols to form alkoxides. The alkoxides are oligomeric and the degree of polymerization can vary depending on the particular metal and the state of aggregation. The *tert*-butoxides, $MOBu^t$, ($Bu^t = OCMe_3$) can be considered as an example. Crystalline $(KOBu^t)_4$ has a cubane-like structure and the tetramer persists in tetrahydrofuran solution and in the gas phase.[34,35] By contrast, $(NaOBu^t)_4$ is exclusively tetrameric in thf, but is a mixture of hexamers and nonamers in the crystalline state and of hexamers and heptamers in the vapour phase. The lithium analogue is tetrameric in thf but is hexameric in benzene, toluene or cyclohexane and in the gas phase. The degree of polymerization can also be influenced by the nature of the organic residue. Thus X-ray crystallography shows that lithium 2,6-di-*tert*-butyl-4-methylphenolate is dimeric whereas the closely related phenolate $\{LiOC_6H_2(CH_2NMe_2)_2\text{-}2,6\text{-}Me\text{-}4\}_3$ provides the first example of a trimeric structure, with an essentially planar central Li_3O_3 heterocyclic ring.[36] The trimer, like the dimer, features unusually short Li–O and C_{ipso}–O bonds (186.5 and 130.1 pm, respectively) perhaps suggesting quasi-aromaticity of the Li_3O_3 ring, the delocalized π-electrons originating from the lone pairs on the oxygen atoms.

The alkali metal hydroxides are also readily absorb CO_2 and H_2S to form carbonates (or hydrogencarbonates) and sulfides (or hydrogensulfides), and are extensively used to remove mercaptans from petroleum products. Amphoteric oxides such as those of Al, Zn, Sn and Pb react with MOH to form aluminates, zincates, stannates and plumbates, and even SiO_2 (and silicate glasses) are attacked.

Production and uses of LiOH have already been discussed (p. 70). Huge tonnages of NaOH and KOH are produced by electrolysis of brine (pp. 71, 73) and the enormous industrial importance of these chemicals has already been alluded to.

4.3.5 Oxoacid salts and other compounds

Many binary and pseudo-binary compounds of the alkali metals are more conveniently treated within the context of the chemistry of the other element and for this reason discussion is deferred to later chapters, e.g. borides (p. 145),

[33] H. Jacobs and U. Metzner, *Z. anorg. allg. Chem.* **597**, 97–106 (1991). D. Mootz and H. Rutter, *Z. anorg. allg. Chem*, **608**, 123–30 (1992).

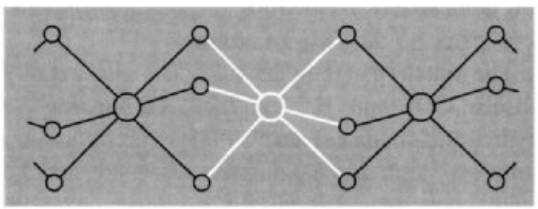
[36] P. A. van der Schaaf, M. P. Hogerheide, D. M. Grove, A. L. Spek and G. van Koten, *J. Chem. Soc., Chem. Commun.*, 1703–5 (1992).

graphite intercalation compounds (p. 293), carbides, cyanides, cyanates, etc. (pp. 297, 319), silicides (p. 335), germanides (p. 393), nitrides, azides and amides (p. 417), phosphides (p. 489), arsenides (p. 554), sulfides (p. 676), selenides and tellurides (p. 765), polyhalides (p. 835), etc. Likewise, the alkali metals form stable salts with virtually all oxoacids and these are also discussed in later chapters.

Lithium salts show a great propensity to crystallize as hydrates, the trihydrates being particularly common, e.g. $LiX.3H_2O$, X = Cl, Br, I, ClO_3, ClO_4, MnO_4, NO_3, BF_4, etc. In most of these Li is coordinated by $6H_2O$ to form chains of face-sharing octahedra:



By contrast Li_2CO_3 is anhydrous and sparingly soluble (1.28 wt% at 25°C, i.e. 0.17 mol l^{-1}). The nitrate is also anhydrous but is hygroscopic and much more soluble (45.8 wt% at 25°C, i.e. 6.64 mol l^{-1}).

The heavier alkali metals form a wide variety of hydrated carbonates, hydrogencarbonates, sesquicarbonates and mixed-metal combinations of these, e.g. $Na_2CO_3.H_2O$, $Na_2CO_3.7H_2O$, $Na_2CO_3.10H_2O$, $Na_2CO_3.NaHCO_3.2H_2O$, $Na_2CO_3.3NaHCO_3$, $NaKCO_3.nH_2O$, $K_2CO_3.NaHCO_3.2H_2O$, etc. These systems have been studied in great detail because of their industrial and geochemical significance (see Panel). Some solubility data are in Fig. 4.7, which indicates the considerable solubility of Rb_2CO_3 and Cs_2CO_3 and the lower solubility of the hydrogencarbonates. The various stoichiometries reflect differing ways of achieving charge balance, preferred coordination polyhedra, and H bonding. Thus $Na_2CO_3.H_2O$ has two types of 6-coordinate Na, half being surrounded by $1H_2O$ plus 5 oxygen atoms from CO_3 groups and half by

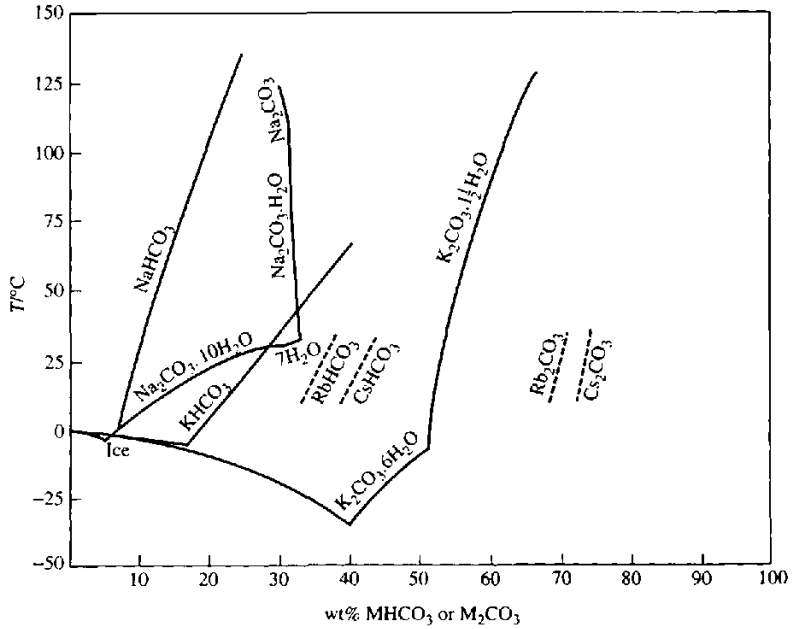


Figure 4.7 Solubilities of alkali carbonates and bicarbonates (hydrogencarbonates). (H. Stephen and T. Stephen, *Solubilities of Inorganic and Organic Compounds*, Vol. 1, Part 1, Macmillan, New York.).

Industrial Production and Uses of Sodium Carbonate, Hydroxide and Sulfate[37]

Na_2CO_3 (soda ash) is interchangeable with NaOH in many of its applications (e.g. paper pulping, soap, detergents) and this gives a valuable flexibility to the chlor-alkali industry. About half the Na_2CO_3 produced is used in the glass industry. One developing application is in the reduction of sulfur pollution resulting from stack gases of power plants and other large furnaces: powdered Na_2CO_3 is injected with the fuel and reacts with SO_2 to give solids such as Na_2SO_3 which can be removed by filtration or precipitation. World production of Na_2CO_3 was 28.7 million tonnes in 1985: the five leading countries were the USA, the USSR, China, Bulgaria and the Federal Republic of Germany, and they accounted for over 70% of production. Most of this material was synthetic (Solvay), but the increasing use of natural carbonate (trona) is notable, particularly in the USA where it is now the sole source of Na_2CO_3, the last synthetic unit having been closed in 1985: reserves in the Green River, Wyoming, deposit alone exceed 10^{10} tonnes and occur in beds up to 3 m thick over an area of 2300 km^2. About one third of the world production is now from natural deposits.

Formerly Na_2CO_3 found extensive use as "washing soda" but this market has now disappeared due to the domestic use of detergents. The related compound $NaHCO_3$ is, however, still used, particularly because of its ready decomposition in the temperature range 50–100°C:

$$2NaHCO_3 \longrightarrow Na_2CO_3 + H_2O + CO_2$$

Production in the USA is ~350 000 tonnes annually of which 30% is used in baking-powder formulations, 20% in animal feedstuffs, 15% in chemicals manufacture, 11% in pharmaceuticals, 9% in fire extinguishers and the remaining 15% in the textile, leather and paper industries and in soaps, detergents and neutralizing agents.

Caustic soda (NaOH) is industry's most important alkali. It is manufactured on a huge scale by the electrolysis of brine (p. 72) and annual production in the USA alone is over 10 million tonnes. Electrolysis is followed by concentration of the alkali in huge tandem evaporators such as those at PPG Industries' Lake Charles plant. The evaporators, which are perhaps the world's largest, are 41 m high and 12 m in diameter. About half the caustic produced is used directly in chemical production; a detailed breakdown of usage (USA, 1985) is: organic chemicals 30%, inorganic chemicals 20%, paper and pulp 20%, export 10%, soap and detergents 5%, oil industry 5%, textiles 4%, bauxite digestion 3% and miscellaneous 3%. Principal applications are in acid neutralization, the manufacture of phenol, resorcinol, β-naphthol, etc., and the production of sodium hypochlorite, phosphate, sulfide, aluminates, etc.

Salt cake (Na_2SO_4) is a byproduct of HCl manufacture using H_2SO_4 and is also the end-product of hundreds of industrial operations in which H_2SO_4 used for processing is neutralized by NaOH. For long it had few uses, but now it is the mainstay of the paper industry, being a key chemical in the kraft process for making brown wrapping paper and corrugated boxes: digestion of wood chips or saw-mill waste in very hot alkaline solutions of Na_2SO_4 dissolves the lignin (the brown resinous component of wood which cements the fibres together) and liberates the cellulose fibres as pulp which then goes to the paper-making screens. The remaining solution is evaporated until it can be burned, thereby producing steam for the plant and heat for the evaporation: the fused Na_2SO_4 and NaOH survive the flames and can be reused. Total world production of Na_2SO_4 (1985) was ~4.5 million tonnes (45% natural, 55% synthetic). Most of this (~70%) is used in the paper industry and smaller amounts are used in glass manufacture and detergents (~10% each). The hydrated form, $Na_2SO_4.10H_2O$, Glauber's salt, is now less used than formerly. Further information on the industrial production and uses of Na_2CO_3, NaOH and Na_2SO_4 are given in *Kirk–Othmer Encyclopedia of Chemical Technology*, 4th edn., Vol. 1, 1991, pp. 1025–39 and Vol. 22, 1997, pp. 354–419.

$2H_2O$ plus 4 oxygen atoms from CO_3 groups. The decahydrate has octahedral $Na(H_2O)_6$ groups associated in pairs by edge sharing to give $[Na_2(H_2O)_{10}]$. The hydrogencarbonate $NaHCO_3$ has infinite one-dimensional chains of HCO_3 formed by unsymmetrical O–H···O bonds (261 pm) which are held laterally by Na ions. The sesquicarbonates $Na_3H(CO_3)_2.2H_2O$ have short, symmetrical O–H–O bonds (253 pm) which link the carbonate ions in pairs, and longer O–H···O bonds (275 pm) which link these pairs to water molecules. Similar phases are known for the other alkali metals.

Alkali metal nitrates can be prepared by direct reaction of aqueous nitric acid on the appropriate hydroxide or carbonate. $LiNO_3$ is used for scarlet flares and pyrotechnic displays. Large deposits of $NaNO_3$ (saltpetre) are found in Chile and were probably formed by bacterial decay of small marine organisms: the NH_3 initially produced

[37] Ref. 4, pp. 149–63 and 219–25. See also *Kirk–Othmer Encyclopedia of Chemical Technology*, 4th edn., Vol. 1, 1991, Chlorine and sodium hydroxide, pp. 938–1025. Sodium carbonate, pp. 1025–39.

presumably oxidized to nitrous acid and nitric acid which would then react with dissolved NaCl. KNO_3 was formerly prepared by metathesis of $NaNO_3$ and KCl but is now obtained directly as part of the synthetic ammonia/nitric acid industry (p. 421).

Alkali metal nitrates are low-melting salts that decompose with evolution of oxygen above about 500°C, e.g.

$$2NaNO_3 \overset{\sim 500^\circ}{\rightleftharpoons} 2NaNO_2 + O_2;$$

$$2NaNO_3 \overset{\sim 800^\circ}{\rightleftharpoons} Na_2O + N_2 + \tfrac{5}{2}O_2$$

Thermal stability increases with increasing atomic weight, as expected. Nitrates have been widely used as molten salt baths and heat transfer media, e.g. the 1:1 mixture $LiNO_3$:KNO_3 melts at 125°C and the ternary mixture of 40% $NaNO_2$, 7% $NaNO_3$ and 53% KNO_3 can be used from its mp 142° up to about 600°C.

The corresponding nitrites, MNO_2, can be prepared by thermal decomposition of MNO_3 as indicated above or by reaction of NO with the hydroxide:

$$4NO + 2MOH \longrightarrow 2MNO_2 + N_2O + H_2O$$

$$6NO + 4MOH \longrightarrow 4MNO_2 + N_2 + 2H_2O$$

Chemical reduction of nitrates has also been employed:

$$KNO_3 + Pb \longrightarrow KNO_2 + PbO$$

$$2RbNO_3 + C \longrightarrow 2RbNO_2 + CO_2$$

The commercial production of $NaNO_2$ is achieved by absorbing oxides of nitrogen in aqueous Na_2CO_3 solution:

$$Na_2CO_3 + NO + NO_2 \longrightarrow 2NaNO_2 + CO_2$$

Nitrites are white, crystalline hygroscopic salts that are very soluble in water. When heated in the absence of air they disproportionate:

$$5NaNO_2 \longrightarrow 3NaNO_3 + Na_2O + N_2$$

$NaNO_2$, in addition to its use with nitrates in heat-transfer molten-salt baths, is much used in the production of azo dyes and other organo-nitrogen compounds, as a corrosion inhibitor and in curing meats.

Other oxoacid salts of the alkali metals are discussed in later chapters, e.g. borates (p. 205), silicates (p. 347), phosphites and phosphates (p. 510), sulfites, hydrogensulfates, thiosulfates, etc. (p. 706) selenites, selenates, tellurites and tellurates (p. 781), hypohalites, halites, halates and perhalates (p. 853), etc.

4.3.6 Coordination chemistry[38–42]

Exciting developments have occurred in the coordination chemistry of the alkali metals during the last few years that have completely rejuvenated what appeared to be a largely predictable and worked-out area of chemistry. Conventional beliefs had reinforced the predominant impression of very weak coordinating ability, and had rationalized this in terms of the relatively large size and low charge of the cations M^+. On this view, stability of coordination complexes should diminish in the sequence Li > Na > K > Rb > Cs, and this is frequently observed, though the reverse sequence is also known for the formation constants of, for example, the weak complexes with sulfate, peroxosulfate, thiosulfate and the hexacyanoferrates in aqueous solutions.[39] It was also known that the alkali metal cations formed numerous hydrates, or aqua-complexes, as discussed in the preceding section, and there is a definite, though smaller tendency to form ammine complexes such as $[Li(NH_3)_4]I$. Other well-defined complexes include the extremely stable adducts $LiX.5Ph_3PO$, $LiX.4Ph_3PO$ and $NaX.5Ph_3PO$, where X is a large anion such as I, NO_3, ClO_4, BPh_4, SbF_6, $AuCl_4$, etc.; these compounds melt in the range 200–315° and are stable to air and water (in which they are insoluble).

[42] C. SCHADE and P. v. R. SCHLEYER, *Adv. Organomet. Chem.* **27**, 169–278 (1987).

They probably all contain the tetrahedral ion $[Li(OPPh_3)_4]^+$ which was established by X-ray crystallography for the compound $LiI.5Ph_3PO$; the fifth molecule of Ph_3PO is uncoordinated.

In recent years this simple picture has been completely transformed and it is now recognized that the alkali metals have a rich and extremely varied coordination chemistry which frequently transcends even that of the transition metals. The efflorescence is due to several factors such as the emerging molecular chemistry of lithium in particular, the imaginative use of bulky ligands, the burgeoning numbers of metal amides, alkoxides, enolates and organometallic compounds, and the exploitation of multidentate crown and cryptand ligands. Some of these aspects will be dealt with more fully in subsequent subsections (4.3.7 and 4.3.8).

Lithium is now known in at least 20 coordination geometries with coordination numbers ranging from 1–12. Some illustrative examples are in Table 4.3 and in the accompanying Figs. 4.8 and 4.9 which will repay close attention. The bulky ligand bis(trimethylsilyl)methyl forms a derivative in which Li is 1-coordinate in the gas phase but which polymerizes in the crystalline form to give bent 2-coordinate Li (and 5-coordinate carbon). The related ligand tris(trimethylsilyl)methyl gives an anionic complex in which Li is linear 2-coordinate, and the

same stereochemistry is observed in the unique structure of Li_3N (Fig. 4.8a) which also features the highly unusual planar 6-coordination mode; the structure comprises hexagonal sheets of overall composition Li_2N stacked alternately with planes containing the 2-coordinate Li. The coordination number of N is 8 (hexagonal bipyramidal). Three-coordinate Li is known in planar, pyramidal and angular geometries, the latter two modes being illustrated in Fig. 4.8b, c and d. Numerous examples of 4-coordinate Li have already been mentioned. Five-coordinate Li can be trigonal bipyramidal as in [$LiBr(phen)_2$] and the aza cage cation shown in Fig. 4.8e, square pyramidal (Fig. 4.8f and g) or planar (Fig. 4.8h).

Table 4.3 indicates that octahedral coordination is a common mode for Li. Less usual is planar 6-fold coordination (Fig. 4.8a), pentagonal pyramidal coordination (Fig. 4.8i) or irregular 6-fold coordination (Fig. 4.9a). Examples of 7-fold coordination are in Fig. 4.9b and c. Lithium has cubic 8-fold coordination in the metallic form and in several of its alloys with metals of large radius. It is also 8-coordinate in the dilithionaphthalene complex shown in Fig. 4.9d; here the aromatic

hydrocarbon bonds to two lithium atoms in a bis-hexahapto bridging mode and each lithium is also coordinated by a chelating diamine. A much more complicated dimeric cluster compound, whose central ($Li_6Na_2Ni_2$) core is shown schematically in Fig. 4.9e, includes 9-coordinate lithium among its many fascinating structural features.

When Li metal is cold-worked it transforms from body-centred cubic to cubic close-packed in which each atom is surrounded by 12 others in twinned cuboctahedral coordination; below 78 K the stable crystalline modification is hexagonal close-packed in which each lithium atom has 12 nearest neighbours in the form of a cuboctahedron. This very high coordination

number is also found in the dimeric sandwich compound that Li forms with the extended planar hydrocarbon 7b*H*-indeno[1,2,3-*jk*]fluorene; in this case, as can be seen from Fig. 4.9f, the coordination geometry about the metal atoms is hexagonal prismatic.

Similar structural diversity has been established for the heavier alkali metals also but it is unnecessary to deal with this in detail. The structural chemistry of the organometallic compounds in particular, and of related complexes, has been well reviewed.[41,42]

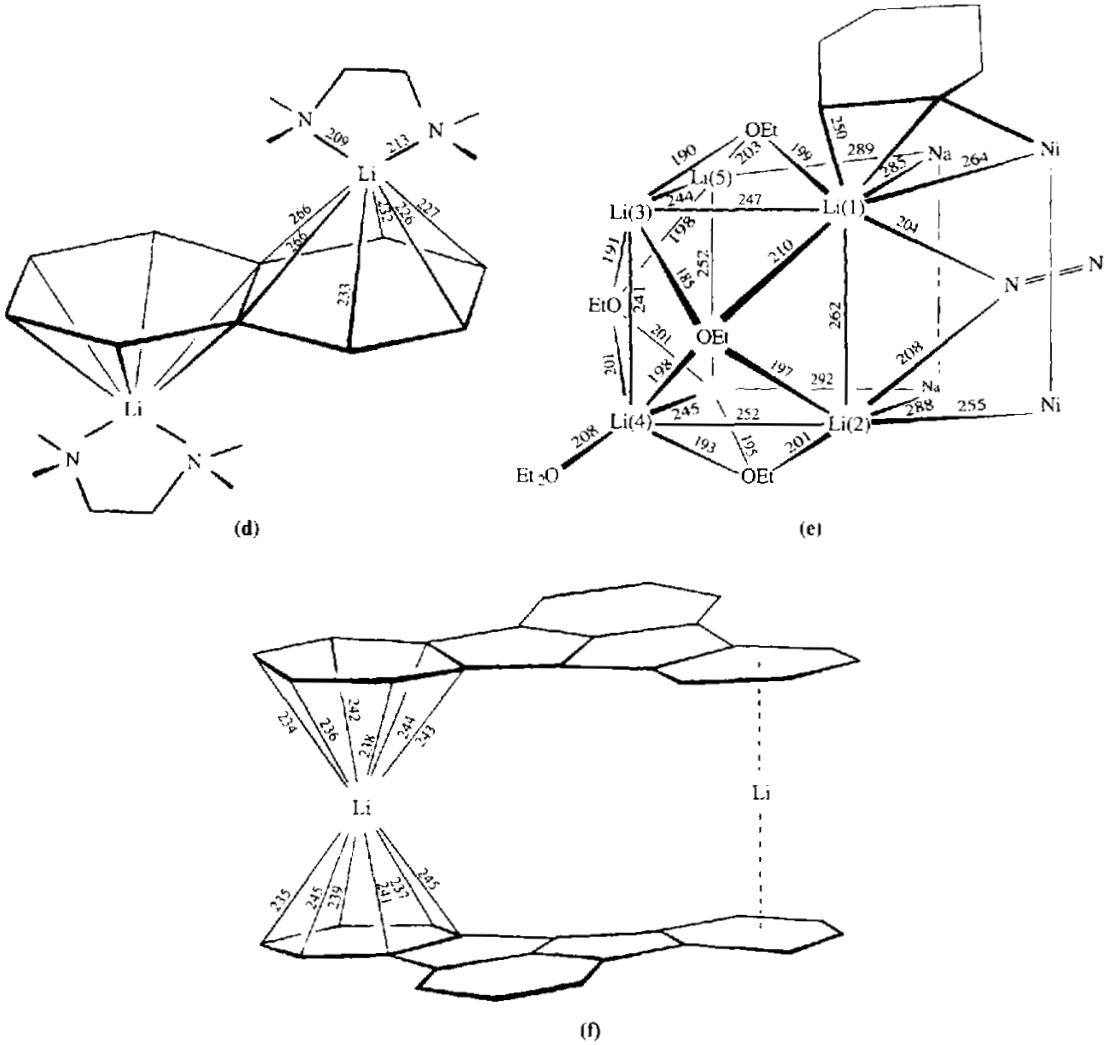

Figure 4.9 *continued*

Complexes with chelating organic reagents such as salicylaldehyde and β-diketonates were first prepared by N. V. Sidgwick and his students in 1925, and many more have since been characterized. Stability, as measured by equilibrium formation constants, is rather low and almost invariably decreases in the sequence Li > Na > K. This situation changed dramatically in 1967 when C. J. Pedersen announced the synthesis of several macrocyclic polyethers which were shown to form stable complexes with alkali metal and other cations.[64] The stability of the complexes was found to depend on the number and geometrical disposition of the ether oxygen atoms and in particular on the size and shape of potential coordination polyhedra relative to the size of the cation. For this reason stability could peak at any particular cation

[64] C. J. PEDERSEN, *J. Am. Chem. Soc.* **89**, 2495, 7017–36 (1967). See also C. J. PEDERSEN and H. K. FRENSDORF, *Angew. Chem. Int. Edn. Engl.* **11**, 16–25 (1972).

and, for M^I, this was often K and sometimes Na or Rb rather than Li. Pedersen, who was awarded a Nobel Prize for these discoveries, coined the epithet "crown" for this class of macrocyclic polyethers because, as he said "the molecular structure looked like one and, with it, cations could be crowned and uncrowned without physical damage to either".[65] Typical examples of such "crown" ethers are given in Fig. 4.10, the numerical prefix indicating the number of atoms in the heterocycle and the suffix the number of ether oxygens. The aromatic rings can be substituted, replaced by naphthalene residues, or reduced to cyclohexyl derivatives. The "hole size" for coordination depends on the number of atoms in the ring and is compared with conventional ionic diameters in Table 4.4. The best complexing agents are rings of 15–24 atoms including 5 to eight oxygen atoms. Nitrogen and sulfur can also serve as the donor atoms in analogous macroheterocycles.

The X-ray crystal structures of many of these complexes have now been determined: representative examples are shown in Fig. 4.11 from which it is clear that, at least for the larger cations, coordinative saturation and bond directionality are far less significant factors than in many transition element complexes.[66,67] Further interest in these ligands stems from their use in biochemical modelling since they sometimes mimic the behaviour of naturally occurring, neutral, macrocyclic antibiotics such as valinomycin, monactin, nonactin, nigericin

and enneatin.[68,69] They may also shed some light on the perplexing and remarkably efficient selectivity between Na and K in biological systems.[68–70]

Another group of very effective ligands that have recently been employed to coordinate alkali metal cations are the macrobicyclic polydentate ligands that J.-M. Lehn has termed "cryptands",[71] e.g. $N\{(CH_2CH_2O)_2CH_2CH_2\}_3N$ (Fig. 4.13a, b). This forms a complex $[Rb(crypt)]CNS.H_2O$ in which the ligand encapsulates the cation with a bicapped trigonal prismatic coordination polyhedron (Fig. 4.12c, d). Such complexes are finding increasing use in solvent extraction, phase-transfer catalysis,[72] the

Figure 4.12 A typical cryptand and its complex.

stabilization of uncommon or reactive oxidation states and the promotion of otherwise improbable reactions. Extraordinarily pronounced selectivity in complexation can be achieved by suitably designed ligands, some of the more spectacular being $K^+/Na^+ \sim 10^5$, $Cu^{2+}/Zn^{2+} \sim 10^8$, $Cd^{2+}/Zn^{2+} \sim 10^9$.

A growing application of cryptands and other macrocyclic polydentate ligands is in protecting sensitive anions from the polarizing and destabilizing effect of cationic charges, by encapsulating or crowning the cation and so preventing its close approach to the anion. For example, ozonides of K, Rb and Cs form stable solutions in typical organic solvents (such as CH_2Cl_2, tetrahydrofuran or MeCN) when the cation is coordinated by crown ethers or cryptands, thus enabling the previously unstudied solution chemistry of O_3^- to be investigated at room temperature.[73] Slow evaporation of ammonia solutions of such complexes yields red crystalline products and an X-ray structure of $[Rb(\eta^6\text{-18-crown-6})(\eta^2\text{-}O_3)(NH_3)]$ reveals 9-coordinate Rb, the chelating ozonide ion itself having O–O distances of 129 and 130 pm and an O–O–O angle of 117°.

[73] N. KORBER and M. JANSEN, *J. Chem. Soc., Chem. Commun.*, 1654–5 (1990).

A particularly imaginative application of this concept has led to the isolation of compounds which contain monatomic alkali metal *anions*. For example, Na was reacted with cryptand in the presence of $EtNH_2$ to give the first example of a sodide salt of Na^-.[74]

$$2Na + N\{(C_2H_4O)_2C_2H_4\})_3N \xrightarrow{EtNH_2} [Na(cryptand)]^+Na^-$$

The Na^- is 555 pm from the nearest N and 516 pm from the nearest O, indicating that it is a separate entity in the structure. Potassides, rubidides and caesides have similarly been prepared.[74] The same technique has been used to prepare solutions and even crystals of electrides, in which trapped electrons can play the role of anion. Typical examples are $[K(cryptand)]^+e^-$ and $[Cs(18\text{-crown-}6)]^+e^-$.[74,75]

Macrocycles, though extremely effective as polydentate ligands, are not essential for the production of stable alkali metal complexes; additional conformational flexibility without loss of coordinating power can be achieved by synthesizing benzene derivatives with 2–6 pendant mercapto-polyether groups $C_6H_{6-n}R_n$, where R is $-SC_2H_4OC_2H_4OMe$, $-S(C_2H_4O)_3Bu$, etc. Such "octopus" ligands are more effective than crowns and often equally as effective as cryptands in sequestering alkali metal cations.[76] Indeed, it is not even essential to invoke organic ligands at all since an inorganic cryptate which completely surrounds Na has been identified in the heteropolytungstate $(NH_4)_{17}Na[NaW_{21}Sb_9O_{86}].14H_2O$; the compound was also found to have pronounced antiviral activity.[77]

4.3.7 Imides, amides and related compounds [78,79]

Before discussing the organometallic compounds of the alkali metals (which contain direct M–C bonds, Section 4.3.8) it is convenient to mention another important class of compounds: those which involve M–N bonds. In this way we shall resume the sequence of compounds which started with those having M–X bonds (i.e. halides, Section 4.3.2), through those with M–O bonds (oxides, hydroxides etc., Sections 4.3.3–4.3.5) to those with M–N and finally those with M–C bonds. As we shall see, several significant perceptions have emerged in this field during the past decade. For example, it is now generally agreed that in all these classes of compound the bond from the main group element to the alkali metal is predominantly ionic. Furthermore, structural studies of compounds with Li–N bonds in particular have led to the seminal concepts of *ring-stacking* and *ring-laddering* which, in turn, have permitted the rationalization of many otherwise puzzling structural features.

Lithium imides (imidolithiums) are air-sensitive compounds of general formula $(RR'C{=}NLi)_n$. They can be prepared in high yield either by the addition of an organolithium compound across the triple bond of a nitrile (equation (1)) or by lithiation of a ketimine (equation (2)).

$$R'Li + RC{\equiv}N \longrightarrow RR'C{=}NLi \quad (1)$$

$$R''Li + RR'C{=}NH \longrightarrow RR'C{=}NLi + R''H \quad (2)$$

Lithium imides have proved to be useful reagents for the synthesis of imino derivatives of a wide variety of other elements, e.g. Be, B, Al, Si, P, Mo, W and Fe as in equation (3).

$$R''_3SiCl + RR'C{=}NLi \longrightarrow RR'C{=}NSiR''_3 + LiCl \quad (3)$$

When R and R′ are both aryl groups the resulting lithium imides are amorphous, insoluble

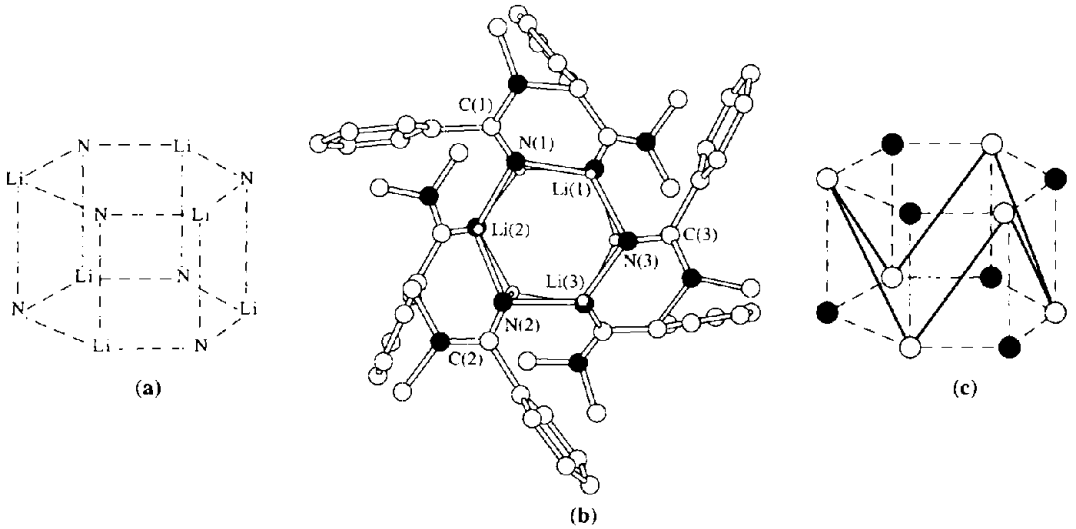

Figure 4.13 (a) Schematic representation of the Li_6N_6 core cluster in hexameric lithium imides. (b) The X-ray structure of $[Me_2N(Ph)C{=}NLi]_6$ viewed from above showing the stacking of two 6-membered Li_3N_3 rings. (c) Each Li atom has two nearest-neighbour Li atoms in the adjacent ring at 248 pm, shown here joined by full lines; the mean Li–N distances (broken lines) are 198 pm within each ring and 206 pm between rings.[80]

(presumably polymeric) solids, but if only one or neither of R, R′ is an aryl group, soluble crystalline hexamers are obtained. The skeletal structure of these hexamers comprises an Li_6N_6 cluster formed by the stacking of two slightly puckered heterocyclic Li_3N_3 rings so that the Li atoms in each ring are almost directly above or below the N atoms in the adjacent ring. This is illustrated schematically in Fig. 4.13a (cf. Fig. 4.8d for the analogous hexameric alkoxide structure). An alternative view, looking down onto the open 6-membered face of the stack, is shown in Fig. 4.13b for the case of $[Me_2N(Ph)C{=}NLi]_6$. Formation of such hexamers can be viewed as a stepwise process. Initially formed ion-pairs (monomers), $Li^+|N{=}CRR'|^-$, with 1-coordinate Li^+, associate at first to cyclic trimers, $(LiN{=}CRR')_3$, containing 2-coordinate Li^+ centres. Such rings are essentially planar systems [the planarity of the $(LiN)_3$ ring itself extending outwards through the imido C up to and including the α-atoms of R and R′] and so two such rings can come together, sharing their $(LiN)_3$ faces and so raising the Li^+ coordination number to 3. Such stacking necessitates a loss in planarity of the original trimeric rings thus normally preventing more extensive stacking. A further feature of the stacked hexameric structure is the close approach of neighbouring Li atoms across the diagonals of the square faces (Fig. 4.13c), each Li atom being only 248 pm from its two nearest neighbours. This is much less that the Li···Li distance in Li metal (304 pm) or even in the necessarily covalent diatomic molecule Li_2 (274 pm), but this does not imply either metallic or covalent metal···metal bonding. Such close approaches merely reflect the small size of the Li^+ ion. For example, the Li···Li distance in LiF (which has the NaCl-type crystal structure) is 284 pm, which is 7% less than the Li–Li distance in Li metal itself.

The ring-stacking concept used in the preceding paragraph to explain the occurrence and structure of lithium imide hexamers can be applied more widely to Li–C, Li–N and Li–O rings and

[80] D. Barr, W. Clegg, R. E. Mulvey, R. Snaith and K. Wade, *J. Chem. Soc., Chem. Commun.*, 295–7 (1986).

clusters of various sizes.[78,79] but the details lie outside the scope of the present treatment.

In contrast to the planar (sp^2) nitrogen centres in lithium imides, lithium amides, $(RR'NLi)_n$, feature tetrahedral (sp^3) nitrogen. The exocyclic R groups are thus above and below the $(LiN)_n$ plane and this prevents ring stacking. Rings of varying size are known, with $n = 2$, 3 or 4 depending on the nature of the substituents (Fig. 4.14a, b and c). In the important case of $n = 2$, the 4-membered Li_2N_2 heterocycles can associate further by edge fusion (rather than by face fusion) to form laddered structures as shown schematically in Fig. 4.14d. Specific examples of amidolithium heterocycles are $[(Me_3Si)_2NLi]_2$ (gas-phase), $[(PhCH_2)_2NLi]_3$ (Fig. 4.15a) and the tetramethylpiperidinatolithium tetramer $[Me_2C(CH_2)_3CMe_2NLi]_4$ (Fig. 4.15b). By contrast, lithiation of the cyclic amine pyrrolidine in the presence of the chelating ligand tetramethylethylenediamine (tmeda) affords the

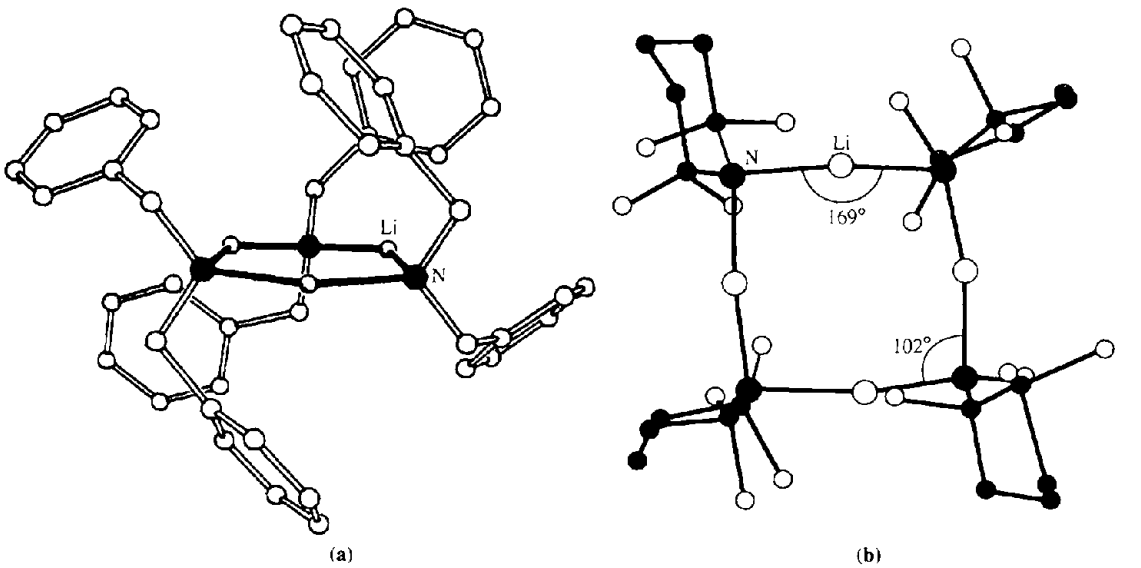

Figure 4.15 X-ray structure of (a) dibenzylamidolithium, $[(PhCH_2)_2NLi]_3$[81] and (b) tetramethylpiperidinatolithium, $[Me_2C(CH_2)_3CMe_2NLi]_4$.[82]

laddered complex $[(H_2\overline{C(CH_2)_3NLi})_2.tmeda]_2$ (Fig. 4.16). Detailed examination of the interatomic distances in this structure clearly indicate that laddering is achieved by the lateral connection of the two outer Li_2N_2 rings. The Li–N bonds in all these compounds are considered to be predominantly ionic.

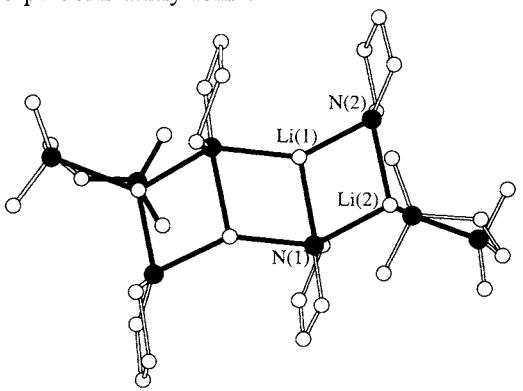

Figure 4.16 X-ray structure of the laddered complex $[H_2\overline{C(CH_2)_3NLi}]_2.tmeda]_2$ where tmeda is tetramethylethylenediamine.[83]

4.3.8 Organometallic compounds [41,42,84,85]

Some structural aspects of the organometallic compounds of the alkali metals have already been briefly mentioned in Section 4.3.6. The diagonal relation of Li with Mg (p. 76), coupled with the known synthetic utility of Grignard reagents (pp. 132–5), suggests that Li, and perhaps the other alkali metals, might afford synthetically useful organometallic reagents. Such is found to be the case.[86]

Organolithium compounds can readily be prepared from metallic Li and this is one of the major uses of the metal. Because of the great reactivity both of the reactants and the products, air and moisture must be rigorously excluded by use of an inert atmosphere. Lithium can be reacted directly with alkyl halides in light petroleum, cyclohexane, benzene or ether, the chlorides generally being preferred:

$$2Li + RX \xrightarrow{\text{solvent}} LiR + LiX$$

Reactivity and yields are greatly enhanced by the presence of 0.5–1% Na in the Li. The reaction is also generally available for the preparation of metal alkyls of the heavier Group 1 metals. Lithium aryls are best prepared by metal–halogen exchange using $LiBu^n$ and an aryl iodide, and transmetalation is the most convenient route to vinyl, allyl and other unsaturated derivatives:

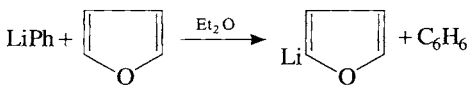
$$LiBu^n + ArI \xrightarrow{\text{ether}} LiAr + Bu^nI$$

$$4LiPh + Sn(CH{=}CH_2)_4 \xrightarrow{\text{ether}} 4LiCH{=}CH_2 + SnPh_4$$

The reaction between an excess of Li and an organomercury compound is a useful alternative when isolation of the product is required, rather than its direct use in further synthetic work:

$$2Li + HgR_2(\text{or } HgAr_2) \xrightarrow[\text{benzene}]{\text{petrol or}} 2LiR(\text{or } LiAr) + Hg$$

Similar reactions are available for the other alkali metals. Metalation (metal–hydrogen exchange) and metal addition to alkenes provide further routes, e.g.



$$2Na + 3C_5H_6 \longrightarrow 2NaC_5H_5 + C_5H_8$$

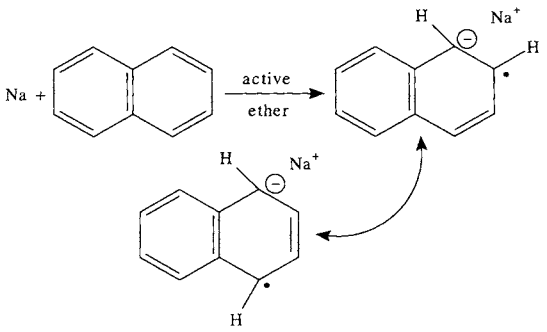
[86] B. J. WAKEFIELD. *Organolithium Methods*, Academic Press, New York, 1988, 189 pp.

$$2Cs + CH_2{=}CH_2 \longrightarrow CsCH_2CH_2Cs$$

In the presence of certain ethers such as Me_2O, $MeOCH_2CH_2OMe$ or tetrahydrofuran, Na forms deep-green highly reactive paramagnetic adducts with polynuclear aromatic hydrocarbons such as naphthalene, phenanthrene, anthracene, etc.:



These compounds are in many ways analogous to the solutions of alkali metals in liquid ammonia (p. 77).

The most ionic of the organometallic derivatives of Group 1 elements are the acetylides and dicarbides formed by the deprotonation of alkynes in liquid ammonia solutions:

$$Li + HC{\equiv}CH \xrightarrow{\text{liq } NH_3} LiC{\equiv}CH + \tfrac{1}{2}H_2$$

$$2Li + HC{\equiv}CH \xrightarrow{\text{liq } NH_3} Li_2C_2 + H_2$$

The largest industrial use of LiC_2H is in the production of vitamin A, where it effects ethynylation of methyl vinyl ketone to produce a key tertiary carbinol intermediate. The acetylides and dicarbides of the other alkali metals are prepared similarly. It is not always necessary to prepare this type of compound in liquid ammonia and, indeed, further substitution to give the bright red perlithiopropyne Li_4C_3 can be effected in hexane under reflux:[87]

$$4LiBu^n + CH_3C{\equiv}CH \xrightarrow{\text{hexane}} Li_3CC{\equiv}CLi + 4C_4H_{10}$$

Organolithium compounds tend to be thermally unstable and most of them decompose to LiH and an alkene on standing at room temperature or above. Among the more stable compounds are the colourless, crystalline solids LiMe (decomp above 200°C), $LiBu^n$ and $LiBu^t$ (which shows little decomposition over a period of days at 100°C). Common lithium alkyls have unusual tetrameric or hexameric structures (see preceding sections). The physical properties of these oligomers are similar to those often associated with covalent compounds (e.g. moderately high volatility, high solubility in organic solvents and low electrical conductivity when fused). Despite this it is now generally agreed that the central $(LiC)_n$ core is held together by predominantly ionic forces, though estimates of the precise extent of charge separation vary from about 55 to 95%.[88–91]. The resolution of this apparent paradox lies in the realization that continued polymerization of (Li^+R^-) monomers into infinite ionic arrays, such as are found in the alkali-metal halides, is hindered by the bulky nature of the R groups. Furthermore, these organic groups, which are covalently bonded within themselves, almost completely surround the ionic core and so dominate the bulk physical properties. Such ionic/covalent oligomers have been termed "supramolecules".[92]

The structure and bonding in lithium methyl have been particularly fully studied. The crystal structure consists of interconnected tetrameric units $(LiMe)_4$ as shown in Fig. 4.17: the individual Li_4C_4 clusters consist of a tetrahedron

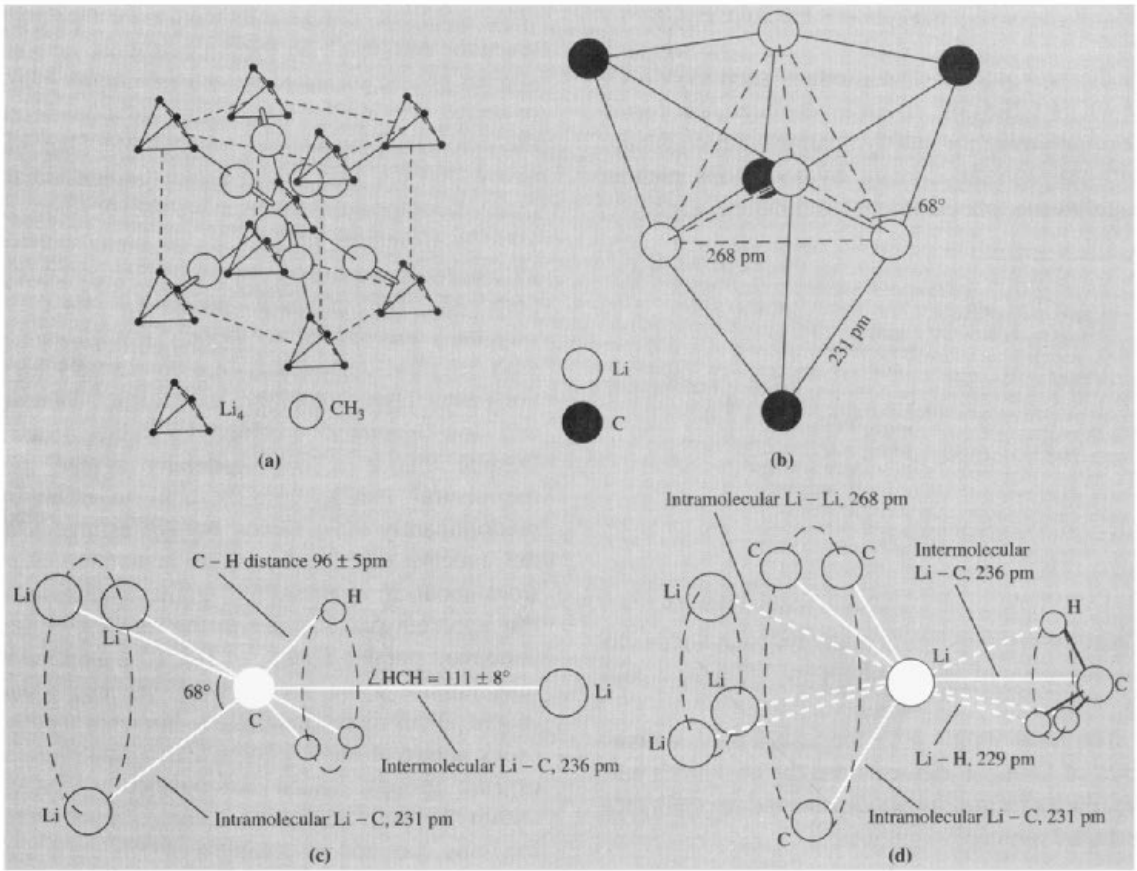

Figure 4.17 Crystal and molecular structure of $(LiMe)_4$ showing (a) the unit cell of lithium methyl, (b) the Li_4C_4 skeleton of the tetramer viewed approximately along one of the threefold axes, (c) the 7-coordinate environment of each C atom, and (d) the (4 + 3 + 3)-coordinate environment of each Li atom. After ref. 93, modified to include Li—H contacts.

of 4Li with a triply-bridging C above the centre of each face to complete a distorted cube. The clusters are interconnected along cube diagonals via the bridging CH_3 groups and the intercluster Li–C distance (236 pm) is very similar to the Li–C distance within each cluster (231 pm). The carbon atoms are thus essentially 7-coordinate being bonded directly to 3H and 4Li. The Li–Li distance within the cluster is 268 pm, which is virtually identical with the value of 267.3 pm for the gaseous Li_2 molecule and substantially smaller than the value of 304 pm in Li metal (where each Li has 8 nearest neighbours). Each Li atom is therefore closely associated with three other Li atoms and three C atoms within its own cluster and with one C and three H atoms in an adjoining cluster. Detailed calculations show that the C–H···Li interactions make a substantial contribution to the overall bonding.[91] Such "agostic" interactions were indeed first noted in lithium methyl long before their importance in transition metal organometallic compounds was recognized. The effect is most pronounced in $(LiEt)_4$ where the α-H on the ethyl group comes within 198 pm of its neighbouring Li atom;[79,91] cf. 204.3 pm in solid LiH, which has the NaCl structure (pp. 65, 82).

Higher alkyls of lithium adopt similar structures in which polyhedral clusters of metal atoms are bridged by alkyl groups located over the triangular faces of these clusters. For example, crystalline lithium *t*-butyl is tetrameric and the structural units $(LiBu^t)_4$ persist in solution; by contrast lithium ethyl, which is tetrameric in the solid state, dissolves in hydrocarbons as the hexamer $(LiEt)_6$ which probably consists of octahedra of Li_6 with triply bridging $-CH_2CH_3$ groups above 6 of the 8 faces. As the atomic number of the alkali metal increases there is a gradual trend away from these oligomeric structures towards structures which are more typical of polarized ionic compounds. Thus, although NaMe is tetrameric like LiMe, NaEt adopts a layer structure in which the CH_2 groups have a trigonal pyramidal array of Na neighbours, and KMe adopts a NiAs-type structure (p. 679) in which each Me is surrounded by a trigonal prismatic array of K. The extent to which this is considered to be $K^+CH_3^-$ is a matter for discussion though it will be noted that CH_3^- is isoelectronic with the molecule NH_3.

The structure of the organometallic complex lithium tetramethylborate $LiBMe_4$ is discussed on pp. 127–8 alongside that of polymeric $BeMe_2$ with which it is isoelectronic.

Organometallic compounds of the alkali metals (particularly LiMe and $LiBu^n$) are valuable synthetic reagents and have been increasingly used in industrial and laboratory-scale organic syntheses during the past 20 y.[86,94,95]. The annual production of $LiBu^n$ alone has leapt from a few kilograms to about 1000 tonnes. Large scale applications are as a polymerization catalyst, alkylating agent and precursor to metalated organic reagents. Many of the synthetic reactions parallel those of Grignard reagents over which they sometimes have distinct advantages in terms of speed of reaction, freedom from complicating side reactions or convenience of handling. Reactions are those to be expected for carbanions, though free-radical mechanisms occasionally occur.

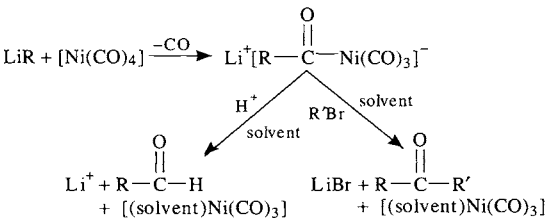
Halogens regenerate the parent alkyl (or aryl) halide and proton donors give the corresponding hydrocarbon:

$$LiR + X_2 \longrightarrow LiX + RX$$

$$LiR + H^+ \longrightarrow Li^+ + RH$$

$$LiR + R'I \longrightarrow LiI + RR'$$

C–C bonds can be formed by reaction with alkyl iodides or more usefully by reaction with metal carbonyls to give aldehydes and ketones: e.g. $Ni(CO)_4$ reacts with LiR to form an unstable acyl nickel carbonyl complex which can be attacked by electrophiles such as H^+ or R′Br to give aldehydes or ketones by solvent-induced reductive elimination:



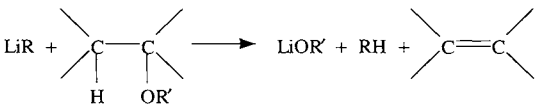
$[Fe(CO)_5]$ reacts similarly. Aldehydes and ketones can also be obtained from *N*,*N*-disubstituted amides, and symmetrical ketones are formed by reaction with CO:

$$LiR + HCONMe_2 \longrightarrow LiNMe_2 + RCHO$$

$$LiR + R'CONMe_2 \longrightarrow LiNMe_2 + R'COR$$

$$2LiR + 3CO \longrightarrow 2LiCO + R_2CO$$

Thermal decomposition of LiR eliminates a β-hydrogen atom to give an olefin and LiH, a process of industrial importance for long-chain terminal alkenes. Alkenes can also be produced by treatment of ethers, the organometallic reacting here as a very strong base (proton acceptor):



Lithium aryls react as typical carbanions in non-polar solvents giving carboxylic acids with CO_2

[94] B. J. WAKEFIELD, *The Chemistry of Organolithium Compounds*, Pergamon Press, Oxford, 1976, 337 pp.

[95] K. SMITH, Lithiation and organic synthesis, *Chem. in Br.* **18(1)**, 29–32 (1982)

and tertiary carbinols with aryl ketones:

$$LiAr + CO_2 \longrightarrow ArCO_2Li \xrightarrow{H_2O} LiOH + ArCO_2H$$

$$LiAr + Ar'_2CO \longrightarrow [Ar'_2C(Ar)OLi] \xrightarrow{H_2O} LiOH + Ar'_2C(Ar)OH$$

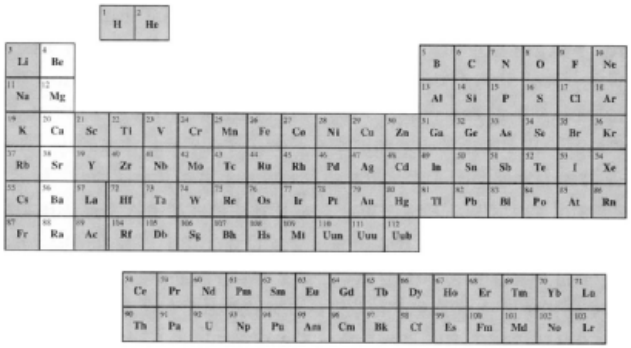
Organolithium reagents are also valuable in the synthesis of other organometallic compounds via metal–halogen exchange:

$$3LiR + BCl_3 \longrightarrow 3LiCl + BR_3$$

$$(4 - x)LiR + SnCl_4 \longrightarrow (4 - x)LiCl + SnCl_xR_{4-x} \quad (1 \leq x \leq 4)$$

$$3LiAr + P(OEt)_3 \longrightarrow 3LiOEt + PAr_3$$

Similar reactions have been used to produce organo derivatives of As, Sb, Bi; Si, Ge and many other elements.



5

Beryllium, Magnesium, Calcium, Strontium, Barium and Radium

5.1 Introduction

The Group 2 or alkaline earth metals exemplify and continue the trends in properties noted for the alkali metals. No new principles are involved, but the ideas developed in the preceding chapter gain emphasis and clarity by their further application and extension. Indeed, there is an impressively close parallelism between the two groups as will become increasingly clear throughout the chapter.

The discovery of beryllium in 1798 followed an unusual train of events.[1] The mineralogist R.-J. Haüy had observed the remarkable similarity in external crystalline structure, hardness and density of a beryl from Limoges and an emerald from Peru, and suggested to L.-N. Vauquelin that he should analyse them to see if they were chemically identical.† As a result, Vauquelin showed that both minerals contained not only alumina and silica as had previously been known, but also a new earth, beryllia, which closely resembled alumina but gave no alums, apparently did not dissolve in an excess of KOH (perhaps because it had been fused?) and had a sweet rather than an astringent taste. *Caution*: beryllium compounds are now known to be extremely toxic, especially as dusts or smokes;[2] it seems likely that this toxicity results from the ability of Be^{II} to displace Mg^{II} from Mg-activated enzymes due to its stronger coordinating ability.

Both beryl and emerald were found to be essentially $Be_3Al_2Si_6O_{18}$, the only difference between them being that emerald also contains ~2% Cr, the source of its green colour. The combining weight of Be was ~4.7 but the similarity (diagonal relation) between Be and

[1] M. E. WEEKS, *Discovery of the Elements*, 6th edn., Journal of Chemical Education, Easton, Pa, 1956, 910 pp.

[2] J. SCHUBERT, Beryllium and berylliosis, Chap. 34 (1958), in *Chemistry in the Environment*, pp. 321–7, Readings from *Scientific American*, W. H. Freeman, San Francisco, 1973.

† A similar observation had been made (with less dramatic consequences) nearly 2000 y earlier by Pliny the Elder when he wrote: "Beryls, it is thought, are of the same nature as the smaragdus (emerald), or at least closely analogous" (*Historia Naturalis*, Book 37).

Al led to considerable confusion concerning the valency and atomic weight of Be (2×4.7 or 3×4.7); this was not resolved until Mendeleev 70 y later stated that there was no room for a tervalent element of atomic weight 14 near nitrogen in his periodic table, but that a divalent element of atomic weight 9 would fit snugly between Li and B. Beryllium metal was first prepared by F. Wöhler in 1828 (the year he carried out his celebrated synthesis of urea from NH_4CNO); he suggested the name by allusion to the mineral (Latin *beryllus* from Greek βηρυλλος). The metal was independently isolated in the same year by A.-B. Bussy using the same method — reduction of $BeCl_2$ with metallic K. The first electrolytic preparation was by P. Lebeau in 1898 and the first commercial process (electrolysis of a fused mixture of BeF_2 and BaF_2) was devised by A. Stock and H. Goldschmidt in 1932. The close parallel with the development of Li technology (pp. 68–70) is notable.

Compounds of Mg and Ca, like those of their Group 1 neighbours Na and K, have been known from ancient times though nothing was known of their chemical nature until the seventeenth century. Magnesian stone (Greek Μαγνησία λιθος) was the name given to the soft white mineral steatite (otherwise called soapstone or talc) which was found in the Magnesia district of Thessally, whereas calcium derives from the Latin *calx, calcis* — lime. The Romans used a mortar prepared from sand and lime (obtained by heating limestone, $CaCO_3$) because these lime mortars withstood the moist climate of Italy better than the Egyptian mortars based on partly dehydrated gypsum ($CaSO_4.2H_2O$); these had been used, for example, in the Great Pyramid of Gizeh, and all the plaster in Tutankhamun's tomb was based on gypsum. The names of the elements themselves were coined by H. Davy in 1808 when he isolated Mg and Ca, along with Sr and Ba by an electrolytic method following work by J. J. Berzelius and M. M. Pontin: the moist earth (oxide) was mixed with one-third its weight of HgO on a Pt plate which served as anode; the cathode was a Pt wire dipping into a pool of Hg and electrolysis gave an amalgam from which the desired metal could be isolated by distilling off the Hg.

A mineral found in a lead mine near Strontian, Scotland, in 1787 was shown to be a compound of a new element by A. Crawford in 1790. This was confirmed by T. C. Hope the following year and he clearly distinguished the compounds of Ba, Sr and Ca, using amongst other things their characteristic flame colorations: Ba yellow-green, Sr bright red, Ca orange-red. Barium-containing minerals had been known since the seventeenth century but the complex process of unravelling the relation between them was not accomplished until the independent work of C. W. Scheele and J. G. Gahn between 1774 and 1779: heavy spar was found to be $BaSO_4$ and called barite or barytes (Greek βαρύς, heavy), whence Scheele's new base baryta (BaO) from which Davy isolated barium in 1808.

Radium, the last element in the group, was isolated in trace amounts as the chloride by P. and M. Curie in 1898 after their historic processing of tonnes of pitchblende. It was named by Mme Curie in allusion to its radioactivity, a word also coined by her (Latin *radius*, a ray); the element itself was isolated electrolytically via an amalgam by M. Curie and A. Debierne in 1910 and its compounds give a carmine-red flame test.

5.2 The Elements

5.2.1 Terrestrial abundance and distribution

Beryllium, like its neighbours Li and B, is relatively unabundant in the earth's crust; it occurs to the extent of about 2 ppm and is thus similar to Sn (2.1 ppm), Eu (2.1 ppm) and As (1.8 ppm). However, its occurrence as surface deposits of beryl in pegmatite rocks (which are the last portions of granite domes to crystallize) makes it readily accessible. Crystals as large as 1 m on edge and weighing up to 60 tonnes have been reported. World reserves in commercial deposits are about 4 million tonnes of contained Be and mined production in 1985–86 was USA

223, USSR 76 and Brazil 37 tonnes of contained Be, which together accounted for 98% of world production. The cost of Be metal was $690/kg in 1987. By contrast, world supplies of magnesium are virtually limitless: it occurs to the extent of 0.13% in sea water, and electrolytic extraction at the present annual rate, if continued for a million years, would only reduce this to 0.12%.

Magnesium, like its heavier congeners Ca, Sr and Ba, occurs in crustal rocks mainly as the insoluble carbonates and sulfates, and (less accessibly) as silicates. Estimates of its total abundance depend sensitively on the geochemical model used, particularly on the relative weightings given to the various igneous and sedimentary rock types, and values ranging from 20 000 to 133 000 ppm are current.[3] Perhaps the most acceptable value is 27 640 ppm (2.76%), which places Mg sixth in order of abundance by weight immediately following Ca (4.66%) and preceding Na (2.27%) and K (1.84%). Large land masses such as the Dolomites in Italy consist predominantly of the magnesian limestone mineral dolomite [$MgCa(CO_3)_2$], and there are substantial deposits of magnesite ($MgCO_3$), epsomite ($MgSO_4.7H_2O$) and other evaporites such as carnallite ($K_2MgCl_4.6H_2O$) and langbeinite [$K_2Mg_2(SO_4)_3$]. Silicates are represented by the common basaltic mineral olivine [$(Mg,Fe)_2SiO_4$] and by soapstone (talc) [$Mg_3Si_4O_{10}(OH)_2$], asbestos (chrysotile) [$Mg_3Si_2O_5(OH)_4$] and micas. Spinel ($MgAl_2O_4$) is a metamorphic mineral and gemstone. It should also be remembered that the green leaves of plants, though not a commercial source of Mg, contain chlorophylls which are the Mg-porphine complexes primarily involved in photosynthesis.

Calcium, as noted above, is the fifth most abundant element in the earth's crust and hence the third most abundant metal after Al and Fe. Vast sedimentary deposits of $CaCO_3$, which represent the fossilized remains of earlier marine life, occur over large parts of the earth's surface. The deposits are of two main types — rhombohedral calcite, which is the more common, and orthorhombic aragonite, which sometimes forms in more temperate seas. Representative minerals of the first type are limestone itself, dolomite, marble, chalk and iceland spar. Extensive beds of the aragonite form of $CaCO_3$ make up the Bahamas, the Florida Keys and the Red Sea basin. Corals, sea shells and pearls are also mainly $CaCO_3$. Other important minerals are gypsum ($CaSO_4.2H_2O$), anhydrite ($CaSO_4$), fluorite (CaF_2: also blue john and fluorspar) and apatite [$Ca_5(PO_4)_3F$].

Strontium (384 ppm) and barium (390 ppm) are respectively the fifteenth and fourteenth elements in order of abundance, being bracketed by S (340 ppm) and F (544 ppm). The most important mineral of Sr is celestite ($SrSO_4$), and strontianite ($SrCO_3$) is also mined. The largest producers are Mexico, Spain, Turkey and the UK, and the world production of these two minerals in 1985 was 10^5 tonnes. The main uses of Sr compounds, especially $SrCO_3$, are in the manufacture of special glasses for colour television and computer monitors (53%), for pyrotechnic displays (14%) and magnetic materials (11%). Strontium carbonate and sulfate are critical raw materials for the USA which is totally dependent on imports for supplies. The sulfate (barite) is also the most important mineral of Ba: it is mined commercially in over 40 countries throughout the world. Production in 1985 was 6.0 million tonnes, of which 44% was mined in the USA. The major use of $BaSO_4$ (92%) is as a heavy mud slurry in well drilling; production of Ba chemicals accounts for only 7%.

Radium occurs only in association with uranium (Chapter 31); the observed ratio $^{226}Ra/U$ is ~1 mg per 3 kg, leading to a terrestrial abundance for Ra of $\sim 10^{-6}$ ppm. As uranium ores normally contain only a few hundred ppm of U, it follows that about 10 tonnes of ore must be processed for 1 mg Ra. The total amount of Ra available worldwide is of the order of a few kilograms, but its use in cancer therapy has been superseded by the use of other isotopes, and the

[3] K. K. TUREKIAN, Elements, geochemical distribution of, *McGraw Hill Encyclopedia of Science and Technology*, Vol. 4, pp. 627–30, 1977.

annual production of separated Ra compounds is probably now only about 100 g. Chief suppliers are Belgium, Canada, Czechoslovakia, the UK, and the former Soviet Union. ^{226}Ra decays by α-emission with a half-life of 1600 y, although 3 in every 10^{11} decays occur by ^{14}C emission ($^{226}_{88}Ra \longrightarrow {}^{212}_{82}Pb + {}^{14}_{6}C$). This exceedingly rare form of radioactivity was discovered in 1984 in the rare naturally occurring radium isotope ^{223}Ra where about 1 in 10^9 of the atoms decays by ^{14}C rather than α-emission.[4]

5.2.2 Production and uses of the metals [5]

Beryllium is extracted from beryl by roasting the mineral with Na_2SiF_6 at 700–750°C, leaching the soluble fluoride with water and then precipitating $Be(OH)_2$ at about pH 12. The metal is usually prepared by reduction of BeF_2 (p. 116) with Mg at about 1300°C or by electrolysis of fused mixtures of $BeCl_2$ and alkali metal chlorides. It is one of the lightest metals known and has one of the highest mps of the light metals. Its modulus of elasticity is one-third greater than that of steel. The largest use of Be is in high-strength alloys of Cu and Ni (see Panel below).

Magnesium is produced on a large scale (400 000 tonnes in 1985) either by electrolysis or silicothermal reduction. The major producers are the USA (43%), the former Soviet Union (26%), and Norway (17%). The electrolytic process uses either fused anhydrous $MgCl_2$ at 750°C or partly hydrated $MgCl_2$ from sea water at a slightly lower temperature. The silicothermal process uses calcined dolomite and ferrosilicon alloy under reduced pressure at 1150°C:

$$2(MgO.CaO) + FeSi \longrightarrow 2Mg + Ca_2SiO_4 + Fe$$

Magnesium is industry's lightest constructional metal, having a density less than two-thirds that of Al (see Panel on the next page). The price of the metal (99.8% purity) was $3.4/kg in 1994.

The other alkaline earth metals Ca, Sr and Ba are produced on a much smaller scale than Mg. Calcium is produced by electrolysis of fused $CaCl_2$ (obtained either as a byproduct of the Solvay process (p. 71) or by the action of HCl or $CaCO_3$). It is less reactive than Sr or Ba, forming a protective oxide-nitride coating in air which enables it to be machined in a lathe or handled by other standard metallurgical techniques. Calcium metal is used mainly as an alloying agent to strengthen Al bearings, to control graphitic C in cast-iron and to remove Bi from Pb. Chemically it is used as a scavenger in the steel industry (O, S and P), as a getter for oxygen and nitrogen, to remove N_2 from argon and as a reducing agent in the production of other metals such as Cr, Zr, Th and U. Calcium also reacts directly with H_2 to give CaH_2, which is a useful source of H_2. World production of

[4] H. J. ROSE and G. A. Jones, *Nature* **307**, 245–7 (1984).

[5] W. BÜCHNER, R. SCHLIEBS, G. WINTER and K. H. BÜCHEL, *Industrial Inorganic Chemistry*, VCH, New York, 1989, pp. 231–46.

Uses of Beryllium Metal and Alloys

The ability of Be to age-harden Cu was discovered by M. G. Corson in 1926 and it is now known that ~2% of Be increases the strength of Cu sixfold. In addition, the alloys (which also usually contain 0.25% Co) have good electrical conductivity, high strength, unusual wear resistance, and resistance to anelastic behaviour (hysteresis, damping, etc.): they are non-magnetic and corrosion resistant, and find numerous applications in critical moving parts of aero-engines, key components in precision instruments, control relays and electronics. They are also non-sparking and are thus of great use for hand tools in the petroleum industry. A nickel alloy containing 2% Be is used for high-temperature springs, clips, bellows and electrical connections. Another major use for Be is in nuclear reactors since it is one of the most effective neutron moderators and reflectors known. A small, but important, use of Be is as a window material in X-ray tubes: it transmits X-rays 17 times better than Al and 8 times better than Lindemann glass. A mixture of compounds of radium and beryllium has long been used as a convenient laboratory source of neutrons and, indeed, led to the discovery of the neutron by J. Chadwick in 1932: $^{9}Be(\alpha,n)^{12}C$.

Magnesium Metal and Alloys

The principal advantage of Mg as a structural metal is its low density ($1.7\,g\,cm^{-3}$ compared with 2.70 for Al and 7.80 for steel). For equal strength, the best Mg alloy weighs only a quarter as much as steel, and the best Al alloy weighs about one-third as much as steel. In addition, Mg has excellent machinability and it can be cast or fabricated by any of the standard metallurgical methods (rolling, extruding, drawing, forging, welding, brazing or riveting). Its major use therefore is as a light-weight construction metal, not only in aircraft but also in luggage, photographic and optical equipment, etc. It is also used for cathodic protection of other metals from corrosion, as an oxygen scavenger, and as a reducing agent in the production of Be, Ti, Zr, Hf and U. World production approaches 400 000 tonnes pa.

Magnesium alloys typically contain >90% Mg together with 2–9% Al, 1–3% Zn and 0.2–1% Mn. Greatly improved retention of strength at high temperature (up to 450°C) is achieved by alloying with rare-earth metals (e.g. Pr/Nd) or Th. These alloys can be used for automobile engine casings and for aeroplane fuselages and landing wheels. Other uses are in light-weight tread-plates, dock-boards, loading platforms, gravity conveyors and shovels.

Up to 5% Mg is added to most commercial Al to improve its mechanical properties, weldability and resistance to corrosion.

For further details see *Kirk–Othmer Encyclopedia of Chemical Technology*, 4th edn., 1995, Vol. 15, pp. 622–74.

the metal is about 2500 tonnes pa of which >50% was in the USA (price $5.00–8.00/kg in 1991).

Metallic Sr and Ba are best prepared by high-temperature reduction of their oxides with Al in an evacuated retort or by small-scale electrolysis of fused chloride baths. They have limited use as getters, and a Ni–Ba alloy is used for spark-plug wire because of its high emissivity. Annual production of Ba metal is about 20–30 tonnes worldwide and the 1991 price about $80–140/kg depending on quality.

5.2.3 Properties of the elements

Table 5.1 lists some of the atomic properties of the Group 2 elements. Comparison with the data for Group 1 elements (p. 75) shows the substantial increase in the ionization energies; this is related to their smaller size and higher nuclear charge, and is particularly notable for Be. Indeed, the "ionic radius" of Be is purely a notional figure since no compounds are known in which uncoordinated Be has a 2+ charge. In aqueous solutions the reduction potential of

Be is much less than that of its congeners, again indicating its lower electropositivity. By contrast, Ca, Sr, Ba and Ra have reduction potentials which are almost identical with those of the heavier alkali metals; Mg occupies an intermediate position.

Be and Mg are silvery white metals whereas Ca, Sr and Ba are pale yellow (as are the divalent rare earth metals Eu and Yb) although the colour is less intense than for Cs (p. 74). All the alkaline earth metals are lustrous and relatively soft, and their physical properties (Table 5.2), when compared with those of Group 1 metals, show that they have a substantially higher mp, bp, density and enthalpies of fusion and vaporization. This can be understood in terms of the size factor mentioned in the preceding paragraph and the fact that 2 valency electrons per atom are now available for bonding. Again, Be is notable in melting more than 1100° above Li and being nearly 3.5 times as dense; its enthalpy of fusion is more than 5 times that of Li. Beryllium resembles Al in being stable in moist air due to the formation of a protective oxide layer, and highly polished specimens retain their shine indefinitely. Magnesium also resists oxidation but the heavier metals tarnish readily. Beryllium, like Mg and the high-temperature form of Ca (>450°C), crystallizes in the hcp arrangement, and this confers a marked anisotropy on its properties; Sr is fcc, Ba and Ra are bcc like the alkali metals.

5.2.4 Chemical reactivity and trends

Beryllium metal is relatively unreactive at room temperature, particularly in its massive form. It does not react with water or steam even at red heat and does not oxidize in air below 600°C, though powdered Be burns brilliantly on ignition to give BeO and Be_3N_2. The halogens (X_2) react above about 600°C to give BeX_2 but the chalcogens (S, Se, Te) require even higher temperatures to form BeS, etc. Ammonia reacts above 1200°C to give Be_3N_2 and carbon forms Be_2C at 1700°C. In contrast with the other Group 2 metals, Be does not react directly with hydrogen, and BeH_2 must be prepared indirectly (p. 115). Cold, concentrated HNO_3 passivates Be but the metal dissolves readily in dilute aqueous acids (HCl, H_2SO_4, HNO_3) with evolution of hydrogen. Beryllium is sharply distinguished from the other alkaline earth metals in reacting with aqueous alkalis (NaOH, KOH) with evolution of hydrogen. It also dissolves rapidly in aqueous NH_4HF_2 (as does $Be(OH)_2$), a reaction of some technological importance in the preparation of anhydrous BeF_2 and purified Be:

$$2NH_4HF_2(aq) + Be(s) \longrightarrow (NH_4)_2BeF_4 + H_2(g)$$

$$(NH_4)_2BeF_4(s) \xrightarrow{280^\circ} BeF_2(s) + 2NH_4F\ (subl)$$

Magnesium is more electropositive than the amphoteric Be and reacts more readily with most of the non-metals. It ignites with the halogens, particularly when they are moist, to give MgX_2, and burns with dazzling brilliance in air to give MgO and Mg_3N_2. It also reacts directly with the other elements in Groups 15 and 16 (and Group 14) when heated and even forms MgH_2 with hydrogen at 570° and 200 atm. Steam produces MgO (or $Mg(OH)_2$) plus H_2, and ammonia reacts at elevated temperature to give Mg_3N_2. Methanol reacts at 200° to give $Mg(OMe)_2$ and ethanol (when activated

by a trace of iodine) reacts similarly at room temperature. Alkyl and aryl halides react with Mg to give Grignard reagents RMgX (pp. 132–5).

The heavier alkaline earth metals Ca, Sr, Ba (and Ra) react even more readily with non-metals, and again the direct formation of nitrides M_3N_2 is notable. Other products are similar though the hydrides are more stable (p. 65) and the carbides less stable than for Be and Mg. There is also a tendency, previously noted for the alkali metals (p. 84), to form peroxides MO_2 of increasing stability in addition to the normal oxides MO. Calcium, Sr and Ba dissolve in liquid NH_3 to give deep blue-black solutions from which lustrous, coppery, ammoniates $M(NH_3)_6$ can be recovered on evaporation; these ammoniates gradually decompose to the corresponding amides, especially in the presence of catalysts:

$$[M(NH_3)_6](s) \longrightarrow M(NH_2)_2(s) + 4NH_3(g) + H_2(g)$$

In these properties, as in many others, the heavier alkaline earth metals resemble the alkali metals rather than Mg (which has many similarities to Zn) or Be (which is analogous to Al).

5.3 Compounds

5.3.1 Introduction

The predominant divalence of the Group 2 metals can be interpreted in terms of their electronic configuration, ionization energies, and size (see Table 5.1). Further ionization to give simple salts of stoichiometry MX_3 is precluded by the magnitude of the energies involved, the third stage ionization being $14\,849\,kJ\,mol^{-1}$ for Be, $7733\,kJ\,mol^{-1}$ for Mg and $4912\,kJ\,mol^{-1}$ for Ca; even for Ra the estimated value of $3281\,kJ\,mol^{-1}$ involves far more energy than could be recovered by additional bonding even if this were predominantly covalent. Reasons for the absence of *univalent* compounds MX are less obvious. The first-stage ionization energies for Ca, Sr, Ba and Ra are similar to that of Li (p. 75) though the larger size of the hypothetical univalent Group 2 ions, when compared to Li, would reduce the lattice energy somewhat (p. 82). By making plausible assumptions about the ionic radius and structure we can estimate the approximate enthalpy of formation of such compounds and they are predicted to be stable with respect to the constituent elements; their non-existence is related to the much higher enthalpy of formation of the conventional compounds MX_2, which leads to rapid and complete disproportionation. For example, the standard enthalpy of formation of hypothetical crystalline MgCl, assuming the NaCl structure, is $\sim -125\,kJ\,mol^{-1}$, which is substantially greater than for many known stable compounds and essentially the same as the experimentally observed value for AgCl: $\Delta H_f^\circ = -127\,kJ\,mol^{-1}$. However, the corresponding (experimental) value for $\Delta H_f^\circ(MgCl_2)$ is $-642\,kJ\,mol^{-1}$, whence an enthalpy of disproportionation of $-196\,kJ\,mol^{-1}$:

$$Mg(c) + Cl_2(g) = MgCl_2(c); \quad \Delta H_f^\circ = -642\ kJ/(mol\ of\ MgCl_2)$$

$$2Mg(c) + Cl_2(g) = 2MgCl(c); \quad \Delta H_f^\circ = -250\ kJ/(2\ mol\ of\ MgCl)$$

$$2MgCl(c) = Mg(c) + MgCl_2(c); \quad \Delta H_{disprop}^\circ = -392\ kJ/(2\ mol\ of\ MgCl)$$

It is clear that, if synthetic routes could be devised which would mechanistically hinder disproportionation, such compounds might be preparable. Although univalent compounds of the Group 2 metals have not yet been isolated, there is some evidence for the formation of Mg^I species during electrolysis with Mg electrodes. Thus H_2 is evolved at the anode when an aqueous solution of NaCl is electrolysed and the amount of Mg lost from the anode corresponds to an oxidation state of 1.3. Similarly, when aqueous Na_2SO_4 is electrolysed, the amount of H_2 evolved corresponds to the oxidation by water of Mg ions having an average oxidation state of 1.4:

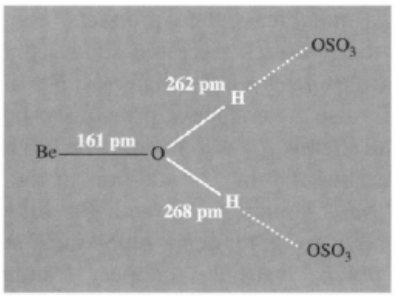
$$Mg^{1.4+}(aq) + 0.6H_2O \longrightarrow Mg^{2+}(aq) + 0.6OH^-(aq) + 0.3H_2(g)$$

Next Page

On the basis of the discussion on pp. 79–81 the elements in Group 2 would be expected to deviate further from simple ionic bonding than do the alkali metals. The charge on M^{2+} is higher and the radius for corresponding ions is smaller, thereby inducing more distortion of the surrounding anions. This is reflected in the decreased thermal stability of oxoacid salts such as nitrates, carbonates and sulfates. For example, the temperature at which the carbonate reaches a dissociation pressure of 1 atm CO_2 is: $BeCO_3$ 250°, $MgCO_3$ 540°, $CaCO_3$ 900°, $SrCO_3$ 1289°, $BaCO_3$ 1360°. The tendency towards covalency is greatest with Be, and this element forms no compounds in which the bonding is predominantly ionic. For similar reasons Be (and to a lesser extent Mg) forms numerous stable coordination compounds; organometallic compounds are also well characterized, and these frequently involve multicentre (electron deficient) bonding similar to that found in analogous compounds of Li and B.

Many compounds of the Group 2 elements are much less soluble in water than their Group 1 counterparts. This is particularly true for the fluorides, carbonates and sulfates of the heavier members, and is related to their higher lattice energies. These solubility relations have had a profound influence on the mineralization of these elements as noted on p. 109. The ready solubility of BeF_2 (~20 000 times that of CaF_2) is presumably related to the very high solvation enthalpy of Be to give $[Be(H_2O)_4]^{2+}$.

Beryllium, because of its small size, almost invariably has a coordination number of 4. This is important in analytical chemistry since it ensures that edta, which coordinates strongly to Mg, Ca (and Al), does not chelate Be appreciably. BeO has the wurtzite (ZnS, p. 1209) structure whilst the other Be chalcogenides adopt the zinc blende modification. BeF_2 has the cristobalite (SiO_2, p. 342) structure and has only a very low electrical conductivity when fused. Be_2C and Be_2B have extended lattices of the antifluorite type with 4-coordinate Be and 8-coordinate C or B. Be_2SiO_4 has the phenacite structure (p. 347) in which both Be and Si are tetrahedrally coordinated, and Li_2BeF_4 has the same structure. $[Be(H_2O)_4]SO_4$ features a tetrahedral aquo-ion which is H bonded to the surrounding sulfate groups in such a way that Be–O is 161 pm and the O–H···O are 262



and 268 pm. Further examples of tetrahedral coordination to Be are to be found in later sections. Other configurations, involving linear (two-fold) coordination (e.g. $BeBu^t_2$) or trigonal coordination [e.g. cyclic $(MeBeNMe_2)_2$] are rare and most compounds which might appear to have such coordination (e.g. $BeMe_2$, $CsBeF_3$, etc.) achieve 4-coordination by polymerization. However K_2BeO_2,[6] Y_2BeO_4[7] and one or two more complex structures[8] do indeed contain trigonal planar $\{BeO_3\}$ units with Be–O ca. 155 pm, i.e. some 11 pm shorter than in tetrahedral $\{BeO_4\}$. Likewise, K_4BeE_2 (E = P, As, Sb) feature linear anions $[E–Be–E]^{4-}$ isoelectronic with $BeCl_2$ molecules (p. 117).[9] (See also p. 123). Six-coordination has been observed in $K_3Zr_6Cl_{15}Be$ and $Be_3Zr_6Cl_{18}Be$, in which the Be atom is encapsulated by and contributes two bonding elections to the octahedral Zr_6 cluster.[10] Trigonal-pyramidal

6-fold coordination of Be by H is found in $Be(BH_4)_2$ (p. 116).

The stereochemistry of Mg and the heavier alkaline earth metals is more flexible than that of Be and, in addition to occasional compounds which feature low coordination numbers (2, 3 and 4), there are many examples of 6, 8 and 12 coordination, some with 7, 9 or 10 coordination, and even some with coordination numbers as high as 22 or 24, as in $SrCd_{11}$, $BaCd_{11}$ and (Ca, Sr or Ba)Zn_{13}.[11] Strontium is 5-coordinate on the hemisolvate $[Sr(OC_6H_2Bu^t_3)_2(thf)_3].\frac{1}{2}thf$ which features a distorted trigonal bipyramidal structure with the two aryloxides in equatorial positions.[11a]

5.3.2 Hydrides and halides

Many features of the structure, bonding and stability of the Group 2 hydrides have already been discussed (p. 65) and it is only necessary to add some comments on BeH_2, which is the most difficult of these compounds to prepare and the least stable. BeH_2 (contaminated with variable amounts of ether) was first prepared in 1951 by reduction of $BeCl_2$ with LiH and by the reaction of $BeMe_2$ with $LiAlH_4$. A purer sample can be made by pyrolysis of $BeBu^t_2$ at 210°C and the best product is obtained by displacing BH_3 from BeB_2H_8 using PPh_3 in a sealed tube reaction at 180°:

$$BeB_2H_8 + 2PPh_3 \longrightarrow 2Ph_3PBH_3 + BeH_2$$

BeH_2 is an amorphous white solid (d 0.65 g cm^{-3}) which begins to evolve hydrogen when heated above 250°; it is moderately stable in air or water but is rapidly hydrolysed by acids, liberating H_2. A hexagonal crystalline form (d 0.78 g cm^{-3}) has been prepared by compaction fusion at 6.2 kbar and 130° in the presence of ~1% Li as catalyst.[12] In all forms BeH_2 appears to be highly polymerized by means of BeHBe 3-centre bonds and its structure is probably similar to that of crystalline $BeCl_2$ and $BeMe_2$ (see below). A related compound is the volatile mixed hydride BeB_2H_8, which is readily prepared (in the absence of solvent) by the reaction of $BeCl_2$ with $LiBH_4$ in a sealed tube:

$$BeCl_2 + 2LiBH_4 \xrightarrow{120°C} BeB_2H_8 + 2LiCl$$

BeB_2H_8 inflames in air, reacts almost explosively with water and reacts with dry HCl even at low temperatures:

$$BeB_2H_8 + 2HCl \longrightarrow BeCl_2 + B_2H_6 + 2H_2$$

The structure of this compound has proved particularly elusive and at least nine different structures have been proposed; it therefore affords an instructive example of the difficulties which attend the use of physical techniques for the structural determination of compounds in the gaseous, liquid or solution phases. In the gas phase it now seems likely that more than one species is present[13] and the compound certainly shows fluxional behaviour which makes all the hydrogen atoms equivalent on the nmr time scale.[14] A linear structure such as (a), with possible admixture of singly bridged B–H–B and triply bridged BeH_3B variants is now favoured, after a period in which triangular structures such as (b) had been vigorously canvassed. Even structure (c), which features planar 3-coordinate Be, had been advocated because it was thought to fit best much of the infrared and electron diffraction data and also accounted for the ready formation of adducts (d) with typical ligands such as Et_2O, thf, R_3N, R_3P, etc. In the solid state the structure has recently been established with some certainty by single-crystal X-ray analysis.[15] BeB_2H_8 consists of helical polymers of BH_4Be

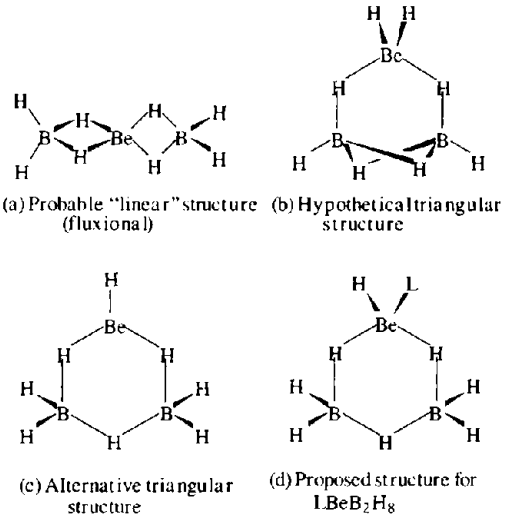

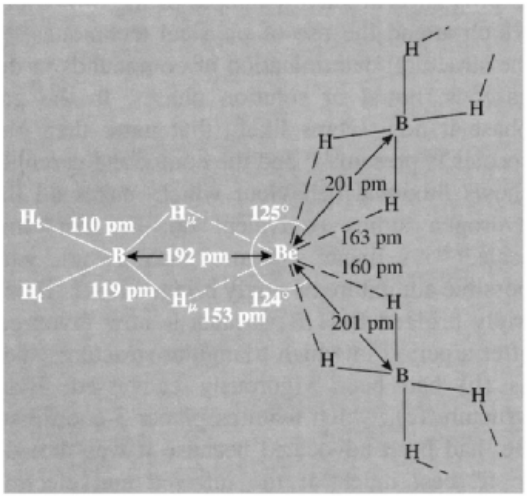

Figure 5.1 Polymeric structure of crystalline $Be(BH_4)_2$ showing a section of the $\cdots(H_2BH_2)Be(H_2BH_2)\cdots$ helix and one "terminal" or non-bridging group $\{(H_t)_2B(H_\mu)_2\}$.

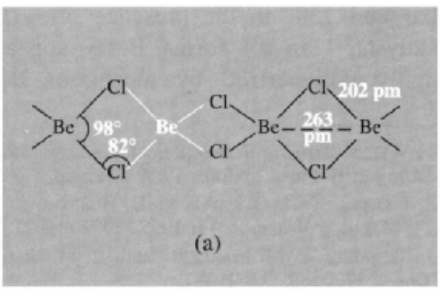
units linked by an equal number of bridging BH_4 units (Fig. 5.1). Of the 8 H atoms only 2 are not involved in bonding to Be; the Be is thus 6-coordinate (distorted trigonal prism) though the H atoms are much closer to B (~110 pm) than to Be (2 at ~153 pm and 4 at ~162 pm). The Be···B distance within the helical chain is 201 pm and in the branch is 192 pm. The relationship of this structure to those of $Al(BH_4)_3$ and AlH_3 itself (p. 227) is noteworthy.

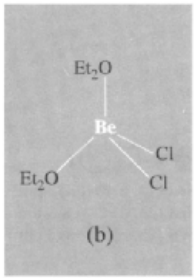
Anhydrous beryllium halides cannot be obtained from reactions in aqueous solutions because of the formation of hydrates such as $[Be(H_2O)_4]F_2$ and the subsequent hydrolysis which attends attempted dehydration. Thermal decomposition of $(NH_4)_2BeF_4$ is the best route for BeF_2, and $BeCl_2$ is conveniently made from the oxide

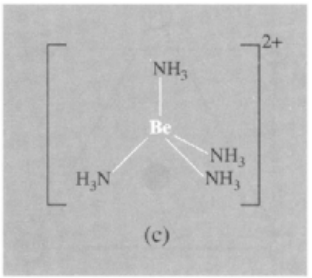
$$BeO + C + Cl_2 \overset{600-800°}{\rightleftharpoons} BeCl_2 + CO$$

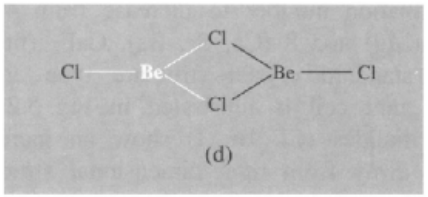
$BeCl_2$ can also be prepared by direct high-temperature chlorination of metallic Be or Be_2C, and these reactions are also used for the bromide and iodide. BeF_2 is a glassy material that is difficult to crystallize; it consists of a random network of 4-coordinate F-bridged Be atoms similar to the structure of vitreous silica, SiO_2. Above 270°, BeF_2 spontaneously crystallizes to give the quartz modification (p. 342) and, like quartz, it exists in a low-temperature α-form which transforms to the β-form at 227°; crystobalite and tridymite forms (p. 343) have also been prepared. The structural similarities between BeF_2 and SiO_2 extend to fluoroberyllates and silicates, and numerous parallels have been drawn: e.g. the phase diagram, compounds, and structures in the system $NaF-BeF_2$ resemble those for $CaO-SiO_2$; the system CaF_2-BeF_2 resembles ZrO_2-SiO_2; the compound $KZnBe_3F_9$ is isostructural with benitoite, $BaTiSi_3O_9$, etc.

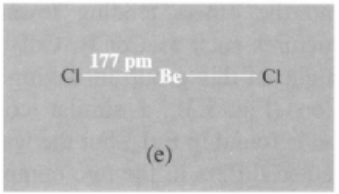
$BeCl_2$ has an unusual chain structure (a) which can be cleaved by weak ligands such as Et_2O to give 4-coordinate molecular complexes L_2BeCl_2 (b); stronger donors such as H_2O or NH_3 lead











to ionic complexes $[BeL_4]^{2+}[Cl]^-_2$ (c). In all these forms Be can be considered to use the s, p_x, p_y and p_z orbitals for bonding; the ClBeCl angle is substantially less than the tetrahedral angle of 109° probably because this lessens the repulsive interaction between neighbouring Be atoms in the chain by keeping them further apart and also enables a wider angle than 71° to be accommodated at each Cl atom, consistent with its predominant use of two p orbitals. The detailed interatomic distances and angles therefore differ significantly from those in the analogous chain structure $BeMe_2$ (p. 128), which is best described in terms of 3-centred "electron-deficient" bonding at the Me groups, leading to a BeCBe angle of 66° and a much closer approach of neighbouring Be atoms (209 pm). In the vapour phase $BeCl_2$ tends to form a bridged sp^2 dimer (d) and dissociation to the linear (sp) monomer (e) is not complete below about 900°; in contrast, BeF_2 is monomeric and shows little tendency to dimerize in the gas phase.

The shapes of the monomeric molecules of the Group 2 halides (gas phase or matrix isolation) pose some interesting problems for those who are content with simple theories of bonding and molecular geometry. Thus, as expected on the basis of either sp hybridization or the VSEPR model, the dihalides of Be and Mg and the heavier halides of Ca and Sr are essentially linear. However, the other dihalides are appreciably bent, e.g. $CaF_2 \sim 145°$, $SrF_2 \sim 120°$, $BaF_2 \sim 108°$; $SrCl_2 \sim 130°$, $BaCl_2 \sim 115°$; $BaBr_2 \sim 115°$; $BaI_2 \sim 105°$. The uncertainties on these bond angles are often quite large (±10°) and the molecules are rather flexible, but there seems little doubt that the equilibrium geometry is substantially non-linear. This has been interpreted in terms of sd (rather than sp) hybridization[16] or by a suitable *ad hoc* modification of the VSEPR theory[17].

The *crystal* structures of the halides of the heavier Group 2 elements also show some interesting trends (Table 5.3). For the fluorides, increasing size of the metal enables its

Table 5.3 Crystal structures of alkaline earth halides[a]

	Be	Mg	Ca	Sr	Ba
F	Quartz	Rutile(TiO_2)	Fluorite	Fluorite	Fluorite
Cl	Chain	$CdCl_2$	Deformed TiO_2	Deformed TiO_2	$PbCl_2$
Br	Chain	CdI_2	Deformed TiO_2	Deformed $PbCl_2$	$PbCl_2$
I	—	CdI_2	CdI_2	SrI_2	$PbCl_2$

[a] For description of these structures see: quartz (p. 342), rutile (p. 961), $CdCl_2$ (p. 1212), CdI_2 (p. 1212), $PbCl_2$ (p. 382); the fluorite, $BeCl_2$-chain and SrI_2 structures are described in this subsection.

coordination number to increase from 4 (Be) to 6 (Mg) and 8 (Ca, Sr, Ba). CaF_2 (fluorite) is a standard crystal structure type and its cubic unit cell is illustrated in Fig. 5.2. The other halides (Cl, Br, I) show an increasing trend away from three-dimensional structures, the Be halides forming chains (as discussed above) and the others tending towards layer-lattice structures such as $CdCl_2$, CdI_2 and PbI_2. SrI_2 is unique in this group in having sevenfold coordination (Fig. 5.3); a similar coordination polyhedron is found in EuI_2, but the way they are interconnected differs in the two compounds.[18]

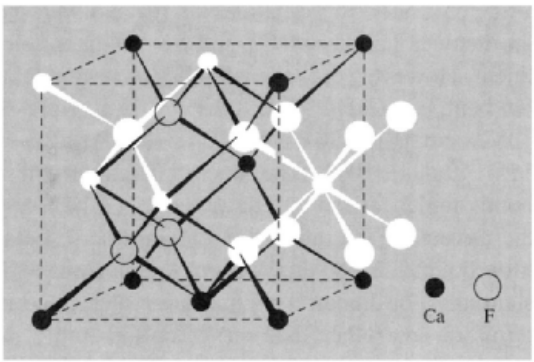

Figure 5.2 Unit cell of CaF_2 showing eightfold (cubic) coordination of Ca by 8F and fourfold (tetrahedral) coordination of F by 4Ca. The structure can be thought of as an fcc array of Ca in which all the tetrahedral interstices are occupied by F.

The most important fluoride of the alkaline earth metals is CaF_2 since this mineral (fluorspar) is the only large-scale source of fluorine (p. 795). Annual world production now exceeds 5 million tonnes the principal suppliers (in 1984) being Mexico (15%), Mongolia (15%), China (14%), USSR (13%) and South Africa (7%). The largest consumer is the USA, though 85% of its needs must be imported. CaF_2 is a white, high-melting (1418°C) solid whose low solubility in water permits quantitative analytical precipitation. The

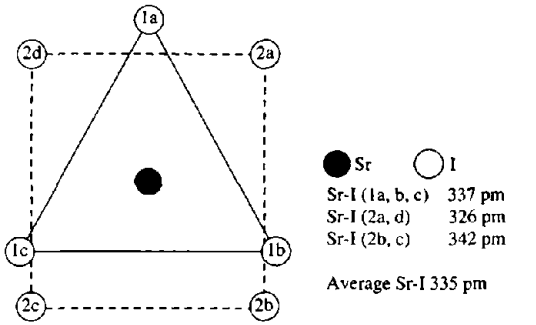

Figure 5.3 Structure of SrI_2 showing sevenfold coordination of Sr by I. The planes 1 and 2 are almost parallel (4.5°) and the planes 1a2a2d and 1b2b2c1c are at an angle of 12° to each other.[9]

other fluorides (except BeF_2) are also high-melting and rather insoluble. By contrast, the chlorides tend to be deliquescent and to have much lower mps (715–960°); they readily form numerous hydrates and are soluble in alcohols. $MgCl_2$ is one of the most important salts of Mg industrially (p. 110) and its concentration in sea water is exceeded only by NaCl. $CaCl_2$ is also of great importance, as noted earlier; its production in the US is in the megatonne region and its 1990 price was: bulk $182/tonne, granules $360/tonne, i.e 36 cents/kg. Its traditional uses include:

(a) brine for refrigeration plants (and for filling inflated tires of tractors and earth-moving equipment to increase traction);
(b) control of snow and ice on highways and pavements (side walks) — the $CaCl_2$–H_2O eutectic at 30 wt% $CaCl_2$ melts at −55°C (compared with NaCl–H_2O at −18°C);
(c) dust control on secondary roads, unpaved streets, and highway shoulders;
(d) freeze-proofing of coal and ores in shipping and stock piling;
(e) use in concrete mixes to give quicker initial set, higher early strength, and greater ultimate strength.

The bromides and iodides continue the trends to lower mps and higher solubilities

[18] E. T. RIETSCHEL and H. BÄRNIGHAUSEN, *Z. anorg. allg. Chem.* **368**, 62–72 (1969).

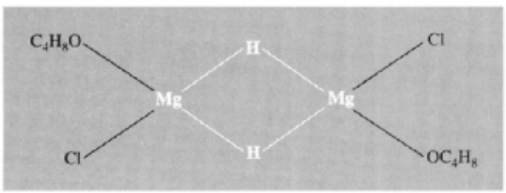
in water and their ready solubility in alcohols, ethers, etc., is also notable; indeed, $MgBr_2$ forms numerous crystalline solvates such as $MgBr_2.6ROH$ (R = Me, Et, Pr), $MgBr_2.6Me_2CO$, $MgBr_2.3Et_2O$, in addition to numerous ammines $MgBr_2.nNH_3$ ($n = 2$–6). The ability of Group 2 cations to form coordination complexes is clearly greater than that of Group 1 cations (p. 90).

Alkaline earth salts MHX, where M = Ca, Sr or Ba and X = Cl, Br or I can be prepared by fusing the hydride MH_2 with the appropriate halide MX_2 or by heating $M + MX_2$ in an atmosphere of H_2 at 900°. These hydride halides appear to have the PbClF layer lattice structure though the H atoms were not directly located. The analogous compounds of Mg have proved more elusive and the preceding preparative routes merely yield physical mixtures. However, MgClH and MgBrH can be prepared as solvated dimers by the reaction of specially activated MgH_2 with MgX_2 in thf:

$$MgR_2 + LiAlH_4 \xrightarrow{Et_2O} MgH_2 + LiAlH_2R_2$$

$$MgH_2 + MgX_2 \xrightarrow{thf} [HMgX(thf)]_2$$

The chloride can be crystallized but the bromide disproportionates. On the basis of mol wt and infrared spectroscopic evidence the proposed structure is:



5.3.3 Oxides and hydroxides [19,20]

The oxides MO are best obtained by calcining the carbonates (pp. 114 and 122); dehydration of the hydroxides at red heat offers an alternative route. BeO (like the other Be chalcogenides) has the wurtzite structure (p. 1210) and is an excellent refractory, combining a high mp (2507°C) with negligible vapour pressure below this temperature; it has good chemical stability and a very high thermal conductivity which is greater than that of any other non-metal and even exceeds that of some metals. The other oxides in the group all have the NaCl structure and this structure is also adopted by the chalcogenides (except MgTe which has the wurtzite structure). Lattice energies and mps are again very high: MgO mp 2832°, CaO 2627°, SrO 2665°, BaO 1913°C (all ± ca. 30°). The compounds are comparatively unreactive in bulk but their reactivity increases markedly with decrease in particle size and increase in atomic weight. Notable reactions (which reverse those used to prepare the oxides) are with CO_2 and with H_2O. MgO is extensively used as a refractory: like BeO it is unusual in being both an excellent thermal conductor and a good electrical insulator, thus finding widespread use as the insulating radiator in domestic heating ranges and similar appliances. CaO (lime) is produced on an enormous scale in many countries and, indeed, is one of the half-dozen largest tonnage industrial chemicals to be manufactured (see Panel on p. 120). Production in 1991 exceeded 16 million tonnes in the USA alone. Its major end uses (in descending tonnages) are as a flux in steel manufacture; in the production of Ca chemicals; in the treatment of municipal water supplies, industrial wastes and sewage; in mortars and cements; in the pulp and paper industries; and in non-ferrous metal production. Price for bulk quantities is ~$45 per tonne.

In addition to the oxides MO, peroxides MO_2 are known for the heavier alkaline earth metals and there is some evidence for yellow superoxides $M(O_2)_2$ of Ca, Sr and Ba; impure ozonides $Ca(O_3)_2$ and $Ba(O_3)_2$ have also been reported.[21] As with the alkali metals, stability

Industrial Uses of Limestone and Lime

Limestone rock is the commonest form of calcium carbonate, which also occurs as chalk, marble, corals, calcite, aragonite, etc., and (with Mg) as dolomite. Limestone and dolomite are widely used as building materials and road aggregate and both are quarried on a vast scale worldwide. $CaCO_3$ is also a major industrial chemical and is indispensable as the precursor of quick lime (CaO) and slaked lime, $Ca(OH)_2$. These chemicals are crucial to large sections of the chemical, metallurgical and construction industries, as noted below, and are produced on a scale exceeded by very few other materials.[22] Thus, world production of lime exceeds 110 million tonnes, and even this is dwarfed by Portland cement (793 million tonnes in 1984) which is made by roasting limestone and sand with clay (p. 252).

Large quantities of lime are consumed in the steel industry where it is used as a flux to remove P, S, Si and to a lesser extent Mn. The basic oxygen steel process typically uses 75 kg lime per tonne of steel, or a rather larger quantity (100–300 kg) of dolomitic quick lime, which markedly extends the life of the refractory furnace linings. Lime is also used as a lubricant in steel wire drawing and in neutralizing waste sulfuric-acid-based pickling liquors. Another metallurgical application is in the production of Mg (p. 110): the ferro-silicon (Pidgeon) process (1) uses dolomitic lime and both of the Dow electrolytic methods (2), (3), also require lime.

$$2(CaO.MgO) + Si/Fe \longrightarrow 2Mg + Ca_2SiO_4/Fe \quad (1)$$

$$CaO.MgO + CaCl_2.MgCl_2(\text{brine}) + CO_2 \longrightarrow 2CaCO_3 + 2MgCl_2 \text{ (then electrolysis)} \quad (2)$$

$$\left.\begin{aligned} Ca(OH)_2 + MgCl_2(\text{seawater}) &\longrightarrow Mg(OH)_2 + CaCl_2 \\ Mg(OH)_2 + 2HCl &\longrightarrow 2H_2O + MgCl_2 \text{ (then electrolysis)} \end{aligned}\right\} \quad (3)$$

Lime is the largest tonnage chemical used in the treatment of potable and industrial water supplies. In conjunction with alum or iron salts it is used to coagulate suspended solids and remove turbidity. It is also used in water softening to remove temporary (bicarbonate) hardness. Typical reactions are:

$$Ca(HCO_3)_2 + Ca(OH)_2 \longrightarrow 2CaCO_3\downarrow + 2H_2O$$

$$Mg(HCO_3)_2 + Ca(OH)_2 \longrightarrow MgCO_3\downarrow + CaCO_3\downarrow + 2H_2O$$

$$MgCO_3 + Ca(OH)_2 \longrightarrow Mg(OH)_2\downarrow + CaCO_3\downarrow \text{etc.}$$

The neutralization of acid waters (and industrial wastes) and the maintenance of optimum pH for the biological oxidation of sewage are further applications. Another major use of lime is in scrubbers to remove SO_2/H_2S from stack gases of fossil-fuel-powered generating stations and metallurgical smelters.

The chemical industry uses lime in the manufacture of calcium carbide (for acetylene, p. 297), cyanamide (p. 323), and numerous other chemicals. Glass manufacturing is also a major consumer, most common glasses having ~12% CaO in their formulation. The insecticide calcium arsenate, obtained by neutralizing arsenic acid with lime, is much used for controlling the cotton boll weavil, codling moth, tobacco worm, and Colorado potato beetle. Lime-sulfur sprays and Bordeaux mixtures [$(CuSO_4/Ca(OH)_2$] are important fungicides.

The paper and pulp industries consume large quantities of $Ca(OH)_2$ and precipitated (as distinct from naturally occurring) $CaCO_3$. The largest application of lime in pulp manufacture is as a causticizing agent in sulfate (kraft) plants (p. 89). Here the waste Na_2CO_3 solution is reacted with lime to regenerate the caustic soda used in the process:

$$Na_2CO_3 + CaO + H_2O \longrightarrow CaCO_3 + 2NaOH$$

About 95% of the $CaCO_3$ mud is dried and recalcined in rotary kilns to recover the CaO. Calcium hypochlorite bleaching liquor (p. 860) for paper pulp is obtained by reacting lime and Cl_2.

The manufacture of high quality paper involves the extensive use of specially precipitated $CaCO_3$. This is formed by calcining limestone and collecting the CO_2 and CaO separately; the latter is then hydrated and recarbonated to give the desired product. The type of crystals obtained, as well as their size and habit, depend on the temperature, pH, rate of mixing, concentration and presence of additives. The fine crystals (<45 μm) are often subsequently coated with fatty acids, resins and wetting agents to improve their flow properties. US prices (1991) range from 5–45 cents per kg depending on grade and the amounts consumed are immense, e.g. 5.9 million tonnes p.a. in the USA alone. $CaCO_3$ adds brightness, opacity, ink receptivity and smoothness to paper and, in higher concentration, counteracts the high gloss produced by kaolin additives and produces a matte or dull finish which is particularly popular for textbooks. Such papers may contain 5–50% by weight of precipitated $CaCO_3$. The compound is also used as a filler in rubbers, latex, wallpaints and enamels, and in plastics (~10% by weight) to improve their heat resistance, dimensional stability, stiffness, hardness and processability.

Panel continues

[22] R. S. BOYNTON, *Chemistry and Technology of Lime and Limestone*, 2nd edn., Wiley, Chichester, 1980, 579 pp.

Domestic and pharmaceutical uses of precipitated $CaCO_3$ include its direct use as an antacid, a mild abrasive in toothpastes, a source of Ca enrichment in diets, a constituent of chewing gum and a filler in cosmetics.

In the dairy industry lime finds many uses. Lime water is often added to cream when separated from whole milk, in order to reduce its acidity prior to pasteurization and conversion to butter. The skimmed milk is then acidified to separate casein which is mixed with lime to produce calcium caseinate glue. Fermentation of the remaining skimmed milk (whey) followed by addition of lime yields calcium lactate which is used as a medicinal or to produce lactic acid on reacidification. Likewise the sugar industry relies heavily on lime: the crude sugar juice is reacted with lime to precipitate calcium sucrate which permits purification from phosphatic and organic impurities. Subsequent treatment with CO_2 produces insoluble $CaCO_3$ and purified soluble sucrose. The cycle is usually repeated several times; cane sugar normally requires ~3–5 kg lime per tonne but beet sugar requires 100 times this amount i.e. ~$\frac{1}{4}$ tonne lime per tonne of sugar.

increases with electropositive character and size: no peroxide of Be is known; anhydrous MgO_2 can only be made in liquid NH_3 solution, aqueous reactions leading to various peroxide hydrates; CaO_2 can be obtained by dehydrating $CaO_2.8H_2O$ but not by direct oxidation, whereas SrO_2 can be synthesized directly at high oxygen pressures and BaO_2 forms readily in air at 500°. Reactions with aqueous reagents are as expected, and the compounds can be used as oxidizing agents and bleaches:

$$CaO_2(s) + H_2SO_4(aq) \longrightarrow CaSO_4(s) + H_2O_2(aq)$$

$$Ca(O_2)_2 + H_2SO_4(aq) \longrightarrow CaSO_4(s) + H_2O_2(aq) + O_2(g)$$

MgO_2 has the pyrite structure (p. 680) and the Ca, Sr and Ba analogues have the CaC_2 structure (p. 298).

The hydroxides of Group 2 elements show a smooth gradation in properties, with steadily increasing basicity, solubility, and heats of formation from the corresponding oxide. $Be(OH)_2$ is amphoteric and $Mg(OH)_2$ is a mild base which, as an aqueous suspension (milk of magnesia), is widely used as a digestive antacid. Note that, though mild, $Mg(OH)_2$ will neutralize 1.37 times as much acid as NaOH, weight for weight, and 2.85 times as much as $NaHCO_3$. $Ca(OH)_2$ and $Sr(OH)_2$ are moderately strong to strong bases and $Ba(OH)_2$ approaches the alkali hydroxides in strength.

Beryllium salts rapidly hydrolyse in water to give a series of hydroxo complexes of undetermined structure; the equilibria depend sensitively on initial concentration, pH, temperature, etc., and precipitation begins when the ratio $OH^-/Be^{2+}(aq) > 1$. Addition of further alkali redissolves the precipitate and the properties of the resultant solution are consistent (at least qualitatively) with the presence of isopolyanions of the type $[(HO)_2\{Be(\mu\text{-}OH)_2\}_nBe(OH)_2]^{2-}$. Further addition of alkali progressively depolymerizes this chain anion by hydroxyl addition until ultimately the mononuclear beryllate anion $[Be(OH)_4]^{2-}$ is formed. The analogy with $Zn(OH)_2$ and $Al(OH)_3$ is clear.

The solubility of $Be(OH)_2$ in water is only $\sim 3 \times 10^{-4}$ g l^{-1} at room temperature, compared with $\sim 3 \times 10^{-2}$ g l^{-1} for $Mg(OH)_2$ and ~1.3 g l^{-1} for $Ca(OH)_2$. Strontium and barium hydroxides have even greater solubilities (8 and 38 g l^{-1} respectively at 20°).

The crystal structures of $M(OH)_2$ also follow group trends.[11] $Be(OH)_2$ crystallizes with 4-coordinate Be in the $Zn(OH)_2$ structure which can be considered as a diamond or cristobalite (SiO_2) lattice distorted by H bonding. $Mg(OH)_2$ (brucite) and $Ca(OH)_2$ have 6-coordinate cations in a CdI_2 layer lattice structure with OH bonds perpendicular to the layers and strong O–H···O bonding between them. Strontium is too large for the CdI_2 structure and $Sr(OH)_2$ features 7-coordinate Sr (3 + 4), the structure being built up of edge-sharing monocapped trigonal prisms with no H bonds. (The monohydrate has bicapped trigonal prismatic coordination about Sr.) The structure of $Ba(OH)_2$ is complex and has not yet been fully determined.

5.3.4 Oxoacid salts and coordination complexes

The chemical trends and geochemical significance of the oxoacid salts of the alkaline earth metals have already been mentioned (p. 109) and the immense industrial importance of the carbonates and sulfates in particular can hardly be over emphasized (see Panel on limestone and lime). A speciality use can also be noted: mother-of-pearl (nacre) is a material composed of thin plates of chalk (in the form of aragonite) stuck together with a protein glue. It is irridescent and highly decorative when polished and, despite being 95% chalk, is very strong.

Calcium sulfate usually occurs as the dihydrate (gypsum) though anhydrite ($CaSO_4$) is also mined. Alabaster is a compact, massive, finegrained form of $CaSO_4.2H_2O$ resembling marble. When gypsum is calcined at 150–165°C it looses approximately three-quarters of its water of crystallization to give the hemihydrate $CaSO_4.\frac{1}{2}H_2O$, also known as plaster of Paris because it was originally obtained from gypsum quarried at Montmartre. Heating at higher temperatures yields various anhydrous forms:

$$CaSO_4.2H_2O \xrightarrow{\sim 150^\circ} CaSO_4.\tfrac{1}{2}H_2O \xrightarrow{\sim 200^\circ}$$

$$\gamma\text{-}CaSO_4 \xrightarrow{\sim 600^\circ} \beta\text{-}CaSO_4 \xrightarrow{\sim 1100^\circ} CaO + SO_3$$

Gypsum, though not mined on the same scale as limestone, is nevertheless still a major industrial mineral. World production in 1990 was 97.7 million tonnes, the major producing countries being the USA (15.2%), Canada (8.4%), Iran (8.2%), China (8.2%), Japan (6.5%), Mexico (6.1%), Thailand (5.9%), France (5.8%) and Spain (5.1%); the remaining 30.6% (30 million tonnes) was distributed between over 20 other countries including the former Soviet Union (4.8%) and the UK (4.1%). A representative price in 1990 was $5.5 per tonne. In the USA about 28% of the gypsum used is uncalcined and most of this is for Portland cement (p. 252) or agricultural purposes. Of calcined gypsum, virtually all (95%) is used for prefabricated products, mainly wall board, and the rest is for industrial and building plasters. The hemihydrate expands slightly (0.2–0.3% linear) on rehydration with water and this is crucial to its use in mouldings and plasters; the expansion can be modified in the range 0.03–1.2% by the use of additives.

Other oxoacid salts and binary compounds are more conveniently discussed under the chemistry of the appropriate non-metals in later chapters.

Beryllium is unique in forming a series of stable, volatile, molecular oxide-carboxylates of general formula $[OBe_4(RCO_2)_6]$, where R = H, Me, Et, Pr, Ph, etc. These white crystalline compounds, of which "basic beryllium acetate" (R = Me) is typical, are readily soluble in organic solvents, including alkanes, but are insoluble in water or the lower alcohols. They are best prepared simply by refluxing the hydroxide or oxide with the carboxylic acid; mixed oxide carboxylates can be prepared by reacting a given compound with another organic acid or acid chloride. The structure (Fig. 5.4) features a central O atom tetrahedrally surrounded by 4 Be. The 6 edges of the tetrahedron so formed are bridged by the 6 acetate groups in such a way that each Be is also tetrahedrally coordinated by 4 oxygens. $[OBe_4(MeCO_2)_6]$ melts at 285° and boils at 330°; it is stable to heat and oxidation except under drastic conditions, is only slowly hydrolysed by hot water, but is decomposed rapidly by mineral acids to give an aqueous solution of the corresponding beryllium salt and free carboxylic acid. The basic nitrate $[OBe_4(NO_3)_6]$ appears to have a similar structure with bridging nitrate groups. The compound is formed by first dissolving $BeCl_2$ in N_2O_4/ethyl-acetate to give the crystalline solvate $[Be(NO_3)_2.2N_2O_4]$; when heated to 50° this gives $Be(NO_3)_2$ which decomposes suddenly at 125°C into N_2O_4 and $[OBe_4(NO_3)_6]$.

In addition to the oxide carboxylates, beryllium forms numerous chelating and bridged complexes with ligands such as the oxalate ion $C_2O_4^{2-}$, alkoxides, β-diketonates and 1,3-diketonates.[20] These almost invariably feature 4-coordinate Be

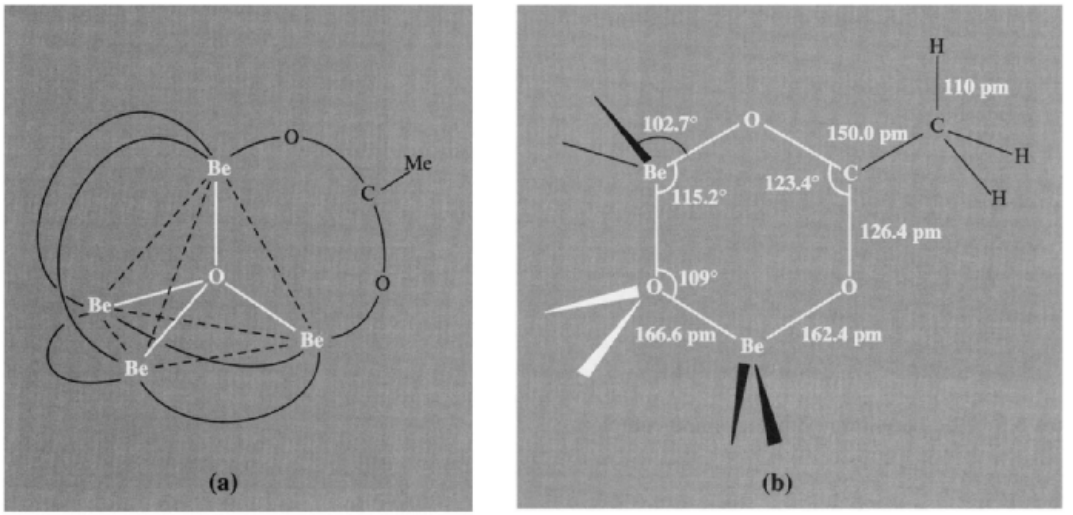

Figure 5.4 The molecular structure of "basic beryllium acetate" showing (a) the regular tetrahedral arrangement of 4 Be about the central oxygen and the octahedral arrangement of the 6 bridging acetate groups, and (b) the detailed dimensions of one of the six non-planar 6-membered heterocycles. (The Be atoms are 24 pm above and below the plane of the acetate group.) The 2 oxygen atoms in each acetate group are equivalent. The central Be–O distances (166.6 pm) are very close to that in BeO itself (165 pm).

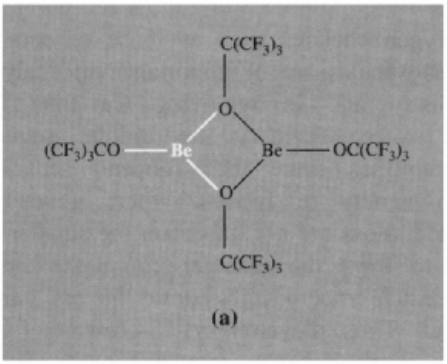
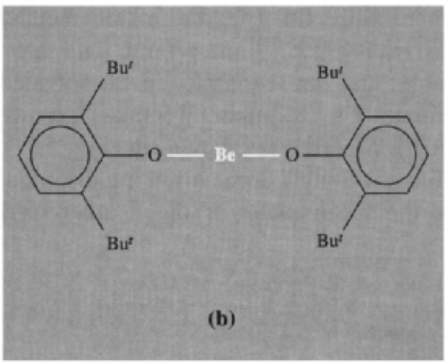
though severe steric crowding can reduce the coordination number to 3 or even 2; for example, the very volatile dimeric perfluoroalkoxide (a) was prepared in 1975 and the unique monomeric bis(2,6-di-t-butylphenoxy)beryllium (b) has been known since 1972.

Halide complexes are also well known but complexes with nitrogen-containing ligands are rare. An exception is the blue phthalocyanine complex formed by reaction of Be metal with phthalonitrile, $1,2\text{-}C_6H_4(CN)_2$, and this affords an unusual example of planar 4-coordinate Be (Fig. 5.5). The complex readily picks up two molecules of H_2O to form an extremely stable dihydrate, perhaps by dislodging 2 adjacent Be–N bonds and forming 2 Be–O bonds at the preferred tetrahedral angle above and below the plane of the macrocycle.

Magnesium forms few halide complexes of the type MX_4^{2-}, though $[NEt_4]_2[MgCl_4]$ has been reported; examples of $MX_n^{(n-2)-}$ for the heavier alkaline earths are lacking, though hydrates and





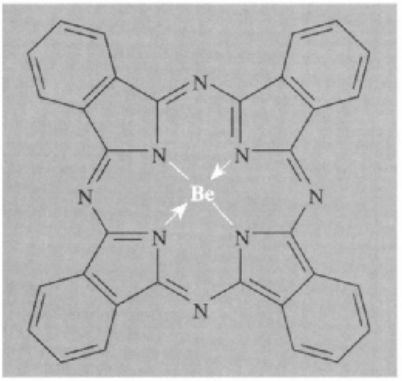


Figure 5.5 The beryllium phthalocyanine complex.

other solvates are well known. The first examples of monomeric six-coordinate (octahedral) complexes of strontium salts have recently been characterized, *viz. trans*-$[SrI_2(hmpa)_4]$ and *cis*-$[Sr(NCS)_2(hmpa)_4]$ where hmpa is $(Me_2N)_3PO$; they were made as colourless crystals by refluxing a mixture of NH_4I (or NH_4SCN) with metallic Sr and hmpa in toluene for 1 hour.[23]

Oxygen chelates such as those of edta and polyphosphates are of importance in analytical chemistry and in removing Ca ions from hard water. There is no unique sequence of stabilities since these depend sensitively on a variety of factors: where geometrical considerations are not important the smaller ions tend to form the stronger complexes but in polydentate macrocycles steric factors can be crucial. Thus dicyclohexyl-18-crown-6 (p. 96) forms much stronger complexes with Sr and Ba than with Ca (or the alkali metals) as shown in Fig. 5.6.[24] Structural data are also available and an example of a solvated 8-coordinate Ca complex [(benzo-15-crown-5)-$Ca(NCS)_2$.MeOH] is shown in Fig. 5.7. The coordination polyhedron is not regular: Ca lies above the mean plane of the 5 ether oxygens

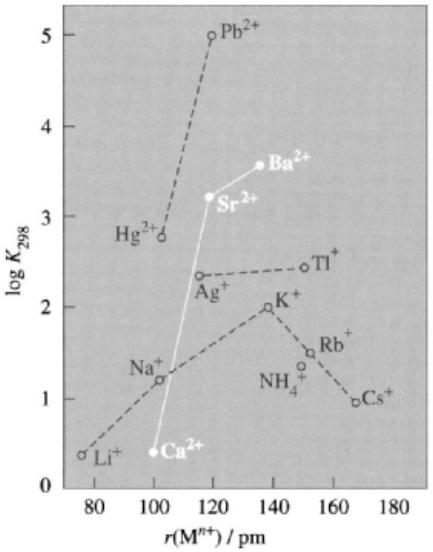

Figure 5.6 Formation constants K for complexes of dicyclohexyl-18-crown-6 ether with various cations. Note that, although the radii of Ca^{2+}, Na^+ and Hg^{2+} are very similar, the ratio of the formation constants is 1:6.3:225. Again, K^+ and Ba^{2+} have similar radii but the ratio of K is 1:35 in the reverse direction (note log scale).

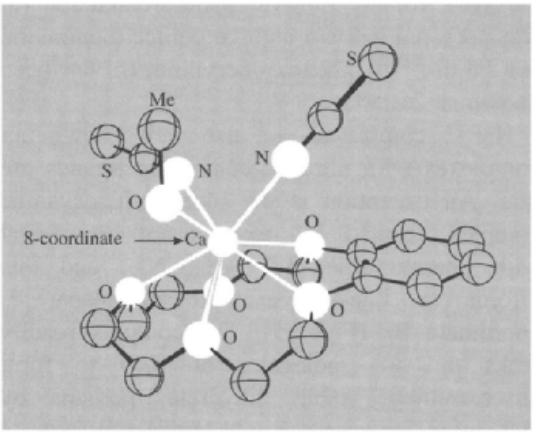

Figure 5.7 Molecular structure of benzo-15-crown-5-$Ca(NCS)_2$.MeOH.

(mean Ca–O 253 pm) and is coordinated on the other side by a methanol molecule (Ca–O 239 pm) and two non-equivalent isothiocyanate

[24] See refs. 38 and 66 of Chapter 4.

groups (Ca–N 244 pm) which make angles Ca–N–CS of 153° and 172° respectively.[25] Cryptates (pp. 97–8) are also known and usually follow the stability sequence Mg < Ca < Sr < Ba.[24] The first monomeric barium alkoxides, $[Ba\{O(CH_2CH_2O)_nMe\}_2]$ ($n = 2$, 3), which incorporate coordinating polyether functions, were isolated in 1991; the compounds, which are unusual in being liquids at room temperature and which feature 6- and 8-coordinate Ba, respectively, were made by direct reaction of Ba metal with the oligoether alcohols in thf.[26]

Preeminent in importance among the macrocyclic complexes of Group 2 elements are the chlorophylls, which are modified porphyrin complexes of Mg. These compounds are vital to the process of photosynthesis in green plants (see Panel). Magnesium and Ca are also intimately involved in biochemical processes in animals: Mg ions are required to trigger phosphate transfer enzymes, for nerve impulse transmissions and carbohydrate metabolism; Mg ions are also involved in muscle action, which is triggered by Ca ions. Ca is required for the formation of bones and teeth, maintaining heart rhythm, and in blood clotting.[27a–f]

Chlorophylls and Photosynthesis

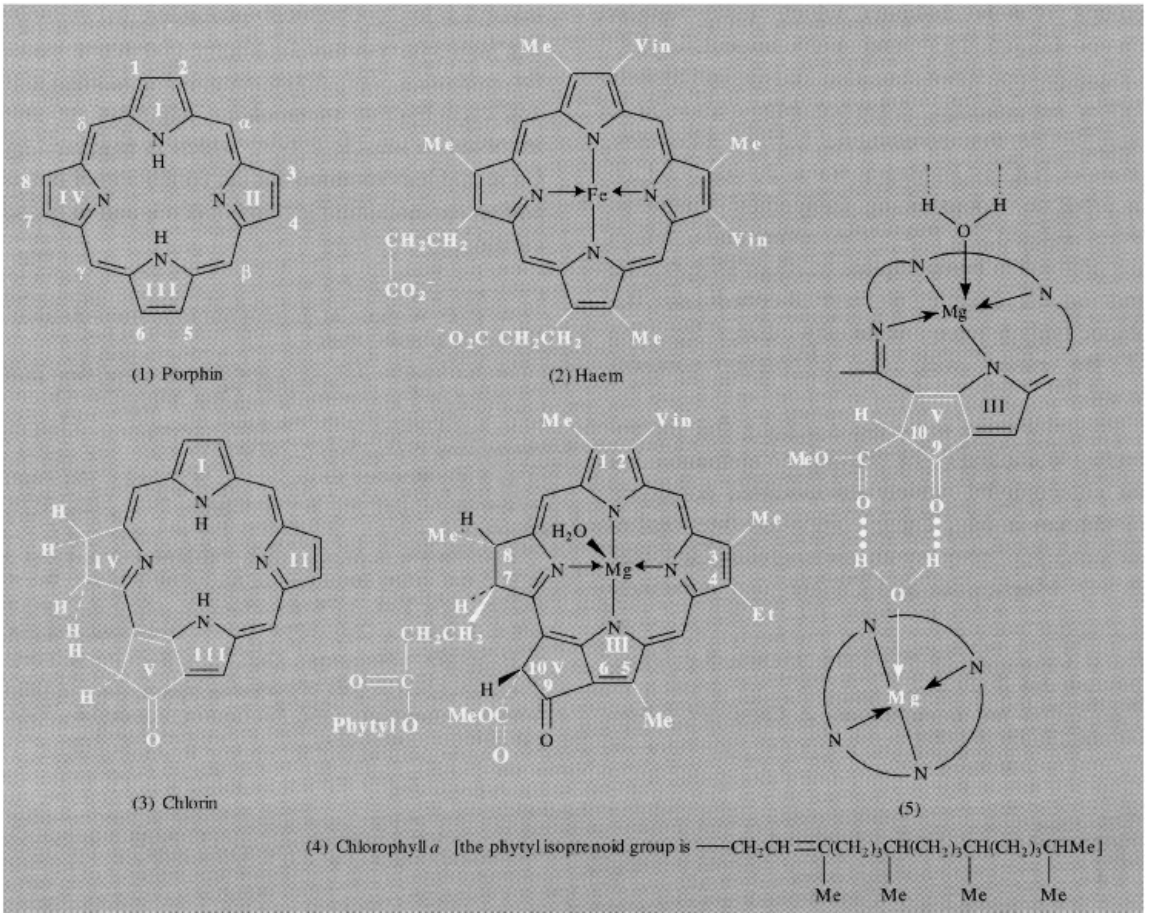
Photosynthesis is the process by which green plants convert atmospheric CO_2 into carbohydrates such as glucose. The overall chemical change can be expressed as

$$6CO_2 + 6H_2O \xrightarrow{h\nu} C_6H_{12}O_6 + 6O_2$$

though this is a gross and somewhat misleading over-simplification. The process is initiated in the photoreceptors of the green magnesium-containing pigments which have the generic name chlorophyll (Greek: χλωρός, *chloros* green; φύλλον, *phyllon* leaf), but many of the subsequent steps can proceed in the dark. The overall process is endothermic ($\Delta H^\circ \sim 469$ kJ per mole of CO_2) and involves more than one type of chlorophyll. It also involves a manganese complex of unknown composition, various iron-containing cytochromes and ferredoxin (p. 1102), and a copper containing plastocyanin.

Photosynthesis is essentially the conversion of radiant electromagnetic energy (light) into chemical energy in the form of adenosine triphosphate (ATP) and reduced nicotinamide adenine dinucleotide phosphate (NADP). This energy eventually permits the fixation of CO_2 into carbohydrates, with the liberation of O_2. As such, the process is the basis for the nutrition of all living things and also provides mankind with fuel (wood, coal, petroleum), fibres (cellulose) and innumerable useful chemical compounds. About 90–95% of the dry weight of crops is derived from the CO_2/H_2O fixed from the air during photosynthesis — only about 5–10% comes from minerals and nitrogen taken from the soil. The detailed sequence of events is still not fully understood but tremendous advances were made from 1948 onwards by use of the then newly available radioactive $^{14}CO_2$ and paper chromatography. With these tools and classical organic chemistry M. Calvin and his group were able to probe the biosynthetic pathways and thus laid the basis for our present understanding of the complex series of reactions. Calvin was awarded the 1961 Nobel Prize in Chemistry "for his research on the carbon dioxide assimilation in plants".[28]

Panel continues



Chlorophylls are complexes of Mg with macrocyclic ligands derived from the parent tetrapyrrole molecule porphin (structure 1). They are thus related to the porphyrin (substituted porphin) complexes which occur in haem proteins† such as haemoglobin, myoglobin and the cytochromes (p. 1101). [The word haem and the prefix haemo derive directly from the Greek word *αἷμα*, blood, whereas porphyrins derive their name from the characteristic purple-red coloration which these alkaloids give when acidified (Greek *πόρφυρ-ος*, *porphyros* purple).] The haem group is illustrated in structure 2. When the C=C double bond in the pyrrole-ring IV of porphin is *trans* hydrogenated and when a cyclopentanone ring is formed between ring III and the adjacent (*γ*) methine bridge then the chlorin macrocycle (structure 3) is produced, and this is the basis for the various chlorophylls. Chlorophyll *a* (Chl *a*) is shown in structure 4; this is the most common of the chlorophylls and is found in all O_2-evolving organisms. It was synthesized with complete chiral integrity by R. B. Woodward and his group in 1960 — an achievement of remarkable virtuosity. Variants of chlorophyll are:

Chlorophyll *b*, in which the 3-Me group is replaced by –CHO; this occurs in higher plants and green algae, the ratio Chl *b*:Chl *a* being ~1:3.
Chlorophyll *c*, in which position 7 is substituted by acrylic acid, –CH=CHCO$_2$H; it occurs in diatoms and brown algae.
Chlorophyll *d*, in which 2-vinyl is replaced by –CHO.

Panel continues

†The first time that these two apparently very different but actually closely related coloured materials, chlorophyll and haemoglobin, were connected was in an extraordinarily percipient poem written in 1612 by the English poet John Donne who mused: Why grass is green or why our blood is red/Are mysteries that none have reached unto.

Next Page

Previous Page

It is important to note that the chlorin macrocycle is "ruffled" rather than completely planar and the Mg atom is ~30–50 pm above the plane of the 4 N atoms. In fact the Mg is not 4-coordinate but carries one (or sometimes two) other ligands, notably water molecules, which play a crucial role in interconnecting the basic chlorophyll units into stacks by H bonding to the cyclopentanone ring V of an adjacent chlorophyll molecule (see structure 5).

The function of the chlorophyll in the chloroplast is to absorb photons in the red part of the visible spectrum (near 680–700 nm) and to pass this energy of excitation on to other chemical intermediates in the complex reaction scheme. At least two photosystems are involved: the initiating photosystem II (P680) which absorbs at 680 nm and the subsequent photosystem I (P700). The detailed redox processes occurring, and the enzyme-catalysed synthetic pathways (dark reactions) in-so-far as they have yet been elucidated, are described in biochemical texts and fall outside our present scope. The Mg ion apparently serves several purposes: (a) it keeps the macrocycles fairly rigid so that energy is not so readily dissipated by thermal vibrations; (b) it coordinates the H_2O molecules which mediate in the H bonding between adjacent molecules in the stack; and (c) it thereby enhances the rate at which the short-lived singlet excited state formed initially by absorption of a photon by the macrocycle is transformed to the corresponding longer-lived triplet state which is involved in the redox chain (since this involves the H bonded system between several individual chlorophyll units over a distance of some 1500–2000 pm). However, it is by no means clear why, of all metals, Mg is uniquely suited for this purpose.

5.3.5 Organometallic compounds [29–31]

Compounds containing M–C bonds are well established for Be and Mg but, as with the alkali metals, reactivity within the group increases with increasing electropositivity, and relatively few organometallic compounds of Ca, Sr or Ba have been isolated.

Beryllium [30]

Beryllium dialkyls (BeR_2, R = Me, Et, Pr^n, Pr^i, Bu^i etc.) can be made by reacting lithium alkyls or Grignard reagents with $BeCl_2$ in ethereal solution, but the products are difficult to free from ether and, when pure compounds rather than solutions are required, a better route is by heating Be metal with the appropriate mercury dialkyl:

$$BeCl_2 + 2LiMe \xrightarrow{Et_2O} BeMe_2.nEt_2O + 2LiCl$$

$$BeCl_2 + 2MeMgCl \xrightarrow{Et_2O} BeMe_2.nEt_2O + 2MgCl_2$$

$$Be + HgMe_2 \xrightarrow{110^\circ} BeMe_2 + Hg$$

$BePh_2$ (mp 245°) can be prepared similarly, using LiPh or $HgPh_2$; an excess of the former reagent yields $Li[BePh_3]$. Beryllium dialkyls are colourless solids or viscous liquids which are spontaneously flammable in air and explosively hydrolysed by water. $BeMe_2$ (like $MgMe_2$, p. 131) has been shown by X-ray analysis to have a chain structure analogous to that found in $BeCl_2$ (p. 116) though the bonding is probably best described in terms of 2-electron 3-centre bridge bonds involving $\cdot CH_3$ groups rather than that adopted by bridging Cl atoms which each form two 2-electron 2-centre bonds involving a total of 4 electrons per Be–Cl–Be bridge (Fig. 5.8). Each C atom has a coordination number of 5 (cf. bonding in boranes, carbaboranes, etc., p. 157). Higher alkyls are progressively less highly polymerized and the sterically crowded $BeBu^t_2$ is monomeric. As with polymeric $BeCl_2$, addition of strong ligands results in depolymerization and the eventual formation of monomeric adducts, e.g. $[BeMe_2(PMe_3)_2]$, $[BeMe_2(Me_2NCH_2CH_2NMe_2)]$, etc. Pyrolysis eliminates alkenes and leads to mixed hydrido species of variable composition (see also p. 115).

[31] W. E. LINDSELL, Chap. 4, Mg, Ca, Sr and Ba, in G. WILKINSON, F. G. A. STONE and E. W. ABEL (eds.) *Comprehensive Organometallic Chemistry*, Pergamon Press, Oxford, 1982, pp. 155–252.

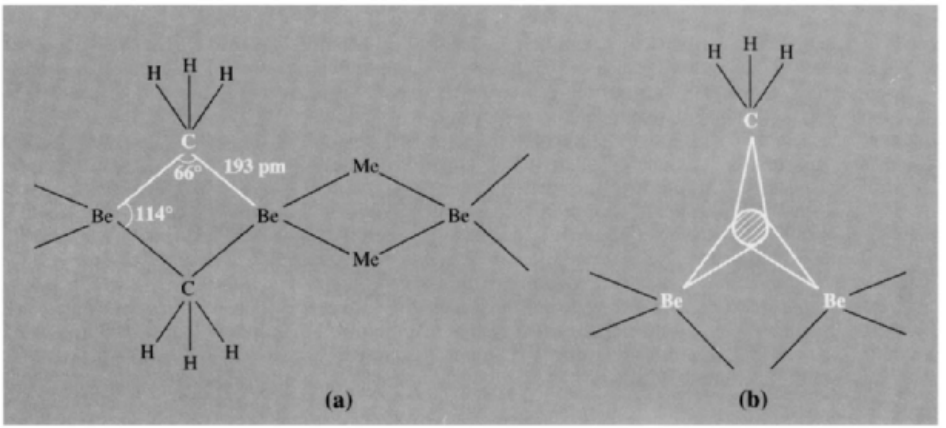

Figure 5.8 (a) Chain structure of $BeMe_2$ showing the acute angle at the bridging methyl group; the Be···Be distance is 209 pm and the distance between the 2 C atoms across the bridge is 315 pm. (b) Pictorial representation of the 3 approximately sp^3 orbitals used to form one 3-centre bridge bond; this description of the bonding is consistent with the acute bridging angle at C and the close approach of adjacent Be atoms noted in (a).

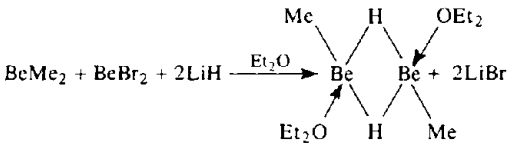
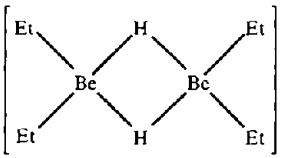
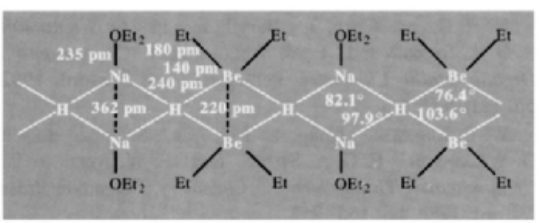
Alkylberyllium hydrides of more precise stoichiometry can be prepared by reducing $BeBr_2$ with LiH in the presence of BeR_2, e.g.:



The coordinated ether molecules can be replaced by tertiary amines. Use of NaH in the absence of halide produces the related compound $Na_2[Me_2BeH_2BeMe_2]$; the corresponding ethyl derivative crystallizes with 1 mole of Et_2O per Na but this can readily be removed under reduced pressure. The crystal structure of the etherate is shown in Fig. 5.9[32] and is important in illustrating once more (cf. p. 103) how misleading it can be to differentiate too sharply between different kinds of bonding in solids, for example: ionic $[Na(OEt_2)]_2^+[Et_2BeH_2BeEt_2]^{2-}$ or polymeric $[Et_2ONaHBeEt_2]_n$. Thus in the structure shown in Fig. 5.9 each Be is surrounded tetrahedrally by 2 Et and 2 bridging H to form a subunit



In addition, each H is coordinated tetrahedrally by 2 Be and 2 Na, and each Na is directly bonded to 1 Et_2O. Be–C is 180 pm and Be–H is 140 pm, close to expected values; Na–H is 240 pm, equal to that in NaH. The distance Na···Na is 362 pm which is less than in Na metal (372 pm) but greater than in NaH (345 pm), where each Na is surrounded by 6H; Be···Be is 220 pm as in Be metal. It is therefore misleading to consider the structure as being built up from the isolated ions $[Na(OEt_2)]^+$ and $[Et_2BeH_2BeEt_2]^{2-}$ and it is perhaps better to regard it as a chain polymer $[Et_2ONaHBeEt_2]_n$ which in plane projection can be written as:



[32] G. W. ADAMSON and H. M. M. SHEARER, *J. Chem. Soc., Chem. Commun.*, 240 (1965).

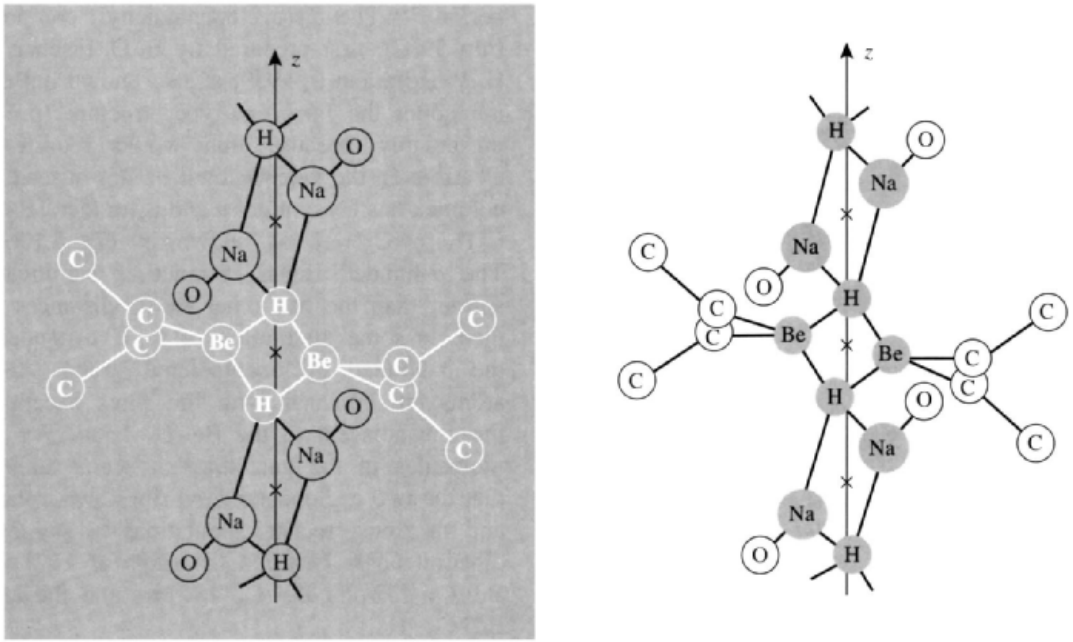


Figure 5.9 Crystal structure of the etherate of polymeric sodium hydridodiethylberyllate $(Et_2ONaHBeEt_2)_n$ emphasizing two features of the structure (see text).

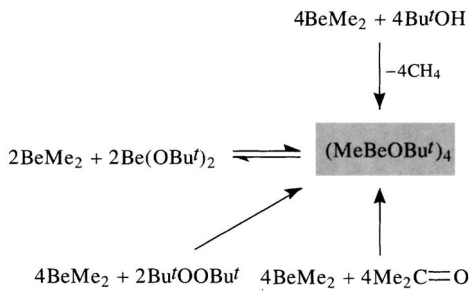
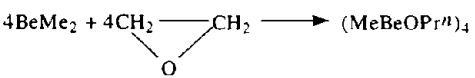
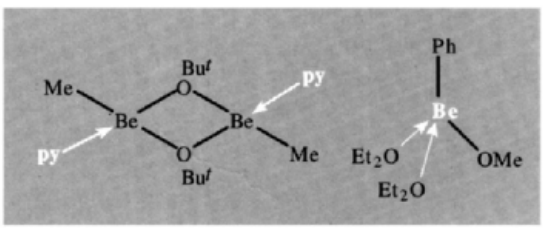
Alkylberyllium alkoxides (RBeOR′) can be prepared from BeR_2 by a variety of routes such as alcoholysis with R′OH, addition to carbonyls, cleavage of peroxides R′OOR′ or redistribution with the appropriate dialkoxide $Be(OR')_2$, e.g.:



Ring opening of ethylene oxide has also been used:

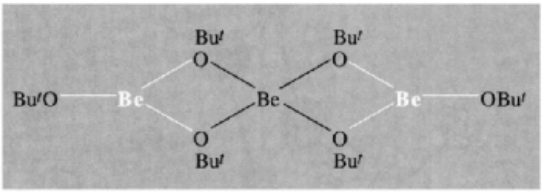


The compounds are frequently tetrameric and probably have the "cubane-like" structure established for the zinc analogue $(MeZnOMe)_4$. The methylberyllium alkoxides $(MeBeOR')_4$ are reactive, low-melting solids (mp for R′ = Me 25°, Et 30°, Pr^n 40°, Pr^i 136°, Bu^t 93°). Bulky substituents may reduce the degree of oligomerization, e.g. trimeric $(EtBeOCEt_3)_3$, and reaction with coordinating solvents or strong ligands can also lead to depolymerization, e.g. dimeric $(MeBeOBu^t.py)_2$ and monomeric $PhBeOMe.2Et_2O$:



Reaction of beryllium dialkyls with an excess of alcohol yields the alkoxides $Be(OR)_2$. The methoxide and ethoxide are insoluble and

probably polymeric, whereas the *t*-butoxide (mp 112°) is readily soluble as a trimer in benzene or hexane; the proposed structure:



involves both 3- and 4-coordinate Be and is consistent with the observation of 2 proton nmr signals at τ 8.60 and 8.75 with intensities in the ratio 2:1. (A precisely analogous structure has been established by X-ray diffraction analysis for the "isoelectronic" linear trimer $[Be(NMe_2)_2]_3$.)[33]

Beryllium forms a series of cyclopentadienyl complexes $[Be(\eta^5\text{-}C_5H_5Y]$ with Y = H, Cl, Br, Me, —C≡CH and BH_4, all of which show the expected C_{5v} symmetry (Fig. 5.10a). If the *pentahapto*-cyclopentadienyl group (p. 937) contributes 5 electrons to the bonding, then these are all 8-electron Be complexes consistent with the octet rule for elements of the first short period.[34] The bis(cyclopentadienyl) compound (mp 59°C), first prepared by E. O. Fischer and H. P. Hofmann in 1959, is also known but does not adopt the ferrocene-type structure (p. 937) presumably because this would require 12 electrons in the valence shell of Be. Instead, the complex has C_s symmetry and is, in fact, $[Be(\eta^1\text{-}C_5H_5)(\eta^5\text{-}C_5H_5)]$, as shown in Fig. 5.10b.[35] The σ-bonded Be–C distance is significantly shorter than the five other Be–C distances and there is some alternation of C–C distances in the σ-bonded cyclopentadienyl group. All H atoms are coplanar with the rings except for the one adjacent to the Be–C_σ bond. For free molecules in the gas phase it seems unlikely that the two cyclopentadienyl rings are coplanar, and the most recent calculations[36] suggest a dihedral angle between the rings of 117° with Be–C_σ 172 pm, Be–C_π 187 pm, and the angle Be–C_σ–H 108°.

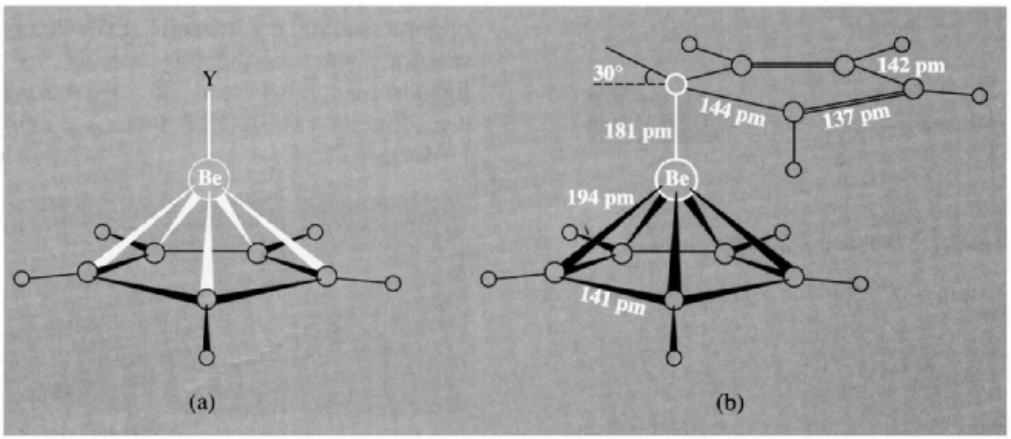

Figure 5.10 Cyclopentadienyl derivatives of beryllium showing (a) the C_{5v} structure of $[Be(\eta^5\text{-}C_5H_5)Y]$ and (b) the structure of crystalline $[Be(\eta^1\text{-}C_5H_5)(\eta^5\text{-}C_5H_5)]$ at −120° (see text).

Pentamethylcyclopentadienyl derivatives are also known, e.g. $[(\eta^5\text{-}C_5Me_5)BeCl]$; this reacts with $LiPBu^t_2$ in Et_2O at −78° to give colourless crystals of $[(\eta^5\text{-}C_5Me_5)BePBu^t_2]$ in high yield.[37] Here the dibutylphosphido group is acting as a 1-electron ligand to Be to form a covalent bond of length 208.3 pm almost perpendicular to the C_5 plane: angle P–Be–C_5(centroid) 168.3° Interestingly, the Be–C_5(centroid) distance (148 pm) is notably shorter than that found in $[(\eta^5\text{-}C_5H_5BeMe]$ (190.7 pm), implying stronger bonding in the pentamethyl derivative. Because the Be nucleus has a spin of 3/2, the $^{31}P\{^1H\}$ nmr signal consists of a 1:1:1:1 quartet with a coupling constant $^1J_{Be-P}$ of 50.0 Hz; this is an order of magnitude greater than for Lewis-base (2-electron) tertiary phosphine adducts of Be.

Magnesium[31]

Magnesium dialkyls and diaryls, though well established, have been relatively little studied by comparison with the vast amount of work which has been published on the Grignard reagents RMgX. The dialkyls (and diaryls) can be conveniently made by the reaction of LiR (LiAr) on Grignard reagents, or by the reaction of HgR_2 ($HgAr_2$) on Mg metal (sometimes in the presence of ether). On an industrial scale, alkenes can be reacted at 100° under pressure with MgH_2 or with Mg in the presence of H_2:

$$LiR + RMgX \xrightarrow{Et_2O} MgR_2 + LiX$$

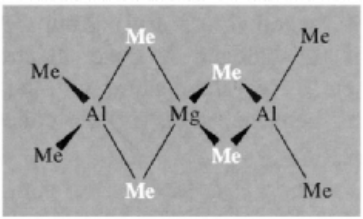
$$HgR_2 + Mg \xrightarrow{Et_2O} MgR_2 + Hg$$

$$2C_2H_4 + H_2 + Mg \xrightarrow[100°]{\text{pressure}} MgEt_2$$

A suitable laboratory method is to shift the Schlenk equilibrium in a Grignard solution (p. 132) by adding dioxan to precipitate the complex $MgX_2.diox$; this enables MgR_2 to be isolated by careful removal of solvent under reduced pressure:

$$2RMgX \rightleftharpoons MgR_2 + MgX_2 \xrightarrow{C_4H_8O_2} MgR_2 + MgX_2.C_4H_8O_2$$

$MgMe_2$ is a white involatile polymeric solid which is insoluble in hydrocarbons and only slightly soluble in ether. Its structure is very similar to that of $BeMe_2$ (p. 128) the corresponding dimensions for $MgMe_2$ being: Mg–C 224 pm, Mg–C–Mg 75°, C–Mg–C 105°, Mg···Mg 272 pm and C···C (across the bridge) 357 pm. Precisely analogous bridging Me groups are found in dimeric Al_2Me_6 (p. 259) and in the monomeric compound $Mg(AlMe_4)_2$ which can be formed by direct reaction of $MgMe_2$ and Al_2Me_6:



$MgEt_2$ and higher homologues are very similar to $MgMe_2$ except that they decompose at a lower temperature (175–200° instead of ~250°C) to give the corresponding alkene and MgH_2 in a reaction which reverses their preparation. $MgPh_2$ is similar: it is insoluble in benzene dissolves in ether to give the monomeric complex $MgPh_2.2Et_2O$ and pyrolyses at 280° to give Ph_2 and Mg metal. Like $BePh_2$ it reacts with an excess of LiPh to give the colourless complex $Li[MgPh_3]$.

The first organosilylmagnesium compound $[Mg(SiMe_3)_2].(\text{-}CH_2OMe)_2$, was isolated in 1977;[38] it was obtained as colourless, spontaneously flammable crystals by reaction of bis(trimethylsilyl)mercury with Mg powder in

[37] J. L. Atwood, S. G. Bott, R. A. Jones and S. U. Koschmieder, *J. Chem. Soc., Chem. Commun.*, 692–3 (1990).

[38] L. Rösch, *Angew. Chem. Int. Edn. Engl.* **16**, 247–8 (1977).

1,2-dimethoxyethane. More recently[39] the bulkier bis{tris(trimethylsilyl)methyl} derivative, [Mg{C(SiMe$_3$)$_3$}$_2$], was obtained as an unsolvated crystalline monomer; this was the first example of 2-coordinate (linear) Mg in the solid state, though this geometry had been established earlier by electron diffraction in the gas phase for bis(neopentyl)magnesium.[40]

Grignard reagents are the most important organometallic compounds of Mg and are probably the most extensively used of all organometallic reagents because of their easy preparation and synthetic versatility. Despite this, their constitution in solution has been a source of considerable uncertainty until recent times.[41] It now seems well established that solutions of Grignard reagents can contain a variety of chemical species interlinked by mobile equilibria whose position depends critically on at least five factors: (i) the steric and electronic nature of the alkyl (or aryl) group R, (ii) the nature of the halogen X (size, electron-donor power, etc.), (iii) the nature of the solvent (Et$_2$O, thf, benzene, etc.), (iv) the concentration and (v) the temperature. The species present may also depend on the presence of trace impurities such as H_2O or O_2. Neglecting solvation in the first instance, the general scheme of equilibria can be set out as shown below. Thus "monomeric" (solvated) RMgX can disproportionate to MgR_2 and MgX_2 by the Schlenk equilibrium or can dimerize to $RMgX_2MgR$. Both the monomer and the dimer can ionize, and reassociation can give the alternative dimer R_2MgX_2Mg. Note that only halogen atoms X are involved in the bridging of these species.

Evidence for these species and the associated equilibria comes from a variety of techniques such as vibration spectroscopy, nmr spectroscopy, molecular-weight determinations, radioisotopic exchange using ^{28}Mg, electrical conductivity, etc. In some cases equilibria can be displaced by crystallization or by the addition of complexing agents such as dioxan (p. 131) or NEt$_3$. The crystal structures of several pertinent adducts have recently been determined (Fig. 5.11). None call for special comment except the curious solvated dimer [EtMg$_2$Cl$_3$(OC$_4$H$_8$)$_3$]$_2$ which features both 5-coordinate trigonal bipyramidal and 6-coordinate octahedral Mg groups; note also that, whilst 4 of the Cl atoms each bridge 2 Mg atoms, the remaining 2 Cl atoms are triply bridging.

Schematic representation of the principal equilbria in Grignard solutions; solvation of the various species has been omitted for clarity.

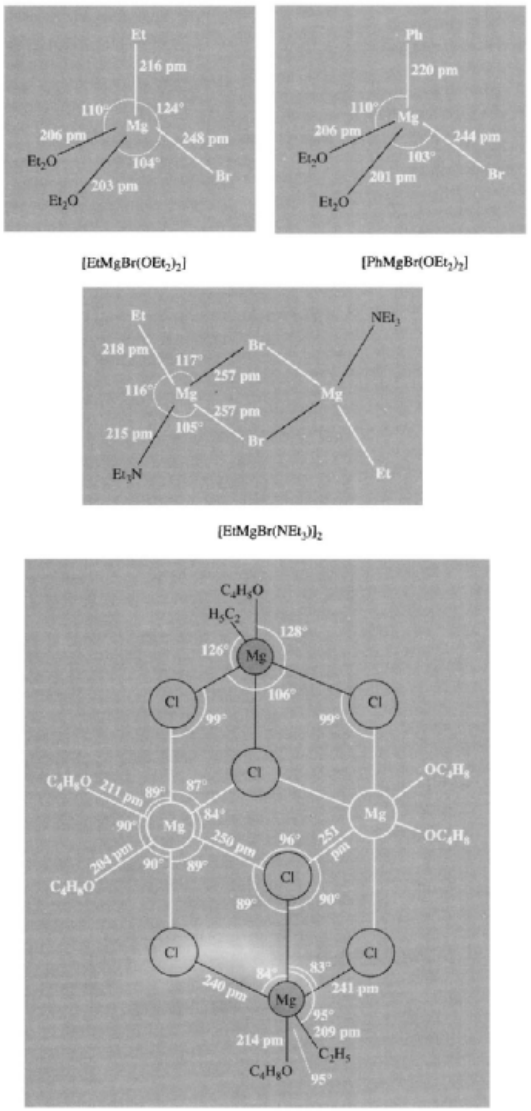

Figure 5.11 Crystal structures of adducts of Grignard reagents.

Grignard reagents are normally prepared by the slow addition of the organic halide to a stirred suspension of magnesium turnings in the appropriate solvent and with rigorous exclusion of air and moisture. The reaction, which usually begins slowly after an induction period, can be initiated by addition of a small crystal of iodine; this penetrates the protective layer of oxide (hydroxide) on the surface of the metal. The order of reactivity of RX is I > Br > Cl and alkyl > aryl. The mechanism has been much studied but is not fully understood.[42] The fluorides RMgF (R = Me, Et, Bu, Ph) can be prepared by reacting MgR_2 with mild fluorinating agents such as $BF_3.OEt_2$, Bu_3SnF or SiF_4.[43] The scope of Grignard reagents in syntheses has been greatly extended by a recently developed method for preparing very reactive Mg (by reduction of MgX_2 with K in the presence of KI).[44] Grignard reagents have a wide range of application in the synthesis of alcohols, aldehydes, ketones, carboxylic acids, esters and amides, and are probably the most versatile reagents for constructing C–C bonds by carbanion (or occasionally[45] free-radical) mechanisms. Standard Grignard methods are also available for constructing C–N, C–O, C–S (Se, Te) and C–X bonds (see Panel on pp. 134–5).

A related class of compounds are the alkylmagnesium alkoxides: these can be prepared by reaction of MgR_2 with an alcohol or ketone or by reaction of Mg metal with the appropriate alcohol and alkyl chloride in methylcyclohexane solvent, e.g.:

$$4MgEt_2 + 4Bu^tOH \longrightarrow (EtMgOBu^t)_4 + 4C_2H_6$$

$$2MgMe_2 + 2Ph_2CO \xrightarrow{Et_2O} (MeMgOCMePh_2.Et_2O)_2$$

$$6Mg + 6Bu^nCl + 3Pr^iOH \longrightarrow (Bu^nMgOPr^i)_3 + 3MgCl_2 + 3C_4H_{10}$$

Synthetic Uses of Grignard Reagents

Victor Grignard (1871–1935) showed in 1900 that Mg reacts with alkyl halides in dry ether at room temperature to give ether-soluble organomagnesium compounds; the use of these reagents to synthesize acids, alcohols, and hydrocarbons formed the substance of his doctorate thesis at the University of Lyon in 1901, and further studies on the synthetic utility of Grignard reagents won him the Nobel Prize for Chemistry in 1912. The range of applications is now enormous and some indication of the extraordinary versatility of organomagnesium compounds can be gauged from the following brief summary.

Standard procedures convert RMgX into ROH, RCH_2OH, RCH_2CH_2OH and an almost unlimited range of secondary and tertiary alcohols:

$$RMgX + O_2 \longrightarrow ROOMgX \xrightarrow{RMgX} 2ROMgX \xrightarrow{acid} 2ROH$$

$$RMgX + HCHO \longrightarrow RCH_2OMgX \xrightarrow{acid} RCH_2OH$$

$$RMgX + \underset{\diagdown\,O\,\diagup}{CH_2{-}CH_2} \longrightarrow RCH_2CH_2OMgX \xrightarrow{acid} RCH_2CH_2OH$$

$$RMgX + R'CHO \longrightarrow RR'CHOMgX \xrightarrow{acid} RR'CHOH$$

$$RMgX + R'COR'' \longrightarrow RR'R''COMgX \xrightarrow{acid} RR'R''COH$$

Aldehydes and carboxylic acids having 1 C atom more than R, as well as ketones, amides and esters can be prepared similarly, the reaction always proceeding in the direction predicted for potential carbanion attack on the unsaturated C atom:

$$RMgX + HC(OEt)_3 \xrightarrow{acid} RCH(OEt)_2 \xrightarrow{acid} RCHO$$

$$RMgX + CO_2 \longrightarrow RCO_2MgX \xrightarrow{acid} RCO_2H$$

$$RMgX + R'CN \longrightarrow [RR'C{=}NMgX] \xrightarrow{acid} RR'C{=}O$$

$$RMgX + R'NCO \longrightarrow [RCNR'(OMgX)] \xrightarrow{acid} RC(O)NHR'$$

$$RMgX + EtOCOCl \longrightarrow [RC(OEt)Cl(OMgX)] \xrightarrow{acid} RCO_2Et$$

Grignard reagents are rapidly hydrolysed by water or acid to give the parent hydrocarbon, RH, but this reaction is rarely of synthetic importance. Hydrocarbons can also be synthesized by nucleophilic displacement of halide ion from a reactive alkyl halide, e.g.

$$MeMgCl + \rangle C{=}CHCH_2Cl \longrightarrow \rangle C{=}CHCH_2Me + MgCl_2$$

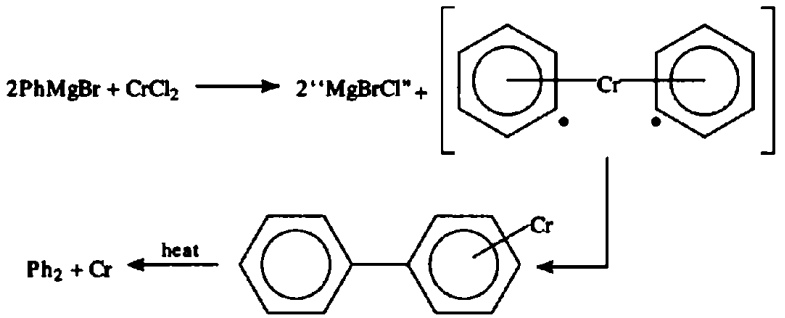
However, other products may be formed simultaneously by a free-radical process, especially in the presence of catalytic amounts of $CoCl_2$ or CuCl:

$$2\,\rangle C{=}CHCH_2Cl \xrightarrow[CoCl_2]{MeMgCl} \rangle C{=}CHCH_2CH{=}C\langle$$

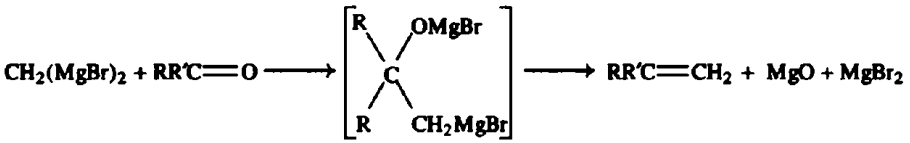
$$2\,\rangle C{=}C\langle \xrightarrow{CuCl/thf} \rangle C{=}C\langle \quad (C{=}C\langle)$$

Panel continues

Similarly, aromatic Grignard reagents undergo free-radical self-coupling reactions when treated with MCl_2 (M=Cr, Mn, Fe, Co, Ni), e.g.:



Alkenes can be synthesized from aldehydes or ketones using the Grignard reagent derived from CH_2Br_2:



The formation of C–N bonds can be achieved by using chloramine or *O*-methylhydroxylamine to yield primary amines; aryl diazonium salts yield azo-compounds:

$$RMgX + ClNH_2 \longrightarrow RNH_2 + \text{"MgClX"}$$
$$RMgX + MeONH_2 \longrightarrow RNH_2 + MeOMgX$$
$$RMgX + [ArN_2]X \longrightarrow RN{=}NAr + MgX_2$$

Carbon-oxygen bonds can be made using the synthetically uninteresting conversion of RMgX into ROH (shown as the first reaction listed above); direct acid hydrolysis of the peroxo compound ROOMgX yields the hydroperoxide ROOH. Carbon-sulfur bonds can be constructed using S_8 to make thiols or thioethers, and similar reactions are known for Se and Te:

$$RMgX + S_8 \longrightarrow RS_xMgX \xrightarrow{RMgX} RSMgX$$

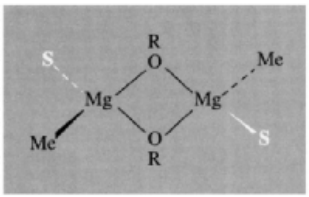
$$RSMgX \xrightarrow{\text{acid}} RSH + MgX_2$$
$$RSMgX \xrightarrow{RMgX} R_2S + MgX_2 + Mg$$
$$RSMgX \xrightarrow{R'I} RSR' + \text{"MgIX"}$$

Formation of C–X bonds is not normally a problem but the Grignard route can occasionally be useful when normal halogen exchange fails. Thus iodination of Me_3CCH_2Cl cannot be achieved by reaction with NaI or similar reagents but direct iodination of the corresponding Grignard effects a smooth conversion:

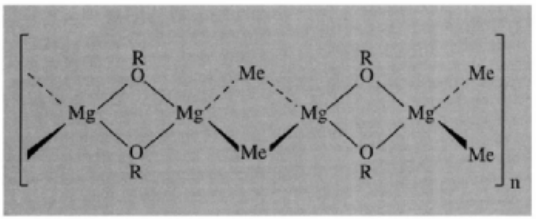
$$Me_3CCH_2MgCl + I_2 \longrightarrow Me_3CCH_2I + \text{"MgClI"}$$

Further examples of the ingenious use of Grignard reagents will be found in many books on synthetic organic chemistry and much recent work in this area was reviewed in a special edition of *Bull. Soc. Chim. France*, 1972, 2127–86, which commemorated the centenary of Victor Grignard's birth.

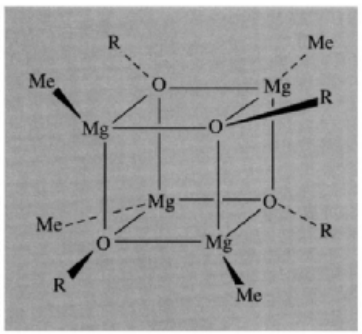
As with the Grignard reagents, the structure and degree of association of the product depend on the bulk of the organic groups, the coordinating ability of the solvent, etc. This is well illustrated by MeMgOR (R = Pr^n, Pr^i, Bu^t, $CMePh_2$) in thf, Et_2O and benzene:[46] the strongly coordinating solvent thf favours solvated dimers (A) but prevents the formation both of oligomers (B) involving the relatively weak Me bridges and of cubane structures (C) involving the relatively weak triply bonding oxygen bridges.



A, solvated dimer



B, linear oligomer (various isomers are possible e.g. involving OR Mg Mg bridges, etc.)



C, cubane tetramer (unsolvated)

By contrast, in the more weakly coordinating solvent Et_2O, Me bridges and μ_3-OR bridges can form, leading to linear oligomers and cubanes, provided OR is not too bulky. Thus when R = $CMePh_2$, oligomerization and cubane formation are blocked and $MeMgOCMePh_2$ exists only as a solvated dimer even in Et_2O. In benzene, R = Bu^t and Pr^i form cubane tetramers but Pr^n can form an oligomer of 7–9 monomer units. The sensitive dependence of the structure of a compound on solvation energy, lattice energy and the relative coordinating abilities of its component atoms and groups will be a recurring theme in many subsequent chapters.

Dicyclopentadienylmagnesium [$Mg(\eta^5\text{-}C_5H_5)_2$], mp 176°, can be made in good yield by direct reaction of Mg and cyclopentadiene at 500–600°; it is very reactive towards air, moisture, CO_2 and CS_2, and reacts with transition-metal halides to give transition-element cyclopentadienyls. It has the staggered (D_{5d}) "sandwich" structure (cf. ferrocene p. 1109) with Mg–C 230 pm and C–C 139 pm;[47] the bonding is thought to be intermediate between ionic and covalent but the actual extent of the charge separation between the central atom and the rings is still being discussed.

Calcium, strontium and barium[31,48]

Organometallic compounds of Ca, Sr and Ba are far more reactive than those of Mg and have been much less studied until recently. For example, although about 50 000 papers have been published on organomagnesium compounds and reagents, less than 1% of this number have appeared for the heavier triad of elements. Many of the differences in reactivity can be traced to the larger radii of the cations (Ca^{2+} 100, Sr^{2+} 118, Ba^{2+} 135 pm) when compared to Mg^{2+} (72 pm) — i.e the lower (charge/size) ratio enhances still further the ionic character of the bonding and thus increases the kinetic lability of the ligands. Coordinative unsaturation also plays a rôle and, indeed, the organometallic behaviour of the heavier alkali metals often resembles

[46] E. C. Ashby, J. Nackashi and G. E. Parris, *J. Am. Chem. Soc.* **97**, 3162–71 (1975).

[47] W. Bünder and E. Weiss, [$Mg(\eta^5\text{-}C_5H_5)_2$], *J. Organometall. Chem.* **92**, 1–6 (1975).

[48] T. P. Hanusa, *Polyhedron* **9**, 1345–62 (1990)

that of the similarly-sized divalent lanthanide elements (Yb^{2+} 102, Eu^{2+} 117, Sm^{2+} 122 pm) rather than that of Mg. In these circumstances it became clear that stability would be enhanced by the use of bulky ligands. Early work showed that the reactive compounds MR_2 (M = Ca, Sr, Ba; R = Me, Et, allyl, Ph, $PhCH_2$, etc.) can be prepared using HgR_2 under appropriate conditions, often at low temperature. Compounds of the type RCaI (R = Bu, Ph, tolyl) have also been known for some time and can now be isolated as crystals.

Calcium (and Sr) dicyclopentadienyl can be made by direct reaction of the metal with either $[Hg(C_5H_5)_2]$ or with cyclo-C_5H_6 itself; cyclopentadiene also reacts with CaC_2 in liquid NH_3 to form $[Ca(C_5H_5)_2]$ and HC≡CH. The barium analogue $[Ba(C_5H_5)_2]$ is best made (though still in small yield) by treating cyclo-C_5H_6 with BaH_2. The structure of $[Ca(C_5H_5)_2]$ is unique.[49] Each Ca is surrounded by 4 planar cyclopentadienyl rings and the overall structure involves a complex sharing of rings which bridge the various Ca atoms. The coordination geometry about a given Ca atom is shown in Fig. 5.12:

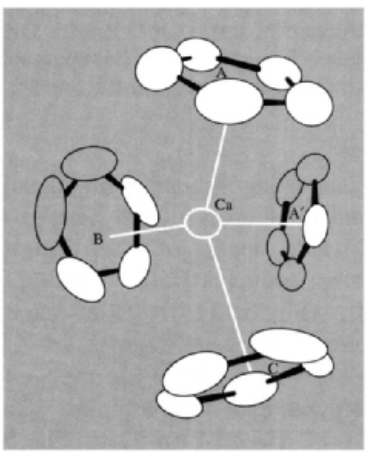


Figure 5.12 Coordination geometry about Ca in polymeric $[Ca(C_5H_5)_2]$ showing $2\times\eta^5$-, η^3- and η^1- bonding (see text).

two of the rings (A, C) are η^5, with all Ca–C distances 275 pm. A third ring (B) is η^3 with one Ca–C distance 270, two at 279, and two longer distances at 295 pm. These three polyhapto rings (A, B, C) are arranged so that their centroids are disposed approximately trigonally about the Ca atom. The fourth ring (A′) is η^1, with only 1 Ca–C within bonding distance (310 pm) and this bond is approximately perpendicular to the plane formed by the centroids of the other 3 rings. The structure is the first example in which η^5-, η^3- and η^1-C_5H_5 groups are all present. Indeed, the structure is even more complex than this implies because of the ring-bridging between adjacent Ca atoms; for example ring A (and A′) is simultaneously bonded η^5 to 1 Ca (248 pm from the ring centre) and η^1 to another on the opposite side of the ring, whereas ring C is equally associated in *pentahapto* mode with 2 Ca atoms each 260 pm from the plane of the ring.

Replacement of the ligand C_5H_5 by the bulkier C_5Me_5 results in improved solubility, volatility and kinetic stability of the compound, and all three complexes $[M(\eta^5\text{-}C_5Me_5)_2]$ have been prepared in >65% yield by the reaction of NaC_5Me_5 (or KC_5Me_5) with the appropriate diiodide, MI_2, in diethyl ether or thf, followed by removal of the coordinated ether (or thf) by refluxing the product in toluene. $[Ca(C_5Me_5)_2(thf)_2]$ has also been prepared in 48% yield by the reaction of C_5HMe_5 and $Ca(NH_2)_2$ in liquid ammonia. The greater tractability of these complexes enabled the first (gas-phase) molecular structures of organo-Sr and organo-Ba compounds to be determined,[50] and also the first organo-Ba crystal structure.[51] Group comparisons show that the angle subtended by the two C_5Me_5 ring centroids at the metal atom in the gas phase is almost the same (to within 1 esd) for the three metals (154 ± 4°) but that this drops to 131.0° for crystalline $[Ba(C_5Me_5)_2]$. A theoretical rationalization for these angles, especially in the gas phase, is not obvious.[48]

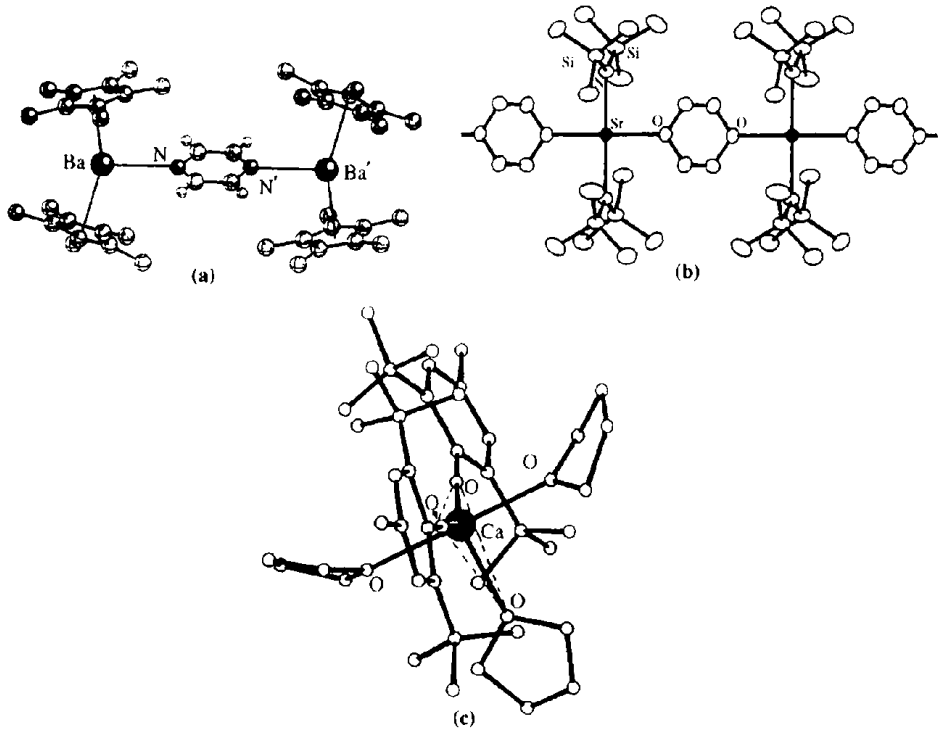

Figure 5.13 (a) Structure of $[\{Ba(\eta^5\text{-}C_5Me_5)_2\}_2(\mu\text{-}1,4\text{-}C_4H_4N_2)]$ in which the pyrazine ligand bridges two bent $\{BaCp^*_2\}$ units to give a centrosymmetric adduct with an essentially linear disposition of the four atoms BaNNBa. (b) The polymeric dioxane-bridged structure of $[\{trans\text{-}Sr(NR_2)_2(\mu\text{-}1,4C_4H_8O_2)]$ ($R = SiMe_3$) showing the 4-coordinate square-planar stereochemistry of the Sr atoms. (c) The 5-coordinate trigonal-bipyramidal structure of $[Ca(OAr)_2(thf)_3]$ ($Ar = C_6H_2\text{-}2,6\text{-}Bu^t_2\text{-}4\text{-}Me$) showing one equatorial and two axial thf ligands.

Attempts to prepare the mono(cyclopentadienyl) derivatives are sometimes frustrated by a Schlenk-type equilibrium (see p. 132), but judicious choice of ligands, solvent etc. occasionally permits the isolation of such compounds, e.g. the centrosymmetric halogen-bridged dimer $[\{(\eta^5\text{-}C_5Me_5)Ca(\mu\text{-}1)(thf)_2\}_2]$ which crystallizes from toluene solution. The complex is isostructural with the dimeric organosamarium(II) analogue.[52]

Other interesting structures of organometallic and related complexes of the heavier Group 2 metals include those of the centrosymmetric pyrazine adduct $[\{Ba(\eta^5\text{-}C_5Me_5)_2\}_2(\mu\text{-}1,4\text{-}C_4H_4N_2)\}]$, (Fig. 5.13a)[48], the square-planar Sr complex $[\{trans\text{-}Sr(NR_2)_2(\mu\text{-}1,4\text{-}C_4H_8O_2)\}]$ ($R = SiMe_3$), Fig. 5.13b[53] and the 5-coordinate trigonal-bipyramidal Ca complex $[Ca(OAr)_2(thf)_3]$ ($Ar = C_6H_2\text{-}2,6\text{-}Bu^t_2\text{-}4\text{-}Me$), Fig. 5.13c.[54]

6 Boron

6.1 Introduction

Boron is a unique and exciting element. Over the years it has proved a constant challenge and stimulus not only to preparative chemists and theoreticians, but also to industrial chemists and technologists. It is the only non-metal in Group 13 of the periodic table and shows many similarities to its neighbour, carbon, and its diagonal relative, silicon. Thus, like C and Si, it shows a marked propensity to form covalent, molecular compounds, but it differs sharply from them in having one less valence electron than the number of valence orbitals, a situation sometimes referred to as "electron deficiency". This has a dominant effect on its chemistry.

Borax was known in the ancient world where it was used to prepare glazes and hard (borosilicate) glasses. Sporadic investigations during the eighteenth century led ultimately to the isolation of very impure boron by H. Davy and by J. L. Gay Lussac and L. J. Thénard in 1808, but it was not until 1892 that H. Moissan obtained samples of 95–98% purity by reducing B_2O_3 with Mg. High-purity boron (>99%) is a product of this century, and the various crystalline forms have been obtained only during the last few decades mainly because of the highly refractory nature of the element and its rapid reaction at high temperatures with nitrogen, oxygen and most metals. The name *boron* was proposed by Davy to indicate the source of the element and its similarity to carbon, i.e. *bor*(ax + carb)*on*.

Boron is comparatively unabundant in the universe (p. 14); it occurs to the extent of about 9 ppm in crustal rocks and is therefore rather less abundant than lithium (18 ppm) or lead (13 ppm) but is similar to praseodymium (9.1 ppm) and thorium (8.1 ppm). It occurs almost invariably as borate minerals or as borosilicates. Commercially valuable deposits are rare, but where they do occur, as in California or Turkey, they can be vast (see Panel). Isolated deposits are also worked in the former Soviet Union, Tibet and Argentina.

The structural complexity of borate minerals (p. 205) is surpassed only by that of silicate minerals (p. 347). Even more complex are the structures of the metal borides and the various allotropic modifications of boron itself. These factors, together with the unique structural and bonding problems of the boron hydrides, dictate that boron should be treated in a separate chapter.

Borate Minerals

The world's major deposits of borate minerals occur in areas of former volcanic activity and appear to be associated with the waters from former hot springs. The primary mineral that first crystallized was normally ulexite, $NaCa[B_5O_6(OH)_6].5H_2O$, but this was frequently mixed with lesser amounts of borax, $Na_2[B_4O_5(OH)_4].8H_2O$ (p. 206). Exposure and subsequent weathering (e.g. in the Mojave Desert, California) resulted in leaching by surface waters, leaving a residue of the less-soluble mineral colemanite,$Ca[B_3O_4(OH)_3].H_2O$ (p. 206). The leached (secondary) borax sometimes reaccumulated and sometimes underwent other changes to form other secondary minerals such as the commercially important kernite, $Na_2[B_4O_5(OH)_4].2H_2O$, at Boron, California: This is the world's largest single source of borates and comprises a deposit 6.5 km long, 1.5 km wide and 25–50 m thick containing material that averages 75% of hydrated sodium tetraborates (borax and kernite). World reserves (expressed as B_2O_3 content) exceed 315 million tonnes (Turkey 45%, USA 21%, Kazakhstan 17%, China 8.6%, Argentina 7.3%). Annual world production of borates was 2.67 million tonnes in 1990. Production in Turkey has expanded dramatically in the last two decades and now exceeds that of the USA, the 1990 production figures being 1.20 and 1.09 Mt respectively. Smaller producers (10^3 t) are: "Russia" 175, Chile 132, China 27. Argentina 26 and Peru 18. The 1991 bulk price per tonne of borax in USA was $264 for technical grade and $2222 for refined granules.

The main chemical products produced from these minerals are (a) boron oxides, boric acid and borates, (b) esters of boric acid, (c) refractory boron compounds (borides, etc.), (d) boron halides, (e) boranes and carbaboranes and (f) organoboranes. The main industrial and domestic uses of boron compounds in Europe (USA in parentheses) are:

Heat resistant glasses (e.g. Pyrex), glass wool, fibre glass	26%	(60%)
Detergents, soaps, cleaners and cosmetics	37%	(7%)
Porcelain enamels	16%	(3%)
Synthetic herbicides and fertilizers	2%	(4%)
Miscellaneous (nuclear shielding, metallurgy, corrosion control, leather tanning, flame-proofing, catalysts)	19%	(26%)

The uses in the glass and ceramics industries reflect the diagonal relation between boron and silicon and the similarity of vitreous borate and silicate networks (pp. 203, 206 and 347). In the UK and continental Europe (but not in the USA or Japan) sodium perborate (p. 206) is a major constituent of washing powders since it hydrolyses to H_2O_2 and acts as a bleaching agent in very hot water (~90°C); in the USA domestic washing machines rarely operate above 70°, at which temperature perborates are ineffective as bleaches.

Details of other uses of boron compounds are noted at appropriate places in the text.

The general group trends, and a comparison with the chemistry of the metallic elements of Group 13 (Al, Ga, In and Tl), will be deferred until the next chapter.

6.2 Boron[1]

6.2.1 Isolation and purification of the element

There are four main methods of isolating boron from its compounds:

(i) Reduction by metals at high temperature, e.g. the strongly exothermic reaction

$$B_2O_3 + 3Mg \longrightarrow 2B + 3MgO$$

(Moissan boron, 95–98% pure)

Other electropositive elements have been used (e.g. Li, Na, K, Be, Ca, Al, Fe), but the product is generally amorphous and contaminated with refractory impurities such as metal borides. Massive crystalline boron (96%) has been prepared by reacting BCl_3 with zinc in a flow system at 900°C.

(ii) Electrolytic reduction of fused borates or tetrafluoroborates, e.g. KBF_4 in molten KCl/KF at 800°. The process is comparatively cheap but yields only powdered boron of 95% purity.

(iii) Reduction of volatile boron compounds by H_2, e.g. the reaction of $BBr_3 + H_2$ on a heated

[1] N. N. GREENWOOD, *Boron*, Pergamon Press, Oxford, 1975, 327 pp.; also as Chap. 11 in *Comprehensive Inorganic Chemistry*, Vol. 1, Pergamon Press, Oxford, 1973.

tantalum metal filament. This method, which was introduced in 1922 and can now be operated on the kilogram scale, is undoubtedly the most effective general preparation for high purity boron (>99.9%). Crystallinity improves with increasing temperature, amorphous products being obtained below 1000°C, α- and β-rhombohedral modifications between 1000–1200° and tetragonal crystals above this. BCl_3 can be substituted for BBr_3 but BI_3 is unsatisfactory because it is expensive and too difficult to purify sufficiently. Free energy calculations indicate that BF_3 would require impracticably high temperatures (>2000°).

(iv) Thermal decomposition of boron hydrides and halides. Boranes decompose to amorphous boron when heated at temperatures up to 900° and crystalline products can be obtained by thermal decomposition of BI_3. Indeed, the first recognized sample of α-rhombohedral B was prepared (in 1960) by decomposition of BI_3 on Ta at 800–1000°, and this is still an excellent exclusive preparation of this allotrope.

6.2.2 Structure of crystalline boron [1-3]

Boron is unique among the elements in the structural complexity of its allotropic modifications; this reflects the variety of ways in which boron seeks to solve the problem of having fewer electrons than atomic orbitals available for bonding. Elements in this situation usually adopt metallic bonding, but the small size and high ionization energies of B (p. 222) result in covalent rather than metallic bonding. The structural unit which dominates the various allotropes of B is the B_{12} icosahedron (Fig. 6.1), and this also occurs in several metal boride structures and in certain boron hydride derivatives. Because of the fivefold rotation symmetry at the individual B atoms, the B_{12} icosahedra pack rather inefficiently and there

[2] V. I. MATKOVICH (ed.), *Boron and Refractory Borides*, Springer-Verlag, Berlin, 1977, 656 pp.

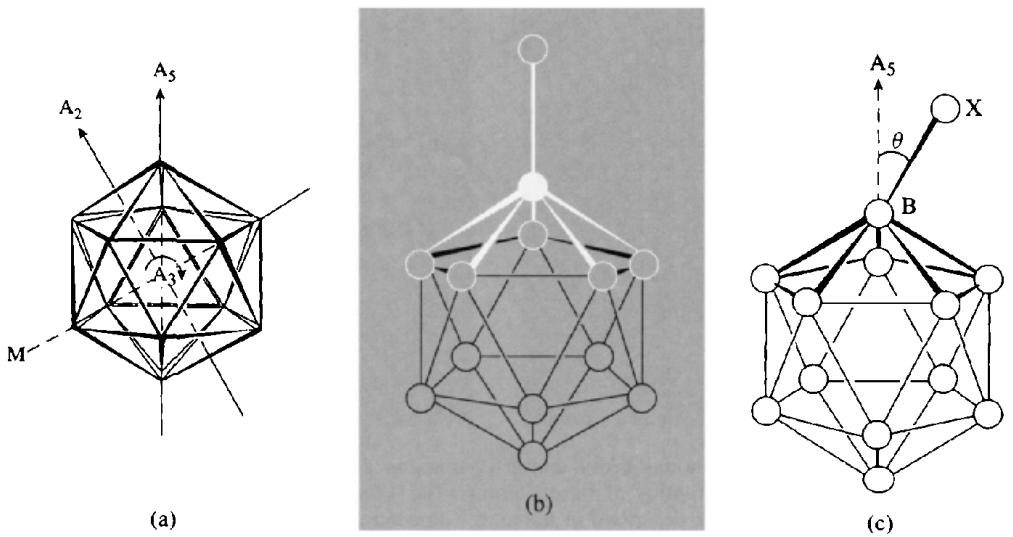

Figure 6.1 The icosahedron and some of its symmetry elements. (a) An icosahedron has 12 vertices and 20 triangular faces defined by 30 edges. (b) The preferred pentagonal pyramidal coordination polyhedron for 6-coordinate boron in icosahedral structures; as it is not possible to generate an infinite three-dimensional lattice on the basis of fivefold symmetry, various distortions, translations and voids occur in the actual crystal structures. (c) The distortion angle θ, which varies from 0° to 25°, for various boron atoms in crystalline boron and metal borides.

are regularly spaced voids which are large enough to accommodate additional boron (or metal) atoms. Even in the densest form of boron, the α-rhombohedral modification, the percentage of space occupied by atoms is only 37% (compared with 74% for closest packing of spheres).

The α-rhombohedral form of boron is the simplest allotropic modification and consists of nearly regular B_{12} icosahedra in slightly deformed cubic close packing. The rhombohedral unit cell (Fig. 6.2) has a_0 505.7 pm, α 58.06° (60° for regular ccp) and contains 12 B atoms. *It is important to remember that in Fig. 6.2, as in most other structural diagrams in this chapter, the lines merely define the geometry of the clusters of boron atoms; they do not usually represent 2-centre 2-electron bonds between pairs of atoms.* In terms of the MO theory to be discussed on p. 157, the 36 valence electrons of each B_{12} unit are distributed as follows: 26 electrons just fill the 13 available bonding MOs within the icosahedron and 6 electrons share with 6 other electrons from 6 neighbouring icosahedra in adjacent planes to

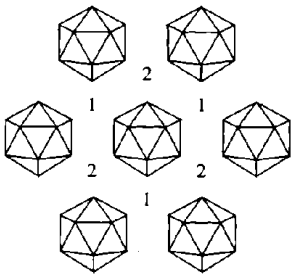

Figure 6.2 Basal plane of α-rhombohedral boron showing close-packed arrangement of B_{12} icosahedra. The B–B distances within each icosahedron vary regularly between 173–179 pm. Dotted lines show the 3-centre bonds between the 6 equatorial boron atoms in each icosahedron to 6 other icosahedra in the same sheet at 202.5 pm. The sheets are stacked so that each icosahedron is bonded by six 2-centre B–B bonds at 171 pm (directed rhombohedrally, 3 above and 3 below the icosahedron). B_{12} units in the layer above are centred over 1 and those in the layer below are centred under 2.

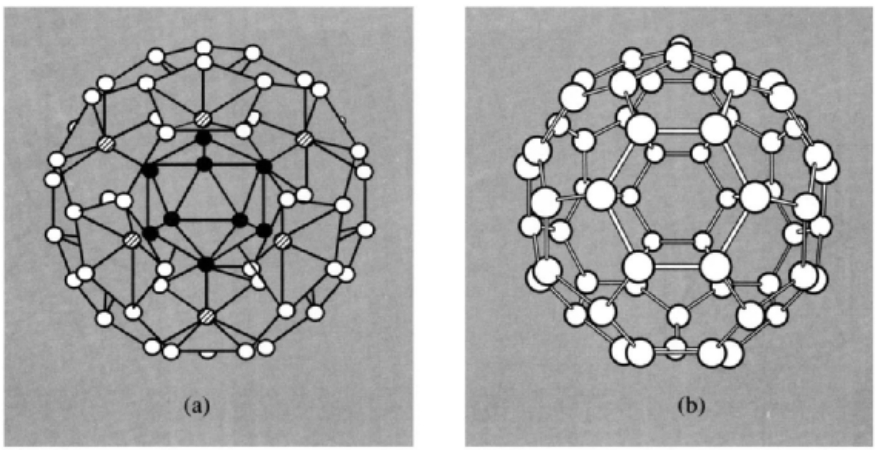

Figure 6.3 (a) The B_{84} unit in β-rhombohedral boron comprising a central B_{12} icosahedron and 12 outwardly directed pentagonal pyramids of boron atoms. The 12 outer icosahedra are completed by linking with the B_{10} subunits as described in the text. The central icosahedron (●) is almost exactly regular with B–B 176.7 pm. The shortest B–B distances (162–172 pm) are between the central icosahedron and the apices of the 12 surrounding pentagonal pyramids (⊘). The B–B distances within the $12B_6$ pentagonal pyramids (half-icosahedra) are somewhat longer (185 pm) and the longest B–B distances (188–192 pm) occur within the hexagonal rings surrounding the 3-fold symmetry axes of the B_{84} polyhedron. Note that if the 24 "internal" B atoms (● and ⊘) are removed from the B_{84} unit then a B_{60} unit (b) remains which has precisely the fullerene structure subsequently found some 25 years later for C_{60} (p. 279).

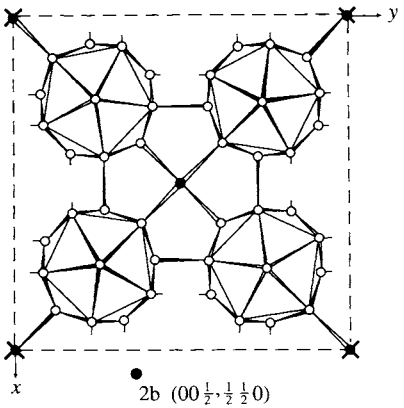

Figure 6.4 Crystal structure of α-tetragonal boron. This was originally thought to be B_{50} ($4B_{12} + 2B$) but is now known to be either $B_{50}C_2$ or $B_{50}N_2$ in which the 2C (or 2N) occupy the 2(b) positions; the remaining 2B are distributed statistically at other "vacant" sites in the lattice. Note that this reformulation solves three problems which attended the description of the α-tetragonal phase as a crystalline modification of pure B:

1. The lattice parameters showed considerable variation from one crystal to another with average values *a* 875 pm, *c* 506 pm; this is now thought to arise from variable composition depending on the precise preparative conditions used.
2. The interatomic distances involving the single 4-coordinate atoms at 2(b) were only 160 pm; this is unusually short for B–B but reasonable for B–C or B–N distances.
3. The structure requires 160 valence electrons per unit cell computed as follows: internal bonding within the 4 icosahedra ($4 \times 26 = 104$); external bonds for the 4 icosahedra ($4 \times 12 = 48$); bonds shared by the atoms in 2(b) positions ($2 \times 4 = 8$). However, 50 B atoms have only 150 valence electrons and even with the maximum possible excess of boron in the unit cell (0.75 B) this rises to only 152 electrons. The required extra 8 or 10 electrons are now supplied by 2C or 2N though the detailed description of the bonding is more intricate than this simple numerology implies.

form the 6 rhombohedrally directed normal 2-centre 2-electron bonds; this leaves 4 electrons which is just the number required for contribution to the 6 equatorial 3-centre 2-electron bonds ($6 \times \frac{2}{3} = 4$).

The thermodynamically most stable polymorph of boron is the β-rhombohedral modification which has a much more complex structure with 105 B atoms in the unit cell (a_0 1014.5 pm, α 65.28°). The basic unit can be thought of as a central B_{12} icosahedron surrounded by an icosahedron of icosahedra; this can be visualized as 12 of the B_7 units in Fig. 6.1b arranged so that the apex atoms form the central B_{12} surrounded by 12 radially disposed pentagonal dishes to give the B_{84} unit shown in Fig. 6.3a. The 12 half-icosahedra are then completed by means of 2 complicated B_{10} subunits per unit cell, each comprising a central 9-coordinate B atom surrounded by 9 B atoms in the form of 4 fused pentagonal rings. This arrangement corresponds to 104 B ($84 + 10 + 10$) and there is, finally, a 6-coordinate B atom at the centre of symmetry between 2 adjacent B_{10} condensed units, bringing the total to 105 B atoms in the unit cell.

The first crystalline polymorph of B to be prepared (1943) was termed α-tetragonal boron and was found to have 50 B atoms in the unit cell ($4B_{12} + 2B$) (Fig. 6.4). Paradoxically, however, more recent work (1974) suggests that this phase never forms in the absence of carbon or nitrogen as impurity and that it is, in reality, $B_{50}C_2$ or $B_{50}N_2$ depending on the preparative conditions; yields are increased considerably when the BBr_3/H_2 mixture is purposely doped with a few per cent of CH_4, $CHBr_3$ or N_2. The

work illustrates the great difficulties attending preparative and structural studies in this area. The crystal structures of other boron polymorphs, particularly the β-tetragonal phase with 192 B atoms in the unit cell (a 1012, c 1414 pm), are even more complex and have so far defied elucidation despite extensive work by many investigators.[3]

6.2.3 Atomic and physical properties of boron

Boron has 2 stable naturally occurring isotopes and the variability of their concentration (particularly the difference between borates from California (low in ^{10}B) and Turkey (high in ^{10}B) prevents the atomic weight of boron being quoted more precisely than 10.811(7) (p. 17). Each isotope has a nuclear spin (Table 6.1) and this has proved particularly valuable in nmr spectroscopy, especially for ^{11}B.[4] The great difference in neutron absorption cross-section of the 2 isotopes is also notable, and this has led to the development of viable separation processes on an industrial scale. The commercial availability of the separated isotopes has greatly assisted the solution of structural and mechanistic problems in boron chemistry and has led to the development of boron-10 neutron capture therapy for the treatment of certain types of brain tumour (see p. 179).

Boron is the fifth element in the periodic table and its ground-state electronic configuration is $[He]2s^2 2p^1$. The first 3 ionization energies are 800.6, 2427.1 and 3659.7 kJ mol^{-1}, all substantially larger than for the other elements in Group 13. (The values for this and other properties of B are compared with those for Al, Ga, In and Tl on p. 222). The electronegativity (p. 25) of B is 2.0, which is close to the values for H (2.1) Si (1.8) and Ge (1.8) but somewhat less than the value for C (2.5). The implied reversal of the polarity of B–H and C–H bonds is an important factor in discussing hydroboration (p. 166) and other reactions.

The determination of precise physical properties for elemental boron is bedevilled by the twin difficulties of complex polymorphism and contamination by irremovable impurities. Boron is an extremely hard refractory solid of high mp, low density and very low electrical conductivity. Crystalline forms are dark red in transmitted light and powdered forms are black. The most stable (β-rhombohedral) modification has mp 2092°C (exceeded only by C among the non-metals), bp ~4000°C, d 2.35 g cm^{-3} (α-rhombohedral form 2.45 g cm^{-3}), $\Delta H_{\text{sublimation}}$ 570 kJ per mol of B, electrical conductivity at room temperature 1.5×10^{-6} ohm^{-1} cm^{-1}.

6.2.4 Chemical properties

It has been argued[1] that the inorganic chemistry of boron is more diverse and complex than that of any other element in the periodic table. Indeed, it is only during the last three decades that the enormous range of structural types has begun to

[4] J. D. KENNEDY, Chap. 8 in J. MASON (ed.), *Multinuclear NMR*, Plenum, New York, pp. 221–58 (1987). T. L. VENABLE, W. C. HUTTON and R. N. GRIMES, *J. Am. Chem. Soc.* **106**, 29–37 (1984). D. REED, *Chem. Soc. Rev.* **22**, 109–16 (1993).

Table 6.1 Nuclear properties of boron isotopes

Property	^{10}B	^{11}B
Relative mass ($^{12}C = 12$)	10.012 939	11.009 305
Natural abundance/(%)	19.055–20.316	80.945–79.684

[a] 1 nuclear magneton = 5.0505×10^{-27} A m^2 in SI.
[b] 1 barn = 10^{-28} m^2 in SI; the cross-section for natural boron (~20% ^{10}B) is ~767 barns.

be elucidated and the subtle types of bonding appreciated. The chemical nature of boron is influenced primarily by its small size and high ionization energy, and these factors, coupled with the similarity in electronegativity of B, C and H, lead to an extensive and unusual type of covalent (molecular) chemistry. The electronic configuration $2s^2 2p^1$ is reflected in a predominant tervalence, and bond energies involving B are such that there is no tendency to form univalent compounds of the type which increasingly occur in the chemistry of Al, Ga, In and Tl. However, the availability of only 3 electrons to contribute to covalent bonding involving the 4 orbitals s, p_x, p_y and p_z confers a further range of properties on B leading to electron-pair acceptor behaviour (Lewis acidity) and multicentre bonding (p. 157). The high affinity for oxygen is another dominant characteristic which forms the basis of the extensive chemistry of borates and related oxo complexes (p. 203). Finally, the small size of B enables many interstitial alloy-type metal borides to be prepared, and the range of these is considerably extended by the propensity of B to form branched and unbranched chains, planar networks, and three-dimensional arrays of great intrinsic stability which act as host frameworks to house metal atoms in various stoichiometric proportions.

It is thus possible to distinguish five types of boron compound, each having its own chemical systematics which can be rationalized in terms of the type of bonding involved, and each resulting in highly individualistic structures and chemical reactions:

(i) metal borides ranging from M_5B to MB_{66} (or even $MB_{>100}$) (see below);
(ii) boron hydrides and their derivatives including carbaboranes and polyhedral borane-metal complexes (p. 151);
(iii) boron trihalides and their adducts and derivatives (p. 195);
(iv) oxo compounds including polyborates, borosilicates, peroxoborates, etc. (p. 203);
(v) organoboron compounds and B–N compounds (B–N being isoelectronic with C–C) (p. 207).

The chemical reactivity of boron itself obviously depends markedly on the purity, crystallinity, state of subdivision and temperature. Boron reacts with F_2 at room temperature and is superficially attacked by O_2 but is otherwise inert. At higher temperatures boron reacts directly with all the non-metals except H, Ge, Te and the noble gases. It also reacts readily and directly with almost all metals at elevated temperatures, the few exceptions being the heavier members of groups 11–15 (Ag, Au; Cd, Hg; Ga, In, Tl; Sn, Pb; Sb, Bi).

The general chemical inertness of boron at lower temperatures can be gauged by the fact that it resists attack by boiling concentrated aqueous NaOH or by fused NaOH up to 500°, though it is dissolved by fused $Na_2CO_3/NaNO_3$ mixtures at 900°C. A 2:1 mixture of hot concentrated H_2SO_4/HNO_3 is also effective for dissolving elemental boron for analysis but non-oxidizing acids do not react.

6.3 Borides[1-3]

6.3.1 Introduction

The borides comprise a group of over 200 binary compounds which show an amazing diversity of stoichiometries and structural types; e.g. M_5B, M_4B, M_3B, M_5B_2, M_7B_3, M_2B, M_5B_3, M_3B_2, $M_{11}B_8$, MB, $M_{10}B_{11}$, M_3B_4, M_2B_3, M_3B_5, MB_2, M_2B_5, MB_3, MB_4, MB_6, M_2B_{13}, MB_{10}, MB_{12}, MB_{15}, MB_{18} and MB_{66}. There are also numerous nonstoichiometric phases of variable composition and many ternary and more complex phases in which more than one metal combines with boron. The rapid advance in our understanding of these compounds during the past few decades has been based mainly on X-ray diffraction analysis and the work has been stimulated not only by the inherent academic challenge implied by the existence of these unusual compounds but also by the extensive industrial interest generated by their unique combination of desirable physical and chemical properties (see Panel).

Properties and Uses of Borides

Metal-rich borides are extremely hard, chemically inert, involatile, refractory materials with mps and electrical conductivities which often exceed those of the parent metals. Thus the highly conducting diborides of Zr, Hf, Nb and Ta all have mps > 3000°C and TiB_2 (mp 2980°C) has a conductivity 5 times greater than that of Ti metal. Borides are normally prepared as powders but can be fabricated into the desired form by standard techniques of powder metallurgy and ceramic technology. TiB_2, ZrB_2 and CrB_2 find application as turbine blades, combustion chamber liners, rocket nozzles and ablation shields. Ability to withstand attack by molten metals, slags and salts have commended borides or boride-coated metals as high-temperature reactor vessels, vaporizing boats, crucibles, pump impellers and thermocouple sheaths. Inertness to chemical attack at high temperatures, coupled with excellent electrical conductivity, suggest application as electrodes in industrial processes.

Nuclear applications turn on the very high absorption cross-section of ^{10}B for thermal neutrons (p. 144) and the fact that this property is retained for high-energy neutrons (10^4–10^6 eV) more effectively than for any other nuclide. Another advantage of ^{10}B is that the products of the (n,α) reaction are the stable, non-radioactive elements Li and He. Accordingly, metal borides and boron carbide have been used extensively as neutron shields and control rods since the beginning of the nuclear power industry. More dramatically, following the disaster at Chernobyl in the early hours of 26 April 1986, some 40 tonnes of boron carbide particles were dumped from helicopters onto the stricken reactor to prevent further runaway fission occurring. (In addition there were 800 tonnes of dolomite to provide a CO_2 gas blanket, 1800 t of clay and sand to quench the fires and filter radionuclides, plus 2400 t of lead to absorb heat by melting and to provide a liquid layer that would in time solidify and seal the top of the core of the vault.)

The principal non-nuclear industrial use of boron carbide is as an abrasive grit or powder for polishing or grinding; it is also used on brake and clutch linings. In addition, there is much current interest in its use as light-weight protective armour, and tests have indicated that boron carbide and beryllium borides offer the best choice; applications are in bullet-proof protective clothing and in protective armour for aircraft. More elegantly, boron carbide can now be produced in fibre form by reacting BCl_3/H_2 with carbon yarn at 1600–1900°C:

$$4BCl_3 + 6H_2 + C(\text{fibres}) \longrightarrow B_4C(\text{fibres}) + 12HCl$$

Fibre curling can be eliminated by heat treatment under tension near the mp, and the resulting fibres have a tensile strength of 3.5×10^5 psi (1 psi = 6895 N m^{-2}) and an elastic modulus of 50×10^6 psi at a density of 2.35 g cm^{-3}; the form was 1 ply, 720 filament yarn with a filament diameter of 11–12 μm. The fibres are inert to hot acid and alkali, resistant to Cl_2 up to 700° and air up to 800°C.

Boron itself has been used for over two decades in filament form in various composites; BCl_3/H_2 is reacted at 1300° on the surface of a continuously moving tungsten fibre 12 μm in diameter. US production capacity is about 20 tonnes pa and the price in about $800/kg. The primary use so far has been in military aircraft and space shuttles, but boron fibre composites are also being studied as reinforcement materials for commercial aircraft. At the domestic level they are finding increasing application in golf shafts, tennis rackets and bicycle frames.

6.3.2 Preparation and stoichiometry

Eight general methods are available for the synthesis of borides, the first four being appropriate for small-scale laboratory preparations and the remaining four for commercial production on a scale ranging from kilogram amounts to tonne quantities. Because high temperatures are involved and the products are involatile, borides are not easy to prepare pure and subsequent purification is often difficult; precise stoichiometry is also sometimes hard to achieve because of differential volatility or high activation energies. The methods are:

(i) Direct combination of the elements: this is probably the most widely used technique, e.g.

$$Cr + nB \xrightarrow{1150°} CrB_n$$

(ii) Reduction of metal oxide with B (rather wasteful of expensive elemental B), e.g.

$$Sc_2O_3 + 7B \xrightarrow{1800°} 2ScB_2 + 3BO$$

(iii) Co-reduction of volatile mixed halides with H_2 using a metal filament, hot tube or plasma torch, e.g.

$$2TiCl_4 + 4BCl_3 + 10H_2 \xrightarrow{1300°} 2TiB_2 + 20HCl$$

(iv) Reduction of BCl_3 (or BX_3) with a metal (sometimes assisted by H_2), e.g.

$$nBX_3 + (x+1)M \longrightarrow MB_n + xMX_{3n/x}$$

$$BCl_3 + W \xrightarrow{H_2/1200^\circ} WB + Cl_2 + HCl$$

(v) Electrolytic deposition from fused salts: this is particularly effective for MB_6 (M = alkaline earth or rare earth metal) and for the borides of Mo, W, Fe, Co and Ni. The metal oxide and B_2O_3 or borax are dissolved in a suitable, molten salt bath and electrolysed at 700–1000° using a graphite anode; the boride is deposited on the cathode which can be graphite or steel.

(vi) Co-reduction of oxides with carbon at temperatures up to 2000°, e.g.

$$V_2O_5 + B_2O_3 + 8C \xrightarrow{1500^\circ} 2VB + 8CO$$

(vii) Reduction of metal oxide (or $M + B_2O_3$) with boron carbide, e.g.

$$Eu_2O_3 + 3B_4C \xrightarrow{1600^\circ} 2EuB_6 + 3CO$$

$$7Ti + B_2O_3 + 3B_4C \xrightarrow{2000^\circ} 7TiB_2 + 3CO$$

Boron carbide (p. 149) is a most useful and economic source of B and will react with most metals or their oxides. It is produced in tonnage quantities by direct reduction of B_2O_3 with C at 1600°: a C resistor is embedded in a mixture of B_2O_3 and C, and a heavy electric current passed.

(viii) Co-reduction of mixed oxides with metals (Mg or Al) in a thermite-type reaction — this usually gives contaminated products including ternary borides, e.g. $Mo_7Al_6B_7$. Alternatively, alkali metals or Ca can be used as reductants, e.g.

$$TiO_2 + B_2O_3 \xrightarrow{\text{molten Na}} TiB_2$$

The various stoichiometries are not equally common, as can be seen from Fig. 6.5; the most frequently occurring are M_2B, MB, MB_2, MB_4 and MB_6, and these five classes account for 75% of the compounds. At the other extreme $Ru_{11}B_8$ is the only known example of this stoichiometry. Metal-rich borides tend to be formed by the transition elements whereas the boron-rich borides are characteristic of the more electropositive elements in Groups 1–3, the lanthanides and the actinides. Only the diborides MB_2 are common to both classes.

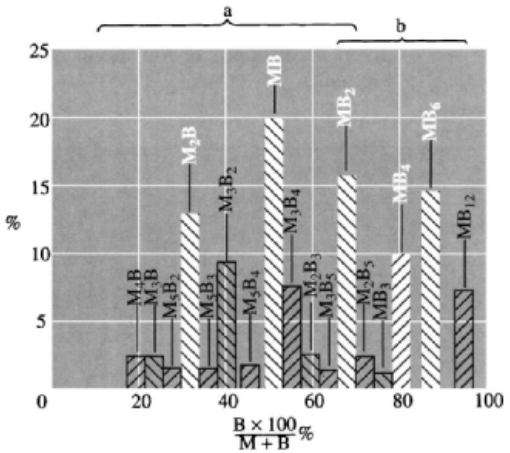

Figure 6.5 Frequency of occurrence of various stoichiometries among boride phases: (a) field of borides of d elements, and (b) field of borides of s, p and f elements.

6.3.3 Structures of borides [1-3,5]

The structures of metal-rich borides can be systematized by the schematic arrangements shown in Fig. 6.6, which illustrates the increasing tendency of B atoms to catenate as their concentration in the boride phase increases; the B atoms are often at the centres of trigonal prisms of metal atoms (Fig. 6.7) and the various stoichiometries are accommodated as follows:

[5] T. LUNDSTROM, *Pure Appl. Chem.* **57**, 1383–90 (1985).

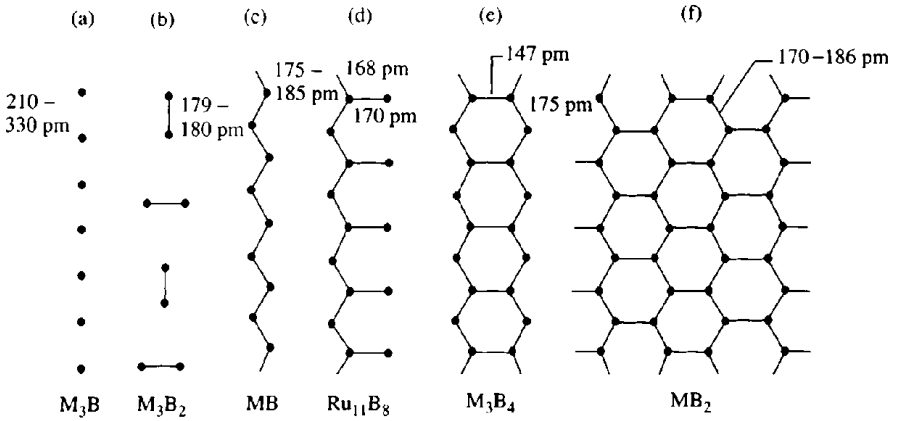

Figure 6.6 Idealized patterns of boron catenation in metal-rich borides. Examples of the structures (a)–(f) are given in the text. Boron atoms are often surrounded by trigonal prisms of M atoms as shown in Fig. 6.7.

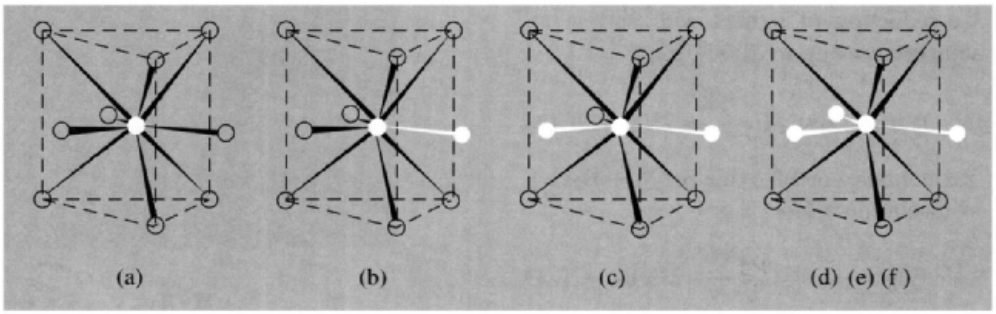

Figure 6.7 Idealized boron environment in metal-rich borides (see text): (a) isolated B atoms in M_3B and M_7B_3; (b) pairs of B atoms in Cr_5B_3 and M_3B_2; (c) zigzag chains of B atoms in Ni_3B_4 and MB; (d) branched chains in $Ru_{11}B_8$; and (e), (f) double chains and plane nets in M_3B_4, MB_2 and M_2B_5.

(a) isolated B atoms:	Mn_4B; M_3B (Tc, Re, Co, Ni, Pd); Pd_5B_2; M_7B_3 (Tc, Re, Ru, Rh); M_2B (Ta, Mo, W, Mn, Fe, Co, Ni);
(b) isolated pairs B_2:	Cr_5B_3; M_3B_2 (V, Nb, Ta);
(c) zigzag chains of B atoms:	M_3B_4 (Ti; V, Nb, Ta; Cr, Mn, Ni); MB (Ti, Hf; V, Nb, Ta; Cr, Mo, W; Mn, Fe, Co, Ni);
(d) branched chains of B atoms:	$Ru_{11}B_8$;
(e) double chains of B atoms:	M_3B_4 (V, Nb, Ta; Cr, Mn);
(f) plane (or puckered) nets:	MB_2 (Mg, Al; Sc, Y; Ti, Zr, Hf; V, Nb, Ta; Cr, Mo, W; Mn, Tc, Re; Ru, Os; U, Pu); M_2B_5 (Ti; Mo, W).

It will be noted from Fig. 6.6 that structures with isolated B atoms can have widely differing interatomic B–B distances, but all other classes involve appreciable bonding between B atoms, and the B–B distances remain almost invariant despite the extensive variation in the size of the metal atoms.

The structures of boron-rich borides (e.g. MB_4, MB_6, MB_{10}, MB_{12}, MB_{66}) are even more effectively dominated by inter-B bonding, and the structures comprise three-dimensional networks of B atoms and clusters in which the metal atoms occupy specific voids or otherwise vacant sites. The structures are often exceedingly complicated (for the reasons given in Section 6.2.2): for example, the cubic unit cell of YB_{66} has a_0 2344 pm and contains 1584 B and 24 Y atoms; the basic structural unit is the 13-icosahedron unit of 156 B atoms found in β-rhombohedral B (p. 142); there are 8 such units (1248 B) in the unit cell and the remaining 336 B atoms are statistically distributed in channels formed by the packing of the 13-icosahedron units.

Another compound which is even more closely related to β-rhombohedral boron is boron carbide, "B_4C"; this is now more correctly written as $B_{13}C_2$,[6] but the phase can vary over wide composition ranges which approach the stoichiometry $B_{12}C_3$. The structure is best thought of in terms of B_{84} polyhedra (p. 142) but these are now interconnected simply by linear C–B–C units instead of the larger B_{10}–B–B_{10} units in β-rhombohedral B. The result is a more compact packing of the 13-icosahedron units so generated and this is reflected in the unit cell dimensions (a 517.5 pm, α 65.74°). A notable feature of the structure (Fig. 6.8) is the presence of regular hexagonal planar rings B_4C_2 (shaded). Stringent tests had to be applied to distinguish confidently between B and C atoms in this structure and to establish that it was indeed B_{12} CBC and not $B_{12}C_3$ as had previously been thought. [This view has recently been challenged as a result of a ^{13}C nmr study using magic-angle spinning, which suggests that the carbon is present only as C_3 chains and that the structure is in fact still best represented as $B_{12}C_3$ (or $B_{12}^{2-}C_3^{2+}$).][7] It is salutory to recall that boron carbide, which was first made by H. Moissan in 1899 and which has been manufactured in tonne amounts for several decades, still waits definitive structural characterization. On one view the wide variation in stoichiometry from "$B_{6.5}C$" to "B_4C" is due to progressive vacancies in the CBC chain ($B_{12}C_2 \equiv B_6C$) and/or progressive substitution of one C for B in the icosahedron [$(B_{11}C)CBC \equiv B_4C$)]. Related phases are $B_{12}PBP$ and $B_{12}X_2$ (X = P, As, O, S). See also p. 288 for B_nC_{60-n} ($n = 1$–6).

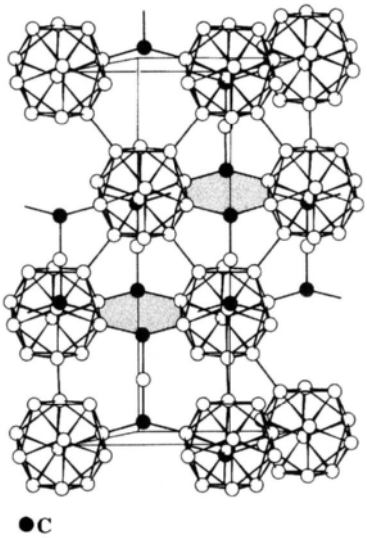

Figure 6.8 Crystal structure of $B_{13}C_2$ showing the planar hexagonal rings connecting the B_{12} icosahedra. These rings are perpendicular to the C–B–C chains.

By contrast with the many complex structures formally related to β-rhombohedral boron, the structures of the large and important groups of cubic borides MB_{12} and MB_6 are comparatively simple. MB_{12} is formed by many large electropositive metals (e.g. Sc, Y, Zr, lanthanides and actinides) and has an "NaCl-type" fcc structure in which M atoms alternate with B_{12} cubo-octahedral clusters (Fig. 6.9). (Note that the B_{12} cluster is not an icosahedron.) Similarly, the cubic hexaborides MB_6 consist of a simple CsCl-type lattice in which the halogen is replaced by B_6 octahedra (Fig. 6.10); these B_6 octahedra are linked together in all 6 orthogonal directions to give a rigid but open framework which can accommodate large,

[6] G. Will and K. H. Kossobutzki, *J. Less-Common Metals* **47**, 43–8 (1976).

[7] T. M. Duncan, *J. Am. Chem. Soc.* **106**, 2270–5 (1984).

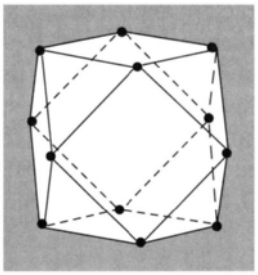

Figure 6.9 B_{12} Cubo-octahedral cluster as found in MB_{12}. This B_{12} cluster alternates with M atoms on an fcc lattice as in NaCl, the B_{12} cluster replacing Cl.

electropositive metal atoms at the corners of the interpenetrating cubic sublattice. The rigidity of the B framework is shown by the very small linear coefficient of thermal expansion of hexaborides ($6-8 \times 10^{-6}$ deg^{-1}) and by the narrow range of lattice constants of these phases which vary by only 4% (410–427 pm), whereas the diameters of the constituent metal atoms vary by 25% (355–445 pm). Bonding theory for isolated groups such as $B_6H_6^{2-}$ (p. 160) requires the transfer of 2 electrons to the borane cluster to fill all the bonding MOs; however, complete transfer of 2e per B_6 unit is not required in a three-dimensional crystal lattice and calculations for MB_6 (Ca, Sr, Ba) indicate the transfer of only 0.9–1.0e.[8] This also explains why metal-deficit phases $M_{1-x}B_6$ remain stable and why the alkali metals (Na, K) can form hexaborides. The $M^{II}B_6$ hexaborides (Ca, Sr, Ba, Eu, Yb) are semiconductors but $M^{III}B_6$ and $M^{IV}B_6$ (M^{III} = Y, La, lanthanides; M^{IV} = Th) have a high metallic conductivity at room temperature ($10^4 - 10^5$ ohm^{-1} cm^{-1}).

The "radius" of the 24-coordinate metal site in MB_6 is too large (215–225 pm) to be comfortably occupied by the later (smaller) lanthanide elements Ho, Er, Tm and Lu, and these form MB_4 instead, where the metal site has a radius of 185–200 pm. The structure of MB_4 (also formed by Ca, Y, Mo and W) consists of a tetragonal lattice formed by chains of B_6 octahedra linked along the *c*-axis and joined laterally by pairs of B_2 atoms in the *xy* plane so as to form a 3D skeleton with tunnels along the *c*-axis that are filled by metal atoms (Fig. 6.11). The pairs of boron atoms are thus surrounded by trigonal prisms of

[8] P. G. Perkins, pp. 31–51 in ref. 2.

Next Page

metal atoms and the structure represents a transition between the puckered layer structures of MB_2 and the cubic MB_6.

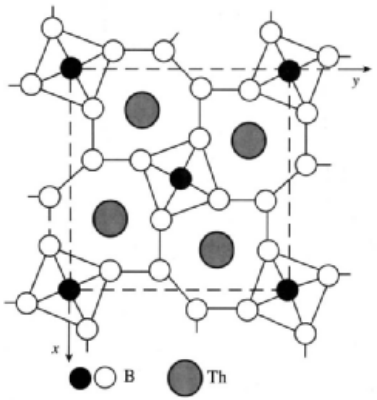

Figure 6.11 Structure of ThB_4.

The structure and properties of many borides emphasize again the inadequacy of describing bonding in inorganic compounds as either ionic, covalent or metallic. For example, in conventional terminology LaB_6 would be described as a rigid, covalently bonded network of B_6 clusters having multicentred bonding within each cluster and 2-centre covalent B–B bonds between the clusters; this requires the transfer of up to 2 electrons from the metal to the boron sublattice and so could be said also to involve ionic bonding ($La^{2+}B_6^{2-}$) in addition to the covalent inter-boron bonding. Finally, the third valency electron on La is delocalized in a conduction band of the crystal (mainly metal based) and the electrical conductivity of the boride is actually greater than that of La metal itself so that this aspect of the bonding could be called metallic. The resulting description of the bonding is an *ad hoc* mixture of four oversimplified limiting models and should more logically be replaced by a generalized MO approach.[8] It will also be clear from the preceding paragraphs that a classification of borides according to the periodic table does not result in the usual change in stoichiometry from one group to the next; instead, a classification in terms of the type of boron network and the size and electropositivity of the other atoms is frequently more helpful and revealing of periodic trends.

6.4 Boranes (Boron Hydrides)[1,9]

6.4.1 Introduction

Borane chemistry began in 1912 with A. Stock's classic investigations,[10] and the numerous compounds prepared by his group during the following 20 y proved to be the forerunners of an amazingly diverse and complex new area of chemistry. During the past few decades the chemistry of boranes and the related carbaboranes (p. 181) has been one of the major growth areas in inorganic chemistry, and interest continues unabated. The importance of boranes stems from three factors: first, the completely unsuspected structural principles involved; secondly, the growing need to extend covalent MO bond theory considerably to cope with the unusual stoichiometries; and finally, the emergence of a versatile and extremely extensive reaction chemistry which parallels but is quite distinct from that of organic and organometallic chemistry. This efflorescence of activity culminated (in the centenary year of Stock's birth) in the award of the 1976 Nobel Prize for Chemistry to W. N. Lipscomb (Harvard) "for his studies of boranes which have illuminated problems of chemical bonding".

Over 50 neutral boranes, B_nH_m, and an even larger number of borane anions $B_nH_m^{x-}$ have been characterized;[11] these can be classified

[9] E. L. MUETTERTIES (ed.), *Boron Hydride Chemistry*, Academic Press, New York, 1975, 532 pp.

[10] A. STOCK, *Hydrides of Boron and Silicon*, Cornell University Press, Ithaca, New York, 1933, 250 pp.

[11] N. N. GREENWOOD, Boron Hydride Clusters, in H. W. ROESKY (ed.) *Rings, Clusters and Polymers of Main Group and Transition Elements*, Elsevier, Amsterdam, 1989, pp. 49–105.

according to structure and stoichiometry into 5 series though examples of neutral or unsubstituted boranes themselves are not known for all 5 classes:

closo-boranes (from Greek κλωβός, *clovos*, a cage) have complete, closed polyhedral clusters of n boron atoms;

nido-boranes (from Latin *nidus*, a nest) have non-closed structures in which the B_n cluster occupies n corners of an $(n+1)$-cornered polyhedron;

arachno-boranes (from Greek ἀράχνη, *arachne*, a spider's web) have even more open clusters in which the B atoms occupy n contiguous corners of an $(n+2)$-cornered polyhedron;

hypho-boranes (from Greek ὑφή, *hyphe*, a net) have the most open clusters in which the B atoms occupy n corners of an $(n+3)$-cornered polyhedron;

conjuncto-boranes (from Latin *conjuncto*, I join together) have structures formed by linking two (or more) of the preceding types of cluster together.

Examples of these various series are listed below and illustrated in the accompanying structural diagrams. Their interrelations are further discussed in connection with carborane structures 51–81.

Closo-boranes:

$B_nH_n^{2-}$ ($n = 6$–12) see structures 1–7. The neutral boranes B_nH_{n+2} are not known.

Nido-boranes:

B_nH_{n+4}, e.g. B_2H_6 (8), B_5H_9 (9), B_6H_{10} (10), $B_{10}H_{14}$(11); B_8H_{12} also has this formula but has a rather more open structure (12) which can be visualized as being formed from $B_{10}H_{14}$ by removal of B(9) and B(10).

$B_nH_{n+3}^-$ formed by removal of 1 bridge proton from B_nH_{n+4}, e.g. $B_5H_8^-$, $B_{10}H_{13}^-$; other anions in this series such as $B_4H_7^-$ and $B_9H_{12}^-$ are known though the parent boranes have proved too fugitive to isolate; BH_4^- can be thought of as formed by addition of H^- to BH_3.

$B_nH_{n+2}^{2-}$, e.g. $B_{10}H_{12}^{2-}$, $B_{11}H_{13}^{2-}$.

Arachno-boranes:

B_nH_{n+6}, e.g. B_4H_{10} (13), B_5H_{11} (14), B_6H_{12} (15), B_8H_{14} (16), *n*-B_9H_{15} (17), *i*-B_9H_{15}.

$B_nH_{n+5}^-$, e.g. $B_2H_7^-$ (18), $B_3H_8^-$ (19), $B_5H_{10}^-$, $B_9H_{14}^-$ (20), $B_{10}H_{15}^-$.

$B_nH_{n+4}^{2-}$, e.g. $B_{10}H_{14}^{2-}$ (21).

Hypho-boranes:

B_nH_{n+8}. No neutral borane has yet been definitely established in this series but the known compounds B_8H_{16} and $B_{10}H_{18}$ may prove to be *hypho*-boranes and several adducts are known to have *hypho*-structures (pp. 171–2).

Conjuncto-boranes:

B_nH_m. At least five different structure types of interconnected borane clusters have been identified; they have the following features:

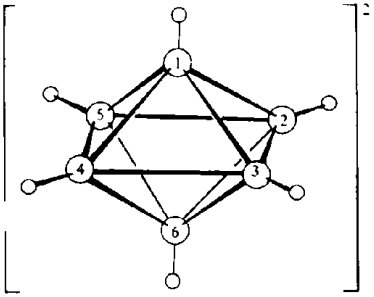
(a) fusion by sharing a single common B atom, e.g. $B_{15}H_{23}$ (22);

(b) formation of a direct 2-centre B–B σ bond between 2 clusters, e.g. B_8H_{18}, i.e. $(B_4H_9)_2$ (23), $B_{10}H_{16}$, i.e. $(B_5H_8)_2$ (3 isomers) (24), $B_{20}H_{26}$, i.e. $(B_{10}H_{13})_2$ (11 possible isomers of which most have been prepared and separated), (e.g. 25a, b, c); anions in this subgroup are represented by the 3 isomers of $B_{20}H_{18}^{4-}$, i.e. $(B_{10}H_9^{2-})_2$ (26);

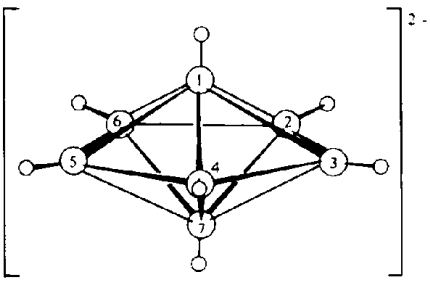
(c) fusion of 2 clusters via 2 B atoms at a common edge, e.g. $B_{13}H_{19}$ (27), $B_{14}H_{18}$ (28), $B_{14}H_{20}$ (29), $B_{16}H_{20}$ (30), *n*-$B_{18}H_{22}$ (31), *i*-$B_{18}H_{22}$ (32);

(d) fusion of two clusters via 3 B atoms at a common face: no neutral borane or borane anion is yet known with this conformation but the solvated complex $(MeCN)_2B_{20}H_{16}$.MeCN has this structure (33);

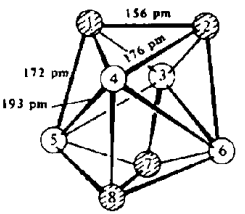
(e) more extensive fusion involving 4 B atoms in various configurations, e.g. $B_{20}H_{16}$ (34), $B_{20}H_{18}^{2-}$ (35).



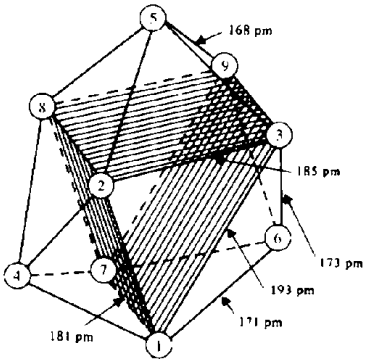
(1) The $B_6H_6^{2-}$ anion The relationship to the structure of the B_6 network in CaB_6 and the boron cluster in B_5H_9 should be noted



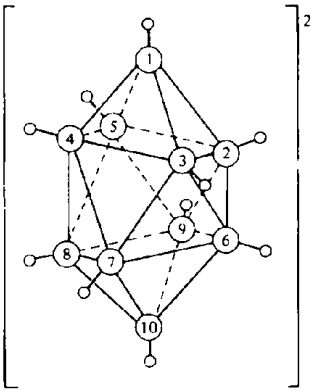
(2) Probable D_{5h} pentagonal bipyramidal structure of the anion $B_7H_7^{2-}$ in solution



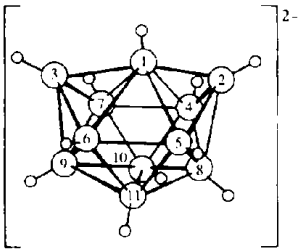
(3) The D_{2d} configuration of the boron atoms in $B_8H_8^{2-}$ showing the two structurally non-equivalent sets of 4 boron atoms



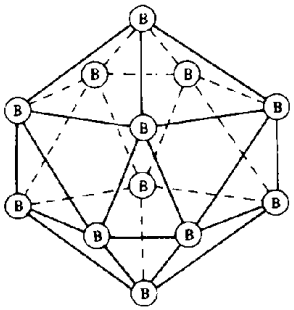
(4) Structure of the boron cluster in $B_9H_9^{2-}$ (interatomic distances ± 1.5 pm) The four unique B-H distances are 107, 110, 127 and 144 ± 15 pm

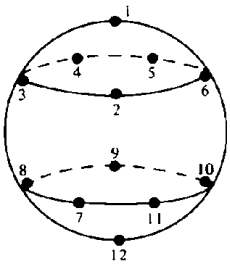


(5) $B_{10}H_{10}^{2-}$: decahydro-*closo*-decaborate (2-)

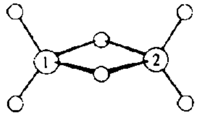


(6) $B_{11}H_{11}^{2-}$

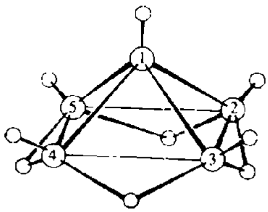




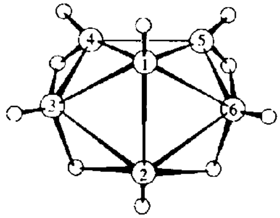
(7) Position of boron atoms and numbering system in the icosahedral borane anion $B_{12}H_{12}^{2-}$ The hydrogen atoms, which are attached radially to each boron atom, are omitted for clarity There are six B-B distances of 175.5 pm and 24 of 178 pm



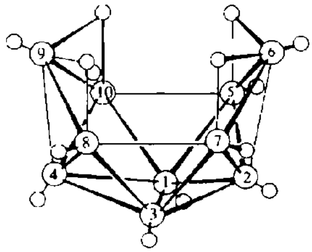
(8) B_2H_6



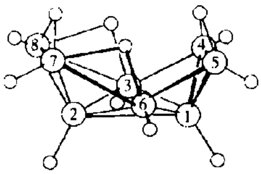
(9) B_5H_9



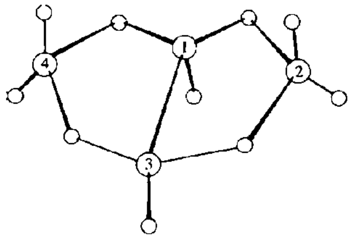
(10) B_6H_{10}



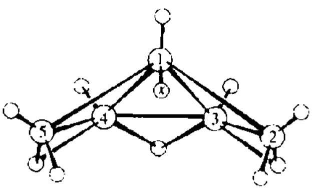
(11) $B_{10}H_{14}$



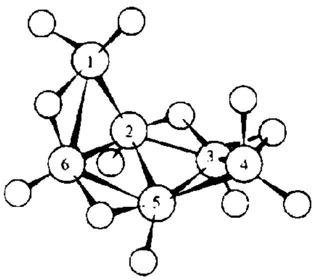
(12) B_8H_{12}



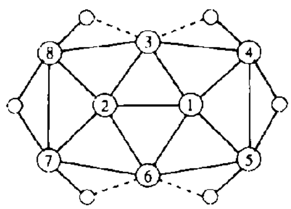
(13) B_4H_{10}



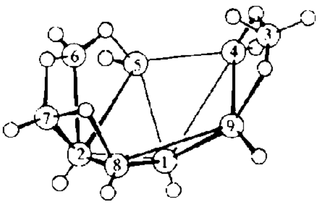
(14) B_5H_{11}



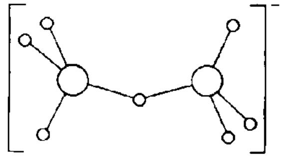
(15) B_6H_{12}



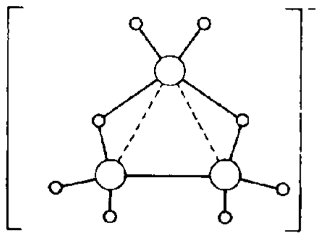
(16) Proposed structure for B_8H_{14} (terminal H atoms omitted)



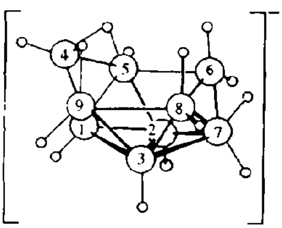
(17) *n*-B_9H_{15}



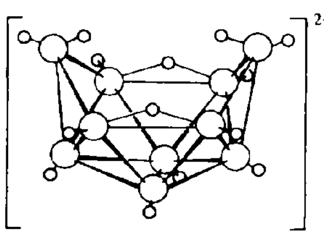
(18) $B_2H_7^-$



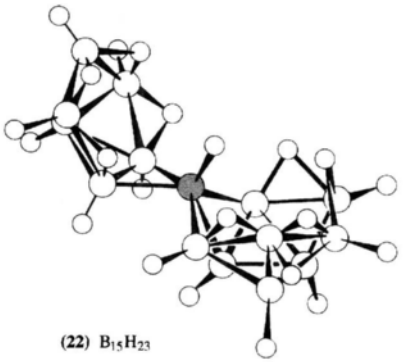
(19) $B_3H_8^-$



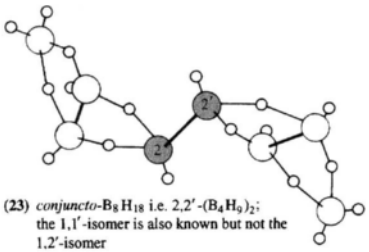
(20) B_9H_{14}



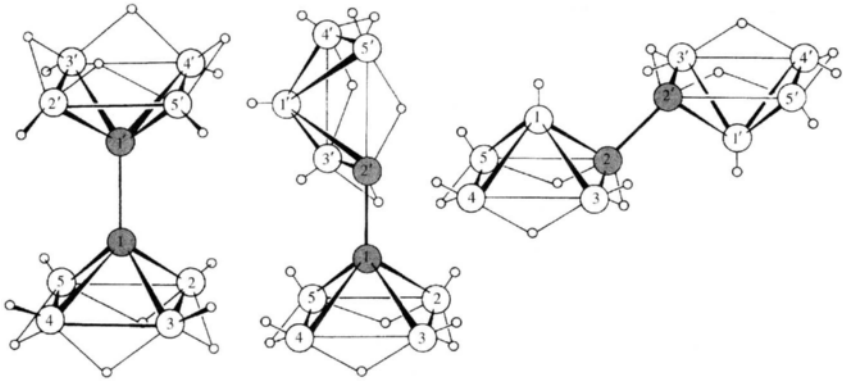
(21) $B_{10}H_{14}^{2-}$



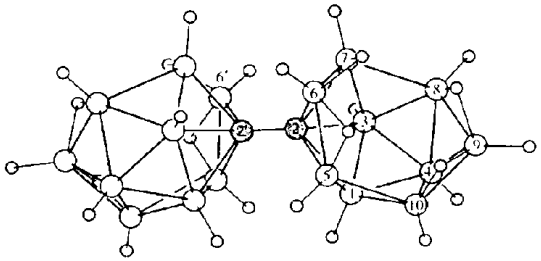
(22) $B_{15}H_{23}$



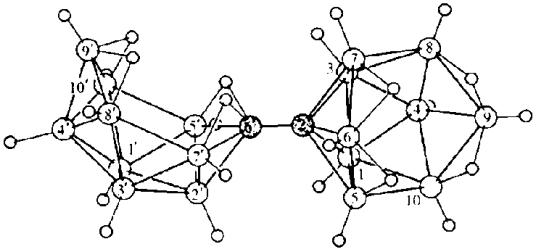
(23) *conjuncto*-B_8H_{18} i.e. 2,2′-$(B_4H_9)_2$; the 1,1′-isomer is also known but not the 1,2′-isomer



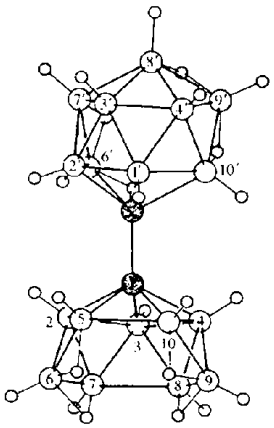
(24) Structures of the three isomers of $B_{10}H_{16}$. The 1,1′ isomer comprises two pentaborane(9) groups linked in eclipsed configuration via the apex boron atoms to give overall D_{4h} symmetry; the B-B bond distances are 174 pm for the linking bond, 176 pm for the slant edge of the pyramids, and 171 pm for the basal boron atoms



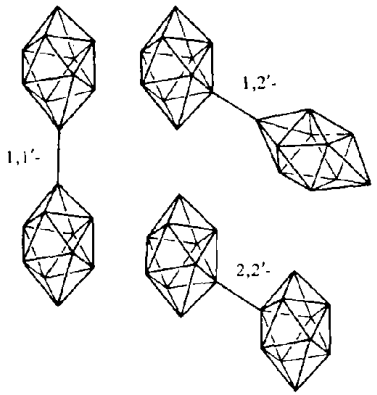
(25a) 2,2′-$(B_{10}H_{13})_2$



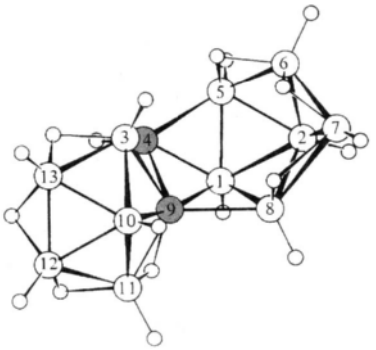
(25b) 2,6′-$(B_{10}H_{13})_2$



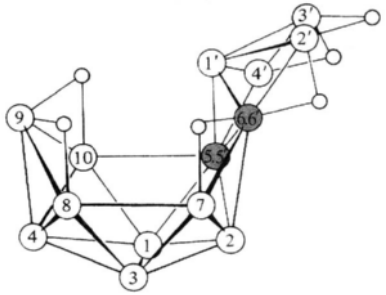
(25c) 1,5-$(B_{10}H_{13})_2$



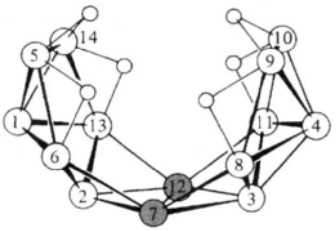
(26) Proposed structures for the three isomers of $[B_{20}H_{18}]^{4-}$; terminal hydrogen atoms omitted for clarity. (See also p. 180)



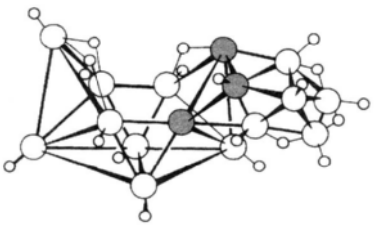
(27) $B_{13}H_{19}$



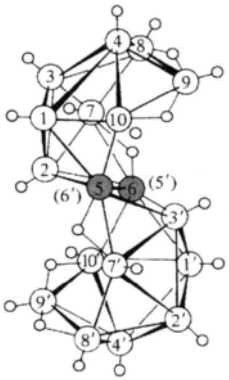
(28) *Proposed structure of* $B_{14}H_{18}$, *omitting* terminal hydrogen atoms for clarity



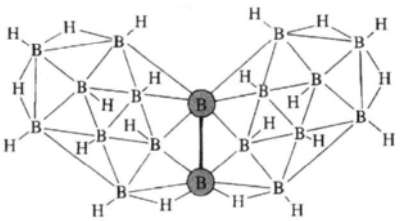
(29) $B_{14}H_{20}$
Terminal hydrogen atoms have been omitted for clarity



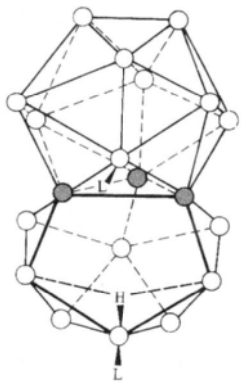
(30) $B_{16}H_{20}$



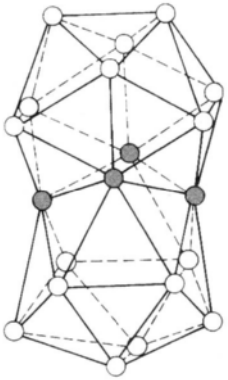
(31) *n*-$B_{18}H_{22}$ (centrosymmetric)



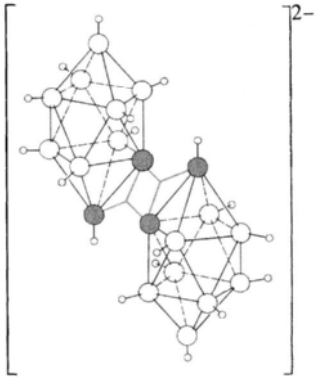
(32) Plane projection of the structure of *i*-$B_{18}H_{22}$. The two decaborane units are fused at the 5(7') *and* 6(6') *positions to give a non-centrosymmetric* structure with C_2 symmetry



(33) Molecular structure of $(MeCN)_2B_{20}H_{16}$ as found in crystals of the solvate $(MeCN)_2B_{20}H_{16}\cdot MeCN$ (see text)



(34) The boron atom arrangement in *closo*-$B_{20}H_{16}$. Each boron atom except the 4 "fusion borons" carries an external hydrogen atom and there are no BHB bridges



(35) Structure of the $B_{20}H_{18}^{2-}$ ion. The two 3-centre BBB bonds joining the 2 $B_{10}H_9^-$ units are shown by broad shaded lines

Boranes are usually named[12] by indicating the number of B atoms with a latin prefix and the number of H atoms by an arabic number in parentheses, e.g. B_5H_9, pentaborane(9); B_5H_{11}, pentaborane(11). Names for anions end in "ate" rather than "ane" and specify both the number of H and B atoms and the charge, e.g. $B_5H_8^-$ octahydropentaborate(1−). Further information can be provided by the optional inclusion of the italicized descriptors *closo-*, *nido-*, *arachno-*, *hypho-* and *conjuncto-*, e.g.:

$B_{10}H_{10}^{2-}$: decahydro-*closo*-decaborate(2−) [structure (5)]

$B_{10}H_{14}$: *nido*-decaborane(14) [structure (11)]

$B_{10}H_{14}^{2-}$: tetradecahydro-*arachno*-decaborate(2−) [structure (21)]

$B_{10}H_{16}$: 1,1′-*conjuncto*-decaborane(16) [structure (24a)]
[i.e. 1,1′-bi(*nido*-pentaboranyl)]

The detailed numbering schemes are necessarily somewhat complicated but, in all other respects, standard nomenclature practices are followed.[12]

Derivatives of the boranes include not only simple substituted compounds in which H has been replaced by halogen, OH, alkyl or aryl groups, etc., but also the much more diverse and numerous class of compounds in which one or more B atom in the cluster is replaced by another main-group element such as C, P or S, or by a wide range of metal atoms or coordinated metal groups. These will be considered in later sections.

6.4.2 Bonding and topology

The definitive structural chemistry of the boranes began in 1948 with the X-ray crystallographic determination of the structure of decaborane(14); this showed the presence of 4 bridging H atoms and an icosahedral fragment of 10 B atoms. This was rapidly followed in 1951 by the unequivocal demonstration of the H-bridged structure of diborane(6) and by the determination of the structure of pentaborane(9). Satisfactory theories of bonding in boranes date from the introduction of the concept of the 3-centre 2-electron B−H−B bond by H. C. Longuet-Higgins in 1949; he also extended the principle of 3-centre bonding and multicentre bonding to the higher boranes. These ideas have been extensively developed and

[12] G. J. LEIGH (ed.), *Nomenclature of Inorganic Chemistry: Recommendations 1990* (The IUPAC "Red Book"), Blackwell, Oxford, 1990, Chap. 11, pp. 207–37.

refined by W. N. Lipscomb and his group during the past four decades.[13]

In simple covalent bonding theory molecular orbitals (MOs) are formed by the linear combination of atomic orbitals (LCAO); for example, 2 AOs can combine to give 1 bonding and 1 antibonding MO and the orbital of lower energy will be occupied by a pair of electrons. This is a special case of a more general situation in which a number of AOs are combined together by the LCAO method to construct an equal number of MOs of differing energies, some of which will be bonding, some possibly nonbonding and some antibonding. In this way 2-centre, 3-centre, and multicentre orbitals can be envisaged. The three criteria that determine whether particular AOs can combine to form MOs are that the AOs must (a) be similar in energy, (b) have appreciable spatial overlap, and (c) have appropriate symmetry. In borane chemistry two types of 3-centre bond find considerable application: B–H–B bridge bonds (Fig. 6.12) and central 3-centre BBB bonds (Fig. 6.13). Open 3-centre B–B–B bonds are not now thought to occur in boranes and their anions though they are still useful in describing the bonding in carbaboranes and other heteroatom clusters (p. 194). The relation between the 3-centre bond formation for B–H–B, where the bond angle at H is ~90° and the 3-centre bond formation for approximately linear H bonds A–H···B is given on pp. 63–4.

Localized 3-centre bond formalism can readily be used to rationalize the structure and bonding in most of the non-*closo*-boranes. This is illustrated for some typical *nido*- and *arachno*-boranes in the following plane-projection diagrams which use an obvious symbolism for normal 2-centre bonds: B–B ○—○, B–H_t ○—●, (t = terminal), central 3-centre bonds  , and B–H_μ–B bridge bonds  . It is particularly important

[13] W. N. Lipscomb, Chap. 2 in ref. 9, pp. 30–78. W. N. Lipscomb, *Boron Hydrides*, Benjamin, New York, 1963, 275 pp. W. N. Lipscomb, Nobel Prize Lecture, *Science* **196**, 1047–55 (1977).

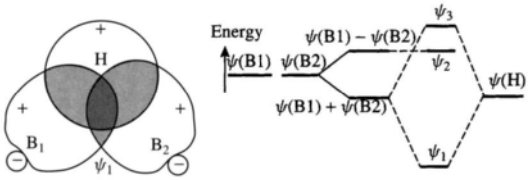


Figure 6.12 Formation of a bonding 3-centre B–H–B orbital ψ_1 from an sp^x hybrid orbital on each of B(1), B(2) and the H 1s orbital, ψ(H). The 3 AOs have similar energy and appreciable spatial overlap, but only the combination $\psi(B1) + \psi(B2)$ has the correct symmetry to combine linearly with ψ(H).

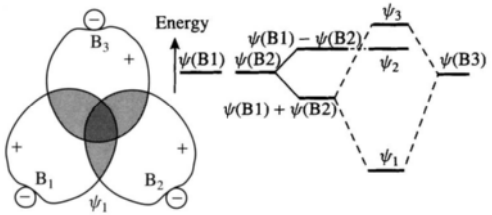

Figure 6.13 Formation of a bonding, central 3-centre bond ψ_1 and schematic representation of the relative energies of the 3 molecular orbitals ψ_1, ψ_2 and ψ_3.

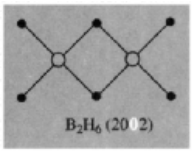
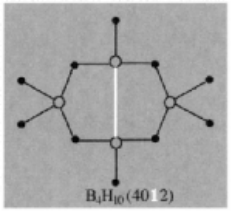
to realize that the latter two symbols each represent a single (3-centre) bond involving one pair of electrons. As each B atom has 3 valence electrons, and each B–H_t bond requires 1 electron from B and one from H, it follows that each B–H_t group can contribute the remaining 2 electrons on B towards the bonding of the cluster (including B–H–B bonds), and likewise each BH_2 group can contribute 1 electron for cluster bonding. The overall bonding is sometimes codified in a 4-digit number, the so-called *styx* number, where *s* is the number of B–H–B bonds, *t* is the number of 3-centre BBB bonds, *y* the number of 2-centre BB bonds, and *x* the number of BH_2 groups.[13] Examples are on p. 159.

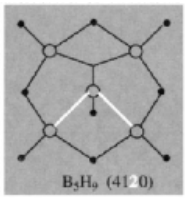
Electron counting and orbital bookkeeping can easily be checked in these diagrams: as each B has 4 valency orbitals (s + 3p) there should be 4 lines emanating from each open circle; likewise, as each B atom contributes 3 electrons in all and each H atom contributes 1 electron, the total



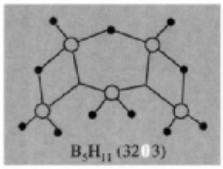
Each terminal BH_2 group and each (bridging) H_μ contributes 1 electron to the bridging; these 4 electrons just fill the two B–H–B bonds.

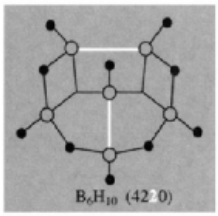


Each of the 4 B and $4H_\mu$ contribute 1 electron to the B–H–B bonds, i.e. 4 pairs of electrons for the 4 (3-centre) bonds. The 2 "hinge" BH_t groups each have 1 remaining electron and 1 orbital which interact to give the 2-centre B–B bond.



In B_5H_9 the bonding can be thought of as involving the structure shown and 3 other equivalent structures in which successive pairs of adjacent basal B atoms are combined with the apex B in a 3-centre bond.

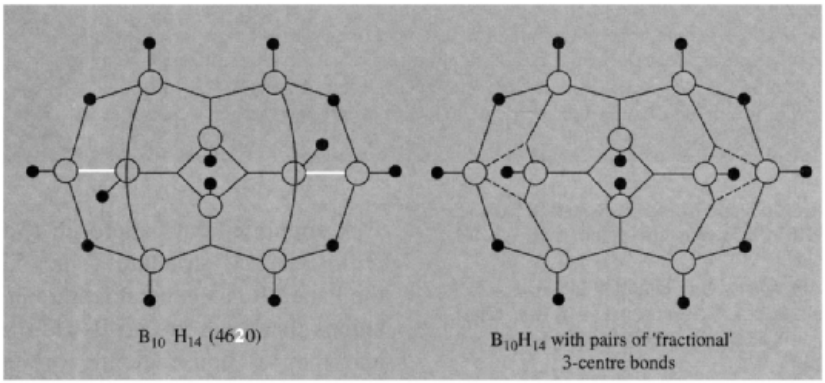




number of valence electrons for a borane of formula B_nH_m is $(3n + m)$ and the number of bonds shown in the structure should be just half this. It follows, too, that the number of electron-pair bonds in the molecule is n plus the sum of the individual *styx* numbers (e.g. 13 for B_5H_{11}, 14 for B_6H_{10}) and this constitutes a further check.† An appropriate number of additional electrons should be added for anionic species.

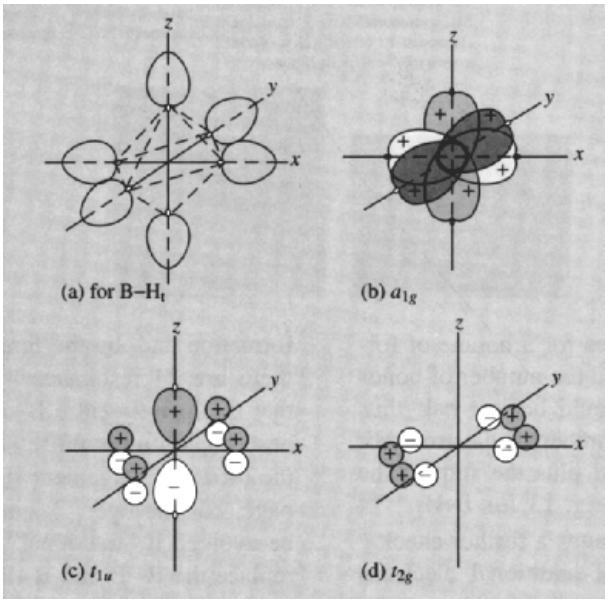
For *closo*-boranes and for the larger open-cluster boranes it becomes increasingly difficult to write a simple satisfactory localized orbital structure, and a full MO treatment is required. Intermediate cases, such as B_5H_9, require several "resonance hybrids" in the localized orbital formation and, by the time $B_{10}H_{14}$ is considered there are 24 resonance hybrids, even assuming that no open 3-centre B–B–B bonds occur. The best single compromise structure in this case is the (4620) arrangement shown at the foot of the page, but the open 3-centre B–B–B bonds can be avoided if "fractional" central 3-centre bonds replace the B–B and B–B–B bonds in pairs:

† Further checks, which can readily be verified from the equations of balance, are (a) the number of atoms in a neutral borane molecule $= 2(s + t + y + x)$, and (b) there are as many framework electrons as there are atoms in a neutral borane B_nH_m since each BH group supplies 2 electrons and each of the $(m - n)$ "extra" H atoms supplies 1 electron, making $n + m$ in all.



MO Description of Bonding in *closo*-$B_6H_6^{2-}$

Closo $B_6H_6^{2-}$ (structure 1) has a regular octahedral cluster of 6 B atoms surrounded by a larger octahedron of 6 radially disposed H atoms. Framework MOs for the B_6 cluster are constructed (LCAO) using the 2s, $2p_x$, $2p_y$ and $2p_z$ boron AOs. The symmetry of the octahedron suggests the use of sp hybrids directed radially outwards and inwards from each B along the cartesian axes (see figure) and 2 pure p orbitals at right angles to these (i.e. oriented tangentially to the B_6 octahedron). These sets of AOs are combined, with due regard to symmetry, to give 24 MOs as follows: the 24 AOs on the 6 B combine to give 24 MOs of which 7 (i.e. $n + 1$) are bonding framework MOs, 6 are used to form B–H_t bonds, and the remaining 11 are antibonding.



Symmetry of orbitals on the B_6 octahedron. (a) Six outward-pointing (sp) orbitals used for σ bonding to 6 H_t. (b) Six inward-pointing (sp) orbitals used to form the a_{1g} framework bonding molecular orbital. (c) Components for one of the t_{1u} framework bonding molecular orbitals — the other two molecular orbitals are in the yz and zx planes. (d) Components for one of the t_{2g} framework bonding molecular orbitals — the other two molecular orbitals are in the yz and zx planes.

The diagrams also indicate why neutral *closo*-boranes B_nH_{n+2} are unknown since the 2 anionic charges are effectively located in the low-lying inwardly directed a_{1g} orbital which has no overlap with protons outside the cluster (e.g. above the edges or faces of the B_6 octahedron). Replacement of the 6 H_t by 6 further B_6 builds up the basic three-dimensional network of hexaborides MB_6 (p. 150) just as replacement of the 4 H_t in CH_4 begins to build up the diamond lattice.

The diagrams, with minor modification, also describe the bonding in isoelectronic species such as *closo*-$CB_5H_6^-$, 1,2-*closo*-$C_2B_4H_6$, 1,6-*closo*-$C_2B_4H_6$, etc. (pp. 181–2). Similar though more complex, diagrams can be derived for all *closo*-$B_nH_n^{2-}$ ($n = 6$–12); these have the common feature of a low lying a_{1g} orbital and n other framework bonding MOs; in each case, therefore $(n + 1)$ pairs of electrons are required to fill these orbitals as indicated in Wade's rules (p. 161). It is a triumph for MO theory that the existence of $B_6H_6^{2-}$ and $B_{12}H_{12}^{2-}$ were predicted by H. C. Longuet-Higgins in 1954–5,[14] a decade before $B_6H_6^{2-}$ was first synthesized and some 5 y before the (accidental) preparation of $B_{10}H_{10}^{2-}$ and $B_{12}H_{12}^{2-}$ were reported.[15,16]

[14] H. C. Longuet-Higgins and M. de V. Roberts, *Proc. R. Soc.* A, **230**, 110–19 (1955); see also idem *ibid.* A, **224**, 336–47 (1954).

[15] J. L. Boone, *J. Am. Chem. Soc.* **86**, 5036 (1964).

[16] M. F. Hawthorne and A. R. Pitochelli, *J. Am. Chem. Soc.* **81**, 5519 (and also 5833–4) (1959); *J. Am. Chem. Soc.* **82**, 3228–9 (1960).

A simplified MO approach to the bonding in *closo*-$B_6H_6^{2-}$ (structure 1, p. 153) is shown in the Panel. It is a general feature of *closo*-$B_nH_n^{2-}$ anions that there are no B–H–B or BH_2 groups and the $4n$ boron atomic orbitals are always

distributed as follows:

n in the $n(B-H_t)$ bonding orbitals
$(n+1)$ in framework bonding MOs
$(2n-1)$ in nonbonding and antibonding framework MOs

As each B atom contributes 1 electron to its $B-H_t$ bond and 2 electrons to the framework MOs, the $(n+1)$ framework bonding MOs are just filled by the $2n$ electrons from nB atoms and the 2 electrons from the anionic charge. Further, it is possible (conceptually) to remove a BH_t group and replace it by 2 electrons to compensate for the 2 electrons contributed by the BH_t group to the MOs. Electroneutrality can then be achieved by adding the appropriate number of protons; this does not alter the number of electrons in the system and hence all bonding MOs remain just filled.

$B_6H_6^{2-} \xrightarrow{-BH+2e^-} \{B_5H_5^{4-}\} \xrightarrow{4H^+} B_5H_9$ (structure 9, p. 154)

(structure 1, p. 153)

$B_5H_9 \xrightarrow{(-BH+2e^-)\ +2H^+} B_4H_{10}$ (structure 13)

$B_6H_6^{2-} \xrightarrow{-2BH+4e^-} \{B_4H_4^{6-}\} \xrightarrow{6H^+} B_4H_{10}$

The structural interrelationship of all the various *closo-*, *nido-* and *arachno*-boranes thus becomes evident; a further example is shown at the foot of the page.

These relationships were codified in 1971 by K. Wade in a set of rules which have been extremely helpful not only in rationalizing known structures, but also in suggesting the probable structures of new species.[17] Wade's rules can be stated in extended form as follows:

closo-borane anions have the formula $B_nH_n^{2-}$; the B atoms occupy all n corners of an n-cornered triangulated polyhedron, and the structures require $(n+1)$ pairs of framework bonding electrons;

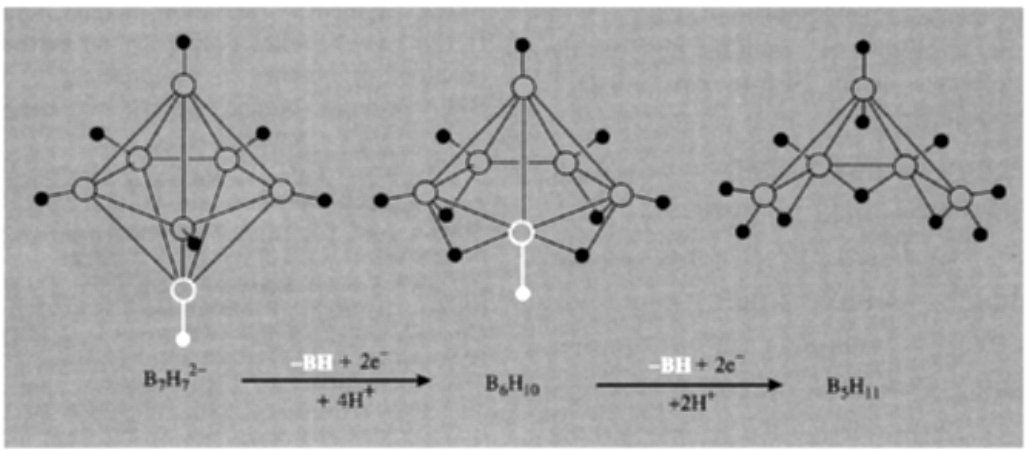
nido-boranes have the formula B_nH_{n+4} with B atoms at n corners of an $(n+1)$ cornered polyhedron; they require $(n+2)$ pairs of framework-bonding electrons;

arachno-boranes: B_nH_{n+6}, n corners of an $(n+2)$ cornered polyhedron, requiring $(n+3)$ pairs of framework-bonding electrons;

hypho-boranes: B_nH_{n+8}: n corners of an $(n+3)$ cornered polyhedron, requiring $(n+4)$ pairs of framework-bonding electrons.

The rules can readily be extended to isoelectronic anions and carbaboranes ($BH{\equiv}B^-{\equiv}C$) and also to metalloboranes (p. 174), metallocarbaboranes (p. 194) and even to metal clusters themselves, though they become less reliable the further one moves away from boron in atomic size, ionization energy, electronegativity, etc.

[17] K. WADE, *Adv. Inorg. Chem. Radiochem.* **18**, 1–66 (1976).



More sophisticated and refined calculations lead to orbital populations and electron charge distributions within the borane molecules and to predictions concerning the sites of electrophilic and nucleophilic attack. In general, the highest electron charge density (and the preferred site of electrophilic attack) occurs at apical B atoms which are furthest removed from open faces; conversely the lowest electron charge density (and the preferred site of nucleophilic attack) occurs on B atoms involved in B–H–B bonding. The consistency of this correlation implies that the electron distribution in the activated complex formed during reaction must follow a similar sequence to that in the ground state. Bridge H atoms tend to be more acidic than terminal H atoms and are the ones first lost during the formation of anions in acid-base reactions.

6.4.3 Preparation and properties of boranes

Earlier methods for preparing the boron hydrides were tedious and inefficient[10] but have now been superseded by modern high-yield routes.[11,18] The first great advance was to replace the reaction between protonic hydrogen and negative boride clusters by the reaction of hydridic species such as LiH or $LiAlH_4$ with boron halides or alkoxides which contain more positive boron centres. Subsequently, S. G. Shore and his group developed a systematic synthesis by using the Lewis acid properties of BX_3 (X = F, Cl, Br) to abstract H^- from the now readily available borane anions such as BH_4^-, $B_3H_8^-$ etc. For example:[19]

$$BX_3 + BH_4^- \longrightarrow HBX_3^- + (BH_3) \longrightarrow 1/2B_2H_6$$

$$BX_3 + B_3H_8^- \longrightarrow HBX_3^- + \{B_3H_7\} \longrightarrow 1/2B_4H_{10} + 1/2\text{“}B_2H_4\text{”} \text{ polymer}$$

$$BX_3 + B_4H_9^- \longrightarrow HBX_3^- + \{B_4H_8\} \longrightarrow 1/2B_5H_{11} + 1/2\text{“}B_3H_5\text{”} \text{ polymer}$$

$$BX_3 + B_9H_{14}^- \longrightarrow HBX_3^- + \{B_9H_{13}\} \longrightarrow 1/2B_{10}H_{14} + 1/2\text{“}B_8H_{10}\text{”} \text{ polymer} + 1/2H_2$$

The perception by R. Schaeffer that *nido*-B_6H_{10} (structure 10, pp. 154, 159) could act as a Lewis base towards reactive (vacant orbital) borance radicals has led to several new *conjuncto*-boranes, e.g.:[20]

$$B_6H_{10} + 1/2B_2H_6 \xrightarrow{-H_2} \{B_7H_{11}\} \xrightarrow{B_6H_{10}} B_{13}H_{19} + H_2$$

$$B_6H_{10} + B_8H_{12} \longrightarrow B_{14}H_{22}$$

$$B_6H_{10} + \textit{iso}\text{-}B_9H_{15} \longrightarrow B_{15}H_{23}(22) + H_2$$

A useful route to B–B bonded *conjuncto*-boranes involves the photolysis of parent *nido*-boranes. Thus, ultraviolet irradiation of B_5H_9 (9) yields the three isomers of *conjuncto*-$B_{10}H_{16}$ (24) and similar treatment of $B_{10}H_{14}$ (11) yields a mixture of 1,2′- and 2,2′-$(B_{10}H_{13})_2$ (25a). High-yield catalytic routes to specific B–B coupled *conjuncto*-boranes (using $PtBr_2$) have been developed by L. G. Sneddon and his group[21], e.g. B_5H_9 gave 1,2′-$(B_5H_8)_2$ (24), B_4H_{10} gave 1,1′-$(B_4H_9)_2$ (i.e. *conjuncto*-B_8H_{18}, of which the 2,2′-isomer is shown in 23), and a mixture of B_4H_{10} and B_5H_9 yielded 1,2′-$(B_4H_9)(B_5H_8)$, i.e. *conjuncto*-B_9H_{17}. When applied to a mixture of B_2H_6 and B_5H_9 in decane at room temperature, the method gave the first authenticated neutral heptaborane, B_7H_{13}, in which one of the bridging H atoms in diborane has been replaced by a basal B atom of the B_5 unit, i.e. 1,2-μ(2-B_5H_8)B_2H_5.

The synthesis of *closo*-borane dianions $B_nH_n^{2-}$ (1–7) relies principally on thermolysis reactions of boranes in the presence of either BH_4^- or amino-borane adducts.[9,11] The yields

$B_{10}H_{14}$	99.5°	213°	32	*n*-B_9H_{15}	2.6°	28°/0.8 mmHg	—

are very sensitive to conditions (solvent, pressure and temperature) and mixtures are often obtained. A more recent variant is the thermolysis of Et_4NBH_4 at 175–190°C for about 12 hours, which yields a mixture of *closo*-$B_9H_9^{2-}$, $B_{10}H_{10}^{2-}$, $B_{12}H_{12}^{2-}$ and *nido*-$B_{11}H_{14}^-$. The smaller *closo*-dianions ($n = 6, 7, 8$) can then be obtained (in smaller yield) by the oxidative (air) degradation of $B_9H_9^{2-}$ salts in the presence of EtOH, thf or 1,2-dimethoxyethane.

Boranes are colourless, diamagnetic, molecular compounds of moderate to low thermal stability. The lower members are gases at room temperature but with increasing molecular weight they become volatile liquids or solids (Table 6.2); bps are approximately the same as those of hydrocarbons of similar molecular weight. The boranes are all endothermic and their free energies of formation ΔG_f° are also positive; however, their thermodynamic instability results from the exceptionally strong interatomic bonds in both elemental B and H_2 rather than any weakness of the B–H bond. In this the boranes resemble the hydrocarbons. Likewise, the remarkable chemical reactivity of the boranes and their ready thermolytic interconversion (p. 164) should not be taken to imply that the bonds holding the boranes together are inherently weak. Indeed, the opposite is the case; the B–B and B–H bonds are among the strongest 2-electron bonds known, and the great reactivity of the boranes is to be sought rather in the availability of alternative structures and vacant orbitals of similar energies. Some comparative data are in Table 6.3[22] which shows that the bond enthalpies E for the 2-centre B–B bond in boranes and for the C–C bond in C_2H_6 are essentially identical and that the value for the 3-centre 2-electron BBB bond in boranes is very similar to that for the B–C bond in BMe_3.

Table 6.3 Some enthalpies of atomization (ΔH_f°, 298 K) and comparative bond-enthalpy contributions, E

	BHB(3c,2e)	441	H–H 436

Boranes are extremely reactive compounds and several are spontaneously flammable in air. *Arachno*-boranes tend to be more reactive (and less stable to thermal decomposition) than *nido*-boranes and reactivity also diminishes with increasing mol wt. *Closo*-borane anions are exceptionally stable and their general chemical behaviour has suggested the term "three-dimensional aromaticity".

Boron hydrides have proved to be extremely versatile chemical reagents but the very diversity of their reactions makes a general classification unduly cumbersome. For this reason, the range of behaviour will be illustrated by typical examples taken from the chemistry of the boranes and their anions, arranged approximately according to the size of the borane cluster being discussed. Nearly all boranes are highly toxic when inhaled or absorbed through the skin though they can be safely and conveniently handled with relatively minor precautions.

6.4.4 The chemistry of small boranes and their anions (B_1–B_4)

Diborane occupies a special place because all the other boranes can be prepared from it (directly or indirectly); it is also one of the most studied and synthetically useful reagents in the whole of chemistry.[1,23] B_2H_6 gas can most conveniently be prepared in small quantities by the reaction of I_2 on $NaBH_4$ in diglyme [$(MeOCH_2CH_2)_2O$], or by the reaction of a solid tetrahydroborate with an anhydrous acid:

$$2NaBH_4 + I_2 \xrightarrow[(98\%\ \text{yield})]{\text{diglyme}} B_2H_6 + 2NaI + H_2$$

$$2NaBH_4(c) + 2H_3PO_4(l) \xrightarrow{(70\%\ \text{yield})} B_2H_6(g) + 2NaH_2PO_4(c) + 2H_2(g)$$

When B_2H_6 is to be used as a reaction intermediate without the need for isolation or purification, the best procedure is to add Et_2OBF_3 to $NaBH_4$ in a polyether such as diglyme:

$$3NaBH_4 + 4Et_2OBF_3 \xrightarrow[25°]{\text{diglyme}} 2B_2H_6(g) + 3NaBF_4 + 4Et_2O$$

On an industrial scale gaseous BF_3 can be reduced directly with NaH at 180° and the product trapped out as it is formed to prevent subsequent pyrolysis:

$$2BF_3(g) + 6NaH(c) \xrightarrow{180°} B_2H_6(g) + 6NaF(c)$$

Some 200 tonnes per annum of B_2H_6 is produced commercially, worldwide. Care should be taken in all these reactions because B_2H_6 is spontaneously flammable; its heat of combustion ($-\Delta H°$) is higher per unit weight of fuel than for any other substance except H_2, BeH_2 and $Be(BH_4)_2$: [$-\Delta H°(B_2H_6) = 2165\,kJ\,mol^{-1} = 78.2\,kJ\,g^{-1}$].

The pyrolysis of gaseous B_2H_6 in sealed vessels at temperatures above 100° is exceedingly complex and has only recently been fully elucidated.[24–27] The initiating step is the unimolecular equilibrium dissociation of B_2H_6 to give $2\{BH_3\}$, and the $\{BH_3\}$ then reacts with further B_2H_6 to give $\{B_3H_7\}$ plus H_2 in a concerted rate-controlling reaction via a $\{B_3H_9\}$ transition state. This explains the observed 1.5-order of the kinetics and also successfully interprets all other aspects of the initial reaction:

$$B_2H_6 \rightleftharpoons 2\{BH_3\}$$

$$\{BH_3\} + B_2H_6 \longrightarrow \{B_3H_7\} + H_2$$

In these and subsequent reactions, unstable intermediates that have but transitory existence are placed in curly brackets, {}.

The first stable intermediate, B_4H_{10}, is then formed followed by B_5H_{11}:

$$\{BH_3\} + \{B_3H_7\} \rightleftharpoons B_4H_{10}$$

$$B_2H_6 + \{B_3H_7\} \longrightarrow \{BH_3\} + B_4H_{10} \rightleftharpoons B_5H_{11} + H_2$$

A complex series of further steps gives B_5H_9, B_6H_{10}, B_6H_{12}, and higher boranes, culminating in $B_{10}H_{14}$ as the most stable end product, together with polymeric materials BH_x and a trace of *conjuncto*-icosaboranes $B_{20}H_{26}$.

Careful control of temperature, pressure and reaction time enables the yield of the various intermediate boranes to be optimized. For example, B_4H_{10} is best prepared by storing B_2H_6 under pressure at 25° for 10 days; this gives a 15% yield and quantitative conversion according to the

overall reaction:

$$2B_2H_6 \longrightarrow B_4H_{10} + H_2$$

B_5H_{11} can be prepared in 70% yield by the reaction of B_2H_6 and B_4H_{10} in a carefully dimensioned hot/cold reactor at $+120°/-30°$:

$$2B_4H_{10} + B_2H_6 \rightleftharpoons 2B_5H_{11} + 2H_2$$

Alternative high-yield syntheses of these various boranes via hydride-ion abstraction from borane anions by BBr_3 and other Lewis acids have recently been devised[19] (see p. 162).

From the foregoing it is clear that $\{BH_3\}$ is a fugitive reaction species: it exists only at exceedingly low concentrations but can be isolated and studied using matrix isolation techniques. Thus it can be generated by thermal dissociation of loosely bound 1:1 adducts with Lewis bases, such as $PF_3.BH_3$, and its reactions studied.[28] The relative stability of the adducts $L.BH_3$ has been determined from thermochemical and spectroscopic data and leads to the following unusual sequence:

$$PF_3 < CO < Et_2O < Me_2O < C_4H_8O < C_4H_8S$$
$$< Et_2S < Me_2S < py < Me_3N < H^-$$

Note that both PF_3 and CO form isolable although weak adducts, and that organic sulfide adducts are more stable than those of ethers, thereby showing that BH_3 has some class b acceptor ("soft acid") characteristics despite the absence of low-lying d orbitals on boron (see p. 909). The ligand H^- is a special case since it gives the symmetrical tetrahedral ion BH_4^-, isoelectronic with CH_4 and NH_4^+. Many other complexes of BH_3 with N, P, As, O, S etc. donor atoms are also known and they are readily formed by symmetrical homolytic (cleavage of the bridge bonds in B_2H_6. Occasionally, however, unsymmetrical (heterolytic) cleavage products result, perhaps partly as a result of steric effects,[29] e.g. NH_3, $MeNH_2$ and Me_2NH give unsymmetrical cleavage products whereas Me_3N gives the symmetrical cleavage product, $Me_3N.BH_3$ (see scheme below).

In addition to pyrolysis and cleavage reactions, B_2H_6 undergoes a wide variety of substitution, redistribution, and solvolytic reactions of which the following are representative. Gaseous HCl yields $B_2H_5Cl_t$ whereas Cl_2 (and F_2) give BX_3 directly even at low temperatures and high dilution. Methylation with $PbMe_4$ yields B_2H_5Me, but comproportionation with BMe_3 affords $Me_nB_2H_{6-n}$ ($n = 1-4$), the two BHB bridge bonds remaining intact. Hydrolysis gives the stoichiometric amount of $B(OH)_3$. The related alcoholysis reaction was much used in earlier times as a convenient means of total analysis

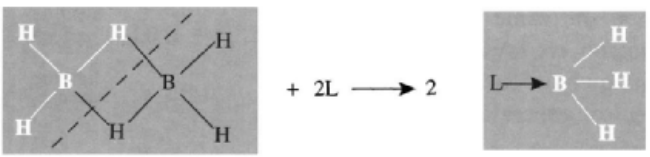
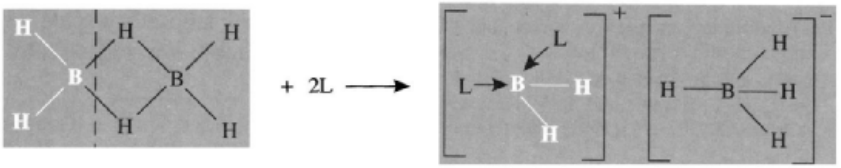
[29] S. G. SHORE, Chap. 3 in ref. 9, pp. 79–174.

Symmetrical (homolytic)



Unsymmetrical (heterolytic)



since the volatile $B(OMe)_3$ could readily be distilled off and determined while the number of moles of H_2 evolved equalled the number of H atoms in the borane molecule:

$$B_2H_6 + 6MeOH \longrightarrow 2B(OMe)_3 + 6H_2$$

This works well for all *nido-* and *arachno-*boranes but not for the *closo*-dianions, which are much less reactive. Reactions of B_2H_6 with NH_3 are complex and, depending on the conditions, yield aminodiborane, $H_2B(\mu\text{-}H)(\mu\text{-}NH_2)BH_2$, or the diammoniate of diborane, $[BH_2(NH_3)_2][BH_4]$ (p. 165); at higher temperatures the benzene analogue borazine, $(HNBH)_3$, results (see p. 210).

The remarkably facile addition of B_2H_6 to alkenes and alkynes in ether solvents at room temperatures was discovered by H. C. Brown and B. C. Subba Rao in 1956:

$$3RCH{=}CH_2 + \tfrac{1}{2}B_2H_6 \longrightarrow B(CH_2CH_2R)_3$$

This reaction, now termed hydroboration, has opened up the quantitative preparation of organoboranes and these, in turn, have proved to be of outstanding synthetic utility.[30,31] It was for his development of this field that H. C. Brown (Purdue) was awarded the 1979 Nobel Prize in Chemistry. Hydroboration is regiospecific, the boron showing preferential attachment to the least substituted C atom (anti-Markovnikov). This finds ready interpretation in terms of electronic factors and relative bond polarities (p. 144); steric factors also work in the same direction. The addition is stereospecific *cis (syn)*. Recent extensions of the methodology have encompassed the significant development of generalized chiral syntheses.[32]

Diborane reacts slowly over a period of days with metals such as Na, K, Ca or their amalgams and more rapidly in the presence of ether:

$$2B_2H_6 + 2Na \longrightarrow NaBH_4 + NaB_3H_8$$

$B_3H_8^-$ prepared in this way was the first polyborane anion (1955); it is now more conveniently made by the reaction

$$B_2H_6 + NaBH_4 \xrightarrow[100°]{\text{diglyme}} NaB_3H_8 + H_2$$

Alternatively, BH_3.thf can be reduced by alkali metal amalgams (M = K, Rb, Cs) to give good yields of solvent-free products:[33]

$$2M/Hg + 4BH_3.thf \xrightarrow{\text{thf}} MBH_4 + MB_3H_8$$

Tetrahydroborates, $M(BH_4)_x$, were first identified in 1940 (M = Li, Be, Al) and since then have been widely exploited as versatile nucleophilic reducing agents which attack centres of low electron density (cf. electrophiles such as B_2H_6 and LBH_3 which attack electron-rich centres). The most stable are the alkali derivatives MBH_4: $LiBH_4$ decomposes above ~380° but the others (Na–Cs) are stable up to ~600°. MBH_4 are readily soluble in water and many other coordinating solvents such as liquid ammonia, amines, ethers ($LiBH_4$) and polyethers ($NaBH_4$). They can be prepared by direct reaction of MH with either B_2H_6 or BX_3 at room temperature though the choice of solvent is often crucial, e.g.:

$$2LiH + B_2H_6 \xrightarrow{Et_2O} 2LiBH_4$$

$$2NaH + B_2H_6 \xrightarrow{\text{diglyme}} 2NaBH_4$$

$$4LiH + Et_2OBF_3 \longrightarrow LiBH_4 + 3LiF + Et_2O$$

$$4NaH + BCl_3 \xrightarrow{Al_2Et_6} NaBH_4 + 3NaCl$$

These laboratory-scale syntheses are clearly unsuitable for large-scale industrial production;

here the preferred route, introduced in the early 1960s is the Bayer process which uses borax (or ulexite), quartz, Na and H_2 under moderate pressure at 450–500°:[34]

$$(Na_2B_4O_7 + 7SiO_2) + 16Na + 8H_2 \longrightarrow 4NaBH_4 + 7Na_2SiO_3$$

The resulting mixture is extracted under pressure with liquid NH_3 and the product obtained as a 98% pure powder (or pellets) by evaporation. An alternative route is:

$$B(OMe)_3 + 4NaH \xrightarrow{250-270°} NaBH_4 + 3NaOMe$$

The resulting mixture is hydrolysed with water and the aqueous phase extracted with Pr^iNH_2.

Worldwide production of $NaBH_4$ is now about 3000 tonnes per annum (1990) and the price for powdered $NaBH_4$ in 1991 was $48.39/kg.

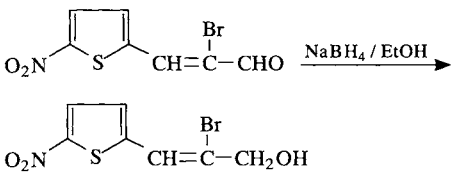
Reaction of MBH_4 with electronegative elements is also often crucially dependent on the solvent and on the temperature and stoichiometry of reagents. Thus $LiBH_4$ reacts with S at −50° in the presence of Et_2O to give $Li[BH_3SH]$, whereas at room temperature the main products are Li_2S, $Li[B_3S_2H_6]$, and H_2; at 200° in the absence of solvent $LiBH_4$ reacts with S to give $LiBS_2$ and either H_2 or H_2S depending on whether S is in excess. Similarly, MBH_4 react with I_2 in cyclohexane at room temperature to give BI_3, HI and MI, whereas in diglyme B_2H_6 is formed quantitatively (p. 164).

The product of reaction of BH_4^- with element halides depends on the electropositivity of the element. Halides of the electropositive elements tend to form the corresponding $M(BH_4)_x$, e.g. M = Be, Mg, Ca, Sr, Ba; Zn, Cd; Al, Ga, Tl^I; lanthanides; Ti, Zr, Hf and U^{IV}. Halides of the less electropositive elements tend to give the hydride or a hydrido-complex since the BH_4 derivative is either unstable or non-existent: thus $SiCl_4$ gives SiH_4; PCl_3 and PCl_5 give PH_3; Ph_2AsCl gives Ph_2AsH; $[Fe(\eta^5\text{-}C_5H_5)(CO)_2Cl]$ gives $[Fe(\eta^5\text{-}C_5H_5)(CO)_2H]$, etc.

A particularly interesting reaction (and one of considerable commercial value in the BOROL process for the *in situ* bleaching of wood pulp) is the production of dithionite, $S_2O_4^{2-}$, from SO_2:

$$NaBH_4 + 8NaOH + 8SO_2 \xrightarrow{90\%\ \text{yield}} 4Na_2S_2O_4 + NaBO_2 + 6H_2O$$

In reactions with organic compounds, $LiBH_4$ is a stronger (less selective) reducing agent than $NaBH_4$ and can be used, for example, to reduce esters to alcohols. $NaBH_4$ reduces ketones, acid chlorides and aldehydes under mild conditions but leaves other functions (such as –CN, $-NO_2$, esters) untouched; it can be used as a solution in alcohols, ethers, dimethylsulfoxide, or even aqueous alkali (pH > 10). Perhaps the classic example of its selectivity is shown below where an aldehyde group is hydrogenated in high yield without any attack on the nitro group, the bromine atom, the olefinic bond, or the thiophene ring:



Industrial interest in $LiBH_4$, and particularly $NaBH_4$, stems not only from their use as versatile reducing agents for organic functional groups and their use in the bleaching of wood pulp, but also for their application in the electroless (chemical) plating of metals. Traditionally, either sodium hypophosphite, NaH_2PO_2, or formaldehyde have been used (as in the silvering of glass), but $NaBH_4$ was introduced on an industrial scale in the early 1960s, notably for the deposition of Ni on metal or non-metallic substrates; this gives corrosion-resistant, hard, protective coatings, and is also useful for metallizing plastics prior to

[34] R. WADE, in R. THOMPSON (ed.), *Speciality Inorganic Chemistry*, Royal Soc. Chem., London, 1981, pp. 25–58; see also *Kirk–Othmer Encyclopedia of Chemical Technology*, 4th edn., John Wiley, New York, 1992, Vol. 4, pp. 490–501.

further electroplating or for depositing contacts in electronics. Chemical plating also achieves a uniform thickness of deposit independent of the geometric shape, however complicated.

The BH_4^- ion is essentially non-coordinating in its alkali metal salts. However, despite the fact that it is isoelectronic with methane, BH_4^- has been found to act as a versatile ligand, forming many coordination compounds by means of 3-centre B–H→M bonds to somewhat less electropositive metals.[35–37] Indeed, BH_4^- affords a rare example of a ligand that can act in at least 6 coordination modes: η^1, η^2, η^3, $\mu(\eta^2,\eta^2)$, $\mu(\eta^3)$ and $\mu(\eta^4)$. Such complexes are usually readily prepared by reacting the corresponding (or closely related) halides with BH_4^- in what are essentially ligand replacement reactions. Some examples follow:

η^1: $[Cu(\eta^1\text{-}BH_4)(PMePh_2)_3]$ (see Fig. 6.14a); $[Cu(\eta^1\text{-}BH_4)\{MeC(CH_2PPh_2)_3\}]$; $[FeH(\eta^1\text{-}BH_4)$-

$\mu(\eta^4)$: $[Ce(\mu{:}\eta^4\text{-}BH_4)(\eta^5\text{-}C_5H_3Bu^t_2)]_2$ (Fig. 6.14f)

Many complexes have more than one coordination mode of BH_4^- featured in their structure, e.g. $[U^{III}(\eta^2\text{-}BH_4)(\eta^3\text{-}BH_4)_2(dmpe)_2]$. Likewise, whereas $[M(BH_4)_4]$ are monomeric 12-coordinate complexes for M = Zr, Hf, Np, Pu, they are polymeric for M = Th, Pa, U: the coordination number rises to 14 and each metal centre is coordinated by two η^3-BH_4^- and four bridging η^2-BH_4^- groups. It is clear that among the factors which determine the mode adopted are the size of the metal atom and the steric requirements of the co-ligands. Many of the complexes are fluxional on an nmr timescale in solution; indeed, this property of fluxionality, which has been increasingly recognized to occur in many inorganic and organometallic systems, was first observed (1955) on the tris-bidentate complex $[Al(\eta^2\text{-}BH_4)_3]$.[38]

The $B_3H_8^-$ ion (p. 166) is a triangular cluster of C_s (rather than C_{2v}) symmetry (see Fig. 6.15a);[39] the bridging H_μ atoms are essentially in the B_3 plane with H_t above and below. While it has been conventional to represent the cluster bonding in terms of two BHB and one B–B bond (Fig. 6.15b), recent high-level computations[40] suggest the presence of a 3-centre BBB bond, as depicted approximately in Fig. 6.15c.

The *arachno*-anion $B_3H_8^-$ is the only binary triboron species that is stable at room temperature and above. It can be viewed as a ligand-stabilized $\{B_3H_7\}$ group, i.e. $(L.B_3H_7]$, in which the ligand is H^- (cf. BH_4^-). However, the ion is completely fluxional in solution, all three boron atoms (and all eight protons) being equivalent on an nmr timescale. The $B_3H_8^-$ anion has an

B_3H_8 (2013) (2103)

(a) (b) (c)

Figure 6.15 (a) Structure of $B_3H_8^-$ showing C_s symmetry; (b) dimensions and representation of the bonding using a direct B–B bond (2013) for the longer (unbridged) B–B distance; (c) most recent (2103) description of the bonding in terms of a 3-centre BBB bond. (See p. 158 for *styx* formalism.)

extensive reaction chemistry both as a reducing agent and as a source of *arachno*-B_4H_{10} (p. 162). Conversely, unsymmetrical (heterolytic) cleavage of B_4H_{10} with ligands, L, such as NH_3 yield $[L_2BH_2]^+[B_3H_8]^-$.

The $B_3H_8^-$ ion is also a versatile ligand and forms bidentate and even tridentate complexes with many metal centres.[41] The octahedrally coordinated 18-electron manganese(I) complex $[Mn(\eta^2\text{-}B_3H_8)(CO)_4]$ is a particularly instructive example. As can be seen from Fig. 6.16a it has a cluster structure that is clearly related to that of B_4H_{10} (13). When heated to 180°C or irradiated with ultraviolet light the complex loses one of the four CO ligands and this enables a further B–H group to coordinate to give the trihapto complex *fac*-$[Mn(\eta^3\text{-}B_3H_8)(CO)_3]$ (Fig. 6.16b). Treatment of this product with an excess of CO under moderate pressure regenerates the original dihapto species by a simple ligand replacement reaction.[42]

6.4.5 Intermediate-sized Boranes and their Anions (B_5–B_9)

Pentaborane(9), *nido*-B_5H_9, is by far the most studied borane in this group. It can be prepared by passing a 1:5 mixture of B_2H_6 and H_2 at subatmospheric pressure through a furnace at 250°C with a residence time of 3 s (or at 225° with a 15 s residence time); there is a 70% yield and 30% conversion. Alternatively B_2H_6 can be pyrolysed for 2.5 days in a static hot/cold reactor at 180°/−80°. B_5H_9 is a colourless, volatile liquid, bp 60.0°; it is thermally stable but chemically very reactive and spontaneously flammable in air. Its structure is essentially a square-based pyramid of B atoms each of which carries a terminal H atom and there are 4 bridging H atoms around the base (structure 9, p. 154). The slant edge of the pyramid, B(1)–B(2), is 168 pm and the basal interboron distances, B(2)–B(3) etc, are 178 pm; other key dimensions are B–H_t 122 pm, B–H_μ 135 pm and B–H_μ–B 83°. Calculations suggest that B(1) has a slightly higher electron density than the basal borons and that H_μ is slightly more positive than H_t. Apex-substituted derivatives 1-XB_5H_8 can

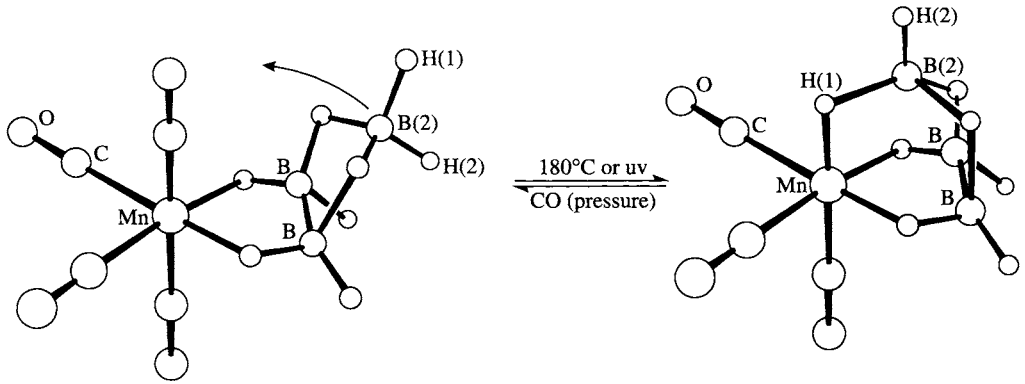

Figure 6.16 Ligand replacement reaction of $[Mn(\eta^2\text{-}B_3H_8)(CO)_4]$ (see text).

readily be prepared by electrophilic substitution (e.g. halogenation or Friedel-Crafts alkylation with RX or alkenes), whereas base-substituted derivatives $2\text{-}XB_5H_8$ result when nucleophilic reaction is induced by amines or ethers, or when $1\text{-}XB_5H_8$ is isomerized in the presence of a Lewis base such as hexamethylenetetramine or an ether:

$$B_5H_9 \xrightarrow{I_2/AlX_3} 1\text{-}IB_5H_8 \xrightarrow[(CH_2)_6N_4]{\text{base}} 2\text{-}IB_5H_8$$

$$\xrightarrow{SbF_3} 2\text{-}FB_5H_8$$

Further derivatives can be obtained by metathesis, e.g.

$$2\text{-}ClB_5H_8 + NaMn(CO)_5 \longrightarrow$$

$$2\text{-}\{(CO)_5Mn\}B_5H_8 \text{ (also Re)}$$

B_5H_9 reacts with Lewis bases (electron-pair donors) to form adducts, some of which have now been recognized as belonging to the new series of *hypho*-borane derivatives B_nH_{n+8} (p. 152). Thus PMe_3 gives the adduct $[B_5H_9(PMe_3)_2]$ which is formally analogous to $[B_5H_{11}]^{2-}$ and the (unknown) borane B_5H_{13}. $[B_5H_9(PMe_3)_2]$ has a very open structure in the form of a shallow pyramid with the ligands attached at positions 1 and 2 and with major rearrangement of the H atoms (Fig. 6.17a). Chelating phosphine ligands such as $(Ph_2P)_2CH_2$ and $(Ph_2PCH_2)_2$ have similar structures but $[B_5H_9(Me_2NCH_2CH_2NMe_2)]$ undergoes a much more severe distortion in which the ligand chelates a single boron atom, B(2), which is joined to the rest of the molecule by a single bond to the apex B(1) (Fig. 6.17b).[43] With NH_3 as ligand (at −78°) complete excision of one B atom occurs by "unsymmetrical cleavage" to give $[(NH_3)_2BH_2]^+[B_4H_7]^-$

B_5H_9 also acts as a weak Brønsted acid and, from proton competition reactions with other boranes and borane anions, it has been established that acidity increases with increasing size of the borane cluster and that *arachno*-boranes are more acidic than *nido*-boranes:

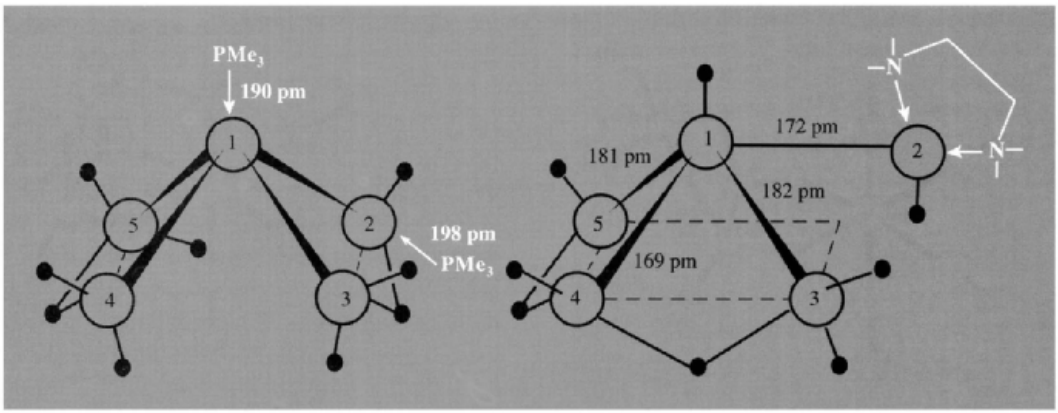
nido : $B_5H_9 < B_6H_{10} < B_{10}H_{14} < B_{16}H_{20} < B_{18}H_{22}$

arachno : $B_4H_{10} < B_5H_{11} < B_6H_{12}$ and

$B_4H_{10} > B_6H_{10}$

Accordingly, B_5H_9 can be deprotonated at low temperatures by loss of H_μ to give $B_5H_8^-$ providing a sufficiently strong base such as a lithium alkyl or alkali metal hydride is used. Bridge-substituted derivatives of B_5H_9 can then be obtained by reacting MB_5H_8 with chloro compounds such as R_2PCl, Me_3SiCl, Me_3GeCl,

[43] N. W. Alcock, H. M. Colquhoun, G. Haran, J. F. Sawyer and M. G. H. Wallbridge, *J. Chem. Soc., Chem. Commun.*, 368–70 (1977); *J. Chem. Soc., Dalton Trans.*, 2243–55 (1982).



(a) $[B_5H_9(PMe_3)_2]$ (b) $[B_5H_9(Me_2NCH_2CH_2NMe_2)]$

Figure 6.17 Structure of *hypho*-borane derivatives: (a) $[B_5H_9(PMe_3)_2]$ — the distances B(1)-B(2) and B(2)-B(3) are as in B_5H_9 (p. 170) but B(3)···B(4) is 295 pm (cf. B···B 297 pm in B_5H_{11}, structure 14, p. 154), and (b) $[B_5H_9(Me_2NCH_2CH_2NMe_2)]$ — the distances B(2)···B(3) and B(2)···B(5) are 273 and 272 pm respectively.

or even Me_2BCl to give compounds in which the 3-centre $B-H_\mu-B$ bond has been replaced by a 3-centre bond between the 2 B atoms and P, Si, Ge or B respectively. Many metal-halide coordination complexes react similarly, and the products can be considered as adducts in which the $B_5H_8^-$ anion is acting formally as a 2-electron ligand via a 3-centre B–M–B bond.[44,45] Thus $[Cu^I(B_5H_8)(PPh_3)_2]$ (Fig. 6.18a) is readily formed by the low-temperature reaction of KB_5H_8 with $[CuCl(PPh_3)_3]$ and analogous 16-electron complexes have been prepared for many of the later transition elements, e.g. $[Cd(B_5H_8)Cl(PPh_3)]$, $[Ag(B_5H_8)(PPh_3)_2]$ and $[M^{II}(B_5H_8)XL_2]$, where M^{II} = Ni, Pd, Pt; X = Cl, Br, I; L_2 = a diphosphine or related ligand. By contrast, $[Ir^I(CO)Cl(PPh_3)_2]$ reacts by oxidative insertion of Ir and consequent cluster expansion to give $[(IrB_5H_8)(CO)(PPh_3)_2]$ which, though superficially of similar formula, has the structure of an irida-*nido*-hexaborane (Fig. 6.18b).[46] In this, the $\{Ir(CO)(PPh_3)_2\}$ moiety replaces a basal BH_tH_μ unit in B_6H_{10} (structure 10, p. 154).

Cluster-expansion and cluster-degradation reactions are a feature of many polyhedral borane species. Examples of cluster-expansion are:[11,47]

$$LiB_5H_8 + \tfrac{1}{2}B_2H_6 \xrightarrow[\text{(fast)}]{Et_2O/-78^\circ} LiB_6H_{11}$$

$$\xrightarrow{HCl} B_6H_{12}$$

$$LiB_5H_8 + B_2H_6 \xrightarrow[\text{(slow)}]{Me_2O/-78^\circ} \{LiB_7H_{14}\}$$

$$\longrightarrow B_6H_{10} + LiBH_4$$

$$1.8B_5H_9 + MH \xrightarrow[15\,h]{thf/r.t.} MB_9H_{14} + H_2 \text{ plus}$$

$$KB_9H_{14} + 0.4B_5H_9 \xrightarrow[20\,h]{\text{glyme/85°}} KB_{11}H_{14} + 1.8H_2$$

Cluster degradation has already been mentioned in connection with the unsymmetrical cleavage reaction (p. 165) and other examples are:

$$[NMe_4]B_5H_8 + 6Pr^iOH \longrightarrow [NMe_4]B_3H_8 + 2B(OPr^i)_3 + 3H_2$$

$$\text{and } B_5H_9 \xrightarrow{\text{tmed}} B_5H_9(\text{tmed}) \xrightarrow{\text{MeOH}} B_4H_8(\text{tmed}) + B(OMe)_3 + 2H_2$$

(where Pr^i is Me_2CH- and tmed is Me_2NCH_2-CH_2NMe_2).

Replacement of a {BH} unit in B_5H_9 by an "isoelectronic" organometallic group such as $\{Fe(CO)_3\}$ or $\{Co(\eta^5\text{-}C_5H_5)\}$ can also occur, and this illustrates the close interrelation between metalloboranes, metal–metal cluster compounds, and organometallic complexes in general (see Panel).

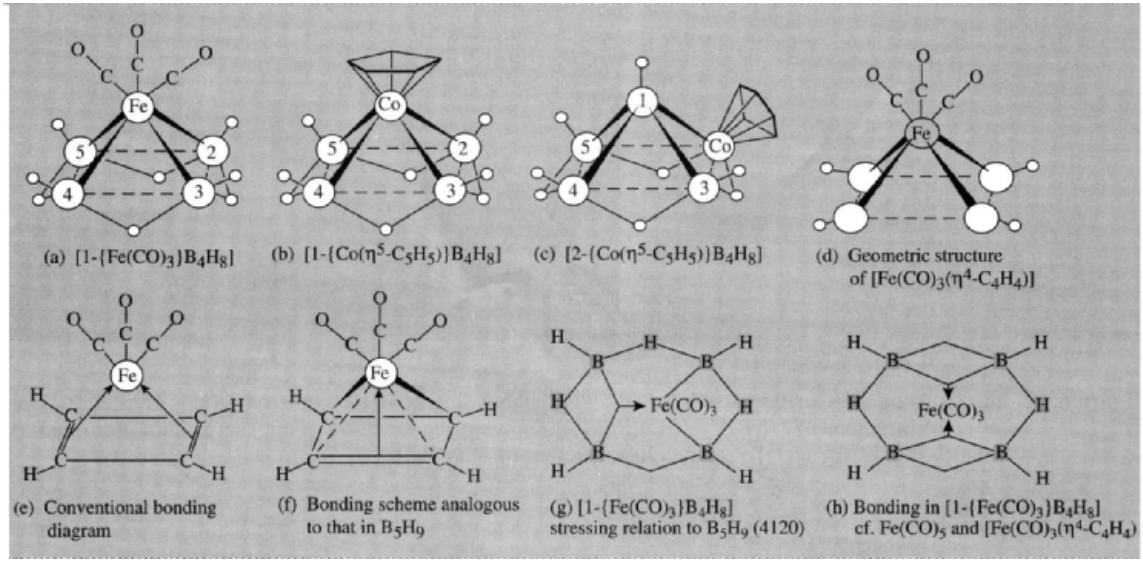
The structures of several other *nido*- and *arachno*- B_5–B_9 boranes are given on page 154 but a detailed discussion of their chemistry is beyond the scope of this treatment. Further information is in refs. 9, 11, 27, 51 and 52.

6.4.6 *Chemistry of* nido-*decaborane*, $B_{10}H_{14}$

Decaborane is the most studied of all the polyhedral boranes and at one time (mid-1950s) was manufactured on a multitonne scale in the USA as a potential high-energy fuel. It is now obtainable in research quantities by the pyrolysis of B_2H_6 at 100–200°C in the presence of catalytic amounts of Lewis bases such as Me_2O. $B_{10}H_{14}$ is a colourless, volatile, crystalline solid (see Table 6.2, p. 163) which

Metalloboranes, Metal Clusters and Organometallic Complexes

Copyrolysis of B_5H_9 and $[Fe(CO)_5]$ in a hot/cold reactor at 220°/20° for 3 days gives an orange liquid (mp 5°C) of formula $[1\text{-}\{Fe(CO)_3\}B_4H_8]$ having the structure shown in (a).[48] The isoelectronic complex $[1\text{-}\{Co(\eta^5\text{-}C_5H_5)\}B_4H_8]$ (structure b) can be obtained as yellow crystals by pyrolysis at 200° of the corresponding basal derivative $[2\text{-}\{Co(\eta^5\text{-}C_5H_5)\}B_4H_8]$ (structure (c)) which is obtained as red crystals from the reaction of NaB_5H_8 and $CoCl_2$ with NaC_5H_5 in thf at −20°.[49] The course of these reactions is obscure and other products are also obtained.



As $\{BH_2\}$ is isoelectronic with $\{CH\}$, these metalloborane clusters are isoelectronic with the cyclobutadiene adduct $[Fe(\eta^4\text{-}C_4H_4)(CO)_3]$, see (d), (e) and (f). Likewise $\{Fe(CO)_3\}$ or $\{Co(\eta^5\text{-}C_5H_5)\}$ can replace a $\{BH\}$ group in B_5H_9 and two descriptions of the bonding are given in (g) and (h): the Fe atom supplies 2 electrons and 3 atomic orbitals to the cluster (as does BH), thereby enabling it to form 2 Fe–B σ bonds and to accept a pair of electrons from adjacent B atoms to form a 3-centre BMB bond. In this description the Fe atom is formally octahedral Fe^{II} (d^6). Alternatively, diagram (h) emphasizes the relation between $[1\text{-}\{Fe(CO)_3\}B_4H_8]$ and $[Fe(CO)_3(\eta^4\text{-}C_4H_4)]$ or $[Fe(CO)_5]$: the Fe atom accepts 2 pairs of electrons to form two 3-centre BMB bonds and is formally Fe^0 with a trigonal bipyramidal arrangement of bonds.

It is possible to replace more than one $\{BH\}$ group in B_5H_9 by a metal centre, e.g in the dimetalla species $[1,2\text{-}\{Fe(CO)_3\}_2B_3H_7]$;[50] it is also notable that the iron carbonyl cluster compound $[Fe_5(CO)_{15}C]$ (p. 1108) features the same square-pyramidal cluster in which 5 $\{Fe(CO)_3\}$ groups have replaced the five $\{BH\}$ groups in B_5H_9, and the C atom (in the centre of the base) replaces the 4 bridging H atoms by supplying the 4 electrons required to complete the bonding.

Many other equivalent groups can be envisaged and the formalism permits a unified approach to possible synthetic routes and to probable structures of a wide variety of compounds.[17,51–53]

[53] T. P. FEHLNER (ed.), *Inorganometallic Chemistry*, Plenum, New York, 1992, 401 pp.

is insoluble in H_2O but readily soluble in a wide range of organic solvents. Its structure (36) can be regarded as derived from the 11 B atom cluster $B_{11}H_{11}^{2-}$ (p. 153) by replacing the unique BH group with 2 electrons and appropriate addition of $4H_\mu$. MO-calculations give the sequence of electron charge densities at the various B atoms as 2, 4 > 1, 3 > 5, 7, 8, 10 > 6, 9 though the total range of deviation from charge neutrality is less than ±0.1 electron per B atom. The chemistry of $B_{10}H_{14}$ can be conveniently discussed under the headings (a) proton abstraction, (b) electron addition, (c) adduct formation, (d) cluster rearrangements, cluster expansions, and cluster degradation reactions, and (e) metalloborane and other heteroborane compounds.

$B_{10}H_{14}$ can be titrated in aqueous/alcoholic media as a monobasic acid, pK_a 2.70:

$$B_{10}H_{14} + OH^- \rightleftharpoons B_{10}H_{13}^- + H_2O$$

Proton abstraction can also be effected by other strong bases such as H^-, OMe^-, NH_2^-, etc. The $B_{10}H_{13}^-$ ion is formed by loss of a bridge proton, as expected, and this results in a considerable shortening of the B(5)–B(6) distance from 179 pm in $B_{10}H_{14}$ to 165 pm in $B_{10}H_{13}^-$ (structures 36, 37). Under more forcing conditions with NaH a second H_μ can be removed to give $Na_2B_{10}H_{12}$; the probable structure of $B_{10}H_{12}^{2-}$ is (38) and the anion acts as a formal bidentate (tetrahapto) ligand to many metals (p. 177).

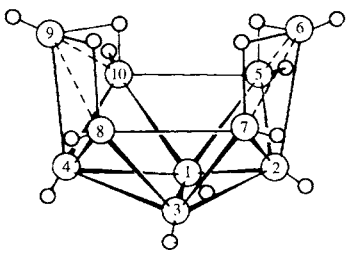
Electron addition to $B_{10}H_{14}$ can be achieved by direct reaction with alkali metals in ethers, benzene or liquid NH_3:

$$B_{10}H_{14} + 2Na \longrightarrow Na_2B_{10}H_{14}$$

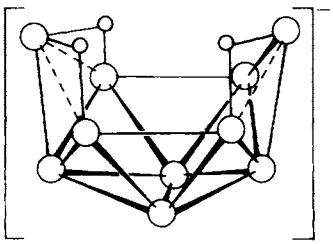
A more convenient preparation of the $B_{10}H_{14}^{2-}$ anion uses the reaction of aqueous BH_4^- in alkaline solution:

$$B_{10}H_{14} \xrightarrow{+BH_4^- - \{BH_3\}} B_{10}H_{15}^- \underset{+H^+}{\overset{-H^+}{\rightleftharpoons}} B_{10}H_{14}^{2-}$$

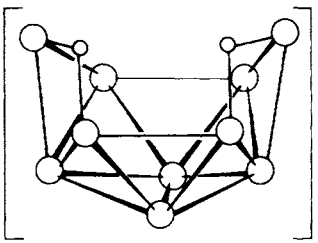
Structure (39) conforms to the predicted (2632) topology (p. 158) and shows that the 2 added electrons have relieved the electron deficiency to the extent that the 2 B–H_μ–B groups have been



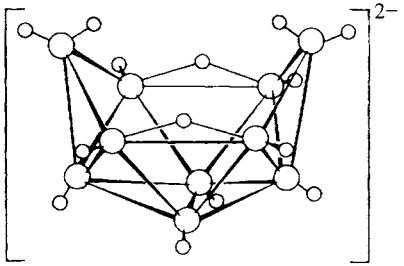
(36) $B_{10}H_{14}$



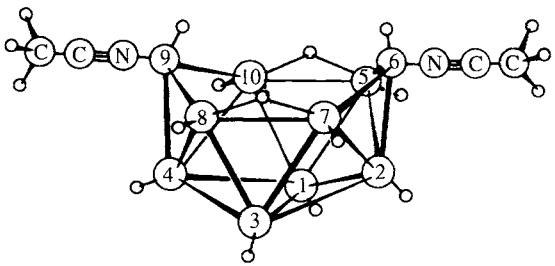
(37) $B_{10}H_{13}^-$



(38) $B_{10}H_{12}^{2-}$



(39) $B_{10}H_{14}^{2-}$



(40) $B_{10}H_{12}(MeCN)_2$

converted to B–H_t with the consequent appearance of $2BH_2$ groups in the structure. Calculations show that this conversion of a *nido*- to an *arachno*-cluster reverses the sequence of electron charge density at the 2, 4 and 6, 9 positions so that for $B_{10}H_{14}^{2-}$ the sequence is 6, 9 > 1, 3 > 5, 7, 8, 10 > 2, 4; this is paralleled by changes in the chemistry. $B_{10}H_{14}^{2-}$ can formally be regarded as $B_{10}H_{12}L_2$ for the special case of $L = H^-$. Compounds of intermediate stoichiometry $B_{10}H_{13}L^-$ are formed when $B_{10}H_{14}$ is deprotonated in the presence of the ligand L:

$$B_{10}H_{14} \xrightarrow{Et_2O/NaH} B_{10}H_{13}^- \xrightarrow{Et_2O/L} [B_{10}H_{13}L]^- \xrightarrow{NMe_4^+} [NMe_4][B_{10}H_{13}L]$$

The adducts $B_{10}H_{12}L_2$ (structure 40) can be prepared by direct reaction of $B_{10}H_{14}$ with L or by ligand replacement reactions:

$$B_{10}H_{14} + 2MeCN \longrightarrow B_{10}H_{12}(MeCN)_2 + H_2$$

$$B_{10}H_{12}L_2 + 2L' \longrightarrow B_{10}H_{12}L'_2 + 2L$$

Ligands L, L′ can be drawn from virtually the full range of inorganic and organic neutral and anionic ligands and, indeed, the reaction severely limits the range of donor solvents in which $B_{10}H_{14}$ can be dissolved. The approximate sequence of stability is:

$$SR_2 < RCN < AsR_3 < RCONMe_2 < P(OR)_3 < py \approx NEt_3 \approx PPh_3$$

The stability of the phosphine adducts is notable as is the fact that thioethers readily form such adducts whereas ethers do not. Bis-ligand adducts of moderate stability play an important role in activating decaborane for several types of reaction to be considered in more detail in subsequent paragraphs, e.g.:

Substitution: $B_{10}H_{12}(SR_2)_2 + HX \xrightarrow{C_6H_6/20^\circ}$ 6-(5-)$XB_{10}H_{13}$ (X = F, Cl, Br, I)

Cluster rearrangement: *arachno*-$B_{10}H_{12}(NEt_3)_2 \longrightarrow [NEt_3H]^+{}_2[$*closo*-$B_{10}H_{10}]^{2-}$

Cluster addition: *arachno*-$B_{10}H_{12}(SR_2)_2 + 2RC{\equiv}CR \longrightarrow$ *closo*-$B_{10}H_{10}(CR)_2 + 2SR_2 + H_2$

Cluster degradation: $B_{10}H_{12}L_2 + 3ROH \longrightarrow B_9H_{13}L + B(OR)_3 + L + H_2$

In this last reaction it is the coordinated B atom at position 9 that is solvolytically cleaved from the cluster.

Electrophilic substitution of $B_{10}H_{14}$ follows the sequence of electron densities in the ground-state molecule. Thus halogenation in the presence of $AlCl_3$ leads to 1- and 2-monosubstituted derivatives and to 2,4-disubstitution. Similarly, Friedel–Crafts alkylations with $RX/AlCl_3$ (or $FeCl_3$) yield mixtures such as 2-$MeB_{10}H_{13}$, 2,4- and 1,2-$Me_2B_{10}H_{12}$, 1,2,3- and 1,2,4-$Me_3B_{10}H_{11}$, and 1,2,3,4-$Me_4B_{10}H_{10}$. By contrast, nucleophilic substitution (like the adduct formation with Lewis bases) occurs preferentially at the 6 (9) position; e.g., LiMe produces 6-$MeB_{10}H_{13}$ as the main product with smaller amounts of 5-$MeB_{10}H_{13}$, 6,5(8)-$Me_2B_{10}H_{12}$ and 6,9-$Me_2B_{10}H_{12}$.

$B_{10}H_{14}$ undergoes numerous cluster-addition reactions in which B or other atoms become incorporated in an expanded cluster. Thus in a reaction which differs from that on p. 175 BH_4^- adds to $B_{10}H_{14}$ with elimination of H_2 to form initially the *nido*-$B_{11}H_{14}^-$ anion (structure 41, p. 178) and then the *closo*-$B_{12}H_{12}^{2-}$:

$$B_{10}H_{14} + LiBH_4 \xrightarrow{\text{monoglyme/90}^\circ} LiB_{11}H_{14} + 2H_2$$

$$B_{10}H_{14} + 2LiBH_4 \longrightarrow Li_2B_{12}H_{12} + 5H_2$$

A more convenient high-yield synthesis of $B_{12}H_{12}^{2-}$ is by the direct reaction of amine-boranes with $B_{10}H_{14}$ in the absence of solvents:

$$B_{10}H_{14} + 2Et_3NBH_3 \xrightarrow{90\text{–}100^\circ} [NEt_3H]_2^+[B_{12}H_{12}]^{2-} + 3H_2$$

Heteroatom cluster addition reactions are exemplified by the following:

$$B_{10}H_{14} + Me_3NAlH_3 \xrightarrow{Et_2O} [NMe_3H]^+[AlB_{10}H_{14}]^- + H_2$$

$$B_{10}H_{14} + 2TlMe_3 \xrightarrow{Et_2O} [TlMe_2]^+[B_{10}H_{12}TlMe_2]^-$$

The Concept of Boranes as Ligands

Boranes are usually regarded as being electron-deficient, in the sense that they have an insufficient number of electrons to form classical 2-centre 2-electron bonds between each contiguous pair of atoms. However, in the mid-1960s several groups began to realize that, far from being deficient in electrons, many boranes and their anions could act as very effective polyhapto ligands: that is, they could form donor–acceptor complexes (coordination compounds, Chap. 19) in which the borane cluster itself was acting as the electron donor or ligand. The application of this astonishing idea has extended enormously the range of boron hydride compounds which can be made.[54] Many aspects have already been alluded to in the preceding pages and these are briefly summarized in this Panel.

Boranes can act as ligands either by forming 3-centre, 2-electron B–H–M bonds (analogous to BHB bonds) or by forming direct B_nM bonds ($n = 1$–6, analogous to B–B, BBB etc bonds). All hapticities from η^1–η^6 and occasionally beyond are known. The various coordination modes of BH_4^- and $B_3H_8^-$ were discussed on pp. 168–71; these involve the conversion of B–H_t bonds to B–H→M bonds. Likewise, the use of $B_5H_8^-$ as an η^2-ligand was described on pp. 172–3, this involves the notional donation to a metal centre of the electron pair in a B–B bond, thus forming a BMB 3-centre bond. $B_5H_8^-$ can also act as a notional η^1-donor by replacement of a terminal H atom in B_5H_9 with a metal centre; e.g. direct reaction of B_5H_8Cl or B_5H_8Br with $NaM(CO)_5$ to give $[M(\eta^1\text{-}2\text{-}B_5H_8)(CO)_5]$ (M = Mn, Re).

It is clear that some boranes are amphoteric Lewis acid/bases — that is they can act either as electron-pair donors as above or as electron-pair acceptors (e.g. in $L.BH_3$ and $L.B_3H_7$). It follows that a borane donor could conceivably ligate to a borane acceptor to form a borane–borane complex, i.e. a larger borane, e.g. $BH_4^- + \{BH_3\} \longrightarrow B_2H_7^-$ (p. 154). In this sense B_2H_6 itself could be regarded either as a coordination complex of BH_4^- with the notional cation $\{BH_2^+\}$, or as the mutual coordination of two monodentate $\{BH_3\}$ units. Replacement of these donors with stronger ligands such as NH_3 or NMe_3 would then result in either unsymmetrical or symmetrical cleavage of B_2H_6 as discussed on p. 165. Likewise, B_4H_{10} could be regarded either as a complex between η^2-$B_3H_8^-$ and $\{BH_2^+\}$ or as a mutual coordination between $\{B_3H_7\}$ and $\{BH_3\}$; reaction with stronger ligands, L, would then yield either $[L_2BH_2]^+[B_3H_8]^-$ or $L.B_3H_7$ and $L.BH_3$ by ligand displacement reactions (pp. 169–70).

The neutral *nido*-borane B_6H_{10} (structure 10) has a basal B–B bond (see p. 159) and this enables it to act as a ligand by displacing ethene from Zeise's salt (p. 930).

$$K[Pt(\eta^2\text{-}C_2H_4)Cl_3] + 2B_6H_{10} \longrightarrow \textit{trans}\text{-}[Pt(\eta^2\text{-}B_6H_{10})_2Cl_2] + C_2H_4 + KCl$$

Similarly, reaction of B_6H_{10} with $Fe_2(CO)_9$ (p. 1104) at room temperature results in the smooth elimination of $Fe(CO)_5$ to form $[Fe(\eta^2\text{-}B_6H_{10})(CO)_4]$ as a stable, volatile yellow solid. Use of these electron-donor properties of B_6H_{10} towards reactive (vacant orbital) borane radicals resulted in the preparation of several new *conjuncto*-boranes, e.g. $B_{13}H_{19}$, $B_{14}H_{22}$ and $B_{15}H_{23}$ (p. 162).

Another important concept is the notion of stabilization by means of coordination. A classic example is the stabilization of the fugitive species cyclobutadiene, $\{C_4H_4\}$ by coordination to $\{Fe(CO)_3\}$ (p. 936). As the C atom is isoelectronic with $\{BH\}$, so $\{C_4H_4\}$ is isoelectronic with the borane fragment $\{B_4H_8\}$ which is similarly stabilized by coordination to $\{Fe(CO)_3\}$ or the isoelectronic $\{Co(\eta^5\text{-}C_5H_5)\}$ (see Panel on p. 174). Indeed it is a general feature of metallaborane chemistry that such clusters are often much more stable than are the parent boranes themselves.

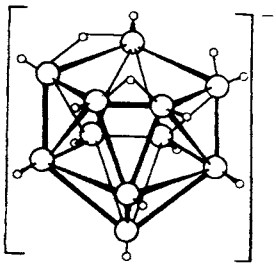
As a result of the systematic application of coordination-chemistry principles, dozens of previously unsuspected structure types have been synthesized in which polyhedral boranes or their anions can be considered to act as ligands which donate electron density to metal centres, thereby forming novel metallaborane clusters.[36,44,45,51–54] Some 40 metals have been found to act as acceptors in this way (see also p. 178). The ideas have been particularly helpful in emphasizing the close interconnection between several previously separated branches of chemistry, notably boron hydride cluster chemistry, metallaborane and metallacarbaborane chemistry (pp. 189–95), organometallic chemistry and metal–metal cluster chemistry. All are now seen to be parts of a coherent whole.

It is also noteworthy that Alfred Stock, who is universally acclaimed as the discoverer of the boron hydrides (1912),[10] was also the first to propose the use of the term "ligand" (in a lecture in Berlin on 27 November 1916).[55] Both events essentially predate the formulation by G. N. Lewis of the electronic theory of valency (1916). It is therefore felicitous that, albeit some 20 years after Stock's death in 1946, two such apparently disparate aspects of his work should be connected in the emerging concept of "boranes as ligands".

---

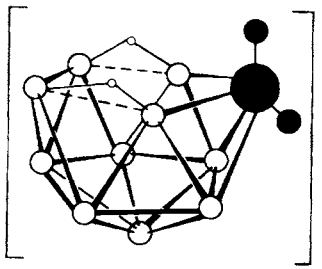
[54] N. N. GREENWOOD, Chap 28 in G. B. KAUFFMAN (ed.), *Coordination Chemistry: A Century of Progress* A.C.S. Symposium Series No. 565 (1994) pp. 333–45.

[55] A. STOCK, *Berichte* **50**, 170 (1917).

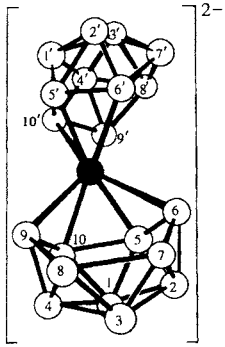


(41) *nido*-$B_{11}H_{14}^-$

(The open face comprises a fluxional system involving the two H_μ atoms and the *endo*-H_t atom of the BH_2 group)



(42) *nido*-$[B_{10}H_{12}TlMe_2]^-$



(43) $[Zn(B_{10}H_{12})_2]^{2-}$

$$B_{10}H_{14} + 2ZnR_2 \xrightarrow{Et_2O} [B_{10}H_{12}Zn(Et_2O)_2]$$

$$\xrightarrow{H_2O/Me_4NCl} [NMe_4]^+{}_2[Zn(B_{10}H_{12})_2]^{2-}$$

The structure of the highly reactive anion $[AlB_{10}H_{14}]^-$ is thought to be similar to *nido*-$B_{11}H_{14}^-$ with one facial B atom replaced by Al. The metal alkyls react somewhat differently to give extremely stable metalloborane anions which can be thought of as complexes of the bidentate ligand $B_{10}H_{12}^{2-}$ (structures 42, 43).[44,51,52] Many other complexes $[M(B_{10}H_{12})_2]^{2-}$ and $[L_2M(B_{10}H_{12})]$ are known with similar structures except that, where M = Ni, Pd, Pt, the coordination about the metal is essentially square-planar rather than pseudo-tetrahedral as for Zn, Cd and Hg. Such compounds were among the first examples to be recognized of the novel and extremely fruitful perception that "electron-deficient" boranes and their anions can, in fact, act as powerful stabilizing electron-donor ligands (see Panel on p. 177).

6.4.7 *Chemistry of* closo-$B_nH_n^{2-}$[1,56,57]

The structures of these anions have been indicated on p. 153. Preparative reactions are often mechanistically obscure but thermolysis under controlled conditions is the dominant procedure (pp. 162–3). Many of the product *closo*-boranes are not degraded even when heated to 600°C. Salts of $B_{12}H_{12}^{2-}$ and $B_{10}H_{10}^{2-}$ are particularly stable and their reaction chemistry has been extensively studied. As expected from their charge, they are extremely stable towards nucleophiles but moderately susceptible to electrophilic attack. For $B_{10}H_{10}^{2-}$ the apex positions 1,10 are substituted preferentially to the equatorial positions; reference to structure (5) shows that there are 2 geometrical isomers for monosubstituted derivatives $B_{10}H_9X_2^-$, 7 isomers for $B_{10}H_8X_2^{2-}$ and 16 for $B_{10}H_7X_3^{2-}$. Many of these isomers exist, additionally, as enantiomeric pairs. Because of its higher symmetry $B_{12}H_{12}^{2-}$ has only 1 isomer for monosubstituted species $B_{12}H_{11}X^{2-}$, 3 for $B_{12}H_{10}X_2^{2-}$ (sometimes referred to as *ortho*-, *meta*- and *para*-) and 5 for $B_{12}H_9X_3^{2-}$. A particularly important derivative of $B_{12}H_{12}^{2-}$ is the thiol $[B_{12}H_{11}(SH)]^{2-}$ which has found use in the treatment of brain tumours by neutron capture therapy (see Panel on next page).

Oxidation of *closo*-$B_{10}H_{10}^{2-}$ with aqueous solutions of Fe^{III} or Ce^{IV} (or electrochemically) yields *conjuncto*-$B_{20}H_{18}^{2-}$ (44) which can be photoisomerized to *neo*-$B_{20}H_{18}^{2-}$ (45). If the oxidation is carried out at 0° with Ce^{IV},

[56] E. L. Muetterties and W. H. Knoth, *Polyhedral Boranes*, Marcel Dekker, New York, 1968, 197 pp.

[57] R. L. Middaugh, Chap. 8 in ref. 9, pp. 273–300.

Boron-10 Neutron Capture Therapy[58,59]

Every year more than 600 000 people throughout the world contract brain tumours and about 1700 die from this cause every day. Treatment by surgical excision is usually impossible because of the site of the malignant growth and the lack of a distinct boundary (gliomas). Likewise, conventional radiotherapy (X-rays, γ-rays etc.) from outside the skull is rarely effective. An ingenious approach to this problem which has given encouraging results so far is impregnation of the tumour with a suitable boron compound, followed by irradiation with thermal neutrons which readily pass harmlessly through normal tissue but are strongly absorbed by the isotope ^{10}B. As can be seen from Table 6.1 (p. 144) ^{10}B is 767 000 times more effective than ^{11}B and, in fact, has one of the highest neutron absorption cross-sections for any nuclide. The strategy is thus to synthesize cluster compounds enriched in ^{10}B, thereby enhancing the neutron absorption cross-section of the boron nearly five-fold, and then to attach these clusters to the cells comprising the brain tumour. A single injection of, say, $Na_2[^{10}B_{12}H_{11}SH]$ usually suffices. Treatment with thermal neutrons from a nuclear reactor then releases huge amounts of energy right within the tumour tissue (and nowhere else) as a result of the nuclear reaction:

$$^{10}_{5}B + {}^{1}_{0}n \longrightarrow \{^{11}_{5}B^*\} \longrightarrow {}^{4}_{2}He + {}^{7}_{3}Li + \gamma$$

The recoiling α-particle ($^4_2$He) and lithium nucleus ($^7_3$Li) between them carry 2.4 MeV of energy and this is shed within just a few μm, the α-particle travelling about 9 μm and the Li nucleus about 5.5 μm in the opposite direction. The radiation damage is thus confined within the cancerous tissue alone.

This is a very active area of research which involves collaboration between synthetic inorganic chemists, biochemists, neurosurgeons, nuclear physicists and reactor engineers, and there is considerable scope for advance in all of these areas.[58,60,61]

or in a two-phase system with Fe^{III} using very concentrated solutions of $B_{10}H_{10}^{2-}$, the intermediate H-bridged species $B_{20}H_{19}^{3-}$ (46) can be isolated. Reduction of *conjuncto*-$B_{20}H_{18}^{2-}$ with Na/NH_3 yields the equatorial–equatorial (ee) isomer of *conjuncto*-$B_{20}H_{18}^{4-}$ (47), and this can be successively converted by acid catalyst to the ae isomer (49) and, finally, to the aa isomer (48). Careful protonation of this aa isomer yields the elusive anion [aa-$B_{20}H_{19}$]$^{3-}$ in which the *conjuncto* B–B bond in structure (48) is replaced by an unsupported B–H_μ–B bond (angle 91(3)°, B–H_μ 136(5) pm, $B_a \cdots B_a$ 193.6 pm), though the two *closo* clusters still share a common axis through their B(1)-B(10) vertices.[61a] An extensive derivative chemistry of these various species has been developed. Another important (though mechanistically obscure) reaction of *conjuncto*-$B_{20}H_{18}^{2-}$ is its degradation in high yield to *n*-$B_{18}H_{22}$ by passage of an enthanolic solution through an acidic ion exchange resin; *i*-$B_{18}H_{22}$ is also formed as a minor product. The relation of these 2 edge-fused decaborane clusters to the B_{20} species is illustrated in structures (31) and (32) (p. 156).

When salts of *closo*-$B_{10}H_{10}^{2-}$ and *closo*-$B_{12}H_{12}^{2-}$ are passed through an acid ion exchange resin, hydrates of the strong acids $H_2B_nH_n$ are obtained. For example, $[NEt_4]^+_2[B_{10}H_{10}]^{2-}$ gives $H_2B_{10}H_{10}.4H_2O$ which, on careful dehydration, yields the dihydrate, $[H_3O]^+_2[B_{10}H_{10}]^{2-}$. Repeated low-pressure evaporation of benzene solutions of this acid at room temperature results in reductive cluster opening to give the *nido*-decaborane derivative [6,6′-$(B_{10}H_{13})_2O$] in good yield, probably via *nido*-6-$B_{10}H_{13}(OH)$.[62] The structure of the readily sublimable bis(*nido*-decaboranyl) oxide,

$(B_{10}H_{13})_2O$, prepared by other routes, had previously been established by X-ray diffraction analysis[63] and by nmr spectroscopy.[64] Another interesting derivative is [*closo*-1,10-$B_{10}H_8(N_2)_2$] in which the apical H atoms in $B_{10}H_{10}^{2-}$ have been replaced by end-on dinitrogen ligands (see pp. 414–6): the B–N distance is 149.9 pm and the N–N distance is 109.1 pm[65] (cf 109.8 pm in gaseous N_2). The isoelectronic ligand CO fulfils the same function in [*closo*-1,10-$B_{10}H_8(CO)_2$].[66,67] The closely related stable, volatile, icosahedral molecule [*closo*-1,12-$B_{12}H_{10}(CO)_2$] can be prepared by the reaction of $H_2B_{12}H_{12}.4H_2O$ with CO at 130°C and 800–1000 atm. pressure in the presence of dicobaltoctacarbonyl as catalyst.[67] In the absence of this catalyst, approximately equal amounts of the 1,7- and 1,12-isomers are formed.

6.5 Carboranes[1,17,68–71]

Carboranes burst onto the chemical scene in 1962–3 when classified work that had been done in the USA during the late 1950s was cleared for publication. The succeeding 30 y has seen a tremendous burgeoning of activity, as a result of which the carboranes and the related metallocarboranes (p. 189) now occupy a strategic position in the chemistry of the elements, since they overlap and give coherence to several other large areas including the chemistry of polyhedral boranes, transition-metal complexes, metal-cluster compounds and organometallic chemistry. The field has become so vast that it is only possible to give a few illustrative examples of the many thousands of known compounds, and to indicate the general structural features and reactivity. The vast majority of carboranes (>95%) have two C atoms in the cluster, reflecting their ready formation from alkynes (see below). A few have one C atom and there are a growing number incorporating three or even four C atoms as cluster vertices.

Carboranes (or more correctly carbaboranes) are compounds having as the basic structural unit a number of C and B atoms arranged on the vertices of a triangulated polyhedron. Their structures are closely related to those of the isoelectronic boranes (p. 161) [$BH \equiv B^- \equiv C$; $BH_2 \equiv BH^- \equiv B.L \equiv CH$]. For example, *nido*-$B_6H_{10}$ (structures 10, 50) provides the basic cluster structure for the 4 carboranes CB_5H_9 (51), $C_2B_4H_8$ (52), $C_3B_3H_7$ (53) and $C_4B_2H_6$ (54), each successive replacement of a basal B atom by C being compensated by the removal of one H_μ. Carboranes have the general formula $[(CH)_a(BH)_mH_b]^{c-}$ with a CH units and m BH units at the polyhedral vertices, plus b "extra" H atoms which are either bridging (H_μ) or *endo* (i.e. tangential to the surface of the polyhedron as distinct from the axial H_t atoms specified in the CH and BH groups; H_{endo} occur in BH_2 groups which are thus more precisely specified as BH_tH_{endo}). It follows that the number of electrons available for skeletal bonding is 3e from each CH unit, 2e from each BH unit, 1e from each H_μ or H_{endo}, and ce from the anionic charge. Hence:

> total number of skeletal bonding electron pairs $= \frac{1}{2}(3a + 2m + b + c) = n + \frac{1}{2}(a + b + c)$, where $n(= a + m)$ is the number of occupied vertices of the polyhedron.
> *closo*-structures have $(n + 1)$ pairs of skeletal bonding electrons (i.e. $a + b + c = 2$).
> *nido*-structures have $(n + 2)$ pairs of skeletal bonding electrons (i.e. $a + b + c = 4$).
> *arachno*-structures have $(n + 3)$ pairs of skeletal bonding electrons (i.e. $a + b + c = 6$).

If $a = 0$ the compound is a borane or borane anion rather than a carborane. If $b = 0$ there are no H_μ or H_{endo}; this is the case for all *closo*-carboranes except for the unique octahedral

monocarbaborane, 1-CB_5H_7, which has a triply bridging H_μ over one B_3 face of the octahedron. If $c = 0$ the compound is a neutral carborane molecule rather than an anion.

Nomenclature[12] follows the well-established oxa-aza convention of organic chemistry. Numbering begins with the apex atom of lowest coordination and successive rings or belts of polyhedral vertex atoms are numbered in a clockwise direction with C atoms being given the lowest possible numbers within these rules.†

Closo-carboranes are the most numerous and the most stable of the carboranes. They are colourless volatile liquids or solids (depending on mol wt.) and can be prepared from an alkyne and a borane by pyrolysis, or by reaction in a silent electric discharge. This route, which generally gives mixtures, is particularly useful for small *closo*-carboranes ($n = 5-7$) and for some intermediate *closo*-carboranes ($n = 8-11$), e.g.

$$\underset{(55)}{\textit{nido}\text{-}B_5H_9} \xrightarrow[500°-600°]{C_2H_2} \underset{(56)}{\textit{closo}\text{-}1,5\text{-}C_2B_3H_5} + \underset{(57)}{\textit{closo}\text{-}1,6\text{-}C_2B_4H_6} + \underset{(58)}{\textit{closo}\text{-}2,4\text{-}C_2B_5H_7}$$

† As frequently happens in a rapidly developing field, nomenclature and numbering for the carboranes gradually evolved to cope with increasing complexity. Consequently, many systems have been used, often by the same author in successive years, and the only safe procedure is to draw a labelled diagram and convert to the preferred numbering system.

Milder conditions provide a route to *nido*-carboranes, e.g.:

$$\textit{nido}\text{-}B_5H_9 \xrightarrow[200°]{C_2H_2} \textit{nido}\text{-}2,3\text{-}C_2B_4H_8 \ (59)$$

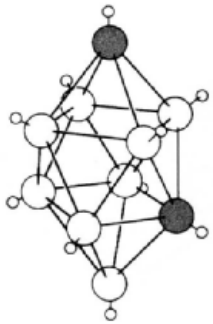
Pyrolysis of *nido*- or *arachno*-carboranes or their reaction in a silent electric discharge also leads to *closo*-species either by loss of H_2 or disproportionation:

$$C_2B_nH_{n+4} \longrightarrow C_2B_nH_{n+2} + H_2$$

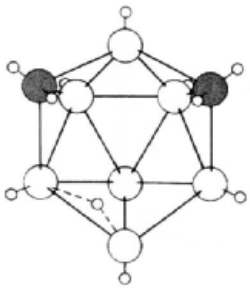
$$2C_2B_nH_{n+4} \longrightarrow C_2B_{n-1}H_{n+1} + C_2B_{n+1}H_{n+3} + 2H_2$$

For example, pyrolysis of the previously mentioned *nido*-2,3-$C_2B_4H_8$ gives the 3 *closo*-species shown above, whereas under the milder conditions of photolytic closure the less-stable isomer *closo*-1,2-$C_2B_4H_6$ is obtained. Pyrolysis of alkyl boranes at 500–600° is a related route which is particularly useful to monocarbaboranes though the yields are often low, e.g.:

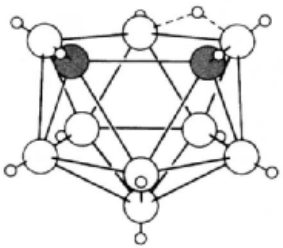
$$\underset{(60)}{1,2\text{-}Me_2\textit{-nido}\text{-}B_5H_7} \longrightarrow \underset{(56)}{\textit{closo}\text{-}1,5\text{-}C_2B_3H_5} + \underset{(61)}{\textit{closo}\text{-}1\text{-}CB_5H_7} + \underset{(62)}{\textit{nido}\text{-}2\text{-}CB_5H_9} + \underset{(63)}{3\text{-Me-}\textit{nido}\text{-}2\text{-}CB_5H_8}$$



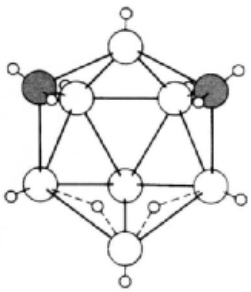
(64) *closo*-1,6-$C_2B_8H_{10}$



(65) *arachno*-1,3-$C_2B_7H_{12}^-$



(66) *nido*-1,7-$C_2B_9H_{12}^-$



(67) *arachno*-1,3-$C_2B_7H_{13}$

Cluster expansion reactions with diborane provide an alternative route to intermediate *closo*-carboranes, e.g.:

$$\textit{closo}\text{-}1,7\text{-}C_2B_6H_8 + \tfrac{1}{2}B_2H_6 \longrightarrow \textit{closo}\text{-}1,6\text{-}C_2B_7H_9 + H_2$$

$$\textit{closo}\text{-}1,6\text{-}C_2B_7H_9 + \tfrac{1}{2}B_2H_6 \longrightarrow \textit{closo}\text{-}1,6\text{-}C_2B_8H_{10} + H_2$$

Conversely, cluster degradation reactions lead to more open structures, e.g.:

$$\underset{(64)}{\textit{closo}\text{-}1,6\text{-}C_2B_8H_{10}} \xrightarrow[OH^- + 2H_2O]{\text{base hydrol}} \underset{(65)}{\textit{arachno}\text{-}1,3\text{-}C_2B_7H_{12}^-} + B(OH)_3$$

$$\underset{(66)}{\textit{nido}\text{-}1,7\text{-}C_2B_9H_{12}^-} \xrightarrow[+6H_2O - 6e^-]{\text{chromic acid oxidn.}} \underset{(67)}{\textit{arachno}\text{-}1,3\text{-}C_2B_7H_{13}} + 2B(OH)_3 + 5H^+$$

Other convenient routes to carboranes, selected from the growing number of recently reported syntheses, are as follows. Monocarbon carboranes can be prepared in good yield by the transition-metal catalysed hydroboration of alkenes followed by thermal rearrangement of the intermediate product, e.g.[72]

$$B_5H_9 + [(MeC{\equiv}CMe)Co_2(CO)_6] \xrightarrow{75^\circ}$$

$$[\textit{nido}\text{-}B_5H_8\text{-}2\text{-}(CMe{=}CHMe)] \xrightarrow{355^\circ}$$

[*nido*-2-CB_5H_7-2-Me-3(or 4)-Et] (see structure 51).

The two isomers are each obtained in about 30% yield. Again, the Me_2S-promoted reaction of *nido*-$B_{10}H_{14}$ with bis(trimethylsilyl) ethyne, $Me_3SiC{=}CSiMe_3$, results in monocarbon insertion by internal hydroboration and $SiMe_3$ group migration to give [*nido*-7-$CB_{10}H_{11}$-7-{$(Me_3Si)_2CH$}-9-(Me_2S)] structure (68) in 28% yield.[73] New dicarbaboranes can be obtained from preformed *nido*-dicarbaboranes either by reducing them to give the corresponding *arachno* species[74] or by a capping reaction to give a *closo*-dicarbaborane,[75] e.g.

$$\textit{nido}\text{-}C_2B_8H_{12} \xrightarrow[EtOH/KOH]{NaBH_4\text{ in}} \textit{arachno}\text{-}6,9\text{-}C_2B_8H_{14}\ (69)$$

$$\textit{nido}\text{-}2,3\text{-}Et_2C_2B_4H_6\ (52) + Et_3NBH_3 \xrightarrow{140^\circ}$$

$$\textit{closo}\text{-}2,3\text{-}Et_2C_2B_5H_5 + 2H_2 + NEt_3$$

A convenient route to three-carbon carboranes is the hydroboration of an alkyne with a preformed dicarbaborane. For example,[76] reaction of ethyne (or propyne) with *arachno*-4,5-$C_2B_7H_{13}$ (70) in hexane at 120°C gives a mixture of tri- and tetra-carbaboranes, e.g. (71), (72), (73), (74) in modest yield. Scheme

tetracarbaboranes was greatly facilitated by the discovery of oxidative fusion reactions in 1974; these involve the construction of large clusters by metal-promoted face-to-face fusion of smaller clusters.[71] For example, bridge-deprotonation of 2,3-$R_2C_2B_4H_6$ (see structure 52) with alkali metal hydride, followed by treatment with $FeCl_2$ and exposure to O_2 yields the desired product $R_4C_4B_8H_8$ (75) (see Scheme above). The starting material is available in multigram amounts via the room-temperature reaction of B_5H_9 with alkynes in the presence of NEt_3:

$$B_5H_9 + R_2C_2 + NEt_3 \longrightarrow 2,3\text{-}R_2C_2B_4H_6\ (52) + Et_3NBH_3$$

Metal-promoted alkyne-insertion reactions afford another good method (see structure 12 for cluster geometry and numbering):[77]

$$2,3\text{-}Et_2C_2B_4H_6\ (52) + NaH + MeC{\equiv}CMe + NiCl_2 \xrightarrow{thf} 4,5,7,8\text{-}Me_2Et_2C_4B_4H_4$$

[77] M. G. L. Mirabelli and L. G. Sneddon, *Organometallics* **5**, 1510–11 (1986).

Some Further Generalizations Concerning Carboranes

1. Carbon tends to adopt the position of lowest coordination number on the polyhedron and to keep as far from other C atoms as possible (i.e. the most stable isomer has the greatest number of B–C connections).
2. Boron-boron distances in the cluster increase with increasing coordination number (as expected). Average B–B distances are: 5-coordinate B 170 pm, 6-coordinate B 177 pm, 7-coordinate B 186 pm.
3. Carbon is somewhat smaller than B and interatomic distances involving C are correspondingly shorter. Thus B–C and C–C distances are about 165 pm and 145 pm, respectively, for 5-coordinate C; the corresponding values for 6-coordinate C are 172 pm and 165 pm.
4. Negative electronic charge on B is computed to decrease in the sequence:

   B (not bonded to C) > B (bonded to 1C) > B (bonded to 2C).

   Within each group the B with lower coordination number has a greater negative charge than those with higher coordination.
5. CH groups tend to be more positive than BH groups with the same coordination number (despite the higher electronegativity of C). This presumably arises because each C contributes 3e for bonding within the cluster whereas each B contributes only 2e.
6. In *nido*- and *arachno*-carboranes H_μ is more acidic than H_t and is the one removed on deprotonation with NaH.

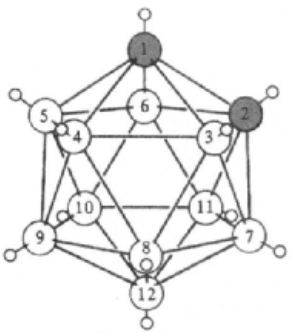
In general *nido*- (and *arachno*-) carboranes are less stable thermally than are the corresponding *closo*-compounds and they are less stable to aerial oxidation and other reactions, due to their more open structure and the presence of labile H atoms in the open face. Most *closo*-carboranes are stable to at least 400° though they may undergo rearrangement to more stable isomers in which the distance between the C atoms is increased. Some other structural and bonding generalizations are summarized in the Panel. Note, however, that kinetic control during synthesis may result in the isolation of a thermodynamically less favoured structure, with contiguous C atoms, while electronic factors in carboranes with as many as four C atoms may result in distortions or other deviations from the structures predicted on the basis of the simple application of electron counting rules.[71]

The three isomeric icosahedral carboranes (76–78) are unique both in their ease of preparation and their great stability in air, and consequently their chemistry has been the most fully studied. The 1,2-isomer in particular is available on the multikilogram scale. It is best prepared in bulk by the direct reaction of ethyne with decaborane in the presence of a Lewis base, preferably Et_2S:

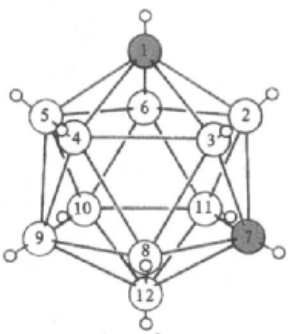
$$\textit{nido}\text{-}B_{10}H_{14} + 2SEt_2 \longrightarrow B_{10}H_{12}(SEt_2)_2 + H_2$$

$$B_{10}H_{12}(SEt_2)_2 + C_2H_2 \longrightarrow \textit{closo}\text{-}1,2\text{-}C_2B_{10}H_{12} + 2SEt_2 + H_2$$

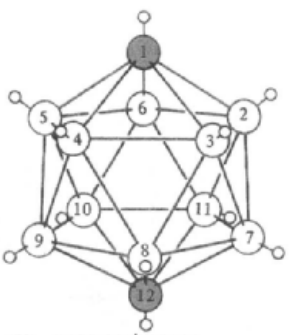
The 1,7-isomer is obtained in 90% yield by heating the 1,2-isomer in the gas phase at 470°C



(76) *ortho*-carborane, $1,2\text{-}C_2B_{10}H_{12}$ (mp 320°C)



(77) *meta*-carborane, $1,7\text{-}C_2B_{10}H_{12}$ (mp 265°C)



(78) *para*-carborane, $1,12\text{-}C_2B_{10}H_{12}$ (mp 261°C)

for several hours (or in quantitative yield by flash pyrolysis at 600° for 30 s). The 1,12-isomer is most efficiently prepared (20% yield) by heating the 1,7-isomer for a few seconds at 700°C. The mechanism of these isomerizations has been the subject of considerable speculation but definitive experiments are hard to devise. The "diamond-square-diamond" mechanism has been proposed (Fig. 6.19) for the 1,2 $\rightleftharpoons$ 1,7 isomerization, but the 1,12 isomer cannot be generated by this mechanism. Moreover, the activation energy required to pass through the cubo-octahedral transition state is likely to be rather high. An alternative proposal, which could, in principle, lead to both the 1,7 and the 1,12 isomers, is the successive concerted rotation of the 3 atoms on a triangular face, and a third possible mechanism involves the concerted basal twisting of two parallel pentagonal pyramids comprising the icosahedron. Vertex extrusion to a capping position, followed by reinsertion at an adjacent site in the cluster has also been suggested. It is extremely difficult to devise experiments to test these mechanisms, but where this has been achieved (as in the case of the disubstituted derivative of (58), *closo*-5-Me-6-Cl-2,4-$C_2B_5H_6$, for example) the results rule out triangular face rotation and are consistent with a "diamond-square-diamond" mechanisms.[78] It is conceivable that for other clusters the various mechanisms operate in different temperature ranges or that two (or more) mechanisms are active simultaneously. For recent definitive work on *closo*-$C_2B_{10}H_{12}$ see refs. 79 and 80.

An entirely different form of isomerism, which is attracting increasing attention, is described in the Panel opposite.

An extensive derivative chemistry of the icosahedral carboranes has been developed, especially for 1,2-$C_2B_{10}H_{12}$. Terminal H atoms attached to B undergo facile electrophilic substitution and the sequence of reactivity follows the sequence of negative charge density on the BH_t group:[81]

closo-1,2-$C_2B_{10}H_{12}$:

$$(8, 10 \approx 9, 12) > 4, 5, 7, 11 > 3, 6$$

closo-1,7-$C_2B_{10}H_{12}$:

$$9, 10 > 4, 6, 8, 11 > 5, 12 > 2, 3$$

Similar reactions occur for other *closo*-carboranes, e.g.:

$$1,6\text{-}C_2B_7H_9 \xrightarrow{Br_2/AlCl_3} 8\text{-}Br\text{-}1,6\text{-}C_2B_7H_8 + HBr$$

$$1,10\text{-}C_2B_8H_{10} \xrightarrow{8Cl_2/CCl_4} 1,10\text{-}(CH)_2B_8Cl_8 + 8HCl$$

It is noteworthy that, despite the greater electronegativity of C, the CH group tends to be more

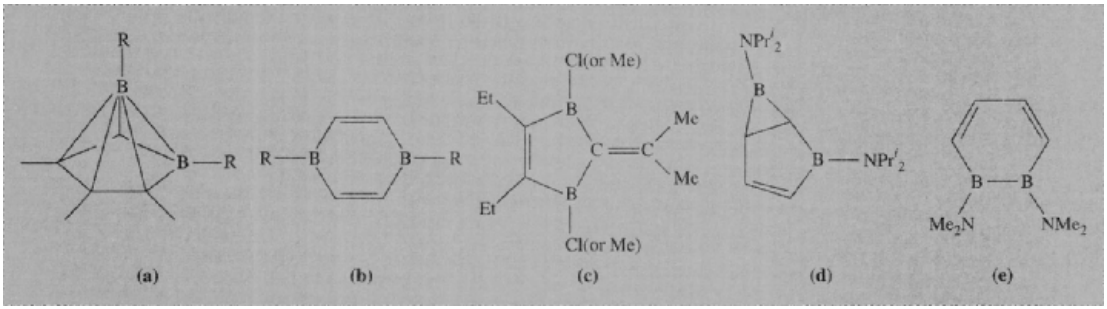
"Classical-Nonclassical" Valence Isomerism

A novel and far-reaching type of isomerism concerns the possibility of valence isomerism between "nonclassical" (electron-deficient) clusters and "classical" organoboron structures. Thus, *n*-vertexed *nido*-boranes, B_nH_{n+4}, have cluster structures with $4H_\mu$ — cf. (9), (10), (11) — whereas the precisely isoelectronic *n*-vertexed *nido*-tetracarbaboranes, $C_4B_{n-4}H_n$ have no bridging H atoms and can, in principle, adopt either a cluster borane structure or one of several classical organic structures. For example, derivatives of $C_4B_2H_6$ could adopt either the *nido*-2,3,4,5-tetracarbahexaborane structure (a) — i.e. (54) — or the 1,4-dibora-2,5-cyclohexadiene structure (b). As might be expected, the 3-coordinate B atoms in (b) are stabilized by π-donor substituents (e.g. R = F, OMe) whereas when R = alkyl, rearrangement to the *nido*-carbaborane (a) occurs.[82] The novel diborafulvene isomer (c) has also been synthesized in good yield[82,83] and two other isomers, (d) and (e) have been stabilized as ligands in Ru- and Rh-complexes.



Similar possibilities arise for 10-atom clusters. Thus, dimerization of the *closo*-C_2B_3 cluster 1,5-$Me_2C_2B_3Et_3$ (56) by means of K metal then I_2 in thf yields the "classical" adamantane derivative $Me_4C_4B_6Et_6$ (f); when this is heated to 160° the *nido*-tetracarbadecaborane cluster (g) is obtained rapidly and quantitatively.[84] It will be noted that in (f) all four C atoms are 4-coordinate and all six B atoms are 3-coordinate, whereas in (g) the three C atoms in the C_3 triangular face are 5-coordinate while the boron atoms are variously 4, 5 or 6 coordinate.

positive than the BH groups and does not normally react under these conditions.

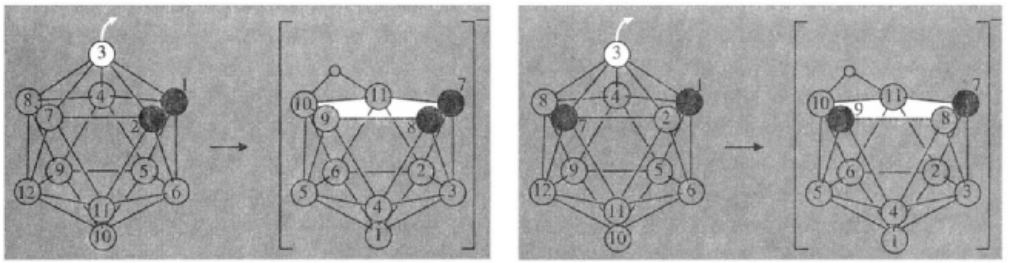
The weakly acidic CH_t group can be deprotonated by strong nucleophiles such as LiBu or RMgX; the resulting metalated carboranes $LiCCHB_{10}H_{10}$ and $(LiC)_2B_{10}H_{10}$ can then be used to prepare a full range of *C*-substituted derivatives –R, –X, $-SiMe_3$, –COOH, –COCl, –CONHR, etc. The possibility of synthesizing extensive covalent C–C or siloxane networks with pendant carborane clusters is obvious and the excellent thermal stability of such polymers has already been exploited in several industrial applications.

Although *closo*-carboranes are stable to high temperatures and to most common reagents, M. F. Hawthorne showed (1964) that they can be specifically degraded to *nido*-carborane anions by the reaction of strong bases in the presence of protonic solvents, e.g.:

$$1,2\text{-}C_2B_{10}H_{12} + EtO^- + 2EtOH \xrightarrow{85°C} 7,8\text{-}C_2B_9H_{12}^- + B(OEt)_3 + H_2$$

$$1,7\text{-}C_2B_{10}H_{12} + EtO^- + 2EtOH \longrightarrow 7,9\text{-}C_2B_9H_{12}^- + B(OEt)_3 + H_2$$

Figure 6.20 indicates that, in both cases, the BH vertex removed is the one adjacent to the two CH vertices: since the C atoms tend to remove electronic charge preferentially from contiguous B atoms, the reaction can be described as a nucleophilic attack by EtO^- on the most positive (most electron deficient) B atom in the



Closo-1,2-$C_2B_{10}H_{12}$ (**76**) *nido*-7,8-$C_2B_9H_{12}^-$ (**79**) *Closo*-1,7-$C_2B_{10}H_{12}$ (**77**) *nido*-7,9-$C_2B_9H_{12}^-$

(**80**) *nido*-7,8-$C_2B_9H_{11}^{2-}$ (η^5-C_5H_5)$^-$ (**81**) *nido*-7,9-$C_2B_9H_{11}^{2-}$

Figure 6.21 Relation between $C_2B_9H_{11}^{2-}$ and $C_5H_5^-$. In this formalism the *closo*-carboranes $C_2B_{10}H_{12}$ are considered as a coordination complex between the pentahapto 6-electron donor $C_2B_9H_{11}^{2-}$ and the acceptor BH^{2+} (which has 3 vacant orbitals). The *closo*-structure can be regained by capping the open pentagonal face with an equivalent metal acceptor that has 3 vacant orbitals.

cluster. Deprotonation of the monoanions by NaH removes the bridge proton to give the *nido*-dianions 7,8-$C_2B_9H_{11}^{2-}$ (80) and 7,9-$C_2B_9H_{11}^{2-}$ (81). It was the perceptive recognition that the open pentagonal faces of these dianions were structurally and electronically equivalent to the pentahapto cyclopentadienide anion (η^5-C_5H_5)$^-$ (Fig. 6.21) that led to the discovery of the metallocarboranes and the development of some of the most intriguing and far-reaching reactions of the carboranes. These are considered in the next section.

6.6 Metallocarboranes[1,17,85–90]

There are now at least a dozen synthetic routes to metallocarboranes including (i) coordination using *nido*-carborane anions as ligands, (ii) polyhedral expansion reactions, (iii) polyhedral contraction reactions, (iv) polyhedral subrogation and (v) thermal metal transfer reactions. These first five routes were all devised by M. F. Hawthorne and his group in the period 1965–74 and have since been extensively exploited and extended by several groups. Examples of each will be given before mentioning some of the more recent routes that have been developed. It is worth noting that the carborane dianions (80) and (81) are both more effective as ligands than is η^5-$C_5H_5^-$, perhaps because of the more favourable angles of the orbitals, the lower electronegativity of boron and the higher formal anionic charge. Thus, the carboranes form stable sandwich complexes with Cu^{II}, Al^{III} and Si^{IV}, for example, whereas cyclopentadienyl does not.[90,91]

(i) Coordination using nido*-carborane anions as ligands (1965).* Reaction of $C_2B_9H_{11}^{2-}$ with $FeCl_2$ in tetrahydrofuran (thf) with rigorous exclusion of moisture and air gives the pink, diamagnetic bis-sandwich-type complex of Fe(II) (structure 82) which can be reversibly oxidized to the corresponding red Fe(III) complex:

$$2C_2B_9H_{11}^{2-} + Fe^{2+} \xrightarrow{\text{thf}} \underset{(82)}{[Fe^{II}(\eta^5\text{-}C_2B_9H_{11})_2]^{2-}} \underset{+e^-}{\overset{\text{air}}{\rightleftharpoons}} [Fe^{III}(\eta^5\text{-}C_2B_9H_{11})_2]^-$$

When the reaction is carried out in the presence of NaC_5H_5 the purple mixed sandwich complex (83) is obtained:

$$C_2B_9H_{11}^{2-} + C_5H_5^- + Fe^{2+} \xrightarrow[-e^-]{\text{thf}} [Fe^{III}(\eta^5\text{-}C_5H_5)(\eta^5\text{-}C_2B_9H_{11})] \quad (83)$$

The reaction is general and has been applied to many transition metals as well as lanthanides and actinides.[92] Variants use metal carbonyls and other complexes to supply the capping unit, e.g.

$$C_2B_9H_{11}^{2-} + Mo(CO)_6 \xrightarrow{h\nu} [Mo(CO)_3(\eta^5\text{-}C_2B_9H_{11})]^{2-} + 3CO$$

(ii) Polyhedral expansion (1970). This entails the 2-electron reduction of a *closo*-carborane with a strong reducing agent such as sodium naphthalide in thf followed by reaction with a transition-metal reagent:

$$2[closo\text{-}C_2B_{n-2}H_n] \xrightarrow[\text{thf}]{4Na/C_{10}H_8} 2[nido\text{-}C_2B_{n-2}H_n]^{2-} \xrightarrow{M^{m+}} [M(C_2B_{n-2}H_n)_2]^{(m-4)+}$$

The reaction, which is quite general for *closo*-carboranes, involves the reductive opening of an *n*-vertex *closo*-cluster followed by metal

Scheme

insertion to give an $(n + 1)$-vertex *closo*-cluster. Numerous variants are possible including the insertion of a second metal centre into an existing metallocarborane, e.g.:

$$\textit{closo}\text{-}1,7\text{-}C_2B_6H_8 \xrightarrow[CoCl_2+NaC_5H_5]{2e^-/thf} [Co(C_5H_5)(C_2B_6H_8)]$$

$$\xrightarrow[CoCl_2 + NaC_5H_5]{2e^-/thf} [\{Co(C_5H_5)\}_2(C_2B_6H_8)] \quad (84)$$

The structure of the bimetallic 10-vertex cluster was shown by X-ray diffraction to be (84). When the icosahedral carborane $1,2\text{-}C_2B_{10}H_{12}$ was used, the reaction led to the first supraicosahedral metallocarboranes with 13- and 14-vertex polyhedral structures (85)–(89). Facile isomerism of the 13-vertex monometallodicarbaboranes was observed as indicated in the scheme above (in which ● = CH and ○ = BH).

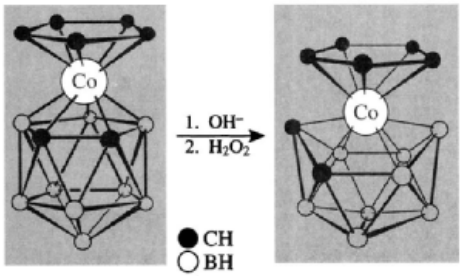
(iii) Polyhedral contraction (1972). This involves the clean removal of one BH group from a *closo*-metallocarborane by nucleophilic base degradation, followed by oxidative closure of the resulting *nido*-metallocarborane complex to a *closo*-species with one vertex less than the original, e.g.:

$$[3\text{-}\{Co(\eta^5\text{-}C_5H_5)\}(1,2\text{-}C_2B_9H_{11})](90) \xrightarrow[(2)\ H_2O_2]{(1)\ OEt^-}$$

$$[1\text{-}\{Co(\eta^5\text{-}C_5H_5)\}(2,4\text{-}C_2B_8H_{10})] \quad (91)$$

Polyhedral contraction is not so general a method of preparing metallocarboranes as is polyhedral expansion since some metallocarboranes degrade completely under these conditions.

(iv) Polyhedral subrogation (1973). Replacement of a BH vertex by a metal vertex without changing the number of vertices in the cluster is termed polyhedral subrogation. It is an offshoot of the polyhedral contraction route in that degradative removal of the BH unit is followed by reaction with a transition metal ion rather than

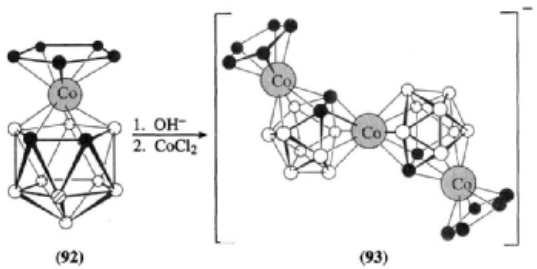


(90) (91)

with an oxidizing agent, e.g.:

$$[Co(\eta^5\text{-}C_5H_5)(C_2B_{10}H_{12})] \xrightarrow[(2)\ Co^{II},\ C_5H_5^-]{(1)\ OH^-} [\{Co(\eta^5\text{-}C_5H_5)\}_2(C_2B_9H_{11})]$$

The method is clearly of potential use in preparing mixed metal clusters, e.g. (Co + Ni) or (Co + Fe), and can be extended to prepare more complicated cluster arrays as depicted below, the subrogated B atom being indicated as a shaded circle in (92).

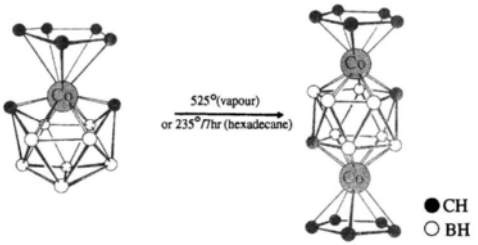


(92) (93)

(*v*) *Thermal metal transfer (1974).* This method is less general and often less specific than the coordination of *nido*-anions or polyhedral expansion; it involves the pyrolysis of pre-existing metallocarboranes and consequent cluster expansion or disproportionation similar to that of the *closo*-carboranes themselves (p. 182). Mixtures of products are usually obtained, e.g.:

$$[(C_5H_5)_2Co]^+[(2,3\text{-}C_2B_8H_{10})_2Co]^- \xrightarrow[\text{or } 270^\circ \text{ hexadecane}]{525^\circ\text{(hot tube)}} [(C_5H_5)_2Co_2C_2B_8H_{10}]$$

Similarly:



(94) $[1\text{-}C_5H_5\text{-}1\text{-}Co\text{-}2,3\text{-}C_2B_8H_{10}]$ (95) $[(C_5H_5)_2Co_2C_2B_8H_{10}]$ (+5 other isomers)

A related technique (R. N. Grimes, 1973) is direct metal insertion by gas-phase reactions at elevated temperatures; typical reactions are shown in the scheme (p. 192). The reaction with $[Co(\eta^5\text{-}C_5H_5)(CO)_2]$ also gave the 7-vertex *closo*-bimetallocarborane (101) which can be considered as a rare example of a triple-decker sandwich compound; another isomer (102) can be made by base degradation of $[\{Co(\eta^5\text{-}C_5H_5)\}(C_2B_4H_6)]$ followed by deprotonation and subrogation with a second $\{Co(\eta^5\text{-}C_5H_5)\}$ unit.[85] It will be noted that the central planar formal $C_2B_3H_5^{4-}$ unit is isoelectronic with $C_5H_5^-$.

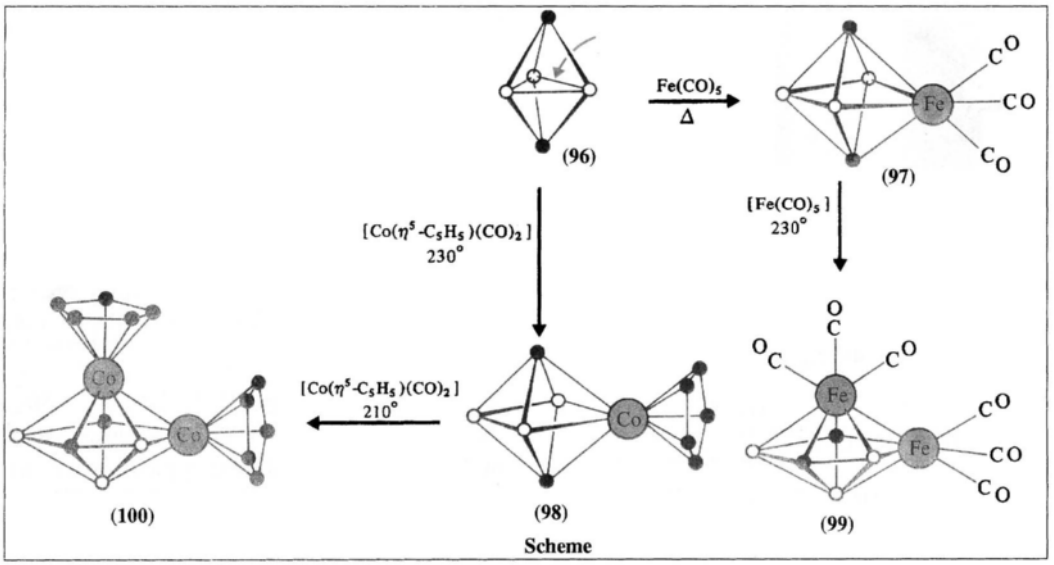
A particularly elegant route to metallacarboranes is the *direct oxidative insertion of a metal centre* into a *closo*-carborane cluster: the reaction uses zero-valent derivatives of Ni, Pd and Pt in a concerted process which involves a nett transfer of electrons from the nucleophilic metal centre to the cage:[93]

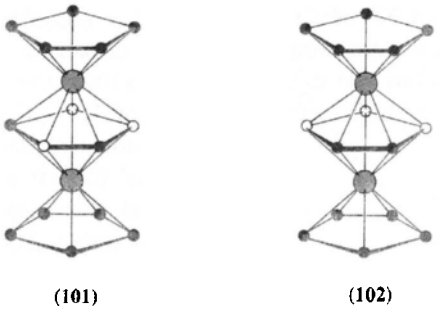
$$M^0L_{x+y} + C_2B_nH_{n+2} \longrightarrow [M^{II}L_x(C_2B_nH_{n+2})] + yL$$

where L = PR_3, C_8H_{12}, RNC, etc. A typical reaction is

$$[Pt(PEt_3)_3] + 2,3\text{-}Me_2\text{-}2,3\text{-}C_2B_9H_9 \xrightarrow[\text{petrol}]{-30^\circ} [1\text{-}\{Pt(PEt_3)_2\}\text{-}2,4\text{-}(MeC)_2B_9H_9] + PEt_3$$

[93] F. G. A. Stone, *J. Organometallic Chem.* **100**, 257–71 (1975).





(101) (102)

Many novel cluster compounds have now been prepared in this way, including mixed metal clusters. Further routes involve the *oxidative fusion of dicarbon metallacarborane anions* to give dimetal tetracarbon clusters such as (103) and (104);[71] the *insertion of isonitriles into metallaborane clusters* to give monocarbon metallacarboranes such as (105);[94] and the reaction of small *nido*-carboranes with alane adducts such as Et_3NAlH_3 to give the *commo* species (106):[95]

$$2[(\eta^5\text{-}C_5H_5)CoMe_2C_2B_3H_4]^{-} \xrightarrow[-2e^-,\ -H_2]{O_2}$$

$$[(\eta^5\text{-}C_5H_5)_2Co_2Me_4C_4B_6H_6] \quad (103)$$

$$2[(Me_2C_2B_4H_4)_2FeH_2] \xrightarrow[\text{(ii) dme}]{\text{(i) thf}}$$

$$[(Me_2C_2B_4H_4)_2Fe_2(MeOCH_2CH_2OMe)] \quad (104)$$

$$2EtNC + [(\eta^5\text{-}C_5Me_5)\text{-}nido\text{-}RhB_9H_{13}] \xrightarrow[-2H_2]{110°/\text{tol}}$$

$$[(\eta^5\text{-}C_5Me_5)(NHEt)(CNEt)\text{-}closo\text{-}RhCB_9H_8] \quad (105)$$

$$Et_3NAlH_3 + 2[nido\text{-}Et_2C_2B_4H_6] \ (52) \xrightarrow[-3H_2]{70°/36\ h}$$

$$[commo\text{-}(Et_2C_2B_4H_4)\text{-}\mu\text{-}(AlNEt_3)(Et_2C_2B_4H_5)] \quad (106)$$

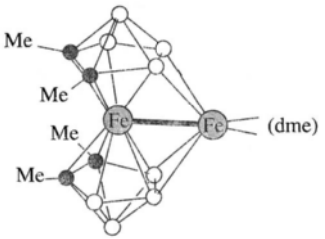
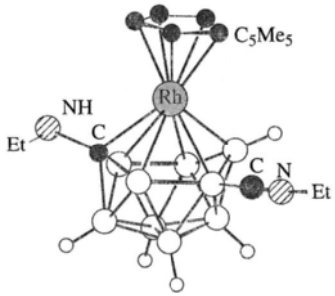
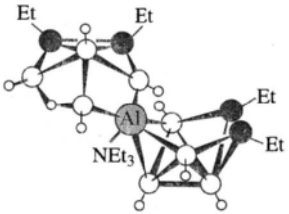
(103)



(104)



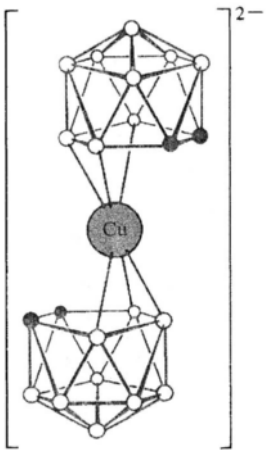
(105)



(106)

Numerous other aluminacarborane structural types have also recently been synthesized by a variety of routes[91] and, indeed, the burgeoning field of metallocarborane chemistry now encompasses the whole Periodic Table with an almost bewildering display of exotic and unprecedented structural types.

The electron-counting rules outlined for boranes (p. 161) and carboranes (p. 181) can readily be extended to the metallocarboranes (see Panel on next page). For bis-complexes of $1,2\text{-}C_2B_{10}H_{11}^{2-}$ which can be regarded as a 6-electron penta-hapto ligand, it has been found that "electron-sufficient" (18-electron) systems such as those involving d^6 metal centres (e.g. Fe^{II}, Co^{III} or Ni^{IV}) have symmetrical structures with the metal atom equidistant from the 2 C and 3 B atoms in the pentagonal face. The same is true for "electron-deficient" systems such as those involving d^2 Ti^{II} (14-electron), d^3 Cr^{III} (15-electron), etc., though here the metal-cluster bonds are somewhat longer. With "electron excess" complexes such as $[Ni^{II}(C_2B_{10}H_{11})_2]^{2-}$ and the corresponding complexes of Pd^{II}, Cu^{III} and Au^{III} (20 electrons), so-called "slipped-sandwich" structures (107) are observed in which the metal atom is significantly closer to the 3 B atoms than to the 2 C atoms. This has been thought by some to indicate π-allylic bonding to the 3 B but is more likely to arise from an occupation of orbitals that are antibonding with respect to both the metal and the cluster thereby leading to an opening of the 12-vertex



(107) $[Cu(C_2B_9H_{11})_2]^{-2}$

closo-structure to a pseudo-*nido* structure in which the 12 atoms of the cluster occupy 12 vertices of a 13-vertex polyhedron.[96] A similar type of distortion accompanies the use of metal centres with increasing numbers of electron-pairs on the metal and it seems that these electrons may also, at least in part, contribute to the framework electron count with consequent cluster opening.[97] Thus, progressive opening of the

Electron-counting Rules for Metallocarboranes and Other Heteroboranes

As indicated on pp. 161 and 174 each framework atom (except H) uses 3 atomic orbitals (AOs) in cluster bonding. For B, C, and other first-row elements this leaves one remaining AO to bond exopolyhedrally to $-H_t$, $-X$, $-R$, etc. In contrast, transition elements have a total of 9 valence AOs (five d, one s, three p). Hence, after contributing 3 AOs to the cluster, they have 6 remaining AOs which can be used for bonding to external ligands and for storage of nonbonding electrons. In *closo*-clusters the $(n + 1)$ MOs require $(2n + 2)$ electrons from the B, C and M vertex atoms. In its simplest form the electron counting scheme invokes only the total number of framework MOs and electrons, and requires no assumptions as to orbital hybridization or formal oxidation state. For example, the neutral moiety $\{Fe(CO)_3\}$ has 8 Fe electrons and 9 Fe AOs: since 3 AOs are involved in bonding to 3 CO and 3 AOs are used in cluster bonding, there remain 3 AOs which can accommodate 6 (nonbonding) Fe electrons, leaving 2 Fe electrons to be used in cluster bonding. Neutral $\{Fe(CO)_3\}$ is thus precisely equivalent to {BH}, as distinct from {CH}, which provides 3 electrons for the cluster. Other groups such as $\{Co(\eta^5\text{-}C_5H_5)\}$ and $\{Ni(CO)_2\}$ are clearly equivalent to $\{Fe(CO)_3\}$.

An alternative scheme that is qualitatively equivalent is to assign formal oxidation states to the metal moiety and to consider the bonding as coordination from a carborane ligand, e.g. $\{Fe(CO)_3\}^{2+}\eta^5$-bonded to a cyclocarborane ring as in $\{C_2B_9H_{11}\}^{2-}$. This is acceptable when the anionic ligand is well characterized as an independent entity, as in the case just cited, but for many metallocarboranes the "ligands" are not known as free species and the presumed anionic charge and metal oxidation state become somewhat arbitrary. It is therefore recommended that the metalloborane cluster be treated as a single covalently bonded structure with no artificial separation between the metal and the rest of the cluster; electron counting can then be done unambiguously on the basis of neutral atoms and attached groups.

To the structural generalizations on carboranes (p. 185) can be added the rule that, in metallocarboranes, the M atom tends to adopt a vertex with high coordination number; M occupancy of a low CN vertex is not precluded, particularly in kinetically controlled syntheses, but isomerization to more stable configurations usually results in the migration of M to high CN vertices.

Other main-group atoms besides C can occur in heteroborane clusters and the electron-counting rules can readily be extended to them.[17] Thus, whereas each {BH} contributes 2 e and {CH} contributes 3 e to the cluster, so {NH} or {PH} contributes 4 e, {SH} contributes 5 e, {S} contributes 4 e, etc. For example, the following 10-vertex thiaboranes (and their isoelectronic equivalents) are known: *closo*-1-SB_9H_9 ($B_{10}H_{10}^{2-}$), *nido*-6-SB_9H_{11} ($B_{10}H_{13}^{-}$) and *arachno*-6-$SB_9H_{12}^{-}$ ($B_{10}H_{14}^{2-}$). Similarly, the structures of 12-, 11- and 9-vertex thiaboranes parallel those of boranes and carbaboranes with the same skeletal electron count, the S atom in each case contributing 4 electrons to the framework plus an *exo*-polyhedral lone-pair.

cluster is noted for complexes of 1,2-$C_2B_9H_{11}^{2-}$ with Re^{I} (d^6), Au^{III} (d^8), Hg^{II} (d^{10}) and Tl^{I} ($d^{10}s^2$) as shown in structures (108)–(111). Thus the Re^{I} (d^6) complex (108) is a symmetrically bonded 12-vertex cluster with Re–B 234 pm and Re–C 231 pm. The Au^{III} (d^8) complex (109) has the metal appreciably closer to the 3 B atoms (221 pm) than to the 2 C atoms (278 pm). With the Hg^{II} (d^{10}) complex (110) this distortion is even more pronounced and the metal is pseudo-σ-bonded to 1 B atom at 220 pm; there is some additional though weak interaction with the other 2 B (252 pm) but the two Hg···C distances (290 pm) are essentially nonbonding. Finally, the Tl^{I} ($d^{10}s^2$) complex (111), whilst having the Tl atom more symmetrically located above the open face, has Tl–cluster distances that exceed considerably the expected covalent Tl^{I}–B distance of ~236 pm; the shortest Tl–B distance is 266 pm and there are two other Tl–B at 274 pm and two Tl–C at 292 pm: the species can thus be regarded formally as being closer to an ion pair $[Tl^{+}(C_2B_9H_{11})^{2-}]$.

In general, metallocarboranes are much less reactive (more stable) than the corresponding metallocenes and they tend to stabilize higher oxidation states of the later transition metals, e.g. $[Cu^{II}(1,2\text{-}C_2B_9H_{11})_2]^{2-}$ and $[Cu^{III}(1,2\text{-}C_2B_9H_{11})_2]^{-}$ are known whereas cuprocene

(108) [3-{Re^{I}(CO)$_3$}-1,2-$C_2B_9H_{11}$]$^-$ (109) [3-{Au^{III}(S_2CNEt_2)}-1,2-$C_2B_9H_{11}$] (110) [3-{Hg^{II}(PPh_3)}-1,2-$C_2B_9H_{11}$] (111) [3-Tl-1,2-$C_2B_9H_{11}$]$^-$

[Cu^{II}(η^5-C_5H_5)$_2$] is not. Likewise, Fe^{III} and Ni^{IV} carborane derivatives are extremely stable. Conversely, metallocarboranes tend to stabilize lower oxidation states of early transition elements and complexes are well established for Ti^{II}, Zr^{II}, Hf^{II}, V^{II}, Cr^{II} and Mn^{II}: these do not react with H_2, N_2, CO or PPh_3 as do cyclopentadienyl derivatives of these elements.

The chemistry of metallocarboranes of all cluster sizes is still rapidly developing and further unusual reactions and novel structures are continually appearing. Furthermore, as Si, Ge, Sn (and Pb) are in the same periodic group as C, heteroboranes containing these elements are to be expected (see p. 394). Likewise, as CC is isoelectronic with BN, the dicarbaboranes such as $C_2B_{10}H_{12}$ can be paralleled by $NB_{11}H_{12}$ etc. Numerous azaboranes and their metalla-derivatives are known (see p. 211) as indeed are clusters incorporating P, As, Sb (and Bi) (p. 212). The incorporation of the more electronegative element O has proved to be a greater challenge but several examples are now known. Sulfur provides an extensive thia- and polythia-borane chemistry (p. 214) and this is paralleled, although to a lesser extent, by Se and Te derivatives (p. 215). Detailed discussion of these burgeoning areas of borane cluster chemistry fall outside this present treatment but the general references cited on the above mentioned pages provide a useful introduction into this important new area of chemistry.

6.7 Boron Halides

Boron forms numerous binary halides of which the monomeric trihalides BX_3 are the most stable and most extensively studied. They can be regarded as the first members of a homologous series B_nH_{n+2}. The second members B_2X_4 are also known for all 4 halogens but only F forms more highly catenated species containing BX_2 groups: B_3F_5, B_4F_6.L, B_8F_{12} (p. 201). Chlorine forms a series of neutral *closo*-polyhedral compounds B_nCl_n ($n = 4, 8-12$) and several similar compounds are known for Br ($n = 7-10$) and I (e.g. B_9I_9). There are also numerous involatile subhalides, particularly of Br and I, but these are of uncertain stoichiometry and undetermined structure.

6.7.1 Boron trihalides

The boron trihalides are volatile, highly reactive, monomeric molecular compounds which show no detectable tendency to dimerize (except perhaps in Kr matrix-isolation experiments at 20K). In

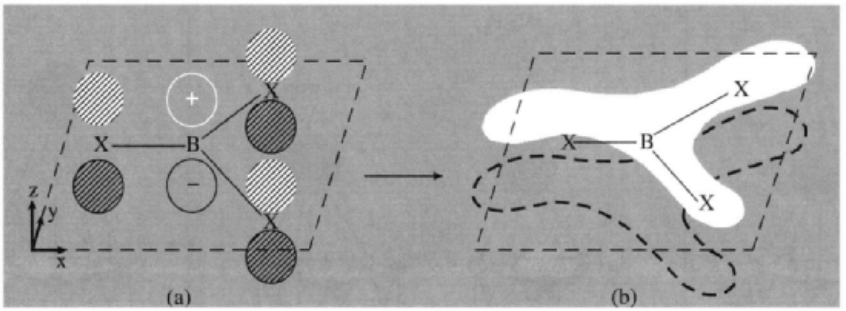

Figure 6.22 Schematic indication of the $p_\pi - p_\pi$ interaction between the "vacant" p_z orbital on B and the 3 filled p_z orbitals on the 3 X atoms leading to a bonding MO of π symmetry.

this they resemble organoboranes, BR_3, but differ sharply from diborane, B_2H_6, and the aluminium halides and alkyls, Al_2X_6, Al_2R_6 (p. 259). Some physical properties are listed in Table 6.4; mps and volatilities parallel those of the parent halogens, BF_3 and BCl_3 being gases at room temperature, BBr_3 a volatile liquid, and BI_3 a solid. All four compounds have trigonal planar molecules of D_{3h} symmetry with angle X–B–X 120° (Fig. 6.22a). The interatomic distances B–X are substantially less than those expected for single bonds and this has been interpreted in terms of appreciable $p_\pi - p_\pi$ interaction (Fig. 6.22b). However, there is disagreement as to whether the extent of this π bonding increases or diminishes with increasing atomic number of the halogen; this probably reflects the differing criteria used (extent of orbital overlap, percentage π-bond character, amount of π-charge transfer from X to B, π-bond energy, or reorganization energy in going from planar BX_3 to tetrahedral LBX_3, etc.).[98] For example, it is quite possible for the extent of π-charge transfer from X to B to increase in the sequence F < Cl < Br < I but for the actual magnitude of the π-bond energy to be in the reverse sequence $BF_3 > BCl_3 > BBr_3 > BI_3$ because of the much greater bond energy of the lighter homologues. Indeed, the mean B–F bond energy in BF_3 is 646 kJ mol^{-1}, which makes it the strongest known "single" bond; if x% of this were due to π bonding, then even if $2.4x$% of the B–I bond energy were due to π bonding, the π-bond energy in BI_3 would be less than that in BF_3 in absolute magnitude. The point is one of some importance since the chemistry of the trihalides is dominated by interactions involving this orbital.

Table 6.4 Some physical properties of boron trihalides

Property	BF_3	BCl_3	BBr_3	BI_3
MP/°C	−127.1	−107	−46	49.9
BP/°C	−99.9	12.5	91.3	210
r(B–X)/pm	130	175	187	210
ΔH_f° (298 K)/kJ mol^{-1} (gas)	−1123	−408	−208	+
E(B–X)/kJ mol^{-1}	646	444	368	267

BF_3 is used extensively as a catalyst in various industrial processes (p. 199) and can be prepared on a large scale by the fluorination of boric oxide or borates with fluorspar and concentrated H_2SO_4:

$$6CaF_2 + Na_2B_4O_7 + 8H_2SO_4 \longrightarrow 2NaHSO_4 + 6CaSO_4 + 7H_2O + 4BF_3$$

[98] Some key references will be found in D. R. Armstrong and P. G. Perkins, *J. Chem. Soc.* (A), 1967, 1218–22; and in M. F. Lappert, M. R. Litzow, J. B. Pedley, P. N. K. Riley and A. Tweedale, *J. Chem. Soc.* (A), 1968, 3105–10. Y. A. Buslaev, E. A. Kravchenko and L. Koldiz, *Coord. Chem. Rev.* **82**, 9–231 (1987). V. Branchadell and A. Oliva, *J. Am. Chem. Soc.* **113**, 4132–6 (1991) and *Theochem.* **236**, 75–84 (1991).

Better yields are obtained in the more modern two-stage process:

$$Na_2B_4O_7 + 12HF \xrightarrow{-6H_2O} [Na_2O(BF_3)_4]$$

$$\xrightarrow{+2H_2SO_4} 2NaHSO_4 + H_2O + 4BF_3$$

On the laboratory scale, pure BF_3 is best made by thermal decomposition of a diazonium tetrafluoroborate (e.g. $PhN_2BF_4 \longrightarrow PhF + N_2 + BF_3$). BCl_3 and BBr_3 are prepared on an industrial scale by direct halogenation of the oxide in the presence of C, e.g.:

$$B_2O_3 + 3C + 3Cl_2 \xrightarrow{500°C} 6CO + 2BCl_3$$

Laboratory samples of the pure compounds can be made by halogen exchange between BF_3 and Al_2X_6. BI_3 is made in good yield by treating $LiBH_4$ (or $NaBH_4$) with elemental I_2 at 125° (or 200°). Both BBr_3 and BI_3 tend to decompose with liberation of free halogen when exposed to light or heat; they can be purified by treatment with Hg or Zn/Hg.

Simple BX_3 undergo rapid scrambling or redistribution reactions on being mixed and the mixed halides BX_2Y and BXY_2 have been identified by vibrational spectroscopy, mass spectrometry, or nmr spectroscopy using ^{11}B or ^{19}F. A good example of this last technique is shown in Fig. 6.23, where not only the species $BF_{3-n}X_n (n = 0, 1, 2)$ were observed but also the trihalogeno species BFClBr.[99] The equilibrium concentration of the various species are always approximately random (equilibrium constants between 0.5 and 2.0) but it is not possible to isolate individual mixed halides because the equilibrium is too rapidly attained from either direction (<1 s). The related systems $RBX_2/R'BY_2$ (and $ArBX_2/Ar'BY_2$) also exchange X and Y but not R (or Ar). The scrambling mechanism probably involves a 4-centre transition state. Consistent with this, complexes such as Me_2OBX_3 or Me_3NBX_3 do not scramble at room temperature, or even above, in the absence of free BX_3[100] (cf. the stability of $CFCl_3$, CF_2Cl_2, etc.) and species that are

Factors Affecting the Stability of Donor–Acceptor Complexes[101–103]

For a given ligand, stability of the adduct LBX_3 usually increases in the sequence $BF_3 < BCl_3 < BBr_3 < BI_3$, probably because the loss of π bonding on reorganization from planar to tetrahedral geometry (p. 196) is not fully compensated for by the expected electronegativity effect. However, if the ligand has an H atom directly bonded to the donor atom, the resulting complex is susceptible to protonolysis of the B–X bond, e.g.:

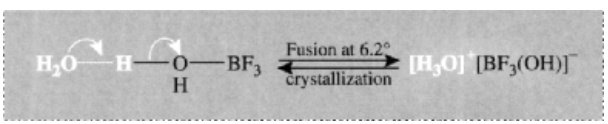
$$ROH + BX_3 \longrightarrow [ROH.BX_3] \longrightarrow ROBX_2 + HX$$

In such cases the great strength of the B–F bond ensures that the BF_3 complex is more stable than the others. For example, BF_3 forms stable complexes with H_2O, MeOH, Me_2NH, etc., whereas BCl_3 reacts rapidly to give $B(OH)_3$, $B(OMe)_3$ and $B(NMe_2)_3$; with BBr_3 and BI_3 such protolytic reactions are sometimes of explosive violence. Even ethers may be cleaved by BCl_3 to give RCl and $ROBCl_2$, etc.

For a given BX_3, the stability of the complex depends on (a) the chemical nature of the donor atom, (b) the presence of polar substituents on the ligand, (c) steric effects, (d) the stoichiometric ratio of ligand to acceptor, and (e) the state of aggregation. Thus the majority of adducts have as the donor atom N, P, As; O, S; or the halide and hydride ions X^-. BX_3 (but not BH_3) can be classified as type-a acceptors, forming stronger complexes with N, O and F ligands than with P, S and Cl. However, complexes are not limited to these traditional main-group donor atoms, and, following the work of D. F. Shriver (1963), many complexes have been characterized in which the donor atom is a transition metal, e.g. $[(C_5H_5)_2H_2W^{IV}\rightarrow BF_3]$, $[(Ph_3P)_2(CO)ClRh^{I}\rightarrow BBr_3]$, $[(Ph_2PCH_2CH_2PPh_2)_2Rh^{I}(BCl_3)_2]^+$, $[(Ph_3P)_2(CO)ClIr^{I}(BF_3)_2]$, $[(Ph_3P)_2Pt^{0}(BCl_3)_2]$, etc. Displacement studies on several such complexes indicate that BF_3 is a weaker acceptor than BCl_3.

The influence of polar substituents on the ligand follows the expected sequence for electronegative groups, e.g. electron donor properties decrease in the order $NMe_3 > NMe_2Cl > NMeCl_2 \gg NCl_3$. Steric effects can also limit the electron-donor strength. For example, whereas pyridine, C_5H_5N, is a weaker base (proton acceptor) than 2-MeC_5H_4N and 2,6-$Me_2C_5H_3N$, the reverse is true when BF_3 is the acceptor due to steric crowding of the α-Me groups which prevent the close approach of BF_3 to the donor atom. Steric effects also predominate in determining the decreasing stability of BF_3 etherates in the sequence $C_4H_8O(thf) > Me_2O > Et_2O > Pr^i_2O$.

The influences of stoichiometry and state of aggregation are more subtle. At first sight it is not obvious why BF_3, with 1 vacant orbital should form not only $BF_3.H_2O$ but also the more stable $BF_3.2H_2O$; similarly, the 1:2 complexes with ROH and RCOOH are always more stable than the 1:1 complexes. The second mole of ligand is held by hydrogen bonding in the solid, e.g. $BF_3.OH_2\ldots OH_2$; however, above the mp 6.2°C the compound melts and the act of coordinate-bond formation causes sufficient change in the electron distribution within the ligand that ionization ensues and the compound is virtually completely ionized as a molten salt:[101]



The greater stability of the 1:2 complex is thus seen to be related to the formation of H_3O^+, ROH_2^+, etc., and the lower stability of the 1:1 complexes HBF_3OH, HBF_3OR, is paralleled by the instability of some other anhydrous oxo acids, e.g. H_2CO_3. The mp of the hydrate is essentially the transition temperature between an H-bonded molecular solid and an ionically dissociated liquid. A transition in the opposite sense occurs when crystalline $[PCl_4]^+[PCl_6]^-$ melts to give molecular PCl_5 (p. 498) and several other examples are known. The fact that coordination can substantially modify the type of bonding should occasion no surprise: the classic example (first observed by J. Priestley in 1774) was the reaction $NH_3(g) + HCl(g) \rightarrow NH_4Cl(c)$.

expected to form stronger π bonds than BX_3 (such as R_2NBX_2) exchange much more slowly (days or weeks).

The boron trihalides form a great many molecular addition compounds with molecules

(ligands) possessing a lone-pair of electrons (Lewis base). Such adducts have assumed considerable importance since it is possible to investigate in detail the process of making and breaking one bond, and to study the effect this has on the rest of the molecule (see Panel). The tetrahalogeno borates BX_4^- are a special case in which the ligand is X^-; they are isoelectronic with BH_4^- (p. 165) and with CH_4 and CX_4. Salts of BF_4^- are readily formed by adding a suitable metal fluoride to BF_3 either in the absence of solvent or in such nonaqueous solvents as HF, BrF_3, AsF_3 or SO_2. The alkali metal salts MBF_4 are stable to hydrolysis in aqueous solutions. Some molecular fluorides such as NO_2F and RCOF react similarly. There is a significant lengthening of the B–F bond from 130 pm in BF_3 to 145 pm in BF_4^-. The other tetrahalogenoborates, BX_4^-, are less stable but may be prepared using large counter cations, e.g. Rb, Cs, pyridinium, tetraalkylammonium, tropenium, triphenylcarbonium, etc. The BF_4^- anion is a very weakly coordinating ligand, indeed one of the weakest;[104] however, unstable complexes are known in which it acts as an η^1-ligand and, in the case of $[Ag(lut)_2(BF_4)]$ it acts as a bis(bidentate) bridging ligand $[\mu_4\text{-}\eta^2,\eta^2\text{-}BF_4]^-$ to form a polymeric chain of 6-coordinate Ag centres[105] [lut = lutidene, i.e. 2,6-dimethylpyridine].

The importance of the trihalides as industrial chemicals stems partly from their use in preparing crystalline boron (p. 141) but mainly from their ability to catalyse a wide variety of organic reactions.[106] BF_3 is the most widely used but BCl_3 is employed in special cases. Thus, BF_3 is manufactured on the multikilotonne scale whereas the production of BCl_3 (USA, 1990) was 250 tonnes and BBr_3 was about 23 tonnes. BF_3 is shipped in steel cylinders containing 2.7 or 28 kg at a pressure of 10–12 atm, or in tube trailers containing about 5.5 tonnes. Prices for BF_3 are in the range \$4.00–5.00/kg depending on purity and quantity; corresponding prices (USA, 1991) for BCl_3 and BBr_3 were \$8.50–16.75/kg and \$81.50/kg, respectively.

Many of the reactions of BF_3 are of the Friedel–Crafts type though they are perhaps not strictly catalytic since BF_3 is required in essentially equimolar quantities with the reactant. The mechanism is not always fully understood but it is generally agreed that in most cases ionic intermediates are produced by or promoted by the formation of a BX_3 complex; electrophilic attack of the substrate by the cation so produced completes the process. For example, in the Friedel–Crafts-type alkylation of aromatic hydrocarbons:

$$RX + BF_3 \rightleftharpoons \{R^+\}\{BF_3X^-\}$$
$$\{R^+\} + PhH \rightleftharpoons PhR + \{H^+\}$$
$$\{H^+\} + \{BF_3X^-\} \rightleftharpoons BF_3 + HX$$

Similarly, ketones are prepared via acyl carbonium ions:

$$RCOOMe + BF_3 \rightleftharpoons \{RCO^+\}\{BF_3(OMe)^-\}$$
$$\{RCO^+\} + PhH \rightleftharpoons PhCOR + \{H^+\}$$
$$\{H^+\} + \{BF_3(OMe)^-\} \rightleftharpoons MeOH.BF_3$$

Evidence for many of these ions has been extensively documented.[101]

$$ROH + BF_3 \rightleftharpoons \{H^+\} + \{BF_3(OR)^-\}$$
$$\{H^+\} + ROH \rightleftharpoons \{ROH_2{}^+\}$$
$$\overset{BF_3}{\rightleftharpoons} \{R^+\} + H_2OBF_3$$
$$\{R^+\} + ROH \longrightarrow R_2O + \{H^+\}$$

A similar mechanism has been proposed for the esterification of carboxylic acids:

$$\{H^+\} + RCOOH \rightleftharpoons \{RCOOH_2{}^+\}$$
$$\overset{BF_3}{\rightleftharpoons} \{RCO^+\} + H_2OBF_3$$
$$\{RCO^+\} + R'OH \longrightarrow RCOOR' + \{H^+\}$$

[104] W. BECK and K. SÜNKEL, *Chem. Rev.* **88**, 1405–21 (1988).

[106] G. OLAH (ed.), *Friedel–Crafts and Related Reactions*, Interscience, New York, 1963 (4 vols).

Nitration and sulfonation of aromatic compounds probably occur via the formation of the nitryl and sulfonyl cations:

$$HONO_2 + BF_3 \rightleftharpoons \{NO_2^+\} + \{BF_3(OH)^-\}$$

$$HOSO_3H + BF_3 \rightleftharpoons \{SO_3H^+\} + \{BF_3(OH)^-\}$$

Polymerization of alkenes and the isomerization of alkanes and alkenes occur in the presence of a cocatalyst such as H_2O, whereas the cracking of hydrocarbons is best performed with HF as cocatalyst. These latter reactions are of major commercial importance in the petrochemicals industry.

6.7.2 Lower halides of boron

B_2F_4 (mp −56°, bp −34°C) has a planar (D_{2h}) structure with a rather long B–B bond; in this it resembles both the oxalate ion $C_2O_4^{2-}$ and N_2O_4 with which it is precisely isoelectronic. Crystalline B_2Cl_4 (mp −92.6°C) has the same structure, but in the gas phase (bp 65.5°) it adopts the staggered D_{2d} configuration (see below) with hindered rotation about the B–B bond (ΔE_r 7.7 kJ mol^{-1}). The structure of gaseous B_2Br_4 is also D_{2d} with B–B 169 pm and ΔE_r 12.8 kJ mol^{-1}. B_2I_4 is presumably similar.

B_2Cl_4 was the first compound in this series to be prepared and is the most studied; it is best made by subjecting BCl_3 vapour to an electrical discharge between mercury or copper electrodes:

$$2BCl_3 + 2Hg \longrightarrow B_2Cl_4 + Hg_2Cl_2$$

The reaction probably proceeds by formation of a {BCl} intermediate which then inserts into a B–Cl bond of BCl_3 to give the product directly.

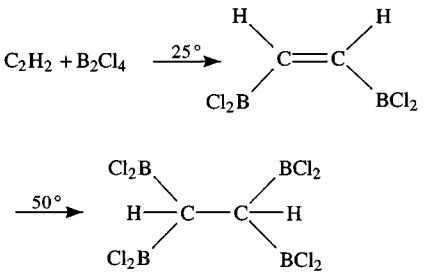
Another route is via the more stable $B_2(NMe_2)_4$ (see reaction scheme). Thermal stabilities of these compounds parallel the expected sequence of p_π–p_π bonding between the substituent and B:

$$B_2(NMe_2)_4 > B_2(OMe)_4 > B_2(OH)_4 > B_2F_4 > B_2Cl_4 > B_2Br_4$$

The halides are much less stable than the corresponding BX_3, the most stable member B_2F_4 decomposing at the rate of about 8% per day at room temperature. B_2Br_4 disproportionates so rapidly at room temperature that it is difficult to purify:

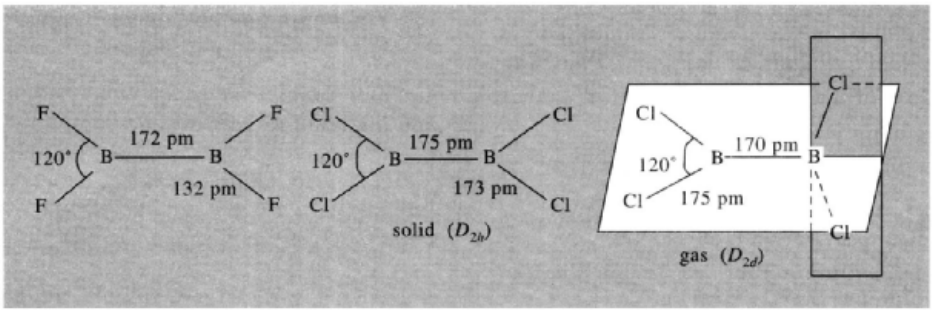
$$nB_2X_4 \longrightarrow nBX_3 + (BX)_n$$

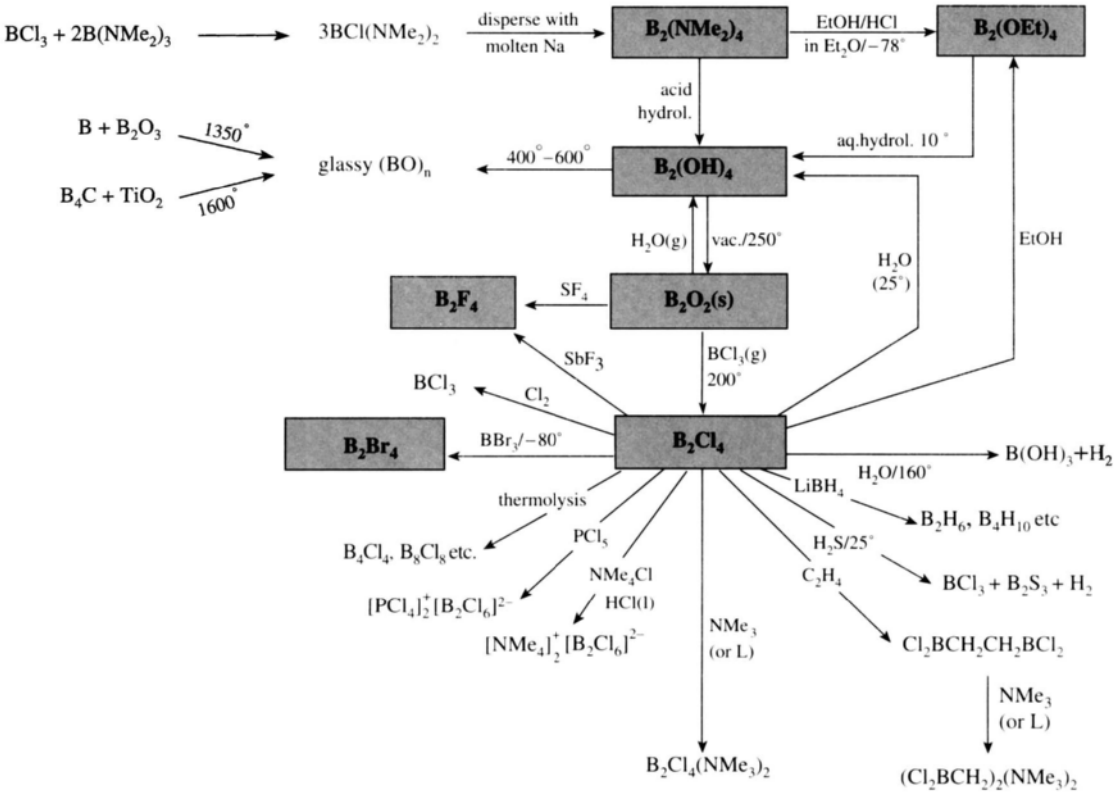
The compounds B_2X_4 are spontaneously flammable in air and react with H_2 to give BHX_2, B_2H_6 and related hydrohalides; they form adducts with Lewis bases ($B_2Cl_4L_2$ more stable than $B_2F_4L_2$) and add across C–C multiple bonds, e.g.



Other reactions of B_2Cl_4 are shown in the scheme and many of these also occur with B_2F_4.

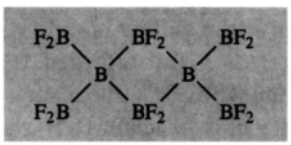
When BF_3 is passed over crystalline B at 1850°C and pressures of less than 1 mmHg, the reactive gas BF is obtained in high yield and can





be condensed out at −196°. Cocondensation with BF_3 yields B_2F_4 then B_3F_5 (i.e. $F_2B{-}B(F){-}BF_2$). However, this latter compound is unstable and it disproportionates above −50° according to

$$4(BF_2)_2BF \longrightarrow 2B_2F_4 + B_8F_{12} \quad (112)$$



(112)

The yellow compound B_8F_{12} appears to have a diborane-like structure (112) and this readily undergoes symmetrical cleavage with a variety of ligands such as CO, PF_3, PCl_3, PH_3, AsH_3 and SMe_2 to give adducts $L.B(BF_2)_3$ which are stable at room temperature in the absence of air or moisture.

Thermolysis of B_2Cl_4[107] and B_2Br_4 at moderate temperatures gives a series of *closo*-halogenoboranes B_nX_n where $n = 4$, 8–12 for Cl, and $n = 7$–10 for Br. Other preparative routes include the high-yield halogenation of $B_9H_9^{2-}$ to $B_9X_9^{2-}$ using *N*-chlorosuccinimide, *N*-bromosuccinimide or I_2.[108] The redox sequences $B_9X_9^{2-} \rightleftharpoons B_9X_9^{\bullet-} \rightleftharpoons B_9X_9$ have also been established, the radical anions $B_9X_9^{\bullet-}$ being isolated as air-stable coloured salts.[108]

B_4Cl_4, a pale-yellow-green solid, has a regular *closo*-tetrahedral structure (Fig. 6.24a); it is hyperelectron deficient when compared with the *closo*-boranes $B_nH_n^{2-}$ (pp. 153, 160) and the

[107] T. DAVAN and J. A. MORRISON, *Inorg. Chem.* **25**, 2366–72 (1986).

[108] E. H. WONG and R. M. KABBANI, *Inorg. Chem.* **19**, 451–5 (1980). See also E. H. WONG, *Inorg. Chem.* **20**, 1300–2 (1981); A. J. MARKWELL, A. G. MASSEY and P. J. PORTAL, *Polyhedron* **1**, 134–5 (1982).

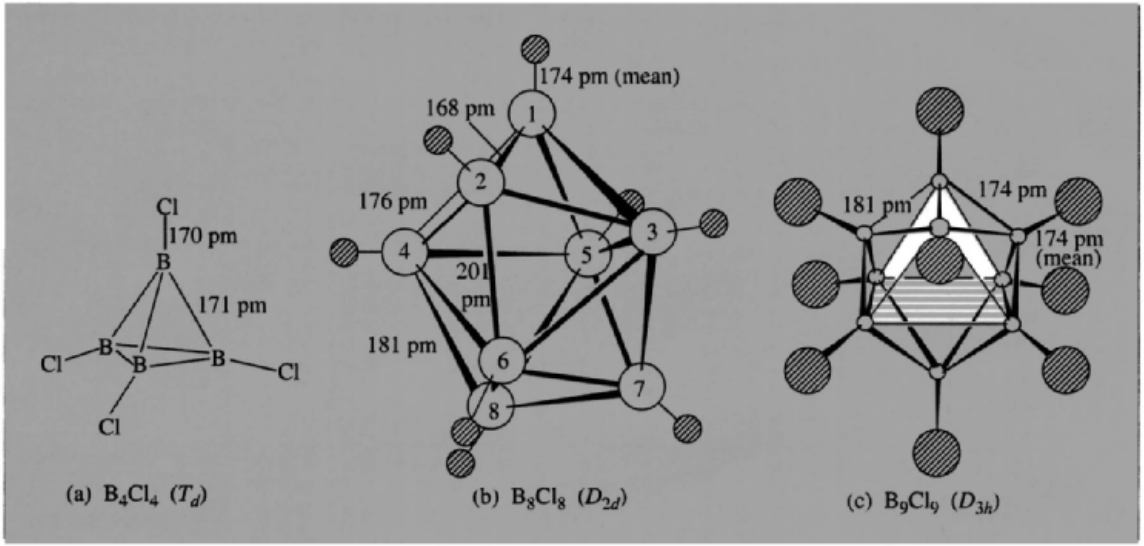


Figure 6.24 Molecular structures of (a) tetrahedral B_4Cl_4, (b) dodecahedral B_8Cl_8, and (c) tricapped trigonal pyramidal B_9Cl_9 and B_9Br_9. In B_8Cl_8 note that the shortest B–B distances are between two 5-coordinate B atoms, e.g. B(1)–B(2) 168 pm; the longest are between two 6-coordinate B atoms, e.g. B(4)–B(6) 201 pm and intermediate distances are between one 5- and one 6-coordinate B atom. A similar trend occurs in B_9Cl_9.

bonding has been discussed in terms of localized 3-centre bonds above the 4 tetrahedral faces supplemented by p_π interaction with p orbitals of suitable symmetry on the 4 Cl atoms: the 8 electrons available for framework bonding from the 4 {BCl} groups fill 4 bonding MOs of class A_1 and T_2 and there are 2 additional bonding MOs of class E which have correct symmetry to mix with the Cl p_π orbitals. B_8Cl_8 (variously described as dark red, dark purple or green-black crystals) has an irregular dodecahedral (bisphenoid) arrangement of the *closo*-B_8 cluster (Fig. 6.24b) with 14 B–B distances in the range 168–184 pm and 4 substantially longer B–B distances at 193–205 pm. B_9Br_9 is a particularly stable compound; it forms as dark-red crystals together with other subbromides (n = 7–10) when gaseous BBr_3 is subjected to a silent electric discharge in the presence of Cu wool, and can be purified by sublimation under conditions (200°C) which rapidly decompose the other products. B_9Br_9 is isostructural with B_9Cl_9 (yellow-orange) (Fig. 6.24c). The photoelectron spectra and bonding in B_4Cl_4, B_8Cl_8 and B_9Cl_9 have been described in detail.[109]

Many mixed halides $B_nBr_{n-x}Cl_x$ (n = 9, 10, 11) have been identified by mass spectrometry and other techniques, but their separation as pure compounds has so far not been achieved. Chemical reactions of B_nX_n resemble those of B_2X_4 except that alkenes do not cleave the B–B bonds in the *closo*-species. Thus, B_4Cl_4 reacts with LiEt to give the yellow liquids B_4Cl_3Et and $B_4Cl_2Et_2$, whereas $LiBu^t$ afforded $B_4Bu^t_4$ as a glassy solid, mp 45°C.[110] By contrast, reaction with Me_3SnH yields *arachno*-B_4H_{10} and $LiBH_4$ yields a mixture of *nido*-B_5H_9 and *nido*-B_6H_{10}, while B_2H_6 gave *nido*-$B_6H_6Cl_4$ and a mixture of *nido*-$B_{10}H_nCl_{14-n}$ (n = 8–12).[111]

6.8 Boron–Oxygen Compounds[112]

Boron (like silicon) invariably occurs in nature as oxo compounds and is never found as the element or even directly bonded to any other element than oxygen.† The structural chemistry of B–O compounds is characterized by an extraordinary complexity and diversity which rivals those of the borides (p. 145) and boranes (p. 151). In addition, vast numbers of predominantly organic compounds containing B–O are known.

6.8.1 Boron oxides and oxoacids[112]

The principal oxide of boron is boric oxide, B_2O_3 (mp 450°, bp (extrap) 2250°C). It is one of the most difficult substances to crystallize and, indeed, was known only in the vitreous state until 1937. It is generally prepared by careful dehydration of boric acid $B(OH)_3$. The normal crystalline form (d 2.56 g cm^{-3}) consists of a 3D network of trigonal BO_3 groups joined through their O atoms, but there is also a dense form (d 3.11 g cm^{-3}) formed under a pressure of 35 kbar at 525°C and built up from irregular interconnected BO_4 tetrahedra. In the vitreous state ($d \simeq 1.83$ g cm^{-3}) B_2O_3 probably consists of a network of partially ordered trigonal BO_3 units in which the 6-membered $(BO)_3$ ring predominates; at higher temperatures the structure becomes increasingly disordered and above 450°C polar —B=O groups are formed. Fused B_2O_3 readily dissolves many metal oxides to give characteristically coloured borate glasses. Its major application is in the glass industry where borosilicate glasses (e.g. Pyrex) are extensively used because of their small coefficient of thermal expansion and their easy workability. US production of B_2O_3 exceeds 25 000 tonnes pa and the price (1990) was $2780–2950 per tonne for 99% grade.

Orthoboric acid, $B(OH)_3$, is the normal end product of hydrolysis of most boron compounds and is usually made (≃160 000 tonnes pa) by acidification of aqueous solutions of borax. Price depends on quality, being $805 per tonne for technical grade and about twice that for refined material (1990). It forms flaky, white, transparent crystals in which a planar array of BO_3 units is joined by unsymmetrical H bonds as shown in Fig. 6.25. In contrast to the short O—H···O distance of 272 pm within the plane, the distance between consecutive layers in the crystal is 318 pm, thus accounting for the pronounced basal cleavage of the waxy, plate-like crystals, and their low density (1.48 g cm^{-3}). $B(OH)_3$ is a very weak monobasic acid and acts exclusively by hydroxyl-ion acceptance rather than proton donation:

$$B(OH)_3 + 2H_2O \rightleftharpoons H_3O^+ + B(OH)_4^-; \quad pK = 9.25$$

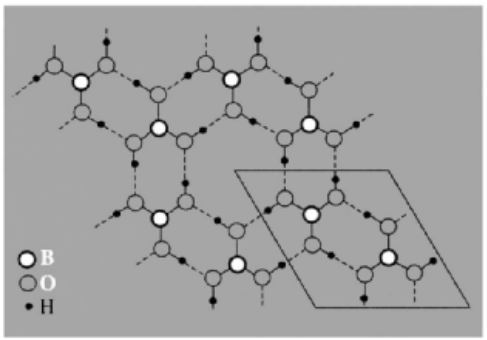

Figure 6.25 Layer structure of $B(OH)_3$. Interatomic distances are B–O 136 pm. O–H 97 pm, O—H···O 272 pm. Angles at B are 120° and at O 126° and 114°. The H bond is almost linear.

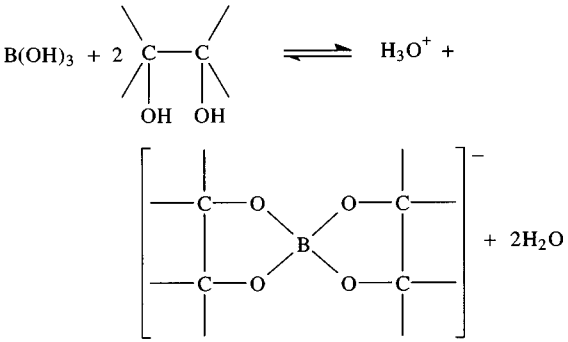
Its acidity is considerably enhanced by chelation with polyhydric alcohols (e.g. glycerol, mannitol) and this forms the basis of its use in analytical chemistry; e.g. with mannitol pK drops to 5.15,

[112] *Supplement to "Mellor's Comprehensive Treatise on Inorganic and Theoretical Chemistry"*, Vol. V, Boron: Part A, *"Boron-Oxygen Compounds"*, Longman, London, 1980, 825 pp. See also J. R. BOWSER and T. P. FEHLNER, Chap. 1 in H. W. ROESKY (ed.), *Rings, Clusters and Polymers of Main Group and Transition Elements*, Elsevier, Amsterdam, 1989, pp. 1–48.

† Trivial exceptions to this sweeping generalization are $NaBF_4$ (ferrucite) and $(K,Cs)BF_4$ (avogadrite) which have been reported from Mt. Vesuvius, Italy.

indicating an increase in the acid equilibrium constant by a factor of more than 10^4:[113]



$B(OH)_3$ also acts as a strong acid in anhydrous H_2SO_4:

$$B(OH)_3 + 6H_2SO_4 \longrightarrow 3H_3O^+ + 2HSO_4^- + [B(HSO_4)_4]^-$$

Other reactions include esterification with ROH/H_2SO_4 to give $B(OR)_3$, and coordination of this with NaH in thf to give the powerful reducing agent $Na[BH(OR)_3]$. Reaction with H_2O_2 gives peroxoboric acid solutions which probably contain the monoperoxoborate anion $[B(OH)_3OOH]^-$. A complete series of fluoroboric acids is also known in aqueous solution and several have been isolated as pure compounds:

$$H[B(OH)_4] \quad H[BF(OH)_3] \quad H[BF_2(OH)_2]$$
$$H[BF_3OH] \quad HBF_4$$

The hypohalito analogues $[B(OH)_3(OX)]^-$ (X=Cl, Br) have recently been characterized in aqueous solutions of $B(OH)_3$ containing NaOX; the stability constants log β' at 25°C being 2.25(1) and 1.83(4), respectively,[114] compared with 5.39(7) for $B(OH)_4^-$.

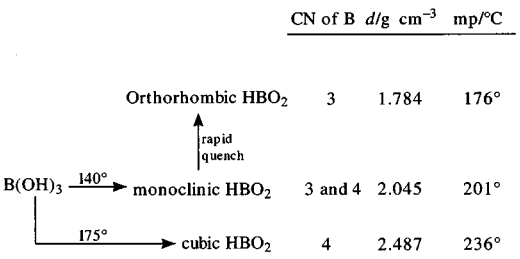
Partial dehydration of $B(OH)_3$ above 100° yields metaboric acid HBO_2 which can exist in several crystalline modifications:



Orthorhombic HBO_2 consists of trimeric units $B_3O_3(OH)_3$ which are linked into layers by H bonding (Fig. 6.26); all the B atoms are 3-coordinate. Monoclinic HBO_2 is built of chains of composition $[B_3O_4(OH)(H_2O)]$ in which some of the B atoms are now 4-coordinate, whereas cubic HBO_2 has a framework structure of tetrahedral BO_4 groups some of which are H bonded. The increase in CN of B is paralleled by an increase in density and mp.

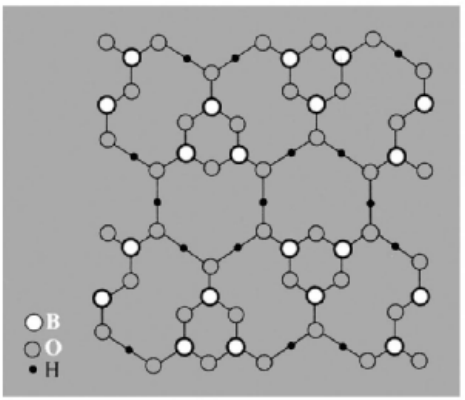


Figure 6.26 Layer structure of orthorhombic metaboric acid HBO_2(III), comprising units of formula $B_3O_3(OH)_3$ linked by $O\cdots H\cdots O$ bonds.

Boron suboxide $(BO)_n$ and subboric acid $B_2(OH)_4$ were mentioned on p. 201.

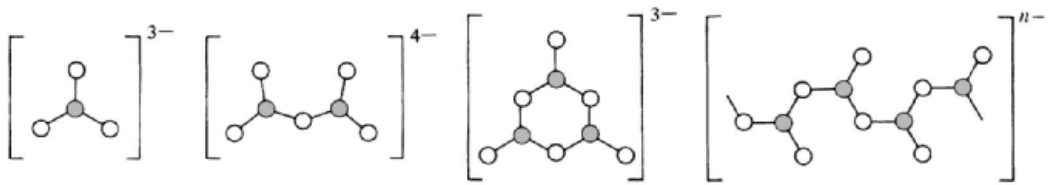
6.8.2 Borates [112,115]

The phase relations, stoichiometry and structural chemistry of the metal borates have been extensively studied because of their geochemical implications and technological importance. Borates are known in which the structural unit is mononuclear (1 B atom), bi-, tri-, tetra- or pentanuclear, or in which there are polydimensional networks including glasses. The main structural principles underlying the bonding in crystalline metal borates are as follows:[116]

1. Boron can link either three oxygens to form a triangle or four oxygens to form a tetrahedron.
2. Polynuclear anions are formed by corner-sharing only of boron-oxygen triangles and tetrahedra in such a manner that a compact insular group results.
3. In the hydrated borates, protonatable oxygen atoms will be protonated in the following sequence: available protons are first assigned to free O^{2-} ions to convert these to free OH^- ions; additional protons are assigned to tetrahedral oxygens in the borate ion, and then to triangular oxygens in the borate ion; finally any remaining protons are assigned to free OH^- ions to form H_2O molecules.
4. The hydrated insular groups may polymerize in various ways by splitting out water; this process may be accompanied by the breaking of boron-oxygen bonds within the polyanion framework.
5. Complex borate polyanions may be modified by attachment of an individual side group, such as (but not limited to) an extra borate tetrahedron, an extra borate triangle, 2 linked triangles, an arsenate tetrahedron, and so on.
6. Isolated $B(OH)_3$ groups, or polymers of these, may exist in the presence of other anions.

Examples of minerals and compounds containing monomeric triangular, BO_3 units (structure 113) are the rare-earth orthoborates $M^{III}BO_3$ and the minerals $CaSn^{IV}(BO_3)_2$ and $Mg_3(BO_3)_2$. Binuclear trigonal planar units (114) are found in the pyroborates $Mg_2B_2O_5$, $Co^{II}{}_2B_2O_5$ and $Fe^{II}{}_2B_2O_5$. Trinuclear cyclic units (115) occur in the metaborates $NaBO_2$ and KBO_2, which should therefore be written as $M_3B_3O_6$ (cf. metaboric acid, p. 204). Polynuclear linkage of BO_3 units into infinite chains of stoichiometry BO_2 (116) occurs in $Ca(BO_2)_2$, and three-dimensional linkage of planar BO_3 units occurs in the borosilicate mineral tourmaline and in glassy B_2O_3 (p. 203).

Monomeric tetrahedral BO_4 units (117) are found in the zircon-type compound Ta^VBO_4 and in the minerals $(Ta,Nb)BO_4$ and $Ca_2H_4BAs^VO_8$. The related tetrahedral unit $[B(OH)_4]^-$ (118) occurs in $Na_2[B(OH)_4]Cl$ and $Cu^{II}[B(OH)_4]Cl$. Binuclear tetrahedral units (119) have been found



(113) $[BO_3]^{3-}$ (114) $[B_2O_5]^{4-}$ (115) $[B_3O_6]^{3-}$ (116) $[(BO_2)^-]_n$

Units containing B in planar BO_3 coordination only

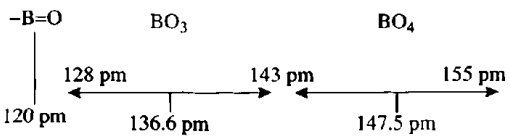
(121) $[B_5O_6(OH)_4]^-$ (122) $[B_3O_3(OH)_5]^{2-}$ (123) $[B_4O_5(OH)_4]^{2-}$

Units containing B in both BO_3 and BO_4 coordination

in $Mg[B_2O(OH)_6]$ and a cyclic binuclear tetrahedral structure (120) characterizes the peroxoanion $[B_2(O_2)_2(OH)_4]^{2-}$ in "sodium perborate" $NaBO_3.4H_2O$, i.e. $Na_2[B_2(O_2)_2(OH)_4].6H_2O$. A more complex polynuclear structure comprising sheets of tetrahedrally coordinated $BO_3(OH)$ units occurs in the borosilicate mineral $CaB(OH)SiO_4$ and the fully three-dimensional polynuclear structure is found in BPO_4 (cf. the isoelectronic SiO_2), $BAsO_4$ and the minerals $NaBSi_3O_8$ and $Zn_4B_6O_{13}$.

The final degree of structural complexity occurs when the polynuclear assemblages contain both planar BO_3 and tetrahedral BO_4 units joined by sharing common O atoms. The structure of monoclinic HBO_2 affords an example (p. 204). A structure in which the ring has but one BO_4 unit is the spiroanion $[B_5O_6(OH)_4]^-$ (structure 121) which occurs in hydrated potassium pentaborate $KB_5O_8.4H_2O$, i.e. $K[B_5O_6(OH)_4].2H_2O$. The anhydrous pentaborate KB_5O_8 has the same structural unit but dehydration of the OH groups link the spiroanions of structure (121) sideways into ribbon-like helical chains. The mineral $CaB_3O_3(OH)_5.H_2O$ has 2 BO_4 units in the 6-membered heterocycle (122) and related chain elements $[B_3O_4(OH)_3{}^{2-}]_n$ linked by a common oxygen atom are found in the important mineral colemanite $Ca_2B_6O_{11}.5H_2O$, i.e. $[CaB_3O_4(OH)_3].H_2O$. It is clear from these examples that, without structural data, the stoichiometry of these borate minerals gives little indication of their constitution. A further illustration is afforded by borax which is normally formulated $Na_2B_4O_7.10H_2O$, but which contains tetranuclear units $[B_4O_5(OH)_4]^{2-}$ formed by fusing 2 B_3O_3 rings which each contain 2 BO_4 (shared) and 1 BO_3 unit (123); borax should therefore be written as $Na_2[B_4O_5(OH)_4].8H_2O$.

There is wide variation of B–O distances in these various structures the values increasing, as expected, with increase in coordination:



The extent to which B_3O_3 rings catenate into more complex structures or hydrolyse into smaller units such as $[B(OH)_4]^-$ clearly depends sensitively on the activity (concentration) of water in the system, on the stoichiometric ratio of metal ions to boron and on the temperature ($T\Delta S$).

Many metal borates find important industrial applications (p. 140) and annual world production exceeds 2.9 million tonnes: Turkey 1.2, USA 1.1, Argentina 0.26, the former Soviet Union 0.18, Chile 0.13 Mt. Main uses are in glass-fibre and cellular insulation, the manufacture of borosilicate glasses and enamels, and as fire retardants. Sodium perborate (for detergents) is manufactured on a 550 000 tonne pa scale.

6.8.3 Organic compounds containing boron–oxygen bonds

Only a brief classification of this very large and important class of compounds will be given; most contain trigonal planar B though many 4-coordinate complexes have also been characterized. The orthoborates $B(OR)_3$ can readily be prepared by direct reaction of BCl_3 or $B(OH)_3$ with ROH, while transesterification with R′OH affords a route to unsymmetrical products $B(OR)_2(OR')$, etc. The compounds range from colourless volatile liquids to involatile white solids depending on molecular weight. R can be a primary, secondary, tertiary, substituted or unsaturated alkyl group or an aryl group, and orthoborates of polyhydric alcohols and phenols are also numerous.

Boronic acids $RB(OH)_2$ were first made over a century ago by the unlikely route of slow partial oxidation of the spontaneously flammable trialkyl boranes followed by hydrolysis of the ester so formed (E. Frankland, 1862):

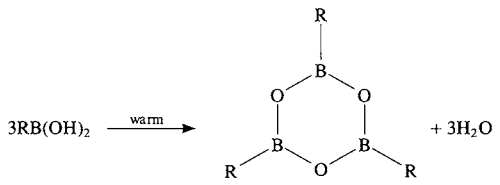
$$BEt_3 + O_2 \longrightarrow EtB(OEt)_2 \xrightarrow{2H_2O} EtB(OH)_2$$

Many other routes are now available but the most used involve the reaction of Grignard reagents or lithium alkyls on orthoborates or boron trihalides:

$$B(OR)_3 + ArMgX \xrightarrow{-50^\circ} [ArB(OR)_3]MgX \xrightarrow{H_3O^+} ArB(OH)_2$$

Phenylboronic acid in particular has proved invaluable, since its complexes with *cis*-diols and -polyols have formed the basis of chromatographic separations, asymmetric syntheses, enzyme immobilization and the preparation of polymers capable of molecular recognition.[117]

Boronic acids readily dehydrate at moderate temperatures (or over P_4O_{10} at room temperature) to give trimeric cyclic anhydrides known as trialkyl(aryl)boroxines:



The related trialkoxyboroxines $(ROBO)_3$ can be prepared by esterifying $B(OH)_3$, B_2O_3 or metaboric acid BO(OH) with the appropriate mole ratio of ROH.

Endless variations have been played on these themes and the B atom can be surrounded by innumerable combinations of groups such as acyloxy (RCOO), peroxo (ROO), halogeno (X), hydrido, etc., in either open or cyclic arrays. However, no new chemical principles emerge.

6.9 Boron–Nitrogen Compounds

Two factors have contributed to the special interest that attaches to B–N compounds. First, the B–N unit is isoelectronic with C–C and secondly, the size and electronegativity of the 3 atoms are similar, C being the mean of B and N:

	B	C	N
Number of valence electrons	3	4	5
Covalent single-bond radius/pm	88	77	70
Electronegativity	2.0	2.5	3.0

The repetition of much organic chemistry by replacing pairs of C atoms with the B–N

[117] C. D'Silva and D. Green, *J. Chem. Soc., Chem. Commun.*, 227–9 (1991) and leading references cited therein.

grouping has led to many new classes of compound but these need not detain us.[118] By contrast, key points emerge from several other areas of B–N chemistry and, accordingly, this section deals briefly with the structure, properties and reaction chemistry of boron nitride, amine-borane adducts, aminoboranes, iminoboranes, cyclic borazines and azaborane clusters.

The synthesis of boron nitride, BN, involves considerable technical difficulty;[119] a laboratory preparation yielding relatively pure samples involves the fusion of borax with ammonium chloride, whereas technical-scale production relies on the fusion of urea with $B(OH)_3$ in an atmosphere of NH_3 at 500–950°C. Only a brave (or foolhardy) chemist would attempt to write a balanced equation for either reaction. An alternative synthesis (>99% purity) treats BCl_3 with an excess of NH_3 (see below) and pyrolyses the resulting mixture in an atmosphere of NH_3 at 750°C. The hexagonal modification of BN has a simple layer structure (Fig. 6.27) similar to graphite but with the significant difference that the layers are packed directly on top of each other so that the B atom in one layer is located over an N atom in the next layer at a distance of 333 pm. Cell dimensions and other data for BN and graphite are compared in Table 6.5. Within each layer the B–N distance is only 145 pm; this is similar to the distance of 144 pm in borazine (p. 210) but much less than the sum of single-bond covalent radii (158 pm) and this has been taken to indicate substantial additional π bonding within the layer. However, unlike graphite, BN is colourless and a good insulator; it also resists attack by most reagents though fluorine converts it quantitatively to BF_3 and N_2 and HF gives NH_4BF_4 quantitatively. Hexagonal BN can be converted into a cubic form (zinc-blende type structure) at 1800°C and 85 000 atm pressure in the presence of an alkali or alkaline-earth metal catalyst. The lattice constant of cubic BN is 361.5 pm (cf. diamond 356.7 pm). A wurtzite-type modification (p. 1210) can be obtained at lower temperatures.

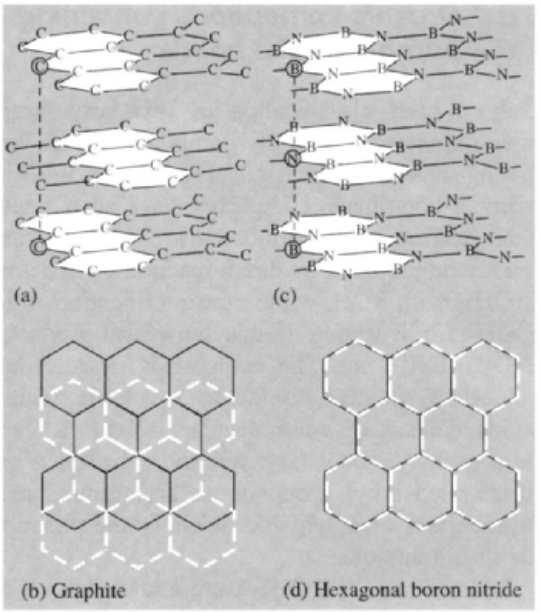


Figure 6.27 Comparison of the hexagonal layer structures of BN and graphite. In BN the atoms of one layer are located directly above the atoms of adjacent layers with B···N contacts; in graphite the C atoms in one layer are located above interstices in the adjacent layer and are directly above atoms in alternate layers only.

Amine-borane adducts have the general formula R_3NBX_3 where R = alkyl, H, etc., and

[118] I. ANDER, Chap. 1.21 in A. R. KATRITZKY and C. W. REES (eds.), *Comprehensive Heterocyclic Chemistry*, Pergamon, Oxford, 1984, pp. 629–63.

[119] R. T. PAINE and C. K. NARULA, *Chem. Rev.* **90**, 73–91 (1990).

Table 6.5 Comparison of hexagonal BN and graphite

	a/pm	*c*/pm	*c*/*a*	Inter-layer spacing/pm	Intra-layer spacing/pm	*d*/g cm^{-3}
BN (hexagonal)	250.4	666.1	2.66	333	144.6	2.29
Graphite	245.6	669.6	2.73	335	142	2.255

X = alkyl, H, halogen, etc. They are usually colourless, crystalline compounds with mp in the range 0–100° for X = H and 50–200° for X = halogen. Synthetic routes, and factors affecting the stability of the adducts have already been discussed (p. 165 and p. 198). In cases where diborane undergoes unsymmetrical cleavage (e.g. with NH_3) alternative routes must be devised:

$$B_2H_6 + 2NH_3 \longrightarrow [BH_2(NH_3)_2]^+BH_4^-$$

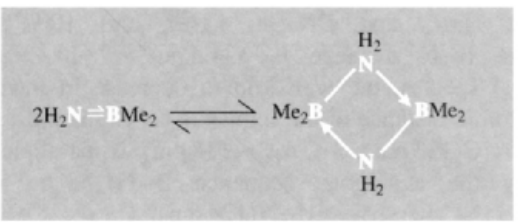
$$NH_4Cl + LiBH_4 \longrightarrow NH_3BH_3 + LiCl + H_2$$

The nature of the bonding in amine-boranes and related adducts has been the subject of considerable theoretical discussion and has also been the source of some confusion. Conventional representations of the donor-acceptor (or coordinate) bond use symbols such as $R_3N{\rightarrow}BX_3$ or $R_3\overset{+}{N}-\overset{-}{B}X_3$ to indicate the origin of the bonding electrons and the direction (but not the magnitude) of charge transfer. It is important to realize that these symbols refer to the relative change in electron density with respect to the individual separate donor and acceptor molecules. Thus, $R_3\overset{+}{N}$ in the adduct has less electron density on N than has free R_3N, and $\overset{-}{B}X_3$ has more electron density on B in the adduct than has free BX_3; this does not necessarily mean that N is positive with respect to B in the adduct. Indeed, several MO calculations indicate that the change in electron density on coordination merely reduces but is insufficient to reverse the initial positive charge on the B atom. Consistent with this, experiments show that electrophilic reagents always attack N in amine-borane adducts, and nucleophilic reagents attack B.

A similar situation obtains in the aminoboranes where one or more of the substituents on B is an R_2N group (R = alkyl, aryl, H), e.g. $Me_2N{-}BMe_2$. Reference to Fig. 6.22 indicates the possibility of some p_π interaction between the lone pair on N and the "vacant" orbital on trigonal B. This is frequently indicated as

$$\rangle N{=}B\langle \quad \text{or} \quad \rangle \overset{+}{N}{=}\overset{-}{B}\langle$$

However, as with the amine-borane adducts just considered, this does not normally indicate the actual sign of the net charges on N and B because the greater electronegativity of N causes the σ bond to be polarized in the opposite sense. Thus, N–B bond moments in aminoboranes have been found to be negligible and MO calculations again suggest that the N atom bears a larger net negative charge than does the B atom. The partial double-bond formulation of these compounds, however, is useful in implying an analogy to the isoelectronic alkenes. Coordinative saturation in aminoboranes can be achieved not only through partial double bond formation but also by association (usually dimerization) of the monomeric units to form $(B{-}N)_n$ rings. For example, in the gas phase, aminodimethylborane exists as both monomer and dimer in reversible equilibrium:



The presence of bulky groups on either B or N hinders dimer formation and favours monomers, e.g. $(Me_2NBF_2)_2$ is dimeric whereas the larger halides form monomers at least in the liquid phase. Association to form trimers (6-membered heterocycles) is less common, presumably because of even greater crowding of substituents, though triborazane $(H_2NBH_2)_3$ and its *N*-methyl derivatives, $(MeHNBH_2)_3$ and $(Me_2NBH_2)_3$, are known in which the B_3N_3 ring adopts the cyclohexane chair conformation.

Preparative routes to these compounds are straightforward, e.g.:

$$R_2NH_2Cl + MBH_4 \longrightarrow R_2NBH_2 + MCl + H_2$$

(R = H, alkyl, aryl)

$$R_2NH + R'_2BX + NEt_3 \longrightarrow R_2NBR'_2 + Et_3NHX$$

(R′ = alkyl, aryl, halide)

$$B(NR_2)_3 + 2BR_3 \longrightarrow 3R_2NBR_2, \text{ etc.}$$

In general monomeric products are readily hydrolysed but associated species (containing 4-coordinate B) are much more stable: e.g. $(Me_2NBH_2)_2$ does not react with H_2O at 50° but is rapidly hydrolysed by dilute HCl at 110° because at this temperature there is a significant concentration of monomer present.

Iminoboranes, R–N≡B–R′, are isoelectronic with alkynes and contain 2-coordinate boron; their chemistry has recently been reviewed.[120,121] Likewise for amino iminoboranes, $R_2N–B{=}NR'$.[122] In both classes of compound inductive and steric effects have an important influence on stability. Another stable 2-coordinate boron species is the linear anion BN_2^{3-} (isoelectronic with CO_2, CNO^-, NCO^-, N_2O, NO_2^+, N_3^- and CN_2^{2-}) which occurs in $M^I_3BN_2$ and $M^{II}_3(BN_2)_2$. For example, Na_3BN_2 can be prepared as light honey-coloured crystals by heating a 2:1 mixture of NaN_3 and BN at 4 GPa and 1000°C; the B–N distance is 134.5 pm.[123] In neutral species, the well known decrease in interatomic distance in the sequence C–C(154 pm) > C=C(133 pm), > C≡C (118 pm) is paralleled by the analogous sequence B–N(158 pm) > B=N(140 pm) > B≡N(124 pm).

The cyclic borazine $(-BH-NH-)_3$ and its derivatives form one of the largest classes of B–N compounds. The parent compound, also known as "inorganic benzene", was first isolated as a colourless liquid from the mixture of products obtained by reacting B_2H_6 and NH_3 (A. Stock and E. Pohland, 1926):

$$3B_2H_6 + 6NH_3 \xrightarrow{180^\circ} 2B_3N_3H_6 + 12H_2$$

It is now best prepared by reduction of the *B*-trichloro derivative:

$$3BCl_3 + 3NH_4Cl \xrightarrow[-9HCl]{\text{heat}} (BClNH)_3$$

$$\xrightarrow{3NaBH_4} B_3N_3H_6 + 3NaCl + \tfrac{3}{2}B_2H_6$$

Borazine has a regular plane hexagonal ring structure and its physical properties closely resemble those of the isoelectronic compound benzene (Table 6.6). Although it is possible to write Kekulé-type structures with N⇒B π bonding superimposed on the σ bonding, the weight of chemical evidence suggests that borazine has but little aromatic character. It reacts readily with H_2O, MeOH and HX to yield 1:3 adducts which eliminate $3H_2$ on being heated to 100°, e.g.:

$$B_3N_3H_6 + 3H_2O \xrightarrow{0^\circ} [BH(OH)NH_2]_3$$

$$\xrightarrow{100^\circ} [B(OH)NH]_3 + 3H_2$$

Table 6.6 Comparison of borazine and benzene

[(a)] 1 dyne = 10^{-5} newton.

Numerous other reactions have been documented, most of which are initiated by nucleophilic attack on B. There is no evidence that electrophilic substitution of the borazine ring occurs and conditions required for such reactions in benzenoid systems disrupt the borazine ring by oxidation or solvolysis. However, it is known that the less-reactive hexamethyl derivative $B_3N_3Me_6$ (which can be heated to 460° for 3 h without significant decomposition)

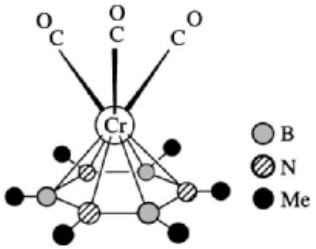

Figure 6.28 Structure of $[Cr(\eta^6\text{-}B_3N_3Me_6)(CO)_3]$.

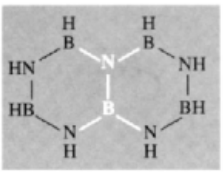
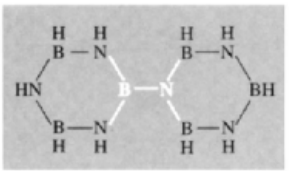
reacts with $[Cr(CO)_3(MeCN)_3]$ to give the complex $[Cr(\eta^6\text{-}B_3N_3Me_6)(CO)_3]$ (Fig. 6.28) which closely resembles the corresponding hexamethylbenzene complex $[Cr(\eta^6\text{-}C_6Me_6)(CO)_3]$.

N-substituted and *B*-substituted borazines are readily prepared by suitable choice of amine and borane starting materials or by subsequent reaction of other borazines with Grignard reagents, etc. Thermolysis of monocyclic borazines leads to polymeric materials and to polyborazine analogues of naphthalene, biphenyl, etc.:





A quite different structural motif is found in the curious cyclic hexamer $[(BNMe_2)_6]$ which can be obtained as orange-red crystals by distilling the initial product formed by dehalogenation of $(Me_2N)_2BCl$ with Na/K alloy:[124]

$$2(Me_2N)_2BCl \xrightarrow{Na/K} [B_2(NMe_2)_4] \xrightarrow{\text{thermolysis}} [(BNMe_2)_6]$$

The B_6 ring has a chair conformation (dihedral angle 57.6°) with mean B–B distances of 172 pm. All 6 B and all 6 N are trigonal planar and the 6-exocyclic NMe_2 groups are each twisted at an angle of ~65° from the adjacent B_3 plane, with B–N 140 pm. Structurally, this cyclohexaborane derivative resembles the radialenes, particularly the isoelectronic $[C_6(=CHMe)_6]$ in which the C_6 ring likewise adopts the chair conformation.

Finally, the conceptual isoelectronic replacement of C–C by B–N can be applied to carbaboranes, thus leading (by appropriate synthetic routes) to azaboranes in which one or more of the cluster vertices of the borane is occupied by an N atom. So far, the following species have been characterized,[125] the relevant cluster geometries and numbering schemes being given by the indicated structures on pp. 153–85: *arachno*-4-NB_8H_{13} (20), *nido*-6-NB_9H_{12} (11), *closo*-1-NB_9H_{10} (5), *arachno*-6,9-$N_2B_8H_{12}$ (21), *nido*-7-$NB_{10}H_{13}$ (41), *nido*-7-$NB_{10}H_{11}^{2-}$ (80), *closo*-1-$NB_{11}H_{12}$ (7, 76) and *anti*-9-$NB_{17}H_{20}$ (31).

6.10 Other Compounds of Boron

6.10.1 Compounds with bonds to P, As or Sb

Only minor echoes of the extensive themes of B–N chemistry occur in compounds containing B–P, B–As or B–Sb bonds but there are signs that the field is now beginning to expand rapidly. Few 1:1 phosphine-borane adducts are known, although the recently characterized white crystalline complex $(C_6F_5)_3B.PH_3$, which dissociates reversibly above room temperature, has been suggested as a useful storage material for the safe purification and generation of PH_3.[126] The interesting compound $Na[B(PH_2)_4]$ can readily be made by reacting BCl_3 with 4 moles of $NaPH_2$; at moderate temperatures and in the presence of thf it rearranges to the diborate analogue $Na[(PH_2)_3B\text{-}PH_2\text{-}B(PH_2)_3]$

and with BH_3.thf it gives the tetrakis(borane) adduct $Na[B(PH_2.BH_3)_4]$.[127]

Phosphinoboranes, like their aminoborane analogues (p. 209), tend to oligomerize, although monomeric examples with planar B and pyramidal P atoms have recently been prepared using bulky substituents, e.g. yellow Mes_2BPPh_2,[128] orange $(Mes_2P)_2BBr$[129] and colourless $(Mes_2P)_2BOEt$, mp 163°C [130](Mes = 2,4,6-$Me_3C_6H_2$-). By contrast, $B(PEt_2)_3$ is a dimer with a planar B_2P_2 ring of 4-coordinate B and P atoms (124).[130] A planar 4-membered ring of 3-coordinate planar B and pyramidal P atoms is featured in the diphosphadiboretane $\{MesPB(tmp)\}_2$ (125) (tmp = 2,2,6,6-tetramethylpiperidino);[131] the corresponding diarsadiboretane is also known. A phosphorus analogue of borazine (p. 210) having a planar B_3P_3 ring is the pale yellow crystalline $(MesBPC_6H_{11})_3$ (126), synthesized by reacting $MesBBr_2$ with $C_6H_{11}PHLi$ in hexane at room temperature;[132] the B–P distances in the boraphosphabenzene are all essentially equal, averaging 184 pm, which is considerably shorter than the known range of single-bond distances (192–196 pm). The cyclohexyl group, C_6H_{11}, can be replaced by Ph, Mes, Bu^t, etc.

Phosphaborane cluster compounds have also been synthesized. For example, thermolysis of a 1:2 mixture of $(Pr^i_2N)BCl$ and $(Pr^i_2N)B(Cl)(SiMe_3)_2$ at 160°C results in the smooth elimination of Me_3SiCl to give colourless crystals of [*closo*-1,5-$P_2(BNPr^i_2)_3$] (127) in high yield:[133]

$$2(Pr^i_2N)B(Cl)P(SiMe_3)_2 + (Pr^i_2N)BCl_2 \longrightarrow 4Me_3SiCl + P_2(BNPr^i_2)_3 \quad \textbf{(127)}$$

The structural analogy with the dicarbaborane $C_2B_3H_5$ (56) is obvious. Likewise, pyrolysis of a mixture of B_2Cl_4 and PCl_3 yields [*closo*-1,2-$P_2B_4Cl_4$] (128) as hygroscopic colourless crystals.[134]

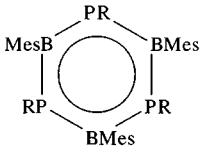
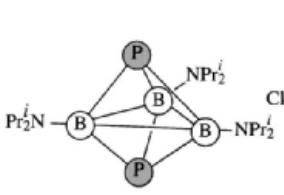
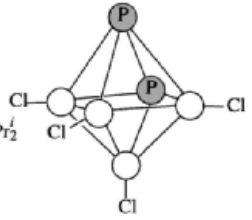
(125)



(126)



(127)



(128)

Typical borane clusters incorporating As or Sb atoms are *closo*-1,2-$B_{10}H_{10}CHAs$ and *closo*-1,2-$B_{10}H_{10}CHSb$ in which the group 15 heteroatom replaces a CH vertex in the dicarbaborane (76); they are prepared in 25 and 41% yield, respectively, by direct reaction of $Na_3B_{10}H_{10}CH$ with $AsCl_3$ or SbI_3, and can be isomerized in high yield below 500°C to the 1,7-isomers. Above 500° the 1,12-isomers can be obtained but this is accompanied by substantial decomposition. The diarsa derivative 1,2-$B_{10}H_{10}As_2$ is also known. Likewise, reaction of *nido*-$B_{10}H_{14}$ with $AsCl_3$ and NaH or $NaBH_4$ affords the 11-vertex anion 7-$B_{10}H_{12}As^-$

and this can be capped using $Et_3N{\cdot}BH_3$ in diglyme at 160° to give the *closo*-icosahedral anion $B_{11}H_{11}As^-$ in 51% yield. Other examples include $B_{11}H_{11}Sb^-$, 1,2-$B_{10}H_{10}Sb_2$, 1,2-$B_{10}H_{10}AsSb$ and the arsenathia- and arsenaselenaboranes $B_8H_8As_2S$ and $B_8H_8As_2Se$.[135]

6.10.2 Compounds with bonds to S, Se and Te

The vast array of B–O minerals and compounds (pp. 139–40 and 203–7) finds no parallel in B–S or B–Se chemistry though thioborates of the type $B(SR)_3$, $R'B(SR)_2$ and $R'_2B(SR)$ are well documented. There are also a growing number of binary boron sulfides and boron–sulfur anions which feature chains, rings and networks. B_2S_3 itself has been known for many years as a pale-yellow solid which tends to form a glassy phase (cf. B_2O_3 and also B_2Se_3). This absence of a suitable crystalline sample prevented the structural characterization of this compound until as late as 1977. It has now been found that B_2S_3 has a fascinating layer structure which bears no resemblance to the three-dimensionally linked B_2O_3 crystal structure but is slightly reminiscent of BN. The structure (Fig. 6.29a) is made up of planar B_3S_3 6-membered rings and B_2S_2 4-membered rings linked by S bridges into almost planar two-dimensional layers.[136] All the boron atoms are trigonal planar with B–S distances averaging 181 pm and the perpendicular interlayer distance is almost twice this at 355 pm. More recently[137] a monomeric form of B_2S_3 was prepared by matrix-isolation techniques at 10 K and shown by vibrational spectroscopy to be a planar V-shaped molecule, S=B–S–B=S, with C_{2v} symmetry, the angle subtended at the central S atom by the linear arms being about 120°.

Another boron sulfide, of stoichiometry BS_2, can be made by heating B_2S_3 and sulfur to 300°C under very carefully defined conditions.[138] It is a colourless, moisture-sensitive material with a porphine-like molecular structure, B_8S_{16}, as shown in Fig. 6.29b. An alternative route to B_8S_{16} involves the reaction of dibromotrithiadiborolane with trithiocarbonic acid in an H_2S generator in dilute CS_2 solution:

$$4BrBSSB(Br)S + 4(HS)_2CS \longrightarrow B_8S_{16} + 4CS_2 + 8HBr$$

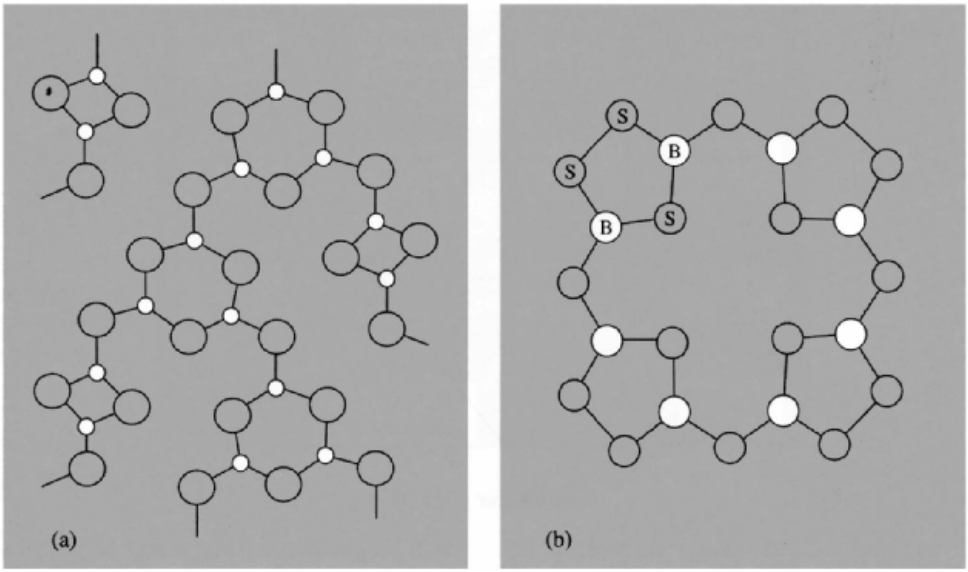

Figure 6.29 (a) Part of the layer structure of B_2S_3 perpendicular to the plane of the layer. (b) Porphine-like structure of the molecule B_8S_{16}.

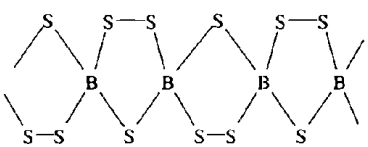
The monomeric selenium compound BSe_2 has been identified mass-spectrometrically in the vapours formed by reacting solid boron with Se_2 and its thermodynamic properties evaluated.[139]

Another expanding area of B–S chemistry is the synthesis and structural characterization of anionic species. The colourless thioborate $RbBS_3$ was formed by heating the stoichiometric amounts of Rb_2S, B and S at 600°. Its structure, and that of the yellow $TlBS_3$, features polymeric anionic chains that are spirocyclically connected via tetrahedral B atoms as shown schematically below:[140]



The sulfur-rich analogue $Tl_3B_3S_{10}$ was likewise prepared as yellow plates from the appropriate stoichiometric mixture of $(3Tl_2S + 6B + 17S)$ at 850° and shown to have a similar polymeric anion with the extra S atoms inserted into each third pentatomic heterocycle to make it a hexatomic unit, $>B(S_2)_2B<$. With the smaller cation, Li^+, similar procedures generate $Li_5B_7S_{13}$ and $Li_9B_{19}S_{33}$ which again have novel polymeric anions. The $\{B_7S_{13}^{5-}\}_\infty$ polymer is formed by sharing B_4S_{10} and $B_{10}S_{20}$ units, i.e. $\{B_4S_6S_{4/2}^{4-}\}$ (cf. P_4O_{10}) and $\{B_{10}S_{16}S_{4/2}^{6-}\}$ both of which are built up from tetrahedral BS_4 subunits, whereas the $\{B_{19}S_{33}^{9-}\}_\infty$ polymer is formed from the conjoining of $\{B_{19}S_{30}S_{6/2}^{9-}\}$ units.[141]

The structural principles and reaction chemistry of B–S compounds have recently been reviewed.[142] This includes not only electron-precise 4-, 5- and 6-membered heterocycles of the types described above, but also electron-deficient polyhedral clusters based on *closo*-,

nido- and *arachno*-boranes. Some typical interconversion reactions of thiaboranes are shown in the scheme on p. 213,[142] and further examples are in references (143) and (144). Selena- and tellura-derivatives are also known[135,145] and, like the thiaboranes, have structures that can be rationalized by the normal electron counting rules, taking the chalcogen atom as a 4-electron donor, e.g. *closo*-$B_{11}H_{11}Te$, *nido*-$B_{10}H_{12}Te$, *nido*-$B_{10}H_{11}Te^-$, *nido*-$B_9H_{11}Te$, *nido*-$B_9H_9Se_2$, *nido*-B_9H_9STe, *arachno*-$B_8H_{10}Se_2$, $[Fe(\eta^5\text{-}B_{10}H_{10}Te)_2]^{2-}$ (green) and $[Co(\eta^5\text{-}C_5H_5)(\eta^5\text{-}B_{10}H_{10}Te)]$ (yellow).

There appears to be no end to the structural ingenuity of boron and, whilst it is true that many regularities can now be discerned in its stereochemistry, much more work is still needed to unravel the reaction pathways by which the compounds are formed and to elucidate the mechanisms by which they isomerize and interconvert.

Aluminium, Gallium, Indium and Thallium

7.1 Introduction

Aluminium derives its name from alum, the double sulfate $KAl(SO_4)_2.12H_2O$, which was used medicinally as an astringent in ancient Greece and Rome (Latin *alumen*, bitter salt). Humphry Davy was unable to isolate the metal but proposed the name "alumium" and then "aluminum"; this was soon modified to aluminium and this form is used throughout the world except in North America where the ACS decided in 1925 to adopt "aluminum" in its publications. The impure metal was first isolated by the Danish scientist H. C. Oersted using the reaction of dilute potassium amalgam on $AlCl_3$. This method was improved in 1827 by H. Wöhler who used metallic potassium, but the first commercially successful process was devised by H. St.-C. Deville in 1854 using sodium. In the same year both he and R. W. Bunsen independently obtained metallic aluminium by electrolysis of fused $NaAlCl_4$. So precious was the metal at this time that it was exhibited next to the crown jewels at the Paris Exposition of 1855 and the Emperor Louis Napoleon III used Al cutlery on state occasions. The dramatic thousand-fold drop in price which occurred before the end of the century (Table 7.1) was due first to the advent of cheap electric power following the development of the dynamo by W. von Siemens in the 1870s, and secondly to the independent development in 1886 of the electrolysis of alumina dissolved in cryolite (Na_3AlF_6) by P. L. T. Héroult in France and C. M. Hall in the USA; both men were 22 years old at the time. World production rose quickly and in 1893 exceeded 1000 tonnes pa for the first time.

Gallium was predicted as eka-aluminium by D. I. Mendeleev in 1870 and was discovered by P. E. Lecoq de Boisbaudran in 1875 by means of the spectroscope; de Boisbaudran was, in fact, guided at the time by an independent theory of his own and had been searching for the missing element for some years. The first indications came with the observation of two new violet lines in the spark spectrum of a sample deposited on zinc, and within a month he had isolated 1 g of the metal starting from several hundred kilograms of crude zinc blende ore. The

Table 7.2 Comparison of predicted and observed properties of gallium

Mendeleev's predictions (1871) for eka-aluminium, M	Observed properties (1993) of gallium (discovered 1875)
Atomic weight ~68	Atomic weight 69.723
Density/g cm^{-3} 5.9	Density/g cm^{-3} 5.904
MP low	MP/°C 29.767
Non-volatile	Vapour pressure 10^{-3} mmHg at 1000°C
Valence 3	Valence 3
M will probably be discovered by spectroscopic analysis	Ga was discovered by means of the spectroscope
M will have an oxide of formula M_2O_3, *d* 5.5 g cm^{-3}, soluble in acids to give MX_3	Ga has an oxide Ga_2O_3, *d* 5.88 g cm^{-3}, soluble in acids to give salts of the type GaX_3
M should dissolve slowly in acids and alkalis and be stable in air	Ga metal dissolves slowly in acids and alkalis and is stable in air
$M(OH)_3$ should dissolve in both acids and alkalis	$Ga(OH)_3$ dissolves in both acids and alkalis
M salts will tend to form basic salts; the sulfate should form alums; M_2S_3 should be precipitated by H_2S or $(NH_4)_2S$; anhydrous MCl_3 should be more volatile than $ZnCl_2$	Ga salts readily hydrolyse and form basic salts; alums are known; Ga_2S_3 can be precipitated under special conditions by H_2S or $(NH_4)_2S$; anhydrous $GaCl_3$ is more volatile than $ZnCl_2$

element was named in honour of France (Latin *Gallia*) and the striking similarity of its physical and chemical properties to those predicted by Mendeleev (Table 7.2) did much to establish the general acceptance of the Periodic Law (p. 20); indeed, when de Boisbaudran first stated that the density of Ga was 4.7 g cm^{-3} rather than the predicted 5.9 g cm^{-3}, Mendeleev wrote to him suggesting that he redetermine the figure (the correct value is 5.904 g cm^{-3}).

Indium and thallium were also discovered by means of the spectroscope as their names indicate. Indium was first identified in 1863 by F. Reich and H. T. Richter and named from the brilliant indigo blue line in its flame spectrum (Latin *indicum*). Thallium was discovered independently by W. Crookes and by C. A. Lamy in the preceding year 1861/2 and named after the characteristic bright green line in its flame spectrum (Greek θαλλός, *thallos*, a budding shoot or twig).

7.2 The Elements

7.2.1 Terrestrial abundance and distribution

Aluminium is the most abundant metal in the earth's crust (8.3% by weight); it is exceeded in abundance only by O (45.5%) and Si (25.7%), and is approached only by Fe (6.2%) and Ca (4.6%). Aluminium is a major constituent of many common igneous minerals including

feldspars and micas. These, in turn, weather in temperate climates to give clay minerals such as kaolinite [$Al_2(OH)_4Si_2O_5$], montmorillonite and vermiculite (p. 349). It also occurs in many well-known though rarer minerals such as cryolite (Na_3AlF_6), spinel ($MgAl_2O_4$), garnet [$Ca_3Al_2(SiO_4)_3$], beryl ($Be_3Al_2Si_6O_{18}$), and turquoise [$Al_2(OH)_3PO_4H_2O$/Cu]. Corundum (Al_2O_3) is one of the hardest substances known and is therefore used as an abrasive; many gemstones are impure forms of Al_2O_3, e.g. ruby (Cr), sapphire (Co), oriental emerald, etc. Commercially, the most important mineral is bauxite $AlO_x(OH)_{3-2x}$ $(0 < x < 1)$; this occurs in a wide belt in tropical and subtropical regions as a result of the leaching out of both silica and various metals from aluminosilicates (see Panel).

Gallium, In and Tl are very much less abundant than Al and tend to occur at low concentrations in sulfide minerals rather than as oxides, though Ga is also found associated with Al in bauxite. Ga (19 ppm) is about as abundant as N, Nb, Li and Pb; it is twice as abundant as B (9 ppm) but is more difficult to extract because of the absence of major Ga-containing ores. The highest concentrations (0.1–1%) are in the rare mineral germanite (a complex sulfide of Zn, Cu, Ge and As); concentrations in sphalerite (ZnS), bauxite or coal, are a hundredfold less. Gallium always occurs in association either with Zn or Ge, its neighbours in the periodic table, or with Al in the same group. It was formerly recovered from flue dusts emitted during sulfide roasting or coal burning (up to 1.5% Ga) but is now obtained as a byproduct of the vast Al industry. Since bauxites contain 0.003–0.01% Ga, complete recovery would yield over 1000 tonnes pa. However, present consumption, though growing rapidly, is little more than 1% of this and production is of the order of 50 tonnes pa (1986). This can be compared with the estimate of 5 tonnes for the total of Ga metal in the 90 y following its discovery (1875–1965). Its price in 1928 was $50 per g; in 1965 it was $1 per g, similar to the then price of gold ($1.1 per g), and in 1986 it was $0.45 per g, i.e. $450/kg for semiconductor grade metal (99.9999%).

Indium (0.24 ppm) is similar in abundance to Sb and Cd, whereas Tl (0.7 ppm) is close to Tm and somewhat less abundant than Mo, W and Tb (1.2 ppm). Both elements are chalcophiles (p. 648), indium tending to associate with the similarly sized Zn in its sulfide minerals whilst the larger Tl tends to replace Pb in galena, PbS. Thallium(I) has a similar radius to Rb^I and so also concentrates with this element in the late magmatic potassium minerals such as feldspars and micas.

Indium is now commercially recovered from the flue dusts emitted during the roasting of Zn/Pb sulfide ores and can also be recovered during the roasting of Fe and Cu sulfide ores. Before 1925 only 1 g of the element was available in the world but production now exceeds 80 000 000 g

Bauxite

The mixed aluminium oxide hydroxide mineral bauxite was discovered by P. Berthier in 1821 near Les Baux in Provence. In temperate countries (such as Mediterranean Europe) it occurs mainly as the "monohydrate" AlOOH (boehmite and diaspore) whereas in the tropics it is generally closer to the "trihydrate" $Al(OH)_3$ (gibbsite and hydrargillite). Since AlOOH is less soluble in aqueous NaOH than is $Al(OH)_3$, this has a major bearing on the extraction process for Al manufacture (p. 219). Typical compositions for industrially used bauxites are Al_2O_3 40–60%, combined H_2O 12–30%, SiO_2 free and combined 1–15%, Fe_2O_3 7–30%, TiO_2 3–4%, F, P_2O_5, V_2O_5, etc., 0.05–0.2%.

World production in 1989 was over 101 million tonnes and this is still increasing. Reserves are immense, being of the order of 22×10^9 tonnes in all (Guinea 5.6, Australia 4.4, Brazil 2.8, Jamaica 2.0, India 1.0, USA 0.038 Gt). Australia is currently the largest producer of alumina with 36.6%, followed by Guinea 16.6%, Brazil 8.7%, Jamaica 8.2% the former Soviet Union 4.6%, India 3.9%, etc. Bauxite is easy to mine by open-cast methods since it occurs typically in broad layers 3–10 m thick with very little topsoil or other overburden. Apart from its preponderant use (>80%) in Al extraction, bauxite is used to manufacture refractories, high-alumina cements and aluminium compounds, and smaller amounts are used as drying agents and as catalysts in the petrochemicals industry.

(i.e. 80 tonnes) each year. Prices have fluctuated widely during the past 20 years, being \$270/kg for 99.97% purity in 1987.

Thallium is likewise recovered from flue dusts emitted during sulfide roasting for H_2SO_4 manufacture, and from the smelting of Zn/Pb ores. Extraction procedures are complicated because of the need to recover Cd at the same time. There are no major commercial uses for Tl metal; world production in 1983 was estimated to be 5–15 tonnes p.a. and the price ranged from \$60 to \$80 per kg depending on purity and amount purchased.

7.2.2 Preparation and uses of the metals [1]

The huge difference in scale between the production of Al metal, on the one hand, and the other elements in the group is clear from the preceding section. The tremendous growth of the Al industry compared with all other non-ferrous metals is indicated in Table 7.3 and Al production is now exceeded only by that of iron and steel (p. 1072).

Production of Al metal involves two stages: (a) the extraction, purification and dehydration of bauxite, and (b) the electrolysis of Al_2O_3 dissolved in molten cryolite Na_3AlF_6. Bauxite is now almost universally treated by the Bayer process; this involves dissolution in aqueous NaOH, separation from insoluble impurities (red muds), partial precipitation of the trihydrate and calcining at 1200°. Bauxites approximating to the "monohydrate" AlOOH require higher concentrations of NaOH (200–300 g l^{-1}) and higher temperatures and pressures (200–250°C, 35 atm) than do bauxites approximating to $Al(OH)_3$ (100–150 g l^{-1} NaOH, 120–140°C). Electrolysis is carried out at 940–980°C in a carbon-lined steel cell (cathode) with carbon anodes. Originally Al_2O_3 was dissolved in molten cryolite (Héroult–Hall process) but cryolite is a rather rare mineral and production from the mines in Greenland provide only about 30 000 tonnes pa, quite insufficient for world needs. Synthetic cryolite is therefore manufactured in lead-clad vessels by the reaction of HF on sodium aluminate (from the Bayer process):

$$6HF + 3NaAlO_2 \longrightarrow Na_3AlF_6 + 3H_2O + Al_2O_3$$

No further cryolite is actually needed once the smelting process is in operation because it is produced in the reduction cells by neutralizing the Na_2O brought into the cell as an impurity in the alumina using AlF_3:

$$4AlF_3 + 3Na_2O \longrightarrow 2Na_3AlF_6 + Al_2O_3$$

Thus operating cells need AlF_3 rather than cryolite, much of it being produced in a fluidized bed reactor from gaseous HF and activated alumina (made by partially calcining the alumina hydrate from the Bayer process). Typical electrolyte composition ranges are Na_3AlF_6 (80–85%), CaF_2 (5–7%), AlF_3 (5–7%), Al_2O_3 (2–8% — intermittently recharged). See also p. 70 for the beneficial use of Li_2CO_3. The detailed electrolysis mechanism is still imperfectly understood but typical operating conditions require up to 10^5 A at 4.5 V and a current density of 0.7 A cm^{-2}. One tonne Al metal requires 1.89 tonnes Al_2O_3, ~0.45 tonnes C anode material, 0.07 tonnes Na_3AlF_6 and about 15 000 kWh of electrical energy. It follows that cheap electric power is the overriding commercial consideration. World production (1988) exceeded 17 million tonnes pa, the leading producers being the USA (23%), China (21%), the former Soviet Union (14%), Canada (9%), Australia (7%),

Table 7.3 World production of some non-ferrous metals/million tonnes pa

[1] *Kirk–Othmer Encyclopedia of Chemical Technology*, 4th edn., Vol. 2, Aluminium and aluminium alloys, pp. 184–251; Aluminium compounds, pp. 252–345. Interscience, New York, 1992.

Brazil, Norway and Czechoslovakia (5% each). In addition to this primary production, recycling of used alloys probably adds a further 3–4 million tonnes pa to the total Al metal consumed.

Some uses of Al and its alloys are noted in the Panel from which it will be seen that many of the mechanical properties of pure Al are greatly improved by alloying it with Cu, Mn, Si, Mg or Zn (Table A). The example of Cu is particularly important because of the insight which it gives into the subtle solid-state diffusion processes that occur during heat treatment. At room temperature

Some Uses of Aluminium Metal and Alloys

Pure aluminium is a silvery-white metal with many desirable properties: it is light, non-toxic, of pleasing appearance, and capable of taking a high polish. It has a high thermal and electrical conductivity, excellent corrosion resistance, is non-magnetic, non-sparking and stands second only to gold for malleability and sixth for ductility. Many of its alloys have high mechanical and tensile strength. Aluminium and its alloys can be cast, rolled, extruded, forged, drawn or machined, and they are readily obtained as pipes, tubes, rods, bars, wires, plates, sheets or foils.

Aluminium resists corrosion not because of its position in the electrochemical series but because of the rapid formation of a coherent, inert, oxide layer. Contact with graphite, Fe, Ni, Cu, Ag or Pb is disastrous for corrosion resistance; the effect of contact with steel, Zn and Cd depends on pH and exposure conditions. Protection is enhanced by anodizing the metal; this involves immersing it in 15–20% H_2SO_4 and connecting it to the positive terminal so that it becomes coated with alumina:

$$2Al + 3O^{2-} - 6e^- \longrightarrow Al_2O_3$$

A layer 10–20 μm thick gives excellent protection between pH 4.5–8.7 and is also adequate for external architectural use; thicker layers (50–100 μm) also impart abrasion resistance. The layer can be coloured by incorporating suitable organic or inorganic compounds in the bath and incorporation of photosensitive material enables photographic images to be developed. Decorative engraving using solutions of nitrate or NH_4HF_2 gives the metal a fine silky texture.

Table A Some aluminium alloys

1000 Series:	Commercially pure Al (<1% of other elements); good properties except for limited mechanical strength. Used in chemical equipment, reflectors, heat exchangers, buildings and decorative trim.
2000 Series:	Cu alloys (~5%); excellent strength and machinability, limited corrosion resistance. Used for components requiring high strength/weight ratio, e.g. truck trailer panels, aircraft structure parts.
3000 Series:	Mn alloys (~1.2%); moderate strength, high workability. Used for cooking utensils, heat exchangers, storage tanks, awnings, furniture, highway signs, roofing, side panels, etc.
4000 Series:	Si alloys (≤12%); low mp and low coefficient of expansion. Used for castings and as filler material for brazing and welding; readily anodized to attractive grey colours.
5000 Series:	Mg alloys (0.3–5%); good strength and weldability coupled with excellent corrosion resistance in marine atmospheres. Used for ornamental and decorative trim, street light standards, ships, boats, cryogenic vessels, gun mounts and crane parts.
6000 Series:	Mg/Si alloys; good formability and high corrosion resistance. Used in buildings, transportation equipment, bridges, railings and welded construction.
7000 Series:	Zn alloys (3–8%) plus Mg; when heat treated and aged have very high strength. Used principally for aircraft structures, mobile equipment and equipment requiring high strength/weight ratio.

Many of the uses listed in Table A are a matter of everyday observation. In addition we may note that the electrical conductivity of pure Al is 63.5% of the conductivity of an equal *volume* of pure Cu; when the lower density of Al is considered its conductivity is 2.1 times that of Cu on a wt. for wt. basis. This, coupled with its corrosion resistance and ready workability makes it an ideal metal for power lines and, indeed, more than 90% of all overhead electrical transmission lines in the USA are Al alloy.

Aluminium is now extensively used in the construction and aérospace industries throughout the world although in the USA packaging has replaced the construction industry as the largest consumer of Al and its alloys. For example, 95% of beer and soft drinks is packaged in two-piece cans comprising an Al/Mn alloy body and Al/Mg alloy ends. There is also extensive use in food packaging, aerosol cans, collapsible tubes for toiletries and pharmaceuticals and as foil (typically 0.18 mm thick).

Al dissolves only about 0.1% Cu and this has little effect on its properties. The solubility rises to a maximum of 5.65% Cu at 548°C and this remains in metastable solid solution to give a soft workable alloy when the alloy is rapidly quenched to temperatures below 65°. Subsequent ageing of the shaped material at 100–150° for a few minutes hardens the alloy due to the formation of Guinier–Preston zones: these zones, independently discovered in 1938 by A. Guinier (France) and G. D. Preston (England), are minute discs of material higher in Cu content than the matrix — they are about 4 atoms thick and up to 100 atoms across; they mesh coherently with the host lattice in two directions, the (100) planes, but not in the third. The coherency strains which thereby develop in the lattice are the basis for the hardening of the alloy. Besides its immense technological importance, this phenomenon is particularly significant in being one of the first recognized examples of a single phase which nevertheless varies regularly in composition throughout its extent.

Gallium metal is now obtained as a byproduct of the Al industry. The Bayer process for obtaining alumina from bauxite gradually enriches the alkaline solutions from an initial weight ratio Ga/Al of about 1/5000 to about 1/300; electrolysis of these extracts with an Hg electrode gives further concentration, and the solution of sodium gallate is then electrolysed with a stainless steel cathode to give Ga metal. Ultra high-purity Ga for semiconductor uses is obtained by further chemical treatment with acids and O_2 at high temperatures followed by crystallization and zone refining. Gallium has a beautiful silvery blue appearance; it wets glass, porcelain, and most other surfaces (except quartz, graphite, and teflon) and forms a brilliant mirror when painted on to glass. Its main use is in semiconductor technology (p. 258). For example, GaAs (isoelectronic with Ge) can convert electricity directly into coherent light (laser diodes) and is employed in electroluminescent light-emitting diodes (LEDs); it is also used for doping other semiconductors and in solid-state devices such as transistors. The compound $MgGa_2O_4$, when activated by divalent impurities such as Mn^{2+}, is used in ultraviolet-activated powders as a brilliant green phosphor. Another very important application is to improve the sensitivity of various bands used in the spectroscopic analysis of uranium. Minor uses are as high-temperature liquid seals, manometric fluids and heat-transfer media, and for low-temperature solders.

Indium, like Ga, is normally recovered by electrolysis after prior concentration in processes leading primarily to other elements (Pb/Zn). It is a soft, silvery metal with a brilliant lustre and (like Sn) it gives out a high-pitched "cry" when bent. Formerly it was much used to protect bearings against wear and corrosion but the pattern of use has been changing in recent years and now its most important applications are in low-melting alloys and in electronic devices. Thus meltable safety devices, heat regulators, and sprinklers use alloys of In with Bi, Cd, Pb and Sn (mp 50–100°C) and In-rich solders are valuable in sealing metal-nonmetal joints in high vacuum apparatus. Indium is of particular importance in the manufacture of p–n–p transistor junctions in Ge (p. 369) and to solder semiconductor leads at low temperature; the softness of the metal also minimizes stress in the Ge during subsequent cooling. So-called III–V semiconductors like InAs and InSb are used in low-temperature transistors, thermistors and optical devices (photoconductors), and InP is used for high-temperature transistors. A further minor use, which exploits the high neutron capture cross-section of In, is as a component in control rods for certain nuclear reactors.

Technical grade Tl is purified from other flue-dust elements (Ni; Zn, Cd; In; Ge, Pb; As; Se, Te) by dissolving it in warm dilute acid, then precipitating the insoluble $PbSO_4$ and adding HCl to precipitate TlCl. Further purification is effected by electrolysing Tl_2SO_4 in dilute H_2SO_4 with short Pt wire electrodes, followed by fusion of the deposited Tl metal at 350–400°C under an atmosphere of H_2. Both the element and its compounds are extremely toxic; skin-contact, ingestion and inhalation are all dangerous, and

the maximum allowable concentration of soluble Tl compounds in air is 0.1 mg m^{-3}. In this context the position of Tl in the periodic table will be noted — it occurs between two other poisonous heavy metals Hg and Pb. Tl_2SO_4 was formerly widely used as a rodenticide and ant killer but it is both odourless and tasteless and is now banned in many countries as being too dangerous for general use. Many suggestions have been made for the use of Tl compounds in industry but none have been substantially developed. A few specialist uses have emerged in infrared technology since TlBr and TlI are transparent to long wavelengths, and there are possibilities for photosensitive diodes and infrared detectors. The very high density of aqueous solutions of Tl formate and malonate have found application in the small-scale separation of minerals and the determination of their densities; a saturated solution containing approximately equal weights of these salts (Clerici's solution) has a density of 4.324 g cm^{-3} at 20° and progressively lower densities can be obtained by dilution.

7.2.3 Properties of the elements

The atomic properties of the Group 13 elements (including boron) are compared in Table 7.4. All have odd atomic numbers and correspondingly few stable isotopes. The varying precision of atomic weights has been discussed (p. 17). The electronic configuration is ns^2np^1 in each case but the underlying core varies considerably: for B and Al it is the preceding noble gas core, for Ga and In it is noble gas plus d^{10}, and for Tl noble gas plus $4f^{14}5d^{10}$. This variation has a substantial influence on the trends in chemical properties of the group and is also reflected in the ionization energies of the elements. Thus, as shown in Fig. 7.1, the expected decrease from B to Al is not followed by a further decrease to Ga because of the "d-block contraction" in atomic size and the higher effective nuclear charge for this element which stems from the fact that the 10 added d electrons do not completely shield the extra 10 positive charges on the nucleus. Similarly, the decrease between Ga and In is reversed for Tl as a result of the further influence of the f block or lanthanide contraction. It is notable that these irregularities for the Group 13 elements do not occur for the Group 3 elements Sc, Y and La, which show a steady decrease in ionization energy from B and Al, all 5 elements having the same type of underlying core (noble gas). This has a decisive influence on the comparative chemistry of the two subgroups.

Boron is a covalently bonded, refractory, non-metallic insulator of great hardness and is thus not directly comparable in its physical properties with Al, Ga, In and Tl, which are all low-melting, rather soft metals having a very low electrical

Table 7.4 Atomic properties of Group 13 elements

resistivity (Table 7.5). The heats of fusion and vaporization of the metals are also much lower than those of boron and tend to decrease with increasing atomic number. In all these properties the metals resemble the neighbouring metals Zn, Cd, Hg; Sn, Pb, etc., and it is probable that in each case the properties are related to the rather small number of electrons available for metallic bonding. Some have seen this as a manifestation of the "inert-pair effect" (see p. 226). The interatomic distances in these elements are also somewhat longer than expected from general trends.

The crystal structure of Al is fcc, typical of many metals, each Al being surrounded by 12 nearest neighbours at 286 pm. Thallium also has a typical metallic structure (hcp) with 12 nearest neighbours at 340 pm. Indium has an unusual structure which is slightly distorted from a regular close-packed arrangement: the structure is face-centred tetragonal and each In has 4 neighbours at 324 pm and 8 at the slightly greater distance of 336 pm Gallium has a unique orthorhombic (pseudotetragonal) structure in which each Ga has 1 very close neighbour at 244 pm and 6 further neighbours, 2 each at 270, 273 and 279 pm. The structure is very similar to that of iodine and the appearance of pseudo-molecules Ga_2 may result from partial pair-wise interaction on neighbouring atoms of the single p electron outside the $[Ar]3d^{10}4s^2$ core which immediately follows the first transition series. As such it can be compared with Hg which also has a very low mp and completes the $[Xe]4f^{14}5d^{10}6s^2$ "pseudo-noble-gas" configuration following the lanthanide elements. Note that all interatomic contacts in metallic Ga are less than those in Al, again emphasizing the presence of a "d-block contraction". Gallium is also unusual in contracting on melting, the volume of the liquid phase being 3.4% less than that of the solid; the

[a]The resistivity of crystalline Ga is markedly anisotropic, the values in the three orthorhombic directions being *a* 17.5, *b* 8.20, *c* 55.3 μohm cm. The resistivity of liquid Ga at 30° is 25.8 μohm cm.
[b]$E°$ for reaction $H_3BO_3 + 3H^+ + 3e^- = B(s) + 3H_2O$.
[c]This is the observed value for $E°(Tl^{3+}/Tl^+)$, hence the calculated value for the corresponding $E°(Tl^{3+}/Tl(s))$ is +0.73 V.

same phenomenon occurs with the next element in the periodic table Ge, and also with Sb and Bi, in addition to the well-known example of H_2O. In each case, a structural feature in the solid is broken down to permit more efficient packing of atoms in the liquid state.

The standard electrode potentials of the heavier Group 13 elements reflect the decreasing stability of the +3 oxidation state in aqueous solution and the tendency, particularly of Tl, to form compounds in the +1 oxidation state (p. 226). The trend to increasing electropositivity of the group oxidation state which was noted for Groups 1 and 2 does not occur with Group 13 but is found, as expected, in Group 3 (Fig. 7.2). Similarly, the steady decrease in electronegativity in the series B > Al > Sc > Y > La > Ac is reversed in Group 13 and there is a steady *increase* in electronegativity from Al to Tl.

7.2.4 Chemical reactivity and trends

The Group 13 metals differ sharply from the non-metallic element boron both in their greater chemical reactivity at moderate temperatures and in their well-defined cationic chemistry for aqueous solutions. The absence of a range of volatile hydrides and other cluster compounds analogous to the boranes and carboranes is also notable. Aluminium combines with most non-metallic elements when heated to give compounds such as AlN, Al_2S_3, AlX_3, etc. It also forms intermetallic compounds with elements from all groups of the periodic table that contain metals. Because of its great affinity for oxygen it is used as a reducing agent to obtain Cr, Mn, V, etc., by means of the thermite process of J. W. Goldschmidt. Finely powdered Al metal explodes on contact with liquid O_2, but for normal samples of the metal a coherent protective oxide film prevents appreciable reaction with oxygen, water or dilute acids; amalgamation with Hg or contact with solutions of salts of certain electropositive metals destroys the film and permits further reaction. Aluminium is also readily soluble in hot concentrated hydrochloric acid and in aqueous NaOH or KOH at room temperature with liberation of H_2. This latter reaction is sometimes written as

$$Al + NaOH + H_2O \longrightarrow NaAlO_2 + \tfrac{3}{2}H_2$$

though it is likely that the species in solution is the hydrated tetrahydroxoaluminate anion $[Al(OH)_4]^-(aq)$ or $[Al(H_2O)_2(OH)_4]^-$.

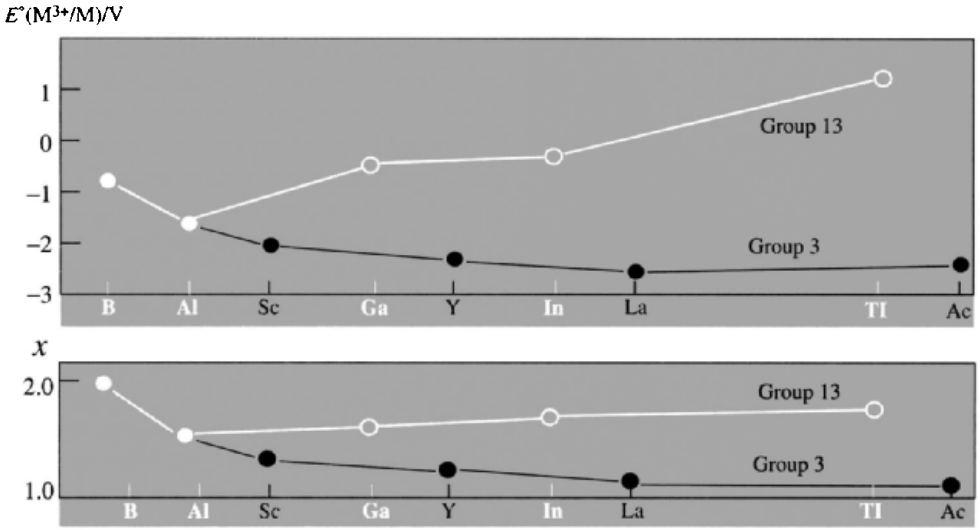

Figure 7.2 Trends in standard electrode potential E° and electronegativity χ for elements in Groups 3 and 13.

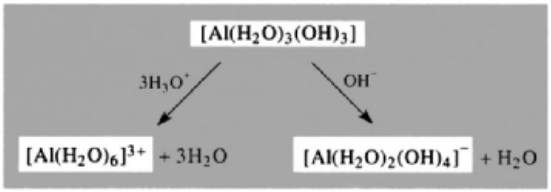
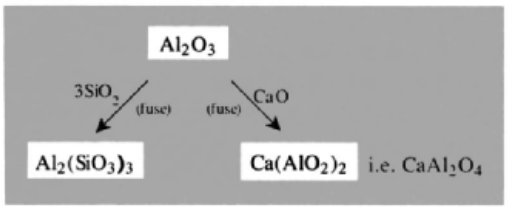
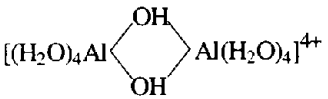
$Al(OH)_3$ is amphoteric, forming both salts and aluminates (Greek ἀμφοτέρως, *amphoteros*, in both ways). Thus the freshly precipitated hydroxide is readily soluble in both acid and alkali:



In these reactions the coordination number of Al has been assumed to be 6 throughout though direct evidence on this point is rarely available. Amphoterism is also exhibited in anhydrous reactions, e.g.:



Aluminium compounds of weak acids are extensively hydrolysed to $[Al(H_2O)_3(OH)_3]$ and the corresponding hydride, e.g. $Al_2S_3 \longrightarrow 3H_2S$, $AlN \longrightarrow NH_3$, and $Al_4C_3 \longrightarrow 3CH_4$. Similarly, the cyanide, acetate and carbonate are unstable in aqueous solution. Hydrolysis of the halides and other salts such as the nitrate and sulfate is incomplete but aqueous solutions are acidic due to the ability of the hydrated cation $[Al(H_2O)_6]^{3+}$ to act as proton donor giving $[Al(H_2O)_5(OH)]^{2+}$, $[Al(H_2O)_4(OH)_2]^{+}$, etc. If the pH is gradually increased this deprotonation of the mononuclear species is accompanied by aggregation via OH bridges to give species such as



and then to precipitation of the hydrous oxide. This is of particular use in water clarification since the precipitating hydroxide nucleates on fine suspended particles which are thereby thrown out of suspension. Still further increase in pH leads to redissolution as an aluminate (Fig. 7.3). Similar behaviour is shown by Be^{II}, Zn^{II}, Ga^{III}, Sn^{II}, Pb^{II}, etc. A detailed quantitative theory of amphoterism is difficult to construct but it is known that amphoteric behaviour occurs when (a) the cation is weakly basic, (b) its hydroxide

LIVE GRAPH

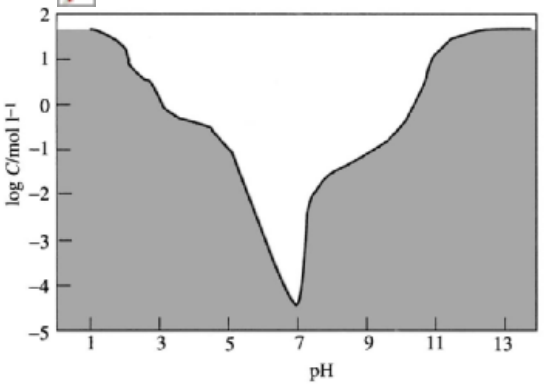


Figure 7.3 Schematic representation of the variation of concentration of an Al salt as a function of pH (see text).

is moderately insoluble, and (c) the hydrated species can also act as proton donors.[2]

Anhydrous Al salts cannot be prepared by heating the corresponding hydrate for reasons closely related to the amphoterism and hydrolysis of such compounds. For example, $AlCl_3.6H_2O$ is, in reality, $[Al(H_2O)_6]Cl_3$ and the strength of the Al–O interaction precludes the formation of Al–Cl bonds:

$$2[Al(H_2O)_6]Cl_3 \xrightarrow{\text{heat}} Al_2O_3 + 6HCl + 9H_2O$$

The amphoteric behaviour of Ga^{III} salts parallels that of Al^{III}; indeed, Ga_2O_3 is slightly *more* acidic than Al_2O_3 and solutions of gallates tend to be more stable than aluminates. Consistent with this, pK_a for the equilibrium

$$[M(H_2O)_6]^{3+} \rightleftharpoons [M(H_2O)_5OH]^{2+} + H^+$$

is 4.95 for Al and 2.60 for Ga. Indium is more basic than Ga and is only weakly amphoteric. The metal does not dissolve in aqueous alkali whereas Ga does. This alternation in the sequence of basicity can be related to the electronic and size factors mentioned on p. 222. Thallium behaves as a moderately strong base but is not strictly comparable with other members of the group because it normally exists as Tl^I in aqueous solution. Thus, Tl metal tarnishes readily and reacts with steam or moist air to give TlOH. The electrode potential data in Table 7.5 show that Tl^I is much more stable than Tl^{III} in aqueous solution and indicate that Tl^{III} compounds can act as strong oxidizing agents.

Compounds of Tl^I have many similarities to those of the alkali metals: TlOH is very soluble and is a strong base; Tl_2CO_3 is also soluble and resembles the corresponding Na and K compounds; Tl^I forms colourless, well-crystallized salts of many oxoacids, and these tend to be anhydrous like those of the similarly sized Rb and Cs; Tl^I salts of weak acids have a basic reaction in aqueous solution as a result of hydrolysis; Tl^I forms polysulfides (e.g. Tl_2S_5) and polyiodides, etc. In other respects Tl^I resembles the more highly polarizing ion Ag^+, e.g. in the colour and insolubility of its chromate, sulfide, arsenate and halides (except F), though it does not form ammine complexes in aqueous solution and its azide is not explosive.

The stability of the +1 oxidation state in Group 13 increases in the sequence Al < Ga < In < Tl, and numerous examples of M^I compounds will be found in the following sections. The occurrence of an oxidation state which is 2 less than the group valency is sometimes referred to as the "inert-pair effect" but it is important to recognize that this is a description not an explanation. The phenomenon is quite general among the heavier elements of the p block (i.e. the post-transition elements in Groups 13–16). For example, Sn and Pb commonly occur in both the +2 and +4 oxidation states; P, As, Sb and Bi in the +3 and +5; S, Se, Te and Po in the +2, +4, and +6 states. The term "inert-pair effect" is somewhat misleading since it implies that the energy required to involve the ns^2 electrons in bonding increases in the sequence Al < Ga < In < Tl. Reference to Table 7.4 shows that this is not so (the sequence is, in fact, In < Al < Tl < Ga). The explanation lies rather in the decrease in bond energy with increase in size from Al to Tl so that the energy required

Previous Page

to involve the s electrons in bonding is not compensated by the energy released in forming the 2 additional bonds. The argument is difficult to quantify since the requisite energy terms are not known. Thus it is unrealistic to use the simple ionic bond model (p. 79) to calculate the heat of formation of MX_3 because compounds like $TlCl_3$ are not ionic, i.e. $[Tl^{3+}(Cl^-)_3]$ — the energy for the ionization of M(g) to $M^{3+}(g)$ is greater than 5000 kJ mol^{-1} for each element and substantial covalent interaction between M^{3+} and X^- would also be expected. In the absence of semi-empirical bond energy data or *ab initio* MO calculations it is only possible to note that the higher oxidation state becomes progressively less stable with respect to the lower oxidation state as atomic number increases within the group. This is seen, for example, by comparing the standard electrode potentials in aqueous solution for M^{III} and M^{I} in Table 7.5. Similarly, from the somewhat fragmentary data available, it appears that the enthalpy of formation of the anhydrous halides remains approximately constant for MX but diminishes irregularly from Al to Tl for MX_3 (X = Cl, Br, I). The overall result depends not only on the simple Born–Haber terms (p. 82) but also on a combination of several other factors including changes in structure and bond type, covalency effects, enthalpies of hydration, entropy effects, etc., and a quantitative rationalization of all the data has not yet been achieved.

Group 13 metals furnish a good example of the general rule that an element is more electropositive in its lower than in its higher oxidation state: the lower oxide and hydroxide are more basic and the higher oxide and hydroxide more acidic. The reasons for this behaviour are similar to those already discussed when comparing Group 2 with Group 1 (p. 111) and turn on the relative magnitude of ionization energies, cationic size, hydration enthalpy and entropy, etc. Again, the higher the charge on an aquo cation $[M(H_2O_x)]^{n+}$ the more readily will it act as a proton donor (p. 51).

Other group trends will emerge in subsequent sections. However, it is worth noting here an important vestigial structural relation of these elements to the icosahedral units in elementary boron (p. 142). Thus, the structures of both β-rhombohedral boron and the cubic alloy phase Al_5CuLi_3 can be constructed from 60-vertex truncated icosahedra, although linked in very different ways in the 3-dimensional crystalline lattice. Likewise, Ga_{12} icosahedra have been found in intermetallic phases such as $RbGa_7$, $CsGa_7$, Li_2Ga_7, K_3Ga_{13} and $Na_{22}Ga_{39}$. This has led to the proposal[3] that the Group 13 elements should be given the collective epithet of 'icosagens'.

7.3 Compounds

7.3.1 Hydrides and related complexes [4–8]

The extensive covalent cluster chemistry of the boron hydrides finds no parallel with the heavier elements of Group 13. AlH_3 is a colourless, involatile solid which is extensively polymerized via Al–H–Al bonds; it is thermally unstable above 150–200°, is a strong reducing agent and reacts violently with water and other protic reagents to liberate H_2. Several crystalline and amorphous modifications have been described and the structure of α-AlH_3 has been determined by X-ray and neutron diffraction:[9] each Al is octahedrally surrounded by 6 H atoms at 172 pm and the Al–H–Al angle is 141°. The participation of each Al in 6 bridges, and the equivalence of all

Al–H distances suggests that 3-centre 2-electron bonding occurs as in the boranes (p. 157). The closest Al···Al distance is 324 pm, which is appreciably shorter than in metallic Al (340 pm), but there is no direct metal–metal bonding and the density of AlH_3 (1.477 g cm^{-3}) is markedly less than that for Al (2.699 g cm^{-3}); this is because in Al metal all 12 nearest neighbours are at 340 pm whereas in AlH_3 there are 6 Al at 324 and 6 at 445 pm.

AlH_3 is best prepared by the reaction of ethereal solutions of $LiAlH_4$ and $AlCl_3$ under very carefully controlled conditions:[10]

$$3LiAlH_4 + AlCl_3 \xrightarrow{Et_2O} 4[AlH_3(Et_2O)_n] + 3LiCl$$

The LiCl is removed and the filtrate, if left at this stage, soon deposits an intractable etherate of variable composition. To avoid this, the solution is worked up with an excess of $LiAlH_4$ and some added $LiBH_4$ in the presence of a large excess of benzene under reflux at 76–79°C. Crystals of α-AlH_3 soon form. Slight variations in the conditions lead to other crystalline modifications of unsolvated AlH_3, 6 of which have been identified.

AlH_3 readily forms adducts with strong Lewis bases (L) but these are more conveniently prepared by reactions of the type

$$LiAlH_4 + NMe_3HCl \xrightarrow{Et_2O} [AlH_3(NMe_3)] + LiCl + H_2$$

$[AlH_3(NMe_3)]$ has a tetrahedral structure and can take up a further mole of ligand to give $[AlH_3(NMe_3)_2]$; this was the first compound in which Al was shown to adopt a 5-coordinate trigonal bipyramidal structure[11] Such complexes are now of interest since their thermal decomposition can be used to prepare ultra-thin carbon-free Al films by chemical vapour deposition on GaAs semiconductor devices.[12]

$LiAlH_4$ is a white crystalline solid, stable in dry air but highly reactive towards moisture, protic solvents, and many organic functional groups. It is readily soluble in ether (~29 g per 100 g at room temperature) and is normally used in this solvent. $LiAlH_4$ has proved to be an outstandingly versatile reducing agent since its discovery some 50 y ago[13,14] (see Panel opposite). It can be prepared on the laboratory (and industrial) scale by the reaction

$$4LiH + AlCl_3 \xrightarrow{Et_2O} LiAlH_4 + 3LiCl$$

On the industrial (multitonne) scale it can also be prepared by direct high-pressure reaction of the elements or preferably via the intermediate formation of the Na analogue.

$$Na + Al + 2H_2 \xrightarrow[350\,atm]{thf/140°/3h} NaAlH_4 \text{ (99\% yield)}$$

The Li salt can then be obtained by metathesis with LiCl in Et_2O. The X-ray crystal structure of $LiAlH_4$ shows the presence of tetrahedral AlH_4 groups (Al–H 155 pm) bridged by Li in such a way that each Li is surrounded by 4H at 188–200 pm (cf. 204 pm in LiH) and a fifth H at 216 pm. The bonding therefore deviates considerably from the simple ionic formulation $Li^+AlH_4^-$ and there appears to be substantial covalent bonding as found in other complex hydrides (p. 67).

Other complex hydrides of Al are known including Li_3AlH_6, M^IAlH_4 (M^I = Li, Na, K, Cs), $M^{II}(AlH_4)_2$ (M^{II} = Be, Mg, Ca), $Ga(AlH_4)_3$, $M^I(AlH_3R)$, $M^I(AlH_2R_2)$, $M^I[AlH(OEt)_3]$, etc. (see Panel). The important complex $Al(BH_4)_3$ has already been mentioned (p. 169); it is a colourless liquid, mp −64.5°, bp +44.5°. It is best prepared

Synthetic Reactions of $LiAlH_4$[4.14]

$LiAlH_4$ is a versatile reducing and hydrogenating reagent for both inorganic and organic compounds. With inorganic halides the product obtained depends on the relative stabilities of the corresponding tetrahydroaluminate, hydride and element. For example, $BeCl_2$ gives $Be(AlH_4)_2$, whereas BCl_3 gives B_2H_6 and HgI_2 gives Hg metal. The halides of Cu, Ag, Au, Zn, Cd and Hg give some evidence of unstable hydrido species at low temperatures but all are reduced to the metal at room temperature. The halides of main groups 14 and 15 yield the corresponding hydrides since the AlH_4 derivatives are unstable or non-existent. Thus $SiCl_4$, $GeCl_4$ and $SnCl_4$ yield MH_4 and substituted halides such as R_nSiX_{4-n} give R_nSiH_{4-n}. Similarly, PCl_3 (and PCl_5), $AsCl_3$ and $SbCl_3$ afford MH_3 but $BiCl_3$ is reduced to the metal. $PhAsCl_2$ gives $PhAsH_2$ and Ph_2SbCl gives Ph_2SbH, etc. Less work has been done on oxides but $COCl_2$ yields MeOH, NO yields hyponitrous acid HON=NOH (which can be isolated as the Ag salt), and CO_2 gives $LiAl(OMe)_4$ or $LiAl(OCH_2O)_2$ depending on conditions.

The real importance of $LiAlH_4$ stems from the applications in organic syntheses. Its commercial introduction dates from 1948. By 1951 the number of functional groups that were known to react was 23 and this rose to more than 60 by the 1970s. Despite this, the heyday of $LiAlH_4$ seems to have been reached in the late 1960s and it has now been replaced in many systems by the more selective borohydrides (p. 167) or by organometallic hydrides (see below). Reaction is usually carried out in ether solution, followed by hydrolysis of the intermediate so formed when appropriate. Typical examples are listed below.

Compound	Product	Compound	Product
Reactive >C=C<	>CH—CH<	RCOSR	RCH_2OH
$RCH{=}CH_2$	$[Al(CH_2CH_2R)_4]^-$	$RCSNH_2$	RCH_2NH_2
C_2H_2	$[AlH(CH{=}CH_2)_3]^-$	RSCN	RSH
$RC{\equiv}CH$	$RCH{=}CH_2$	R_2SO	R_2S
RX	RH (not aryl)	R_2SO_2	R_2S
ROH	$[Al(OR)_4]^-$ or $[AlH(OR)_3]^-$	RSO_2X	RSH
RCHO	RCH_2OH	$ROSO_2R'$, $(ArOSO_2R')$	RH, (ArOH)
R_2CO	R_2CHOH	RSO_2H	RSSR + RSH
Quinone	Hydroquinone	RNC or RNCO or RNCS	RNHMe
RCO_2H or $(RCO)_2O$ or RCOX	RCH_2OH	RCN	RCH_2NH_2 or RCHO
RCO_2R'	$RCH_2OH + R'OH$	$R_2C{=}NOH$	R_2CHNH_2
Lactones, i.e. $\overbrace{O(CH_2)_nC}{=}O$	Diols, i.e. $HO(CH_2)_{n+1}OH$	R_3NO	R_3N
$RCONH_2$	RCH_2NH_2 (also 2^{ry}, 3^{ry})	R_2NNO	R_2NNH_2
Epoxides $\overbrace{OCR_2CHR}$	$R_2C(OH)CH_2R$	RNO_2, RNHOH or RN_3	RNH_2
$\overbrace{SCR_2—CR_2}$	$R_2C(SH)CHR_2$	$ArNO_2$	ArN=NAr
RSSR	RSH		

More recently, $LiAlH_4$ has been eclipsed as an organic reducing agent by the emergence of several cheaper organoaluminium hydrides which are also safer and easier to handle than $LiAlH_4$. Pre-eminent among these are Bu^i_2AlH and $Na[AlEt_2H_2]$ which were introduced commercially in the early 1970s and $Na[Al(OCH_2CH_2OMe)_2H_2]$, VITRIDE®, which became available in bulk during 1979. All three reagents can be prepared directly:

$$2Me_2CH{=}CH_2 + Al + H_2 \longrightarrow Bu^i_2AlH$$

$$2CH_2{=}CH_2 + Al + 2H_2 \longrightarrow \tfrac{1}{2}(Et_2AlH)_2 \xrightarrow{NaH} Na[AlEt_2H_2]$$

$$2MeOCH_2CH_2OH + Al + Na \xrightarrow{H_2/PhMe} Na[Al(OCH_2CH_2OMe)_2H_2]$$

All three are substantially cheaper than $LiAlH_4$ and are now produced on a far larger scale as indicated in the table overleaf. Data refer to US industrial use in 1980 and even larger markets are available outside the chemical industry (e.g. in polymerization catalysis).

Compound	Production/kg	Price/\$ kg^{-1}	\$ per kg 'H'
$LiAlH_4$	6 000	88.00	835.00
Bu^i_2AlH	195 000	5.10	715.00
$Na[AlEt_2H_2]$	91 000	11.00	605.00
$Na[Al(OCH_2CH_2OMe)_2H_2]$	123 000	6.25	638.00

in the absence of solvent by the reaction

$$3NaBH_4 + AlCl_3 \longrightarrow Al(BH_4)_3 + 3NaCl$$

$Al(BH_4)_3$ was the first fluxional compound to be recognized as such (1955) and its thermal decomposition led to a new compound which was the first to be discovered and structurally characterized by means of nmr:

$$2Al(BH_4)_3 \xrightarrow{70^\circ} Al_2B_4H_{18} + B_2H_6$$

This binuclear complex is also fluxional and has the structure shown in Fig. 7.4a. $Al(BH_4)_3$ reacts readily with NMe_3 to give a 1:1 adduct in which Al adopts the unusual pentagonal bipyramidal 7-fold coordination as shown in Fig. 7.4b.[15]

At room temperature $Al(BH_4)_3$ reacts quantitatively in the gas phase with Al_2Me_6 (p. 259) to give $[Al(\eta^2\text{-}BH_4)_2Me]$ (mp -76°) in which one of the BH_4 groups of the parent compound has been replaced by a Me group:

$$4Al(BH_4)_3 + Al_2Me_6 \xrightarrow{rt/2\ h} 6[Al(BH_4)_2Me]$$

Electron diffraction studies in the gas phase reveal an unusual structure in which the 5-coordinate Al atom has square-pyramidal

[15] N. A. Bailey, P. H. Bird and M. G. H. Wallbridge, *Chem. Commun.*, 286–7 (1966); *Inorg. Chem.* 7, 1575–81 (1968).

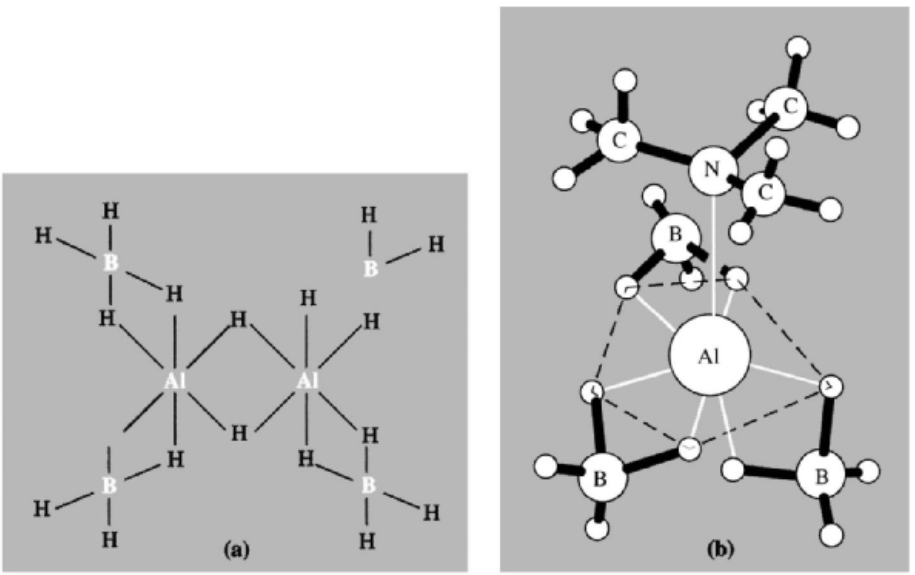

Figure 7.4 (a) Structure of $Al_2B_4H_{18}$ showing 6-coordinate Al, (b) Structure of the adduct $Me_3N.Al(BH_4)_3$ showing 7-coordinate pentagonal bipyramidal Al.

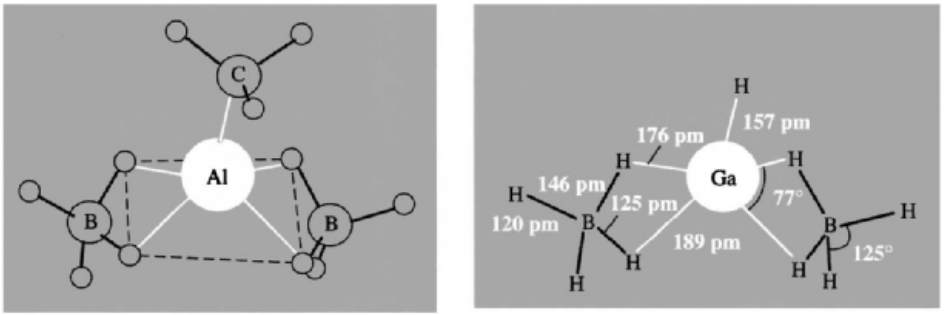

Figure 7.5 (a) Structure of $[MeAl(\eta^2\text{-}BH_4)_2]$ as revealed by electron diffraction, and (b) structure and key dimensions of $[HGa(\eta^2\text{-}BH_4)_2]$ as determined by low temperature X-ray diffractometry.

geometry (Fig. 7.5a).[16] The heavy atoms $CAlB_2$ are coplanar and the symmetry is close to C_{2v}. A similar structure (Fig. 7.5b) has been found by X-ray diffraction for $[Ga(\eta^2\text{-}BH_4)_2H]$, which was prepared by the dry reaction of $LiBH_4$ and $GaCl_3$ at $-45°C$,[17] and this geometry is emerging as a notable structural feature of many AlH_4^- complexes (see next paragraph).

Many complexes in which AlH_4^- acts as a dihapto (or bridging bis-dihapto) ligand to transition metals have recently been characterized. These are usually stabilized by coligands such as tertiary phosphines or η^5-cyclopentadienyls and are readily prepared by treating the corresponding chloro-complexes with $LiAlH_4$ in ether. Typical examples, frequently dimeric, are:[6] $[\{(C_5H_5)_2Y(AlH_4.thf)\}_2]$, $[\{(C_5Me_5)_2Ti(AlH_4)\}_2]$ (Fig. 7.6a), $[\{(C_5Me_5)_2Ta(AlH_4)\}_2]$, $[\{(PMe_3)_3H_3W\}_2\text{-}\mu\text{-}(\eta^2,\eta^2\text{-}AlH_5)]$ (Fig. 7.6b), $[\{(dmpe)_2Mn(AlH_4)\}_2]$ and $[\{(PPh_3)_3HRu(AlH_4)\}_2]$. A few transition metal tetrahydroaluminates $[M(AlH_4)_n]$ are also known but their structures have not yet been determined by X-ray crystallography, e.g.:[6] $[Y(AlH_3)_3]$, $[Ti(AlH_4)_4]$, $[Nb(AlH_4)_5]$ and $[Fe(AlH_4)_2]$.

The synthesis and characterization of gallane, the binary hydride of gallium, has proved even more elusive than that of alane, AlH_3. Success was finally achieved[18,19] by first preparing dimeric monochlorogallane, $\{H_2Ga(\mu\text{-}Cl)\}_2$,[20] and then reducing a freshly prepared sample of this liquid with freshly prepared $LiGaH_4$ under solvent-free conditions in an all-glass apparatus at $-30°C$:

$$2GaCl_3 + 4Me_3SiH \xrightarrow{-23°} Ga_2Cl_2H_4 + 4Me_3SiCl$$

$$Ga_2Cl_2H_4 + 2LiGaH_4 \xrightarrow{-30°} Ga_2H_6 + 2LiGaH_3Cl$$

The volatile product, obtained in about 5% yield, condensed as a white solid at $-50°$ and had a vapour pressure of about 1 mmHg at $-63°$. Gallane decomposes into its elements at ambient temperatures. In the vapour phase it has a diborane-like structure, Ga_2H_6, with Ga–H_t 152 pm, Ga–H_μ 171 pm, Ga···Ga 258 pm and angle GaHGa 98° (electron diffraction).[19] In the solid state gallane tends to aggregate via Ga–H–Ga bonds to give $(GaH_3)_n$ with n, perhaps equal to 4 but, in contrast to the structure

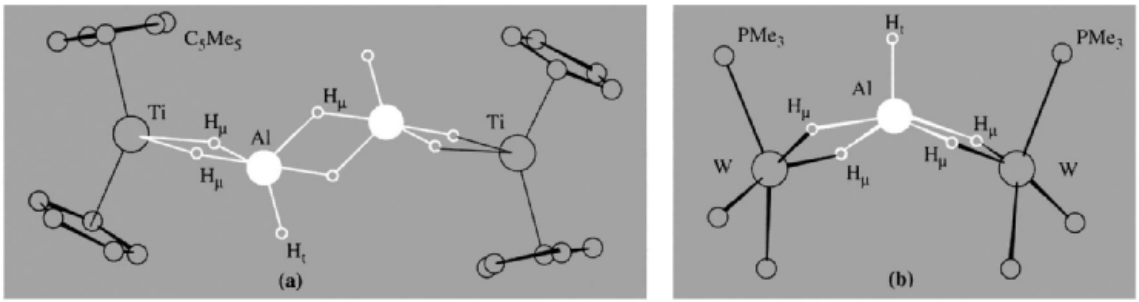

Figure 7.6 (a) The structure of $[\{(C_5Me_5)_2Ti(AlH_4)\}_2]$, i.e. $[\{(\eta^5\text{-}C_5Me_5)_2Ti(\mu\text{-}H)_2Al(H_t(\mu\text{-}H)\}_2]$; the Me groups have been omitted for clarity. (b) The structure of $[\{(PMe_3)_3H_3W\}_2\text{-}\mu\text{-}(\eta^2, \eta^2\text{-}AlH_5)]$; the Me groups have been omitted for clarity and the three H atoms on each W were not located with certainty.

of α-AlH_3 (p. 227), some terminal Ga–H_t bonds remain.

The known reactions of gallane appear mostly to parallel those of diborane (p. 165). Thus, at −95°, NH_3 causes unsymmetrical cleavage to give $[H_2Ga(NH_3)_2]^+[GaH_4]^-$ whereas NMe_3 effects symmetrical clevage to give $Me_3N.GaH_3$ or $(Me_3N)_2GaH_3$ according to the amount used.[19] These last two adducts were already well known. $Me_3N.GaH_3$ can readily be prepared as a colourless crystalline solid, mp 70.5°, by the reaction of ethereal solutions of $LiGaH_4$ and Me_3NHCl.[21] It is one of the most stable complexes of GaH_3 and, like its Al analogue, can take up a further mole of ligand to give the trigonal bipyramidal 2:1 complex.[22] Numerous other complexes have been prepared and the stabilities of the 1:1 adducts decrease in the following sequences:[5]

$$Me_2NH > Me_3N > C_5H_5N > Et_3N$$
$$> PhNMe_2 \gg Ph_3N$$
$$Me_3N \approx Me_3P > Me_2PH$$
$$Ph_3P > Ph_3N > Ph_3As$$
$$R_3N \text{ or } R_3P > R_2O \text{ or } R_2S$$

Complexes of the type $[GaH_2X(NMe_3)]$ and $[GaHX_2(NMe_3)]$ are readily prepared by reaction of HCl or HBr on the GaH_3 complex at low temperatures or by reactions of the type

$$2[GaH_3(NMe_3)] + [GaX_3(NMe_3)] \xrightarrow{C_6H_6} 3[GaH_2X(NMe_3)] \quad X = Cl, Br, I$$

The relative stabilities of these various complexes can be rationalized in terms of the factors discussed on p. 198. A few mixed hydrides have also been characterized, e.g. gallaborane, $H_2Ga(\mu\text{-}H)_2BH_2$,[23] and *arachno*-2-gallatetraborane(10), $H_2GaB_3H_8$,[24] as well as derivatives such as tetramethyldigallane, $Me_2Ga(\mu\text{-}H)_2GaMe_2$.[25]

InH_3 and TlH_3 appear to be too unstable to exist in the uncoordinated state though they may have transitory existence in ethereal solutions at low temperatures. A similar decrease in thermal stability is noted for the tetrahydro complexes; e.g.the temperature at which the Li salts decompose rapidly, follows the sequence

7.3.2 Halides and halide complexes

Several important points emerge in considering the wide range of Group 13 metal halides and their complexes. Monohalides are known for all 4 metals with each halogen though for Al they occur only as short-lived diatomic species in the gas phase or as cryogenically isolated solids. This may seem paradoxical, since the bond dissociation energies for Al–X are substantially greater than for the corresponding monohalides of the other elements and fall in the range 655 kJ mol^{-1} (AlF) to 365 kJ mol^{-1} (AlI). The corresponding values for the gaseous TlX decrease from 460 to 270 kJ mol^{-1} yet it is these latter compounds that form stable crystalline solids. In fact, the instability of AlX in the condensed phase at normal temperatures is due not to the weakness of the Al–X bond but to the ready disproportionation of these compounds into the even more stable AlX_3:

$$AlX(s) \longrightarrow \tfrac{2}{3}Al(s) + \tfrac{1}{3}AlX_3(s);$$
$$\Delta H_{disprop} \text{ (see table below)}$$

The reverse reaction to give the gaseous species AlX(g) at high temperature accounts for the enhanced volatility of AlF_3 when heated in the presence of Al metal, and the ready volatilization of Al metal in the presence of $AlCl_3$. Using calculations of the type outlined on p. 82 the standard heats of formation of the crystalline monohalides AlX and their heats of disproportionation have been estimated as:

Compound (s)	AlF	AlCl	AlBr	AlI
ΔH_f°/kJ mol^{-1}	−393	−188	−126	−46
$\Delta H_{disprop}^\circ$/kJ mol^{-1}	−105	−46	−50	−59

The crystalline dihalides AlX_2 are even less stable with respect to disproportionation, value of $\Delta H_{disprop}$ falling in the range −200 to −230 kJ mol^{-1} for the reaction

$$AlX_2(s) \longrightarrow \tfrac{1}{3}Al(s) + \tfrac{2}{3}AlX_3(s)$$

Very recently the first AlI compound to be stable at room temperature, the tetrameric complex $[\{AlI(NEt_3)\}_4]$, has been prepared and shown to feature a planar Al_4 ring with Al–Al 265 pm, Al–I 265 pm and Al–N 207 pm.[25a]

Aluminium trihalides

AlF_3 is made by treating Al_2O_3 with HF gas at 700° and the other trihalides are made by the direct exothermic combination of the elements. AlF_3 is important in the industrial production of Al metal (p. 219) and is made on a scale approaching 700 000 tonnes per annum world wide. $AlCl_3$ finds extensive use as a Friedel–Crafts catalyst (p. 236): its annual production approaches 100 000 tpa and is dominated by Western Europe, USA and Japan. The price for bulk $AlCl_3$ is about $0.35/kg.

AlF_3 differs from the other trihalides of Al in being involatile and insoluble, and in having a much greater heat of formation (Table 7.6). These differences probably stem from differences in coordination number (6 for AlF_3; change from 6 to 4 at mp for $AlCl_3$; 4 for $AlBr_3$ and AlI_3) and from the subtle interplay of a variety of other factors mentioned below, rather than from any discontinuous change in bond type between the fluoride and the other halides. Similar differences dictated by change in coordination number are noted for many other metal halides, e.g. SnF_4 and SnX_4 (p. 381), BiF_3 and BiX_3 (p. 559), etc., and even more dramatically for some oxides such as CO_2 and SiO_2. In AlF_3 each Al is surrounded by

Table 7.6 Properties of crystalline AlX_3

Property	AlF_3	$AlCl_3$	$AlBr_3$	AlI_3

[25a] A. ECKER and H.-G. SCHNÖCKEL, *Z. anorg. allg. Chem.* **622**, 149–52 (1996).

a distorted octahedron of 6 F atoms and the 1:3 stoichiometry is achieved by the corner sharing of each F between 2 octahedra. The structure is thus related to the ReO_3 structure (p. 1047) but is somewhat distorted from ideal symmetry for reasons which are not understood. Maybe the detailed crystal structure data are wrong.[26] The relatively "open" lattice of AlF_3 provides sites for water molecules and permits the formation of a range of nonstoichiometric hydrates. In addition, well-defined hydrates $AlF_3.nH_2O$ (n = 1, 3, 9) are known but, curiously, no hexahydrate corresponding to the familiar $[Al(H_2O)_6]Cl_3$. In the gas phase at 1000°C the AlF_3 molecule has trigonal planar symmetry (D_{3h})[27] with Al–F 163.0(3) pm which is considerably shorter than in the solid phase 170–190 pm (for 6-coordinate Al).

The complex fluorides of Al^{III} (and Fe^{III}) provide a good example of a family of structures with differing stoichiometries all derived by the sharing of vertices between octahedral $\{AlF_6\}$ units;[26] edge sharing and face sharing are not observed, presumably because of the destabilizing influence of the close (repulsive) approach of 2 Al atoms each of which carries a net partial positive charge. Discrete $\{AlF_6\}$ units occur in cryolite, Na_3AlF_6, and in the garnet structure $Li_3Na_3Al_2F_{12}$ (i.e. $[Al_2Na_3(LiF_4)_3]$, see p. 348) but it is misleading to think in terms of $[AlF_6]^{3-}$ ions since the Al–F bonds are not appreciably different from the other M–F bonds in the structure. Thus the Na_3AlF_6 structure is closely related to perovskite ABO_3 (p. 963) in which one-third of the Na and all the Al atoms occupy octahedral $\{MF_6\}$ sites and the remaining two-thirds of the Na occupy the 12-coordinate sites. When two opposite vertices of $\{AlF_6\}$ are shared the stoichiometry becomes $\{AlF_5\}$ as in $Tl^I_2AlF_5$ (and $Tl^I_2GaF_5$). The sharing of 4 equatorial vertices of $\{AlF_6\}$ leads to the stoichiometry $\{AlF_4\}$ in Tl^IAlF_4. The same structural motif is found in each of the "isoelectronic" 6-coordinate layer lattices of $K_2Mg^{II}F_4$, $KAl^{III}F_4$ and $Sn^{IV}F_4$, none of which contain tetrahedral $\{MF_4\}$ units.

More complex patterns of sharing give intermediate stoichiometries as in $Na_5Al_3F_{14}$ which features layers of $\{Al_3F_{14}{}^{5-}\}$ built up by one-third of the $\{AlF_6\}$ octahedra sharing 4 equatorial vertices and the remainder sharing 2 opposite vertices. Again, Na_2MgAlF_7 comprises linked $\{AlF_6\}$ and $\{MgF_6\}$ octahedra in which 4 vertices of $\{AlF_6\}$ and all vertices of $\{MgF_6\}$ are shared. Likewise, $Sm^{II}AlF_5$ features $\{Al_2F_{10}{}^{4-}\}$ bioctahedra and linear chains of *trans* corner-sharing $\{AlF_6\}$,[28] and $Ba_3Al_2F_{12}$ has a tetrameric $\{(F_4AlF_{2/2})_4{}^{8-}\}$ ring, i.e $[Ba_6F_4(Al_4F_{20})]$,[29] which is unique for fluorometallates, being previously encountered only in neutral molecules $(MF_5)_4$ where M is Nb, Ta (p. 990); Mo, W (p. 1020); Ru, Os (p. 1083). In all of these structures the degree of charge separation, though considerable, is unlikely to approach the formal group charges: thus AlF_3 should not be regarded as a network of alternating ions Al^{3+} and F^- nor, at the other extreme, as an alternating set of Al^{3+} and $AlF_6{}^{3-}$, and lattice energies calculated on the basis of such formal charges placed at the observed interatomic distances are bound to be of limited reliability. Equally, the structure is not well described as a covalently bonded network of Al atoms and F atoms, and detailed MO calculations would be required to assess the actual extent of charge separation, on the one hand, and of interatomic covalent bonding, on the other.

The structure of $AlCl_3$ is similarly revealing. The crystalline solid has a layer lattice with 6-coordinate Al but at the mp 192.4° the structure changes to a 4-coordinate molecular dimer Al_2Cl_6; as a result there is a dramatic increase in volume (by 85%) and an even more dramatic drop in electrical conductivity almost to zero. The mp therefore represents a substantial change in the nature of the bonding. The covalently bonded

molecular dimers are also the main species in the gas phase at low temperatures (~150–200°) but at higher temperature there is an increasing tendency to dissociate into trigonal planar $AlCl_3$ molecules isostructural with BX_3 (p. 196).

By contrast, Al_2Br_6 and Al_2I_6 form dimeric molecular units in the crystalline phase as well as in the liquid and gaseous states and fusion is not attended by such extensive changes in properties. In the gas phase $\Delta H_{dissoc} = 59\,kJ\,mol^{-1}$ for $AlBr_3$ and $50\,kJ\,mol^{-1}$ for AlI_3. In all these dimeric species, as in the analogous dimers Ga_2Cl_6, Ga_2Br_6, Ga_2I_6 and In_2I_6, the $M-X_t$ distance is 10–20 pm shorter than the $M-X_\mu$ distance; the external angle X_tMX_t is in the range 110–125° whereas the internal angle $X_\mu MX_\mu$ is in the range 79–102°

The trihalides of Al form a large number of addition compounds or complexes and these have been extensively studied because of their importance in understanding the nature of Friedel–Crafts catalysis.[30,31] The adducts vary enormously in stability from weak interactions to very stable complexes, and they also vary widely in their mode of bonding, structure and properties. Aromatic hydrocarbons and olefins interact weakly though in some cases crystalline adducts can be isolated, e.g. the clathrate-like complex $Al_2Br_6.C_6H_6$, mp 37° (decomp). With mesitylene ($C_6H_3Me_3$) and the xylenes ($C_6H_4Me_2$) the interaction is slightly stronger, leading to dissociation of the dimer and the formation of weak monomeric complexes $AlBr_3L$ both in solution and in the solid state. At the other end of the stability scale NMe_3 forms two crystalline complexes: $[AlCl_3(NMe_3)]$ mp 156.9° which features molecular units with 4-coordinate tetrahedral Al, and $[AlCl_3(NMe_3)_2]$ which has 5-coordinate Al with trigonal bipyramidal geometry and *trans* axial ligands. By contrast, the adduct $AlCl_3.3NH_3$ has been shown by X-ray diffraction analysis to consist of elongated octahedra $[AlCl_2(NH_3)_4]^+$ and compressed octahedra $[AlCl_4(NH_3)_2]^-$, the

[31] K. WADE and A. J. BANISTER, Chap. 12 in *Comprehensive Inorganic Chemistry*, Vol. 1, pp. 993–1172, Pergamon Press, Oxford, 1973.

arrangement being further stabilized by a network of N–H···Cl hydrogen bonds.[32]

Alkyl halides interact rather weakly and vibrational spectroscopy suggests bonding of the type $R{-}X\cdots AlX_3$. However, for readily ionizable halides such as Ph_3CCl the degree of charge separation is much more extensive and the complex can be formulated as $Ph_3C^+AlCl_4^-$ Acyl halides RCOX may interact either through the carbonyl oxygen, $PhC(Cl){=}O{\rightarrow}AlCl_3$, or through the halogen, $RCOX\cdots AlX_3$ or $RCO^+AlX_4^-$. Again, vibrational spectroscopy is a sensitive, though not always reliable, diagnostic for the mode of bonding. X-ray crystal structures of several complexes have been obtained but these do not necessarily establish the predominant species in nonaqueous solvents because of the delicate balance between the various factors which determine the structure (p. 198). Even in the crystalline state the act of coordination may lead to substantial charge separation. For example, X-ray analysis has established that $AlCl_3ICl_3$ comprises chains of alternating units which are best described as ICl_2^+ and $AlCl_4^-$ with rather weaker interactions between the ions.

Another instructive example is the ligand $POCl_3$ which forms 3 crystalline complexes $AlCl_3POCl_3$ mp 186.5°, $AlCl_3(POCl_3)_2$ mp 164° (d), and $AlCl_3(POCl_3)_6$ *mp* 41° (d). Although the crystal structures of these adducts have not been established it is known that $POCl_3$ normally coordinates through oxygen rather than chlorine and very recently a Raman spectroscopic study of the 1:1 adduct in the gas phase suggests that it is indeed $Cl_3P{=}O{\rightarrow}AlCl_3$ with C_s symmetry.[33] Also consistent with oxygen ligation is the observation that there is no exchange of radioactive ^{36}Cl when $AlCl_3$ containing ^{36}Cl is dissolved in inactive $POCl_3$. However, such solutions are good electrical conductors and spectroscopy reveals $AlCl_4^-$ as a predominant solute species. The resolution of this apparent paradox was provided by means of ^{27}Al nmr spectroscopy[34] which showed that ionization occurred according to the reaction

$$4AlCl_3 + 6POCl_3 \longrightarrow [Al(OPCl_3)_6]^{3+} + 3[AlCl_4]^-$$

It can be seen that all the Cl atoms in $[AlCl_4]^-$ come from the $AlCl_3$. It was further shown that the same two species predominated when Al_2I_6 was dissolved in an excess of $POCl_3$:

$$2Al_2I_6 + 12POCl_3 \rightleftharpoons 4\{AlCl_3\} + 12POCl_2I$$

$$4\{AlCl_3\} + 6POCl_3 \longrightarrow [Al(OPCl_3)_6]^{3+} + 3[AlCl_4]^-$$

No mixed Al species were found by ^{27}Al nmr in this case.

$AlCl_3$ is a convenient starting material for the synthesis of a wide range of other Al compounds, e.g.:

$$AlCl_3 + 3LiY \longrightarrow 3LiCl + AlY_3 \qquad (Y = R, NR_2, N{=}CR_2)$$

$$AlCl_3 + 4LiY \longrightarrow 3LiCl + LiAlY_4 \qquad (Y = R, NR_2, N{=}CR_2, H)$$

Similarly, NaOR reacts to give $Al(OR)_3$ and $NaAl(OR)_4$. $AlCl_3$ also converts non-metal fluorides into the corresponding chloride, e.g.

$$BF_3 + AlCl_3 \longrightarrow AlF_3 + BCl_3$$

This type of transhalogenation reaction, which is common amongst the halides of main group elements, always proceeds in the direction which pairs the most electropositive element with the most electronegative, since the greatest amount of energy is evolved with this combination.[35]

The major industrial use of $AlCl_3$ is in catalytic reactions of the type first observed in 1877 by C. Friedel and J. M. Crafts. $AlCl_3$ is now extensively used to effect alkylations (with RCl, ROH or $RCH{=}CH_2$), acylations (with RCOCl), and

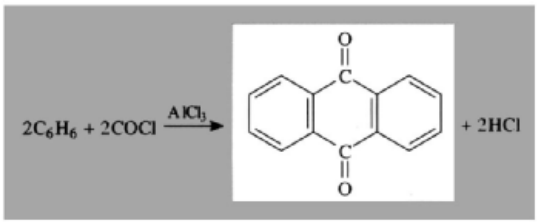
various condensation, polymerization, cyclization, and isomerization reactions.[36] The reactions are examples of the more general class of electrophilic reactions that are catalysed by metal halides and other Lewis acids (electron pair acceptors). Of the 30 000 tonnes of $AlCl_3$ produced annually in the USA, about 15% is used in the synthesis of anthraquinones for the dyestuffs industry:



A further 15% of the $AlCl_3$ is used in the production of ethyl benzene for styrene manufacture, and 13% in making EtCl or EtBr (for $PbEt_4$):

$$CH_2{=}CH_2 + PhH \xrightarrow{AlCl_3} PhEt$$

$$CH_2{=}CH_2 + HX \xrightarrow{AlCl_3} EtX$$

The isomerization of hydrocarbons in the petroleum industry and the production of dodecyl benzene for detergents accounts for a further 10% each of the $AlCl_3$ used.

Trihalides of gallium, indium and thallium

These compounds have been mentioned several times in the preceding sections. As with AlX_3 (p. 233), the trifluorides are involatile and have much higher mps and heats of formation than the other trihalides;[31] e.g. GaF_3 melts above 1000°, sublimes at ~950° and has the 6-coordinate FeF_3-type structure, whereas $GaCl_3$ melts at 77.8°, boils at 201.2°, and has the 4-coordinate molecular structure Ga_2Cl_6. GaF_3 and InF_3 are best prepared by thermal decomposition of $(NH_4)_3MF_6$, e.g.:

$$(NH_4)_3InF_6 \xrightarrow{120-170^\circ} NH_4InF_4 \xrightarrow{300^\circ} InF_3$$

Preparations using aqueous HF on $M(OH)_3$, M_2O_3, or M metal give the trihydrate. TlF_3 is best prepared by the direct fluorination of Tl_2O_3 with F_2, BrF_3 or SF_4 at 300°. Trends in the heats of formation of the Group 13 trihalides show the same divergence from BX_3, AlX_3 and the Group 3 trihalides as was found for trends in other properties such as I_M, E° and χ (pp. 223–5) and for the same reasons. For example, the data for ΔH_f° for the trifluorides and tribromides are compared in Fig. 7.7 from which it is clear that the trend noted for the sequence B, Al, Sc, Y, La, Ac is not followed for the Group 13 metal trihalides which become progressively less stable from Al to Tl.

The volatile trihalides MX_3 form several ranges of addition compounds MX_3L, MX_3L_2, MX_3L_3, and these have been extensively studied because of the insight they provide on the relative influence of the underlying d^{10} electron configuration on the structure and stability of the complexes. With halide ions X^- as ligands the stoichiometry depends sensitively on crystal lattice effects or on the nature of the solvent and the relative concentration of the species in solution. Thus X-ray studies have established the tetrahedral ions $[GaX_4]^-$, $[InCl_4]^-$, etc., and these persist in ethereal

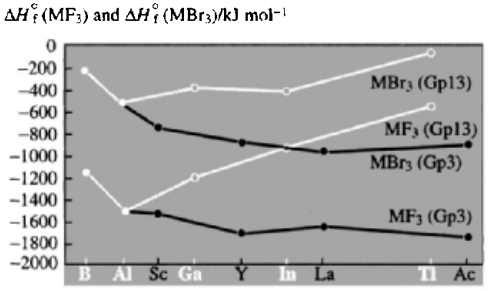


Figure 7.7 Trends in the standard enthalpies of formation ΔH_f° for Groups 3 and 13 trihalides as illustrated by data for MF_3 and MBr_3.

[36] G. A. OLAH (ed.), *Friedel–Crafts and Related Reactions*, Vols. 1–4, Interscience, New York, 1963. See especially Chap. 1, Historical, by G. A. OLAH and R. E. A. DEAR, and Chap. 2, Definition and scope by G. A. OLAH.

solution, though in aqueous solution $[InCl_4]^-$ loses its T_d symmetry due to coordination of further molecules of H_2O. $[NEt_4]_2[InCl_5]$ is remarkable in featuring a square-pyramidal ion of C_{4v} symmetry (Fig. 7.8) and was one of the first recorded examples of this geometry in nontransition element chemistry (1969), cf $SbPh_5$ on p. 598 and the hydrido aluminate species on p. 231. The structure is apparently favoured by electrostatic packing considerations though it also persists in nonaqueous solution, possibly due to the formation of a pseudo-octahedral solvate $[InCl_5S]^{2-}$. It will be noted that $[InCl_5]^{2-}$ is not isostructural with the isoelectronic species $SnCl_5^-$ and $SbCl_5$ which have the more common D_{3h} symmetry. Substituted 5-coordinate chloroderivatives of In^{III} and Tl^{III} often have geometries intermediate between square pyramidal and trigonal bipyramidal.[37]

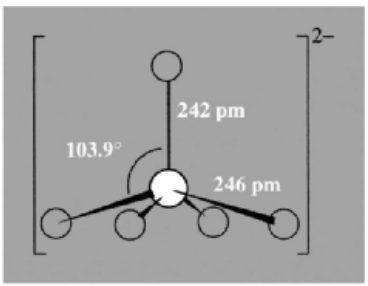

Figure 7.8 The structure of $InCl_5^{2-}$ showing square-pyramidal (C_{4v}) geometry. The $In-Cl_{apex}$ distance is significantly shorter than the $In-Cl_{base}$ distances and In is 59 pm above the basal plane; this leads to a $Cl_{apex}-In-Cl_{base}$ angle of 103.9° which is very close to the theoretical value required to minimize $Cl\cdots Cl$ repulsions whilst still retaining C_{4v} symmetry (103.6°) calculated on the basis of a simple inverse square law for repulsion between ligands. $[NEt_4]_2[TlCl_5]$ is isomorphous with $[NEt_4]_2[InCl_5]$ and presumably has a similar structure for the anion.

With neutral ligands, L, GaX_3 tend to resemble AlX_3 in forming predominantly MX_3L and some MX_3L_2, whereas InX_3 are more varied.[38] InX_3L_3 is the commonest stoichiometry for N and O donors and these are probably predominantly 6-coordinate in the solid state, though in coordinating solvents (S) partial dissociation into ions frequently occurs:

$$InX_3L_3 + S \longrightarrow [InX_2SL_3]^+ + X^-$$

More extensive ionization occurs if, instead of the halides X^-, a less strongly coordinating anion Y^- such as ClO_4^- or NO_3^- is used; in such cases the coordinating stoichiometry tends to be 1:6, e.g. $[InL_6]^{3+}(Y^-)_3$, L = Me_2SO, Ph_2SO, $(Me_2N)_2CO$, $HCO(NMe_2)$, $P(OMe)_3$, etc. Bulky ligands such as PPh_3 and $AsPh_3$ tend to give 1:4 adducts $[InL_4]^{3+}(Y^-)_3$. The same effect of ionic dissociation can be achieved in 1:3 complexes of the trihalides themselves by use of bidentate chelating ligands (B) such as en, bipy, or phen, e.g. $[InB_3]^{3+}(X^-)_3$ (X = Cl, Br, I, NCO, NCS, NCSe). InX_3 complexes having 1:2 stoichiometry also have a variety of structures. Trigonal bipyramidal geometry with axial ligands is found for InX_3L_2, where L = MNe_3, PMe_3, PPh_3, Et_2O, etc. By contrast, the crystal structure of the 1:2 complex of InI_3 with Me_2SO shows that it is fully ionized as $[cis\text{-}InI_2(OSMe_2)_4]^+[InI_4]^-$, and fivefold coordination is avoided by a disproportionation into 6- and 4-coordinate species. Complexes having 1:1 stoichiometry are rare for InX_3; $InCl_3$ forms $[InCl_3(OPCl_3)]$, $[InCl_3(OCMe_2)]$ and $[InCl_3(OCPh_2)]$ and py forms a 1:1 (and a 1:3) adduct with InI_3. Frequently, of course, a given donor–acceptor pair combines in more than one stoichiometric ratio.

The thermochemistry of the Group 13 trihalide complexes has been extensively studied[30,31,39] and several stability sequences have been

established which can be interpreted in terms of the factors listed on p. 198. In addition, Ga and In differ from B and Al in having an underlying d^{10} configuration which can, in principle, take part in $d_\pi - d_\pi$ back bonding with donors such as S (but not N or O); alternatively (or additionally), some of the trends can be interpreted in terms of the differing polarizabilities of B and Al, as compared to Ga and In, the former pair behaving as class-a or "hard" acceptors whereas Ga and In frequently behave as class-b or "soft" acceptors. Again, it should be emphasized that these categories tend to provide descriptions rather than explanations. Towards amines and ethers the acceptor strengths as measured by gas-phase enthalpies of formation decrease in the sequence $MCl_3 > MBr_3 > MI_3$ for M = Al, Ga or In. Likewise, towards phosphines the acceptor strength decreases as $GaCl_3 > GaBr_3 > GaI_3$. However, towards the "softer" sulfur donors Me_2S, Et_2S and C_4H_8S, whilst AlX_3 retains the same sequence, the order for GaX_3 and InX_3 is reversed to read $MI_3 > MBr_3 > MCl_3$. A similar reversal is noted when the acceptor strengths of individual AlX_3 are compared with those of the corresponding GaX_3: towards N and O donors the sequence is invariably $AlX_3 > GaX_3$ but for S donors the relative acceptor strength is $GaX_3 > AlX_3$. These trends emphasize the variety of factors that contribute towards the strength of chemical bonds and indicate that there are no unique series of donor or acceptor strengths when the acceptor atom is varied, e.g.:

towards $MeCO_2Et$:	$BCl_3 > AlCl_3 > GaCl_3 > InCl_3$
towards py:	$AlPh_3 > GaPh_3 > BPh_3 \approx InPh_3$
towards py:	$AlX_3 > BX_3 > GaX_3$ (X = Cl, Br)
towards Me_2S:	$GaX_3 > AlX_3 > BX_3$ (X = Cl, Br)

Regularities are more apparent when the acceptor atom remains constant and the attached groups are varied; e.g., for all ligands so far studied the acceptor strength diminishes in the sequence

$$MX_3 > MPh_3 > MMe_3 \quad (M = B, Al, Ga, In)$$

It has also been found that halide-ion donors (such as X^- in AlX_4^- and GaX_4^-) are more than twice as strong as any neutral donor such as X in M_2X_6, or N, P, O and S donors in MX_3L.[39] Finally, the complexity of factors influencing the strength of such bonds can be gauged from the curious alternation of the gas-phase enthalpies of dissociation of the dimers M_2X_6 themselves; e.g. ΔH°_{298}(dissoc) for Al_2Cl_6, Ga_2Cl_6 and In_2Cl_6 are respectively 126.8, 93.9 and 121.5 kJ mol^{-1}.[40] The corresponding entropies of dissociation ΔS°_{298} are 152.3, 150.4 and 136.0 J mol^{-1}.

The trihalides of Tl are much less stable than those of the lighter Group 13 metals and are chemically quite distinct from them. TlF_3, mp 550° (decomp), is a white crystalline solid isomorphous with β-BiF_3 (p. 560); it does not form hydrates but hydrolyses rapidly to $Tl(OH)_3$ and HF. Nor does it give TlF_4^- in aqueous solution, and the compounds $LiTlF_4$ and $NaTlF_4$ have structures related to fluorite, CaF_2 (p. 118): in $NaTlF_4$ the cations have very similar 8-coordinate radii (Na 116 pm, Tl 100 pm) and are disordered on the Ca sites (Ca 112 pm); in $LiTlF_4$, the smaller size of Li (~83 pm for eightfold coordination) favours a superlattice structure in which Li and Tl are ordered on the Ca sites. Na_3TlF_6 has the cryolite structure (p. 234).

$TlCl_3$ and $TlBr_3$ are obtained from aqueous solution as the stable tetrahydrates and $TlCl_3.4H_2O$ can be dehydrated with $SOCl_2$ to give anhydrous $TlCl_3$, mp 155°; it has the YCl_3-type structure which can be described as NaCl-type with two-thirds of the cations missing in an ordered manner.

TlI_3 is an intriguing compound which is isomorphous with NH_4I_3 and CsI_3 (p. 836); it therefore contains the linear I_3^- ion† and is a compound of Tl^I rather than Tl^{III}. It is obtained as black crystals by evaporating an equimolar solution of TlI and I_2 in concentrated aqueous HI. The formulation $Tl^I(I_3^-)$ rather than $Tl^{III}(I^-)_3$ is consistent with the standard reduction potentials $E^\circ(Tl^{III}/Tl^I) + 1.26$ V and $E^\circ(\frac{1}{2}I_2/I^-) + 0.54$ V,

[40] K. KRAUSZE, H. OPPERMANN, U. BRUHN and M. BALARIN, *Z. anorg. allg. Chem.* **550**, 116–22 (1987).

† Note that this X-ray evidence by itself does not rule out the possibility that the compound is $[I-Tl^{III}-I]^+I^-$.

which shows that uncomplexed Tl^{III} is susceptible to rapid and complete reduction to Tl^{I} by I^- in acid solution. The same conclusion follows from a consideration of the $I_3^-/3I^-$ couple for which $E^\circ = +0.55$ V. Curiously, however, in the presence of an excess of I^-, the Tl^{III} state is stabilized by complex formation

$$Tl^{I}I_3(s) + I^- \rightleftharpoons [Tl^{III}I_4]^-$$

Moreover, solutions of TlI_3 in MeOH do not show the visible absorption spectrum of I_3^- and, when shaken with aqueous Na_2CO_3, give a precipitate of Tl_2O_3, i.e.:

$$2TlI_3 + 6OH^- \rightleftharpoons Tl_2O_3 + 6I^- + 3H_2O$$

This is due partly to the great insolubility of Tl_2O_3 (2.5×10^{-10} g l^{-1} at 25°) and partly to the enhanced oxidizing power of iodine in alkaline solution as a result of the formation of hypoiodate:

$$I_3^- + 2OH^- \rightleftharpoons OI^- + 2I^- + H_2O$$

Consistent with this, even KI_3 is rapidly decolorized in alkaline solution. The example is a salutory reminder of the influence of pH, solubility, and complex formation on the standard reduction potentials of many elements.

Numerous tetrahedral halogeno complexes $[Tl^{III}X_4]^-$ (X = Cl, Br, I) have been prepared by reaction of quaternary ammonium or arsonium halides on TlX_3 in nonaqueous solution, and octahedral complexes $[Tl^{III}X_6]^{3-}$ (X = Cl, Br) are also well established. The binuclear complex $Cs_3[Tl_2^{III}Cl_9]$ is an important structural type which features two $TlCl_6$ octahedra sharing a common face of 3 bridging Cl atoms (Fig. 7.9); the same binuclear complex structure is retained when Tl^{III} is replaced by Ti^{III}, V^{III}, Cr^{III} and Fe^{III} and also in $K_3W_2Cl_9$ and $Cs_3Bi_2I_9$, etc.

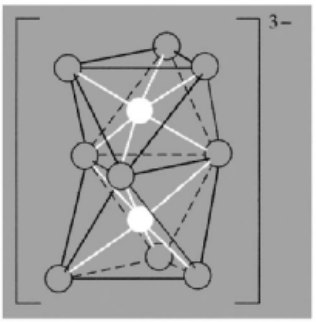

Figure 7.9 The structure of the ion $[Tl_2Cl_9]^{3-}$ showing two octahedral $TlCl_6$ units sharing a common face: Tl–Cl_t 254 pm, Tl–Cl_μ 266 pm. The Tl···Tl distance is nonbonding (281 pm. cf. $2 \times Tl^{III}$ = 177 pm).

Lower halides of gallium, indium and thallium

Like AlX (p. 233), GaF and InF are known as unstable gaseous species. The other monohalides are more stable. GaX can be obtained as reactive sublimates by treating GaX_3 with 2Ga: stability increases with increasing size of the anion and GaI melts at 271°. Stability is still further enhanced by coordination of the anion with, for example, AlX_3 to give $Ga^{I}[Al^{III}X_4]$. Likewise, the very stable "dihalides" $Ga^{I}[Ga^{III}Cl_4]$, $Ga[GaBr_4]$, and $Ga[GaI_4]$ can be prepared by heating equimolar amounts of GaX_3 and Ga, or more conveniently by halogenation of Ga with the stoichiometric amount of Hg_2X_2 or HgX_2. They form complexes of the type $[Ga^{I}L_4]^+[Ga^{III}X_4]^-$ with a wide range of N, As, O, S and Se donors. See also p. 264 for arene complexes of the type $[Ga^{I}(ar)_n]^+[Ga^{III}X_4]^-$. Note, however, that the complexes with dioxan $[Ga_2X_4(C_4H_8O_2)_2]$, do in fact contain Ga^{II} and a Ga–Ga bond, e.g. the chloro complex is a discrete molecule with Ga–Ga 240.6 pm (cf. 239.0 pm in $Ga_2Cl_6^{2-}$);[41] the coordination about each Ga atom is essentially tetrahedral and the compound surprisingly adopts an essentially eclipsed structure rather than the staggered structure of $Ga_2Cl_6^{2-}$. Likewise $[Ga_2I_4.2L]$, where L is a wide range of organic ligands with N, P, O or S donor atoms, have been shown by vibration spectroscopy to have a Ga–Ga bond.[42]

[41] J. C. Beamish, R. W. H. Small and I. J. Worrall, *Inorg. Chem.* **18**, 220–3 (1979).

[42] J. C. Beamish, A. Boardman and I. J. Worrall, *Polyhedron* **10**, 95–9 (1991).

Indium monohalides, InX, can be prepared as red crystals either directly from the elements or by heating In metal with HgX_2 at 320–350°. They have a TlI-type structure (p. 242) with [1 + 4 + 2] rather than 6-fold coordination of In by X, leading to rather close $In^I \ldots In^I$ contacts of 362, 356 and 357 pm respectively for X = Cl, Br and I.[43] Again, InI is the most stable, and mixed halides of the type $In^I[Al^{III}Cl_4]$, $In^I[Ga^{III}Cl_4]$ and $Tl^I[In^{III}Cl_4]$ are known. Numerous intermediate halides have also been reported and structural assignments of varying degrees of reliability have been suggested, e.g. $In^I[In^{III}X_4]$ for InX_2 (Cl, Br, I); and $In^I_3[In^{III}Cl_6]$ for In_2Cl_3. In contrast to the chloride, In_2Br_3 has the unexpected structure $[(In^+)_2\ (In^{II}_2Br_6)^{2-}]$.[44] The compounds In_4X_7 and In_5X_7 (Cl, Br) and In_7Br_9 are also known. In all of these halides the observed stoichiometry is achieved by varying the ratio of In^I to In^{II} or In^{III}, e.g. $[(In^+)_5(InBr_4^-)_2(InBr_6^{3-})]$, $[(In^+)_3(In_2Br_6^{2-})Br^-]$ and $[(In^+)_6(InBr_6^{3-})(Br^-)_3]$.[45,46] Compounds containing In^{II} were unknown until 1976 when the $[In_2X_6]^{2-}$ dianions having an ethane-like structure were prepared:[47]

$$2Bu_4NX + In_2X_4 \xrightarrow{\text{xylene}} [NBu_4]^+_2[X_3In{-}InX_3]^{2-}$$

(X = Cl, Br, I)

The analogous Ga compounds, e.g. $[NEt_4]_2[Cl_3Ga{-}GaCl_3]$, have been known for rather longer (1965). Oxidation of $In_2X_6^{2-}$ with halogens Y_2 yields the mononuclear mixed halide complexes InX_3Y^- and $InX_2Y_2^-$ ($X \neq Y$ = Cl, Br, I).[48]

Thallium(I) is the stable oxidation state for the halides of this element (p. 226) and some physical properties are in Table 7.7. TlF is readily obtained by the action of aqueous HF on Tl_2CO_3; it is very soluble in water (in contrast to the other TlX) and has a distorted NaCl structure in which there are 3 pairs of Tl–F distances at 259, 275 and 304 pm. TlCl, TlBr and TlI are all prepared by addition of the appropriate halide ion to acidified solutions of soluble Tl^I salts (e.g. perchlorate, sulfate, nitrate). TlCl and TlBr have the CsCl structure (p. 80) as befits the large Tl^I cation and both salts (and TlI) are photosensitive (like AgX). Yellow TlI has a curious orthorhombic layer structure related to NaCl (Fig. 7.10), and this transforms at 175° or at 4.7 kbar to a metastable red cubic form with 8-iodine neighbours at 364 pm (CsCl type). This transformation is accompanied by 3% reduction in volume. Further application of pressure steadily reduces the volume and at pressures above about 160 kbar, when the volume has decreased by about 35%, the compound becomes a metallic conductor with a resistivity of the order of 10^{-4} ohm cm at room temperature and a positive temperature coefficient. TlCl and TlBr behave similarly. All three compounds are excellent insulators at normal pressures with negligible conductivity and an energy gap between the valence band and conduction band

(a) (b)

Figure 7.10 Structure of yellow TlI (a) showing its relation to NaCl (b). Tl has 5 nearest-neighbour I atoms at 5 of the vertices of an octahedron and then 2I + 2Tl as next-nearest neighbours; there is one I at 336 pm. 4 at 349 pm, and 2 at 387 pm, and the 2 close Tl–Tl approaches, one at 383 pm. InX (X = Cl, Br, I) have similar structures in their red forms.[43].

of about 3 eV (~300 kJ mol^{-1}), and the onset of metallic conduction is presumably due to the spreading and eventual overlap of the two bands as the atoms are forced closer together.[49]

Several other lower halides of Tl are known: $TlCl_2$ and $TlBr_2$ are $Tl^I[Tl^{III}X_4]$, Tl_2Cl_3 and Tl_2Br_3 are $Tl^I_3[Tl^{III}X_6]$. In addition there is Tl_3I_4, which is formed as an intermediate in the preparation of Tl^II_3 from TlI and I_2 (p. 239).

7.3.3 Oxides and hydroxides

The structural relations between the many crystalline forms of aluminium oxide and hydroxide are exceedingly complex but they are of exceptional scientific interest and immense technological importance. The principal structural types are listed in Table 7.8 and many intermediate and related structures are also known. Al_2O_3 occurs as the mineral corundum (α-Al_2O_3, d 4.0 g cm^{-3}) and as emery, a granular form of corundum contaminated with iron oxide and silica. Because of its great hardness (Mohs 9),† high mp (2045°C), involatility (10^{-6} atm at 1950°), chemical inertness and good electrical insulating properties, it finds many applications in abrasives (including toothpaste), refractories, and ceramics, in addition to its major use in the electrolytic production of Al metal (p. 219). Larger crystals, when coloured with metal-ion impurities, are prized as gemstones, e.g. ruby (Cr^{III} red), sapphire ($Fe^{II/III}$, Ti^{IV} blue), oriental emerald (?Cr^{III}/V^{III} green), oriental amethyst (Cr^{III}/Ti^{IV} violet) and oriental topaz (Fe^{III}, yellow). Many of these gems are also made industrially on a large scale by the fusion process first developed at the turn of the century by A. Verneuil. Pure α-Al_2O_3 is made industrially by igniting $Al(OH)_3$ or AlO(OH) at high temperatures (~1200°); it is also formed by the combustion of Al and by calcination of various Al salts. It has a rhombohedral crystal structure comprising a hcp array of oxide ions with Al ordered on two-thirds of the octahedral interstices as shown in Fig. 7.11.[26] The same α-M_2O_3 structure is adopted by several other elements with small M^{III} (r 62–67 pm), e.g. Ga, Ti, V, Cr, Fe and Rh.‡

[49] G. A. SAMARA and H. G. DRICKAMER, *J. Chem. Phys.* **37**, 408–10 (1962); see also E. A. PEREZ-ALBUERNE and H. G. DRICKAMER, *J. Chem. Phys.* **43**, 1381–7 (1965).

† On the Mohs scale diamond is 10 and quartz 7. An alternative measure is the Knoop hardness (kg mm^{-2}) as measured with a 100-g load: typical values on this scale are diamond 7000, boron carbide 2750, corundum 2100, topaz 1340, quartz 820, hardened tool steel 740.

‡ For somewhat larger cations (r 70–96 pm) the C-type rare-earth M_2O_3 structure (p. 1238) is adopted, e.g. for In,

Table 7.8 The main structural types of aluminium oxides and hydroxides[a]

Formula	Mineral name	Idealized structure
α-Al_2O_3	Corundum	hcp O with Al in two-thirds of the octahedral sites
α-AlO(OH)	Diaspore	hcp O (OH) with chains of octahedra stacked in layers interconnected with H bonds, and Al in certain octahedral sites
α-$Al(OH)_3$	Bayerite	hcp (OH) with Al in two-thirds of the octahedral sites
γ-Al_2O_3	—	ccp O defect spinel with Al in $21\frac{1}{3}$ of the 16 octahedral and 8 tetrahedral sites
γ-AlO(OH)	Boehmite	ccp O (OH) within layers; details uncertain
γ-$Al(OH)_3$	Gibbsite (Hydrargillite)	ccp OH within layers of edge-shared $Al(OH)_6$; octahedra stacked vertically via H bonds

[a]The Greek prefixes α- and γ- are not used consistently in the literature, e.g. bayerite is sometimes designated as β-$Al(OH)_3$ and gibbsite as α-$Al(OH)_3$. The UK usage adopted here is consistent with Wells[26] and emphasizes the structural relations between the hcp α-series and the ccp γ-series. Numerous other intermediate crystalline phases have been characterized during partial dehydration and designated as γ', δ, ζ, η, θ, κ, κ', ρ, χ, etc.

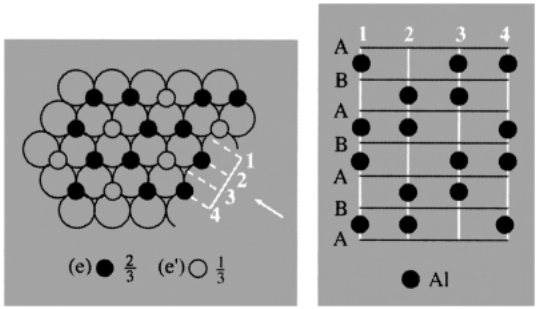

Figure 7.11 Schematic representation of the structure of α-Al_2O_3. (a) pattern of occupancy by Al (●) of the octahedral sites between hcp layers of oxide ion (○), and (b) stacking sequence of successive planes of Al atoms viewed in the direction of the arrow in (a).

The second modification of alumina is the less compact cubic γ-Al_2O_3 (d 3.4 g cm^{-3}); it is formed by the low-temperature dehydration (<450°) of gibbsite, γ-$Al(OH)_3$, or boehmite, γ-AlO(OH). It has a defect spinel-type structure (p. 248) comprising a face-centred cubic (fcc) arrangement of 32 oxide ions and a random occupation of $21\frac{1}{3}$ of the 24 available cation sites (16 octahedral, 8 tetrahedral). This structure forms the basis of the so-called "activated aluminas" and progressive dehydration in the γ-series leads to open-structured materials of great value as catalysts, catalyst-supports, ion exchangers and chromatographic media. Calcination of γ-Al_2O_3 above 1000° converts it irreversibly to the more stable and compact α-form (ΔH_{trans} − 20 kJ mol^{-1}). Yet another form of Al_2O_3 occurs as the protective surface layer on the metal: it has a defect NaCl-type structure with Al occupying two-thirds of the octahedral (Na) interstices in the fcc oxide lattice. Perhaps the most ingenious and sophisticated development in aluminium technology has been the recent production of Al_2O_3 fibres which can be fabricated into a variety of textile forms, blankets, papers, and boards. Some idea of the many possibilities of such high-temperature inert fabrics is indicated in the Panel on p. 244.

Diaspore, α-AlO(OH) occurs in some types of clay and bauxite; it is stable in the range 280–450° and can be made by hydrothermal treatment of boehmite, γ-AlO(OH), in 0.4% aqueous NaOH at 380° and 500 atm. Crystalline boehmite is readily prepared by warming the amorphous, gelatinous white precipitate which first forms when aqueous NH_3 is added to cold solutions of Al salts. In α-AlO(OH) the O atoms are arranged in hcp; continuous chains of edge-shared octahedra are stacked in layers

Tl, Sc, Y, Sm and the subsequent lanthanoids, and perhaps surprisingly for Mn^{III} (r 65 pm); the largest lanthanoids La, Ce, Pr and Nd (r 106–100 pm) adopt the A-type rare-earth M_2O_3 structure (p. 1238).

Fibrous Alumina and Zirconia[50,51]

A new family of lightweight inorganic fibres made its commercial debut in 1974 when ICI announced the production of "Saffil", fibrous Al_2O_3 and ZrO_2 on an initial scale of 100 tonnes pa. Du Pont also has a process for α-Al_2O_3 fibres and the current world production of fibrous Al_2O_3 is of the order of 1000 tonnes per annum. The price is about \$60/kg (1986). The fibres, which have no demonstrable toxic effects (cf. asbestos), have a diameter of ~3 μm (cf. human hair ~70 μm), and each fibre is extremely uniform along its length (2–5 cm). The fibres are microcrystalline (5–50 pm diam) and are both flexible and resilient with a high tensile strength. They have a soft, silky feel and can be made into rope, yarn, cloth, blankets, fibre matts, paper of various thickness, semi-rigid and rigid boards, and vacuum-formed objects of any required shape. The surface area of Saffil alumina is 100–150 $m^2\ g^{-1}$ due to the presence of small pores 2–10 pm diameter between the microcrystals, and this enhances its properties as an insulator, filtration medium, and catalyst support. The fibres withstand extended heating to 1400° (Al_2O_3) or 1600°C (ZrO_2) and are impervious to attack by hot concentrated alkalis and most hot acids except conc H_2SO_4, conc H_3PO_4 and aq HF. This unique combination of properties provides the basis for their use in high-temperature insulation, heat shields, thermal barriers, and expansion joints and seals. Fibrous alumina and zirconia are also valuable in thermocouple protection, electric-cable sheathing, and heating-element supports in addition to their use in the high-temperature filtration of corrosive liquids. Both oxides are stabilized by incorporation of small amounts of other inorganic oxides which inhibit disruptive transformation to other crystalline forms.

Alumina fibres can also be used to strengthen metals. Molten metals (e.g. Al, Mg, Pb) or their alloys are forced into moulds containing up to 70% by volume of α-Al_2O_3 fibre. For example, fibre-reinforced Al containing 55% fibre by volume is 4–6 times stiffer than unreinforced Al even up to 370°C and has 2–4 times the fatigue strength. Potential applications for which high structural stiffness, heat resistance, and low weight are required include helicopter housings, automotive and jet engines, aerospace structures and lead-acid batteries. For example, fibre reinforced composites of Al or Mg could eventually replace much of the steel used in car bodies without decreasing safety, since the composite has the stiffness of steel but only one-third of its density.

In addition to the production of stabilized Al_2O_3 fibres there is also a huge production of melt-spun glassy fibres containing approximately equal proportions by weight of Al_2O_3 and SiO_2. This is used mainly for thermal insulation at temperatures up to 1400°C and current world production exceeds 20 000 tonnes per annum.

and are further interconnected by H bonds. The underlying hcp structure ensures that diaspore dehydrates directly to α-Al_2O_3 (corundum) which has the same basic hcp arrangement of O atoms. The structure is also adopted by several other α-MO(OH) (M = Ga, V, Mn and Fe); this contrasts with the structure of boehmite, γ-AlO(OH), which as a whole is not close-packed, though within each layer the O atoms are arranged in cubic close packing. Dehydration at temperatures up to 450° proceeds via a succession of phases to the cubic γ-Al_2O_3 and the α (hexagonal) structure cannot be attained without much more reconstruction of the lattice at 1100–1200° as noted above [and of γ-ScO(OH) and γ-FeO(OH)].

Bayerite, α-$Al(OH)_3$, does not occur in nature but can be made by rapid precipitation from alkaline solutions in the cold:

$$2[Al(OH)_4]^-aq + CO_2(g) \longrightarrow 2Al(OH)_3 + CO_3^{2-}(aq) + H_2O$$

Gibbsite (or hydrargillite), γ-$Al(OH)_3$, is a more stable form and can be prepared by slow precipitation from warm alkaline solutions or by digesting the α-form in aqueous sodium aluminate solution at 80°. In both bayerite (α) and gibbsite (γ) there are layers of composition $Al(OH)_3$ built up by the edge sharing of $Al(OH)_6$ octahedra to give a pair of approximately close-packed OH layers with Al atoms in two-thirds of the octahedral interstices (Fig. 7.12a). The two crystalline modifications differ in the way this layer is stacked: it is approximately hcp in α-$Al(OH)_3$ but in the γ-form the OH groups on the under side of one layer rest directly above the OH groups of the layer below as shown in Fig. 7.12b. A third form of $Al(OH)_3$, nordstrandite, is obtained from the gelatinous

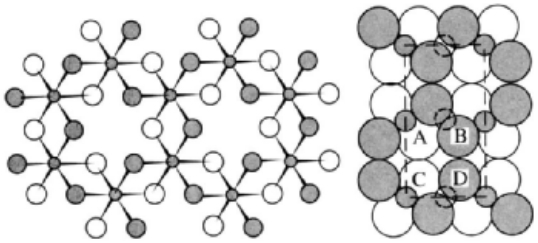

Figure 7.12 (a) Part of a layer of $Al(OH)_3$ (idealized); the heavy and light open circles represent OH groups above and below the plane of the Al atoms. In α-$Al(OH)_3$ the layers are stacked to give approximately hcp. (b) Structure of γ-$Al(OH)_3$ viewed in a direction parallel to the layers; the OH groups labelled C and D are stacked directly beneath A and B. The six OH groups A, B, C, D and B′, D′ (behind B and D), form a distorted H-bonded trigonal prism.

hydroxide by ageing it in the presence of a chelating agent such as ethylenediamine, ethylene glycol, or edta; this aligns the OH to give a stacking arrangement which is intermediate between those of the α- and γ-forms.

As expected from the foregoing structural discussion, gibbsite can be dehydrated to boehmite at 100° and to anhydrous γ-Al_2O_3 at 150°, but ignition above 800° is required to form α-Al_2O_3. Numerous recipes have been devised for preparing catalysts of differing reactivity and absorptive power, based on the partial dehydration and progressive reconstitution of the Al/O/OH system.[1] In addition to pore size, surface area and general reactivity, the basic character of the surface diminishes (and its acidic character increases) in the following series as indicated by the pH of the isoelectric point:

(amorph. Al oxide hydrate)	> γ-AlO(OH)	> α-$Al(OH)_3$	> γ-$Al(OH)_3$	> γ-Al_2O_3
	boehmite	bayerite	gibbsite	
pH: 9.45 (isoelec. pt.)	9.45–9.40	9.20	–	8.00

The aqueous solution chemistry of Al and the other group 13 metals is rather complicated. The aquo ions are acidic with $pK_A \approx 10^{-5}$, 10^{-3}, 10^{-4} and 10^{-1}, respectively, for $[M(H_2O)_6]^{3+} \rightleftharpoons [M(OH)(H_2O)_5]^{2+} + H^+$ (M = Al, Ga, In, Tl). The solution chemistry of Al in particular has been extensively investigated because of its industrial importance in water treatment plants, its use in many toiletry formulations, its possible implication in both Altzheimer's disease and the deleterious effects of acid rain, and the ubiquity of Al cooking utensils.[52–54] For example, hydrated aluminium sulphate (10–30 g m^{-3}) can be added to turbid water supplies at pH 6.5–7.5 to flocculate the colloids, some 3 million tonnes per annum being used worldwide for this application alone. Likewise kilotonne amounts of "$Al(OH)_{2.5}Cl_{0.5}$" in concentrated (6M) aqueous solution are used in the manufacture of deodorants and antiperspirants.

The use of ^{27}Al nmr (see Panel) has been particularly valuable in characterizing the species present in aqueous solution of Al salts.[55] These depend very much on both concentration and pH and include the mononuclear ions $[Al(OH)_4]^-$, $[Al(H_2O_6]^{3+}$ and $[Al(OH)(H_2O)_5]^{2+}$. This latter species can deprotonate further to $[Al(OH)_2(H_2O)_4]^+$ and readily dimerizes via hydroxyl bridges to $[(H_2O)_4Al(\mu\text{-}OH)_2Al(H_2O)_4]^{4+}$, i.e. $[H_{18}Al_2O_{10}]^{4+}$, which has also been found in several crystalline salts. Higher oligomers probably include appropriately hydrated forms of $[Al_3(OH)_{11}]^{2-}$, $[Al_6(OH)_{15}]^{3+}$ and $[Al_8(OH)_{22}]^{2+}$. A particularly important species is the well-characterized tridecameric cation $[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$ which has the well-known Keggin structure (p. 1014),

^{27}Al in Nuclear Magnetic Resonance Spectroscopy

Aluminium is a very convenient element for nmr spectroscopy because ^{27}Al is 100% abundant and has a high nmr sensitivity, its receptivity being 0.206 when compared to ^{1}H and 1170 when compared to ^{13}C. It also has a high operating frequency (26.077 MHz when scaled to 100 MHz for ^{1}H) and a wide range of chemical shifts, δ (>300 ppm). The nuclear spin quantum number is 5/2 and the magnetogyric ratio γ is 6.9763 rad $s^{-1}T^{-1}$. The only disadvantage is the presence of a nuclear quadrupole moment ($Q = 0.149 \times 10^{-28}$ m^2) which leads to substantial line broadening for many species. The narrowest lines ($\omega_{1/2} \sim 2$ Hz) are obtained for highly symmetrical species such as $[Al(H_2O)_6]^{3+}$ and $[Al(OH)_4]^-$, but line widths of 1000 Hz or more are not uncommon and the use of special curve-analysis techniques is needed to extract the required parameters.

As expected, chemical shifts depend on coordination number (CN) and also on the nature of the atoms directly bonded to Al. Organometallic species, i.e. those with Al–C bonds, resonate at low field (high frequency): those with CN 3 have δ in the range 275–220 ppm, those with CN 4 have δ 220–140 ppm and those with CN 5 have δ 140–110 ppm. Tetrahalogenoaluminates, AlX_4^-, $AlX_nY_{4-n}^-$, and 4-coordinate ligand adducts in general have δ in the range 120–50 ppm with the curious exception of AlI_4^- which shows a resonance at a higher field than for any other Al species so far, δ being −26.7 ppm. Five-coordinate adducts have δ in the range 65–25 ppm and octahedral species have δ in the range +40 to −25 ppm. Typical parameters for some of the species mentioned in the main text are:

Species	$[Al(OH)_4]^-$	$[Al(H_2O)_6]^{3+}$	$[Al_2(OH)_2(H_2O)_8]^{4+}$	$[Al_{13}O_4(OH)_{24}(H_2O)_{12}]^{7+}$
δ/ppm	80	0.00 (std)	4	12Al @ ~12, 1Al @ 625
$\omega_{1/2}$/Hz	10	2	500	8000, 25

These values show some dependence on concentration, pH and temperature. Note also the much smaller linewidth for the central, symmetrically 4-coordinated Al atom of the tridecameric Al_{13} species when compared with that of the twelve less symmetrically coordinated octahedral Al atoms, and the possibility of extracting a reasonably precise value of δ for this latter resonance which has a linewidth of some 8000 Hz.

Solid-state ^{27}Al nmr spectroscopy has been much used in recent years to study the composition and structure of aluminisilcates (pp. 351–9) and other crystalline or amorphous Al compounds. The technique of magic angle spinning (MAS) must be used in such cases.[55]

$[AlO_4\{Al(OH)_2(H_2O)\}_{12}]^{7+}$, in which the central tetrahedral AlO_4 group is surrounded by corner- and edge-shared AlO_6 octehedra. The ion, which is almost spherical, has been further characterized by an X-ray diffraction study of crystalline $Na[Al_{13}O_4(OH)_{24}(H_2O)_{12}](SO_4)_4.13H_2O$.

The binary oxides and hydroxides of Ga, In and Tl have been much less extensively studied. The Ga system is somewhat similar to the Al system and a diagram summarizing the transformations in the systems is in Fig. 7.13. In general the α- and γ-series have the same structure as their Al counterparts. β-Ga_2O_3 is the most stable crystalline modification (mp 1740°); it has a unique crystal structure with the oxide ions in distorted ccp and Ga^{III} in distorted tetrahedral and octahedral sites. The structure appears to owe its stability to these distortions and, because of the lower coordination of half the Ga^{III}, the density is ~10% less than for the α-(corundum-type) form. This preference of Ga^{III} for fourfold coordination despite the fact that it is larger than Al^{III} may again indicate the polarizing influence of the d^{10} core; a similar tetrahedral site preference is observed for Fe^{III}.

In_2O_3 has the C-type M_2O_3 structure (p. 1238) and InO(OH) (prepared hydrothermally from $In(OH)_3$ at 250–400°C and 100–1500 atm) has a deformed rutile structure (p. 961) rather than the layer lattice structure of AlO(OH) and GaO(OH). Crystalline $In(OH)_3$ is best prepared by addition of NH_3 to aqueous $InCl_3$ at 100° and ageing the precipitate for a few hours at this temperature; it has the simple ReO_3-type structure distorted somewhat by multiple H bonds.[26]

Thallium is notably different. Tl^{I}_2O forms as black platelets when Tl_2CO_3 is heated in N_2 at 700° (mp 596°, d 10.36 g cm^{-3}); it is hygroscopic and gives TlOH with water. $Tl^{III}_2O_3$ is brown-black (mp 716°, d 10.04 g cm^{-3}) and can be made by oxidation of aqueous $TlNO_3$ with Cl_2 or Br_2 followed by precipitation

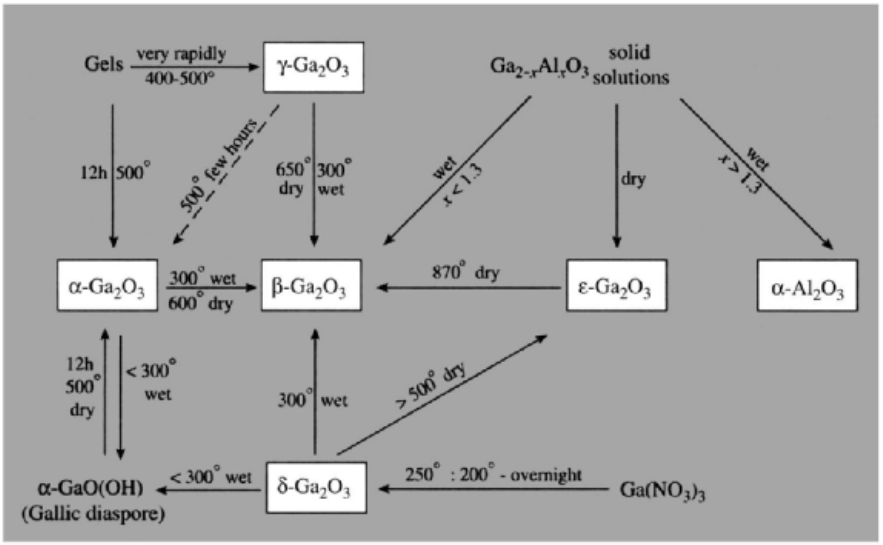

Figure 7.13 Chart illustrating transformation relationships among the forms of gallium oxide and its hydrates. Conversion (wet) of the phase designated as $Ga_{2-x}Al_xO_3$ to β-Ga_2O_3 occurs only where $x < 1.3$; where $x > 1.3$ an α-Al_2O_3 structure forms.

of the hydrated oxide $Tl_2O_3.1\frac{1}{2}H_2O$ and desiccation; single crystals have a very low electrical resistivity (e.g. 7×10^{-5} ohm cm at room temperature). A mixed oxide Tl_4O_3 (black) is known and also a violet peroxide $Tl^{I}O_2$ made by electrolysis of an aqueous solution of Tl_2SO_4 and oxalic acid between Pt electrodes. TlOH has been mentioned previously (p. 226).

7.3.4 Ternary and more complex oxide phases

This section considers a number of extremely important structure types in which Al combines with one or more other metals to form a mixed oxide phase. The most significant of these from both a theoretical and an industrial viewpoint are spinel ($MgAl_2O_4$) and related compounds, Na-β-alumina ($NaAl_{11}O_{17}$) and related phases, and tricalcium aluminate ($Ca_3Al_2O_6$) which is a major constituent of Portland cement. Each of these compounds raises points of fundamental importance in solid-state chemistry and each possesses properties of crucial significance to modern technology. For aluminosilicates see p. 351 and for aluminophosphates see p. 526.

Spinels and related compounds [56]

Spinels form a large class of compounds whose crystal structure is related to that of the mineral spinel itself, $MgAl_2O_4$. The general formula is AB_2X_4 and the unit cell contains 32 oxygen atoms in almost perfect ccp array, i.e. $A_8B_{16}O_{32}$. In the normal spinel structure (Fig. 7.14) 8 metal atoms (A) occupy tetrahedral sites and 16 metal atoms (B) occupy octahedral sites, and the structure can be regarded as being built up of alternating cubelets of ZnS-type and NaCl-type structures. The two factors that determine which combinations of atoms can form a spinel-type structure are (a) the total formal cation charge, and (b) the relative sizes of the 2 cations with respect both to each other and to the

[56] N. N. GREENWOOD, *Ionic Crystals, Lattice Defects and Nonstoichiometry*, Butterworths. London, 1968, 194 pp. See also J. K. BURDETT, G. D. PRICE and S. L. PRICE, *J. Am. Chem. Soc.* **104**, 92–5 (1982).

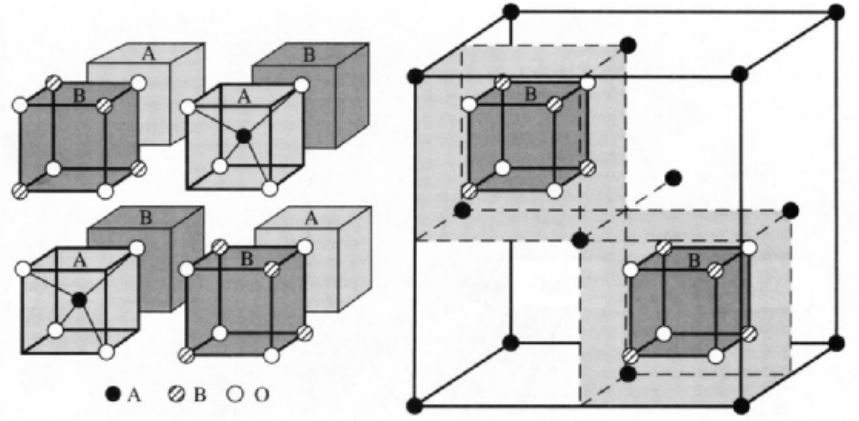

Figure 7.14 Spinel structure AB_2O_4. The structure can be thought of as 8 octants of alternating AO_4 tetrahedra and B_4O_4 cubes as shown in the left-hand diagram; the 4O have the same orientation in all 8 octants and so build up into a fcc lattice of 32 ions which coordinate A tetrahedrally and B octahedrally. The 4 A octants contain 4 A ions and the 4 B octants contain 16 B ions. The unit cell is completed by an encompassing fcc of A ions (●) as shown in the right-hand diagram; this is shared with adjacent unit cells and comprises the remaining 4 A ions in the complete unit cell $A_8B_{16}O_{32}$. The location of two of the B_4O_4 cubes is shown for orientation.

anion. For oxides of formula AB_2O_4 charge balance can be achieved by three combinations of cation oxidation state: $A^{II}B_2^{III}O_4$, $A^{IV}B_2^{II}O_4$, and $A^{VI}B_2^{I}O_4$. The first combination is the most numerous and examples are known with

A^{II} = Mg, (Ca); Cr, Mn, Fe, Co, Ni, Cu;
Zn, Cd, (Hg); Sn

B^{III} = Al, Ga, In;
Ti, V, Cr, Mn, Fe, Co, Ni; Rh

The anion can be O, S, Se or Te. Most of the A^{II} cations have radii (6-coordinate) in the range 65–95 pm and larger cations such as Ca^{II} (100 pm) and Hg^{II} (102 pm) do not form oxide spinels. The radii of B^{III} fall predominantly in the range 60–70 pm though Al^{III} (53 pm) is smaller, and In^{III} (80 pm) normally forms sulfide spinels only.

Examples of spinels with other combinations of oxidation state are:

$A^{IV}B_2^{II}X_4^{-II}$: $TiMg_2O_4$, $PbFe_2O_4$, $SnCu_2S_4$

$A^{VI}B_2^{I}X_4^{-II}$: $MoAg_2O_4$, $MoNa_2O_4$, WNa_2O_4

$A^{II}B_2^{I}X_4^{-I}$: $NiLi_2F_4$, $ZnK_2(CN)_4$, $CdK_2(CN)_4$

Many of the spinel-type compounds mentioned above do not have the normal structure in which A are in tetrahedral sites (t) and B are in octahedral sites (o); instead they adopt the inverse spinel structure in which half the B cations occupy the tetrahedral sites whilst the other half of the B cations and all the A cations are distributed on the octahedral sites, i.e. $(B)_t[AB]_oO_4$. The occupancy of the octahedral sites may be random or ordered. Several factors influence whether a given spinel will adopt the normal or inverse structure, including (a) the relative sizes of A and B, (b) the Madelung constants for the normal and inverse structures, (c) ligand-field stabilization energies (p. 1131) of cations on tetrahedral and octahedral sites, and (d) polarization or covalency effects.[56]

Thus, if size alone were important it might be expected that the smaller cation would occupy the site of lower coordination number, i.e. $Al_t[MgAl]_oO_4$; however, in spinel itself this is outweighed by the greater lattice energy achieved by having the cation of higher charge, (Al^{III}) on the site of higher coordination and

the normal structure is adopted: $(Mg)_t[Al_2]_oO_4$. An additional factor must be considered in a spinel such as $NiAl_2O_4$ since the crystal field stabilization energy of Ni^{II} is greater in octahedral than tetrahedral coordination; this redresses the balance, making the normal and inverse structures almost equal in energy and there is almost complete randomization of all the cations on all the available sites: $(Al_{0.75}Ni_{0.25})_t[Ni_{0.75}Al_{1.25}]_oO_4$.

Inverse and disordered spinels are said to have a defect structure because all crystallographically identical sites within the unit cell are not occupied by the same cation. A related type of defect structure occurs in valency disordered spinels where, for example, the divalent A^{II} cations in AB_2O_4 are replaced by equal numbers of M^{I} and M^{III} of appropriate size. Thus, in spinel itself, which can be written $Mg_8Al_{16}O_{32}$, the $8Mg^{II}$ (72 pm) can be replaced by $4Li^{I}$ (76 pm) and $4Al^{III}$ (53 pm) to give $Li_4Al_{20}O_{32}$, i.e. $LiAl_5O_8$. This has a defect spinel structure in which two-fifths of the Al occupy all the tetrahedral sites: $(Al^{III}_2)_t[Li^{I}Al^{III}_3]_oO_8$. Other compounds having this cation-disordered spinel structure are $LiGa_5O_8$ and $LiFe_5O_8$. Disordering on the tetrahedral sites occurs in $CuAl_5S_8$, $CuIn_5S_8$, $AgAl_5S_8$ and $AgIn_5S_8$, i.e. $(Cu^{I}Al^{III})_t[Al^{III}_4]_oS_8$, etc. Valency disordering can also be achieved by replacing A^{II} completely by M^{I}, thus necessitating replacement of half the B^{III} by M^{IV}, e.g. $(Li^{I})_t[Al^{III}Ti^{IV}]_oO_4$. Even more extensive substitution of cations has been achieved in many cubic spinel phases, e.g. $Li^{I}_5Zn^{II}_8Al^{III}_5Ge^{IV}_9O_{36}$ (and the Ga^{III} and Fe^{III} analogues), and the possibilities are virtually limitless.

The sensitive dependence of the electrical and magnetic properties of spinel-type compounds on composition, temperature, and detailed cation arrangement has proved a powerful incentive for the extensive study of these compounds in connection with the solid-state electronics industry. Perhaps the best-known examples are the ferrites, including the extraordinary compound magnetite Fe_3O_4 (p. 1080) which has an inverse spinel structure $(Fe^{III})_t[Fe^{II}Fe^{III}]_oO_4$.

It will also be recalled that γ-Al_2O_3 (p. 243) has a defect spinel structure in which not all of the cation sites are occupied, i.e. $Al^{III}_{21\frac{1}{3}}\square_{2\frac{2}{3}}O_{32}$: the relation to spinel ($Mg^{II}_8Al^{III}_{16}O_{32}$) is obvious, the $8Mg^{II}$ having been replaced by the isoelectronically equivalent $5\frac{1}{3}Al^{III}$. This explains why $MgAl_2O_4$ can form a complete range of solid solutions with γ-Al_2O_3: the oxygen builds on to the complete fcc oxide ion lattice and the Al^{III} gradually replaces Mg^{II}, electrical neutrality being achieved simply by leaving 1 cation site vacant for each $3Mg^{II}$ replaced by $2Al^{III}$.

Sodium-β-alumina and related phases [57]

Sodium-β-alumina has assumed tremendous importance as a solid-state electrolyte since its very high electrical conductivity was discovered at the Ford Motor Company by J. T. Kummer and N. Weber in 1967. The compound, which has the idealized formula $NaAl_{11}O_{17}(Na_2O.11Al_2O_3)$ was originally thought to be a form of Al_2O_3 and hence called β-alumina (1916); the presence of Na, which was at first either undetected or ignored, is now known to be essential for stability. X-ray analysis shows that the structure is closely related to that of spinel, no fewer than 50 of the 58 atoms in the unit cell being arranged exactly as in spinel. The large Na atoms are situated exclusively in loosely packed planes together with an equal number of O atoms as shown in Fig. 7.15; these planes are 1123 pm apart, being separated by the "spinel blocks". The close-packed oxygen layers above and below the Na planes are mirror images of each other 476 pm apart and they are bound together not only by the Na atoms but by an equal number of Al–O–Al bonds. There are several other sites in the mirror plane which can physically accommodate Na and this permits rapid two-dimensional diffusion of Na within the basal

[57] J. T. KUMMER, *Prog. Solid State Chem.* **7**, 141–75 (1972). J. H. KENNEDY, *Topics in Applied Physics* **21**, 105–41 (1977).

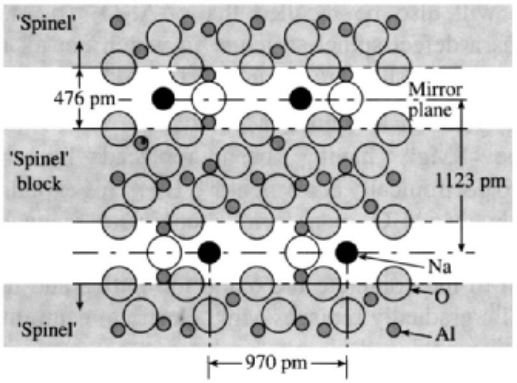

Figure 7.15 Crystal structure of Na-β-alumina (see text). This section, which is a plane parallel to the c-axis, does not show the closest Na–Na distance.

plane; it also explains the very low resistivity of the order of 30 ohm cm. The structure can also accommodate supernumerary Na ions, and the compound, even in the form of single crystals, is massively defective, having typically 20–30% more Na than indicated by the idealized formula; this is probably compensated by additional Al vacancies in the "spinel blocks" adjacent to the mirror planes, e.g. $Na_{2.58}Al_{21.8}O_{34}$.

Sodium-β-alumina can be prepared by heating Na_2CO_3 (or $NaNO_3$ or NaOH) with any modification of Al_2O_3 or its hydrates to ~1500° in a Pt vessel suitably sealed to avoid loss of Na_2O (as $Na + O_2$). In the presence of NaF or AlF_3 a temperature of 1000° suffices. Na-β-alumina melts at ~2000° (probably incongruently) and has d 3.25 g cm^{-3}. The Na can be replaced by Li, K, Rb, Cu^I, Ag^I, Ga^I, In^I or Tl^I by heating with a suitable molten salt, and Ag^I can be replaced by NO^+ by treatment with molten $NOCl/AlCl_3$. The ammonium compound is also known and H_3O^+-β-alumina can be prepared by reduction of the Ag compound. Similarly, Al^{III} can be replaced by Ga^{III} or Fe^{III} in the preparation, leading to compounds of (idealized) formulae $Na_2O.11Ga_2O_3$, $Na_2O.11Fe_2O_3$, $K_2O.11Fe_2O_3$, etc. Altervalent substitution is also possible, e.g. in Na-β''-alumina, $Na_{1+x}M_xAl_{11-x}O_{17}$, in which M is a divalent cation such as Mg, Ni or Zn. A typical composition is $Na_{1.67}Mg_{0.67}Al_{10.33}O_{17}$ and the excess Na charge is compensated for by substituting the divalent or univalent cation into the lattice sites normally occupied by Al.[58]

Apart from the intriguing structural implications of these fast-ion solid-state conductors, Na-β-alumina and related phases have been extensively used as permeable membranes in the Na/S battery system (p. 678): this requires an air-stable membrane that is readily permeable to Na ions but not to Na atoms or S, that is non-reactive with molten Na and S, and that is not an electronic conductor. Not surprisingly, few compounds have been found to compete with Na-β-alumina in this field, although Na-β''-alumina has the remarkable additional property of enabling the rapid diffusion of a large proportion of cations in the periodic table (whereas Na-β-alumina itself is restricted mainly to univalent cations). Indeed, the β''-aluminas are the first family of high conductivity solid electrolytes which permit fast ion transport of multivalent cations in solids.[58]

Unrelated to the β- and β''-aluminas are a group of white, hygroscopic sodium-rich aluminates which have recently been prepared by heating Na_2O and Al_2O_3 in appropriate stoichiometric ratios at 700°C for 18–24 hours.[59] Na_5AlO_4, which is isostructural with Na_5FeO_4, contains isolated $[AlO_4]$ tetrahedra with Al–O 176–179 pm. $Na_7Al_3O_8$ features a novel ring structure made up of six AlO_4 tetrahedra sharing corners to form a non-planar 12-membered ring which is then joined by pairs of oxygen atom bridges to adjacent rings, thus generating an infinite chain of alternating 12- and 8-membered rings with $Al–O_\mu$ 175–179 pm and $Al–O_t$ 173–4 pm. Finally, $Na_{17}Al_5O_{16}$ has discrete chains composed of five AlO_4 tetrahedra sharing corners with almost linear angles (160° and 173°) at the bridging O atoms and with

[59] M. G. BARKER, P. G. GADD and M. J. BEGLEY, *J. Chem. Soc., Chem. Commun.*, 379–81 (1981). M. G. BARKER, P. G. GADD and S. C. WALLWORK, *J. Chem. Soc., Chem. Commun.*, 516–7 (1982).

the various Al–O distances again falling in the range 170–180 pm. Note that the unusual formula $Na_{17}Al_5O_{16}$ (i.e. $Na_{3.4}AlO_{3.2}$) is nearly the same as Na_3AlO_3 which would have been the stoichiometry if the chains of AlO_4 tetrahedra had been infinite.

Tricalcium aluminate, $Ca_3Al_2O_6$

Tricalcium aluminate is an important component of Portland cement yet, despite numerous attempts dating back over the preceding 50 y, its structure remained unsolved until 1975.[60] The basic unit is now known to be a 12-membered ring of 6 fused $\{AlO_4\}$ tetrahedra $[Al_6O_{18}]^{18-}$ as shown in Fig. 7.16; there are 8 such rings per unit cell surrounding holes of radius 147 pm, and the rings are held together by Ca ions in distorted sixfold coordination to give the structural formula $Ca_9Al_6O_{18}$. The rather short Ca–O distance (226 pm) and the observed compression of the $\{CaO_6\}$ octahedra may indicate some strain and this, together with the large holes in the lattice, facilitate the rapid reaction with water. The products of hydration depend sensitively on the temperature. Above 21° $Ca_3Al_2O_6$ gives the hexahydrate $Ca_3Al_2O_6.6H_2O$, but below this temperature hydrated di- and tetra-calcium aluminates are formed of empirical composition $2CaO.Al_2O_3.5–9H_2O$ and $4CaO.Al_2O_3.12–14H_2O$. This is of great importance in cement technology (see Panel) since, in the absence of a retarder, cement reacts rapidly with water giving a sharp rise in temperature and a "flash set" during which the various calcium aluminate hydrates precipitate and congeal into an unmanageable mass. This can be avoided by grinding in 2–5% of gypsum ($CaSO_4.2H_2O$) with the cement clinker; this reacts rapidly with dissolved aluminates in the presence of $Ca(OH)_2$ to give the calcium sulfatoaluminate, $3CaO.Al_2O_3.3CaSO_4.31H_2O$, which is much less soluble than the hydrated calcium aluminates and therefore preferentially precipitates and prevents the premature congealing.

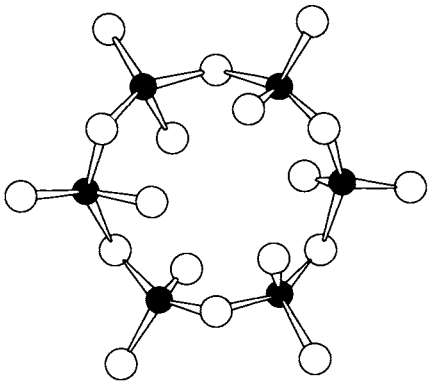

Figure 7.16 Structure of the $[Al_6O_{18}]^{18+}$ unit in $Ca_3Al_2O_6$ (i.e. $Ca_9Al_6O_{18}$). The Al–O distances are all in the range 175 ± 2 pm.

Another important calcium aluminate system occurs in high-alumina cement (*ciment fondu*). This is not a Portland cement but is made by *fusing* limestone and bauxite with small amounts of SiO_2 and TiO_2 in an open-hearth furnace at 1425–1500°; rotary kilns with tap-holes for the molten cement can also be used. Typical analytical compositions for a high-alumina cement are ~40% each of Al_2O_3 and CaO and about 10% each of Fe_2O_3 and SiO_2; the most important compounds in the cement are $CaAl_2O_4$, $Ca_2Al_2SiO_7$ and $Ca_6Al_8FeSiO_{21}$. Setting and hardening of high-alumina cement are probably due to the formation of calcium aluminate gels such as $CaO.Al_2O_3.10H_2O$, and the more basic $2CaO.Al_2O_3.8H_2O$, $3CaO.Al_2O_3.6H_2O$ and $4CaO.Al_2O_3.13H_2O$, though these empirical formulae give no indication of the structural units involved. The most notable property of high-alumina cement is that it develops very high strength at a very early stage (within 1 day). Long exposure to warm, moist conditions may lead to failure but resistance to corrosion by sea water and sulfate brines, or by weak mineral acids, is outstanding. It has also been much used as a refractory cement to withstand temperatures up to 1500°.

Portland Cement[61]

The name "Portland cement" was first used by J. Aspdin in a patent (1824) because, when mixed with water and sand the powder hardened into a block that resembled the natural limestone quarried in the Isle of Portland, England. The two crucial discoveries which led to the production of strong, durable, hydraulic cement that did not disintegrate in water, were made in the eighteenth and nineteenth centuries. In 1756 John Smeaton, carrying out experiments in connection with building the Eddystone Lighthouse (UK), recognized the importance of using limes which contained admixed clays or shales (i.e. aluminosilicates), and by the early 1800s it was realized that firing must be carried out at sintering temperatures in order to produce a clinker now known to contain calcium silicates and aluminates. The first major engineering work to use Portland cement was in the tunnel constructed beneath the Thames in 1828. The first truly high-temperature cement (1450–1600°C) was made in 1854, and the technology was revolutionized in 1899 by the introduction of rotary kilns.

The important compounds in Portland cement are dicalcium silicate (Ca_2SiO_4) 26%, tricalcium silicate (Ca_3SiO_5) 51%, tricalcium aluminate ($Ca_3Al_2O_6$) 11% and the tetracalcium species $Ca_4Al_2Fe^{III}_2O_{10}$ (1%). The principal constituent of moistened cement paste is a tobermorite gel which can be represented schematically by the following idealized equations:

$$2Ca_2SiO_4 + 4H_2O \longrightarrow 3CaO.2SiO_2.3H_2O + Ca(OH)_2$$

$$2Ca_3SiO_5 + 6H_2O \longrightarrow 3CaO.2SiO_2.3H_2O + 3Ca(OH)_2$$

The adhesion of the tobermorite particles to each other and to the embedded aggregates is responsible for the strength of the cement which is due, ultimately, to the formation of –Si–O–Si–O bonds.

Portland cement is made by heating a mixture of limestone (or chalk, shells, etc.) with aluminosilicates (derived from sand, shales, and clays) in carefully controlled amounts so as to give the approximate composition CaO ~70%, SiO_2 ~20%, Al_2O_3 ~5%, Fe_2O_3 ~3%. The presence of Na_2O, K_2O, MgO and P_2O_5 are detrimental and must be limited. The raw materials are ground to pass 200-mesh sieves and then heated in a rotary kiln to ~1500° to give a sintered clinker; this is reground to 325-mesh and mixed with 2–5% of gypsum. An average-sized kiln can produce 1000–3000 tonnes of cement per day and the world's largest plants can produce up to 8000 tonnes per day. The vast scale of the industry can be gauged from the US production figures in the table below. Price (1990) was $45–55 per tonne for bulk supplies. In the same year China emerged as the world's largest cement producer (200 million tonnes per annum). Total world production continues to grow dramatically, from 590 Mtpa in 1970 and 881 Mtpa in 1980 to nearly 1200 Mtpa in 1990, of which Europe (including the European parts of the former Soviet Union) accounted for some 40%.

7.3.5 Other inorganic compounds

Chalcogenides

At normal temperatures the only stable chalcogenides of Al are Al_2S_3 (white), Al_2Se_3 (grey) and Al_2Te_3 (dark grey). They can be prepared by direct reaction of the elements at ~1000° and all hydrolyse rapidly and completely in aqueous solution to give $Al(OH)_3$ and H_2X (X = S, Se, Te). The small size of Al relative to the chalcogens dictates tetrahedral coordination and the various polymorphs are related to wurtzite (hexagonal ZnS, p. 1210), two-thirds of the available metal sites being occupied in either an ordered (α) or a random (β) fashion. Al_2S_3 also has a γ-form related to γ-Al_2O_3 (p. 243), and very recently a novel high-temperature hexagonal modification of Al_2S_3 containing 5-coordinate Al has been obtained by annealing α-Al_2S_3 at 550°C;[62] in this new form half the Al atoms are tetrahedrally coordinated (Al–S 223–227 pm) whereas the other half are in trigonal bipyramidal coordination with Al–S_{eq} 227–232 pm and Al–S_{ax} 250–252 pm.

The chalcogenides of Ga, In and Tl are much more numerous and at least a dozen different structure types have been established by X-ray

crystallography.[63] The compounds have been extensively studied not only because of their intriguing stoichiometries, but also because many of them are semiconductors, semi-metals, photoconductors or light emitters, and Tl_5Te_3 has been found to be a superconductor at low temperatures. (See p. 1182 for high-temperature super conductors, including $Tl_2Ca_2Ba_2Cu_3O_{10+x}$ which has one of the highest known superconducting transition temperatures, $T_c = 125$ K.) The chalogenides, as expected from their position in the periodic table, are far from ionic, but formal oxidation states remain a useful device for electron counting and for checking the overall charge balance. Well-established compounds are summarized in Table 7.9. The following points are noteworthy. The hexagonal α- and β-forms of Ga_2S_3 are isostructural with the Al analogues and an additional form, γ-Ga_2S_3, adopts the related defect sphalerite structure derived from cubic ZnS (zinc blende, p. 1210). The same structure is found for Ga_2Se_3 and Ga_2Te_3 but for the larger In^{III} atom octahedral coordination also becomes possible. The corresponding Tl^{III} sesquichalcogenides Tl_2X_3 are either

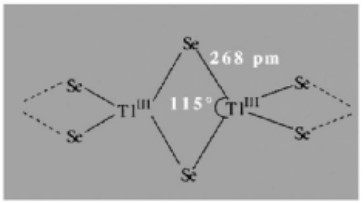
non-existent or of dubious authenticity, perhaps because of the ready reduction to Tl^{I} (see TlI_3, p. 239).

GaS (yellow, mp 970°) has a hexagonal layer structure with Ga–Ga bonds (248 pm); each Ga is coordinated by 3S and 1Ga, and the sequence of layers along the *c*-axis is· · · SGaGaS,SGaGaS· · ·; the compound can therefore be considered as an example of Ga^{II}. The structures of GaSe, GaTe, red InS and InSe are similar. By contrast, InTe, TlS (black) and TlSe (black, metallic) have a structure which can be formalized as $M^{I}[M^{III}X_2]$; each Tl^{III} is tetrahedrally coordinated by 4 Se at 268 pm and the tetrahedra are linked into infinite chains by edge sharing along the *c*-axis (see structure), whereas each Tl^{I} lies between these chains and is surrounded by a distorted cube of 8 Se at 342 pm. This explains the marked anisotropy of properties, especially the metallic conductivity in the (001) plane and the semiconductivity along the *c*-axis. Similar edge-linked $\{GeSe_4\}$ tetrahedra are found in $Cs_{10}Ga_6Se_{14}$ which was obtained as transparent pale-yellow crystals by heating an equimolar mixture of GaSe and Cs in a carefully controlled temperature programme; the compound features the unprecedented finite complex anion $[Se_2Ga(\mu\text{-}Se_2Ga)_5Se_2]^{10-}$ which is 1900 pm long.[64]



In_6S_7 (and the isostructural In_6Se_7) have a curious structure comprising two separate blocks of almost ccp S which are rotated about the *b*-axis by 61° with respect to each other; the In is in octahedral coordination. The compound can be formulated as $In^{I}(In_2^{III})^{IV}In_3^{III}S_7^{-II}$. There are also numerous ternary In/Tl sulfides in which In^{I} has been replaced by Tl^{I}, e.g.: $Tl^{I}In_5^{III}S_8$, $Tl^{I}In_3^{III}S_5$, $Tl^{I}In^{III}S_2$, $Tl_3^{I}In^{III}S_3$, $Tl^{I}(In_2^{III})_2^{IV}In^{III}S_6$, $Tl_3^{I}In^{I}In_4^{III}S_8$ and $Tl^{I}(In_2^{III})^{IV}In_3^{III}S_7$.[64a]

The crystal structures of In_4Se_3 and In_4Te_3 show that they can be regarded to a first approximation as $In^{I}[In_3]^{V}(X^{-II})_3$ but the compound does not really comprise discrete ions. The triatomic unit $[In^{III}—In^{III}—In^{III}]$ is bent, the angle at the central atom being 158° and the In–In distances 279 pm (cf. 324–326 pm in metallic In). However, it is also possible to discern non-planar 5-membered heterocycles in the structure formed by joining 2 In from 1 $\{In_3\}$ to the terminal In of an adjacent $\{In_3\}$ via 2 bridging Se (or Te) atoms so that the structure can be represented schematically as in Fig. 7.17. The In^{III}–Se distances average

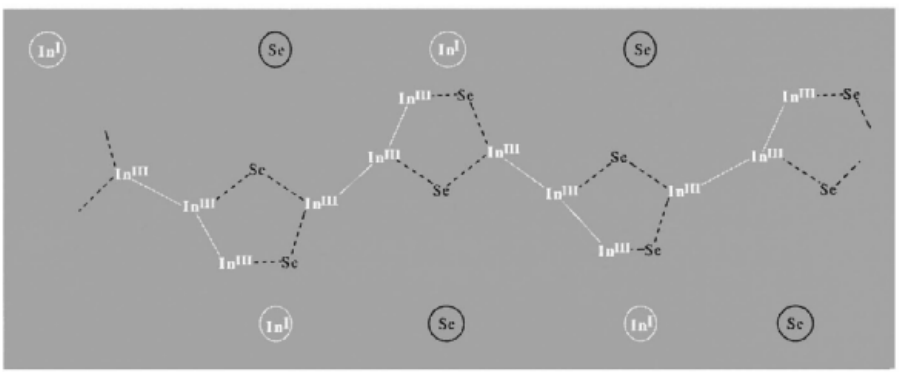

Figure 7.17 Schematic structure of In_4Se_3.

269 pm compared with the closest In^{I}–Se contact of 297 pm. The $[In_3^{III}]^{V}$ unit can be compared with the isoelectronic species $[Hg_3^{II}]^{II}$. The compound Tl_4S_3, which has the same stoichiometry as In_4X_3, has a different structure in which chains of corner-shared $\{Tl^{III}S_4\}$ tetrahedra of overall stoichiometry $[TlS_3]$ are bound together by Tl^{I}; within the chains the Tl^{III}–S distance is 254 pm whereas the Tl^{I}–S distances vary between 290–336 pm. A comparison of the formal designation of the two structures $In^{I}[(In_3^{III})]^{V}(Se^{-II})_3$ and $(Tl^{I})_3[Tl^{III}S_3]^{-III}$ again illustrates the increasing preference of the heavier metal for the +1 oxidation state. The trend continues with the polysulfides $Tl^{I}S_2$, $Tl_2^{I}S_5$ and $Tl_2^{I}S_9$ already alluded to on p. 253.

Compounds with bonds to N, P, As, Sb or Bi

The binary compounds of the Group 13 metals with the elements of Group 15 (N, P, As, Sb, Bi) are structurally less diverse than the chalcogenides just considered but they have achieved considerable technological application as III–V semiconductors isoelectronic with Si and Ge (cf. BN isoelectronic with C, p. 207). Their structures are summarized in Table 7.10: all adopt the cubic ZnS structure except the nitrides of Al, Ga and In which are probably more ionic (less covalent or metallic) than the others. Thallium does not form simple compounds

W = wurtzite, hexagonal ZnS structure (p. 1210).

$M^{III}X^{V}$: the explosive black nitride $Tl_3^{I}N$ is known, and the azides $Tl^{I}N_3$ and $Tl^{I}[Tl^{III}(N_3)_4]$; the phosphides Tl_3P, TlP_3 and TlP_5 have been reported but are not well characterized. With As, Sb and Bi thallium forms alloys and intermetallic compounds Tl_3X, Tl_7Bi_2 and $TlBi_2$.

The III–V semiconductors can all be made by direct reaction of the elements at high temperature and under high pressure when necessary. Some properties of the Al compounds are in Table 7.11 from which it is clear that there are trends to lower mp and energy band-gap E_g with increasing atomic number.

Analogous compounds of Ga and In are grey or semi-metallic in appearance and show similar trends (Table 7.12). These data should be compared with those for Si, Ge, Sn and Pb on p. 373 and for the isoelectronic II–VI semiconductors of Zn, Cd and Hg with S, Se and Te (p. 1210). In addition, GaN is obtained by reacting Ga and NH_3 at 1050° and InN by reducing and nitriding In_2O_3 with NH_3 at 630°. The

nitrides show increasing susceptibility to chemical attack, AlN being inert to both acids and alkalis, GaN being decomposed by alkali, but not acid, and InN being decomposed by both acids and alkalis. Most of the other III–V compounds decompose slowly in moist air, e.g. AlP gives $Al(OH)_3$ and PH_3. As a consequence, semiconductor devices must be completely encapsulated to prevent reaction with the atmosphere. The great value of III–V semiconductors is that they extend the range of properties of Si and Ge and by judicious mixing in ternary phases they permit a continuous interpolation of energy band gaps, current-carrier mobilities and other characteristic properties. Some of their uses are summarized in the Panel on p. 258.

Other compounds containing Al–N or Ga–N bonds, including heterocyclic compounds and cluster organometallic compounds, are considered in section 7.3.6.

Some unusual stereochemistries

While it remains true that tetrahedral and octahedral coordination modes are the predominant stereochemistries adopted by the group 13 metals, nevertheless increasing diversity is being achieved by carefully selecting appropriate electronic and geometric features to enhance the stabilization of unusual stereochemistries. Some representative examples follow.

Trigonal planar Al is found in the $[AlSb_3]^{6-}$ "anions" in $[Cs_6K_3Sb(AlSb_3)]$, which is formed by heating a stoichiometric mixture of 6Cs, 3KSb and AlSb in a sealed Nb ampoule at 677°C.[65] The Ga analogue was prepared similarly. The planar anions are embedded between columns of condensed icosahedra $(Cs_6K_{6/2})^{9+}$ which in turn are centred by the remaining unique monatomic Sb^{3-} anion.

The indium molybdate $In_{11}Mo_{40}O_{62}$, prepared by heating the appropriate mixture of In, Mo and MoO_2 at 1100°C, features novel quasi-linear chain cations. In_5^{7+} and In_6^{8+} in channels between condensed clusters of Mo_6 octahedra.[66] The intrachain distances are 262–266 pm in In_5^{7+} and 265–269 pm in In_6^{8+}, which are the shortest known In–In interatomic distances cf. 325 and 337 pm in In metal itself, and 333 pm for the closest distances between In atoms in neighbouring chains in the molybdate. Interatomic angles within the chains are 158° and 163° respectively and, when the coordination around each In atom by contiguous In and O atoms is considered, the chains can be formulated as $[In^{2+}(In^+)_nIn^{2+}]$, $n = 3, 4$.

Square-pyramidal 5-coordinate In^{III} occurs in certain organoindium compounds such as the bis(2-methylaminopyridino-) adduct $[MeIn\{MeN\bar{C}(CH)_4\bar{N}\}_2]$[67] — cf. $InCl_5^{2-}$ (p. 238). The less familiar pentagonal planar coordination has been established for the $InMn_5$ group in the dianion $[(\mu_5\text{-In})\{Mn(CO)_4\}_5]^{2-}$ which is readily prepared by treatment of $InCl_3$ with the manganese carbonyl cluster compound $K_3[Mn_3(\mu\text{-}CO)_2(CO)_{10}]$.[68] The mean Mn–Mn distance in the encircling plane-pentagonal "ligand" $\{Mn(CO)_4\}_5$ is 317 pm; the mean In–Mn distance is 265 pm, and the In atom is only 4.6 pm from the best plane of the five Mn atoms. Note also that the ligand is isolobal with cyclopentadienyl, C_5H_5.

Seven-coordinate pentagonal-bipyramidal In^{III} has been found in the chloroindium complex of 1,4,7-triazacyclononanetriacetic acid $[\{\text{-}(CH_2)_2\bar{N}(CH_2CO_2H)\}_3]$, (LH_3).[69] The neutral, monoprotonated 7-coordinate complex [InCl(LH)] features Cl and one N in axial positions (angle Cl–In–N 168°) with the other two N atoms and three carboxylate O atoms in the pentagonal plane. Interest in such compounds stems

Figure 7.18 (a) 1,4,7,10-tetraazacyclododecane triacetic acid, (LH_3). (b) Structure of the 7-coordinate complex [InL]; the coordination polyhedron (shown in white) comprises a trigonal prism of 4N and 2O capped on one of its quadrilateral faces by the third O atom.

from the use of the γ-active ^{111}In isotope (E_γ 173, 247 keV, $t_{1/2}$ 2.81 d) in radio-labelled monoclonal antibodies to detect tumours. Interestingly, the 7-coordinate crystalline complex reverts to a stable neutral hexacoordinate species in aqueous solution. Other 7-coordinate macrocyclic In^{III} complexes of potential relevance in radiopharmaceutical applications have been prepared, including [InL] where L is the triacetate of the tetraaza macrocycle shown in Fig. 7.18(a).[70] In this case the coordination polyhedron is a trigonal prism with one of its quadrilateral faces capped by a carboxylate O atom as shown schematically in Fig. 7.18(b).

Indium clusters have also recently been characterized, notably in intermetallic compounds. Thus, the Zintl phase, Rb_2In_3, (prepared by direct reaction between the two metals at 1530°C) has layers of octahedral *closo*-In_6 clusters joined into sheets through exo bonds at four coplanar vertices.[71] These four In atoms are therefore each bonded to five neighbouring In atoms at the corners of a square-based pyramid, whereas the remaining two (*trans*) In atoms in the In_6 cluster show pyramidal 4-fold bonding only, to contiguous In atoms in the same cluster. Cs_2In_3 is isostructural. The intermetallic compound $K_3Na_{26}In_{48}$ (synthesized from the elements in sealed Nb ampoules at 600°C) has a more complicated structure in which the In forms both *closo* icosahedral In_{12} clusters and hexagonal antiprismatic In_{12} clusters.[72] All the various In_{12} clusters are interconnected by 12 exo bonds forming a covalent 3D network (In–In 291–315 pm) and the In_{12} hexagonal antiprisms are additionally centred by single Na atoms. The phase contains several other interesting structural features and the original paper (in English) makes rewarding reading.

7.3.6 Organometallic compounds

Many organoaluminium compounds are known which contain 1, 2, 3 or 4 Al–C bonds per Al atom and, as these have an extensive reaction chemistry of considerable industrial importance, they will be considered before the organometallic compounds of Ga, In and Tl are discussed.

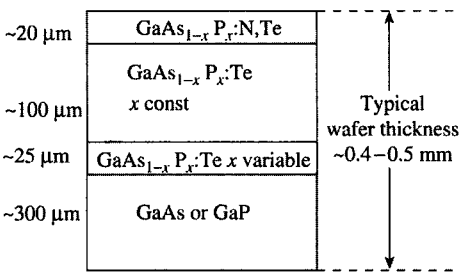
Organoaluminium Compounds

Aluminium trialkyls and triaryls are highly reactive, colourless, volatile liquids or low-melting solids which ignite spontaneously in air and react violently with water; they should therefore be handled circumspectly and with suitable precautions. Unlike the boron trialkyls and triaryls they are often dimeric, though with branched-chain alkyls such as Pr^i, Bu^i and Me_3CCH_2 this tendency is less marked. Al_2Me_6 (mp 15°, bp 126°) has the methyl-bridged structure shown and the same dimeric structure is found for Al_2Ph_6 (mp 225°).

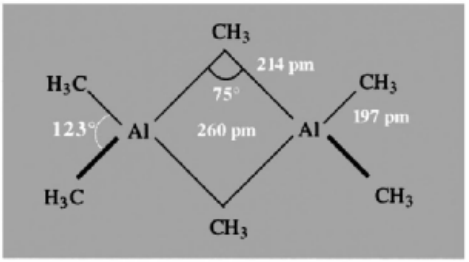
Applications of III–V Semiconductors

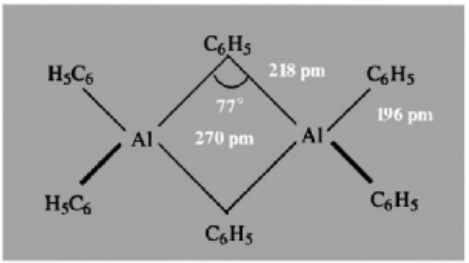
The 9 compounds that Al, Ga and In form with P, As and Sb have been extensively studied because of their many applications in the electronics industry, particularly those centred on the interconversion of electrical and optical (light) energy. For example, they are produced commercially as light-emitting diodes (LEDs) familiar in pocket calculators, wrist watches and the alpha-numeric output displays of many instruments; they are also used in infrared-emitting diodes, injection lasers, infrared detectors, photocathodes and photomultiplier tubes. An extremely elegant chemical solid-state technology has evolved in which crystals of the required properties are deposited, etched and modified to form the appropriate electrical circuits. The ternary system $GaAs_{1-x}P_x$ now dominates the LED market for α-numeric and graphic displays following the first report of this activity in 1961. $GaAs_{1-x}P_x$ is grown epitaxially on a single-crystal substrate of GaAs or GaP by chemical vapour deposition and crystal wafers as large as 20 cm^2 have been produced commercially. The colour of the emitted radiation is determined by the energy band gap E_g; for GaAs itself E_g is 138 kJ mol^{-1} corresponding to an infrared emission (λ 870 nm), but this increases to 184 kJ mol^{-1} for $x \sim 0.4$ corresponding to red emission (λ 650 nm). For $x > 0.4$ E_g continues to increase until it is 218 kJ mol^{-1} for GaP (green, λ 550 nm). Commercial yellow and green LEDs contain the added isoelectronic impurity N to improve the conversion efficiency. A schematic cross-section of a typical $GaAs_{1-x}P_x$ epitaxial wafer doped with Te and N is shown in the diagram: Te (which has one more valence electron per atom than As or P) is the most widely used dopant to give *n*-type impurities in this system at concentrations of 10^{16}–10^{18} atoms cm^{-3} (0.5–50 ppm). The p–n junction is then formed by diffusing Zn (1 less electron than Ga) into the crystal to a similar concentration.



An even more recent application is the construction of semiconductor lasers. In normal optical lasers light is absorbed by an electronic transition to a broad band which lies above the upper laser level and the electron then drops into this level by a non-radiative transition. By contrast the radiation in a semiconductor laser originates in the region of a p–n junction and is due to the transitions of injected electrons and holes between the low-lying levels of the conduction band and the uppermost levels of the valence band. (Impurity levels may also be involved.) The efficiency of these semiconductor injection lasers is very much higher than those of optically pumped lasers and the devices are much smaller; they are also easily adaptable to modulation. As implied by the band gaps on p. 255, emission wavelengths are in the visible and near infrared. A heterostructure laser based on the system $GaAs–Al_xGa_{1-x}As$ was the first junction laser to run continuously at 3000 K and above (1970).

In the two types of device just considered, namely light emitting diodes and injection lasers, electrical energy is converted into optical energy. The reverse process of converting optical energy into electrical energy (photoconductivity and photovoltaic effects) has also been successfully achieved by III–V semiconductor systems. For example, the small band-gap compound InSb is valuable as a photoconductive infrared detector, and several compounds are being actively studied for use in solar cells to convert sunlight into useful sources of electrical power. The maximum photon flux in sunlight occurs at 75–95 kJ mol^{-1} and GaAs shows promise, though other factors make Cu_2S–CdS cells more attractive commercially at the present time.





In each case Al–C_μ is about 10% longer than Al–C_t (cf. Al_2X_6, p. 235; B_2H_6, p. 157). The enthalpy of dissociation of Al_2Me_6 into monomers is 84 kJ mol^{-1}. Al_2Et_6 (mp −53°) and $Al_2Pr^n_6$ (mp −107°) are also dimeric at room temperature but crystalline trimesitylaluminium (mesityl = 2,4,5-trimethylphenyl) is monomeric with planar 3-coordinate Al; the mesityl groups adopt a propeller-like configuration with a dihedral angle of 56° between the aromatic ring and the AlC_3 plane and with Al–C 199.5 pm.[73]

As with $Al(BH_4)_3$ and related compounds (p. 230), solutions of Al_2Me_6 show only one proton nmr signal at room temperature due to the rapid interchange of bridging and terminal Me groups; at −75° this process is sufficiently slow for separate resonances to be observed.

Al_2Me_6 can be prepared on a laboratory scale by the reaction of $HgMe_2$ on Al at ~90°C. Al_2Ph_6 can be prepared similarly using $HgPh_2$ in boiling toluene or by the reaction of LiPh on Al_2Cl_6. On the industrial (kilotonne) scale Al is alkylated by means of RX or by alkenes plus H_2. In the first method the sesquichloride $R_3Al_2Cl_3$ is formed in equilibrium with its disproportionation products:†

$$2Al + 3RCl \xrightarrow[AlCl_3 \text{ or } AlR_3]{\text{trace of } I_2} R_3Al_2Cl_3 \rightleftharpoons \tfrac{1}{2}R_4Al_2Cl_2 + \tfrac{1}{2}R_2Al_2Cl_4$$

Addition of NaCl removes $R_2Al_2Cl_4$ as the complex ($2NaAlCl_3R$) and enables $R_4Al_2Cl_2$ to be distilled from the mixture. Reaction with Na yields the trialkyl, e.g.:

$$3Me_4Al_2Cl_2 + 6Na \longrightarrow 2Al_2Me_6 + 2Al + 6NaCl$$

Higher trialkyls are more readily prepared on an industrial scale by the alkene route (K. Ziegler *et al.*, 1960) in which H_2 adds to Al in the presence of preformed AlR_3 to give a dialkylaluminium hydride which then readily adds to the alkene:

$$2Al + 3H_2 + 2Al_2Et_6 \xrightarrow{150°} \{6Et_2AlH\} \xrightarrow[70°]{6CH_2CH_2} 3Al_2Et_6$$

Similarly, Al, H_2 and $Me_2C{=}CH_2$ react at 100° and 200 atm to give $AlBu^i_3$ in a single-stage process, provided a small amount of this compound is present at the start; this is required because Al does not react directly with H_2 to form AlH_3 prior to alkylation under these conditions. Alkene exchange reactions can be used to transform $AlBu^i_3$ into numerous other trialkyls. $AlBu^i_3$ can also be reduced by potassium metal in hexane at room temperature to give the novel brown compound $K_2Al_2Bu^i_6$ (mp 40°) which is notable in providing a rare example of an Al–Al bond in the diamagnetic anion $[Bu^i_3AlAlBu^i_3]^{2-}$.[74]

Al_2R_6 (or AlR_3) react readily with ligands to form adducts, $LAlR_3$. They are stronger Lewis acids than are organoboron compounds, BR_3, and can be considered as 'hard' (or class a)

[73] J. J. Jerius, J. M. Hahn, A. F. M. M. Rahman, O. Mols, W. H. Isley and J. P. Oliver, *Organometallics* **5**, 1812–14 (1986).

† It is interesting to note that the reaction of EtI with Al metal to give the sesqui-iodide "$Et_3Al_2I_3$" was the first recorded preparation of an organoaluminium compound (W. Hallwachs and A. Schafarik, 1859).

[74] H. Hoberg and S. Krause, *Angew. Chem. Int. Edn. Engl.* **17**, 949–50 (1979).

acids; for example, the stability of the adducts $LAlMe_3$ decreases in the following sequence of L: $Me_3N > Me_3P > Me_3As > Me_2O > Me_2S > Me_2Se$. With protonic reagents they react to liberate alkanes:

$$Al_2R_6 + 6HX \longrightarrow 6RH + 2AlX_3$$

(X = OH, OR, Cl, Br)

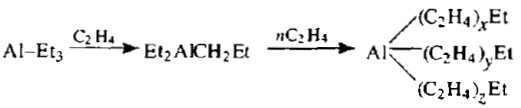
Reaction with halides or alkoxides of elements less electropositive than Al affords a useful route to other organometallics:

$$MX_n \xrightarrow{\text{excess } AlR_3} MR_n + \tfrac{n}{3}AlX_3$$

(M = B, Ga, Si, Ge, Sn, etc.)

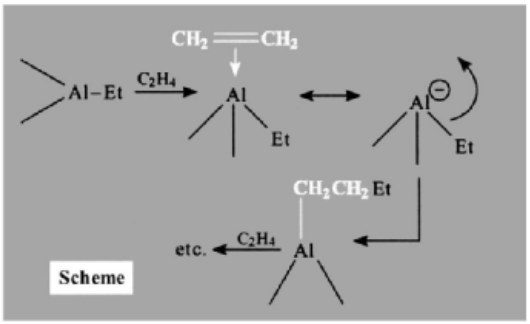
The main importance of organoaluminium compounds stems from the crucial discovery of alkene insertion reactions by K. Ziegler,[75] and an industry of immense proportions based on these reactions has developed during the past 40 y. Two main processes must be distinguished: (a) "growth reactions" to synthesize unbranched long-chain primary alcohols and alkenes (K. Ziegler *et al.*, 1955), and (b) low-pressure polymerization of ethene and propene in the presence of organometallic mixed catalysts (1955) for which K. Ziegler (Germany) and G. Natta (Italy) were jointly awarded the Nobel Prize for Chemistry in 1963.

In the first process alkenes insert into the Al–C bonds of monomeric AlR_3 at ~150° and 100 atm to give long-chain derivatives whose composition can be closely controlled by the temperature, pressure and contact time:



The reaction is thought to occur by repeated η^2-coordination of ethene molecules to Al followed by migration of an alkyl group from Al to the alkene carbon atom (see Scheme).

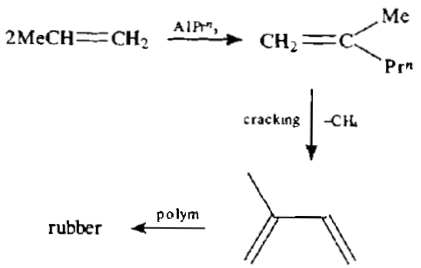
Unbranched chains up to C_{200} can be made, but prime importance attaches to chains of 14–20 C



atoms which are synthesized industrially in this way and then converted to unbranched aliphatic alcohols for use in the synthesis of biodegradable detergents:

$$Al(CH_2CH_2R)_3 \xrightarrow{\text{(i) } O_2,\ \text{(ii) } H_3O^+} 3RCH_2CH_2OH$$

Alternatively, thermolysis yields the terminal alkene $RCH{=}CH_2$. Note that, if propene or higher alkenes are used instead of ethene, then only single insertion into Al–C occurs. This has been commercially exploited in the catalytic dimerization of propene to 2-methylpentene-1, which can then be cracked to isoprene for the production of synthetic rubber (*cis*-1,4-polyisoprene):



Even more important is the stereoregular catalytic polymerization of ethene and other alkenes to give high-density polyethene ("polythene") and other plastics. A typical Ziegler–Natta catalyst can be made by mixing $TiCl_4$ and Al_2Et_6 in heptane: partial reduction to Ti^{III} and alkyl transfer occur, and a brown suspension forms which rapidly absorbs and polymerizes ethene even at room temperature and atmospheric pressure. Typical industrial conditions are 50–150°C and 10 atm. Polyethene

[75] K. ZIEGLER, *Adv. Organometallic Chem.* **6**, 1–17 (1968).

produced at the surface of such a catalyst is 85–95% crystalline and has a density of 0.95–0.98 g cm^{-3} (compared with low-density polymer 0.92 g cm^{-3}); the product is stiffer, stronger, has a higher resistance to penetration by gases and liquids, and has a higher softening temperature (140–150°). Polyethene is produced in megatonne quantities and used mainly in the form of thin film for packaging or as molded articles, containers and bottles; electrical insulation is another major application. Stereoregular (isotactic) polypropene and many copolymers of ethene are also manufactured. Much work has been done in an attempt to elucidate the chemical nature of the catalysts and the mechanism of their action; the active site may differ in detail from system to system but there is now general agreement that polymerization is initiated by η^2 coordination of ethene to the partly alkylated lower-valent transition-metal atom (e.g. Ti^{III}) followed by migration of the attached alkyl group from transition-metal to carbon (the Cossee mechanism, see Scheme below). An alternative suggestion involves a metal–carbene species generated by α-hydrogen transfer from carbon to the transition metal.[76]

Coordination of the ethene or propene to Ti^{III} polarizes the C–C bond and allows ready migration of the alkyl group with its bonding electron-pair. This occurs as a concerted process, and transforms the η^2-alkene into a σ-bonded alkyl group. As much as 1 tonne of polypropylene can be obtained from as little as 5 g Ti in the catalyst.

Finally, in this subsection, we mention a few recent examples of the use of specific ligands to stabilize particular coordination geometries about the organoaluminium atom (see also p. 256). Trigonal planar stereochemistry has been achieved in $R_2AlCH_2AlR_2$ {R = $(Me_3Si)_2CH-$}, which was prepared as colourless crystals by reacting $CH_2(AlCl_2)_2$ with 4 moles of $LiCH(SiMe_3)_2$ in pentane.[77] It is also noteworthy that the bulky R groups permit the isolation for the first time of a molecule having the $AlCH_2Al$ grouping, by preventing the dismutation which spontaneously occurs with the Me an Et derivatives.

The linear cation $[AlMe_2]^+$ has been stabilized by use of crown ethers (p. 96).[78] For example, 15-crown-5 gives overall pentagonal bipyramidal 7-fold coordination around Al with axial Me groups having Al–C 200 pm and angle Me–Al–Me 178° (see Fig. 7.19a). With the larger ligand 18-crown-6, the Al atom is bonded to only three of the six O atoms to give unsymmetrical 5-fold coordination with Al–C 193 pm and angle Me–Al–Me 141°. Symmetrical (square-pyramidal) 5-coordinate Al is found

Scheme

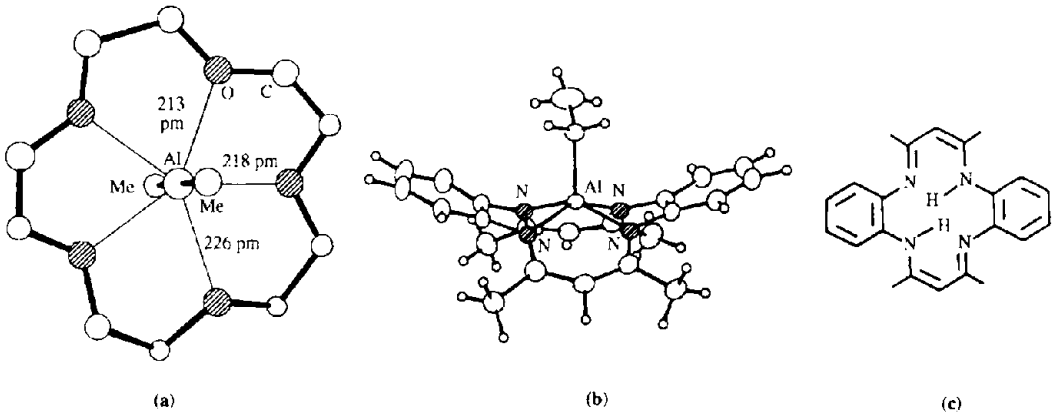

Figure 7.19 (a) Structure of the cation in $[AlMe_2(15\text{-crown-}5)]^+[AlMe_2Cl_2]^-$ showing pentagonal bipyramidal coordination of Al with axial Me groups. (b) Structure of [AlEtL] where L is the bis(deprotonated) form of the macrocycle $H_2[C_{22}H_{22}N_4]$ shown in (c).

in the complex [AlEt.L] (Fig. 7.19b) formed by reacting Al_2Et_6 in hexane solution with $H_2[C_{22}H_{22}N_4]$, i.e. H_2L, shown in Fig. 7.19c.[79] The average Al–N distance is 196.7 pm, Al–C is 197.6 pm (close to the value for the terminal Al C in Al_2Me_6, p. 259) and the Al atom is 57 pm above the N_4 plane. A further notable feature is the great stability of the Al–C bond: the compound can be recrystallized unchanged from hydroxyllic or water-containing solvents and does not decompose even when heated to 300°C in an inert atmosphere.

Heterocyclic and cluster organoaluminium compounds containing various sequences of Al–N bonds are discussed on p. 265.

Organometallic compounds of Ga, In and Tl

Organometallic compounds of Ga, In and Tl have been less studied than their Al analogues. The trialkyls do not dimerize and there is a general tendency to diminishing thermal stability with increasing atomic weight of M. There is also a general decrease of chemical reactivity of the M–C bond in the sequence Al > Ga ≈ In > Tl, and this is particularly noticeable for compounds of the type R_2MX; indeed, Tl gives air-stable non-hydrolysing ionic derivatives of the type $[TlR_2]X$, where X = halogen, CN, NO_3, $\frac{1}{2}SO_4$, etc. For example, the ion $[TlMe_2]^+$ is stable in aqueous solution, and is linear like the isoelectronic $HgMe_2$ and $[PbMe_2]^{2+}$.

GaR_3 can be prepared by alkylating Ga with HgR_2 or by the action of RMgBr or AlR_3 on $GaCl_3$. They are low-melting, mobile, flammable liquids. The corresponding In and Tl compounds are similar but tend to have higher mps and bps; e.g.

Compound	$GaMe_3$	$InMe_3$	$TlMe_3$
MP	−16°	88.4°	38.5°
BP	56°	136°	147° (extrap)
Compound	$GaEt_3$	$InEt_3$	$TlEt_3$
MP	−82°	–	−63°
BP	143°	84°/12 mmHg	192° (extrap)

The triphenyl analogues are also monomeric in solution but tend to associate into chain structures in the crystalline state as a result of weak intermolecular M···C interactions: $GaPh_3$ mp

[79] V. L. Goedken, H. Ito and T. Ito, *J. Chem. Soc., Chem. Commun.*, 1453–5 (1984).

166°, $InPh_3$ mp 208°, $TlPh_3$ mp 170°. For Ga and In compounds the primary M–C bonds can be cleaved by HX, X_2 or MX_3 to give reactive halogen-bridged dimers $(R_2MX)_2$. This contrasts with the unreactive ionic compounds of Tl mentioned above, which can be prepared by suitable Grignard reactions:

$$TlX_3 + 2RMgX \longrightarrow [TlR_2]X + 2MgX_2$$

As in the case of organoaluminium compounds, unusual stereochemistries can be imposed by suitable design of ligands. Thus, reaction of $GaCl_3$ with 3,3′,3″-nitrilotris(propylmagnesium chloride), $[N[(CH_2)_3MgCl]_3]$, yields colourless crystals of $[\overbrace{Ga(CH_2)_3N}]$ in which intramolecular N→Ga coordination stabilizes a planar trigonal monopyramidal geometry about Ga as shown schematically in Fig. 7.20(a).[80] Because of steric constraints, the Ga–N distance of 209.5 pm is about 7% longer than the sum of the covalent radii (195 pm), although not so long as in Me_3GaNMe_3 (220 pm). Long bonds are also a feature of the unique 6-coordinate complex of $InMe_3$ with the heterocyclic triazine ligand $(Pr^iNCH_2)_3$. The air-sensitive adduct, $[Me_3In\{\eta^3\text{-}(Pr^iNCH_2)_3\}]$, can be prepared by direct reaction of the donor and acceptor in ether solution, and is the first example of a tridentate cyclotriazine complex; it is also the first example of $InMe_3$ accepting three lone pairs of electrons rather than the more usual one or two.[81] The structure (Fig. 7.20b) features a shallow InC_3 pyramid with C–In–C angles of 114°–117° and extremely acute N–In–N angles (48.6°) associated with the long In–N bonds (278 pm). The three Pr^i groups are all in equatorial positions.

Cyclopentadienyl and arene complexes of Ga, In and Tl have likewise attracted increasing attention during the past decade and provide a rich variety of structural types and of chemical diversity. $[Ga(C_5H_5)_3]$, prepared directly from $GaCl_3$ and an excess of LiC_5H_5 in Et_2O, was found to have simple trigonal planar Ga bonded to three η^1-C_5H_5 groups. The more elusive C_5Me_5 derivative was finally prepared from $GaCl_3$ and an excess of the more reactive NaC_5Me_5 in thf solution, or by reduction of $Ga(C_5Me_5)_nCl_{3-n}$ $(n = 1, 2)$ with sodium naphthalenide in thf.[82] $[Ga(C_5Me_5)_3]$

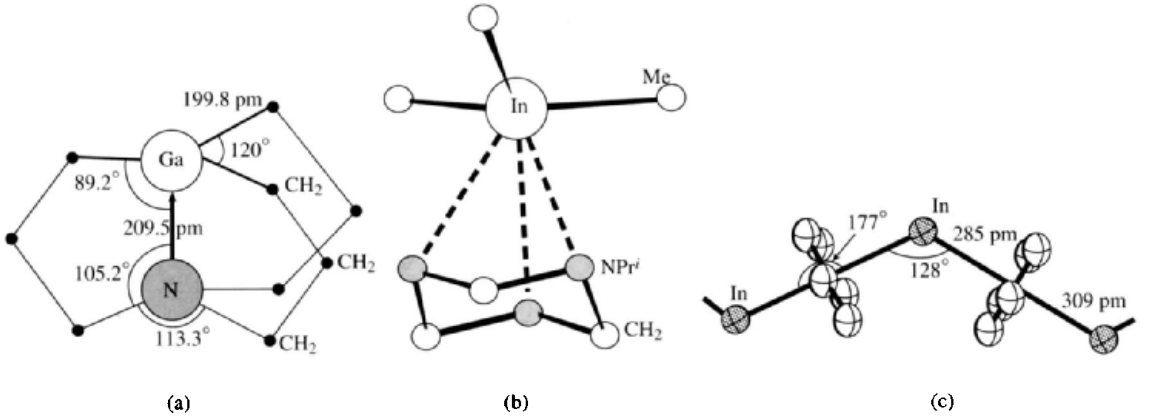

Figure 7.20 (a) Structure of $[\overbrace{Ga(CH_2)_3N}]$ showing trigonal planar monopyramidal 4-fold coordination about Ga and tetrahedral coordination about N. (b) Structure of $[Me_3In\{\eta^3\text{-}(Pr^iNCH_2)_3\}]$ — see text for dimensions. (c) Structure of polymeric $[In(\eta^5\text{-}C_5H_5)]$.

is a colourless, sublimable, crystalline solid, mp 168°, and appears to be a very weak Lewis acid.

As distinct from the cyclopentadienyls of Ga^{III}, those of In and Tl involve the +1 oxidation state of the metal and pentahapto bonding of the ligand. $[In(\eta^5\text{-}C_5H_5)]$ is best prepared by metathesis between LiC_5H_5 and a slurry of InCl in Et_2O.[83] It is monomeric in the gas phase with a 'half-sandwich' structure, the In–C_5(centroid) distance being 232 pm, but in the solid state it is a zig-zag polymer with significantly larger In–C_5(centroid) distances as shown in Fig. 7.20c.[84] The crystalline pentamethyl derivative, by contrast, is hexameric and features an octahedral In_6 cluster each vertex of which is η^5-coordinated by C_5Me_5.[85] $[Tl(\eta^5\text{-}C_5H_5)]$ precipitates as air-stable yellow crystals when aqueous TlOH is shaken with cyclopentadiene. In the gas phase the compound is monomeric with C_{5v} symmetry, the Tl atom being 241 pm above the plane of the ring (microwave), whereas in the crystalline phase there are zig-zag chains of equispaced alternating C_5H_5 rings and Tl atoms similar to the In homologue.

Hexahapto (η^6-arene) complexes of Ga^I and In^I can be obtained from solutions of the lower halides (p. 240) in aromatic solvents, and some of these have surprisingly complex structures.[86] With bulky ligands such as C_6Me_6 simple adducts crystallize in which the cations $[M(\eta^6\text{-}C_6Me_6)]^+$ have the C_{6v} 'half-sandwich' structure shown in Fig. 7.21a, e.g. $[Ga(\eta^6\text{-}C_6Me_6)][GaCl_4]$ mp 168° and $[Ga(\eta^6\text{-}C_6Me_6)][GaBr_4]$ mp 146°.[87] With less bulky ligands such as mesitylene (1,3,5-$C_6H_3Me_3$), a 2:1 stoichiometry is possible to give cations $[M(\eta^6\text{-}C_6H_3Me_3)_2]^+$ shown schematically in Fig. 7.21b, although further ligation from the anion may also occur; e.g. $[In(\eta^6\text{-}C_6H_3Me_3)_2][InBr_4]$ features polymeric helical chains in which bridging $[\mu\text{-}\eta^1,\eta^2\text{-}InBr_4]$ units connect the cations as shown in Fig. 7.21c.[88] With still less bulky ligands such as benzene itself, discrete dimers can be formed as in the solvated complex $[Ga(\eta^6\text{-}C_6H_6)_2][GaCl_4].3C_6H_6$. This features tilted bis(arene)Ga^I units linked through bridging $GaCl_4$ units to form the dimeric structure shown in Fig. 7.22a.[86] Mixed adducts can also be prepared. Thus, when

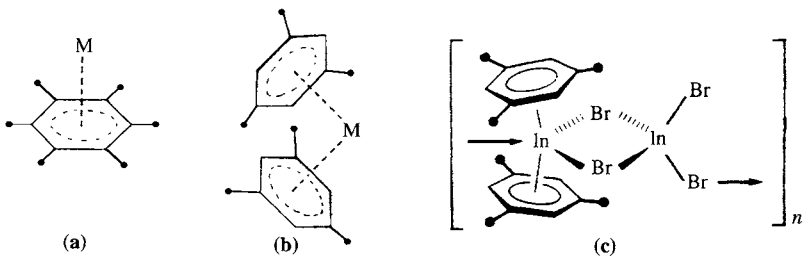

Figure 7.21 (a) The 'half-sandwich' C_{6v} structure characteristic of $[Ga(\eta^6\text{-}C_6Me_6)]^+$. (b) The 'bent-sandwich' structure found in ions of the type $[In(\eta^6\text{-}C_6H_3Me_3)_2]^+$. (c) A section of the helical chain in $[In(\eta^6\text{-mes})_2][InBr_4]$ showing the $[\mu\text{-}\eta^1,\eta^2\text{-}InBr_4]$ unit bridging ions of the type shown in (b); the tilting angle is 133° and the ring-centres of the two arene ligands are almost equidistant from In (283 and 289 pm).

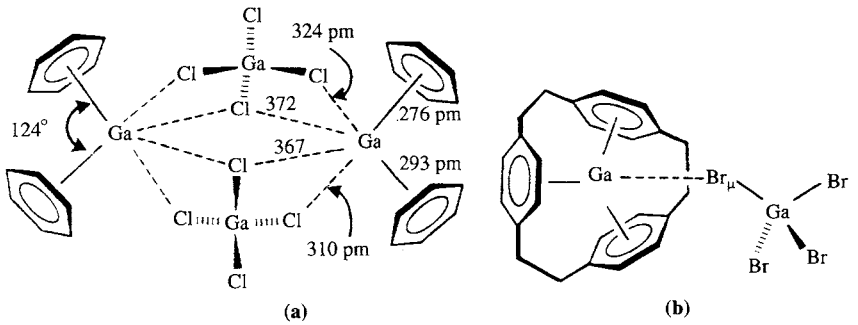

Figure 7.22 (a) Structure of the dimeric unit in the solvated complex $[Ga(\eta^6\text{-}C_6H_6)_2][GaCl_4].3C_6H_6$ indicating the principal dimensions; the six benzene molecules of solvation per dimer lie outside the coordination spheres of the gallium atoms. (b) Structure of the ion-pair $[Ga(\eta^{18}\text{-}[2.2.2]$ paracyclophane)$][GaBr_4]$; the four Ga–Br distances within the tetrahedral anion are in the range 230.5–233.3 pm, the distance for Ga–Br_μ being 231.9 pm; the $Ga^I \cdots Br_\mu$ distance is 338.8 pm.

dilute toluene solutions of Ga_2Cl_4 and durene ($1,2,4,5\text{-}C_6H_2Me_4$) are cooled to 0°, crystals containing the centrosymmetric dimer $[\{Ga(\eta^6\text{-dur})(\eta^6\text{-tol})\}GaCl_4]_2$ are obtained.[89] The structure resembles that in Fig. 7.22a, with each Ga^I centre η^6-bonded to one durene molecule at 264 pm and one toluene molecule at 304 pm. These bent-sandwich moieties are then linked into dimeric units via three of the four Cl atoms of each of the two $GaCl_4$ tetrahedra.

An even more remarkable structure emerges for the monomeric complex of Ga_2Br_4 with the tris(arene) ligand [2.2.2]paracyclophane (Fig. 7.22b):[90] the Ga^I centre is encapsulated in a unique η^{18} environment which has no parallels even in transition-metal coordination chemistry. The Ga^+ cation is almost equidistant from the three ring centres (265 pm) but is displaced away from the ligand centre by 43 pm towards the $GaBr_4^-$ counter anion. The complex was prepared by dissolving the dimeric benzene complex $[\{(C_6H_6)_2Ga.GaBr_4\}_2]$ (cf. Fig. 7.22a) in benzene and adding the cyclophane.

Al–N heterocycles and clusters

Finally, in this chapter, attention should be drawn to a remarkable range of heterocyclic and cluster organoaluminium compounds containing various sequences of Al–N bonds[91] (cf. B–N compounds, p. 207). Thus the adduct $[AlMe_3(NH_2Me)]$ decomposes at 70°C with loss of methane to give the cyclic amido trimers *cis*- and *trans*-$[Me_2AlNHMe]_3$ (structures 2 and 3) and at 215° to give the oligomeric imido cluster compounds $(MeAlNMe)_7$ (structure 6) and $(MeAlNMe)_8$ (structure 7), e.g.:

$$21AlMe_3 + 21NH_2Me \xrightarrow[-21CH_4]{70°} 7(Me_2AlNHMe)_3$$

$$\xrightarrow[-21CH_4]{215°} 3(MeAlNMe)_7$$

Similar reactions lead to other oligomers depending on the size of the R groups and the conditions of the reaction, e.g. *cyclo*-$(Me_2AlNMe_2)_2$ (structure 1) and the imido-clusters $(PhAlNPh)_4$, $(HAlNPr^i)_4$ or 6,

Organometallic Chem.* **400**, 49–69 (1990); K. M. WAGGONER, M. M. OLMSTEAD and P. P. POWER, *Polyhedron* **9**, 257–63 (1990); A. J. DOWNS, D. DUCKWORTH, J. C. MACHELL and C. R. PULHAM, *Polyhedron* **11**, 1295–304 (1992).

$(HAlNPr^n)_{6 \text{ or } 8}$, $(HAlNBu^t)_4$, and $(MeAlNPr^i)_{4or6}$ (see structures 4, 5, 7). Intermediate amido-imido compounds have also been isolated from the reaction, e.g. $[Me_2AlNHMe)_2(MeAlNMe)_6]$ (structure 8). Oligomers up to $(RAlNR')_{16}$ have been obtained although not necessarily structurally characterized. The known structures are all built up from varying numbers of fused 4-membered and 6-membered AlN heterocycles.

Until recently tetramers such as (4) were the smallest oligomers involving alternating Al and N atoms. It will be noted, however, that the hexamer (5) comprises a hexagonal prism formed by conjoining two plane six-membered rings. By increasing the size of the exocyclic groups it has proved possible to isolate a planar trimer, $(MeAlNAr)_3$, which is isoelectronic with borazine (p. 210). Thus, thermolysis of a mixture of $AlMe_3$ and $ArNH_2$ $(Ar = 2, 6\text{-}Pr^i_2C_6H_3)$ in toluene at 110° results in the smooth elimination of CH_4 to give the dimer, $(Me_2AlNHAr)_2$, which, when heated to 170°, loses more methane to give a high yield of the trimer, $(MeAlNAr)_3$, as colourless, air- and moisture-sensitive crystals.[92] The six *ipso*-C atoms are coplanar with the planar 6-membered Al_3N_3 ring and the Al–N distance of 178 pm is significantly shorter than in the higher (4-coordinate) oligomers (189–196 pm). Comparison with other 3-coordinate Al and N centres is difficult because of the paucity of examples but the homoleptic monomer $[Al\{N(SiMe_3)_2\}_3]$ has also been reported to have Al–N distances of 178 pm.

Several analogous gallium compounds are also known, e.g. $[(Me_2GaNHMe)_2(MeGaNMe)_6]$

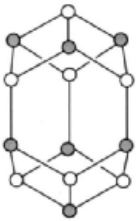
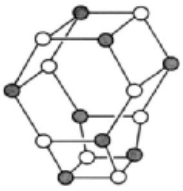
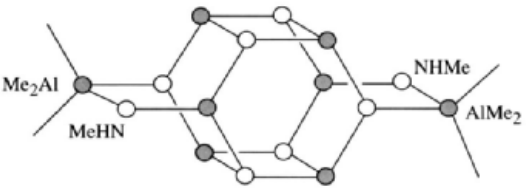
(5) $(HAlNPr^i)_6$



(6) $(MeAlNMe)_7$



(7) $(MeAlNMe)_8$



(8) $[Me_2AlNHMe)_2(MeAlNMe)_6]$

(structure 8).[91] Likewise, $(R_2GaPBu^t_2)_2$ and $(R_2GaAsBu^t_2)_2$ (R = Me, Bu^n) have structures analogous to (1).[93] A more complex 12-membered Ga_5As_7 cluster has been characterized in $[(PhAsH)(R_2Ga)(PhAs)_6(RGa)_4]$ ($R = Me_3SiCH_2$).[94] The cyclic trimer, [{(triph)GaP(chex)}$_3$], (where triph = 2,4,6-$Ph_3C_6H_2$ and chex = cyclo-C_6H_{11}) is of interest in being the first well characterized heterocycle consisting entirely of heavier main-group elements. It is obtained as pale yellow crystals by reacting (triph)$GaCl_2$ with Li_2P(chex) and is formally isoelectronic with borazine (p. 210). Indeed, it has short Ga–P distances (mean 229.7 pm) but the ring is markedly non-planar and there is a slight, statistically significant alternation in Ga–P distances with three averaging at 228.5(4) pm and three at 230.8(4) pm.[95] Much of the burgeoning interest in this area of volatile compounds of Group 13 elements has come from attempts to devise effective routes to thin films of III–V semiconductors such as GaP, GaAs, etc. via MOCVD (metal-organic chemical vapour deposition).

8

Carbon

8.1 Introduction

One thing is absolutely certain — it is quite impossible to do justice to the chemistry of carbon in a single chapter; or, indeed, a single book. The areas of chemistry traditionally thought of as organic chemistry will largely be omitted except where they illuminate the general chemistry of the element. The field of organometallic chemistry is discussed in Section 19.7: this has been one of the most rapidly developing areas of the subject during the past 40 y and has led to major advances in our understanding of the structure, bonding and reactivity of molecular compounds. In fact, the unifying concepts emerging from organometallic chemistry emphasize the dangers of erecting too rigid a barrier between various branches of the subject, and nowhere is the boundary between inorganic and organic chemistry more arbitrary and less helpful than here. The present chapter gives a general account of the chemistry of carbon and its compounds; a more detailed discussion of specific organometallic systems will be found under the individual elements. Discussion of Group trends and the comparative chemistry of the Group 14 elements C, Si, Ge, Sn and Pb is deferred until Chapter 10.

Carbon was known as a substance in prehistory (charcoal, soot) though its recognition as an element came much later, being the culmination of several experiments in the eighteenth century.[1] Diamond and graphite were known to be different forms of the element by the close of the eighteenth century, and the relationship between carbon, carbonates, carbon dioxide, photosynthesis in plants, and respiration in animals was also clearly delineated by this time (see Panel). The great upsurge in synthetic organic chemistry began in the 1830s and various structural theories developed following the introduction of the concept of valency in the 1850s. Outstanding achievements in this area were F. A. Kekulé's use of structural formulae for organic compounds and his concept of the benzene ring, L. Pasteur's work on optical activity and the concept of tetrahedral carbon (J. H. van't Hoff).†

[1] M. E. WEEKS, *Discovery of the Elements*, Chaps. 1 and 2, pp. 58–89. J. Chem. Educ. Publ., 1956.

† J. A. Le Bel, whose name is often also associated with this concept, did indeed independently suggest a 3-dimensional model for the 4-coordinate C atom, but vigorously opposed the tetrahedral stereochemistry of van't Hoff for many years and favoured an alternative square pyramidal arrangement of the bonds.

Early History of Carbon and Carbon Dioxide

	Carbon known as a substance in prehistory (charcoal, soot) but not recognized as an element until the second half of the eighteenth century.
BC	"Indian inks" made from soot used in the oldest Egyptian hieroglyphs on papyrus.
AD 1273	Ordinance prohibiting use of coal in London as prejudicial to health — the earliest known attempt to reduce smoke pollution in Britain.
~1564	Lead pencils first manufactured commercially during Queen Elizabeth's reign, using Cumberland graphite.
1752/4	CO_2 ("fixed air"), prepared by Joseph Black (aged 24–26), was the first gas other than air to be characterized: (i) chalk when heated lost weight and evolved CO_2 (genesis of quantitative gravimetric analysis), and (ii) action of acids on carbonates liberates CO_2.
1757	J. Black showed that CO_2 was produced by fermentation of vegetables, by burning charcoal and by animals (humans) when breathing; turns lime water turbid.
1771	J. Priestley established that green plants use CO_2 and "purify air" when growing. He later showed that the "purification" was due to the new gas oxygen (1774).
1779	Elements of photosynthesis elucidated by J. Ingenhousz: green plants in daylight use CO_2 and evolve oxygen; in the dark they liberate CO_2.
1789	The word "carbon" (Fr. *carbone*) coined by A. L. Lavoisier from the Latin *carbo*, charcoal. The name "graphite" was proposed by A. G. Werner and D. L. G. Harsten in the same year: Greek γραφίεν (*graphein*), to write. The name "diamond" is probably a blend of Greek διάφανής (*diaphanes*), transparent, and αδαμας (*adamas*), indomitable or invincible, in reference to its extreme hardness.
1796	Diamond shown to be a form of carbon by S. Tennant who burned it and weighed the CO_2 produced; graphite had earlier been shown to be carbon by C. W. Scheele (1779); carbon recognized as essential for converting iron to steel (R.-A.-F de Réaumur and others in the late eighteenth century).
1805	Humphry Davy showed carbon particles are the source of luminosity in flames (lamp black).

The first metal carbonyl compounds $Ni(CO)_4$ and $Fe(CO)_5$ were prepared and characterized by L. Mond and his group in 1889–91 and this work has burgeoned into the huge field of metal carbonyl cluster compounds which is still producing results of fundamental importance. Even more extensive is the field of organometallic chemistry which developed rapidly after the seminal papers on the "sandwich" structure of ferrocene (E. O. Fischer and W. Pfab, 1952; G. Wilkinson, M. Rosenblum, M. C. Whiting and R. B. Woodward, 1952) and the "π bonding" of ethylene complexes (M. J. S. Dewar 1951, J. Chatt, and L. A. Duncanson, 1953). The constricting influence of classical covalent-bond theory was finally overcome when it was realized that carbon in many of its compounds can be 5-coordinate (Al_2Me_6, p. 258), 6-coordinate ($C_2B_{10}H_{12}$, p. 185) or even 7-coordinate (Li_4Me_4, p. 104). A compound featuring an 8-coordinate carbon atom is shown on p. 1142. In parallel with these developments in synthetic chemistry and bonding theory have been technical and instrumental advances of great significance; foremost amongst these have been the development of ^{14}C radioactive dating techniques (W. F. Libby, 1949), the commercial availability of ^{13}C nmr instruments in the early 1970s, and the industrial production of artificial diamonds (General Electric Company, 1955). These and other notable dates in carbon chemistry are summarized in the Panel on p. 270.

The most exciting recent development in the chemistry of carbon has been the intriguing discovery of a whole new range of soluble molecular forms of elemental carbon, the fullerenes, of which C_{60} and C_{70} are the most prominent members. This was recognized by the 1996 Nobel Prize for Chemistry and has stimulated an enormous amount of research which is discussed in Section 8.2.4 (p. 279).

8.2 Carbon

8.2.1 Terrestrial abundance and distribution

Carbon occurs both as the free element (graphite, diamond) and in combined form (mainly as the

Some Notable Dates in Carbon Chemistry

1807	J. J. Berzelius classified compounds as "organic" or "inorganic" according to their origin in living matter or inanimate material.
1825–7	W. C. Zeise prepared $K[Pt(C_2H_4)Cl_3]$ and related compounds; though of unknown structure at the time they later proved to be the first organometallic compounds.
1828	The vitalist theory of Berzelius challenged by F. Wöhler (aged 28) who synthesized urea, $(NH_2)_2CO$, from $NH_4(OCN)$.
1830+	Rise of synthetic organic chemistry.
1848	L. Pasteur (aged 26) began work on optically active sodium ammonium tartrate.
1849	First metal alkyls, e.g. $ZnEt_2$, made by E. Frankland (aged 24); he also first propounded the theory of valency (1852).
1858	F. A. Kekulé's structural formulae for organic compounds; ring structure of benzene 1865.
1874	Tetrahedral, 4-coordinate carbon proposed by J. H. van't Hoff (aged 22) see also footnote to p. 268.
1890	First paper on metal carbonyls $[Ni(CO)_4]$ by L. Mond, C. Langer and F. Quincke.
1891	Carborundum, SiC, made by E. G. Acheson.
1900	First paper by V. Grignard (aged 29) on RMgX syntheses. Nobel Prize 1912.
1924	Solid CO_2 introduced commercially as a refrigerant.
1926	C_8K prepared — the first alkali metal-graphite intercalation compound.
1929	Isotopes of C (^{12}C and ^{13}C) discovered by A. S. King and R. T. Birge in the band spectrum of C_2, CO and CN (previously undetected by mass spectrometry).
1932	First metal halide-graphite intercalation compound made with $FeCl_3$.
1936	Radiocarbon $^{14}_{6}C^*$ established as the product of an (n,p) reaction on $^{14}_{7}N$ by W. E. Burcham and M. Goldhaber.
1940	Chemically significant amounts of ^{14}C synthezied by S. Ruben and M. D. Kamen.
1947–9	Concept and feasibility of ^{14}C dating established by W. F. Libby (awarded Nobel Prize in 1960).
1952	Structure of ferrocene elucidated; organometallic chemistry burgeons: Nobel Prize awarded jointly to E. O. Fischer and G. Wilkinson 1973.
1953	First authentic production of artificial diamonds by ASEA, Sweden; commercial production achieved by General Electric (USA) in 1955.
1955	Stereoregular polymerization of ethene and propene by catalysts developed by K. Ziegler and by G. Natta (shared Nobel Prize 1963).
1956	Cyclobutadiene–transition metal complexes predicted by H. C. Longuet-Higgins and L. E. Orgel 3 y before they were first synthesized.
1960	π-allylic metal complexes first recognized.
1961	$^{12}C = 12$ internationally adopted as the unified atomic weight standard by both chemists and physicists.
1964	6-coordinate carbon established in various carboranes by W. N. Lipscomb and others. (Nobel Prize 1976 for structure and bonding of boranes).
1965	Mass spectrometric observation of CH_5^+ by F. H. Field and M. S. B. Munson, and subsequent extensive study of hypercoordinate C compounds by G. A. Olah *et al.*
1966	CS_2 complexes such as $[Pt(CS_2)(PPh_3)_2]$ first prepared in G. Wilkinson's laboratory.
1971	^{13}C fourier-transform nmr commercially available following first observation of ^{13}C nmr signal by P. C. Lauterbur and by C. H. Holm in 1957.
1976	8-coordinate carbon established in $[Co_8C(CO)_{18}]^{2-}$ by V. G. Albano, P. Chini *et al.* (Cubic coordination of C in the antifluorite structure of Be_2C known since 1948.)
1985	Discovery of C_{60} and C_{70} molecules (fullerenes) by H. Kroto, R. E. Smalley and their colleagues.
1989	Large-scale synthesis of C_{60} and C_{70} by D. Huffmann and W. Krätschmer.
1994	Nobel Prize to G. A. Olah for contributions to carbocation chemistry.
1996	Nobel Prize to R. Curl, H. Kroto and R. E. Smalley for discovery of the fullerenes.

carbonates of Ca, Mg and other electropositive elements). It also occurs as CO_2 a minor but crucially important constituent of the atmosphere. Estimates of the overall abundance of carbon in crustal rocks vary considerably, but a value of 180 ppm can be taken as typical; this places the element seventeenth in order of abundance after Ba, Sr and S but before Zr, V, Cl and Cr.

Graphite is widely distributed throughout the world though much of it is of little economic importance. Large crystals or "flake" occur in metamorphosed sedimentary silicate rocks such as quartz, mica schists and gneisses; crystal size varies from <1 mm up to about 6 mm (average ~4 mm) and the deposits form lenses up to 30 m thick stretching several

Production and Uses of Graphite[2]

There is a world shortage of natural graphite which is particularly marked in North America and Europe. As a result, prices have risen steeply; they vary widely in the range \$500–1500 per tonne (1989) depending on crystalline quality; "amorphous" graphite is \$220–440 per tonne. The annual world production of 649 ktonnes was distributed as follows in 1988: China 200 kt, South Korea 108, the former Soviet Union 84, India 52, Mexico 42, Brazil 32, North Korea 25, Czechoslovakia 25, Others 81 kt.

The USA used 37 ktonnes of natural graphite in 1989, nearly all imported; in addition, over 300 ktonnes of graphite was manufactured. Natural graphite is used in refractories (27%), lubricants (17%), foundries (14%), brake linings (12%), pencils (5.3%), crucibles, retorts, stoppers, sleeves and nozzles (4.0%) etc.

Artificial graphite was first manufactured on a large scale by A. G. Acheson in 1896. In this process coke is heated with silica at ~2500°C for 25–35 h:

$$SiO_2 + 2C \xrightarrow{-2CO} \{SiC\} \xrightarrow{2500^\circ} Si(g) + C(\text{graphite})$$

In the USA artificial graphite is now made on a scale exceeding 300 kilotonnes pa (1989), and is used mainly for electrodes, crucibles and vessels, and various unmachined shapes; specialist uses include motor brushes and contacts and refractories of various sorts.

Carbon (graphite) fibres are also being manufactured on an increasing scale: The global market (1990) is of the order of 6 million kg per annum and prices range from \$20–2000/kg depending on specifications (diameter, strength, stiffness, etc.). The two main production methods are the oxidative thermolysis of polyacrilonitrile fibres at 200–300°C under tension or the thermolysis of pitch at 370° followed by die-extrusion and stretching to give filaments which are then heated progressively in dry air to 2500°. Ultra-high-purity graphite is made on a substantial scale for use as a neutron moderator in nuclear reactors. Carbon whiskers grown from highly purified graphite are finding increasing use in high-strength composites; the whiskers are manufactured by striking a carbon arc at 3600°C under 90 atm Ar — the maximum length is ~50 mm and the average diameter 5 μm.

kilometres across country. Average carbon content is 25% but can rise as high as 60% (Malagasy). Beneficiation is by flotation followed by treatment with HF and HCl, and then by heating to 1500°C *in vacuo*. Microcrystalline graphite (sometimes referred to as "amorphous") occurs in carbon-rich metamorphosed sediments and some deposits in Mexico contain up to 95% C. World production has remained fairly constant for the past few years and was 649 ktonnes in 1988 (see Panel above).

Diamonds are found in ancient volcanic pipes embedded in a relatively soft, dark coloured basic rock called "blue ground" or "kimberlite", from the South African town of Kimberley where such pipes were first discovered in 1870. Diamonds are also found in alluvial gravels and marine terraces to which they have been transported over geological ages by the weathering and erosion of pipes. The original mode of formation of the diamond crystals is still a subject of active investigation. The diamond content of a typical kimberlite pipe is extremely low, of the order of 1 part in 15 million, and the mineral must be isolated mechanically by crushing, sluicing and passing the material over greased belts to which the diamonds stick. This, in part, accounts for the very high price of gem-quality diamonds which is about 1 million times the price of flake graphite. The pattern of world production has changed dramatically over the past few decades as indicated in the Panel on p. 272.

Three other forms of carbon are manufactured on a vast scale and used extensively in industry: coke, carbon black, and activated carbon. The production and uses of these impure forms of carbon are briefly discussed in the Panel on p. 274.

In addition to its natural occurrence as the free element, carbon is widely distributed in the

Production and Uses of Diamond[2,2a]

Gemstone diamonds have been greatly prized in eastern countries for over 2000 y though their introduction and recognition in Europe is more recent. The only sources were from India and Borneo until they were also found in Brazil in 1729. In South Africa diamonds were discovered in alluvial deposits in 1867 and the first kimberlite pipe was identified in 1870 with dramatic consequences. Many other finds of economic importance were made in Africa during the first half of this century: most notably in Tanzania where large-scale production began in 1940 following the discovery of the enormous Williamson pipe — still the largest in the world and covering an area of 1.4 km^2. During the 1950s 99% of the world output of diamonds was from Africa but then the USSR began to emerge as a major producer following the discovery of alluvial diamonds in Siberia in 1948 and the first kimberlite-type pipe at Yakutia later the same year. Within a decade more than 20 pipes had been located in the great basin of the Vilyui River 4000 km east of the Urals, and Siberia was established as a major producer of both gem-quality and industrial diamonds. However, year-round production in Siberian conditions posed severe developmental problems, and production is now supplemented by newer finds in the Urals near Sverdlovsk. Impressive finds of kimberlite pipes have also been made in North-western Australia since 1978 and this area is now one of the world's largest producers of industrial diamonds.

Diamond is the hardest and least perishable of all minerals, and these qualities, coupled with its brilliant sparkle, which derives from its transparency and high refractive index, make it the most prized of gemstones. By far the largest natural diamond ever found (25 January 1905) was the Cullinan; it weighed 3106 carats (621.2 g) and measured $\sim 10 \times 6.5 \times 5\,cm^3$ (the size of a man's clenched fist). Other famous stones are in the range 100–800 carats though specimens larger than 50 carats are only rarely encountered. Most naturally occurring diamonds, however, are of industrial rather than gem-stone quality. They are used as single-point tools for engraving or cutting, and for surgical knives, bearings and wire dies, as well as for industrial abrasives for grinding and polishing. Other uses are as thermistors and radiation detectors, and as optical windows for lasers, etc.

Since the late 1950s the supply of natural diamonds has been progressively augmented by diamonds synthesized at high pressures and temperatures (p. 278) and this source now accounts for 90% of all industrial diamonds. The price for such diamond grit is relatively low, about \$5–25 per g, the higher prices being for the largest crystals (0.3–1 mm on edge). Total world production (1990) approached 100 tonnes (500 megacarats) and was worth about $\$10^9$. In 1985, Sumitomo Electric (Japan) began commercial production of diamond crystals of up to 2 carats (as large as 8 mm in length) and de Beer's (South Africa) have made single crystals up to 17 mm long. Such diamonds, which are pale yellow due to nitrogen inclusions, are used as heat sinks in the electronics industry because of the very high thermal conductivity of diamond. The synthetic stones are machined and laser cut to about $3 \times 3 \times 1\,mm^3$ and are commercially available for \$150 a piece. Synthetic industrial diamonds are manufactured in 16 countries, the major producers being in USA, Japan, China and Russia.

Exciting developments are also occurring in the emerging technology of large-area thin films of synthetic diamond. Such films are of interest as heat sinks for components in the electronics industry and, when bonded to inexpensive non-diamond surfaces, can also provide the unexcelled hardness, wear resistance and chemical inertness of diamond at lower cost than that of the bulk element. The films are made by low pressure (50 mbar) chemical vapour deposition of metastable diamond at 1000°C, the crucial feature of the method being the simultaneous presence of a plasma of atomic H to prevent the concurrent deposition of graphite from the decomposing organic vapours (see p. 278).

form of coal and petroleum, and as carbonates of the more electropositive† elements (e.g. Group 1, p. 88, Group 2, pp. 109, 122). The great bulk of carbon is immobilized in the form of coal, limestone, chalk, dolomite and other deposits, but there is also a dynamic equilibrium as a result of the numerous natural processes which constitute the so-called carbon cycle. The various reservoirs of carbon and the flow between them are illustrated in Fig. 8.1 from which it is clear that there are two distinct cycles — one on land and one in the sea, dynamically inter-connected by the atmosphere. CO_2 in the atmosphere ($\sim 6.7 \times 10^{11}$ tonnes) accounts for only 0.003% of carbon in the earth's crust ($\sim 2 \times 10^{16}$ tonnes). It is in rapid circulation with the biosphere being removed by plant photosynthesis and added to by plant and animal respiration, and the decomposition of dead organic matter; it is also produced by the activities of man, notably the combustion of fossil fuels for energy and the calcination of limestone for cement. These last

† Note that the *weight* of diamonds is usually quoted in carats (1 carat = 0.200 g); this unit is quite different from the carat used to describe the *quality* of gold (p. 1176).

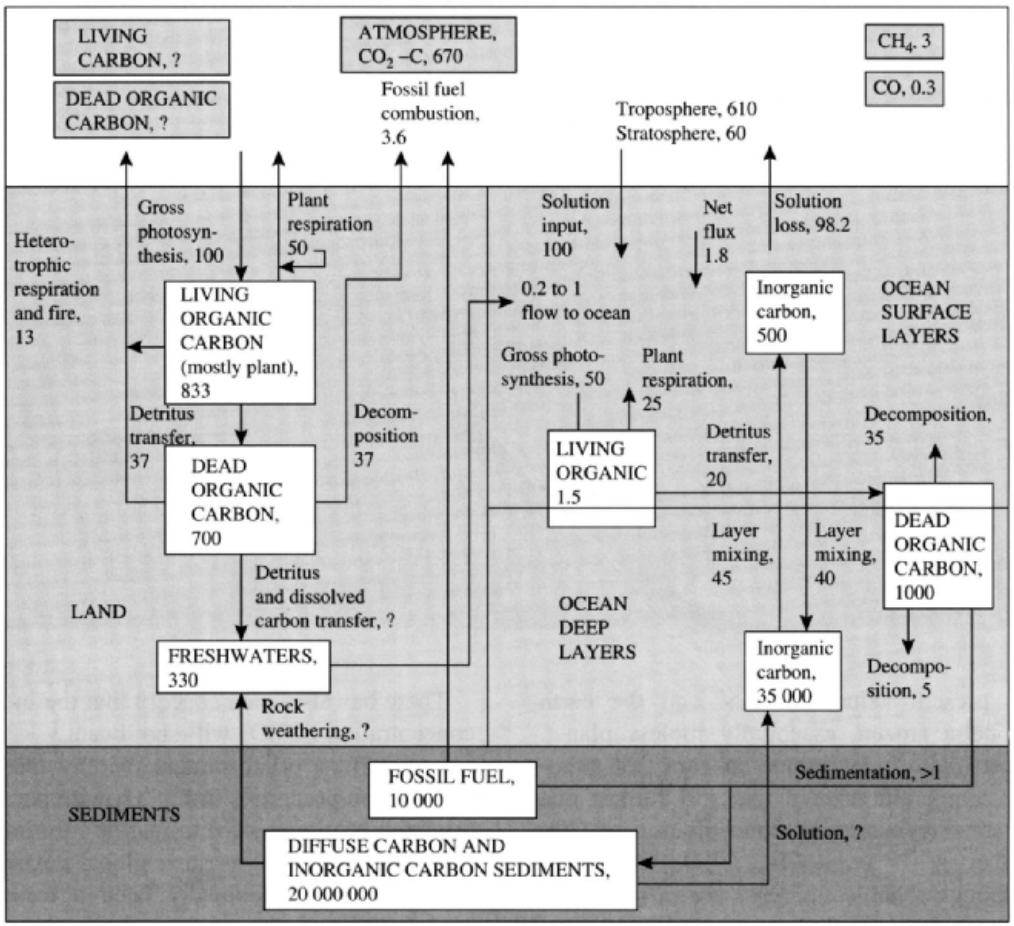

Figure 8.1 Diagrammatic model of the global carbon cycle. Questions marks indicate that no estimates are available. Figures are in units of 10^9 tonnes of contained carbon but estimates from various sources sometimes differ by factors of 3 or more. The diagram is based on one by B. Bolin[3] modified to include more recent data.[4]

two activities have increased dramatically in recent years and give some cause for concern. Interchange on a similar scale occurs between the atmosphere and ocean waters, and the total residence time of CO_2 in the atmosphere is ~10–15 y (as measured by ^{14}C experiments).

An increase in the concentration of atmospheric CO_2 has been thought by some to expose the planet to the dangers of a "greenhouse effect" whereby the temperature is raised due to the trapping of the earth's thermal radiation by infrared absorption in the CO_2 molecules. In fact, the greenhouse gases, especially water vapour and CO_2, play a crucial role in regulating the temperature of the earth and its atmosphere. In the absence of these gases the average surface temperature would be −18°C instead

Production and Uses of Coke, Carbon Black and Activated Carbon[2]

The high-temperature carbonization of coal yields metallurgical coke, a poorly graphitized form of carbon; most of this (92%) is used in blast furnaces for steel manufacture (p. 1072). World production of coke is of the order of 400 million tonnes per annum and was dominated, as expected, by the large industrial nations. Carbon black (soot) is made by the incomplete combustion of liquid hydrocarbons or natural gas; the scale of operations is enormous, world production in 1992 being nearly 7 million tonnes. The particle size of carbon black is exceedingly small (0.02–0.30 μm) and its principal application (90%) is in the rubber industry where it is used to strengthen and reinforce the rubber in a way that is not completely understood. For example, each car tyre uses 3 kg carbon black and each truck tyre ~9 kg. Its other main uses are as a pigment in plastics (4.4%) in printing inks (3.6%) and paints (0.7%).

Activated carbons, being highly specialized products, are produced on a correspondingly smaller scale. World production capacity in 1990 being some 400 kilotonnes (USA 146, Western Europe 108, Japan 72 kt). They are distinguished by their enormous surface area which is typically in the range 300–2000 $m^2 g^{-1}$. Activated carbon can be made either by chemical or by gas activation. In chemical activation the carbonaceous material (sawdust, peat, etc.) is mixed or impregnated with materials which oxidize and dehydrate the organic substrate when heated to 500–900°, e.g. alkali metal hydroxides, carbonates or sulfates, alkaline earth metal chlorides, carbonates or sulfates, $ZnCl_2$, H_2SO_4 or H_3PO_4. In gas activation, the carbonaceous matter is heated with air at low temperature or with steam, CO_2 or flue gas at high temperature (800–1000°).

Activated carbon is used extensively in the sugar industry as a decolorizing agent and this accounts for some 20% of the output; related applications are in the purification of chemicals and gases including air pollution (15%), and in water and waste water treatment (50%). Notable catalytic uses are the aerial oxidation in aqueous solutions of Fe^{II}, $[Fe^{II}(CN)_6]^{4-}$, $[As^{III}O_3]^{3-}$ and $[N^{III}O_2]^-$, the manufacture of $COCl_2$ from CO and Cl_2, and the production of SO_2Cl_2 from SO_2 and Cl_2. The cost of activated carbon (USA, 1990) was \$0.70–5.50 per kg depending on the grade.

of the present value of +15° and the earth would be a frozen, essentially lifeless planet. However, there is legitimate concern that atmospheric temperatures may rise still further due to the steadily increasing concentration of CO_2 and other gases (e.g. CH_4, N_2O, CFCs and O_3) although reliable estimates are extraordinarily difficult to obtain and depend sensitively on the computer modelling of the many interacting effects.[5] Perhaps the most reliable estimate is that there will be a temperature rise from the greenhouse effect of 1.5 ± 1.0°C and a resulting average rise in sea level of 20 ± 14 cm by the year AD 2030, though even this assumes that other unrelated effects of potentially similar magnitude will not occur. The best estimates of all the various counterbalancing effects leads to the conclusion that the change in sea level will probably not exceed ±10 cm during the next century.

There has also been concern that the increased concentration of CO_2 will significantly lower the pH of surface ocean waters thereby modifying the solution properties of $CaCO_3$ with potentially disastrous consequences to marine life. Informed opinion now discounts such global catastrophes but there has undoubtedly been a measurable perturbation of the carbon cycle in the last few decades, and the prudent course is to conserve resources, minimize wasteful practices and improve efficiency, whilst simultaneously collecting reliable data on the magnitude of the various carbon-containing reservoirs and the rates of transfer between them.[6]

8.2.2 Allotropic forms

Carbon can exist in at least 6 crystalline forms in addition to the many newly prepared fullerenes described in Section 8.2.4: α- and β-graphite, diamond, Lonsdaleite (hexagonal

diamond), chaoite, and carbon(VI). Of these, α- (or hexagonal) graphite is thermodynamically the most stable form at normal temperatures and pressures. The various modifications differ either in the coordination environment of the carbon atoms or in the sequence of stacking of layers in the crystal. These differences have a profound effect on both the physical and the chemical properties of the element.

Graphite is composed of planar hexagonal nets of carbon atoms as shown in Fig. 8.2. In normal α- (or hexagonal) graphite the layers are arranged in the sequence ···ABAB··· with carbon atoms in alternate layers vertically above each other, whereas in β- (or rhombohedral) graphite the stacking sequence is ···ABCABC···. In both forms the C–C distance within the layer is 141.5 pm and the interlayer spacing is much greater, 335.4 pm. The two forms are interconvertible by grinding ($\alpha \rightarrow \beta$) or heating above 1025°C ($\beta \rightarrow \alpha$), and partial conversion leads to an increase in the average spacing between layers; this reaches a maximum of 344 pm for turbostratic graphite in which the stacking sequence of the parallel layers is completely random. The enthalpy difference between α- and β-graphite is only $0.59 \pm 0.17\ \text{kJ mol}^{-1}$.

In diamond, each C atom is tetrahedrally surrounded by 4 equidistant neighbours at 154.45 pm, and the tetrahedra are arranged to give a cubic unit cell with a_0 356.68 pm as in Fig. 8.3. Note that, although the diamond structure itself is not close-packed, it is built up of 2 interpenetrating fcc lattices which are off-set along the body diagonal of the unit cell by one-quarter of its length. Nearly all naturally occurring diamonds (~98%) are of this type but contain, in addition, a small amount of nitrogen atoms (0.05–0.25%) in platelets of approximate composition C_3N (type Ia) or, very occasionally (~1%), dispersed throughout the

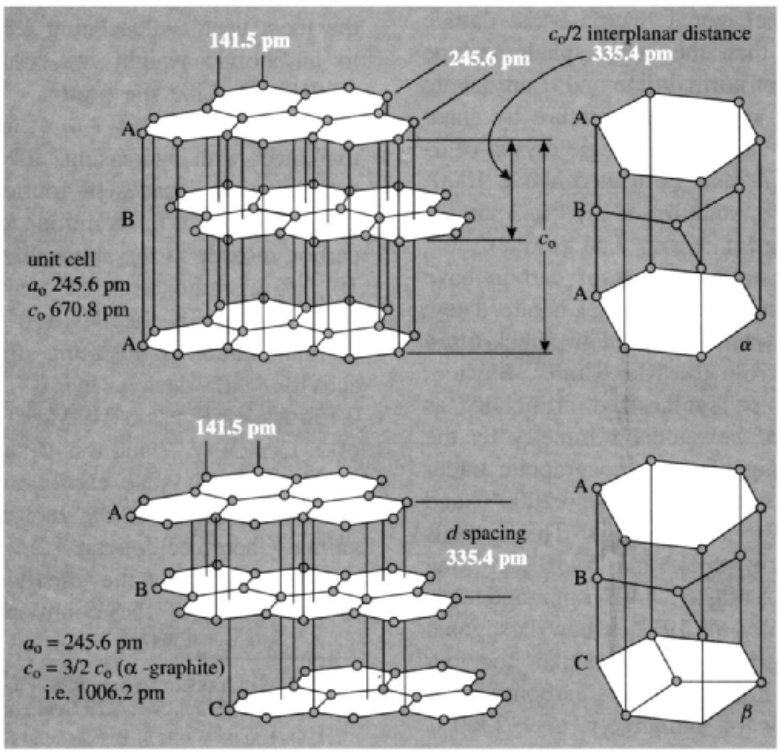

Figure 8.2 Structure of the α (hexagonal) and β (rhombohedral) forms of graphite.

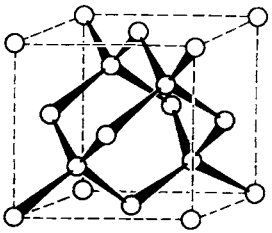

Figure 8.3 Structure of diamond showing the tetrahedral coordination of C; the dashed lines indicate the cubic unit cell containing 8 C atoms.

crystal (type Ib). A small minority of natural diamonds contain no significant amount of N (type IIa) and a very small percentage of these (including the highly valued blue diamonds, type IIb), contain Al. The exceedingly rare hexagonal modification of diamond, Lonsdaleite, was first found in the Canyon Diablo Meteorite, Arizona, in 1967: each C atom is tetrahedrally coordinated but the tetrahedra are stacked so as to give a hexagonal wurtzite-like lattice (p. 1210) rather than the cubic sphalerite-type lattice (p. 1210) of normal diamond. Lonsdaleite can be prepared at room temperature by static pressure along the *c*-axis of a single crystal of α-graphite, though it must be heated above 1000° under pressure to stabilize it (a_o 252 pm, c_o 412 pm, d_{obs} 3.3 g cm^{-3}, d_{calc} 3.51 g cm^{-3}).

Two other crystalline forms of carbon have been discovered in the recent past. Chaoite, a new white allotrope, was first found in shock-fused graphitic gneiss from the Ries Crater, Bavaria, in 1968; it can be synthesized artificially as white dendrites of hexagonal symmetry by the sublimation etching of pyrolytic graphite under free vaporization conditions above ~2000°C and at low pressure (~10^{-4} mmHg). The crystals were only 0.5 μm thick and 5–10 μm long and had a_o 894.5 pm, c_o 1407.1 pm and d_{calc} 3.43 g cm^{-3}. Finally, in 1972, a new hexagonal allotrope, carbon(VI), was obtained together with chaoite when graphitic carbons were heated resistively or radiatively at ~2300°C under any pressure of argon in the range 10^{-4} mmHg to 1 atm; laser heating was even more effective (a_o 533 pm, c_o 1224 pm, $d >$ 2.9 g cm^{-3}). The detailed crystal structures of chaoite and carbon(VI) have not yet been determined but they appear to be based on a carbyne-type motif —C≡C—C≡C;[7] both are much more resistant to oxidation and reduction than graphite is and their properties are closer to those of diamond. Indeed, it now seems possible that there is a sequence of at least 6 stable carbyne allotropes in the region between stable graphite and the mp of carbon.

The structural differences between graphite and diamond are reflected in their differing physical and chemical properties, as outlined in the following sections.

8.2.3 Atomic and physical properties

Carbon occurs predominantly as the isotope ^{12}C but there also is a small amount of ^{13}C; the concentration of ^{13}C varies slightly from 0.99 to 1.15% depending on the source of the element, the most usual value being 1.10% which leads to an atomic weight for "normal" carbon of 12.0107(8). Like the proton, ^{13}C has a nuclear spin quantum number $I = \frac{1}{2}$, and this has been exploited with increasing effectiveness during the past two decades in fourier transform nmr spectroscopy.[8] In addition to ^{12}C and ^{13}C, carbon dioxide in the atmosphere contains 1.2 × 10^{-10}% of radioactive ^{14}C which is continually being formed by the $^{14}_{7}$N(n,p)$^{14}_{6}$C reaction with thermal neutrons resulting from cosmic ray activity. ^{14}C decays by β^- emission (E_{max} 0.156 MeV, E_{mean} 0.049 MeV) with a half-life of 5715 ± 30 y,[9] and this is sufficiently long to enable a steady-state equilibrium concentration to be established in the biosphere. Plants and animals therefore contain 1.2 × 10^{-10}% of their carbon as ^{14}C whilst they are living, and this leads to a β-activity of 15.3 counts per min per gram

[7] A. G. WHITTAKER, *Science* **200**, 763–4 (1978). See also Anon, *Chem. & Eng. News*, 29 Sept., p. 12 (1980).

[9] N.E. HOLDEN, *Pure Appl. Chem.* **62**, 941–58 (1990).

of contained C. However, after death the dynamic interchange with the environment ceases and the ^{14}C concentration decreases exponentially. This is the basis of W. F. Libby's elegant radio-carbon dating technique for which he was awarded the Nobel Prize for Chemistry in 1960. It is particularly valuable for archeological dating.[10] (A modern variant is to count the number of ^{14}C atoms directly in a mass spectrometer.) The practical limit is about 50 000 y since by this time the ^{14}C activity has fallen to about 0.2% of its original valuable and becomes submerged in the background counts. ^{14}C is also extremely valuable as a radioactive tracer for mechanistic studies using labelled compounds, and many such compounds, particularly organic ones, are commercially available (p. 310).

Carbon is the sixth element in the periodic table and its ground-state electronic configuration is $[He]2s^22p^2$. The first 4 ionization energies of C are 1086.5, 2352.6, 4620.5 and 6222.7 kJ mol^{-1}, all much higher than those for the other Group 14 elements Si, Ge, Sn and Pb (p. 372). Excitation energies from the ground-state to various low-lying electron configurations of importance in valence theory are also well established:

Configuration	$2s^22p^2$	$2s^22p^2$	$2s^22p^2$
Term symbol	^3P	^1D	^1S
Energy/kJ mol^{-1}	0.000	121.5	258.2
Configuration	$2s^12p^3$	$2s^12p^3$	
Term symbol	$^5S^\circ$	$^5S_{\text{valence state}}$	
Energy/kJ mol^{-1}	402.3	~632	

Of these, all are experimentally observable except the $^5S_{\text{valence state}}$ level which is a calculated value for a carbon atom with 4 unpaired and uncorrelated electron spins; this is a hypothetical state, not amenable to experimental observation, but is helpful in some discussions of bond energies and covalent bonding theory.

The electronegativity of C is 2.5, which is fairly close to the values for other members of the group (1.8–1.9) and for several other elements: B, As (2.0); H, P (2.1); Se (2.4); S, I (2.5); many of the second- and third-row transition metals also have electronegativities in the range 1.9–2.4.

The "single-bond covalent radius" of C can be taken as half the interatomic distance in diamond, i.e. $r(C) = 77.2$ pm. The corresponding values for "doubly-bonded" and "triply-bonded" carbon atoms are usually taken to be 66.7 and 60.3 pm respectively though variations occur, depending on details of the bonding and the nature of the attached atom (see also p. 292). Despite these smaller perturbations the underlying trend is clear: the covalent radius of the carbon atom becomes smaller the lower the coordination number and the higher the formal bond order.

Some properties of α-graphite and diamond are compared in Table 8.1. As expected from its structure, graphite is less dense than diamond and many of its properties are markedly anisotropic. It shows ready cleavage parallel to the basal plane, and this accounts for its flaky appearance, softness, and use as a lubricant although this latter property is due not so much to weak interplanar forces on an atomic scale as to the presence of adsorbed gases, since the coefficient of friction of graphite increases 5-fold at high altitudes and by a factor of 8 in a vacuum. By contrast, diamond can be cleaved in many directions, thus enabling many facets to be cut in gem-stones, but it is extremely hard and involatile because of the strong C–C bonding throughout the crystal. Interestingly, diamond has the highest thermal conductivity of any known substance (more than 5 times that of Cu) and for this reason the points of diamond cutting tools do not become overheated. Diamond also has one of the lowest known coefficients of thermal expansion: 1.06×10^{-6} at room temperature.

The optical and electrical properties of the two forms of carbon likewise reflect their differing structures. Graphite is a black, highly reflecting semi-metal with a resistivity $\rho \sim 10^{-4}$ ohm cm within the basal plane though this increases by a factor of ~5000 along the c-axis. Diamond, on the other hand, is transparent and has a high refractive index; there is a band energy gap of

[10] J. M. MICHELS, *Dating Methods in Archeology*, Seminar Press, New York, 1973, 230 pp., S. FLEMING, *Dating in Archeology: A Guide to Scientific Techniques*, Dent, London, 1976, 272 pp.

Table 8.1 Some properties of α-graphite and diamond

Property	α-Graphite	Diamond
Density/g cm^{-3}	2.266 (ideal) varies from 2.23 (petroleum coke) to 1.48 (activated C)	3.514
Hardness/Mohs	<1	10
MP/K	4100 ± 100 (at 9 kbar)	4100 ± 200 (at 125 kbar)
ΔH_{subl}/kJ mol^{-1}	715[a]	~710[a]
Refractive index, n (at 546 nm)	2.15 (basal) 1.81 (c-axis)	2.41
Band gap E_g/kJ mol^{-1}	—	~580
ρ/ohm cm	(0.4–5.0) × 10^{-4} (basal) 0.2–1.0 (c-axis)	10^{14}–10^{16}
$\Delta H_{combustion}$/kJ mol^{-1}	393.51	395.41
ΔH_f°/kJ mol^{-1}	0.00 (standard state)	1.90

[a]Sublimation to monatomic C(g).

~580 kJ mol^{-1} so that diamond has a negligible electrical conductivity, the specific resistivity being of the order 10^{14}–10^{16} ohm cm. (For other properties and industrial applications of diamond, see ref. 11.)

As may be seen from the heats of combustion, α-graphite is more stable than diamond at room temperature, the heat of transformation being about 1.9 kJ mol^{-1}. However, as the molar volume of diamond (3.418 cm^3) is much smaller than that of graphite (5.301 cm^3), it follows that diamond can be made from graphite by application of a suitably high pressure, provided that the temperature is also sufficiently high to permit movement of the atoms. Such transformations were first successfully achieved in 1953–5, using pressures up to 100 kbar and temperatures in the range 1200–2800 K;[2a] the presence of molten-metal catalysts such as Cr, Fe, or Ni was also found to be necessary, suggesting that the transformation may proceed via the formation of unstable metal carbide intermediates. Very recently red phosphorus has also been shown to catalyse the conversion of graphite to diamond at 77 kbar and 1800°C.[12] The use of kinetically controlled non-equilibrium processes to deposit thin films of crystalline diamond has already been mentioned (p. 272). The relationship between the conditions for these various processes is summarized in Fig. 8.4 which shows the phase diagram of carbon near its triple point.[13] This schematic representation does not explicitly include the several carbyne-like carbon phases[7] which have been identified at very low pressures (10^{-4}–10^{-8} kbar) in the region marked X.

8.2.4 Fullerenes

One of the most exciting and challenging developments in recent chemistry has been the synthesis and characterization of many new, soluble, *molecular* modifications of carbon. As a result, the number of identified allotropes of this element has increased enormously and their intriguing chemistry is gradually being elucidated. The new allotopes form an extensive series of polyhedral cluster molecules, C_n (n even), comprising fused pentagonal and hexagonal rings of C atoms. The first member to be characterized was C_{60} which features 12 pentagons separated by 20 fused hexagons as shown in Fig. 8.5. It has full icosahedral symmetry (p. 141) and was given the name buckminsterfullerene in honour of the architect R. Buckminster Fuller whose buildings popularized the geodesic dome, which uses the same tectonic principle. Other fullerenes which have been isolated and characterized include C_{70}, C_{76} (chiral), C_{78} (3 isomers), C_{84} (3 isomers), C_{90} and C_{94}, but there is mass spectrometric evidence for all even C_n from C_{30} to $C_{>600}$, (m.wt. 7206.6).

The fullerene story began in September 1985 when a group lead by H. W. Kroto (Sussex, UK) and R. E. Smalley (Rice, Texas) laser-blasted graphite at $T > 10^4$ °C and showed mass spectrometrically that the product contained a series of molecules with even numbers of atoms from C_{44} to C_{90}.[14] Concentrations of the individual molecules varied with conditions but the peak for C_{60} was always by far the strongest, followed by C_{70}. This experiment showed the existence of new molecular forms of carbon but was not a bulk preparation. However, in a brilliant flash of insight it was conjectured that the stability of C_{60} might result from the football-like "spherical" structure of a truncated icosahedron, the most symmetrical of all possible structures in 3-dimensional space (Nobel Prize, 1996, see p. 270).

Three years later two astrophysicists, W. Krätschmer (Heidelberg, Germany) and D. R. Huffman (Tucson, Arizona), remembered an unusual and unexpected UV spectrum they had obtained in 1983 from soot obtained by striking an arc between graphite electrodes at about 3500°C under a low pressure of helium gas. They re-examined the material mass-spectrometrically and found it contained high concentrations of C_{60} and C_{70} which were soluble in aromatic hydrocarbon solvents such as benzene and toluene.[15] Here was a stunningly simple preparation of fullerenes in bulk, although separation of individual members proved to

be more difficult. Pure C_{60} and C_{70} were obtained for the first time on 22 August 1990 by chromatographic separation (alumina, hexane).[16] The process can easily be scaled up using multi-rod apparatus to give about 20 g/day of soot containing up to 10% of fullerenes; this can be extracted with toluene to yield about 15 g/week of mixed fullerenes which can be further separated if required. Commercial availability has also assisted progress, typical prices (1994) being £150/g for C_{60} (99.9%) and £2000/g for C_{70} (98%).

Other routes to C_{60} and C_{70} are being developed, e.g. (*i*) heating naphthalene vapour ($C_{10}H_8$) in argon at about 1000°C followed by extraction with CS_2; (*ii*) burning soot in a benzene/oxygen flame at about 1500°C with argon as a diluent. C_{60} and C_{70} have also been detected in several naturally occurring minerals, e.g. in carbon-rich semi-anthracite deposits from the Yarrabee mine in Queensland, Australia;[17a] in shungite, a highly metamorphosed meta-anthracite from Shunga, Karelia, Russia;[17b] and in a Colorado, USA fulgurite (a glassy mineral which can be formed when lightning strikes the ground).[17c] Most recently, significant finds of naturally occurring fullerenes have been made in Sudbury (Canada) and New Zealand.[17d]

The purified fullerenes have very attractive colours. Thin films of C_{60} are mustard-coloured (dark brown in bulk) and solutions in aromatic hydrocarbons are a beautiful magenta. Thin films of C_{70} are reddish brown (greyish black in bulk) and solutions are port-wine red. C_{76}, C_{78} and C_{84} are yellow.[16]

Structure of the fullerenes

The structural motif of the fullerenes is a sequence of polyhedral clusters, C_n, each with 12 pentagonal faces and $(\frac{1}{2}n - 10)$ hexagonal faces. C_{60} itself has 20 hexagonal faces and, significantly, is the first member for which all 12 pentagonal faces are non-adjacent. Smaller homologues have increasing numbers of contiguous pentagonal faces; e.g. C_{32} is expected to have only 6 hexagonal faces. As can be seen from Fig. 8.5, all C atoms in C_{60} are structurally identical and, consistent with this, only one signal is observed in the ^{13}C nmr spectrum (at 142.68 ppm). However, there are two geometrically distinct types of C–C bond: those at an edge shared between two fused hexagons, and those at an edge between a hexagon and a pentagon.

By contrast, C_{70} has 25 hexagonal faces and D_{5h} symmetry (Fig. 8.6a) with 5 types of C atom (a, b, c, d, e) and 8 types of C–C bond. Five ^{13}C nmr signals are therefore expected, with intensities in the ratio 10:10:20:20:10, and these are observed in the range 150.77–130.28 ppm.[16] Again, a ^{13}C nmr study of chromatographically isolated of C_{76} showed it to have 28 hexagonal faces and a fascinating chiral structure of D_2 symmetry, consisting of a spiralling double helical arrangement of edge-sharing pentagons and hexagons (Fig. 8.6b and c) uniquely consistent with the observed 19 ^{13}C nmr signals in the range 150.03–129.56 ppm, and each of equal intensity ($19 \times 4 = 76$).[18]

The total potential number of geometric isomers increases enormously with increase in cluster size, being, for example, three for C_{30}, 40 for C_{40}, 271 for C_{50} and no fewer than 1812 for C_{60}.[19] However, the number becomes much more manageable if one considers only those isomers that have no contiguous pentagons. The theoretical justifications for this

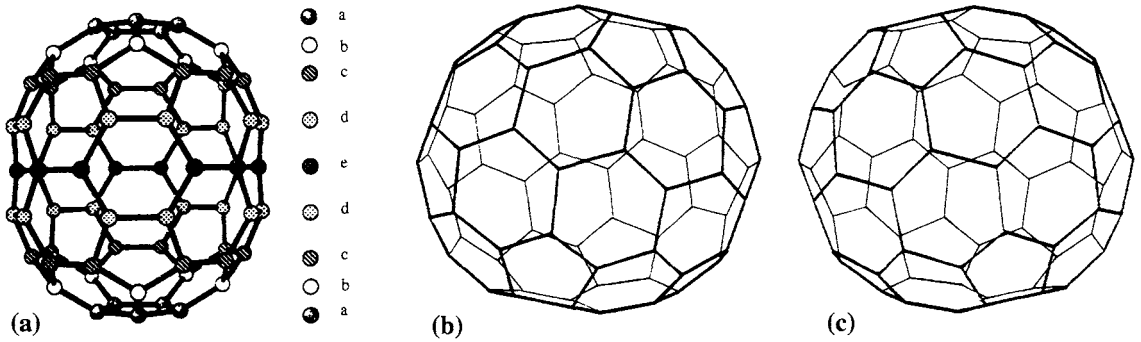

Figure 8.6 (a) The D_{5h} structure of C_{70} with the 5-fold rotation axis vertical; the five sets of geometrically distinct C atoms are labelled a-e (see text). (b), (c) Line drawings of the two enantiomers of C_{76} viewed along the short C_2 rotation axis and illustrating the chiral D_2 symmetry of the molecule.

restriction would be (a) that isomers with fused pentagons are expected to have greater σ-bonding strain energy and (b) that, since two fused pentagons have an 8-cycle around their periphery, there would be a further Hückel antiaromatic destabilizing effect on the overall π electron system. In fact, in the range C_{20}–C_{70} this restriction of isolated pentagons eliminates all structures except the observed $C_{60}(I_h)$ and $C_{70}(D_{5h})$. From mass-spectrometric evidence other oligomers clearly exist, though not yet in isolable concentrations. Above C_{70} the number of distinct geometric isomers (i) with isolated pentagons increases rather rapidly with n as indicated below:[19]

n	72	74	76	78	80	82	84	86
i	1	1	2	5	7	9	24	19
n	88	90	92	94	96	98	100	
i	35	46	86	134	187	259	450	

Numerous other fullerenes have been isolated by the same techniques and their structures elucidated by ^{13}C nmr spectroscopy, e.g. C_{76} (see above); C_{78} [3 isomers: C_{2v}\{18(4C) + 3(2C) nmr lines\}, D_3\{13(6C)\} and C_{2v}\{17(4C) + 5(2C)\}]; C_{82} [3 isomers: C_2\{41(2C)\}, C_{2v}\{17(4C) + 7(2C)\} and C_{3v}\{12(6C) + 3(3C) + 1(1C)\}]; and C_{84} [2 isomers: D_2\{21(4C)\} and D_{2d}\{10(8C) + 1(4C)\}].[20] A copiously illustrated atlas of fullerenes elaborating and enumerating the numbers and structures of all possible fullerenes and fullerene isomers C_n as a function of n up to high n has recently been published.[20a]

Except for C_{60},† lack of sufficient quantities of pure material has prevented more detailed structural characterization of the fullerenes by X-ray diffraction analysis, and even for C_{60} problems of orientational disorder of the quasi-spherical molecules in the lattice have exacerbated the situation. At room temperature C_{60} crystallizes in a face-centred cubic lattice ($Fm\bar{3}$) but below 249 K the molecules become orientationally ordered and a simple cubic lattice ($Pa\bar{3}$) results. A neutron diffraction analysis of the ordered phase at 5 K led to the structure shown in Fig. 8.7a;[21] this reveals that the ordering results from the fact that

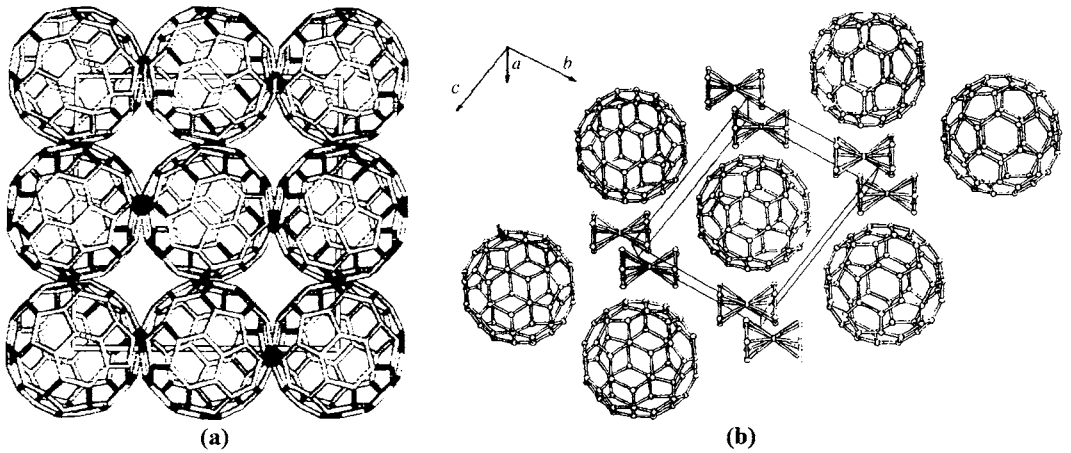

Figure 8.7 (a) The low-temperature, ordered, simple cubic arrangement of C_{60} molecules as revealed by neutron diffraction at 5 K; above 249 K the molecules become orientationally disordered and the lattice becomes fcc. (b) The packing arrangement for $[C_{60}(\text{ferrocene})_2]$ in the *bc* plane.

the electron-rich short bonds *between* pentagons (139.1 ± 1.8 pm)are positioned directly above the electron-poor pentagon face-centres of adjacent C_{60} units. The bonds *within* a given pentagon are somewhat longer (145.5 ± 1.2 pm).

The structures of the black crystalline benzene solvate $C_{60}.4C_6H_6$,[22] the black charge-transfer complex with bis(ethylenedithio)tetrathiafulvene, $[C_{60}(\text{BEDT-TTF})_2]$,[23] and the black ferrocene adduct $[C_{60}\{Fe(Cp)_2\}_2]$ (Fig. 8.7b)[24] have also been solved and all feature the packing of C_{60} clusters.

Other molecular allotropes of carbon

Quite apart from the fullerene cluster molecules, numerous other molecular allotropes of carbon, C_n, have been discovered in the gases formed by the laser vaporization/supersonic expansion of graphite. The products are detected by mass spectrometry after separation into identifiable series by gas-ion chromatography.[25] The technique suggests that linear oligomers exist from $n = 3$–10 and an overlapping series of monocyclic planar ring isomers from $n = 7$–36. Planar bicyclic rings appear for $n = 21$–44 and yet other series of condensed rings occur in the ranges $n = 37$–54 and 55–61. Three-dimensional fused ring clusters form a series with $n = 28$–35, and the fullerenes from C_{30}–C_{70} were seen as a quite distinct series. For each value of n from 29–41 there are at least three isomers: e.g. C_{32}^+ comprises 23% monocyclic ring, 71% bicyclic ring, 2.4% open 3D cluster and 3.2% fullerene. The structural assignments are tentative.

Chemistry of the fullerenes

The tremendous burst of excitement which attended the initial isolation in 1990 of weighable amounts of separated fullerenes has been followed by an unparalleled and sustained surge of activity as chemists throughout the world rushed to investigate the chemical reactivity of these novel molecular forms of carbon.

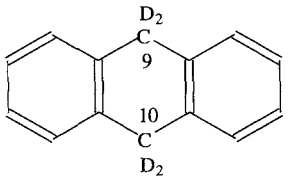
[24] J. D. CRANE, P. B. HITCHCOCK, H. W. KROTO, R. TAYLOR and D. R. M. WALTON, *J. Chem. Soc., Chem. Commun.*, 1764–5 (1992).

[25] G. VON HELDEN, M.-T. HSU, P. R. KEMPER and M. T. BOWERS, *J. Chem. Phys.* **95**, 3835–7 (1991).

Considerable attention has been paid to possible mechanisms of formation[26,27] since a firm understanding of this aspect could lead to the development of more effective synthetic routes to the individual fullerenes. It is also known that, when thin films of C_{60} and C_{70} are laser-vaporized into a rapid stream of an inert gas, individual molecules of C_{60} or C_{70} can themselves coalesce to form stable larger fullerenes such as C_{120} or C_{140}, and higher multiples. Even more dramatically, when a sample of C_{60} is subjected to a pressure of 20 GPa (i.e. 200 kbar), it apparently immediately transforms into polycrystalline diamond.

Most solvents will only dissolve a few mg/l of the fullerenes. Solubility in benzene, toluene or CS_2 is somewhat higher but even so the acquisition of ^{13}C nmr data is still a lengthy and tedious business. By far the best solvents to date for C_{60} at 25°C are *o*-dichlorobenzene (25 mg cm^{-3}), 1-methylnaphthalene (33 mg cm^{-3}) and 1-Br-2-Me-naphthalene (35 mg cm^{-3}).[28] Colours in a range of some 30 solvents are variously pink, magenta, magenta-brown, brown-yellow, brown-green and brown, no doubt reflecting the varying interaction of the solute with the solvent (cf. I_2, p. 807).

Hydrogenation — One of the first chemical reactions of C_{60} to be studied was its Birch reduction. In a typical procedure, Li metal was added under an argon atmosphere to a suspension of C_{60} in liquid NH_3/thf, followed after 30 min by addition of Bu^tOH. Initially the off-white product was thought to be $C_{60}H_{36}$ but subsequent work using a variety of techniques[29] has shown that the product at low temperatures is a mixture of polyhydrofullerenes ranging from $C_{60}H_{18}$ to $C_{60}H_{36}$ with $C_{60}H_{32}$ being the predominant species. This mixture is thermally labile and in the mass spectrometer probe (>250°C) $C_{60}H_{36}$ predominates, consistent with a molecule in which the 12 isolated pentagons of the C_{60} cluster each retain one double bond, i.e. $[(C_2)_{12}(CH)_{36}]$. A cleaner route to pure, white $C_{60}H_{36}$ is by using a 120-fold molar excess of 9,10-dihydroanthracene (1) as a H-transfer reagent at 350°C for 30 min. Prolonging the reaction time to 24 h produces $C_{60}H_{18}$ as a second product and the method has the added advantage that it permits the ready synthesis of $C_{60}D_{36}$, by use of 9,9′,10,10′[D_4]dihydroanthracene.[30]



(1)

Oxidation reactions — Direct fluorination of solid C_{60} with F_2 gas at 70° proceeds slowly in a stepwise manner *via* several coloured partially fluorinated materials to give, after a period of several days, the colourless fully fluorinated product $C_{60}F_{60}$.[31] Rapid fluorination under more forcing conditions (F_2 gas/UV irradiation/250°) yields $C_{60}F_{48}$ as the main product, plus an intractable mixture of other fluorides $C_{60}F_{2n}$ including some hyperfluorinated materials ($2n > 60$) which would require the opening of some skeletal C–C bonds.[32] $C_{60}F_{48}$ itself has over 20 million possible isomers but, astonishingly, the high-yield synthesis of just one of these has recently been achieved by heating a mixture of C_{60} and NaF under F_2 at 275° for several days.[33] Actually a racemic mixture of the two

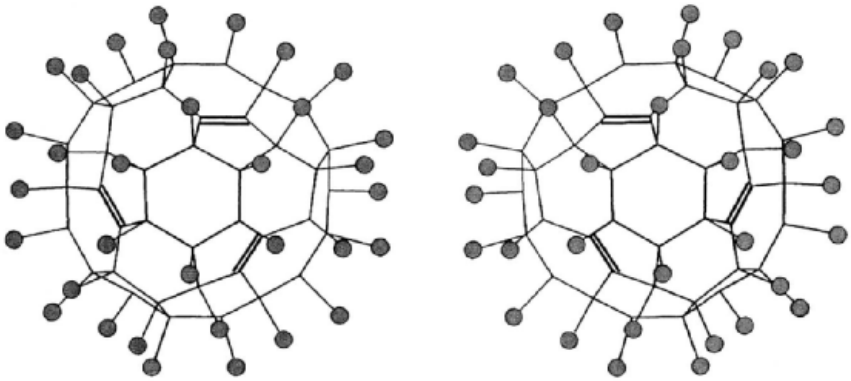

Figure 8.8 The enantiomeric pair of isomers of $C_{60}F_{48}$.[33]

chiral enantiomers shown in Fig. 8.8 is obtained. Shorter reaction times give complex mixtures of $C_{60}F_{46}$ and $C_{60}F_{48}$ isomers.

Direct chlorination of C_{60} with Cl_2 gas at 250–400°C led to an intractable pale orange mixture of polychlorinated species having on average about 24 Cl atoms per cluster molecule, but milder conditions using Cl_2 at various temperatures in a range of chloro organic solvents produced no detectable reaction.[34] By contrast, treatment of C_{60} with an excess of ICl in benzene or toluene at room temperature gave a quantitative yield of deep orange $C_{60}Cl_6$[35] which is isostructural with $C_{60}Br_6$ (see below).

Bromination of C_{60} in solution gives $C_{60}Br_6$ (magenta plates) and $C_{60}Br_8$ (dark brown prisms). The former has a structure involving one monobrominated pentagon with a long C–Br bond (203 pm) itself adjacent to five other monobrominated pentagons (C–Br 196 pm) as shown in Fig. 8.9a. It disproportionates on being warmed to give C_{60} and $C_{60}Br_8$ which has a C_{2v} structure with pairs of Br atoms arranged *meta* on four 6-membered rings (Fig. 8.9b).[36] Bromination with liquid Br_2 yields the somewhat more stable $C_{60}Br_{24}$ which has T_h symmetry (Fig. 8.9c) with 12 hexagons disubstituted *para* and in pairs with boat conformation but mutually *meta* on the other 8 hexagons which have the chair conformation. The structure has 18 C=C arranged one per pentagon (12) and one at each 6:6 bond (6).[37] All three bromides can be completely dehalogenated on strong heating, as can the polychlorides. Iodine appears not to add directly to C_{60} but forms an intercalation product.

Fullerene epoxide, $C_{60}O$, is formed by the UV irradiation of an oxygenated benzene solution of C_{60}.[38] The O atom bridges a 6:6 bond of the closed fullerene structure. The same compound is also formed as one of the products of the reaction of C_{60} with dimethyldioxirane, $Me_2\overline{COO}$ (see later).[39]

Fullerols, $C_{60}(OH)_n$ ($n = 24–26$), can be synthesized directly by aerobic oxidation of a benzene solution of C_{60} using an aqueous solution of NaOH containing a few drops of Bu_4NOH as the most efficient catalyst: the deep violet benzene solution rapidly decolorizes and a brown sludge precipitates; further reaction with more water over a period of 10 h gives a clear red-brown solution from which the

brown solid product is obtained by vacuum evaporation.[40] Hydroboration of C_{60} followed by treatment either with glacial acetic acid or aqueous $NaOH/H_2O_2$ affords another route to water-soluble fullerols, suggesting that C–H bonds on the fullerene cluster are readily oxidized to C–OH groups.[41]

Reduction of fullerenes to fullerides — Reversible electrochemical reduction of C_{60} in anhydrous dimethylformamide/toluene mixtures at low temperatures leads to the air-sensitive coloured anions C_{60}^{n-}, $(n = 1-6)$. The successive mid-point reduction potentials, $E_{1/2}$, at −60°C are −0.82, −1.26, −1.82, −2.33, −2.89 and −3.34 V, respectively.[42] Liquid NH_3 solutions can also be used.[43] C_{60} is thus a very strong oxidizing agent, its first reduction potential being at least 1 V more positive than those of polycyclic aromatic hydrocarbons. C_{70} can also be reversibly reduced and various ions up to C_{70}^{6-} have been detected.

Chemical reduction by alkali metals leads to solid fullerides which are sometimes solvated. Thus, fullerides M_nC_{60} are known for $n = 1$ when M = Rb, Cs and for $n = 2, 3, 4$ and 6 when M = Na, K, Rb and Cs. An important alternative route treats C_{60} in toluene with a solution of $Na[Mn(\eta^5\text{-}C_5Me_5)_2]$ in thf to give an 80% yield of the dark-purple, air- and moisture-sensitive crystalline solvate $NaC_{60}.5thf$.[44]

Interest in the unsolvated compounds M_nC_{60} increased dramatically when several were found to be good electrical conductors. C_{60} films when doped with alkali metal vapour become organic metals, some of which show superconductivity at low temperatures. For example, K_3C_{60}, prepared from stoichiometric amounts of solid C_{60} and potassium vapour, has T_c 19.3 K: it has an fcc structure derived from that of C_{60} itself by incorporating K ions into all the octahedral and tetrahedral interstices of the host lattice as shown in Fig. 8.10.[45] Rb_3C_{60} has an even higher superconducting critical temperature, $T_c \sim 28$ K. It seems that, when electrons are added to C_{60} from an alkali metal, they enter a conduction band composed of the triply degenerate t_{1u} π orbitals of the individual C_{60} molecules. Maximum conductivity is observed when this band is half-filled (at C_{60}^{3-}) after which the conductivity gradually decreases until the composition M_6C_{60} when it is full, consistent

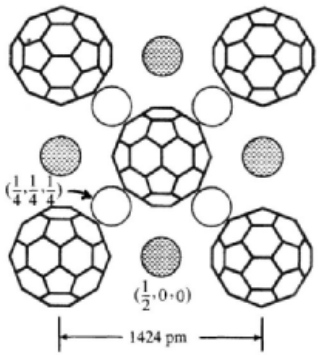

Figure 8.10 The fcc structure of K_3C_{60}, showing potassium ions occupying the tetrahedral (○) and octahedral (◍) sites. The shortest K–K distance is 617 pm (much larger than in metallic K) and the diameter of C_{60}^{3-} is 708 pm.

with the observation that K_6C_{60} (bcc lattice) is an insulator.[46]

Addition reactions — The fullerenes C_{60} and C_{70} react as electron-poor olefins with fairly localized double bonds. Addition occurs preferentially at a double bond common to two annelated 6-membered rings (a 6:6 bond) and a second addition, when it occurs is generally in the opposite hemisphere. The first characterizable mono adduct was $[C_{60}OsO_4(NC_5H_4Bu^t)_2]$, formed by reacting C_{60} with an excess of OsO_4 in 4-butylpyridine. The structure is shown in Fig. 8.11 and was, in fact, the first definitive X-ray structural determination of a fullerene derivative.[47]

Other addition reactions are shown in the scheme.[48] Thus, C_{60} reacts as an olefin towards $[Pt^0(PPh_3)_2]$ to give the η^2 adduct $[Pt(\eta^2\text{-}C_{60})(PPh_3)_2]$. Indeed six M^0 centres can simultaneously be coordinated by a single fullerene cluster to give $[C_{60}\{M(PEt_3)_2\}_6]$, (M = Ni, Pd, Pt), with the 6M arranged octahedrally about the $(\eta^2)_6\text{-}C_{60}$ core.[49] Likewise, reaction of C_{60} with $[Ir(CO)Cl(PMe_2Ph)_2]$ provides two conformational isomers of $[(\eta^2,\eta^2\text{-}C_{60})\text{-}\{Ir(CO)Cl(PMe_2Ph)_2\}_2]$ in both of which the Ir atoms are ligated by 6:6 double bonds at diametrically opposite sides of the fullerene. Similarly,[50] C_{70} reacts with $[Ir(CO)Cl(PPh_3)_2]$ in benzene solution to give brown crystals of $[Ir(\eta^2\text{-}C_{70})(CO)Cl(PPh_3)_2]$, ligation occurring from a 6:6 double bond near one of the poles (i.e. an a–b bond in Fig. 8.6), and the bis-adduct $[(\eta^2,\eta^2\text{-}C_{70}\{Ir(CO)Cl(PPh_3)_2\}_2]$ involves a–b bonds at opposite poles. Very recently, in addition to η^2 dihapto and

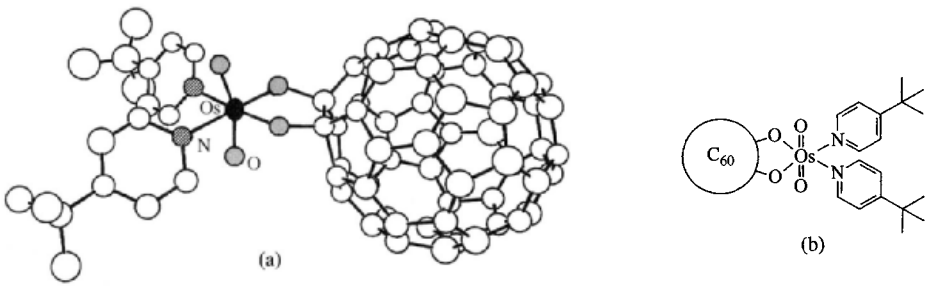

Figure 8.11 (a) Structure of $C_{60}OsO_4(NC_5H_4Bu^t)_2$ as determined by X-ray diffraction analysis.[47] (b) A schematic representation of the structure.

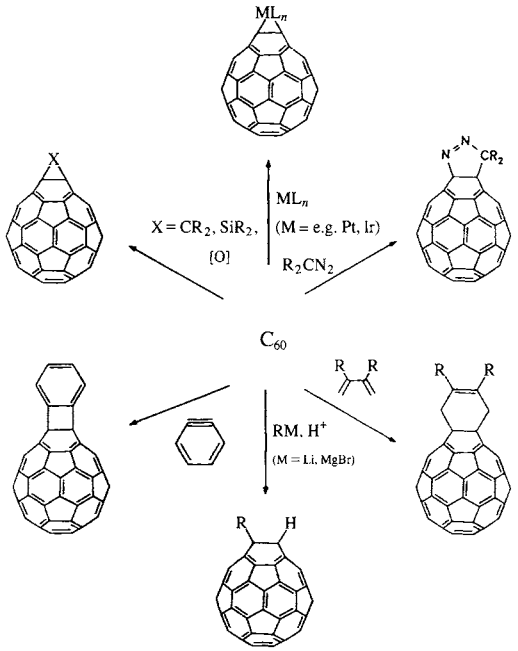

Scheme Syntheses of exohedral fullerene derivatives. For clarity only the front sides of the fullerenes are shown.[48]

η^2,η^2 tetrahapto ligation of C_{60}, an example of η^2,η^2,η^2 hexahapto coordination has been identified in the red crystalline complex $[Ru_3[\mu_3\text{-}\eta^2,\eta^2,\eta^2\text{-}C_{60})(CO)_9]$, formed by heating C_{60} with $Ru_3(CO)_{12}$ in *n*-hexane, the three C=C bonds from one hexagonal face displacing one CO from each Ru atom in the cluster.[50a)(50b)] Extensive cluster opening can also occur, as in the cobalt(I) cyclopentadienyl adduct of the purple C_{60}/butadiene fulleroid, $[Co(\eta^5\text{-}C_5H_5)(\eta^2,\eta^2\text{-}C_{60}C_4H_4)]$, which features an unprecedented fifteen-membered "trimethano[15]annulene" opening within the C_{60} framework.

Returning now to the reactions in the scheme it can be seen that carbenes and silenes yield the derivatives $C_{60}CR_2$ and $C_{60}SiR_2$. The structurally related epoxide $C_{60}O$ has already been mentioned (p. 284). Benzyne yields a [2 + 2] adduct as shown, since the [4 + 2] adduct would require the formation of an energetically unfavourable 5:6 double bond. Nucleophilic reactions with Grignard reagents and Li alkyls yield intermediates which, after protonolysis, afford 1,9-C_{60}RH derivatives, whereas hydroboration (not shown) yields $C_{60}H(BH_2)$ which on protonolysis gives the parent 1,9-dihydrofullerene, $C_{60}H_2$. Diels–Alder reactions give highly regiospecific addition products which can be isolated in high yield. By contrast, diphenyldiazomethane and related diazoalkanes and diazoacetates give substituted dihydropyrazole intermediates (via a [3 + 2] cycloaddition reaction) which then lose N_2 to form the thermally stable final products; these may be *opened* π homoaromatic structures bridged at either a 5:6 or a 6:6 ring junction (Fig. 8.12a,b), or a *closed* σ homoaromatic fullerene bridged at a 6:6 ring junction (Fig. 8.12c). In the special case of diazomethane, $C_{60}(CH_2N_2)$ is formed as a thermally unstable brown solution in toluene; this loses N_2 when heated under reflux and $C_{61}H_2$ can be isolated as a dark powder from the now purple solution.[51] Structure type a (Fig. 8.12) in which the CH_2 group bridges an opened 5:6 junction is assigned on the basis of spectroscopic evidence. The opened azafulleroids C_{60}NR (Fig. 8.12d) can be

obtained from C_{60} and organic azides, RN_3, by [3 + 2] cycloaddition and subsequent loss of N_2.

Heteroatom fullerene-type clusters — The possibility of incorporation of hetero atoms into C_n clusters has excited the attention of both theoreticians and experimentalists since the earliest days of fullerene chemistry, particularly in view of the known stability and ubiquity of organic heterocycles. The structural relationship between C_{60} and β-rhombohedral boron has already been alluded to (p. 142).

Laser vaporization of a composite pressed disc of graphite and BN using He as carrier gas, followed by mass spectrometric analysis, gave a range of clusters with even numbers of atoms from less than 50 to well above 72:[52] the peak with 60 atoms was the most abundant and, in a typical run, was shown to be a mixture of clusters: C_{60} (22%), $C_{59}B$ (21%), $C_{58}B_2$ (24%), $C_{57}B_3$ (18%), $C_{56}B_4$ (9%), $C_{55}B_5$ (4%) and $C_{54}B_6$ (2%). Brief exposure of this mixture of 60-atom clusters to NH_3 at 1 μtorr for 2 s led, typically, to the formation of $C_{60-x}\{B.NH_3\}_x$ ($x = 0$–4).

Preliminary experiments with contact-arc vaporization of graphite in a stream of He containing N_2 or NH_3 yielded nitrogen-containing products tentatively assigned to species such as $C_{70}N_2$ and $C_{59}N_x$ ($x = 2, 4, 6$) of as yet undetermined structure.

The possibility of the isoelectronic replacement of pairs of C atoms by contiguous BN groups (p. 207) in fullerenes is particularly intriguing, e.g. $C_{58}BN$, $C_{60-2x}(BN)_x$. Because each fullerene, C_n, contains 12 pentagonal faces, the limit of such substitution of C_2 by alternating BN would seem to be at $C_{12}B_{24}N_{24}$, since there is a structural frustration at the odd (fifth) C atom of each pentagon.[54]

Encapsulation of metal atoms by fullerene clusters — It is readily apparent that there is sufficient space inside fullerene clusters to accommodate several other atoms: the trick has been in learning how to synthesize such species. When a composite rod of graphite/La_2O_3 was vaporized at 1200°C in argon and the resulting "soot" extracted with pyridine, the products included not only C_{60} and C_{70} but also LaC_{60}, LaC_{70}, LaC_{74} and LaC_{82}.[55] Photo fragmentation by laser irradiation can then strip off C atoms pairwise to "shrink wrap" the metal with ever smaller clusters down to about LaC_{44}. In each of these compounds the La is encapsulated by C_n, i.e. it is an *endo* compound, in contradistinction to the alkali metal fullerides discussed on p. 285. The accepted symbolism for this novel type of compound is [La@C_{60}] etc., and esr shows that the correct electronic formulation is [La^{3+}@C_{60}^{3-}]. The smallest endohedral metallafullerene so far is [U@C_{28}].[56] It is notable that C_{28} would have its 12 pentagons as 4 sets of 3, plus 4 hexagons, all arranged tetrahedrally to give T_d symmetry. MO calculations suggest that neutral C_{28} lacks $4e^-$ to fill completely its bonding MOs and these are supplied by M in [M^{4+}@C_{28}^{4-}], (M = U, Ti, Zr, Hf).

The first dimetalla analogue to be characterized was [La_2@C_{60}], and mixed metal and trimetalla compounds are also known, e.g. [YLa@C_{80}][57] and [Sc_3@C_{82}].[58] Other known compounds include the monometalla species [M@C_{82}] for M = La, Ce, Nd, Sm, Eu, Gd, Tb, Dy, Ho and Er,[59] the dimetalla compounds [Ce_2@C_{80}], [Tb_2@C_{80}], [Sc_2@C_{82}], [Y_2@C_{82}], [La_2@C_{82}] and [Sc_2@C_{84}], and the trimetalla species [La_3@C_{106}] and [La_3@C_{112}]. The products

obtained depend sensitively on the relative concentrations of metal oxide and carbon in the electrode material.[59] Note also that only metals from the left-hand side of the periodic table have so far been encapsulated and there are no substantiated examples with M = Fe, Cu, Ag, Au, etc.

Some recent books and general reviews on the preparation, properties and chemical reactions of the fullerenes and their derivatives are in ref. 60.

The endohedral metallofullarenes just described (and the alkali metal fullerides described on p. 285) are all formally examples of metal carbides, M_xC_y, but they have entirely different structure motifs and properties from the classical metal carbides and the more recently discovered metallacarbohedrenes (metcars) on the one hand (both to be considered in Section 8.4) and the graphite intercalation compounds to be discussed in Section 8.3. Before that, however, we must complete this present section on the various forms of the element carbon by describing and comparing the chemical properties of the two most familiar forms of the element, diamond and graphite.

8.2.5 Chemical properties of carbon

Carbon in the form of diamond is extremely unreactive at room temperature. Graphite, although thermodynamically more stable than diamond under normal conditions, tends to react more readily due to its more vulnerable layer structure. For example, it is oxidized by hot concentrated HNO_3 to mellitic acid, $C_6(CO_2H)_6$, in which planar-hexagonal C_{12} units are preserved. Graphite reacts with a suspension of $KClO_4$ in a 1:2 mixture (by volume) of conc HNO_3/H_2SO_4 to give "graphite oxide" an unstable, pale lemon-coloured product of variable stoichiometry and structure. Similar products can be prepared by anodic oxidation of graphite or by reaction with $NaNO_3/KMnO_4$/conc H_2SO_4. Graphite oxide decomposes slowly at 70°C, and at 200° it undergoes a spectacular deflagration with the formation of CO, CO_2, H_2O and soot. Infrared and X-ray evidence suggest that the structure-motif is a puckered hexagonal network of C_6 rings predominantly in the "chair" conformation but with a few remaining C=C bonds; in addition there are terminal and bridging O atoms and pendant OH groups; keto-enol tautomerism is implied and the empirical formula can be represented as $C_6O_x(OH)_y$ with $x \sim 1.0$–1.7 and $y \sim 2.25$–1.7.

Graphite reacts with an atmosphere of F_2 at temperatures between 400–500°C to give "graphite monofluoride" CF_x ($x \sim 0.68$–0.99). The reaction is catalysed by HF and can then occur at much lower temperatures (leading, on occasion, to the destruction of graphite electrodes during the preparation of F_2 by the electrolysis of KF/HF melts, p. 797). At ~600° the reaction proceeds with explosive violence to give a mixture of CF_4, C_2F_6, and C_5F_{12}. The colour of CF_x depends on the reaction temperature and on the fluorine content, becoming progressively lighter from black ($x \sim 0.7$) to grey ($x \sim 0.8$), silver ($x \sim 0.9$) and transparent white ($x > 0.98$).[61] The structure has not been definitely established but the idealized layer lattice shown in Fig. 8.13a accounts for the observed interplanar spacings, infrared data, colour, and lack of electrical conductivity ($\rho > 3000$ ohm cm). CF is very unreactive, but when heated slowly between

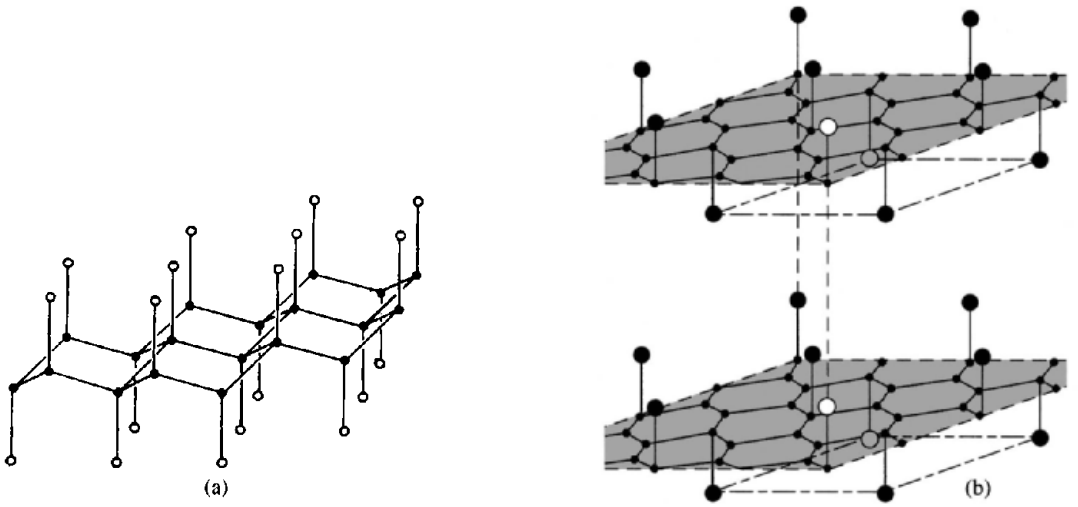

Figure 8.13 (a) Idealized structure of CF showing puckered layer lattice of fused C_6 rings in "chair" conformation and axial F atoms. The spacing between successive C layers is ~817 pm (cf. graphite 335.4 pm) and the density 2.43 g cm^{-3}. (b) Proposed structure for C_4F showing retention of the planar graphite sheets but with regularly spaced F atoms above and below each layer.The spacing between successive C layers is ~534 pm and the density is 2.077 g cm^{-3}.

600–1000° it gradually liberates fluorocarbons, C_nF_{2n+2}.

When gaseous mixtures of F_2/HF are allowed to react with finely powdered graphite at room temperature an inert bluish-black compound with a velvety appearance is formed with a composition which varies in the range C_4F to $C_{3.57}F$. The in-plane C–C distance remains as in graphite but the interlayer spacing increases to 534–550 pm depending on the F content. The infrared and X-ray data are best interpreted in terms of the structure shown in Fig. 8.13b. The electrical conductivity, though less than that of graphite, is still appreciable, the resistivity being ~2–4 ohm cm. Other chemical and electrochemical routes to C_xF ($x < 2$) and $C_{14}F(HF)_y$ have also been explored.[62]

At high temperatures, C reacts with many elements including H (in the presence of a finely divided Ni catalyst), F (but not the other halogens), O, S, Si (p. 334), B (p. 149) and many metals (p. 297). It is an active reducing agent and reacts readily with many oxides to liberate the element or form a carbide. These reactions, which reflect the high enthalpy of formation of CO and CO_2, are of great industrial importance (p. 307).

Carbon is known with all coordination numbers from 0 to 8 though compounds in which it is 3- or 4-coordinate are the most numerous. Some typical examples are summarized in the Panel (p. 291). Particular mention should also be made of hypercoordinate "non-classical" carbonium ions such as 5-coordinate CH_5^+, square pyramidal $C_5H_5^+$ (cf. the isoelectronic cluster B_5H_9, p. 154), pentagonal pyramidal $C_6Me_6^{2+}$ (cf. iso-electronic B_6H_{10}, p. 154) and the bicyclic cation 2-norbornyl, $C_7H_{11}^+$.[63]

Coordination Numbers of Carbon

CN	Examples	Comments
0	C atoms	High-temp, low-press, gas phase
1	CO	Stable gas
	$CH^{\bullet}$ (carbynes)	Reactive free-radical intermediates
2 (linear)	CO_2, CS_2	Stable gas, liquid
	HCN, $HC{\equiv}CH$, NCO^-, NCS^-	The ions are isoelectronic with CO_2 and COS respectively
	$M(CO)_n$	Terminal M–CO groups sometimes <180°
	$RP{=}C{=}PR$ (R = 2,4,6-$Bu^t_3C_6H_2$)	Angle PCP 172.6°[63]
2 (bent)	$Ph_3P{:}C{:}PPh_3$	A bis(ylide) with angle PCP 130.1° (and 143.8°)[64]
	$:CH_2$, $:CX_2$ (carbenes)	Reactive intermediates with 1 lone-pair and 1 vacant orbital; (carbenes are bent for X = H, F, OH, OMe, NH_2, but linear if X is less electronegative, e.g. BH_2, BeH, Li)[65]
	$\bullet CH_2\bullet$, $\bullet CPh_2\bullet$ (methylenes)	Reactive intermediates with 2 unpaired electrons
3 (planar)	COXY (X = H, hal, OH, O^- R, Ar)	Stable oxohalides, carbonates, carboxylic acids, aldehydes, ketones, etc.
	$[C(N{=}PCl_3)_3]^+[SbCl_6]^-$	Colourless crystals prepared from $[C(N_3)_3]^+ + PCl_3$[66]
	$M_m(CO)_n$	Metal carbonyl clusters with bridging CO groups M–C(O)–M
	$[PhC(OMe)M(CO)_5]$	Stable metal — carbene complexes, e.g. M = Cr, W
	CH_3^+ (carbonium ions)	Unstable reaction intermediates with 1 vacant orbital[67]
3 (pyramidal)	CH_3^-, CPh_3^- (carbanions), RMgX	Unstable reaction intermediates with 1 lone pair of electrons
	$Ph_3C^{\bullet}$, $R_3C^{\bullet}$ (free radicals)	Paramagnetic species of varying stability
3 (T-shaped)	$[Ta(=CHCMe_3)_2(2,4,6\text{-}Me_3C_6H_2)(PMe_3)_2]$	The unique H is equatorial and angle $Ta{=}C{-}CMe_3$ is 169°[68]
4 (tetrahedral)	CX_4, etc.	4-coord covalent compds such as CF_4, C_2H_6, CHXYZ, etc.
	$M_n(CO)_n$	Metal carbonyl clusters with triply bridging CO groups (p. 928)
4 (see-saw, C_{2v})	$[Fe_4C(CO)_{13}]$	The μ_4-carbido C caps Fe_4 "butterfly"[69]
5	Al_2Me_6	Alkyl-bridged organometallics involving 3c–2e, bonds (pp. 259, etc.)
	$C_2B_4H_6$, etc.	Several stable carboranes (p. 183)
	$[(\eta^5\text{-}C_5H_5)NiRu_3(CO)_9CCHBu^t]$	The C atom bonds to $CHBu^t$ and to M_4 "butterfly"[70]
	$[Os_5C(CO)_{13}HL_2]$	The μ_5-carbido C bonds to all 5 Os[71]
	$[C\{AuPPh_3\}_5]^+BF_4^-$	trigonal bipyramidal cation[72]
6	$C_2B_{10}H_{12}$, etc.	Several stable carboranes (p. 185)
	$[C(AuPPh_3)_6]^{2+}[BF_3(OMe)]_2^-$	octahedral dication[73]
7	$(LiMe)_4$ crystals	See structure, p. 104
8	Be_2C (antifluorite),	See structure, p. 118
	$[Co_8C(CO)_{18}]^{2-}$	See structure, p. 1142

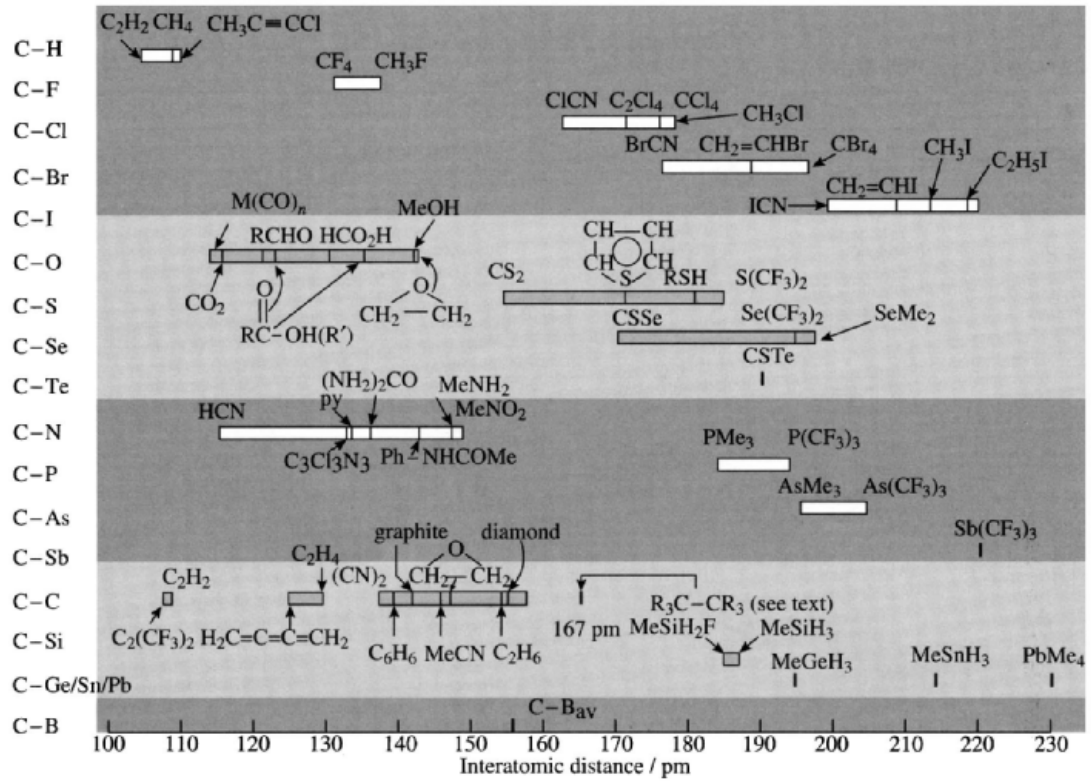

Figure 8.14 Some interatomic distances involving carbon.

Interatomic distances vary with the type of bond and the nature of the other atoms or groups attached to the bonded atoms. For example, the formally single-bonded C–C distance varies from 146 pm in Me–CN to 163.8 pm in $Bu^n_2PhC–CPhBu^n_2$[74] and 167 pm in 3,5-Bu^t_2-$C_6H_3)_2C–C(C_6H_3$-3,5-$Bu^t_2)_3$ and $(CF_3)_2$(4-$FC_6H_4)C–C(C_6H_4$-4-F)$(CF_3)_2$.[75] Some typical examples are in Fig. 8.14. Note that because of the breadth of some of these ranges the interatomic distance between quite different pairs of atoms can be identical. For example, the value 133 pm includes C–F, C–O, C–N and C–C; likewise the value of 185 pm includes C–Br, C–S, C–Se, C–P and C–Si. The conventional classification into single, double and triple bonds is adopted for simplicity, but bonding is frequently more subtle and more extended than these localized descriptions imply. Bond energies are listed on p. 374, where they are compared with those for other elements of Group 14. It should perhaps be emphasized that interatomic distances are experimentally observable, whereas bond orders depend on theoretical models and the estimation of bond energies in polyatomic molecules depends additionally on various assumptions as to how the total energy is apportioned. Nevertheless, taken together, the data indicate that an increase in the order of a bond between 2 atoms is accompanied both by a decrease in bond length and by an increase in bond energy. Similarly, for a given bond order between C and a series of other elements (e.g. C–X), the bond energy increases as the bond length decreases.

8.3 Graphite Intercalation Compounds[76]

The large interlayer distance between the parallel planes of C atoms in graphite implies that the interlayer bonding is relatively weak. This accounts for the ready cleavage along the basal plane and the remarkable softness of the crystals. It also enables a wide range of substances to intercalate between the planes under mild conditions to give lamellar compounds of variable composition. These reactions are often reversible (unlike those with O and F discussed above) and the graphitic nature of the host lattice is retained. The compounds have quite different structures and properties from those previously encountered in this book and so will be described in some detail. They may be compared with the materials formed by intercalation into certain sheet silicates (p. 349).

The first alkali–metal graphite compound was reported in 1926: bronze-coloured C_8K was formed by direct reaction of graphite with K vapour at 300°C. Rubidium and Cs behave similarly. When heated at ~360° under reduced pressure the metal is removed in stages to give a series of intercalation compounds C_8M (bronze-red), $C_{24}M$ (steel-blue), $C_{36}M$ (dark blue), $C_{48}M$ (black) and $C_{60}M$ (black). The compounds can also be prepared by electrolysis of fused melts with graphite electrodes, by reaction of graphite with solutions of M in liquid ammonia or amines, and by exchange reactions using M/aromatic radical anions. Intercalation is more difficult to achieve with Li and Na though direct reaction with highly purified graphite at 500° yields C_6Li (brass coloured), $C_{12}Li$ (copper), and $C_{18}Li$ (steel), and reaction with Li/naphthalene in thf yields $C_{16}Li$ and $C_{40}Li$. Corresponding reaction of graphite and molten Na at 450° gives $C_{64}Na$ (deep violet) whereas Na/naphthalene gives $C_{32}Na$ and $C_{120}Na$.

The crystal structure of C_8K is shown in Fig. 8.15(a); the graphite layers remain intact but are stacked vertically above each other instead of in the sequence ···ABAB··· found in α-graphite itself. Each graphite layer is interleaved by a layer of K atoms having a commensurate lattice in which the spacing between each K is twice the spacing between the centres of the graphite hexagons (Fig. 8.15(b)). The stoichiometries of the other stages can then be achieved by varying the frequency of occurrence of the intercalated M layers in the host lattice. An idealized representation of this model is shown in Fig. 8.16. Difficulties are encountered in devising a plausible mechanistic route to the formation of these compounds since the direct preparation of one stage from an adjacent stage apparently requires both the complete emptying and the complete filling of inserted layers. It may be that the situation is more complex, with distributions of stages rather than a single uniform arrangement for each stoichiometry. Very recently a new metal-rich phase has been prepared by reacting graphite with molten potassium; the composition is very close to C_4K and the structure comprises double planes of K atoms intercalated between each graphite sheet, with a consequent increase in the interplanar spacing to 850 pm.[77]

The electrical resistance of graphite intercalation compounds is even lower than for graphite itself, resistance along the *a*-axis dropping by a factor of ~10 and that along the *c*-axis by ~100; moreover, in contrast to graphite, which is diamagnetic, the compounds have a temperature-independent (Pauli) paramagnetism and also behave as true metals in having a resistivity that increases with increase in temperature. This is illustrated by the comparative data shown in Table 8.2.

These data, and the other properties of C_nM, suggest that bonding occurs by transfer of electrons from the alkali metal atoms to the conduction band of the host graphite. Consistent with

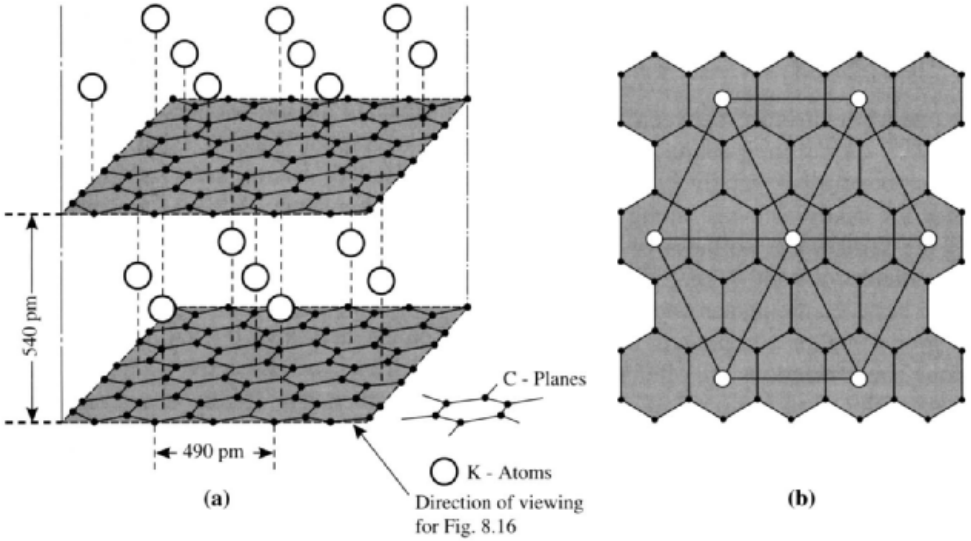

Figure 8.15 (a) Crystal lattice of C_8K showing the vertical packing of graphitic layers. The C–C distance within layers almost identical to that in graphite itself but the interplanar spacing (540 pm) is much larger than for graphite (335 pm) due to the presence of K atoms. The spacing increases still further to 561 pm for C_8Rb and to 595 pm for C_8Cs. (b) Triangular location of K atoms in C_8K showing the relation to the host graphite layers. In the other alkali-metal graphite compounds $C_{12n}M$ the central M atom is missing, leading to a stoichiometry of $C_{12}M$ if every alternate layer is M, $C_{24}M$ if each third layer is M, etc.

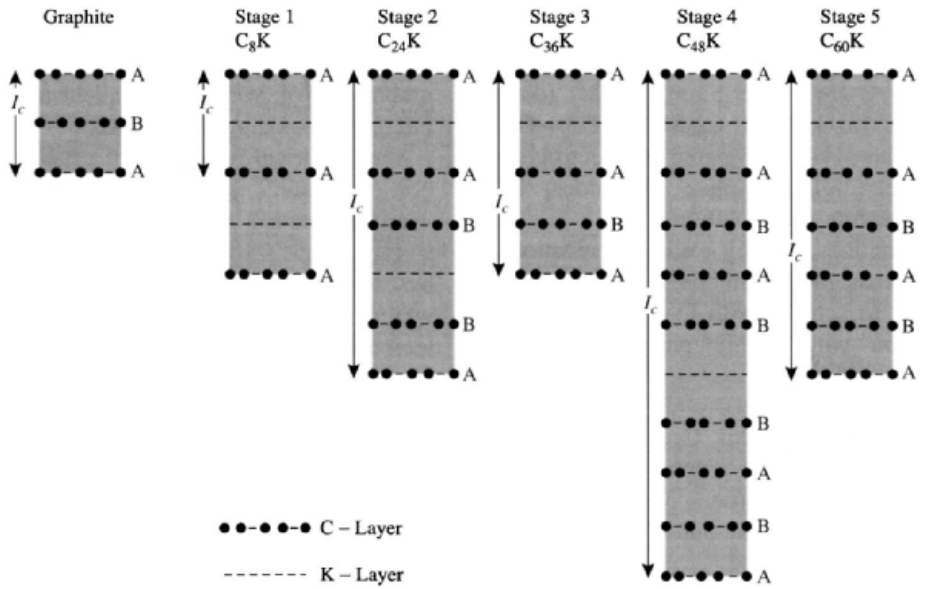

Figure 8.16 Layer-plane sequence along the c-axis for graphite in various stage 1–5 of alkali-metal graphite intercalation compounds. Comparison with Fig. 8.15 shows that the horizontal planes are being viewed diagonally across the figure. I_c is the interlayer repeat distance along the c-axis.

Table 8.2 Resistivity of graphite and its intercalates

Material	ρ (90 K)/ohm cm	ρ (285 K)/ohm cm	ρ_{90}/ρ_{285}
α-graphite	37.7	28.4	1.33
C_8K	0.768	1.02	0.75
$C_{12}K$	0.932	1.15	0.81

this, direct metal intercalation has only been observed with the most electropositive elements (Group 1) though Ba, with a first-stage ionization energy intermediate between those of Li and Na, was recently (1974) found to give C_6Ba.

Alkali-metal graphites are extremely reactive in air and may explode with water. In general, reactivity decreases with ease of ionization of M in the sequence Li > Na > K > Rb > Cs. Under controlled conditions H_2O or ROH produce only H_2, MOH and graphite, unlike the alkali-metal carbides M_2C_2 (p. 297) which produce hydrocarbons such as acetylene. In an important new reaction C_8K has been found to react smoothly with transition metal salts in tetrahydrofuran at room temperature to give the corresponding transition metal lamellar compounds:[78]

$$nC_8K + MX_n \xrightarrow{\text{thf}} C_{8n}M + nKX$$

Examples include reaction of $Ti(OPr^i)_4$, $MnCl_2.4H_2O$, $FeCl_3$, $CoCl_2.6H_2O$, $CuCl_2.2H_2O$, and $ZnCl_2$ to give $C_{32}Ti$, $C_{16}Mn$, $C_{24}Fe$, $C_{16}Co$, $C_{16}Cu$ and $C_{16}Zn$, respectively.

A quite different sort of graphite intercalation compound is formed by the halides of many elements, particularly those halides which themselves have layer structures or weak intermolecular binding. The first such compound (1932) was with $FeCl_3$; chlorides, in general, have been the most studied, but fluoride and bromide intercalates are also known. Halides which have been reported to intercalate include the following:

HF; ClF_3, BrF_3, IF_5; XeF_6, $XeOF_4$; CrO_2F_2, SbF_3Cl_2, TiF_4

MF_5 (M = As, Sb, Nb, Ta); UF_6
MCl_2: M = Be; Mn, Co, Ni, Cu; Zn, Cd, Hg
MCl_3: M = B, Al, Ga, In, Tl; Y; Sm, Eu, Gd, Tb, Dy; Cr, Fe, Co; Ru, Rh, Au; I
MCl_4: M = Zr, Hf; Re, Ir; Pd, Pt
MCl_5: M = Sb; Mo; U
MCl_6: M = W, U; also CrO_2Cl_2, UO_2Cl_2
Mixtures of $AlCl_3$ plus Br_2, I_2, ICl_3, $FeCl_3$, WCl_6
Bromides: $CuBr_2$; $AlBr_3$, $GaBr_3$; $AuBr_3$

The intercalates are usually prepared by heating a mixture of the reactants though sometimes the presence of free Cl_2 is also necessary, particularly for "non-oxidizing" chlorides such as $MnCl_2$, $NiCl_2$, $ZnCl_2$, $AlCl_3$, etc. Many of the compounds appear to show various stages of intercalation, the first stage usually exhibiting a typical blue colour. A common feature of many of the intercalated halides is their ability to act as electron-pair acceptors (Lewis acids). Low heat of sublimation is a further characteristic of most of the intercalating compounds. It may be that an important feature is an ability of the guest molecule to form a layer lattice commensurate with the host graphite. For example, in $C_{6.69}FeCl_3$ the intercalated $FeCl_3$ has a layer structure similar to that in $FeCl_3$ itself with Cl in approximately close-packed arrangement though with some distortion, and with extensive stacking disorder. The "first-stage" compound varies in composition in the range $C_{\sim 6-7}FeCl_3$; in addition a "second-stage" compound corresponding to $C_{\sim 12}FeCl_3$ is known, and also a "third-stage" with composition in the range $C_{\sim 24-30}FeCl_3$. Another well-characterized phase occurs with $MoCl_5$: layers of close-packed Mo_2Cl_{10} molecules alternate with sets of 4 graphite layers along the *c*-axis.

There appears to be a small but definite transfer of electron charge from the graphite to the guest species and this has led to formulations such as $C_{70}^+Cl^-.FeCl_2.5FeCl_3$. Similarly, the intercalate of $AlCl_3$ (which is formed in the presence of free Cl_2) has been formulated as $C_{27}^+Cl^-.3AlCl_3$ or $C_{27}^+AlCl_4^-.2AlCl_3$. This would explain the enhanced conductivity of the graphite–metal

[78] D. Braga, A. Ripamonti, D. Savoia, C. Trombini and A. Umani-Ronchi, *J. Chem. Soc., Dalton Trans.*, 2026–8 (1979).

halide compounds, due to the formation of positive holes near the top of the valence band. However, despite extensive work using a variety of techniques, many structural problems remain unresolved and there is still no consensus on the detailed description of the bonding. Recent work includes studies on intercalation and staging in main-group element fluoride systems, e.g. (using ionic formulations)

$$2C_{12}{}^{+}AsF_6{}^{-} + AsF_3 \rightleftharpoons 3C_8AsF_5{}^{(79)}$$

$$C_{12}{}^{+}GeF_5{}^{-} + \tfrac{1}{2}F_2 \rightleftharpoons C_{12}{}^{2+}GeF_6{}^{2-(80)}$$

$$C_{24}{}^{+}SiF_5{}^{-} + 2PF_5 \longrightarrow SiF_4(g) + [C_{24}{}^{+}PF_6{}^{-}.PF_5]^{(81)}$$

$$20^\circ \uparrow\downarrow \pm PF_5(g)$$

$$24C + PF_5 + \tfrac{1}{2}F_2 \xrightarrow{20^\circ/24\text{–}32\ h} C_{24}{}^{+}PF_6{}^{-}$$

The halogens themselves show a curious alternation of behaviour towards graphite. F_2 gives the compounds CF, C_2F and C_4F (p. 289) whereas liquid Cl_2 reacts slowly to give C_8Cl, and I_2 appears not to intercalate at all. By contrast, Br_2 readily intercalates in several stages to give compounds of formula C_8Br, $C_{12}Br$, $C_{16}Br$ and $C_{20}Br$; the compounds $C_{14}Br$ and $C_{28}Br$ have also been well-characterized crystallographically but may be metastable phases. A notable feature of the Br_2 intercalation reaction is that it is completely prevented by prior coating of the *basal* plane of the sample of graphite with a layer impervious to Br_2. The lamellar character of blue C_8Br has been confirmed by X-ray diffraction and the intercalation of bromine, is accompanied by a marked decrease in the resistivity of the graphite — more than tenfold along the *a*-axis and twofold along the *c*-axis. C_8ICl and $C_{36}ICl$ have also been prepared.

Numerous oxides, sulfides and oxoacids have been found to intercalate into graphite. For example, lamellar compounds with SO_3, N_2O_5 and Cl_2O_7 are known (but not with SO_2, NO or NO_2). CrO_3 and MoO_3 readily intercalate as do several sulfides such as V_2S_3, $Cr_2S_3(+S)$, WS_2, $PdS(+S)$ and Sb_2S_5. Metal nitrates and oxonitrates can also form intercalates, e.g. $Cu(NO_3)_2$, $Zn(NO_3)_2$, $Zr(NO_3)_4$, $CrO_2(NO_3)_2$, $NbO(NO_3)_3$ and $TaO(NO_3)_3$. A recent example is $[C_{28}MoO_2(NO_3)_2.0.3N_2O_5]$[82]

The reversible intercalation of various oxoacids under oxidizing conditions leads to lamellar graphite "salts" some of which have been known for over a century and are now particularly well characterized structurally. For example, the formation of the blue, "first-stage" compound with conc H_2SO_4 can be expressed by the idealized equation

$$24C + 3H_2SO_4 + \tfrac{1}{4}O_2 \longrightarrow C_{24}{}^{+}HSO_4{}^{-}.2H_2SO_4 + \tfrac{1}{2}H_2O$$

The overall stoichiometry is thus close to $C_8H_2SO_4$ and the structure is very similar to that of C_8K (p. 293) except for the detail of vertical alignment of the carbon atoms in the *c* direction which is $\cdots ABAB \cdots$. Several later stages (2, 3, 4, 5, 11) have been established and their properties studied. Intercalation is accompanied by a marked decrease in electrical resistance. A series of graphite nitrates can be prepared similarly, e.g. $C_{24}{}^{+}NO_3{}^{-}.2HNO_3$ (blue), $C_{48}{}^{+}NO_3{}^{-}.3HNO_3$ (black), etc. Other oxoacids which intercalate (particularly under electrolytic conditions) include $HClO_4$, HSO_3F, HSO_3Cl, H_2SeO_4, H_3PO_4, $H_4P_2O_7$, H_3AsO_4, CF_3CO_2H, CCl_3CO_2H, etc. The extent of intercalation depends both on the strength of the acid and its concentration, and the reactions are of considerable technological importance because they can lead to the swelling and eventual destruction of the graphite electrodes used in many electrochemical processes.

8.4 Carbides

Carbon forms binary compounds with most elements: those with metals are considered in this section whilst those with H, the halogens, O, and the chalcogens are discussed in subsequent sections. Alkali metal fullerides and encapsulated (endohedral) metallafullerenes have already been considered (pp. 285, 288 respectively) and metallacarbohedrenes (metcars) will be dealt with later in this section (p. 300). Silicon carbide is discussed on p. 334. General methods of preparation of metal carbides are:[83]

(1) Direct combination of the elements above ~2000°C.
(2) Reaction of the metal oxide with carbon at high temperature.
(3) Reaction of the heated metal with gaseous hydrocarbon.
(4) Reaction of acetylene with electropositive metals in liquid ammonia.

Attempts to classify carbides according to structure or bond type meet the same difficulties as were encountered with hydrides (p. 64) and borides (p. 145) and for the same reasons. The general trends in properties of the three groups of compounds are, however, broadly similar, being most polar (ionic) for the electropositive metals, most covalent (molecular) for the electronegative non-metals and somewhat complex (interstitial) for the elements in the centre of the d block. There are also several elements with poorly characterized, unstable, or non-existent carbides, namely the later transition elements (Groups 11 and 12), the platinum metals, and the post transition-metal elements in Group 13.

Salt-like carbides containing individual C "anions" are sometimes called "methanides" since they yield predominantly CH_4 on hydrolysis. Be_2C and Al_4C_3 are the best-characterized examples, indicating the importance of small compact cations. Be_2C is prepared from BeO and C at 1900–2000°C; it is brick-red, has the antifluorite structure (p. 118), and decomposes to graphite when heated above 2100°. *Ab initio* calculations suggest that the structure is predominantly ionic with charges close to the nominal $Be^{2+}{}_2C^{4-}$.[84] Al_4C_3, prepared by direct union of the elements in an electric furnace, forms pale-yellow crystals, mp 2200°C. It has a complex structure in which $\{AlC_4\}$ tetrahedra of two types are linked to form a layer lattice: this defines two types of C atom, one surrounded by a deformed octahedron of 6 Al at 217 pm and the other surrounded by 4 Al at 190–194 pm and a fifth Al at 221 pm. The closest C···C approach is at the nonbonding distance of 316 pm. Although it is formally possible to describe the structure as ionic, $(Al^{3+})_4(C^{4-})_3$, such a gross separation of charges is unlikely to occur over the observed interatomic distances.

Carbides containing a C_2 unit are well known; they are exemplified by the acetylides (ethynides) of the alkali metals, $M^{I}_2C_2$, alkaline earth metals, $M^{II}C_2$, and the lanthanoids LnC_2 and Ln_2C_3 i.e. $Ln_4(C_2)_3$. The corresponding compounds of Group 11 (Cu, Ag, Au) are explosive and those of Group 12 (Zn, Cd, Hg) are poorly characterized. $M^{I}_2C_2$ are best prepared by the action of C_2H_2 on a solution of alkali metal in liquid NH_3; they are colourless crystalline compounds which react violently with water and oxidize to the carbonate on being heated in air. $M^{II}C_2$ can be prepared by heating the alkaline earth metal with ethyne above 500°C. By far the most important compound in this group is CaC_2 — it is manufactured on a huge scale, 6.4 million tonnes worldwide in 1982 and is used as a major source of ethyne for the chemical industry and for oxyacetylene welding. US production peaked at 1.03 Mt in 1964 but then declined substantially as ethyne became available from petrochemical feedstocks, from the thermal cracking of hydrocarbons and as a byproduct of C_2H_4 manufacture. US production of CaC_2

[83] Reference 2, pp. 841–911: Carbides (p. 841); Cemented carbides (p. 848); Industrial hard carbides (p. 861); Calcium carbide (p. 878); Silicon carbide (p. 891).

[84] P. W. FOWLER and P. TOLE, *J. Chem. Soc., Chem. Commun.*, 1652–4 (1989).

has been below 250 000 tonnes per annum for the past 20 years and was 236 000 tonnes in 1990 (price $515/t). Europe (3.25 Mtpa) and Asia/Australia (2.42 Mtpa) are currently the major producers.

Industrially, CaC_2 is produced by the endothermic reaction of lime and coke:

$$CaO + 3C \xrightarrow{2200\text{–}2250^\circ C} CaC_2 + CO; \quad \Delta H = 465.7\,kJ\,mol^{-1}$$

Subsequent hydrolysis is highly exothermic and must be carefully controlled:

$$CaC_2 + 2H_2O \longrightarrow C_2H_2 + Ca(OH)_2; \quad \Delta H = -120\,kJ\,mol^{-1}$$

Another industrially important reaction of CaC_2 is its ability to fix N_2 from the air by formation of calcium cyanamide:

$$CaC_2 + N_2 \xrightarrow{1000^\circ\text{–}1200^\circ} CaCN_2 + C; \quad \Delta H = -296\,kJ\,mol^{-1}$$

$CaCN_2$ is widely used as a fertilizer because of its ready hydrolysis to cyanamide, H_2NCN (p. 323).

Pure CaC_2 is a colourless solid, mp 2300°C. It can be prepared on the laboratory scale by passing ethyne into a solution of Ca in liquid NH_3, followed by decomposition of the complex so formed, under reduced pressure at ~325°:

$$Ca(liq\ NH_3) + 2C_2H_2 \xrightarrow{-80^\circ} H_2 + CaC_2.C_2H_2 \xrightarrow{325^\circ} CaC_2 + C_2H_2$$

It exists in at least four crystalline forms, the one stable at room temperature being a tetragonally distorted NaCl-type structure (Fig. 8.17) in which the C_2 units are aligned along the *c*-axis. The ethynides of Mg, Sr and Ba have the same structure and also hydrolyse to give ethyne. In addition, BaC_2 absorbs N_2 from the atmosphere to give $Ba(CN)_2$ (cf. CaC_2 above).

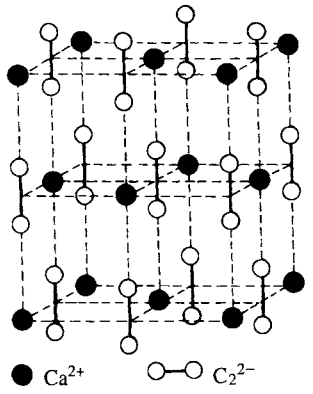

Figure 8.17 Crystal structure of tetragonal CaC_2 showing the resemblance to NaCl (p. 242). Above 450°C the parallel alignment of the C_2 units breaks down and the structure becomes cubic.

Carbides containing the essentially linear C_3^{4-} unit are known, e.g. Li_4C_3, Mg_2C_3, and the recently characterized $Ca_3C_3Cl_2$ and Sc_3C_4.[85] Thus $Ca_3C_3Cl_2$ forms as transparent red crystals when $CaCl_2$ is heated with graphite in sealed Ta capsules at 900°C for 1 day (C–C 134.6 pm, angle 169.0°). By contrast Sc_3C_4 is a grey-black metallic substance with Pauli paramagnetism: it contains C^{4-} and C_2^{2-} ions, and supernumerary electrons e^- in addition to C_3^{4-} (C–C 134.2 pm, angle 175.8°). It can best be represented as $10Sc_3C_4 \equiv [(Sc^{3+})_{30}(C^{4-})_{12}(C_2^{2-})_2(C_3^{4-})_8(e^-)_6]$.[85]

The carbides of the lanthanoids and actinoids can be prepared by heating M_2O_3 with C in an electric furnace or by arc-melting compressed pellets of the elements in an inert atmosphere. They contain the C_2 unit and have a stoichiometry MC_2 or $M_4(C_2)_3$. MC_2 have the CaC_2 structure or a related one of lower symmetry in which the C_2 units lie at right-angles to the *c*-axis of an orthogonal NaCl-type cell.[86] They are more reactive than the alkaline-earth metal

[85] R. HOFFMANN and H.-J. MEYER, *Z. anorg. allg. Chem.* **607**, 57–71 (1992).

[86] A. F. WELLS, *Structural Inorganic Chemistry*, 5th edn., Oxford University Press, Oxford, 1984, 1382 pp.

carbides, combining readily with atmospheric oxygen and hydrolysing to a complex mixture of hydrocarbons. This derives from their more complicated electronic structure and, indeed, LnC_2 are metallic conductors (not insulators like CaC_2); they are best regarded as ethynides of Ln^{III} with the supernumerary electron partly delocalized in a conduction band of the crystal. This would explain the evolution of H_2 as well as C_2H_2 on hydrolysis, and the simultaneous production of the reduced species C_2H_4 and C_2H_6 together with various other hydrocarbons up to C_6H_{10}:

$$LnC_2 + 3H_2O \longrightarrow Ln(OH)_3 + C_2H_2 + [H]$$

An interesting feature of the ethynides MC_2 and $M_4(C_2)_3$ is the variation in the C–C distance as measured by neutron diffraction. Typical values (in pm) are:

CaC_2	YC_2	CeC_2	LaC_2	UC_2
119.2	127.5	128.3	130.3	135.0
$La_4(C_2)_3$	$Ce_4(C_2)_3$	$U_4(C_2)_3$		
123.6	127.6	129.5		

The C–C distance in CaC_2 is close to that in ethyne (120.5 pm) and it has been suggested that the observed increase in the lanthanoid and actinoid carbides results from a partial localization of the supernumerary electron in the antibonding orbital of the ethynide ion $[C{\equiv}C]^{2-}$ (see p. 932). The effect is noticeably less in the sesquicarbides than in the dicarbides. The compounds EuC_2 and YbC_2 differ in their lattice parameters and hydrolysis behaviour from the other LnC_2 and this may be related to the relative stability of Eu^{II} and Yb^{II} (p. 1237).

The lanthanoids also form metal-rich carbides of stoichiometry M_3C in which individual C atoms occupy at random one-third of the octahedral Cl sites in a NaCl-like structure. Several of the actinoids (e.g. Th, U, Pu) form monocarbides, MC, in which all the octahedral Cl sites in the NaCl structure are occupied and this stoichiometry is also observed for several other carbides of the early transition elements, e.g. M = Ti, Zr, Hf; V, Nb, Ta; Mo, W. These are best considered as interstitial carbides and in this sense the lanthanoids and actinoids occupy an intermediate position in the classification of the carbides, as they did with the hydrides (p. 66).

Interstitial carbides are infusible, extremely hard, refractory materials that retain many of the characteristic properties of metals (lustre, metallic conductivity).[87] Reported mps are frequently in the range 3000–4000°C. Interstitial carbides derive their name from the fact that the C atoms occupy octahedral interstices in a close-packed lattice of metal atoms, though the arrangement of metal atoms is not always the same as in the metal itself. The size of the metal atoms must be large enough to generate a site of sufficient size to accommodate C, and the critical radius of M seems to be ~135 pm: thus the transition metals mentioned in the preceding paragraph all have 12-coordinate radii >135 pm, whereas metals with smaller radii (e.g. Cr, Mn, Fe, Co, Ni) do not form MC and their interstitial carbides have a more complex structure (see below). If the close-packed arrangement of M atoms is hexagonal (h) rather than cubic (c) then the 2 octahedral interstices on either side of a close-packed M layer are located directly above one another and only one of these is ever occupied. This gives a stoichiometry M_2C as in V_2C, Nb_2C, Ta_2C and W_2C. Intermediate stoichiometries are encountered when the M atom stacking sequence alternates, e.g. Mo_3C_2 (hcc) and V_4C_3 (hhcc). Ordered defect NaCl-type structures are also known, e.g. V_8C_7 and V_6C_5, thus illustrating the wide range of stoichiometries which occur among interstitial carbides. Unlike the "ionic" carbides, interstitial carbides do not react with water and are generally very inert, though some do react with air when heated above 1000° and most are degraded by conc HNO_3 or HF. The extreme hardness and inertness of WC and TaC have led to their extensive use as high-speed cutting tools.

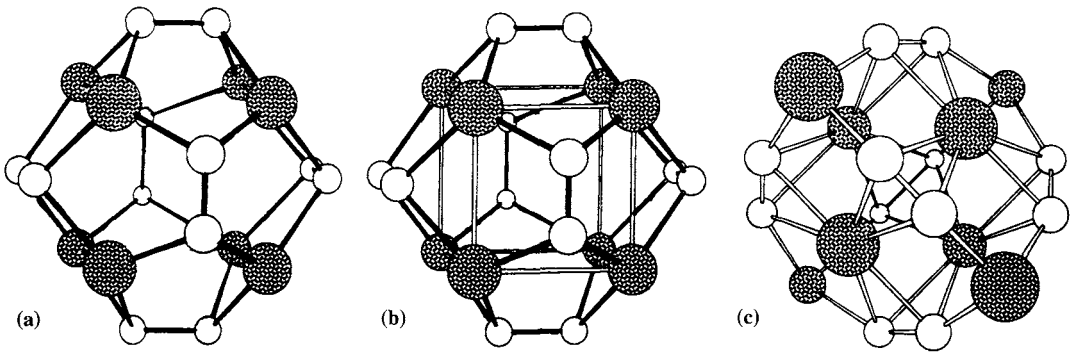

Figure 8.18 (a) Proposed pentagonal dodecahedral structure of Ti_8C_{12}. (b) The same structure viewed as a Ti_8 cube with each face capped by a C_2 group. (c) An alternative T_h structure (see text).

Table 8.3 Stoichiometries of some transition element carbides

V_2C, V_4C_3	$Cr_{23}C_6$	$Mn_{23}C_6$, $Mn_{15}C_4$	Fe_3C, Fe_7C_3	Co_3C	Ni_3C
V_6C_5, V_8C_7	Cr_7C_3	Mn_3C, Mn_5C_2	Fe_2C	Co_2C	
VC	Cr_3C_2	Mn_7C_3			

The carbides of Cr, Mn, Fe, Co and Ni are profuse in number, complicated in structure, and of great importance industrially. Cementite, Fe_3C, is an important constituent of steel (p. 1075). Typical stoichiometries are listed in Table 8.3 though it should be noted that several of the phases can exist over a range of composition.

The structures, particularly of the most metal-rich phases, are frequently related to those of the corresponding metal-rich borides (and silicides, germanides, phosphides, arsenides, sulfides and selenides), in which the non-metal is surrounded by a trigonal prism of M atoms with 0, 1, 2, or 3 additional neighbours beyond the quadrilateral prism faces (p. 148). e.g. Fe_3C (cementite), Mn_3C and Co_3B; Mn_5C_2 and Pd_5B_2; Cr_7C_3 and Re_7B_3. Numerous ternary carbides, carbonitrides, and oxocarbides are also known.

The carbides of Cr, Mn, Fe, Co and Ni are much more reactive than the interstitial carbides of the earlier transition metals. They are rapidly hydrolysed by dilute acid and sometimes even by water to give H_2 and a mixture of hydrocarbons. For example, M_3C give H_2 (75%), CH_4 (15%) and C_2H_6 (8%) together with small amounts of higher hydrocarbons.

Metallocarbohedrenes (met-cars)

An entirely novel group of binary metal carbides, reminiscent of the fullerenes (p. 279), were discovered by accident in 1992.[88] When Ti metal is vaporized in a laser plasma reactor in the presence of He gas containing a hydrocarbon such as methane, ethene, ethyne or benzene, the mass spectrum of the emerging beam contains a single dominant peak at 528 corresponding to Ti_8C_{12} [isotope ^{48}Ti 73.8% abundant: $(8 \times 48) + (12 \times 12) = 528$]. Detailed isotope distribution studies confirmed the molecular formula. The proposed structure, shown in Fig. 8.18a, is a pentagonal dodecahedron of T_h symmetry comprising 12 mutually fused Ti_2C_3 pentagons.

Each Ti bonds to 3C via σ bonds and each C bonds to 2Ti and one C. The all-carbon analogue, C_{20}, is not expected to be stable because of severe internal strain; (it would be the smallest possible fullerene, p. 280). Note, however, that dodecahedrane, $C_{20}H_{20}$, is known.[89] An alternative description of the structure (Fig. 8.18b) would be as a weakly bonded cube, Ti_8, each face of which is capped by a C_2 unit. The calculated distances[90] are Ti···Ti 302 pm, Ti–C 199 pm and C–C 140 pm (implying some multiple bonding: cf. 140 pm in benzene). An alternative T_h structure for Ti_8C_{12}, which is calculated to have a lower energy, has also been proposed.[90] In this, the Ti_8 array is a tetracapped tetrahedron containing six Ti_4 faces in butterfly conformation; each of these Ti_4 faces can then accommodate a C_2 unit as shown in Fig. 8.18c.

Other met-cars that have been detected mass spectrometrically are M_8C_{12} (M = V, Zr, Hf) and there is some evidence for higher members such as $Zr_{13}C_{22}$, $Zr_{14}C_{23}$, $Zr_{18}C_{29}$ and $Zr_{23}C_{32}$ which may feature fused clusters of clusters. The possibility of a super-pentagonal cluster, $M_{30}C_{45}$, of D_{5h} symmetry has also been mooted.[91]

As with the fullerenes, further detailed studies will depend on the discovery of viable bulk preparations of the met-cars. Macroscopic amounts of Ti_8C_{12} and V_8C_{12} have indeed been made by DC arc discharge techniques using electrodes of compacted metal and graphite powders and He as the quenching carrier gas.[92] The resulting soot contains about 1% of air-stable M_8C_{12} plus some C_{60} (unstable in air). Solution studies have not yet been reported but there is mass spectrometric evidence for $Ti_8C_{12}L_8$ (L = NH_3, ND_3, H_2O) as well as for $Ti_8C_{12}(MeOH)_4$.

8.5 Hydrides, Halides and Oxohalides

The ability of C to catenate (i.e. to form bonds to itself in compounds) is nowhere better illustrated than in the compounds it forms with H. Hydrocarbons occur in great variety in petroleum deposits and elsewhere, and form various homologous series in which the C atoms are linked into chains, branched chains and rings. The study of these compounds and their derivatives forms the subject of organic chemistry and is fully discussed in the many textbooks and treatises on that subject. The matter is further considered on p. 374 in relation to the much smaller ability of other Group 14 elements to form such catenated compounds. Methane, CH_4, is the archetype of tetrahedral coordination in molecular compounds; some of its properties are listed in Table 8.4 where they are compared with those of the

[92] S. F. CARTIER, Z. Y. CHEN, G. J. WALDER and A. W. CASTLEMAN, *Science* **260**, 195–6 (1993).

corresponding halides. Unsaturated hydrocarbons such as ethene (C_2H_4), ethyne (C_2H_2), benzene (C_6H_6), cyclooctatetraene (C_8H_8) and homocyclic radicals such as cyclopentadienyl (C_5H_5) and cycloheptatrienyl (C_7H_7) are effective ligands to metals and form many organometallic complexes (pp. 930–43).

Methane is unique among hydrocarbons in being thermodynamically stable with respect to its elements. It follows that pyrolytic reactions to convert it to other hydrocarbons are energetically unfavourable and will be strongly equilibrium-limited. This is in marked contrast to the boranes where mild thermolysis of B_2H_6 or B_4H_{10}, for example, readily yields mixtures of the higher boranes (p. 164). Vast natural reserves of CH_4 gas exist but much is wasted by flaring (direct burning off at the petroleum production site) because of the uneconomical cost of transport. However, in convenient locations such as the North Sea, natural gas is piped ashore for use as domestic or industrial fuel or as chemical feedstock. After CO_2, methane is the most important "greenhouse gas" (p. 273) accounting for an estimated 15–20% of the atmospheric global warming (CO_2 > 50%). The major sources of atmospheric CH_4 are natural wetlands (25%), rice cultivation (22%), animals (mainly domestic ruminants) (17%) and the mining of fossil fuels (16%), the total "production" being some 460 million tonnes per annum.

Notable recent advances in the chemistry of hydrocarbons include the synthesis and

molecular structure determination of the tetrahedrane derivative, $C_4Bu^t_4$ (1),[93] the carbon-rich molecules tetraethynylmethane, $C(C{\equiv}CH)_4$ i.e. C_9H_4[94] and tetraethynylethene, $C_2(C{\equiv}CH)_4$ i.e. $C_{10}H_4$ (2),[95] the highly strained [1.1.1]propellane (3)[96] and the preparation of the largest discrete hydrocarbon molecules yet synthesized, the polyphenylethyne dendrimers $C_{1134}H_{1146}$ and $C_{1398}H_{1278}$ (mol wts 14 777.6 and 18 079.6).[97] There is also increasing interest in hydrocarbon salts $R_1{}^+R_2{}^-$. The first example was the stable, greenish-black crystalline compound $C_{48}H_{51}{}^+C_{61}H_{39}{}^-$ (mp 230°C decomp.) obtained by mixing thf solutions of Agranat's carbocation (4) and Kuhn's carbanion (5).[98] Of special interest is the covalent molecular hydrocarbon $R_3{-}R_2$ (6) which exists in chloroform solution but which crystallizes on evaporation or cooling to give the ionic salt $R_3{}^+R_2{}^-$ (7).[99] This reversible ionic-covalent equilibrium is reminiscent of similar behaviour in certain halides such as $AlCl_3$ (p. 234), PCl_5 (p. 499) and $TeCl_4$ (p. 772), etc.

Fullerene derivatives such as $C_{60}H_n$ (p. 283), $C_{60}H_2$ (p. 287), and $C_{61}H_2$ (p. 287), and hypercoordinated non-classical carbonium ions (p. 290) have already been briefly mentioned.

Turning next to the simple halides of carbon: tetrafluoromethane (CF_4) is an exceptionally stable gas with mp close to that of CH_4 (see Table 8.4). It can be prepared on a laboratory scale by reacting SiC with F_2 or by fluorinating CO_2, CO or $COCl_2$ with SF_4. Industrially it is prepared by the aggressive reaction of F_2 on CF_2Cl_2 or CF_3Cl, or by electrolysis of MF or MF_2 using a C anode. CF_4 was first obtained pure in 1926; C_2F_6 was isolated in 1930 and C_2F_4 in 1933; but it was not until 1937 that the various homologous series of fluorocarbons were isolated and identified. Replacement of H by F greatly increases both thermal stability and chemical inertness because of the great strength of the C–F

bond (Table 8.4). Accordingly, fluorocarbons are resistant to attack by acids, alkalis, oxidizing agents, reducing agents and most chemicals up to 600°. They are immiscible with both water and hydrocarbon solvents, and when combined with other groups they confer water-repellance and stain-resistance to paper, textiles and fabrics.[100] Tetrafluoroethene (C_2F_4) can be polymerized to a chemically inert, thermosetting plastic PTFE (polytetrafluoroethene); this has an extremely low coefficient of friction and is finding increasing use as a protective coating in non-stick kitchen utensils, razor blades and bearings. PTFE is made by partial fluorination of chloroform using HF in the presence of $SbFCl_4$ as catalyst, followed by thermolysis to C_2F_4 and subsequent polymerization:

$$CCl_3H \longrightarrow CF_2ClH \xrightarrow{\Delta} C_2F_4 \longrightarrow (C_2F_4)_n$$

As a ligand towards metals, C_2F_4 and other unsaturated fluorocarbons differ markedly from alkenes (p. 931).

CCl_4 is a common laboratory and industrial solvent with a distinctive smell, usually prepared by reaction of CS_2 or CH_4 with Cl_2. Its use as a solvent has declined somewhat because of its toxicity, but CCl_4 is still extensively used as an intermediate in preparing "Freons" such as $CFCl_3$, CF_2Cl_2 and CF_3Cl:[100]

$$CCl_4 + HF \xrightarrow{SbFCl_4} CFCl_3 + HCl$$

$$CFCl_3 + HF \xrightarrow{SbFCl_4} CF_2Cl_2 + HCl$$

The catalyst is formed by reaction of HF on $SbCl_5$. The Freons have a unique combination of properties which make them ideally suited for use as refrigerants and aerosol propellants. They have low bp, low viscosity, low surface tension and high density, and are non-toxic, non-flammable, odourless, chemically inert and thermally stable. The most commonly used is CF_2Cl_2, bp, −29.8°. The market for Freons and other fluorocarbons expanded rapidly in the sixties: production in the USA alone exceeded 200 000 tonnes in 1964 (417 000 tonnes in 1990) and global production was about three times this amount. Already in 1977 there was an annual production of 2.4×10^9 spray-cans. However, there has been growing concern that chlorofluorocarbons from spray-cans gradually work their way into the upper atmosphere where they may, through a complex chemical reaction, deplete the earth's ozone layer (p. 608). For this reason there was an enforced progressive elimination of this particular application in the USA starting 15 October 1978 and production of CFCs will effectively be completely phased out following the Montreal Protocol of September 1981.

CBr_4 is a pale-yellow solid which is markedly less stable than the lighter tetrahalides. Preparation involves bromination of CH_4 with HBr or Br_2 or, more conveniently, reaction of CCl_4 with Al_2Br_6 at 100°. The trend to diminishing thermal stability continues to CI_4 which is a bright-red crystalline solid with a smell reminiscent of I_2. It is prepared by the $AlCl_3$-catalysed halogen exchange reaction between CCl_4 and EtI.

Carbon oxohalides are reactive gases or volatile liquids which feature planar molecules of C_{2v} symmetry; they are isoelectronic with BX_3 (p. 196) and the bonding is best described in terms of molecular orbitals spanning all 4 atoms rather than in terms of localized orbitals as implied by the formulation  . Some physical properties and molecular dimensions are in Table 8.5. The values call for little comment except to note that the XCX angle is significantly less (as expected) than the value of 120° found for the more symmetrical isoelectronic species BX_3 and CO_3^{2-}. The C–Br distance is unusually long; it comes from a very early diffraction measurement and could profitably be checked.

Mixed oxohalides are also known and their volatilities are intermediate between those of the

parent species, e.g. COFCl (bp −42°), COFBr (bp −20.6°). COI_2 is unknown but COFI has been prepared (mp −90°, bp 23.4°). Synthetic routes are as follows: COFCl from $COCl_2$/HF; COFBr from CO/BrF_3; COFI from CO/IF_3; and COClBr from CCl_3Br/H_2SO_4.

COF_2 can be made by fluorinating $COCl_2$ with standard fluorinating agents such as NaF/MeCN or SbF_5/SbF_3; direct fluorination of CO with AgF_2 affords an alternative route. COF_2 is rapidly hydrolysed by water to CO_2 and HX, as are all the other COX_2. It is a useful laboratory reagent for producing a wide range of fluoroorganic compounds and the heavier alkali metal fluorides react in MeCN to give trifluoromethoxides $MOCF_3$.

$COCl_2$ (phosgene) is highly toxic and should be handled with great caution. It was first made in 1812 by John Davy (Sir Humphry Davy's brother) by the action of sunlight on $CO + Cl_2$, whence its otherwise surprising name (Greek *φως phos*, light; *-γενη′ς*, *-genes*, born of). It is now a major industrial chemical and is made on the kilotonne scale by combining the two gases catalytically over activated C (p. 274). It was used briefly and rather ineffectively as a chemical warfare gas in 1916 but is now principally used to prepare isocyanates as intermediates to polyurethanes. It also acts as a ligand (Lewis base) towards $AlCl_3$, $SnCl_4$, $SbCl_5$, etc., forming adducts $Cl_2CO{\rightarrow}MCl_n$, and is a useful chlorinating agent, converting metal oxides into highly pure chlorides. It reacts with NH_3 to form mainly urea, $CO(NH_2)_2$, together with more highly condensed products such as guanidine, $C(NH)(NH_2)_2$; biuret, $NH_2CONHCONH_2$; and cyanuric acid, i.e. *cyclo*-$[CO(NH)]_3$ (p. 323).

$COBr_2$ has recently been shown to be a useful general brominating reagent for the preparation of d- and f-block bromides and oxide bromides.[101] Thus, when V_2O_5 is heated with an excess of $COBr_2$ in a sealed Carius tube at 125°C for 10 days, a quantitative yield of $VOBr_2$ is obtained by a reaction that is driven thermodynamically by the formation of CO_2: $[V_2O_5 + 3COBr_2 \longrightarrow 2VOBr_2 + 3CO_2 + Br_2]$. Similarly, MoO_2, Re_2O_7, Sm_2O_3 and UO_3 were smoothly converted to MoO_2Br_2, $ReOBr_4$, $SmBr_3$ and $UOBr_3$, respectively.

8.6 Oxides and Carbonates

Carbon forms 2 extremely stable oxides, CO and CO_2, 3 oxides of considerably lower stability, C_3O_2, C_5O_2 and $C_{12}O_9$, and a number of unstable or poorly characterized oxides including C_2O, C_2O_3 and the nonstoichiometric graphite oxide (p. 289). Of these, CO and CO_2 are of outstanding importance and their chemistry will be discussed in subsequent paragraphs after a few brief remarks about some of the others.

Tricarbon dioxide, C_3O_2, often called "carbon suboxide" and ponderously referred to in *Chemical Abstracts* as 1,2-propadiene-1,3-dione, is a foul-smelling gas obtained by dehydrating malonic acid, $CH_2(CO_2H)_2$, at

[101] J. S. YADAV and V. R. GADGIL, *J. Chem. Soc., Chem. Commun.*, 1824–5 (1989).

Table 8.6 Some properties of CO, CO_2 and C_3O_2

Property	CO	CO_2	C_3O_2

reduced pressure over P_4O_{10} at 140°, or by thermolysis of bis(trimethylsilyl) malonate, $CH_2(CO_2SiMe_3)_2$.[102] It has mp −112.5°, bp 6.7°, is stable at −78°, and polymerizes at room temperature to a yellow solid. C_3O_2 forms linear molecules ($D_{\infty h}$ symmetry) which can be written as O=C=C=C=O, consistent with the short interatomic distances C–C 128 pm and C–O 116 pm. Above 100°, polymerization yields a ruby-red solid; at 400° the product is violet and at 500° the polymer decomposes to C. The basic structure of all the polymers appears to be a polycyclic 6-membered lactone. C_3O_2 readily rehydrates to malonic acid, and reacts with NH_3 and HCl to give respectively the corresponding amide and acid chloride: $CH_2(CONH_2)_2$ and $CH_2(COCl)_2$. Thermolysis of C_3O_2 in a flow system has been reported to give a liquid product C_5O_2 though a better preparation is the photolysis or thermolysis of the tris(diazo)ketone, cyclo-1,3,5-$C_6O_3(N_2)_3$.[103] C_5O_2 is a yellow solid which decomposes above −90°; in solution it apparently remains unchanged for several days even at room temperature. Note that C_5O_2 is the next member after CO_2 and C_3O_2 of the linear catenated series OC_nO with n odd as required by simple π-bond theory. The other moderately stable lower oxide is $C_{12}O_9$, a white sublimable solid which is the anhydride of mellitic acid, $C_6(COOH)_6$.

Direct oxidation of C in a limited supply of oxygen or air yields CO; in a free supply CO_2 results. Some properties of these familiar gases and of C_3O_2 are in Table 8.6. The great strength of the C–O bond confers considerable thermal stability on these molecules but the compounds are also quite reactive chemically, and many of the reactions are of major industrial importance. Some of these are discussed more fully in the Panel.

The nature of the bonding, particularly in CO, has excited much attention because of the unusual coordination number (1) and oxidation state (+2) of carbon: it is discussed on p. 926 in connection with the formation of metal–carbonyl complexes.

Pure CO can be made on a laboratory scale by dehydrating formic acid (HCOOH) with conc H_2SO_4 at ~140°. CO is a colourless, odourless, flammable gas; it has a relatively high toxicity due to its ability to form a complex with haemoglobin that is some 300 times more stable than the oxygen–haemoglobin complex (p. 1099): the oxygen-transport function of the red corpuscles in the blood is thereby impeded. This can result in unconsciousness or death, though recovery from mild poisoning is rapid and complete in fresh air and the effects are not cumulative. CO can be detected by its ability to reduce an aqueous solution of $PdCl_2$ to metallic Pd:

$$CO + PdCl_2 + H_2O \longrightarrow Pd + CO_2 + 2HCl$$

Quantitative estimation relies on the liberation of I_2 from I_2O_5 or (in the absence of C_2H_2) on absorption in an acid solution of CuCl to form the adduct $[Cu(CO)Cl(H_2O)_2]$.

Industrially Important Reactions of Oxygen and Oxides with Carbon

Carbon monoxide is widely used as a fuel in the form of producer gas or water gas and is also formed during the isolation of many metals from their oxides by reduction with coke. Producer gas is obtained by blowing air through incandescent coke and consists of about 25% CO, 4% CO_2 and 70% N_2, together with traces of H_2, CH_4 and O_2. The reactions occurring during production are:

$$2C + O_2 \longrightarrow 2CO;\ \Delta H^\circ = -221.0\ \text{kJ/mol}\ O_2;\ \Delta S^\circ + 179.4\ \text{J K}^{-1}\ \text{mol}^{-1}$$

$$C + O_2 \longrightarrow CO_2;\ \Delta H^\circ = -393.5\ \text{kJ mol}^{-1};\ \Delta S^\circ + 2.89\ \text{J K}^{-1}\ \text{mol}^{-1}$$

Water gas is made by blowing steam through incandescent coke: it consists of about 50% H_2, 40% CO, 5% CO_2 and 5% $N_2 + CH_4$. The oxidation of C by H_2O is strongly endothermic:

$$C + H_2O \longrightarrow CO + H_2;\quad \Delta H^\circ = +131.3\ \text{kJ mol}^{-1};\quad \Delta S^\circ + 133.7\ \text{J K}^{-1}\ \text{mol}^{-1}$$

Consequently, the coke cools down and the steam must be intermittently replaced by a flow of air to reheat the coke.

At high temperatures, particularly in the presence of metal catalysts, CO undergoes reversible disproportionation:†

$$2CO \rightleftharpoons C + CO_2;\quad \Delta H^\circ = -172.5\ \text{kJ/mol}\ CO_2;\quad \Delta S^\circ = -176.5\ \text{J K}^{-1}\ \text{mol}^{-1}$$

The equilibrium concentration of CO is 10% at 550°C and 99% at 1000°. As the forward reaction involves a reduction in the number of gaseous molecules it is accompanied by a large decrease in entropy. Remembering that $\Delta G = \Delta H - T\Delta S$ this implies that the reverse reaction becomes progressively more favoured at higher temperatures. The thermodynamic data for the formation of CO and CO_2 can be represented diagramatically on an Ellingham diagram (Fig. 19) which plots standard free energy changes per mol of O_2 as a function of the absolute temperature. The oxidation of C to CO results in an increase in the number of gaseous molecules; it is therefore accompanied by a large increase in entropy and is favoured at high temperature. By contrast, oxidation to CO_2 leaves the number of gaseous molecules unchanged; there is little change in entropy (ΔS° 2.93 J K^{-1} mol^{-1}), and the free energy is almost independent of temperature. The two lines (and that for the oxidation of CO to CO_2) intersect at 983 K; it follows that ΔG for the disproportionation reaction is zero at this temperature. The diagram also includes the plots of ΔG (per mole of O_2) for the oxidation of several representative metals. On the left of the diagram (at $T = 0$ K) $\Delta G = \Delta H$ and the sequence of elements is approximately that of the electrochemical series. The slope of most of the lines is similar and corresponds to the loss of 1 mol of gaseous O_2; small changes of slope occur at the temperature of phase changes or the mp of the metal, and a more dramatic increase in slope signals the bp of the metal. For example, for MgO(s), the slope increases about three-fold at the bp of Mg since, above this temperature, reaction removes three gaseous species ($2Mg + O_2$) rather than one (O_2).

Such diagrams are of great value in codefying a mass of information of use in extractive metallurgy.[105] For example, it is clear that below 710°C (983 K) carbon is a stronger reducing agent when it is converted into CO_2 rather than CO, whereas above this temperature the reverse is true. Again, as reduction of metal oxides with C will occur when the accompanying ΔG is negative, such reduction becomes progressively more feasible the higher the temperature: Zn (and Cd) can be reduced at relatively low temperatures but MgO can only be reduced at temperatures approaching 2000 K. Caution should be exercised, however, in predicting the outcome of such reactions since a number of otherwise reasonable reductions cannot be used because the metal forms a carbide (e.g. Cr, Ti). The temperature at which the oxygen dissociation pressure of the various metal oxides reaches a given value can also be obtained from the diagram: as $-\Delta G = RT \ln K_p [= 2.303RT \log\{p(O_2)/\text{atm}\}$ for the reactions considered] it follows that the line drawn from the point ⊙($\Delta G = 0, T = 0$) to the appropriate scale mark on the right-hand side of the diagram intercepts the free-energy line for the element concerned at the required temperature. (Establish to your own satisfaction that this statement is approximately true — what assumptions does it embody?)

† Note however that, at all pressures, there is a fairly wide range of temperatures in which CO_2 dissociates directly into CO and O_2 without precipitation of carbon:[104]

$$CO_2 \rightleftharpoons CO + \tfrac{1}{2}O_2$$

For example, the temperature range is 250–370°C at 10^{-2} atm, 320–480°C at 1 atm, and 405–630°C at 100 atm. At higher temperatures in each case, C is also formed, but always in the presence of some O_2.

[104] M. H. Lietzke and C. Mullins, *J. Inorg. Nucl. Chem.* **43**, 1769–71 (1981).

[105] C. B. Alcock, *Principles of Pyrometallurgy*, Academic Press, London, 1976, 348 pp.

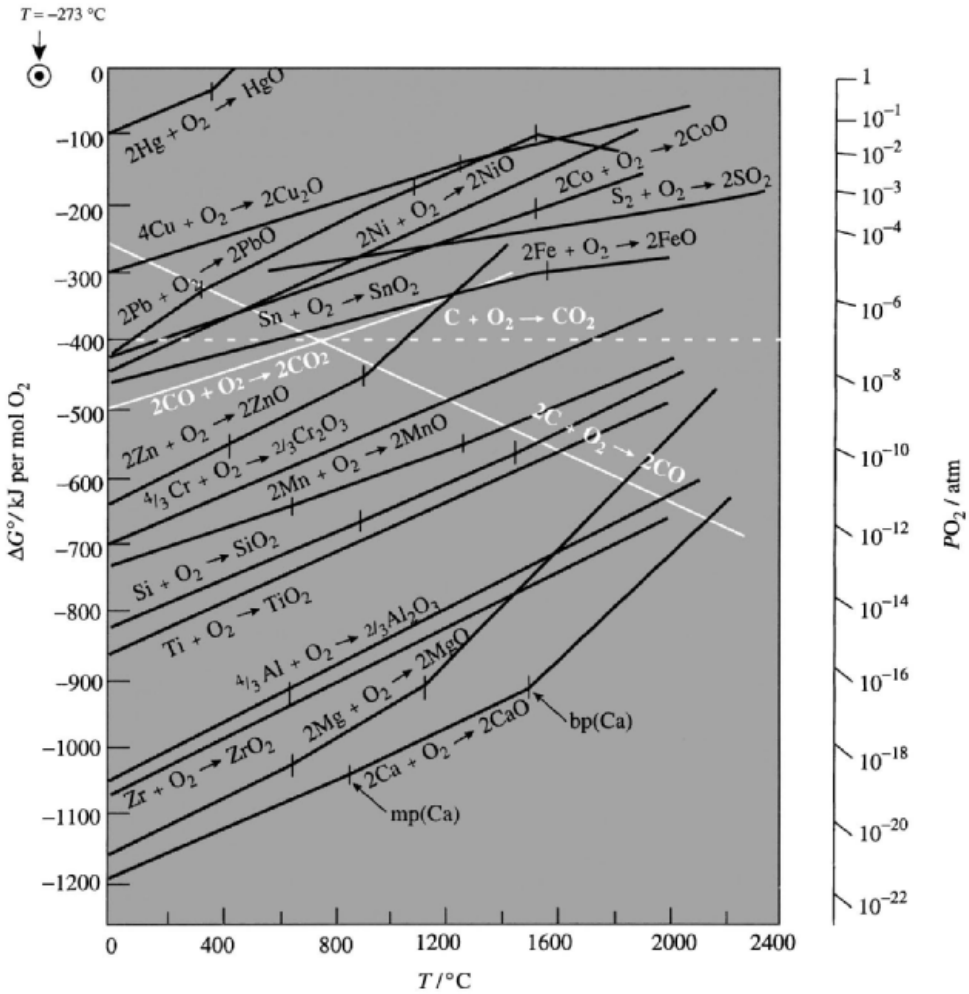

Figure 8.19 Ellingham diagram for the free energy of formation of metallic oxides. (After F. D. Richardson and J. H. E. Jeffes, *J. Iron Steel Inst.* **160**, 261 (1948).) The oxygen dissociation pressure of a given M–MO system at a given temperature is obtained by joining ⊙ on the top left hand to the appropriate point on the M–MO free-energy line, and extrapolating to the scale on the right hand ordinate for p_{O_2} (atm).

CO reacts at elevated temperatures to give formates with alkali hydroxides, and acetates with methoxides:

$$CO + NaOH \longrightarrow HCO_2Na;$$

$$CO + MeONa \longrightarrow MeCO_2Na$$

Reaction with alkali metals in liquid NH_3 leads to reductive coupling to give colourless crystals of the salt $Na_2C_2O_2$ which contains linear groups $NaOC{\equiv}CONa$ packed in chains. CO reacts with Cl_2 and Br_2 to give COX_2 (p. 305) and with liquid S to give COS. It cleaves B_2H_6 at high pressures to give the "symmetrical" adduct BH_3CO (p. 165), but in the presence of $NaBH_4$/thf the reaction takes a different course to yield the cyclic *B*-trimethylboroxine:

$$\tfrac{3}{2}B_2H_6 + 3CO \xrightarrow[thf]{NaBH_4/} MeBOB(Me)OB(Me)O$$

With BR_3, CO inserts in successive stages to give, ultimately, the corresponding trialkylmethylboroxine $(R_3CBO)_3$. Alternative products are obtained in the presence of other reagents, e.g. aqueous alkali yields R_3COH; water followed by alkaline peroxide yields R_2CO; and alkaline $NaBH_4$ yields RCH_2OH (p. 167). CO can also insert into M–C bonds (M = Mo, W; Mn, Fe, Co; Ni, Pd, Pt):

$$MeMn(CO)_5 + CO \longrightarrow MeC(O)Mn(CO)_5$$

A detailed discussion of CO as a ligand and the chemistry of metal carbonyls is on pp. 926–9. CO is a key intermediate in the catalytic production of a wide variety of organic compounds on an industrial scale. These include:[106,107]

1. Catalytic reduction to methanol (230–400°C, 50–100 atm):

$$CO + 2H_2 \longrightarrow CH_3OH$$

2. Homogeneous methanol carboxylation with I^-/Rh catalyst (175–195°C, 30 atm), this is now a leading route to acetic acid:

$$MeOH + CO \longrightarrow MeCO_2H$$

3. Hydroformylation of olefins to alcohols (the oxo process):[108]

$$RCH{=}CH_2 + CO + H_2 \longrightarrow RCH_2CH_2CHO \xrightarrow{H_2O} R(CH_2)_3OH$$

4. The Reppe synthesis of methyl acrylate and acrylic acid (100–190°C, 30 atm, Ni catalyst: **or** 40°C and 1 atm using $Ni(CO)_4$ as both the source of CO and the catalyst):

$$HC{\equiv}CH + MeOH + CO \longrightarrow CH_2{=}CHCO_2Me \xrightarrow{H_2O} CH_2{=}CHCO_2H$$

5. Sabatier methanation (230–450°C, 1–100 atm, Ni catalyst):

$$CO + 3H_2 \longrightarrow CH_4 + H_2O$$

6. Fischer-Tropsch hydrogenation to a mixture of straight chain aliphatic, olefinic and oxygenated hydrocarbons.[109] Despite an enormous amount of research during the past two decades, this is still not an economically viable process except in special circumstances, such as in South Africa.[110]

Most industrial CO is produced and used on site. Prices for commercial supplies vary enormously depending on volume and purity required.[106] For large volumes (~28 000 m^3/day), "over the fence" prices can be as low as \$0.30/m^3 whereas for tube-trailer loads (1500–3000 m^3) prices are nearer \$1.40/m^3. For CO supplied in high-pressure cylinders current prices (1993) are \$15.00–35.00/m^3 for commercial grade (98–99% purity), \$63/m^3 for ultra high purity grade (99.8%) and \$68–1580/m^3 for research grades (99.97–99.98%).

Further reactions of CO of potential industrial or research significance are continually being explored. Recent examples include:

1. Amination with ammonia over zeolite catalysts at 350–400°C to give methylamine (and some dimethylamine):[111]

$$CO + 3NH_3 \xrightarrow{HZSM\text{-}5} CH_3NH_2 + H_2O + N_2 + H_2$$

2. Reductive coupling of two CO ligands to form a coordinated alkyne derivative, e.g. treatment of the Ta^{I} complex $[Ta(CO)_2(dmpe)_2Cl]$ with activated Zn dust in thf and then with Me_3SiCl gave a 25% yield of $[Ta(Me_3SiOC{\equiv}COSiMe_3)(dmpe)_2Cl]$ which can in turn be hydrolysed to the corresponding complex of the novel dihydroxyacetylene, HOC=COH.[112]

CO_2 is much less volatile than CO (p. 306). It is a major industrial chemical but its uses, though occasionally chemical, more frequently depend on its properties as a refrigerant, as an inert atmosphere, or as a carbonating (gasifying) agent in drinks and foam plastic (see Panel).[113] Of more chemical interest is the synthesis of radioactive ^{14}C compounds from $^{14}CO_2$ which is conveniently stored as a carbonate. ^{14}C is generated by an (n,p) reaction on a nitride or nitrate in a nuclear reactor (see p. 1256). More than 500 compounds specifically labelled with ^{14}C are now available commercially, the starting point of many of the syntheses being one of the following reactions:

1. $NaH^{14}CO_3 + H_2/Pd/C \longrightarrow H^{14}CO_2H$
2. $^{14}CO_2 + RMgX \longrightarrow R^{14}CO_2H$
3. $^{14}CO_2 + LiAlH_4 \longrightarrow {}^{14}CH_3OH$
4. $Ba^{14}CO_3 + Ba \longrightarrow Ba^{14}C_2 \xrightarrow{H_2O} {}^{14}C_2H_2$
5. $Ba^{14}CO_3 + NH_3 \longrightarrow Ba^{14}CN_2 \longrightarrow {}^{14}C/N$ compounds

When CO_2 dissolves in water at 25° it is only partly hydrated to carbonic acid according to the equilibrium

$$H_2CO_3 \rightleftharpoons CO_2 + H_2O;$$

$$K = [CO_2]/[H_2CO_3] \approx 600$$

Interpretation of acid–base behaviour in this system is further complicated by the slowness of some of the reactions and their dependence on pH. The main reactions are:

$$\left.\begin{array}{l} CO_2 + H_2O \rightleftharpoons H_2CO_3 \text{ (slow)} \\ H_2CO_3 + OH^- \rightleftharpoons HCO_3^- + H_2O \text{ (fast)} \end{array}\right\} \text{pH} < 8$$

$$\left.\begin{array}{l} CO_2 + OH^- \rightleftharpoons HCO_3^- \text{ (slow)} \\ HCO_3^- + OH^- \rightleftharpoons CO_3^{2-} + H_2O \text{ (fast)} \end{array}\right\} \text{pH} > 10$$

In the range pH 8–10 both sets of equilibria are important. The apparent dissociation constant of carbonic acid is

$$K_1 = [H^+][HCO_3^-]/[CO_2 + H_2CO_3]$$
$$= 4.45 \times 10^{-7} \text{ mol l}^{-1}$$

As $[CO_2]/[H_2CO_3] = K \approx 600$, it follows that the true dissociation constant is:

$$K_a = [H^+][HCO_3^-]/[H_2CO_3]$$
$$= K_1(1 + K) \approx 2.5 \times 10^{-4} \text{ mol l}^{-1}$$

This value is in the range expected from an acid of structure $(HO)_2CO$ (p. 50). The second dissociation constant is given by

$$K_2 = [H^+][CO_3^{2-}]/[HCO_3^-]$$
$$= 4.84 \times 10^{-11} \text{ mol l}^{-1}$$

A hydrate $CO_2.8H_2O$ can be crystallized from aqueous solutions at 0° and $p(CO_2) \sim 45$ atm. There is also evidence for a hydrogen-bonded sesquicarbonate ion, $H_3C_2O_6^-$; this was originally suggested to have the sandwich

Production and Uses of CO_2

CO_2 can be readily obtained in small amounts by the action of acids on carbonates. On an industrial scale the main source is as a byproduct of the synthetic ammonia process in which the H_2 required is generated either by the catalytic reaction (a) or by the water-gas shift reaction (b):

$$\text{(a) } CH_4 + 2H_2O \longrightarrow CO_2 + 4H_2; \quad \text{(b) } CO + H_2O \rightleftharpoons CO_2 + H_2$$

CO_2 is also recovered economically from the flue gases resulting from combustion of carbonaceous fuels, from fermentation of sugars and from the calcination of limestone: recovery is by reversible absorption either in aqueous Na_2CO_3 or aqueous ethanolamine (Girbotol process).

$$Na_2CO_3 + H_2O + CO_2 \underset{\text{heat}}{\overset{\text{cool}}{\rightleftharpoons}} 2NaHCO_3$$

$$2HOC_2H_4NH_2 + H_2O + CO_2 \underset{100\text{–}150^\circ}{\overset{25\text{–}65^\circ}{\rightleftharpoons}} (HOC_2H_4NH_3)_2CO_3$$

In certain places CO_2 can be obtained from natural gas wells. H_2S impurity is removed by oxidation using a buffered alkaline solution saturated with $KMnO_4$:

$$3H_2S + 2KMnO_4 + 2CO_2 \longrightarrow 3S + 2MnO_2 + 2KHCO_3 + 2H_2O$$

The scale of production has increased rapidly in recent years and in 1980 exceeded 33 million tonnes in the USA alone though much of this is used in integrated plants, on site.

The most extensive application of CO_2 is as a refrigerant, some 52% of production being consumed in this way. CO_2 can be liquefied at any temperature between its triple point -56.6° (5.11 atm) and its critical point $+31.1^\circ$ (72.9 atm). The gas can either be pressurized to 75 atm and then water-cooled to room temperature, or precooled to about -15° ($\pm 5^\circ$) and then pressurized to 15.25 atm. Solid CO_2 is obtained by expanding liquid CO_2 from cylinders to give a "snow" which is then mechanically compressed into blocks of convenient size. Until about 40 y ago the bulk of CO_2 refrigerant was in the form of solid CO_2, but since 1960 production of liquid CO_2 has overtaken the solid form because of lower production costs and ease of transporting and metering the material. Some typical production figures are shown in the Table. Supercritical CO_2 is also finding increasing use as a versatile solvent for chemical reactions.[113a]

USA production of CO_2

CO_2 production/kilotonnes	1955	1960	1962	1977	1987
Solid	520	426	406	340	310
Liquid and gas	185	432	522	1660	7310
Total	705	858	928	2000	7620

Solid CO_2 is used as a refrigerant for ice-cream, meat and frozen foods, and as a convenient laboratory cooling agent and refrigerant. Liquid CO_2 is extensively used to improve the grindability of low-melting metals (and hamburger meat), and for the rapid cooling of loaded trucks and rail cars; it is also used for inflating life rafts, in fire extinguishers, and in blasting shells for coal mining. A related application of growing importance is as a replacement for chlorofluorocarbon aerosol propellants (p. 304) though this application will never consume large amounts of the gas since the amount in each tin is extremely small.

Gaseous CO_2 is extensively used to carbonate soft drinks and this use alone accounts for 20% of production. Other quasi-chemical applications are its use as a gas purge, as an inert protective gas for welding, and for the neutralization of caustic and alkaline waste waters. Small amounts are also used in the manufacture of sodium salicylate, basic lead carbonate ("white lead"), and various carbonates such as $M^I_2CO_3$ and M^IHCO_3 (M^I = Na, K, NH_4, etc.). One of the most important uses of CO_2 is to manufacture urea via ammonium carbamate:

$$CO_2 + 2NH_3 \underset{200\text{ atm}}{\overset{185^\circ}{\longrightarrow}} NH_2CO_2NH_4 \xrightarrow{-H_2O} CO(NH_2)_2$$

Urea is used to make urea-formaldehyde plastics and resins and, increasingly, as a nitrogenous fertilizer (46.7% N). World production of urea was 23 million tonnes in 1984.

[113a] M. POLIAKOFF and S. HOWDLE, *Chem in Brit.*, February 1995, pp. 118–21, and references cited therein.

structure (1)[114] though later *ab initio* calculations favour the all-planar structure (2).[115] Solid alkali-metal peroxocarbonates Li_2CO_4, $MHCO_4$ and $M_2C_2O_6$ (M = Na, K, Rb, Cs) are known and the anion HCO_4^- (CO_4^{2-} at high pH) can be prepared in solution by reaction of HCO_3^- with aqueous H_2O_2.[116] The peroxodianion, $C_2O_6^{2-}$ (3), can be prepared in aprotic solvents such as MeCN, dmf and dmso, via nucleophilic oxidation of CO_2 by the superoxide ion $O_2^{\bullet-}$: $[2CO_2 + 2O_2^{\bullet-} \rightarrow C_2O_6^{2-} + O_2]$.[117] The amusing all-planar squarate ion, $C_4O_4^{2-}$ (4), although chemically unrelated to the preceding species, may be mentioned here as a further well-characterized binary C/O anion.[118,119] The short C–C and C–O distances have been interpreted in terms of π-electron delocalization.

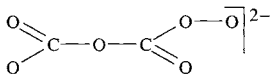
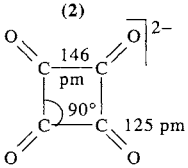
(2)



(3)



(4)

The coordination chemistry of CO_2 is by no means as extensive as that of CO (p. 926) but some exciting developments have recently been published.[120] The first transition metal complexes with CO_2 were claimed by M. E. Volpin's group in 1969: tertiary phosphine or N_2 ligands were displaced from Rh and Ni complexes to give binuclear products whose definitive structure has not yet been established. CO_2 also displaced N_2 from $[Co(N_2)(PPh_3)_3]$ to give $[Co(CO_2)(PPh_3)_3]$. The Ni^0 complexes $[Ni(PEt_3)_4]$ (violet) and $[Ni(PBu^n_3)_4]$ (red) react in toluene at room temperature with CO_2 (1 atm) to give the yellow complexes $[Ni(CO_2)L_3]$. The structure of the analogous complex with $P(C_6H_{11})_3$ was established by X-ray diffraction analysis; it features a pseudo-3-coordinate Ni atom μ-bonded to a bent CO_2 ligand as in Fig. 8.20a. The isoelectronic Rh^I appears to form two types of complex: an orange-red series $[Rh(CO_2)ClL_2]$ (L = tertiary phosphine) with a μ-bonded bent CO_2 as in Fig. 8.20a and a somewhat less-stable yellow series $[Rh(CO_2)ClL_3]$ which is thought to contain the ligand configuration  . A Pt compound which had earlier (1965) been thought to contain CO_2 as a ligand was subsequently found to require the presence of O_2 for its formation and to be, in fact, a novel bidentate carbonato complex (Fig. 8.20b).

$$[Pt(PPh_3)_3] + CO_2 + O_2 \xrightarrow{C_6H_6/25^\circ} [Pt(CO_3)(PPh_3)_2] + Ph_3PO$$

If the starting material contains M–H or M–C bonds a further complication can arise due to the possibility of a CO_2 insertion reaction. Thus, both $[Ru(H)_2(N_2)(PPh_3)_3]$ and $[Ru(H)_2(PPh_3)_4]$ react to give the formate $[Ru(H)(OOCH)(PPh_3)_3]$, and similar CO_2 insertions into M–H are known for M = Co, Fe, Os, Ir, Pt. These "normal" insertion reactions are consistent with the expected bond polarities $M^{\delta+}-H^{\delta-}$ and $O^{\delta-}=C^{\delta+}=O$, but occasionally "abnormal" insertion occurs to give metal carboxylic acids

M–COOH. Likewise, normal insertion into M–C yields alkyl carboxylates M–OOCR, though metalloacid esters M–COOR are sometimes obtained. The reactions have obvious catalytic implications and are being actively studied at the present time by several groups.[121]

CO_2 insertion into M–C bonds has, of course, been known since the first papers of V. Grignard in 1901 (p. 134). Organo-Li (and other M^I and M^{II}) also react extremely vigorously to give salts of carboxylic acids, RCO_2Li, $(RCO_2)_2Be$, etc. Zinc dialkyls are much less reactive towards CO_2, e.g.

$$ZnEt_2 + 2CO_2 \xrightarrow{150^\circ} (EtCOO)_2Zn,$$

and organo-Cd and -Hg compounds are even less reactive. With AlR_3, one CO_2 inserts at room temperature and a second at 220° under pressure to give $R_2Al(OOCR)$ and $RAl(OOCR)_2$ respectively. B–C, Si–C, Ge–C, and Sn–C are rather inert to CO_2 but insertion readily occurs into bonds between these elements and N. A few examples are:

$$PhB(NHEt)_2 + CO_2 \xrightarrow{25^\circ} PhB(OCONHEt)_2$$

$$Me_3SiNEt_2 + CO_2 \xrightarrow{Et_2NH/25^\circ} Me_3SiOCONEt_2$$

$$Me_3SnNMe_2 + CO_2 \xrightarrow{20^\circ} Me_3SnOCONMe_2$$

$$As(NMe_2)_3 + 1(3)CO_2 \xrightarrow{20^\circ - 40^\circ} (Me_2N)_2AsOCONMe_2,\ As(OCONMe_2)_3$$

$$Ti(NMe_2)_4 + CO_2 \xrightarrow{20^\circ} Ti(OCONMe_2)_4, \text{ etc.}$$

Returning briefly to CO_2 as a ligand: in addition to the various mono-CO_2 complexes referred to above, several bis(η^2-CO_2) transition-metal adducts are known, e.g. *trans*-$[Mo(\eta^2\text{-}CO_2)_2(PMe_3)_4]$ (5) and *trans,mer*-$[Mo(\eta^2\text{-}CO_2)_2(PMe_3)_3(CNPr^i)]$.[122] The first homo-bimetallic bridging-CO_2 complex has also been structurally characterized by X-ray analysis, *viz.* $[(dppp)(CO)_2Re(\mu,\eta^2\text{-}O,O':\eta'\text{-}C)Re(CO)_3(dppp)]$ (6) [dppp = 1,3-bis(diphenylphosphino)propane].[123]

The carbonate ion, CO_3^{2-}, by contrast, is a classic Werner ligand which forms innumerable complexes as a monohapto, dihapto or bridging donor. Examples of this latter mode

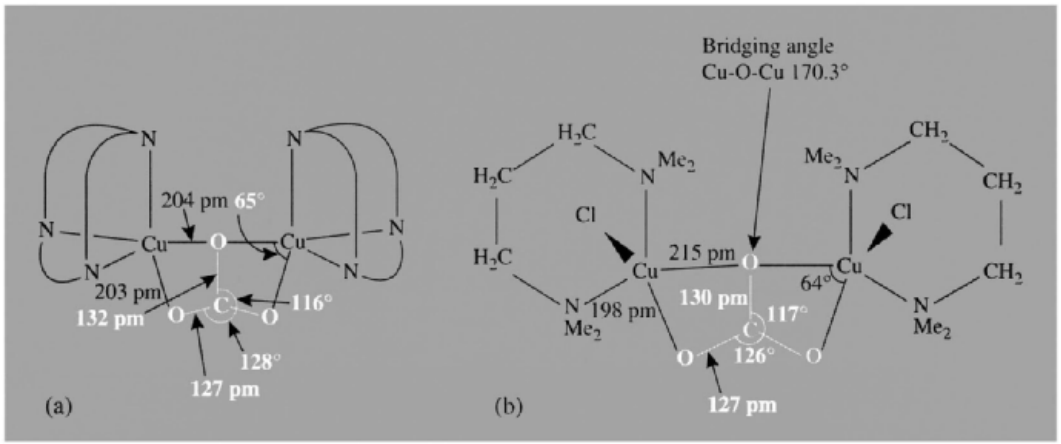

Figure 8.21 (a) The complex cation $[Cu(L_2)_2(\mu\text{-}\eta^2,\eta^2\text{-}CO_3)]^{2+}$. (b) The binuclear complex $[\{CuCl(Me_2N\text{-}CH_2CH_2CH_2NMe_2)\}_2(\mu\text{-}\eta^2,\eta^2\text{-}CO_3)]$.

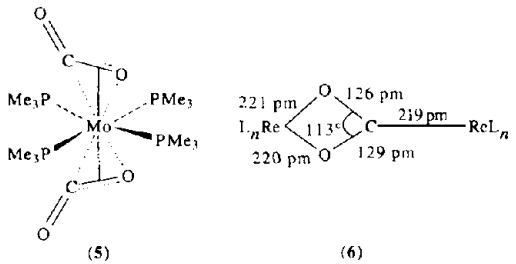

are the complex cation $[(CuL_2)_2(\mu\text{-}CO_3)]^{2+}$, where L is a tridentate macrocylic triaza ligand (Fig. 8.21a),[124] and in the binuclear molecular complex molecule $[\{CuCl(Me_2NCH_2CH_2 - CH_2NMe_2\}_2(\mu\text{-}CO_3)]$ (Fig. 8.21b).[125] This mode of coordination confers some unusual properties including diamagnetism on these Cu^{II} complexes. Even more extensive ligation occurs in the deep violet hexanuclear vanadium (IV) complex $(NH_4)_5[(VO)_6(CO_3)_4(OH)_9].10H_2O$ which was made by reacting $VOCl_2$ with aqueous NH_4HCO_3 under CO_2.[126] The novel anion (Fig. 8.22) features a unique tris(bidentate) sextuply bridging carbonato ligand as well as three bidentate μ_2-carbonato ligands. Other chelating and bridging coordination modes are also known.[126a]

8.7 Chalcogenides and Related Compounds

Carbon forms a great many sulfides in addition to the well known CS_2. CS (unlike CO) is an unstable reactive radical even at −196°: it reacts with the other chalcogens and with halogens to give CSSe, CSTe, and CSX_2. It is formed by action of a high-frequency discharge on CS_2 vapour. (See p. 319 for complexes of CS.) Passage of an electric discharge or arc through liquid or gaseous CS_2 yields C_3S_2, a red liquid mp −5°; it has a linear molecular structure, S=C=C=C=S, which polymerizes slowly at room temperature (cf. C_3O_2).[127]

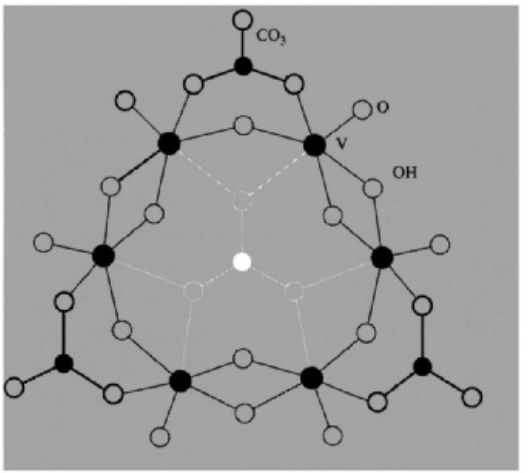

Figure 8.22 Perspective view of the hexanuclear anion $[(VO)_6(\mu_6\text{-}\eta^2,\eta^2,\eta^2\text{-}CO_3)(\mu\text{-}CO_3)_3(\mu\text{-}OH)_9]^{5-}$. Averaged interatomic distances: vanadyl V=O 161.6 pm, V-OH(*syn*) 195.6 pm, V-OH(*anti*) 201.2 pm, V-O (μ_2-CO_3) 200.2 pm, V-O (μ_6-CO_3) 228.7 pm, C-O(μ) 129.1 pm, C-O(*exo*) 126.6 pm.[126]

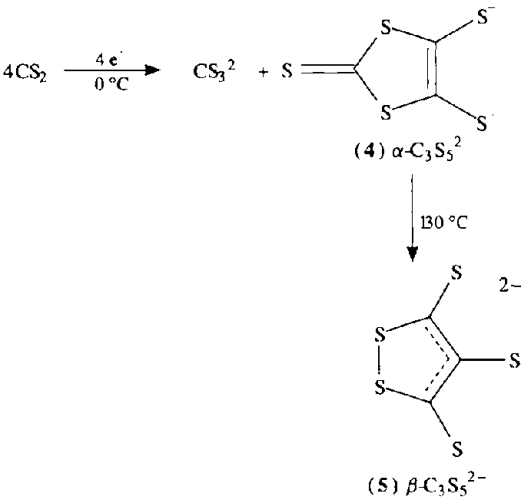
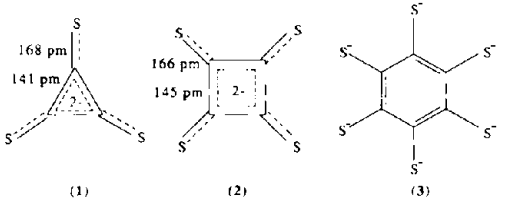
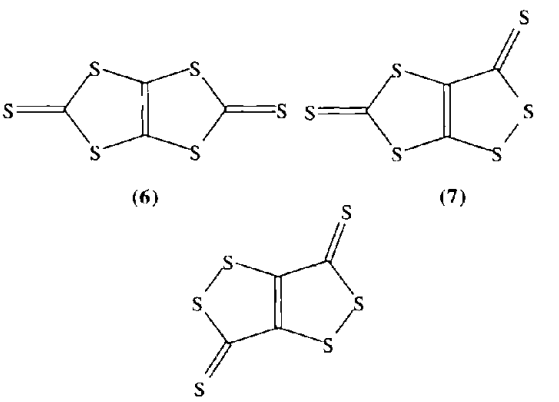
During the past decade there has been an astonishing proliferation of further binary carbon-sulfur species, both anionic and neutral.[128] Of the anions, the beige coloured dianion $C_3S_3^{2-}$ (made from tetrachlorocyclopropene) has the D_{3h} structure (1) and the yellow $C_4S_4^{2-}$ (made from squaric acid, p. 312) has the D_{4h} structure (2). The off-white $C_6S_6^{6-}$, (3), (made from C_6Cl_6) is air-sensitive but can readily be protonated to give the more stable hexathiol $C_6(SH)_6$. Reduction of CS_2 either electrochemically or by alkali metals yields $C_3S_5^{2-}$ which can exist in two isomeric forms, (4) and (5):



Treatment of the primary product with a zinc salt leads to separation of α-$C_3S_5^{2-}$ from its coproduct CS_3^{2-}, and multigram amounts of its complexes $[NR_4]_2[Zn(\alpha\text{-}C_3S_5)_2]$ and of the corresponding β-isomer's complexes afford convenient starting points for the synthesis of *molecular* binary sulfides as indicated below.

The sulfide C_4S_6 is known in three isomeric forms (6), (7) and (8).[128] The yellow-orange D_{2h} isomer (6) is readily prepared



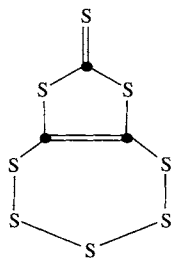


[128] C. P. GALLOWAY, T. B. RAUCHFUSS and X. YANG, in R. STEUDEL (ed.) *The Chemistry of Inorganic Ring Systems*, Studiecs in Inorganic Chemistry, Vol. 14, Elsevier, Amsterdam, 1992, pp. 25-34. See also X. YANG, T. B. RAUCHFUSS and S. R. WILSON, *J. Am. Chem. Soc.* **111**, 3465-6 (1989) and *J. Chem. Soc., Chem. Commun.*, 34-5 (1990).

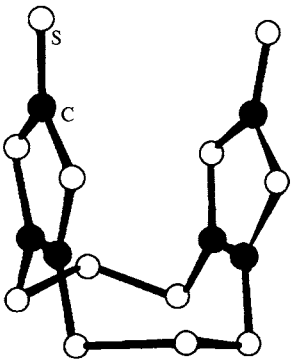
by the reaction of $CSCl_2$ with α-$C_3S_5^{2-}$, whilst the C_1 isomer (7) results from the corresponding reaction with β-$C_3S_5^{2-}$. The C_{2h} isomer (8) is less well characterized but is said to result from the reaction of hexachlorobutadiene, $CCl_2{=}CCl{-}CCl{=}CCl_2$, with polysulfide anions. The treatment of S_2Cl_2 with $[NBu_4]_2[Zn(\alpha\text{-}C_3S_5)_2]$ yields a mixture of C_3S_8 and C_6S_{12} which can be separated by fractional crystallization from CS_2:

$$[Zn(C_3S_5)_2]^{2-} + 2S_2Cl_2 \longrightarrow [ZnCl_4]^{2-} + 0.5C_6S_{12} + C_3S_8$$

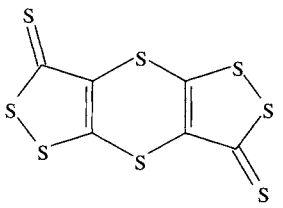
C_3S_8 is a bicyclic species composed of the α-C_3S_5 unit capped by a polysulfide linkage (9), whereas C_6S_{12} features two cisoid eclipsed planar α-C_3S_5 units conjoined by further sulfur linkages to form a third ring (10); note that, if each of the two C_2 groups in this 10-membered ring are notionally replaced by an S atom, the conformation of the resulting S_8 ring is reminiscent of the familiar crown configuration for this species (p. 655). Oxidation of $[NEt_4]_2[Zn(\beta\text{-}C_3S_5)_2]$ with $SOCl_2$ affords small amounts of the yellow C_6S_8 (11) which features an almost planar molecule with S···S fold angles <3.8°. By contrast, oxidation of $[NBu_4]_2[Zn(\alpha\text{-}C_3S_8)_2]$ with SO_2Cl_2 yields the orange dimer C_6S_{10} (12) in which the two planar C_3S_5 groups are interconnected by a pair of transoid S_2 linkages to give an overall chair configuration. Finally we should mention the two known isomers of C_9S_9. The simpler, formed by the reaction of $C_6S_6^{6-}$ (3) with $CSCl_2$, is the tris(trithiocarbonate) (13) which sublimes at 310° and can be recrystallized from 1,2-$C_6H_4Cl_2$. The second C_9S_9 isomer is synthesized by



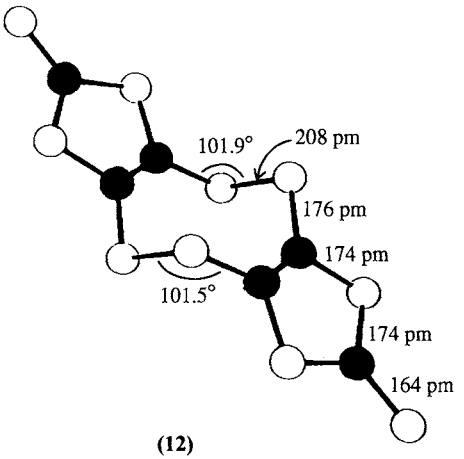
(9)



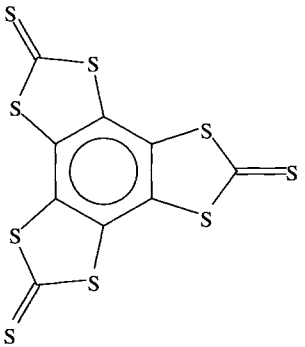
(10)



(11)

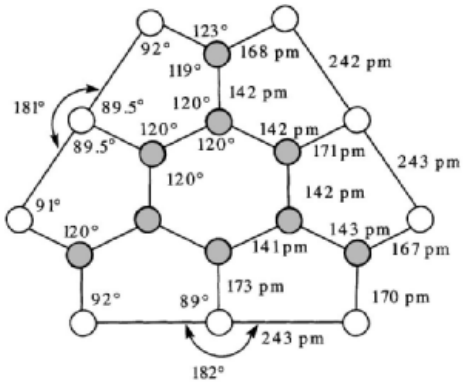


(12)



(13)

reaction of the benzene derivative 1,3,5-C_6Cl_3-2,4,6-$(CH_2NMe_2)_3$ with sulfur and H_2S in boiling quinoline; it forms red crystals of the planar D_{3h} molecule (14) which has a non-classical structure with three 3-coordinate S atoms. Both isomers are formally also oligomeric isomers of the diatomic monomer CS (p. 314).



(14)

By far the most important sulfide is CS_2, a colourless, volatile, flammable liquid (mp −111.6°, bp 46.25°, flash point −30°, auto-ignition temperature 100°, explosion limits in air 1.25–50%). Impure samples have a fetid almost nauseating stench due to organic impurities but the purified liquid has a rather pleasant ethereal smell; it is very poisonous and can have disastrous effects on the nervous system and brain. CS_2 was formerly manufactured by direct reaction of S vapour and coke in Fe or steel retorts at 750–1000°C but, since the early 1950s, the preferred synthesis has been the catalysed reaction between sulfur and natural gas:

$$CH_4 + 4S \xrightarrow[SiO_2 \text{ gel or } Al_2O_3]{\sim 600^\circ} CS_2 + 2H_2S$$

World production in 1991 was about 1 million tonnes the principal industrial uses being in the manufacture of viscose rayon (35–50%), cellophane films (15%) (see below), and CCl_4 (15–30%) depending on country. Indeed the CCl_4 application dropped to zero in USA in 1991 because of environmental concerns (p. 304).

CS_2 reacts with aqueous alkali to give a mixture of M_2CO_3 and the trithiocarbonate M_2CS_3. NH_3 gives ammonium dithiocarbamate $NH_4[H_2NCS_2]$; under more forcing conditions in the presence of Al_2O_3 the product is NH_4CNS and this can be isomerized at 160° to thiourea, $(NH_2)_2CS$. Water itself reacts only reluctantly, yielding COS at 200° and $H_2S + CO_2$ at higher temperatures; many other oxocompounds also convert CS_2 to COS, e.g. MgO, SO_3, HSO_3Cl and urea. With aqueous NaOH/EtOH carbon disulfide yields sodium ethyl dithiocarbonate (xanthate):

$$CS_2 + NaOH + EtOH \longrightarrow Na[SC(S)OEt]$$

When ethanol is replaced by cellulose, sodium cellulose xanthate is obtained; this dissolves in aqueous alkali to give a viscous solution (viscose) from which either viscose rayon or cellophane can be obtained by adding acid to regenerate the (reconstituted) cellulose. Trithiocarbonates (CS_3^{2-}), dithiocarbonates (COS_2^{2-}), xanthates (CS_2OR^-), dithiocarbamates ($CS_2NR_2^-$) and 1,2-dithiolates have an extensive coordination chemistry which has been reviewed.[129]

Chlorination of CS_2, when catalysed by Fe/$FeCl_3$, proceeds in two steps:

$$CS_2 + 3Cl_2 \longrightarrow CCl_4 + S_2Cl_2$$

$$CS_2 + 2S_2Cl_2 \longrightarrow CCl_4 + 6S$$

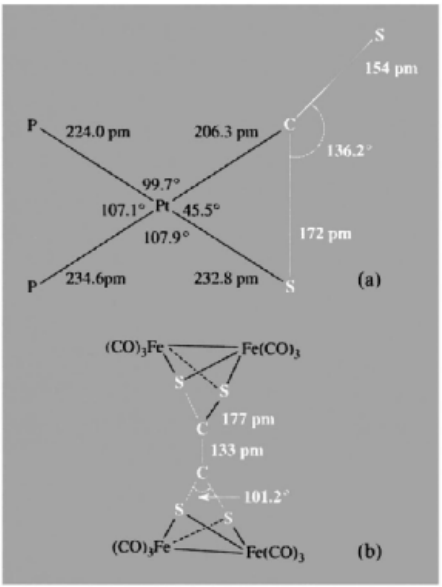
With I_2 as catalyst the main product is perchloromethylthiol (Cl_3CSCl). Reaction products with F_2 depend on the conditions used, typical products being SF_4, SF_6, S_2F_{10}, $F_2C(SF_3)_2$, $F_2C(SF_5)_2$, F_3CSF_5 and $F_3SCF_2SF_5$.

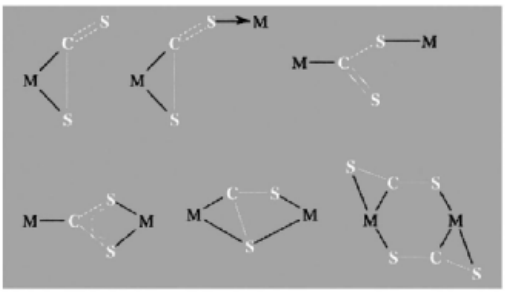
CS_2 is rather more reactive than CO_2 in forming complexes and in undergoing insertion reactions. The field was opened up by G. Wilkinson and his group in 1966 when they showed that $[Pt(PPh_3)_3]$ reacts rapidly and

[129] G. D. THORN and R. A. LUDWIG, *The Dithiocarbamates and Related Compounds*, Elsevier 1962, 298 pp. J. A. MCCLEVERTY, *Prog. Inorg. Chem.* **10**, 49–221 (1968) (188 refs.). D. COUCOUVANIS, *Prog. Inorg. Chem.* **11**, 233–71 (1970) (516 refs.). R. E. EISENBERG, *Prog. Inorg. Chem.* **12**, 295–369 (1971) (173 refs.).

quantitatively with CS_2 at room temperature to give orange needles of $[Pt(CS_2)(PPh_3)_2]$, mp 170°. X-ray crystal diffraction analysis revealed the structure shown diagramatically in Fig. 8.23(a). The geometry of the bent CS_2 ligand is similar to that in the first excited state of the molecule and the CS_2 is almost coplanar with PtP_2 (dihedral angle 6°). Bonding is considered to involve a 1-electron transfer via the intermediary of Pt from the highest filled π MO of the ligand to its lowest antibonding MO, and the Pt can be thought of as being oxidized from Pt^0 to Pt^{II}. However, the substantial difference between the two Pt-P distances and the wide deviation of the angles of Pt from 90° emphasize the inadequacy of describing the bonding of such complicated species in terms of simple localized bonding theory. The orange complex $[Pd(CS_2)(PPh_3)_2]$ is isostructural and further work yielded deep-green $[V(\eta^5\text{-}C_5H_5)_2(CS_2)]$, dimeric $[(Ph_3P)Ni(\mu\text{-}CS_2)_2Ni(PPh_3)]$ and various CS_2 complexes of Fe, Ru, Rh and Ir. The deep-red complex $[Rh(CS_2)_2Cl(PPh_3)_2]$ probably involves pseudo-octahedral Rh^{III} with one of the CS_2 ligands η^2-bonded as above and the other one σ-bonded via a single S atom. By contrast, reaction of $[Fe_3(CO)_{12}]$ with an excess of CS_2 in hexane for several hours at 80°C under a 10 atm pressure of CO/Ar gave the orange complex $[\{Fe_2(CO)_6\}_2(\mu_4\text{-}C_2S_4)]$ as one of the products (1–2%). As can be seen from Fig. 8.23(b), the structure has two $\{Fe_2(CO)_6\}$ units bridged by a planar $\{S_2C=CS_2\}$ group, which can in turn be regarded as an ethenetetrathiol moiety formed by the C–C coupling of two CS_2 molecules.[130]

The numerous η^1,η^2, and bridging modes of coordination now known for CS_2 are indicated schematically below:[131]





Insertion reactions of CS_2 are known for all the elements which undergo CO_2 insertion

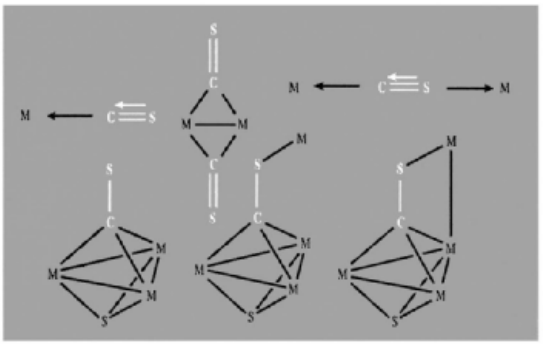
(p. 312) and also for M–N bonds involving Sb^{III}, Zr^{IV}, Nb^{V}, Ta^{V}, etc. Reaction of CS_2 with Au_2Cl_6 results in its novel insertion into Au–Cl bonds to form orange crystals of the chlorodithioformate complex $[AuCl_2(\eta^2\text{-}S_2CCl]$.[132] The parent dithioformate ligand, HCS_2^-, has been prepared by insertion of CS_2 into the Ru–H bond of $[RuH(CO)Cl(PPh_3)_2$(4-vinyl pyridine)] to form the yellow complex $[Ru(CO)Cl(PPh_3)_2(\eta^2\text{-}S_2CH)]$.thf.[133] Perhaps even more intriguingly, treatment of the orange *nido* 11-vertex metallathiaborane cluster [8,8-$(PPh_3)_2$-8,7-*nido*-$RhSB_9H_{10}$] (cf. structure (42), p. 178) with CS_2 under reflux gives a 37% yield of the pale orange *nido* cluster [8,8-$(PPh_3)_2$-μ-8,9-$(\eta^2\text{-}S_2CH)$-8,7-$RhSB_9H_9$] which features a unique dithioformate bridge between Rh(8)–B(9), perhaps by addition of $B\text{–}H_t(9)$ across a C=S bond.[134]

Stable thiocarbonyl complexes containing the elusive CS ligand are also now well established and known coordination modes, which include terminal, bridging and polyhapto, are as shown at the top of the next column.[135]

Likewise complexes of CSe and CTe have been characterized.[136] The structure and reactivity of



CS complexes has been well reviewed[137] and exciting work in this area continues.[138]

8.8 Cyanides and Other Carbon–Nitrogen Compounds

The chemistry of compounds containing the CN group is both extensive and varied. The types of compound to be discussed are listed in Table 8.7, which also summarizes some basic structural information. The names cyanide, cyanogen, etc., refer to the property of forming deep-blue pigments such as Prussian blue (p. 1094) with iron salts (Greek κύανος, *cyanos*, dark blue).

A useful theme for cohering much of the chemistry of compounds containing the CN group is the concept of pseudohalogens, a term introduced in 1925 for certain strongly bound, univalent radicals such as CN, OCN, SCN, SeCN, (and N_3, etc.). These groups can form anions X^-, hydracids HX, and sometimes neutral species X_2,

Table 8.7 Some compounds containing the CN group

Name	Conventional formula	r(C–N)/pm	Remarks[a]
Cyanogen	N≡C–C≡N	115	Linear; r(C–C) 138 pm (short)
Paracyanogen	$(CN)_x$	—	Involatile polymer, see text
diisocyanogen	CN–NC	118 (calc.)	Linear, symmetric, unstable[140]
isocyanogen	CN–CN	118&116 (calc.)	Zig-zag, unsymmetric, stable[140]
Hydrogen cyanide	H–C≡N	115.6	Linear; r(C–H) 106.5 pm
Cyanide ion	$(C{\equiv}N)^-$	116	r_{eff} 192 pm when "freely rotating" in MCN
Cyanides (nitriles)	M–C≡N (R–C≡N)	115.8	Linear; r(C–C) 146.0 pm (for MeCN)
Isocyanides	R–N≡C	116.7	Linear, $r(H_3C–N)$ 142.6 pm (for MeNC). Coordinated isocyanides are slightly bent, e.g. $[M(\leftarrow C{=}N–C_6H_5)_6]$ angle CNC 173°. r(C=N) 117.6 pm: bridging modes are also known, e.g. structure (1), p. 321
Cyanogen halides (halogen cyanides)	X–C≡N	116	Linear
Cyanamide	$H_2N–C{\equiv}N$	115	Linear NCN; $r(C–NH_2)$ 131 pm
Dicyandiamide	$N{\equiv}C–N{=}C(NH_2)_2$	122–136	See structure (2), p. 321
Cyanuric compounds	$\{–C(X){=}N–\}_3$	134	Cyclic trimers; X = halogen, OH, NH_2
Cyanate ion	$(O–C{\equiv}N)^-$	~121	Linear
Isocyanates	R–N=C=O	120	Linear NCO; ∠RNC ~ 126°
Fulminate ion	$>(C{=}N–O)^-$	109	Linear; another form of AgCNO has r(C–N) 112 pm
Thiocyanate ion	$(S–C{\equiv}N)^-$	115	Linear
Thiocyanates	R–S–C≡N (M–S–C≡N)	116	Linear NCS; ∠RSC 100° in MeSCN; ∠MSC variable (80–107°)
Isothiocyanates	R–N=C=S	122	Linear NCS; ∠HNC 135° in HNCS; ∠MNC variable (111–180°)
Selenocyanate ion	$(Se–C{\equiv}N)^-$	~112	Linear NCSe

[a] Several groups can also act as bridging ligands in metal complexes, e.g. –CN–, >NCO, –SCN–

XY, etc. It is also helpful to recognize that CN^- is isoelectronic with C_2^{2-} (p. 299) and with several notable ligands such as CO, N_2 and NO^+. Similarly, the cyanate ion OCN^- is isoelectronic with CO_2, N_3^-, fulminate (CNO^-), etc.[139]

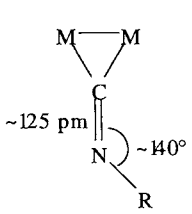
Cyanogen, $(CN)_2$, is a colourless poisonous gas (like HCN) mp −27.9°, bp −21.2° (cf. Cl_2, Br_2). When pure it possesses considerable thermal stability (800°C) but trace impurities normally facilitate polymerization at 300–500° to paracyanogen a dark-coloured solid which may have a condensed polycyclic structure (3).

The polymer reverts to $(CN)_2$ above 800° and to CN radicals above 850°. $(CN)_2$ can be prepared in 80% yield by mild oxidation of CN^- with aqueous Cu^{II}; the reaction is complex but can be idealized as

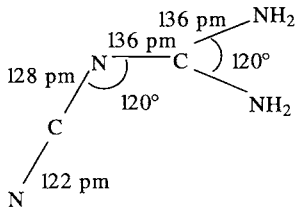
$$2CuSO_4 + 4KCN \xrightarrow{H_2O/60°} (CN)_2 + 2CuCN + 2K_2SO_4$$

[139] A. M. Golub, H. Köhler and V. V. Skopenko (eds.), *Chemistry of Pseudohalides*, Elsevier, Amsterdam, 1986, 479 pp., 4217 refs.

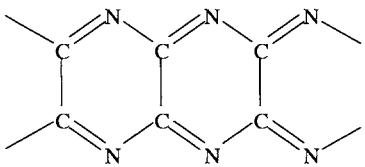
[140] L. S. Cederbaum, F. Tarantelli, H. G. Weikert, M. Scheller and H. Köppel, *Angew. Chem. Int. Edn. Engl.* **28**, 761–2 (1989).



(1)



(2)



(3)

CO_2 which is also formed (20%) can be removed by passage of the product gas over solid NaOH and the byproduct CuCN can be further oxidized with hot aqueous Fe^{III} to complete the conversion:

$$2CuCN + 2FeCl_3 \xrightarrow{H_2O/heat} (CN)_2 + 2CuCl + 2FeCl_2$$

Industrially it is now made by direct gas-phase oxidation of HCN with O_2 (over a silver catalyst), or with Cl_2 (over activated charcoal), or NO_2 (over CaO glass). $(CN)_2$ is fairly stable in H_2O, EtOH and Et_2O but slowly decomposes in solution to give HCN, HNCO, $(H_2N)_2CO$ and $H_2NC(O)C(O)NH_2$ (oxamide). Alkaline solutions yield CN^- and $(OCN)^-$ (cf. halogens).

$$(CN)_2 + 2OH^- \longrightarrow CN^- + OCN^- + H_2O$$

Hydrogen cyanide, mp −13.3° bp 25.7°, is an extremely poisonous compound of very high dielectric constant (p. 55). It is miscible with H_2O, EtOH and Et_2O. In aqueous solution it is an even weaker acid than HF, the dissociation constant K_a being 7.2×10^{-10} at 25°C. It was formerly produced industrially by acidifying NaCN or $Ca(CN)_2$ but the most modern catalytic processes are based on direct reaction between CH_4 and NH_3, e.g.:[141]

Andrussow process:

$$CH_4 + NH_3 + 1\tfrac{1}{2}O_2 \xrightarrow[2\text{ atm}/1000-1200^\circ]{Pt/Rh\text{ or }Pt/Ir} HCN + 3H_2O$$

Degussa process:

$$CH_4 + NH_3 \xrightarrow[1200-1300^\circ]{Pt} HCN + 3H_2$$

Both processes rely on a fast flow system and the rapid quenching of product gases; yields of up to 90% can be attained. It is salutory to note that US production of this highly toxic compound is 600 000 tonnes pa (1992) and world production exceeds one million tonnes pa. Of this, 41% is used to manufacture adiponitrile for nylon and 28% for acrylic plastics:

$$HCN + Me_2CO \longrightarrow \text{acetone cyanohydrin}$$

$$\xrightarrow{H_2SO_4} \text{methacrylamide sulfate} \xrightarrow{MeOH}$$

methyl methacrylate

HCN is now also used to make $(ClCN)_3$ for pesticides (9%), NaCN for gold recovery (13%), and chelating agents such as edta (4%), etc.

As noted above, $CN^-(aq)$ is fairly easily oxidized to $(CN)_2$ or OCN^-; E° values calculated from free energy data (p. 435) are:

$$\tfrac{1}{2}(CN)_2 + H^+ + e^- \rightleftharpoons HCN; \quad E^\circ + 0.37\text{ V}$$

$$OCN^- + 2H^+ + 2e^- \rightleftharpoons CN^- + H_2O; \quad E^\circ - 0.14\text{ V}$$

HCN can also be reduced to $MeNH_2$ by powerful reducing agents such as Pd/H_2 at 140°.

The alkali metal cyanides MCN are produced by direct neutralization of HCN; they crystallize

[141] Ref. 2, Vol. 7 (1993), Cyanides (including HCN, M^ICN, and $M^{II}(CN)_2$, pp. 753–82; Cyanamides including CaNCN, H_2NCN, dicyandiamide, and melamine), pp. 736–52; cyanuric and isocyanuric acids, pp. 834–51.

with the NaCl structure (M = Na, K, Rb) or the CsCl structure (M = Cs, Tl) consistent with "free" rotation of the CN^- group. The effective radius is ~190 pm, intermediate between those of Cl^- and Br^-. At lower temperatures the structures transform to lower symmetries as a result of alignment of the CN^- ions. LiCN differs in having a loosely packed 4-coordinate arrangement and this explains its low density (1.025 g cm^{-3}) and unusually low mp (160°, cf. NaCN 564°, KCN 634°C). World production of alkali metal cyanides was ~340 000 tonnes in 1989. NaCN readily complexes metallic Ag and Au under mildly oxidizing conditions and is much used in the extraction of these metals from their low-grade ores (first patented in 1888 by R. W. Forrest, W. Forrest and J. S. McArthur):

$$8NaCN + 4M + 2H_2O + O_2 \longrightarrow 4Na[M(CN)_2] + 4NaOH$$

Until the 1960s, when HCN became widely available, NaCN was made by the Castner process via sodamide and sodium cyanamide:

$$2Na + C + 2NH_3 \xrightarrow{750°} 2NaCN + 3H_2$$

The CN^- ion can act either as a monodentate or bidentate ligand.[142] Because of the similarity of electron density at C and N it is not usually possible to decide from X-ray data whether C or N is the donor atom in monodentate complexes, but in those cases where the matter has been established by neutron diffraction C is always found to be the donor atom (as with CO). Very frequently CN acts as a bridging ligand -CN- as in AgCN, and AuCN (both of which are infinite linear chain polymers), and in Prussian-blue type compounds (p. 1094). The same tendency for a coordinated M CN group to form a further donor–acceptor bond using the lone-pair of electrons on the N atom is illustrated by the mononuclear BF_3 complexes with tetracyanonickelates and hexacyanoferrates, e.g. $K_2[Ni(CN.BF_3)_4]$ and $K_4[Fe(CN.BF_3)_6]$.

The complex $CuCN.NH_3$ provides an unusual example of CN acting as a bridging ligand at C, a mode which is common in μ-CO complexes (p. 928); indeed, the complex is unique in featuring tridentate CN groups which link the metal atoms into plane nets via the grouping Cu, Cu >C–N–Cu as shown in Fig. 8.24. Other cyanide complexes are discussed under the appropriate metals. In organic chemistry, both nitriles R–CN and isonitriles (isocyanides) R–NC are known. Isocyanides have been extensively studied as ligands (p. 926).[143] More

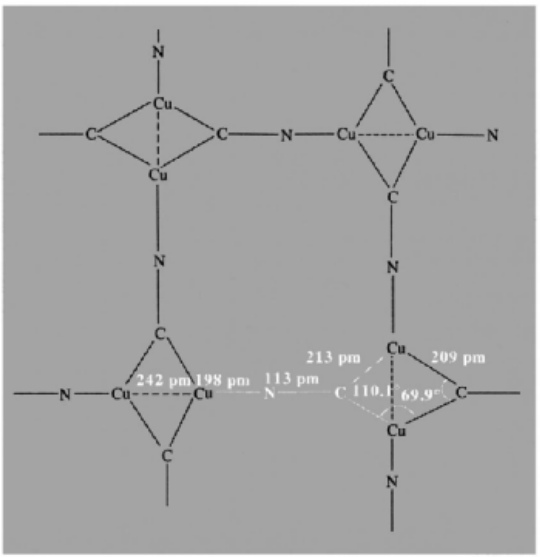


Figure 8.24 Schematic diagram of the layer structure of $CuCN.NH_3$ showing the tridentate CN groups; each Cu is also bonded to 1 NH_3 molecule at 207 pm. Note also the unusual 5-coordination of Cu including one near neighbour Cu at 242 pm (13 pm closer than Cu–Cu in the metal). The lines in the diagram delineate the geometry and do not represent pairs of electrons.

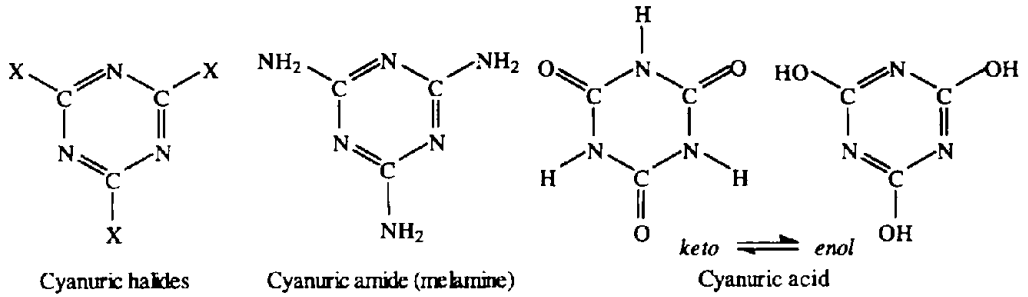

Figure 8.25 The planar structure of various cyanuric compounds: all 6 C–N distances within the ring are equal.

complex coordination modes are now also well documented for CN , RCN and RNC.[144]

Cyanogen halides, X CN, are colourless, volatile, reactive compounds which can be regarded as pseudohalogen analogues of the interhalogen compounds, XY (p. 824) (Table 8.8). All tend to trimerize to give cyclic cyanuric halides (Fig. 8.25) especially in the presence of free HX. FCN is prepared by pyrolysis of $(FCN)_3$ which in turn is made by fluorinating $(ClCN)_3$ with NaF in tetramethylene sulfone. ClCN and BrCN are prepared by direct reaction of X_2 on MCN in water or CCl_4, and ICN is prepared by a dry route from $Hg(CN)_2$ and I_2. Similarly, colourless crystals of cyanamide (H_2NCN mp 46°) result from the reaction of NH_3 on ClCN and trimerize to melamine at 150° (Fig. 8.25). The industrial preparation is by acidifying CaNCN (see Panel). The "dimer", dicyandiamide, $CNC(NH_2)_2$, can be made by boiling calcium cyanamide with water: the colourless crystals are composed of nonlinear molecules which feature three different C N distances (see Table 8.7).

The hydroxyl derivative of X–CN is cyanic acid HO–CN: it cannot be prepared pure due to rapid decomposition but it is probably present to the extent of about 3% when its tautomer, isocyanic acid (HNCO) is prepared from sodium cyanate and HCl. HNCO rapidly trimerizes to cyanuric acid (Fig. 8.25) from which it can be regenerated by pyrolysis. It is a fairly strong acid (K_a 1.2×10^{-4} at 0°) freezing at −86.8° and boiling at 23.5°C. Thermolysis of urea is an alternative route to HNCO and $(HNCO)_3$; the reverse reaction, involving the isomerization of ammonium cyanate, is the classic synthesis of urea by F. Wöhler (1828).[145]

Table 8.8 Cyanogen halides

Property	FCN	ClCN	BrCN	ICN
MP/°C	−82	−6.9	51.3	146

The Cyanamide Industry[141]

The basic chemical of the cyanamide industry is calcium cyanamide CaNCN, mp 1340°, obtained by nitrogenation of CaC_2.

$$CaC_2 + N_2 \xrightarrow{1000°} CaNCN + C$$

CaNCN is used as a direct application fertilizer, weed killer, and cotton defoliant; it is also used for producing cyanamide, dicyandiamide and melamine plastics. Production formerly exceeded 1.3 million tonnes pa, but this has fallen considerably in the last few years, particularly in the USA where the use of CaNCN as a nitrogenous fertilizer has been replaced by other materials. In 1990 most of the world's supply was made in Japan, Germany and Canada.

Acidification of CaNCN yields free cyanamide, H_2NCN, which reacts further to give differing products depending on pH: at pH ≤ 2 or >12 urea is formed, but at pH 7–9 dimerization to dicyandiamide $NCNC(NH_2)_2$ occurs. Solutions are most stable at pH ~ 5; accordingly commercial preparation of H_2NCN is by continuous carbonation of an aqueous slurry of CaNCN in the presence of graphite: the overall reaction can be represented

$$CaNCN + CO_2 + H_2O \longrightarrow H_2NCN + CaCO_3$$

Reaction of H_2NCN with H_2S gives thiourea, $SC(NH_2)_2$.

Dicyandiamide forms white, non-hygroscopic crystals which melt with decomposition at 209°. Its most important reaction is conversion to melamine (Fig. 8.25) by pyrolysis above the mp under a pressure of NH_3 to counteract the tendency to deammonation. Melamine is mainly used for melamine-formaldehyde plastics. Total annual production of both H_2NCN and $NCNC(NH_2)_2$ is on the 30 000 tonne scale.

Several of these compounds and their derivatives are commercially and industrially important. Urea has already been mentioned on p. 311. Again, world production of chloroisocyanurates, $(ClNC{=}O)_3$, in 1987 was ca. 80 000 tonnes (50 000 tonnes in USA alone, of which 75% went for swimming pool disinfection and most of the rest for scouring powders, household bleaches and dishwashing powder formulations).[141]

Alkali metal cyanates are stable and readily obtained by mild oxidation of aqueous cyanide solutions using oxides of Pb^{II} or Pb^{IV}. The commercial preparation of NaNCO is by reaction of urea with Na_2CO_3.

$$Na_2CO_3 + 2OC(NH_2)_2 \xrightarrow[\text{(dry)}]{\text{heat}} 2NaNCO + CO_2 + 2NH_3 + H_2O$$

The pseudohalogen concept (p. 319) might lead one to expect the existence of a cyanate analogue of cyanogen but there is little evidence for NCO–OCN, consistent with the known reluctance of oxygen to catenate. By contrast, thiocyanogen $(SCN)_2$ is moderately stable; it can be prepared as white crystals by suspending AgSCN in Et_2O or SO_2 and oxidizing the anion at low temperatures with Br_2 or I_2. $(SCN)_2$ melts at $\sim -7°$ to an unstable orange suspension which rapidly polymerizes to the brick-red solid parathiocyanogen $(SCN)_x$.[146] This ready polymerization hampers structural studies but it is probable that the molecular structure is N≡C–S–S–C≡N with a nonlinear central C–S–S–C group. $(SeCN)_2$ can be prepared similarly as a yellow powder which polymerizes to a red solid.

Thiocyanates and selenocyanates can be made by fusing the corresponding cyanide with S or Se. The SCN^- and $SeCN^-$ ions are both linear, like OCN^-. (See p. 779 for $TeCN^-$) Treatment of KSCN with dry $KHSO_4$ produces free isothiocyanic acid HNCS, a white crystalline solid which is stable below 0° but which decomposes rapidly at room temperatures to HCN and a yellow solid $H_2C_2N_2S_3$. Thiocyanic acid, HSCN, (like HOCN) has not been prepared

Table 8.9 Modes of bonding established by X-ray crystallography

Mode	Example	Comment
Ag–NCO	$[AsPh_4][Ag(NCO)_2]$	Linear anion
Mo–OCN	$[Mo(OCN)_6]^{3-}$, $[Rh(OCN)(PPh_3)_3]$	Based on infrared data only
	AgNCO	Cf. fulminate in Table 8.7
	$[Ni_2(NCO)_2\{N(CH_2CH_2NH_2)_3\}_2][BPh_4]_2$	Note bent Ni···N–C
Co–NCS Co–SCN	$[Co(NH_3)_5(NCS)]Cl_2$ $[Co(NH_3)_5(SCN)]Cl_2$	Linkage isomerism
Pd–NCS SCN	$[Pd(NCS)(SCN)\{Ph_2P(CH_2)_3PPh_2\}]$	Both *N* and *S* monodentate in a single crystal
	$K_2[Pd(SCN)_4]$	Weak *S* bridging to a second Pd
	$[NBu^n_4]_3[Re_2(NCS)_{10}]$	*N*-bonded bridging (and terminal)[154]
Co–NCS–Hg	$[Co(NCS)_4Hg]$	Bidentate, different metals
	$[Pt_2(Cl)_2(PPr_3)_2(SCN)_2]$	Bidentate, same metal
	Ph_2SbSCN	Spiral chain polymer[149]
	$[Co(NCS)_6Hg_2]\cdot C_6H_6$	Tridentate
Ni–NCSe	$[Ni(HCONMe_2)_4(NCSe)_2]$	*N* donor
Co–SeCN	$K[Co(Me_2glyoxime)_2(SeCN)_2]$	*Se* donor

pure but compounds such as MeSCN and $Se(SCN)_2$ are known.

The thiocyanate ion has been much studied as an ambidentate ligand (in which either S or N is the donor atom); it can also act as a bidentate bridging ligand –SCN–, and even as a tridentate ligand >SCN–.[147,148,149] The ligands OCN^- and $SeCN^-$ have been less studied but appear to be generally similar. A preliminary indication of the mode of coordination can sometimes be obtained from vibrational spectroscopy since *N* coordination raises both ν(CN) and ν(CS) relative to the values of the uncoordinated ion, whereas *S* coordination leaves ν(CN) unchanged and increases ν(CS) only somewhat. The bridging mode tends to increase both ν(CN) and ν(CS). Similar trends are noted for OCN^- and $SeCN^-$ complexes. However, these "group vibrations" are in reality appreciably mixed with other modes both in the ligand itself and in the complex as a whole, and vibrational spectroscopy is therefore not always a reliable criterion. Increasing use is being made of ^{14}N and ^{13}C nmr data[150] but the most reliable data, at least for crystalline complexes, come from X-ray diffraction studies.[151] The variety of coordination modes so revealed is illustrated in Table 8.9, which is based on one by A. H. Norbury.[147] Phenomenologically it is observed that class a metals tend to be *N*-bonded whereas class b tend to be *S*-bonded (see below), though it should be stressed that kinetic and solubility factors as well as relative thermodynamic stability are sometimes implicated, and so-called 'linkage isomerism" is well established, e.g. $[Co(NH_3)_5(NCS)]Cl_2$ and $[Co(NH_3)_5(SCN)]Cl_2$. In terms of the a and b (or "hard" and "soft") classification of ligands and acceptors it is noted that metals in Groups 3–8 together with the lanthanoids and actinoids tend to form –NCS complexes; in the later transition groups Co, Ni, Cu and Zn also tend to form –NCS complexes whereas their heavier congeners Rh, Ir; Pd, Pt; Au; and Hg are predominantly *S*-bonded. Ag and Cd are intermediate and readily form both types of complex. See also refs. 152, 153. The interpretation to be placed on these observations is less certain. Steric influences have been mentioned (*N* bonding, which is usually linear, requires less space than the bent M–S–CN mode). Electronic factors also play a role, though the detailed nature of the bonding is still a matter of debate and devotees of the various types of electronic influence have numerous interpretations to select from. Solvent effects (dielectric constant ε, coordinating power, etc.) have also been invoked and it is clear that these various explanations are not mutually exclusive but simply tend to emphasize differing aspects of an extremely complicated and delicately balanced situation. The interrelation of these various interpretations is summarized in Table 8.10.

Table 8.10 Mode of bonding in thiocyanate complexes

Metal type[a]	σ-Donor ligand	High-ε solvent	Low-ε solvent	π-Acceptor ligand
Class a	–NCS	–NCS	–SCN	–SCN
Class b	–SCN	–SCN	–NCS	–NCS

[a]Sometimes discussed in terms of "hard" and "soft" acids and bases.

Fewer data are available for $SeCN^-$ complexes but similar generalizations seem to hold. By contrast, OCN^- complexes are not so readily discussed in these terms: in fact, very few cyanato

(–OCN) complexes have been characterized and the ligand is usually *N*-bonded (isocyanato).[151]

8.9 Organometallic Compounds

Compounds which contain direct M–C bonds comprise a vast field which spans the traditional branches of inorganic and organic chemistry. A general overview is given in Section 19.7 (p. 924) and specific aspects are treated separately under the chemistry of each individual element, e.g. alkali metals (pp. 102–6), alkaline earth metals (pp. 127–38), Group 13 metals (pp. 257–67) etc. In addition to the references cited on p. 924, useful general accounts can be found in refs. 155–160.

9 Silicon

9.1 Introduction

Silicon shows a rich variety of chemical properties and it lies at the heart of much modern technology.[1] Indeed, it ranges from such bulk commodities as concrete, clays and ceramics, through more chemically modified systems such as soluble silicates, glasses and glazes to the recent industries based on silicone polymers and solid-state electronics devices. The refined technology of ultrapure silicon itself is perhaps the most elegant example of the close relation between chemistry and solid-state physics and has led to numerous developments such as the transistor, printed circuits and microelectronics (p. 332).

In its chemistry, silicon is clearly a member of Group 14 of the periodic classification but there are notable differences from carbon, on the one hand, and the heavier metals of the group on the other (p. 371). Perhaps the most obvious questions to be considered are why the vast covalent chemistry of carbon and its organic compounds finds such pallid reflection in the chemistry of silicon, and why the intricate and complex structural chemistry of the mineral silicates is not mirrored in the chemistry of carbon–oxygen compounds.†

Silica (SiO_2) and silicates have been intimately connected with the evolution of mankind from prehistoric times: the names derive from the Latin *silex*, gen. *silicis*, flint, and serve as a reminder of the simple tools developed in paleolithic times (~500 000 years ago) and the shaped flint knives and arrowheads of the neolithic age which began some 20 000 years ago. The name of the element, silicon, was proposed by Thomas Thomson in

[1] *Kirk–Othmer Encyclopedia of Chemical Technology*, 3rd edn., Vol. 20, pp. 748–973 (1982) (Silica, silicon and silicon alloys; Silicon compounds); 4th edn., Vol. 5 (1993) Cement pp. 564–98; Ceramics, pp. 599–697; Ceramics as electrical materials, pp. 698–728; Clays, Vol. 6, pp. 381–423 (1993).

† Throughout this chapter we will notice important differences between the chemical behaviour of carbon and silicon, and one is reminded of Grant Urry's memorable words: "It is perhaps appropriate to chide the polysilane chemist for milking the horse and riding the cow in attempting to adapt the success of organic chemistry in the study of polysilanes. A valid argument can be made for the point of view that the most effective chemistry of silicon arises from the differences with the chemistry of carbon compounds rather than the similarities" (see ref. 35 on p. 342).

1831, the ending *on* being intended to stress the analogy with carbon and boron.

The great affinity of silicon for oxygen delayed its isolation as the free element until 1823 when J. J. Berzelius succeeded in reducing K_2SiF_6 with molten potassium. He first made $SiCl_4$ in the same year, SiF_4 having previously been made in 1771 by C. W. Scheele who dissolved SiO_2 in hydrofluoric acid. The first volatile hydrides were discovered by F. Wöhler who synthesized $SiHCl_3$ in 1857 and SiH_4 in 1858, but major advances in the chemistry of the silanes awaited the work of A. Stock during the first third of the twentieth century. Likewise, the first organosilicon compound $SiEt_4$ was synthesized by C. Friedel and J. M. Crafts in 1863, but the extensive development of the field was due to F. S. Kipping in the first decades of this century.[2] The unique properties and industrial potential of siloxanes escaped attention at that time and the dramatic development of silicone polymers, elastomers, and resins has occurred during the past 50 years (p. 365).

The solid-state chemistry of silicon has shown similar phases. The bizarre compositions derived by analytical chemistry for the silicates only became intelligible following the pioneering X-ray structural work of W. L. Bragg in the 1920s[3] and the concurrent development of the principles of crystal chemistry by L. Pauling[4] and of geochemistry by V. M Goldschmidt.[5] More recently the complex crystal chemistry of the silicides has been elucidated and the solid-state chemistry of doped semiconductors has been developed to a level of sophistication that was undreamt of even in the 1960s.

9.2 Silicon

9.2.1 Occurrence and distribution

Silicon (27.2 wt%) is the most abundant element in the earth's crust after oxygen (45.5%), and together these 2 elements comprise 4 out of every 5 atoms available near the surface of the globe. This implies that there has been a substantial fractionation of the elements during the formation of the solar system since, in the universe as a whole, silicon is only seventh in order of abundance after H, He, C, N, O and Ne (p. 4). Further fractionation must have occurred within the earth itself: the core, which has 31.5% of the earth's mass, is commonly considered to have a composition close to $Fe_{25}Ni_2Co_{0.1}S_3$; the mantle (68.1% of the mass) probably consists of dense oxides and silicates such as olivine $(Mg,Fe)_2SiO_4$, whereas the crust (0.4% of the mass) accumulates the lighter siliceous minerals which "float" to the surface. The crystallization of igneous rocks from magma (molten rock, e.g. lava) depends on several factors such as the overall composition, the lattice energy, mp and crystalline complexity of individual minerals, the rate of cooling, etc. This has been summarized by N. L. Bowen in a reaction series which gives the approximate sequence of appearance of crystalline minerals as the magma is cooled: olivine $[M^{II}_2SiO_4]$, pyroxene $[M^{II}_2Si_2O_6]$, amphibole $[M^{II}_7\{(Al,Si)_4O_{11}\}(OH)_2]$, biotite mica $[(K,H)_2(Mg,Fe)_2(Al,Fe)_2(SiO_4)_3]$, orthoclase feldspar $[KAlSi_3O_8]$, muscovite mica $[KAl_2(AlSi_3O_{10}(OH)_2]$, quartz $[SiO_2]$, zeolites and hydrothermal minerals. The structure of these mineral types is discussed later (p. 347), but it is clear that the reaction series leads to progressively more complex silicate structural units and that the later part of the series is characterized by the introduction of OH (and F) into the structures. Extensive isomorphous substitution among the metals is also possible. Subsequent weathering, transport and deposition leads to sedimentary rocks such as clays, shales and sandstones. Metamorphism at high temperatures and pressures can effect further

changes during which the presence or absence of water plays a vital role.[6,7]

Silicon never occurs free: it invariably occurs combined with oxygen and, with trivial exceptions, is always 4-coordinate in nature. The $\{SiO_4\}$ unit may occur as an individual group or be linked into chains, ribbons, rings, sheets or three-dimensional frameworks (pp. 347–59).

9.2.2 Isolation, production and industrial uses

Silicon (96–99% pure) is now invariably made by the reduction of quartzite or sand with high purity coke in an electric arc furnace; the SiO_2 is kept in excess to prevent the accumulation of SiC (p. 334):

$$SiO_2 + 2C = Si + 2CO;$$

$$2SiC + SiO_2 = 3Si + 2CO$$

The reaction is frequently carried out in the presence of scrap iron (with low P and S content) to produce ferrosilicon alloys: these are used in the metallurgical industry to deoxidize steel, to manufacture high-Si corrosion-resistant Fe, and Si/steel laminations for electric motors. The scale of operations can be gauged from the 1980 world production figures which were in excess of 5 megatonnes. Consumption of high purity (semiconductor grade) Si leapt from less than 10 tonnes in 1955 to 2800 tonnes in 1980.

Silicon for the chemical industry is usually purified to ~98.5% by leaching the powdered 96–97% material with water. Very pure Si for semiconductor applications is obtained either from $SiCl_4$ (made from the chlorination of scrap Si) or from $SiHCl_3$ (a byproduct of the silicone industry, p. 338). These volatile compounds are purified by exhaustive fractional distillation and then reduced with exceedingly pure Zn or Mg; the resulting spongy Si is melted, grown into cylindrical single crystals, and then purified by zone refining. Alternative routes are the thermal decomposition of SiI_4/H_2 on a hot tungsten filament (cf. boron, p. 140), or the epitaxial growth of a single-crystal layer by thermal decomposition of SiH_4. A one-step process has also been developed to produce high-purity Si for solar cells at one-tenth of the cost of rival methods. In this process Na_2SiF_6 (which is a plentiful waste product from the phosphate fertilizer industry) is reduced by metallic Na; the reaction is highly exothermic and is self-sustaining without the need for external fuel.

Hyperfine Si is one of the purest materials ever made on an industrial scale: the production of transistors (p. 332) requires the routine preparation of crystals with impurity levels below 1 atom in 10^{10}, and levels below 1 atom in 10^{12} can be attained in special cases.

9.2.3 Atomic and physical properties

Silicon consists predominantly of ^{28}Si (92.23%) together with 4.67% ^{29}Si and 3.10% ^{30}Si. No other isotopes are stable. The ^{29}Si isotope (like the proton) has a nuclear spin $I = \frac{1}{2}$, and is being increasingly used in nmr spectroscopy.[8] ^{31}Si, formed by neutron irradiation of ^{30}Si, has $t_{\frac{1}{2}}$ 2.62 h; it can be detected by its characteristic β^- activity (E_{max} 1.48 MeV) and is very useful for the quantitative analysis of Si by neutron activation. The radioisotope with the longest half-life (~172 y) is the soft β^- emitter ^{32}Si (E_{max} 0.2 MeV).

In its ground state, the free atom Si has the electronic configuration $[Ne]3s^23p^2$. Ionization energies and other properties are compared with those of the other members of Group 14 on p. 372. Silicon crystallizes in the diamond

lattice (p. 275) with a_0 543.10204 pm at 25°, corresponding to an Si–Si distance of 235.17 pm and a covalent atomic radius of 117.59 pm. The density and lattice constant of pure single-crystal Si are now known sufficiently accurately to give a direct value of the Avogadro constant ($N_A = 6.022\,1367 \times 10^{23}\,\text{mol}^{-1}$) which is as precise as the best currently accepted value ($6.022\,1367 \times 10^{23}\,\text{mol}^{-1}$).[9] There appear to be no allotropes of Si at ambient pressure but the 4-coordinate diamond lattice of Si–I transforms to several other modifications at higher pressures, of which distorted-diamond Si–II, primitive hexagonal Si–V and eventually hexagonal close packed Si–VII may be mentioned; the structural sequence corresponds to a systematic increase in coordination number:[10]

$$4(\text{Si–I}) \xrightarrow{8.8\ \text{GPa}} 6(\text{Si–II}) \xrightarrow{16\ \text{GPa}} 8(\text{Si–V}) \xrightarrow{\sim 40\ \text{GPa}} 12(\text{Si–VII})$$

[1 GPa = 10 kbar ≈ 9869 atm.]

Physical properties are summarized in Table 9.1 (see also p. 373). Silicon is notably more volatile than C and has a substantially lower energy of vaporization, thus reflecting the smaller Si–Si bond energy. The element is a semiconductor with a distinct shiny, blue-grey metallic lustre; the resistivity decreases with increase of temperature, as expected for a semiconductor. The actual value of the resistivity depends markedly on purity but is ~40 ohm cm at 25° for very pure material.

Table 9.1 Some physical properties of silicon

MP/°C	1420
BP/°C	~3280
Density (20°C)/g cm^{-3}	2.53259
ΔH_{fus}/kJ mol^{-1}	50.6 ± 1.7
ΔH_{vap}/kJ mol^{-1}	383 ± 10
ΔH_{f} (monatomic gas)/kJ mol^{-1}	454 ± 12

[10] H. OLIJNYK, S. K. SIKKA and W. B. HOLZAPFEL, *Phys. Lett.* **103A**, 137–40 (1984).

The immense importance of Si in transistor technology stems from the chance discovery of the effect in Ge at Bell Telephone Laboratories, New Jersey, in 1947, and the brilliant theoretical and practical development of the device by J. Bardeen, W. H. Brattain and W. Shockley for which they were awarded the 1956 Nobel Prize for Physics. A brief description of the physics and chemistry underlying transistor action in Si is given in the Panel (p. 332).

9.2.4 Chemical properties

Silicon in the massive, crystalline form is relatively unreactive except at high temperatures. Oxygen, water and steam all have little effect probably because of the formation of a very thin, continuous, protective surface layer of SiO_2 a few atoms thick (cf. Al, p. 224). Oxidation in air is not measurable below 900°; between 950° and 1160° the rate of formation of vitreous SiO_2 rapidly increases and at 1400° the N_2 in the air also reacts to give SiN and Si_3N_4. Sulfur vapour reacts at 600° and P vapour at 1000°. Silicon is also unreactive towards aqueous acids, though the aggressive mixture of conc HNO_3/HF oxidizes and fluorinates the element. Silicon dissolves readily in hot aqueous alkali due to reactions of the type $Si + 4OH^- = SiO_4^{4-} + 2H_2$. Likewise, the thin film of SiO_2 is no barrier to attack by halogens, F_2 reacting vigorously at room temperature, Cl_2 at ~300°, and Br_2, I_2 at ~500°. Even alkyl halides will react at elevated temperatures and, in the presence of Cu catalysts, this constitutes the preferred "direct" synthesis of organosilicon chlorides for the manufacture of silicones (p. 364).

In contrast to the relative inertness of solid Si to gaseous and liquid reagents, molten Si is an extremely reactive material: it forms alloys or

The Physics and Chemistry of Transistors

In ultrapure semiconductor grade Si there is an energy gap E_g between the highest occupied energy levels (the valence band) and the lowest unoccupied energy levels (the conduction band). This is shown diagrammatically in Fig. a: the valence band is completely filled, the conduction band is empty, the Fermi level (E_F), which is the energy at which the chance of a state being occupied by an electron is $\frac{1}{2}$, lies approximately midway between these, and the material is an insulator at room temperature. If the Si is doped with a Group 15 element such as P, As or Sb, each atom of dopant introduces a supernumerary electron and the impurity levels can act as a source of electrons which can be thermally or photolytically excited into the conduction band (Fig. b): the material is an n-type semiconductor with an activation energy ΔE_n (where n indicates negative current carriers, i.e. electrons). Conversely, doping with a Group 13 element such as B, Al or Ga introduces acceptor levels that can act as traps for electrons excited from the filled valence band (Fig. c): the material is a p-type semiconductor and the current is carried by the positive holes in the valence band.

When an n-type sample of Si is joined to a p-type sample, a p–n junction is formed having a common Fermi level as in Fig. d: electrons will flow from n to p and holes from p to n thereby producing a voltage drop V_0 across the space charge region. A p–n junction can thus act as a diode for rectifying alternating current, the current passing more easily in one direction than the other. In practise a large p–n junction might cover $10\,mm^2$, whereas in integrated circuits such a device might cover no more than $10^{-4}\,mm^2$ (i.e. a square of side $10\,\mu m$).

A transistor, or n–p–n junction, is built up of two n-type regions of Si separated by a thin layer of weakly p-type (Fig. e). When the emitter is biased by a small voltage in the forward direction and the collector by a larger voltage in the reverse direction, this device acts as a triode amplifier. The relevant energy level diagram is shown schematically in Fig. f.

The large-scale reproducible manufacture of minute, electronically-stable, single-crystal transistor junctions is a triumph of the elegant techniques of solid-state chemical synthesis. The sequence of steps is illustrated in diagrams (i)–(v).

(i) A small wafer of single-crystal n-type Si is oxidized by heating it in O_2 or H_2O vapour to form a thin surface layer of SiO_2.
(ii) The oxide coating is covered by a photosensitive film called "photoresist".
(iii) A mask is placed over the photoresist to confine the exposure to the desired pattern and the chip is exposed to ultraviolet light; the exposed photoresist is then removed by treatment with acid, leaving a tough protective layer over the parts of the oxide coating that are to be retained.
(iv) The unprotected areas of Si are etched away with hydrofluoric acid and the remaining photoresist is also removed.
(v) The surface is exposed to the vapour of a Group 13 element and the impurity atoms diffuse into the unprotected area to form a layer of p-type Si.
(vi) Steps (i)–(v) are repeated, with a different mask, and then the newly exposed areas are treated with the vapour of a Group 15 element to produce a patterned layer of n-type Si.
(vii) Finally, again with a different mask, the surface is reoxidized and then re-etched to produce openings into which metal is deposited so as to connect the n- and p-regions into an integrated circuit.

Each individual p–n diode or n–p–n transistor can be made almost unbelievably minute by these techniques; for example computer memory units storing over 10^5 bits of information on a single small chip are routinely used. Further information can be obtained from textbooks of solid-state physics or electronic engineering.

silicides with most metals (see below) and rapidly reduces most metal oxides because of the very large heat of formation of SiO_2 ($\sim 900\,kJ\,mol^{-1}$). This presents problems of containment when working with molten Si, and crucibles must be made of refractories such as ZrO_2 or the borides of transition metals in Groups 4–6 (p. 146).

Chemical trends within Group 14 are discussed on p. 373. Silicon does not form binary compounds with the heavier members of the group (Ge, Sn, Pb) but its compound with carbon, SiC, is of outstanding academic and practical interest, and is manufactured on a huge scale industrially (see Panel on p. 334).

In the vast majority of its compounds Si is tetrahedrally coordinated but sixfold coordination also occurs, and occasional examples of other coordination geometries are known as indicated in Table 9.2 (p. 335). Unstable 2-coordinate Si has been known for many years but in 1994 the stable, colourless, crystalline silylene [:SiNBu^{t}CH=CHNBu^t], structure (1), p. 336, was

Silicon Carbide, SiC[11,12]

Silicon carbide was made accidently by E. G. Acheson in 1891; he recognized its abrasive power and coined the name "carborundum" from carbo(n) and (co)rundum (Al_2O_3) to indicate that its hardness on the Mohs scale (9.5) was intermediate between that of diamond (10) and Al_2O_3 (9). Within months he had formed the Carborundum Co. for its manufacture, and current world production approaches 1 million tonnes annually.

Despite its simple formula, SiC exists in at least 200 crystalline modifications based on hexagonal α-SiC (wurtzite-type ZnS, p. 1210) or cubic β-SiC (diamond or zincblende-type, p. 1210). The complexity arises from the numerous stacking sequences of the *a* and *b* "layers" in the crystal.[13] The α-form is marginally the more stable thermodynamically. Industrially, α-SiC is obtained as black, dark green or purplish iridescent crystals by reducing high-grade quartz sand with a slight excess of coke or anthracite in an electric furnace at 2000–2500°C:

$$SiO_2 + 2C \longrightarrow Si + 2CO; \quad Si + C \longrightarrow SiC$$

The dark colour is caused by impurities such as iron, and the iridescence is due to a very thin layer of SiO_2 formed by surface oxidation. Purer samples are pale yellow or colourless. Even higher temperatures (and vacuum conditions) are required to produce the β-form. Alternatively, very pure β-SiC can be obtained by heating grains of ultrapure Si with graphite at 1500° or by gas-phase plasma decomposition of Me_2SiCl_2, $MeSiCl_3$ or $SiCl_4/CH_4$ mixtures. Fibres of SiC are made by the progressive pyrolysis of organosilicon polymers such as $-CH_2SiHMe-$ or $-CH_2SiMe_2-$. Lattice constants for α-SiC are *a* 307.39 pm, *c* 1006.1 pm, *c*/*a* 3.273; for cubic β-SiC, a_0 435.02 pm (cf. diamond 356.68, Si 543.10, mean 449.89 pm).

SiC has greater thermal stability than any other binary compound of Si and decomposition by loss of Si only becomes appreciable at ~2700°. It resists attack by most aqueous acids (including HF but not H_3PO_4) and is oxidized in air only above 1000° because of the protective layer of SiO_2; this can be removed by molten hydroxides or carbonates and oxidation is much more rapid under these conditions, e.g.:

$$SiC + 2NaOH + 2O_2 \longrightarrow Na_2SiO_3 + H_2O + CO_2$$

Cl_2 attacks SiC vigorously, yielding $SiCl_4 + C$ at 100° and $SiCl_4 + CCl_4$ at 1000°.

Technical interest in SiC originally stemmed from its excellence as an abrasive powder; this derives not only from the great intrinsic hardness of the compound but also from its peculiar fracture to give sharp cutting edges. As a refractory, α-SiC combines great strength and chemical stability, with an extremely low thermal expansion coefficient ($\sim 6 \times 10^{-6}$) which shows no sudden discontinuities due to phase transitions. Pure α-SiC is an intrinsic semiconductor with an energy band gap sufficiently large (1.90 ± 0.10 eV) to make it a very poor electrical conductor ($\sim 10^{-13}$ ohm^{-1} cm^{-1}). However, the presence of controlled amounts of impurities makes it a valuable extrinsic semiconductor ($10^{-2} - 3$ ohm^{-1} cm^{-1}) with a positive temperature coefficient. This, combined with its mechanical and chemical stability, accounts for its extensive use in electrical heating elements. In recent years pure β-SiC has received much attention as a high-temperature semiconductor with applications in transistors, diode rectifiers, electroluminescent diodes, etc. (see p. 332). In fact, these various electrical and refractory uses account for only about 2% of the vast tonnages of SiC manufactured each year. About 43% is still used for its original application as an abrasive, and the remaining 55% is used in metallurgical processes, especially as a refining agent in the casting of iron and steel: the SiC reacts with free oxygen and with metal oxides to form CO and a siliceous slag.

isolated;[14] it distils without change at 85°C/0.1 torr and can be kept in solution in a sealed tube for several months at 150°C without apparent change. A recent example of pyramidal 3-coordinate Si is the Si_4^{4-} anion (isoelectronic with the tetrahedral P_4 molecule, p. 479), which has been shown to occur in the long-known red silicide CsSi.[17] There has been much discussion about the possibility of planar 4-coordinate Si in orthosilicate esters of pyrocatechol (2) but this is

Table 9.2 Coordination geometries of silicon

Coordination number	Examples
2 (bent)	SiF_2(g), $SiMe_2$ (matrix, 77 K), [:SiNBu^{t}CH=CHNBu^t] (1)[14]
3 (planar)	Silabenzene, SiC_5H_6;[15] silatoluene, C_5H_5SiMe[16]
3 (pyramidal)	Si_4^{4-}, (?)SiH_3^- in $KSiH_3$ (NaCl structure)
4 (tetrahedral)	SiH_4, SiX_4, SiX_nY_{4-n}, SiO_2, silicates, etc.
4 (planar)	(see text)[18] (2)
4 (see-saw, C_{2v})	$SiLi_4$ (3)[19]
5 (trigonal bipyramidal)	SiX_5^-, *cyclo*-[$Me_2NSiH_3]_5$, [$Si(O_2C_6H_4)_2(OPPh_3)$] (4)[20]
5 (square pyramidal)	[$Si(O_2C_6H_4)_2\{OP(NC_5H_{10})\}$] (5),[20] [$SiF(O_2C_6H_4)_2]^-$[21]
6 (octahedral)	SiF_6^{2-}, $[Si(acac)_3]^+$, $[L_2SiX_4]$, SiO_2 (stishovite), SiP_2O
7 (capped trig. antiprism)	[{2-$(Me_2NCH_2)C_6H_4\}_3SiH$] (6)[22]
8 (cubic)	Mg_2Si (antifluorite)
9 (capped square antiprism)	$[\mu_8$-$SiCo_9(CO)_{21}]^{2-}$ (7)[23]
10 (various)	$TiSi_2$, $CrSi_2$, $MoSi_2$;[24] [$Si(\eta^5$-$C_5Me_5)_2$] (8)[25]

still far from being unequivocally established.[18] However, a 'one-sided' C_{2v} geometry for $SiLi_4$ (3) seems probable.[19] Five-coordinate Si can be either trigonal bipyramidal or square pyramidal, e.g. (4), (5), etc.[20,21] Numerous examples of octahedral 6-coordination are known. A single example of 7-coordinate Si has been identified, (6)[22] and there are occasional examples of higher coordination numbers. Thus, Si has cubic 8-fold coordination in Mg_2Si which has the antifluorite structure, Si occupying the Ca sites and Mg the F sites of the fluorite lattice (p. 118). The capped square antiprismatic structure of the anion $[SiCo_9(CO)_{21}]^{2-}$ has essentially 9-fold coordination about the encapsulated Si atom (7), with Si–Co_{base} 231 pm, Si–Co_{upper} 228 pm and Si–Co_{cap} 252.7 pm; each of the four basal Co atoms has two terminal CO ligands, each of the other five Co atoms has one, and there are eight bridging CO groups.[23] The coordination number 10 is found in the structures of several transition metal silicides[24] and in decamethylsilicocene (8). The crystal structure of this latter compound reveals two types of molecular geometry; one-third of the molecules have the two rings parallel and staggered as in $[Fe(C_5Me_5)_2]$ with Si–C 242 pm whereas the other two-thirds have non-parallel rings, implying a stereochemically active lone pair of electrons on the Si atom.[25] The bent (C_s) structure persists in the gas phase, the angle between the two C_5 planes being 22°.

the bonding varies from essentially metallic to ionic and covalent. Observed stoichiometries include M_6Si, M_5Si, M_4Si, $M_{15}Si_4$, M_3Si, M_5Si_2, M_2Si, M_5Si_3, M_3Si_2, MSi, M_2Si_3, MSi_2, MSi_3 and MSi_6. Silicon, like boron, is more electropositive than carbon, and structurally the silicides are more closely related to the borides than the carbides (cf. diagonal relation, p. 27). However, the covalent radius of Si (118 pm) is appreciably larger than for B (88 pm) and few silicides are actually isostructural with the corresponding borides. Silicides have been reported for virtually all elements in Groups 1–10 except Be, the greatest range of stoichiometries being shown by the transition metals in Groups 4–10 and uranium. No silicides are known for the metals in Groups 11–15 except Cu; most form simple eutectic mixtures, but the heaviest post-transition metals Hg, Tl, Pb and Bi are completely immiscible with molten Si.

Some metal-rich silicides have isolated Si atoms and these occur either in typical metal-like structures or in more polar structures. With increasing Si content, there is an increasing tendency to catenate into isolated Si_2 or Si_4, or into chains, layers or 3D networks of Si atoms. Examples are in Table 9.3 and further structural details are in refs. 24, 26 and 27.

Silicides are usually prepared by direct fusion of the elements but coreduction of SiO_2 and a metal oxide with C or Al is sometimes used. Heats of formation are similar to those of borides and carbides but mps are substantially lower; e.g. TiC 3140°, TiB_2 2980°, $TiSi_2$ 1540°; and TaC 3800°, TaB_2 3100°, $TaSi_2$ 1560°C. Few silicides melt as high as 2000–2500°, and above this temperature only SiC is solid (decomp ~2700°C).

Silicides of groups 1 and 2 are generally much more reactive than those of the transition elements (cf. borides and carbides). Hydrogen and/or silanes are typical products; e.g.:

$$Na_2Si + 3H_2O \xrightarrow[\text{complete}]{\text{rapid and}} Na_2SiO_3 + 3H_2$$

$$Mg_2Si + 2H_2SO_4(aq) \longrightarrow 2MgSO_4 + SiH_4$$

Products also depend on stoichiometry (i.e. structural type). For example, the polar, non-conducting Ca_2Si (anti-$PbCl_2$ structure with isolated Si atoms) reacts with water to give $Ca(OH)_2$, SiO_2 (hydrated), and H_2, whereas CaSi (which features zigzag Si chains) gives silanes and the polymeric SiH_2. By contrast $CaSi_2$, which has puckered layers of Si atoms, does not react with pure water, but with dilute hydrochloric acid it yields a yellow polymeric solid of overall composition Si_2H_2O. Transition metal silicides

Table 9.3 Structural units in metal silicides

Unit	Examples	
Isolated Si	Cu_5Si (β-Mn structure) M_3Si (β-W structure) M = V, Cr, Mo Fe_3Si (Fe_3Al superstructure) Mn_3Si (random bcc)	Metal structures (good electrical conductors)
	M_2Si (anti-CaF_2); M = Mg, Ge, Sn, Pb M_2Si (anti-$PbCl_2$); M = Ca, Ru, Ce, Rh, Ir, Ni	Non-metal structures (non-conductors)
Si_2 pairs	U_3Si_2 (Si–Si 230 pm), also for Hf and Th	
Si_4 tetrahedra	KSi (Si–Si 243 pm), i.e. $[M^+]_4[Si_4]^{4-}$ cf. isoelectronic P_4 (M = Li, K, Rb, Cs; also for M_4Ge_4)	
Si chains	USi (FeB structure) (Si–Si 236 pm); also for Ti, Zr, Hf, Th, Ce, Pu CaSi (CrB structure) (Si–Si 247 pm); also for Sr, Y	
Plane hexagonal Si nets	β-USi_2 (AlB_2 structure) (Si–Si 222–236 pm); also for other actinoids and lanthanoids	
Puckered hexagonal Si nets	$CaSi_2$ (Si–Si 248 pm) — as in "puckered graphite" layer	
Open 3D Si frameworks	$SrSi_2$, α-$ThSi_2$ (Si–Si 239 pm; closely related to AlB_2), α-USi_2	

are usually inert to aqueous reagents except HF, but yield to more aggressive reagents such as molten KOH, or F_2 (Cl_2) at red heat.

9.3.2 Silicon hydrides (silanes)

The great development which occurred in synthetic organic chemistry from the 1830s onward encouraged early speculations that a similar extensive chemistry might be generated based on Si. The first silanes were made in 1857 by F. Wöhler and H. Buff who reacted Al/Si alloys with aqueous HCl; the compounds prepared were shown to be SiH_4 and $SiHCl_3$ by C. Friedel and A. Ladenburg in 1867 but it was not until 1902 that the first homologue, Si_2H_6, was prepared by H. Moissan and S. Smiles from the protonolysis of magnesium silicide. The thermal instability and great chemical reactivity of the compounds precluded further advances until A. Stock developed his greaseless vacuum techniques and first began to study them as contaminants of his boron hydrides in 1916. He proposed the names silanes and boranes (p. 151) by analogy with the alkanes.

Silanes Si_nH_{2n+2} are now known as unbranched and branched chains (up to $n = 8$) and as cyclic compounds Si_nH_{2n} ($n = 5, 6$). Silanes are colourless gases or volatile liquids; they are extremely reactive and spontaneously ignite or explode in air. Thermal stability decreases with increasing chain length and only SiH_4 is stable indefinitely at room temperature; Si_2H_6 decomposes very slowly (2.5% in 8 months), Si_3H_8 slowly and the tetrasilanes more rapidly, at room temperature. Some physical properties are in Table 9.4 from which it can be seen that silanes are less volatile than both the alkanes and boranes (p. 163) of similar formula, but more volatile than the corresponding germanes (p. 375).

There are three general types of preparative route to the silanes and their derivatives. Early methods (pre-1945) treated materials such as metal silicides which contained negatively charged $Si^{\delta-}$ with a protonic reagent such as an aqueous acid. Concurrent hydrolysis of the products limited the yield but considerable improvement resulted from the use of nonaqueous systems such as NH_4Br/liq NH_3 (1934). The second general preparative route involves treatment of compounds such as SiX_4 ($Si^{\delta+}$) with hydridic reagents such as LiH, NaH, $LiAlH_4$, etc., in ether solvents at low temperatures. This is now the preferred route: e.g. reaction of Si_nCl_{2n+2} ($n = 1$, 2, 3) with $LiAlH_4$ gives essentially quantitative

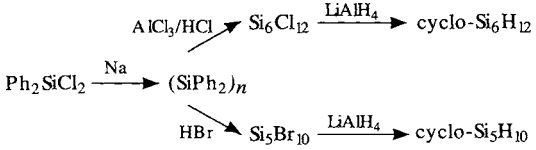
yields of SiH_4, Si_2H_6, and Si_3H_8. Organosilanes can be prepared similarly, e.g. Me_2SiCl_2 gives Me_2SiH_2. The third general method for preparing Si−H compounds involves direct reaction of HX or RX with Si or a ferrosilicon alloy in the presence of a catalyst such as Cu when necessary (p. 364), e.g.:

$$Si + 3HCl \xrightarrow{350°} SiHCl_3 + H_2$$

$$Si + 2MeCl \xrightarrow{Cu/300°} MeSiHCl_2 + H_2 + C$$

Combination of these various methods has led to a vast number of derivatives in which H is progressively replaced by one or more monofunctional group such as F, Cl, Br, I, CN, R, Ar, OR, SH, SR, NH_2, NR_2, etc.[1] The cyclic silanes Si_5H_{10} and Si_6H_{12} were prepared in the late 1970s[29] via $(SiPh)_n$ which were themselves the first known homocyclic silane derivatives (F. S. Kipping, 1921):



Silanes are much more reactive than the corresponding C compounds.[1,2,30] This has been ascribed to several factors including: (a) the larger radius of Si which would facilitate attack by nucleophiles, (b) the great polarity of Si−X bonds, and (c) the presence of low-lying d orbitals which permit the formation of 1:1 and 1:2 adducts, thereby lowering the activation energy of the reaction. The relative magnitude of the various bond energies is also an important factor in deciding which bonds will survive and which will be formed. Thus, it can be seen in Table 9.5, Si−Si < Si−C < C−C and Si−H < C−H, whereas for bonds for the other elements the energy C−X < Si−X. These data should

[30] E. WIBERG and E. AMBERGER, *Hydrides of the Elements of Main Groups I–IV*, Chap. 7, pp. 462–638, Elsevier, Amsterdam, 1971. A comprehensive review of compounds containing Si−H bonds; over 700 references.

be used only for broad comparisons since the estimated bond energies depend markedly on the particular compounds being studied and also on the experimental technique employed and the method of computation.

The pyrolysis of silanes leads to polymeric species and ultimately to Si and H_2; indeed, pyrolysis of SiH_4 is a commercial route to ultrapure Si. The reactions occurring have been less studied than those of alkanes (and boranes, p. 164), but it is clear that there are significant differences. Thus the initial step in the thermal decomposition of alkanes is the cleavage of a C–H or C–C bond with formation of radical intermediates $R_3C^{\bullet}$. However, studies using deuterium-substituted compounds suggest that the initial step in the decomposition of polysilanes is the elimination of silenes $:SiH_2$ or :SiHR.[31] Activation energies for this process ($\sim$210 kJ mol^{-1}) are substantially less than Si–Si and Si–H bond energies and the reaction appears to involve a 1,2-H shift with a 5-coordinate transition state.

Pure silanes do not react with pure water or dilute acids in silica vessels, but even traces of alkali dissolved out of glass apparatus catalyse the hydrolysis which is then rapid and complete ($SiO_2.nH_2O + 4H_2$). Solvolysis with MeOH can be controlled to give several products $SiH_{4-n}(OMe)_n$ ($n = 2, 3, 4$). Si–H adds (with difficulty) to alkenes though the reaction occurs more readily with substituted silanes. Similarly, SiH_4 adds to Me_2CO at 450° to give $C_3H_7OSiH_3$, and it ring-opens ethylene oxide at the same temperature to give $EtOSiH_3$ and other products. Silanes explode in the presence of Cl_2 or Br_2 but the reaction with Br_2 can be moderated at −80° to give good yields of SiH_3Br and SiH_2Br_2. More conveniently, halogenosilanes SiH_3X can be made by the catalysed reaction of SiH_4 and HX in the presence of Al_2X_6, or by the reaction with solid AgX in a heated flow reactor, e.g.:

$$SiH_4 + 2AgCl \xrightarrow{260^\circ} SiH_3Cl + HCl + 2Ag$$

SiH_3I in particular is a valuable synthetic intermediate and some of its reactions are summarized in Table 9.6. SiH_3I is a dense, colourless, mobile liquid, mp −57.0°, bp +45.4°, d(15°) 2.035 g cm^{-3}.

Another valuable reagent is $KSiH_3$, a colourless crystalline compound with NaCl-type

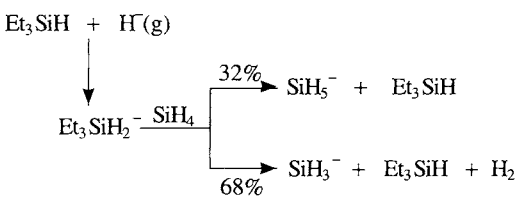
[a] See footnote (a) to Table 9.6.

When hexamethylphosphoramide, $(NMe_2)_3PO$, is used as solvent only the second reaction occurs. The synthetic utility of $KSiH_3$ can be gauged from Table 9.7 which summarizes some of its reactions. In addition, PCl_3 gives polymeric $(PH)_x$, CO_2 gives CO plus HCO_2K (formate), and N_2O gives $N_2 + H_2$ (plus) some SiH_4 in each case.[32]

The hypervalent silicon hydride anion, SiH_5^- (cf. SiF_5^- below), has been synthesized as a reactive species in a low-pressure flow reactor:[33]



9.3.3 Silicon halides and related complexes

Silicon and silicon carbide both react readily with all the halogens to form colourless volatile reactive products SiX_4. $SiCl_4$ is particularly important and is manufactured on the multikilotonne scale for producing boron-free transistor grade Si, fumed silica (p. 345), and various silicon esters. When two different tetrahalides are heated together they equilibrate to form an approximately random distribution of silicon halides which, on cooling, can be separated and characterized:

$$n SiX_4 + (4-n)SiY_4 \rightleftharpoons 4SiX_nY_{4-n}$$

Mixed halides can also be made by halogen exchange reaction, e.g. by use of SbF_3 to successively fluorinate $SiCl_4$ or $SiBr_4$. The mps and bps of these numerous species are compared with those of the parent hydride and halides in Fig. 9.1. While there is a clear trend to higher mps and bps with increase in molecular weight, this is by no means always regular. More notable is the enormous drop in mp (bp) which occurs for the halides of Si when compared with Al and earlier elements in the same row of the periodic table, e.g.:

Compound	NaF	MgF_2	AlF_3	SiF_4	PF_5	SF_6
MP/°C	988	1266	1291 (subl)	−90	−94	−50

This is sometimes erroneously ascribed to a discontinuous change from "ionic" to "covalent" bonding, but the electronegativity and other bonding parameters of Al are fairly similar to those of Si and the difference is more convincingly seen merely as a consequence of the change from an infinite lattice structure (in which each Al is surrounded by 6 F) to a lattice of discrete SiF_4 molecules as dictated by stoichiometry and size. Several other examples of this effect will be noticed amongst compounds of the Group 14 elements. Another instructive trend is in the Si–F interatomic distance in binary Si/F species: in tetrahedral SiF_4(c) it is 154.0 pm; in trigonal bipyramidal SiF_5^- it is 159.4 and 164.6 pm, respectively, for equatorial and axial bonds, and in SiF_6^{2-} it is 168.5 pm. The trend is to longer distances with increase in coordination number, presumably reflecting a gradual decrease in bond order. The 3.3% increase in going from

[33] D. J. HAJDASZ and R. R. SQUIRES, *J. Am. Chem. Soc.* **108**, 3139–40 (1986).

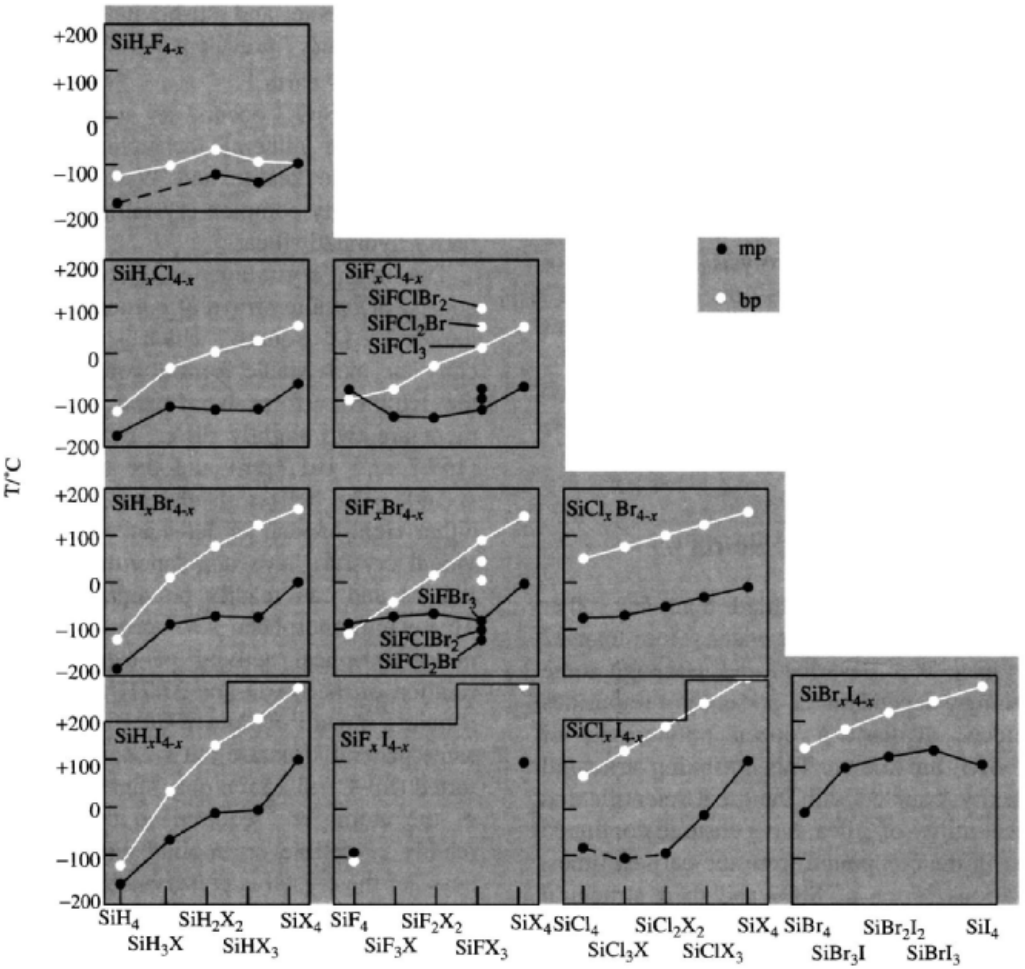

Figure 9.1 Trends in the mp and bp of silicon hydride halides and mixed halides.

equatorial to axial bonding in SiF_5^- is also in the usual direction.

The reactions of SiX_4 are straightforward and call for little comment.[1,2]

Higher homologues Si_nX_{2n+2} are volatile liquids or solids and, contrary to the situation in carbon chemistry, catenation in Si compounds reaches its maximum in the halides rather than the hydrides. This has been ascribed to additional back-bonding from filled halogen p_π orbitals into the Si d_π orbitals which thus synergically compensates for electron loss from Si via σ bonding to the electronegative halogens (cf. CO, pp. 926–8). Fluoropolysilanes up to $Si_{14}F_{30}$ and other series up to at least Si_6Cl_{14} and Si_4Br_{10} are known. Preparative routes are exemplified by the following reactions:

$$Si + SiF_4 \xrightarrow[\text{system/1250°C}]{\text{low press. flow}} 2SiF_2(g) \xrightarrow[-196°]{\text{condense}}$$

$$(SiF_2)_x \text{ polymer} \xrightarrow{\sim 200°} Si_nF_{2n+2} \text{ mixture}$$

$$Si + SiCl_4 \xrightarrow{\text{red heat}} Si_2Cl_6 \text{ plus higher homologues}$$

$$Si_2Cl_6 + ZnF_2 \longrightarrow Si_2F_6 + ZnCl_2$$

$$5Si_2Cl_6 \xrightarrow[0.1\,mol\%\ NMe_3]{\text{heat with}} Si_6Cl_{14} + 4SiCl_4$$

$$3Si_2Cl_6 \xrightarrow{NMe_3\ catalyst} Si_5Cl_{12} + 2Si_2Cl_6$$

These compounds show many unusual reactions and reviews of their chemistry make fascinating reading.[34,35] Partial hydrolysis of $SiCl_4$ (or the reaction of $Cl_2 + O_2$ on Si at 700°) leads to a series of volatile chlorosiloxanes $Cl_3Si(OSiCl_2)_nOSiCl_3 (n = 0–5)$ and to the cyclic $(SiOCl_2)_4$. The corresponding bromo compounds are prepared similarly, using Br_2 and O_2.

9.3.4 Silica and silicic acids

Silica has been more studied than any other chemical compound except water. More than 22 phases have been described and, although some of these may depend on the presence of impurities or defects, at least a dozen polymorphs of "pure" SiO_2 are known. This intriguing structural complexity, coupled with the great scientific and technical utility of silica, have ensured continued interest in the compound from the earliest times. The various forms of SiO_2 and their structural inter relations will be described in the following paragraphs. By far the most commonly occurring form of SiO_2 is α-quartz which is a major mineral constituent of many rocks such as granite and sandstone; it also occurs alone as rock crystal and in impure forms as rose quartz, smoky quartz (red brown), morion (dark brown), amethyst (violet) and citrine (yellow). Poorly crystalline forms of quartz include chalcedony (various colours), chrysoprase (leek green), carnelian (deep red), agate (banded), onyx (banded), jasper (various), heliotrope (bloodstone) and flint (often black due to inclusions of carbon). Less-common crystalline modifications of SiO_2 are tridymite, cristobalite and the extremely rare minerals coesite and stishovite. Earthy forms are particularly prevalent as kieselguhr and diatomaceous earth.†

Vitreous SiO_2 occurs as tectites, obsidian and the rare mineral lechatelierite. Synthetic forms include keatite and W-silica. Opals are an exceedingly complex crystalline aggregate of partly hydrated silica.

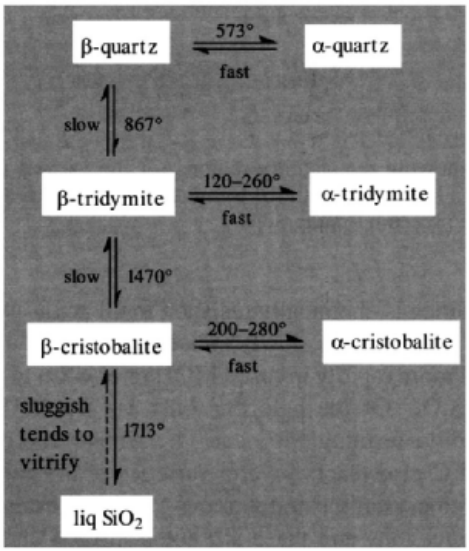
The main crystalline modifications of SiO_2 consist of infinite arrays of corner-shared $\{SiO_4\}$ tetrahedra. In α-quartz, which is thermodynamically the most stable form at room temperature, the tetrahedra form interlinked helical chains; there are two slightly different Si–O distances (159.7 and 161.7 pm) and the angle Si–O–Si is 144°. The helices in any one crystal can be either right-handed or left-handed so that individual crystals have non-superimposable mirror images and can readily be separated by hand. This enantiomorphism also accounts for the pronounced optical activity of α-quartz (specific rotation of the Na D-line 27.71°/mm). At 573°C α-quartz transforms into β-quartz which has the same general structure but is somewhat less distorted (Si–O–Si 155°): only slight displacements of the atoms are required so the transition is readily reversible on cooling and the "handedness" of the crystal is preserved throughout. This is called a non-reconstructive transformation. A more drastic structural change occurs at 867° when β-quartz transforms into β-tridymite. This is a reconstructive transformation which requires the breaking of Si–O bonds to enable the $\{SiO_4\}$

[34] J. L. MARGRAVE and P. W. WILSON, *Acc. Chem. Res.* **4**, 145–52 (1971).

[35] G. URRY, *Acc. Chem. Res.* **3**, 306–12 (1970).

† The names of minerals often give a clue to their properties or discovery. Coesite, stishovite, and keatite are named after their discoverers (p. 343). Quartz derives from *kwardy*, a West Slav dialectal equivalent of the Polish *twardy*, hard. Tridymite was recognized as a new polymorph by von Rath in 1861 because of its typical occurrence as trillings or groups of 3 crystals (Greek τριδυμος, *tridymos*, threefold). Cristobalite was discovered by von Rath in 1884 on the slopes of Mt San Cristobal, Mexico, where tridymite had also first been discovered. Kieselguhr is a combination of the German *Kiesel*, flint, and *Guhr*, earthy deposit. Diatomaceous earth refers to its origin as the remains of minute unicellular algae called diatoms: these marine organisms (0.01–0.1 mm diam) have the astonishing property of accreting silica on their cell walls and this preserves the shape of the organism after death — enormous deposits occur in many places (see p. 345).

tetrahedra to be rearranged into a simpler, more open hexagonal structure of lower density. For this reason the change is often sluggish and this enables tridymite to occur as a (metastable) mineral phase below the transition temperature. When β-tridymite is cooled to ~120° it undergoes a fast, reversible, non-reconstructive transition to (metastable) α-tridymite by slight displacements of the atoms. Conversely, when β-tridymite is heated to 1470° it undergoes a sluggish reconstructive transformation into β-cristobalite and this, in turn, can retain its structure as a metastable phase when cooled below the transition temperature; further slight displacements occur rapidly and reversibly in the temperature range 200–280° to give α-cristobalite (Si–O 161 pm, Si–O–Si 147°). These transitions are summarized below.



The α-form of each of the three minerals can thus be obtained at room temperature and, because of the sluggishness of the reconstructive interconversions of the β-forms, it is even possible to melt β-quartz (1550°) and β-tridymite (1703°) if they are heated sufficiently rapidly. The bp of SiO_2 is not accurately known but is about 2800°C.

Other forms of SiO_2 can be made at high pressure (Fig. 9.2). Coesite was first made by L. Coes in 1953 by heating dry Na_2SiO_3 and $(NH_4)_2HPO_4$ at 700° and 40 kbar, and was subsequently found in nature at Meteor Crater, Arizona (1960). Its structure consists of 4-connected networks of $\{SiO_4\}$ in which the smallest rings are 4- and 8-membered, and this compact structure explains its high density (Table 9.8). On being heated it rapidly converts to tridymite or cristobalite. At still higher pressures (40–120 kbar, 380–585°) keatite is formed under hydrothermal conditions from amorphous silica and dilute alkali (P. P. Keat, 1959); the $\{SiO_4\}$ are connected into 5-, 7-, and 8-membered rings as in ice(III) (p. 624). The highest density form of SiO_2 was predicted in 1952 by J. B. Thompson who visualized 6-coordinate Si in a rutile structure (p. 961). It was first synthesized in S. M. Stishov's laboratory (1961) at 1200–1400° and 160–180 kbar, and found to have the predicted structure. It was discovered in association with coesite at Meteor Crater in 1962: presumably both minerals were formed under transient shock pressures following meteorite impact and then preserved by rapid quenching from high temperature. The rapid melting and cooling of pre-existing silica phases also occurs during lightning strikes, and this leads to the formation of lechatelierite, a glassy or vitreous silica mineral.

Finally, a very low-density form of fibrous silica, W-SiO_2 has been made by the disproportionation of (metastable) crystalline SiO:

$$SiO_2 + Si \xrightarrow[10^{-4}\ \text{mmHg}]{1250\text{–}1300^\circ} 2SiO \longrightarrow \text{W-}SiO_2 + Si$$

W-SiO_2 features $\{SiO_4\}$ tetrahedra linked by sharing opposite edges to form infinite parallel chains analogous to SiS_2 and $SiSe_2$; this edge-sharing of pairs of O atoms between pairs of Si atoms is not observed elsewhere in Si–O chemistry where linking is by corner sharing of single O atoms. The configuration is unstable, and fibrous SiO_2 rapidly reverts to amorphous SiO_2 on heating or in the presence of traces of moisture. It has also recently been shown that reaction of $(SiO)_2$ and O_2 in an argon matrix results in the formation of dimeric molecules

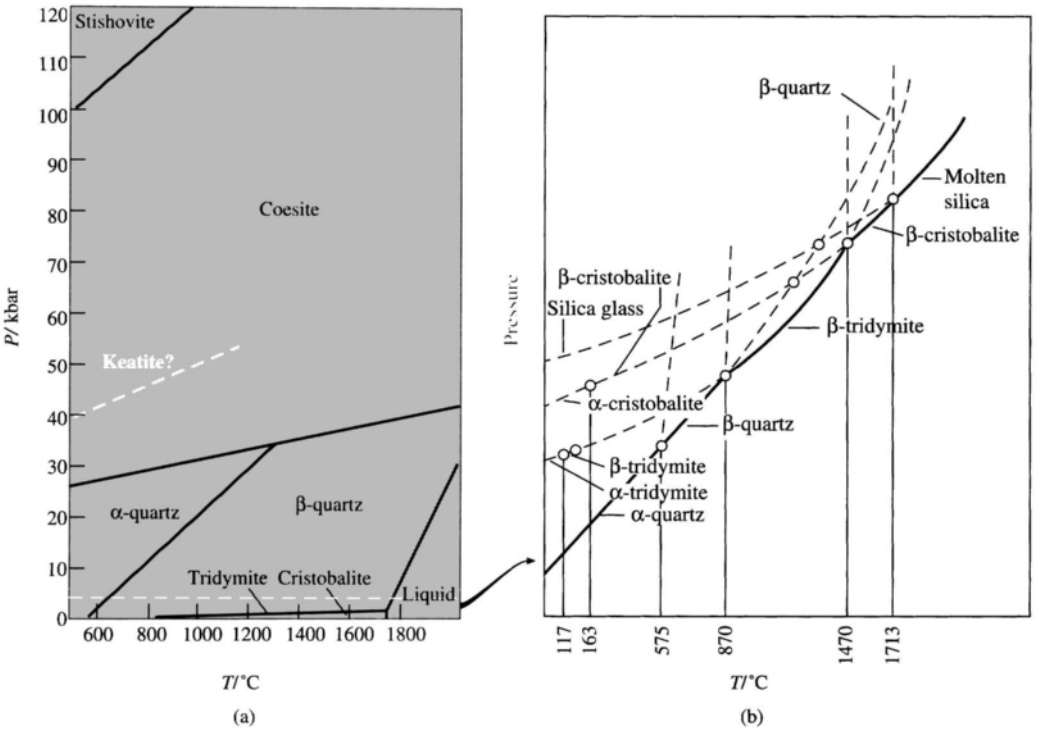


Figure 9.2 (a) Pressure-temperature phase diagram for SiO_2 showing the stability regions for the various polymorphs. The low-pressure segment below the broken line is shown in (b) using an (arbitrary) expanded scale to illustrate the relationships described in the preceding paragraphs.

of silica, O=Si(μ-O)$_2$Si=O.[36] Interaction of molecular SiO with Ag atoms in an argon matrix gives cyclic AgSiO with the angle at Si being $\leq 90°$.[37]

Table 9.8 Density of the main forms of SiO_2 (room temperature)

	d/g cm^{-3}		d/g cm^{-3}
W (fibrous)	1.97	β-quartz (600°)	2.533
Lechatelierite	2.19	α-quartz	2.648

Silica is chemically resistant to all acids except HF but dissolves slowly in hot concentrated alkali and more rapidly in fused MOH or M_2CO_3 to give M_2SiO_3. Of the halogens only F_2 attacks SiO_2 readily, forming SiF_4 and O_2. Above 1000° H_2 and C also react. Several varieties of crystalline, cryptocrystalline and vitreous SiO_2 find extensive applications and these are noted in the Panel. In vitreous silica {SiO_4} tetrahedra are again linked by sharing corners with each O linked to 2Si but the extended three-dimensional network lacks the symmetry and periodicity of the crystalline forms. The Si–O distances are similar to those in other forms of SiO_2 (158–162 pm) but the Si–O–Si angles vary by as much as 15–20° on either side of the mean value of 153°.

The detailed reactions of SiO_2 with the oxides of the metals and semi-metals are of great importance in glass technology and ceramics

but will not be treated here.[1,2,38] Suffice it to say that, in addition to innumerable crystalline compounds and vitreous phases, many water-soluble compositions are known and many of these find extensive commercial application. Perhaps the best known are the soluble sodium (and potassium) silicates which are made by fusing sand with the appropriate carbonate in a glass-making furnace at ~1400°. The resulting soluble glass is dissolved in hot water under pressure and any insoluble glass or unreacted sand filtered off. The ternary phase diagram for Na_2O–SiO_2–H_2O (Fig. 9.3) indicates that only certain limited regions are of commercial interest, e.g. the stable liquid materials (area 9) in the composition range

Some Uses of Silica[1]

The main types of SiO_2 used in industry are high-purity α-quartz, vitreous silica, silica gel, fumed silica and diatomaceous earth. The most important application of quartz is as a piezoelectric material (p. 58); it is used in crystal oscillators and filters for frequency control and modulation, and in electromechanical devices such as transducers and pickups: tens of millions of such devices are made each year. There is insufficient natural quartz of adequate purity so it must be synthesized by hydrothermal growth of a seed crystal using dilute aqueous NaOH and vitreous SiO_2 at 400°C and 1.7 kbar. The technique was first successfully employed by G. R. Spezia in 1905. (Crystal growth from molten SiO_2 cannot be used — why?)

Vitreous silica combines exceptionally low thermal expansion† and high thermal shock resistance with high transparency to ultraviolet light, good refractory properties, and general chemical inertness. As a glass it is hard to work because of its very high softening point, high viscosity, short liquid range and high volatility at forming temperatures. It is familiar in high-quality laboratory glassware, particularly for photolysis experiments and as sample cells in ultraviolet/visible spectroscopy; it is also much used as a protective sheath in the form of tubing or as thin films deposited from the vapour.

Silica gel is an amorphous form of SiO_2 with a very porous structure, formed by acidification of aqueous solutions of sodium silicate; the gelatinous precipitate is washed free of electrolytes and then dehydrated either by roasting or spray drying. The properties of the resulting microporous material depend critically on the conditions of preparation, but typical samples have a pore diameter of 2200–2600 pm, a surface area of 750–800 $m^2\,g^{-1}$, and an apparent bulk density of 0.67–0.75 $g\,cm^{-3}$. Such material finds extensive use as a desiccant, selective absorbant, chromatographic support, catalyst substrate and insulator (thermal and sound). It can absorb more than 40% of its own weight of water and, when stained with cobalt salts such as the nitrate or $(NH_4)_2CoCl_4$, is familiar as a self-indicating desiccant that can readily be regenerated by heating (anhydrous, blue; hydrated, pink). It is chemically inert, non-toxic and dimensionally stable, and finds a growing application in the food industry as an anticaking agent in cocoa, fruit juice powders, $NaHCO_3$ and powdered sugar and spices. It is also used as a flatting agent to produce an attractive matte finish on lacquers, varnishes and paints, and on the surface of vinyl plastics and synthetic fabrics.

Another manufactured form of ultrafine powdered SiO_2 is pyrogenic or fumed silica, formed by the high-temperature hydrolysis of $SiCl_4$ in an oxyhydrogen flame in specially designed burners; the SiO_2 is formed as a very fine white smoke which is collected on cooled rotating rollers. The bulk density is only 0.03–0.06 $g\,cm^{-3}$ and the surface area 150–500 $m^2\,g^{-1}$. Its main use is as a thixotropic thickening agent in the processing of epoxy and polyester resins and plastics, and as a reinforcing filler in silicone rubbers where, in contrast to carbon black fillers (p. 271), its chemical inertness does not interfere with the peroxide initiated cure (p. 365).

Diatomaceous earth or kieselguhr (p. 342) is mined by open-cast methods on a very substantial scale, particularly in Europe and North America, which respectively account for 59% and 39% of the world production (1.8 million tonnes in 1977). The principal use is in filtration plants, and this accounts for about 60% of the supply; a further 20% is used in abrasives, fillers, light-weight aggregates and insulation material, and the remainder is used as an inert carrier, coating agent or in the manufacture of pozzolan.

† The linear coefficient of thermal expansion of vitreous silica is ~ 0.25×10^{-6}. This can be compared with a value of ~ 100×10^{-6} for ordinary soda-lime glasses (~ 79% SiO_2, ~ 12.5% Na_2O, ~ 8.5% CaO). Addition of B_2O_3 (as in Pyrex) sharply reduces this value to 3×10^{-6} (typical laboratory glassware has a composition 83.9% SiO_2, 10.6% B_2O_3, 1.2% Al_2O_3, 3.9% Na_2O, 0.4% K_2O).

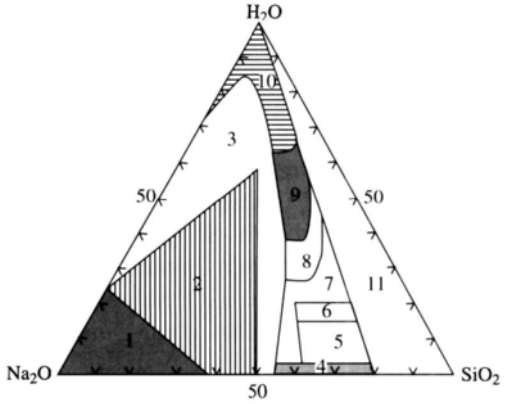

Figure 9.3 Simplified schematic ternary phase diagram for the system Na_2O–SiO_2–H_2O. Commercially important areas are shaded. (1) anhydrous "Na_4SiO_4" and its granular mixtures with NaOH; (2) granular crystalline alkaline silicates such as Na_2SiO_3 and its hydrates; (3) uneconomic partially crystallized mixtures; (4) glasses; (5) uneconomic hydrated glasses; (6) dehydrated liquids; (7) uneconomic semi-solids and gels; (8) uneconomic, unstable viscous liquids; (9) ordinary commercial liquids; (10) dilute liquids; (11) unstable liquids and gels. (From J. G. Vail, *Soluble Silicates*, Reinhold, New York, 1952.)

30–40% SiO_2, 10–20% Na_2O, 60 40% H_2O, i.e. $\sim Na_2Si_2O_5.6H_2O$. These find extensive use in industrial and domestic liquid detergents because they maintain high pH by means of their buffering ability and can saponify animal and vegetable oils and fats; they also emulsify mineral oils, deflocculate dirt particles, and prevent redeposition of suspended dirt and soil. The more dilute solutions (area 10) are used in production of silica gels by acidification (pp. 345 and below). There are numerous other uses of soluble silicates including adhesives, glues and binders, especially for corrugated cardboard boxes, and as refractory acid-resistant cements and sealants. World production in 1981 was ~3.0 million tonnes of which the sodium silicates formed the major part. Price range from $220-450/tonne depending on composition.

Potassium silicate solutions are equally complex; for example, an aqueous solution prepared from KOH and SiO_2 in which the ratio K:Si is 1:1 contains 22 different discrete silicate anions as identified by ^{29}Si COSY nmr studies.[39]

The system SiO_2–H_2O, even in the absence of metal oxides, is particularly complex and of immense geochemical and industrial importance.[40] The mp of pure SiO_2 decreases dramatically by as much as 800° on addition of 1–2% H_2O (at high pressure), presumably as a result of the structure-breaking effect of replacing Si–O–Si links by "terminal" Si-OH groups. With increasing concentrations of H_2O one obtains hydrated silica gels and colloidal dispersions of silica; there are also numerous hydrates and distinct silicic acids in very dilute aqueous solutions, but these tend to be rather insoluble and rapidly precipitate with further condensation when aqueous solutions of soluble silicates are acidified. Structural information is sparse, particularly for the solid state, but in solution evidence has been claimed for at least 5 species (Table 9.9). It is unlikely that any of these species exist in the solid state since precipitation is accompanied by further condensation and cross-linking to form "polysilicic acids" of indefinite and variable composition $[SiO_x(OH)_{4-2x}]_n$ (cf B, Al, Fe, etc.). However, the crystal structure of $[(c\text{-}C_6H_{11})_7Si_7O_9\{O_3W(NMe_2)_3\}_3]$ has been

Table 9.9 Silicic acids in solution

Formula	n[a]	Name	Sol. (H_2O, 20°)/ mol l^{-1}

determined[41] and various crystalline methyl and ethyl esters of cyclic silicic acids have been isolated.[42]

9.3.5 Silicate minerals [24,43,44]

The earth's crustal rocks and their breakdown products — the various soils, clays and sands — are composed almost entirely (~95%) of silicate minerals and silica. This predominance of silicates and aluminosilicates is reflected in the abundance of O, Si and Al, which are the commonest elements in the crust (p. 329). Despite the great profusion of structural types and the widely varying stoichiometries which are unmatched elsewhere in chemistry, it is possible to classify these structures on the basis of a few simple principles. Almost invariably Si is coordinated tetrahedrally by 4 oxygen atoms and these $\{SiO_4\}$ units can exist either as discrete structural entities or can combine by corner sharing of O atoms into larger units. The resulting O lattice is frequently close-packed, or approximately so, and charge balance is achieved by the presence of further cations in tetrahedral, octahedral, or other sites depending on their size. Typical examples are as follows (radii in pm):†

CN 4 : Li^{I} (59) Be^{II} (27) Al^{III} (39) Si^{IV} (26)
CN 6 : Na^{I} (102) Mg^{II} (72) Al^{III} (54) Ti^{IV} (61) Fe^{II} (78)
CN 8 : K^{I} (151) Ca^{II} (112)
CN 12: K^{I} (164)

The quoted radii, which in turn depend on the CN, are the empirical "effective ionic radii" deduced by R. D. Shannon (and C. T. Prewitt)[45] and do not imply full charge separation such as $\{Si^{4+}(O^{2-})_4\}$, etc. Note that Al^{III} can occupy either 4- or 6-coordinate sites so that it can replace either Si or M in the lattice — this is particularly important in discussing the structures of the aluminosilicates. Several other cations can occupy sites of differing CN, e.g. Li (4 and 6), Na (6 and 8), K (6–12), though they are most commonly observed in the CN shown.

As with the borates (p. 205) and to a lesser extent the phosphates (p. 526), the $\{SiO_4\}$ units can build up into chains, multiple chains (or ribbons), rings, sheets and three-dimensional networks as summarized below and elaborated in the following paragraphs.

Neso-silicates	discrete $\{SiO_4\}$	no O atoms shared
soro-silicates	discrete $\{Si_2O_7\}$	1 O atom shared
cyclo-silicates	closed ring structures	2 O atoms shared
ino-silicates	continuous chains or ribbons	2 O atoms shared
phyllo-silicates	continuous sheets	3 O atoms shared
tecto-silicates	continuous 3D frameworks	all 4 O atoms shared

Silicates with discrete units

Discrete $\{SiO_4\}$ units occur in the orthosilicates $M^{II}_2SiO_4$ (M = Be, Mg, Mn, Fe and Zn) and in $ZrSiO_4$ as well as in the synthetic orthosilicates Na_4SiO_4 and K_4SiO_4.[46] In phenacite, Be_2SiO_4, both Be and Si occupy sites of CN 4 and the structure could equally well be described as a 3D network M_3O_4. When octahedral sites are occupied, isomorphous replacement of M^{II} is often extensive as in olivine, $(Mg,Fe,Mn)_2SiO_4$ which derives its name from its olive-green colour (Fe^{II}). In zircon, $ZrSiO_4$, the stoichiometry

of the crystal and the larger radius of Zr (84 pm) dictate eightfold coordination of the cation. Another important group of orthosilicates is the garnets, $[M^{II}_3M^{III}_2(SiO_4)_3]$, in which M^{II} are 8-coordinate (e.g. Ca, Mg, Fe) and M^{III} are 6-coordinate (e.g. Al, Cr, Fe).[47] Orthosilicates are also vital components of Portland cement (p. 252): β-Ca_2SiO_4 has discrete $\{SiO_4\}$ groups with rather irregularly coordinated Ca in sixfold and eightfold environments (the α-form has the K_2SO_4 structure and the γ-form has the olivine structure). Again alite, Ca_3SiO_5, which is intimately involved in the "setting" process, has individual Ca, $\{SiO_4\}$ and O as the structural units.

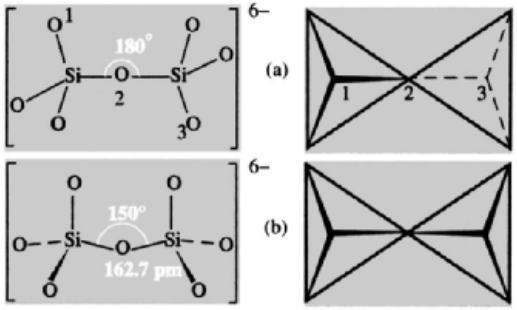

Figure 9.4 (a) Two representations of the $\{Si_2O_7\}$ unit in $Sc_2Si_2O_7$ showing the linear Si–O–Si link between the two tetrahedra and the D_{3d} (staggered) conformation, and (b) eclipsed (C_{2v}) conformation of the $\{Si_2O_7\}$ unit in hemimorphite, $[Zn_4Si_2O_7(OH)_2].H_2O$.

Disilicates, containing the discrete $\{Si_2O_7^{6-}\}$ unit, are rare. One example is the mineral thortveitite, $Sc_2Si_2O_7$, which features octahedral Sc^{III} (r 75 pm) and a linear Si–O–Si bond between staggered tetrahedra (Fig. 9.4a). There is also a series of lanthanoid disilicates $Ln_2Si_2O_7$ in which the Si–O–Si angle decreases progressively from 180° to 133° and the CN of Ln increases from 6 through 7 to 8 as the size of Ln increases from 6-coordinated Lu^{III} (86 pm) to 8-coordinated Nd^{III} (111 pm). In the Zn mineral hemimorphite the angle is 150° but the conformation of the 2 tetrahedra is eclipsed (C_{2v}) rather than staggered (Fig. 9.4b); the mineral was originally formulated as $Zn_2SiO_4.H_2O$ or $H_2Zn_2SiO_5$, but X-ray studies showed that the correct formula was $[Zn_4(OH)_2Si_2O_7].H_2O$, i.e."$2H_2Zn_2SiO_5$". Two further features of importance also emerged. The first was that there was no significant difference between the Si–O distances to "bridging" and "terminal" O atoms as would be expected for isolated $\{Si_2O_7^{6-}\}$ groups, and the structure is best considered as a 3D framework of $\{ZnO_3(OH)\}$ and $\{SiO_4\}$ tetrahedra linked in threes to form 6-atom rings $\overline{Zn-O-Si-O-Zn-OH}$. The rings are linked into infinite sheets in the (010) planes which are themselves linked via Zn–O(H)–Zn or Si–O–Si bonds. The 3D framework so generated leaves large channels which open into large cavities that accommodate the removable H_2O molecules. The structure is thus very similar in principle to that of the framework aluminosilicates (p. 354) and its conventional description in terms of discrete $Si_2O_7^{6-}$ ions is rather misleading and uninformative.

Structures having triple tetrahedral units are extremely rare but they exist in aminoffite, $Ca_3(BeOH)_2(Si_3O_{10})$, and kinoite, $Cu_2Ca_2(Si_3O_{10}).2H_2O$. The first chain-tetrasilicate, $[O_3Si(OSiO_2)_2OSiO_3]^{10-}$, was synthesized as recently as 1979:[48] $Ag_{10}Si_4O_{13}$ was prepared as stable vermilion crystals by heating AgO and SiO_2 for 1–3 days at 500–600°C under a pressure of 2–4.5 kbar of O_2. At lower temperatures (<470°C) the bright red mixed silicate $[Ag_{18}(SiO_4)_2(Si_4O_{13})]$ crystallizes.[49]

When every $\{SiO_4\}$ shares 2 O with contiguous tetrahedra, metasilicates of empirical

[47] See p. 500 of ref. 24 for a description of the garnet structure which is also adopted by many synthetic and non-silicate compounds; these have been much studied recently because of their important optical and magnetic properties, e.g. ferrimagnetic yttrium iron garnet (YIG), $Y^{III}_3Fe^{III}_2(Al^{III}O_4)_3$.

[49] K. HEIDEBRECHT and M. JANSEN, *Z. anorg. allg. Chem.* **597**, 79–86 (1991).

formula SiO_3^{2-} are formed. Cyclic metasilicates $\{(SiO_3)_n\}^{2n-}$ having 3, 4, 6 or 8 linked tetrahedra are known, though 3 and 6 are the most common. These anions are shown schematically in Fig. 9.5 and are exemplified by the mineral benitoite [$BaTi\{Si_3O_9\}$], the synthetic compound [$K_4\{Si_4O_8(OH)_4\}$], and by beryl [$Be_3Al_2\{Si_6O_{18}\}$] (p. 107) and murite [$Ba_{10}(Ca,Mn,Ti)_4\{Si_8O_{24}\}(Cl,OH,O)_{12}].4H_2O$.

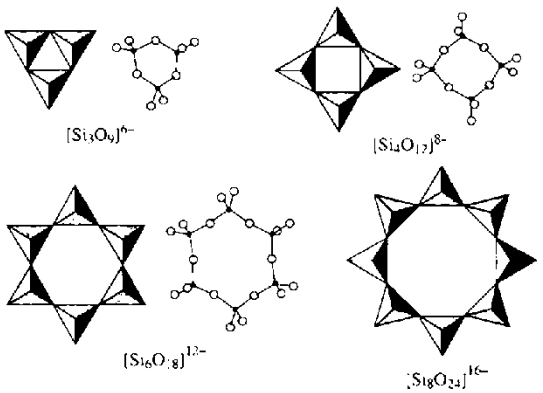

Figure 9.5 Schematic representations of the structures of cyclic metasilicate anions with $n = 3$, 4, 6, and 8.

Silicates with chain or ribbon structures

Chain metasilicates $\{SiO_3^{2-}\}_\infty$ formed by corner-sharing of $\{SiO_4\}$ tetrahedra are particularly prevalent in nature and many important minerals have this basic structural unit (cf. polyphosphates, p. 528). Despite the apparent simplicity of their structure motif and stoichiometry considerable structural diversity is encountered because of the differing conformations that can be adopted by the linked tetrahedra. As a result, the repeat distance along the *c*-axis can be (1), 2, 3, ..., 7, 9 or 12 tetrahedra (T), as illustrated schematically in Fig. 9.6. The most common conformation for metasilicates is a repeat after every second tetrahedron (2T) with the chains stacked parallel so as to provide sites of 6- or 8-coordination for the cations; e.g. the pyroxene minerals enstatite [$Mg_2Si_2O_6$], diopside [$CaMgSi_2O_6$], jadeite [$NaAlSi_2O_6$], and spodumene [$LiAlSi_2O_6$] (p. 69). The synthetic metasilicates Li_2SiO_3 and Na_2SiO_3 are similar; for the latter compound Si–O–Si is 134° and the Si–O distance is 167 pm within the chain and 159 pm for the other two O. The minerals wollastonite [$Ca_3Si_3O_9$] and pectolite [$Ca_2NaHSi_3O_9$] have a 3T repeat unit, haradaite [$Sr_2(VO)Si_4O_{12}$] is 4T, rhodonite [$CaMn_4Si_5O_{15}$] has a 5T repeat, etc.[24,44]

In the next stage of structural complexity the single $\{SiO_3^{2-}\}_\infty$ chains can link laterally to form double chains or ribbons whose stoichiometry depends on the repeat unit of the single chain (Fig. 9.7). By far the most numerous are the amphiboles or asbestos minerals which adopt the $\{Si_4O_{11}^{6-}\}$ double chain, e.g. tremolite [$Ca_2Mg_5(Si_4O_{11})_2(OH)_2$]; the structure of this compound is very similar to that of diopside (above) except that the length of the *b*-axis of the unit cell is doubled. The fibrous nature of the asbestos minerals thus finds a ready interpretation on the basis of their crystal structures (see Panel on p. 351). In addition to these well-established double chains of linked $\{SiO_4\}$ tetrahedra, examples of infinite one-dimensional structures consisting of linked triple, quadruple and even sextuple chains have been discovered in nephrite jade by means of electron microscopy,[50] and these form a satisfying link between the pyroxenes and amphiboles, on the one hand, and the sheet silicates (to be described in the next paragraph), on the other.

Silicates with layer structures

Silicates with layer structures include some of the most familiar and important minerals known to man, particularly the clay minerals [such as kaolinite (china clay), montmorillonite (bentonite, fuller's earth), and vermiculite], the micas (e.g. muscovite, phlogopite, and biotite), and others such as chrysotile (white asbestos),

[50] L. G. Mallinson, J. L. Hutchinson, D. A. Jefferson and J. M. Thomas, *J. Chem. Soc., Chem. Commun.*, 910–11 (1977).

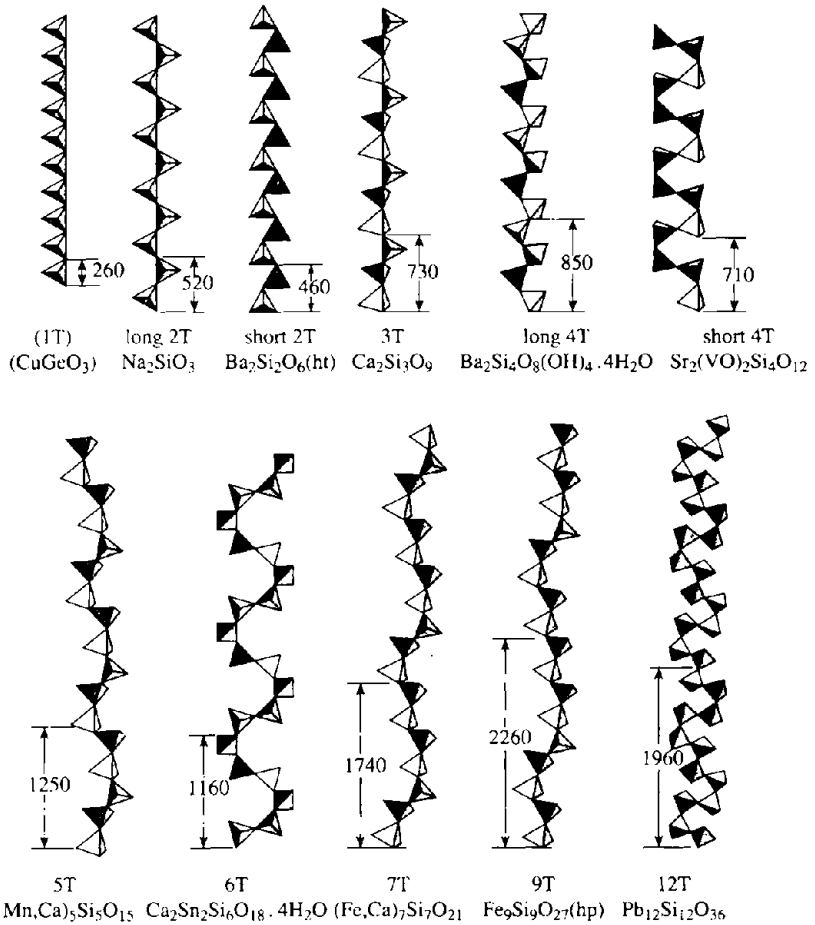

Figure 9.6 Schematic representation and examples of various chain metasilicates $\{SiO_3^{2-}\}_\infty$ with repeat distances (in pm) after 1, 2, . . ., 7, 9 or 12 tetrahedra (T), [(ht) high-temperature form; (hp) high-pressure form].

talc, soapstone, and pyrophyllite. The physical and chemical properties of these minerals, which have made many of them so valued for domestic and industrial use for several milleniums (p. 328), can be directly related to the details of their crystal structure. The simplest silicate layer structure can be thought of as being formed either by the horizontal cross-linking of the 2T metasilicate chain $\{Si_2O_6^{4-}\}$ in Fig. 9.6 or by the planar condensation of the $\{Si_6O_{18}^{12-}\}$ unit in Fig. 9.5 to give a 6T network of composition $\{Si_2O_5^{2-}\}$ in which 3 of the 4 O atoms in each tetrahedron are shared; this is shown in both plan and elevation in Fig. 9.8. In fact, such a structure with a completely planar arrangement is extremely rare though closely related puckered 6T networks are found in $M_2Si_2O_5$ (M=Li, Na, Ag, H) and in petalite ($LiAlSi_4O_{10}$, p. 69). More complex arrangements are also found in which the 6T rings forming the network are replaced by alternate 4T and 8T rings, or by equal numbers of 4T, 6T, and 8T rings, or even by a network of 4T, 6T and 12T rings.[24.44]

Double layers can be generated by sharing the fourth (apical) O atom between pairs of tetrahedra as in Fig. 9.9(a). This would give a stoichiometry SiO_2 (since each O atom is shared between 2 Si atoms) but if half the Si^{IV} were replaced by

Production and Uses of Asbestos

The fibrous silicate minerals known collectively as asbestos (Greek ἄ'σβεστος, unquenchable) have been used both in Europe and the Far East for thousands of years. In ancient Rome the wicks of the lamps of the vestal virgins were woven from asbestos, and Charlemagne astounded his barbarian guests by throwing the festive table cloth into the fire whence, being woven asbestos, it emerged cleansed and unburnt. Its use has accelerated during the past 100 y and it is now an important ingredient in over 3000 different products. Its desirable characteristics are high tensile strength, great flexibility, resistance both to heat and flame and also to corrosion by acids or alkalis, good thermal insulation properties and low cost.

Asbestos is derived from two large groups of rock-forming minerals — the serpentines and the amphiboles. Chrysotile, or white asbestos $[Mg_3(Si_2O_5)(OH)_4]$, is the sole representative of the serpentine layer silicate group (p. 352) but is by far the most abundant kind of asbestos and constitutes more than 98% of world production. The amphibole group includes the blue asbestos mineral crocidolite $[Na_2Fe^{II}_3Fe^{III}_2Si_8O_{22}(OH)_2]$ (<1% of world production) and the grey-brown mineral amosite $[(Mg,Fe)_7Si_8O_{22}(OH)_2]$. (<1%). Annual production in 1989 was 4.3 million tonnes having fallen from a maximum of 5 Mt in 1979.[51] The main producing countries are Russia (55%), Canada (20%), South Africa (4.7%) and Zimbabwe, China, Italy and Brazil (3–4% each).

Asbestos-reinforced cements (~12.5% asbestos) absorb nearly two-thirds of the world's annual production of chrysotile: it is used in corrugated and flat roofing sheets, pressure pipes and ducts, and many other hard-wearing, weather-proof, long-lasting products. About 8% is used in asbestos papers and a further 7% is used for making vinyl floor tiles. Other important uses include composites for brake linings, clutch facings, and other friction products. Long-fibred chrysotile (fibre length >20 mm) is woven into asbestos textiles for fire-fighting garments and numerous fire-proofing and insulating applications.

Prolonged exposure to airborne suspensions of asbestos fibre dust can be very dangerous and there has been increasing concern at the incidence of asbestosis (non-malignent scarring of lung tissue) and lung carcinoma among certain workers in the industry. Unfortunately, there is an extended latent period (typically 20–30 y) before these diseases are manifest. Stringent precautions are now enforced in many countries and the incidence of the disease appears to be falling steadily. There is also general (though not universal) agreement that white asbestos (chrysotile), which is the overwhelmingly predominant type of asbestos in use, is not implicated in the incidence of asbestosis and lung carcinoma which seems to be confined mainly (perhaps exclusively) to the blue crocidolite and brown amosite amphibole varieties. Asbestosis is dose-related and the best form of control is to reduce the level of dust exposure in places where the mineral is mined, processed or fabricated.

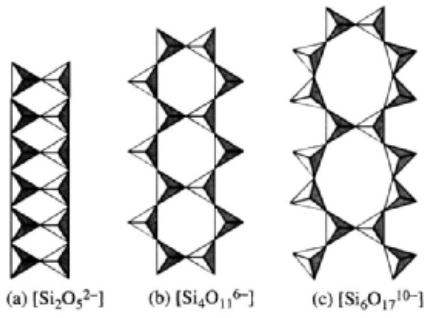

Figure 9.7 Double chains of $\{SiO_4\}$ tetrahedra: (a) the double chain based on the 1T metasilicate structure, stoichiometry $\{Si_2O_5^{2-}\}$ – it is found in the aluminosilicate sillimanite $[Al(AlSiO_5)]$; (b) $\{Si_4O_{11}^{6-}\}$ chain based on the 2T metasilicate occurs in the amphiboles (see text); and (c) the rare 3T double chain $Si_6O_{17}^{10-}$ occurs in xonotlite $[Ca_6Si_6O_{17}(OH)_2]$. More complex 3T, 4T and 6T double chains are also known.[44]

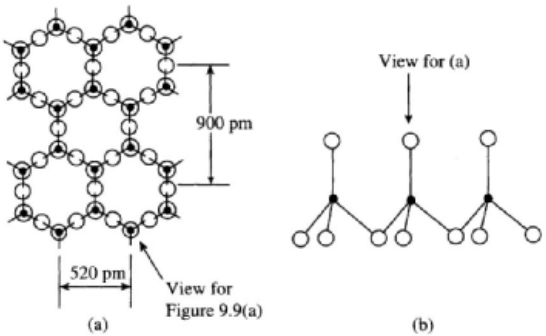

Figure 9.8 Planar network formed by extended 2D condensation of rings of 6 $\{SiO_4\}$ tetrahedra to give $\{Si_2O_5^{2-}\}$. (a) Plan as seen looking down the O-Si direction, and (b) side elevation.

Al^{III} then the composition would be $\{Al_2Si_2O_8^{2-}\}$ as found in $Ca_2Al_2Si_2O_8$ and $Ba_2Al_2Si_2O_8$ (Fig. 9.9b). Another way of building up double layers involves the interleaving of layers of the

[51] Reference 1, 4th edn., Asbestos **3**, 659–88 (1992).

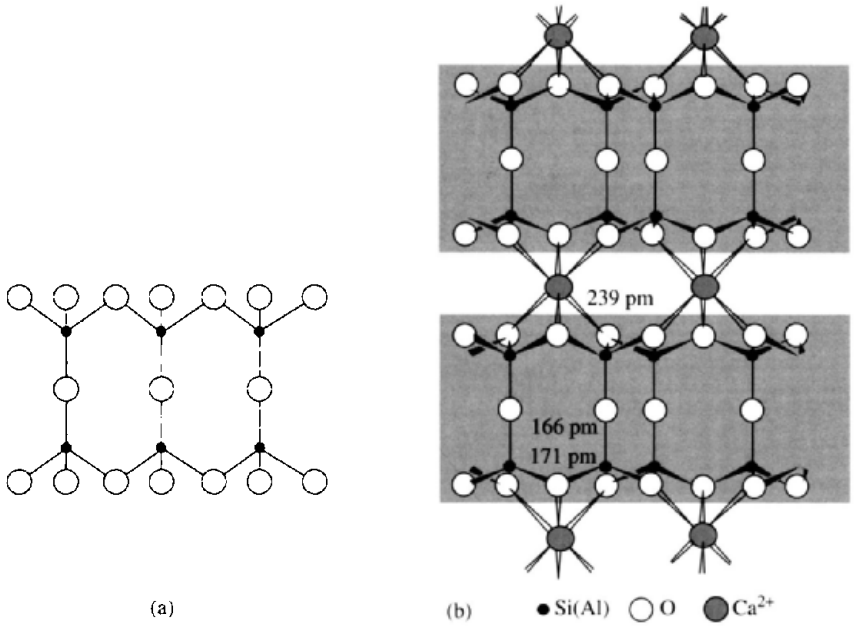

Figure 9.9 (a) Side elevation of double layers of formula $\{Al_2Si_2O_8^{2-}\}$ formed by sharing the fourth (apical) O in Fig. 9.9(b). Sites marked • are occupied by equal numbers of Al and Si atoms. (b) Structure of $Ca_2Al_2Si_2O_8$ formed by interleaving 6-coordinated Ca^{II} atoms between the double layers depicted in (a).

gibbsite $Al(OH)_3$ or brucite $Mg(OH)_2$ structure (pp. 243–5, 121) which happen to have closely similar dimensions and can thus share O atoms with the silicate network. This leads to the china-clay mineral kaolinite $[Al_2(OH)_4Si_2O_5]$ illustrated in Figs. 9.10(a) and 9.11(a). [The mineral was so-named in 1867 from "kaolin", a corruption of the Chinese *kauling*, or high-ridge, the name of the hill where this china clay was found some 300 miles north of Hong Kong.]

Repetition of the process on the other side of the Al/O layer leads to the structure of pyrophyllite $[Al_2(OH)_2Si_4O_{10}]$ (Fig. 9.10b,c). Replacement of $2Al^{III}$ by $3Mg^{II}$ in kaolinite $[Al_2(OH)_4Si_2O_5]$ gives the serpentine asbestos mineral chrysotile $[Mg_3(OH)_4Si_2O_5]$ and a similar replacement in pyrophyllite gives talc $[Mg_3(OH)_2Si_4O_{10}]$. The gibbsite series is sometimes called dioctahedral and the brucite series trioctahedral in obvious reference to the number of octahedral sites occupied in the "non-silicate" layer.

Alternative representations of the structures are given in Fig. 9.11, and it is well worth while looking carefully at these various diagrams since they have the pleasing property of becoming simpler and easier to understand the longer they are contemplated. It should be stressed that the formulae given are ideal limiting compositions and that Al^{III} or Mg^{II} can be replaced by several other cations of appropriate size. The stoichiometry is further complicated by the possibility that Si^{IV} can be partly replaced by Al^{III} in the tetrahedral sites thereby giving rise to charged layers. These layers can be interleaved with M^{I} or M^{II} cations to give the micas or by layers of hydrated cations to give montmorillonite. Alternatively, charge balance can be achieved by interleaving positively charged $(Mg,Al)(OH)_2$ layers as in the chlorites. These possibilities are shown schematically in Figs. 9.12 and 9.13 (p. 355) and elaborated in the following paragraphs.

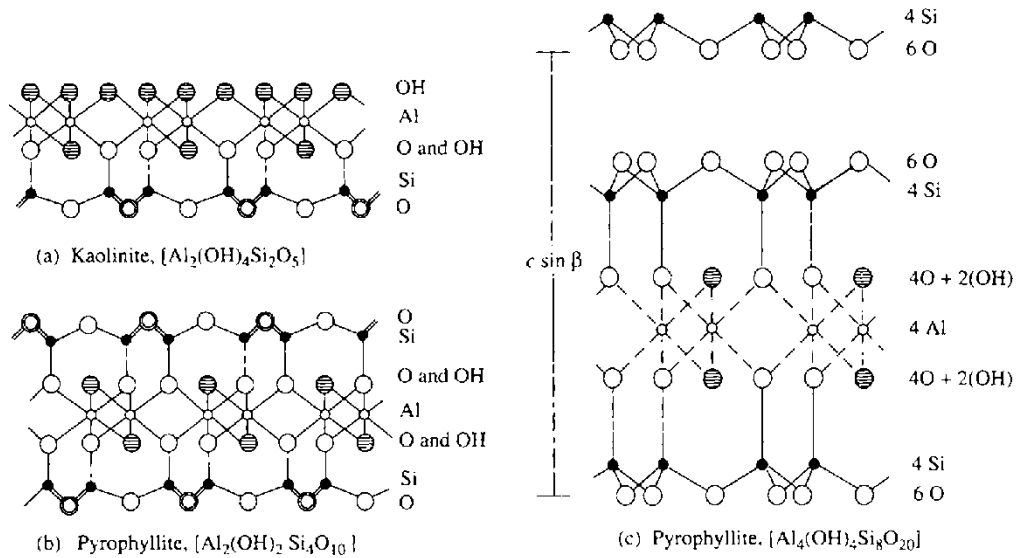

Figure 9.10 (a) Schematic representation of the structure of kaolinite (side elevation) showing $\{SiO_3O\}$ tetrahedra (bottom) sharing common O atoms with $\{Al(OH)_2O\}$ to give a composite layer of formula $[Al_2(OH)_4Si_2O_5]$. The double lines and double circles in the tetrahedra indicate bonds to 2 O atoms (one in front and one behind). (b) Similar representation of the structure of pyrophyllite, showing shared $\{SiO_3O\}$ tetrahedra above and below the $\{Al(OH)O_2\}$ layer to give a composite layer of formula $[Al_2(OH)_2Si_4O_{10}]$. (c) Alternative representation of pyrophyllite to be compared with (b), and showing the stoichiometry of each layer.

The technological importance of the clay minerals is outlined in the Panel on p. 356.

Micas are formed when one-quarter of the Si^{IV} in pyrophyllite and talc are replaced by Al^{III} and the resulting negative charge is balanced by K^{I}:

pyrophyllite $[Al_2(OH)_2Si_4O_{10}] \longrightarrow$

$[KAl_2(OH)_2(Si_3AlO_{10})]$ muscovite (white mica)

talc $[Mg_3(OH)_2Si_4O_{10}] \longrightarrow$

$[KMg_3(OH)_2(Si_3AlO_{10})]$ phlogopite

The OH can be partly replaced by F and, in phlogopite, partial replacement of Mg^{II} by Fe^{II} gives biotite (black mica) $[K(Mg,Fe^{II})_3(OH,F)_2(Si_3AlO_{10})]$. The presence of K^{I} between the layers makes the micas appreciably harder than pyrophyllite and talc but the layers are still a source of weakness and micas show perfect cleavage parallel to the layers. With further substitution of up to half the Si by Al charge balance can be restored by the more highly charged Ca^{II} and brittle micas result, such as margarite $[CaAl_2(OH)_2(Si_2Al_2O_{10})]$ which is even harder than muscovite.

Another set of minerals, the montmorillonites, result if, instead of replacing tetrahedral Si^{IV} by Al^{III} in phlogopite, the octahedral Al^{III} is *partially* replaced by Mg^{II} (not *completely* as in talc). The resulting partial negative charge per unit formula can be balanced by incorporating hydrated M^{I} or M^{II} between the layers; this leads to the characteristic swelling, cation exchange and thixotropy of these minerals (see Panel, p. 356). A typical sodium montmorillonite might be formulated $Na_{0.33}[Mg_{0.33}Al_{1.67}(OH)_2(Si_4O_{10})].nH_2O$, but more generally they can be written as $M_x[(Mg,Al,Fe)_2(OH)_2(Si_4O_{10})].nH_2O$ where M = H, Na, K, $\frac{1}{2}$Mg or $\frac{1}{2}$Ca. Simultaneous altervalent substitution in both the octahedral and tetrahedral sites in talc leads to the vermiculites

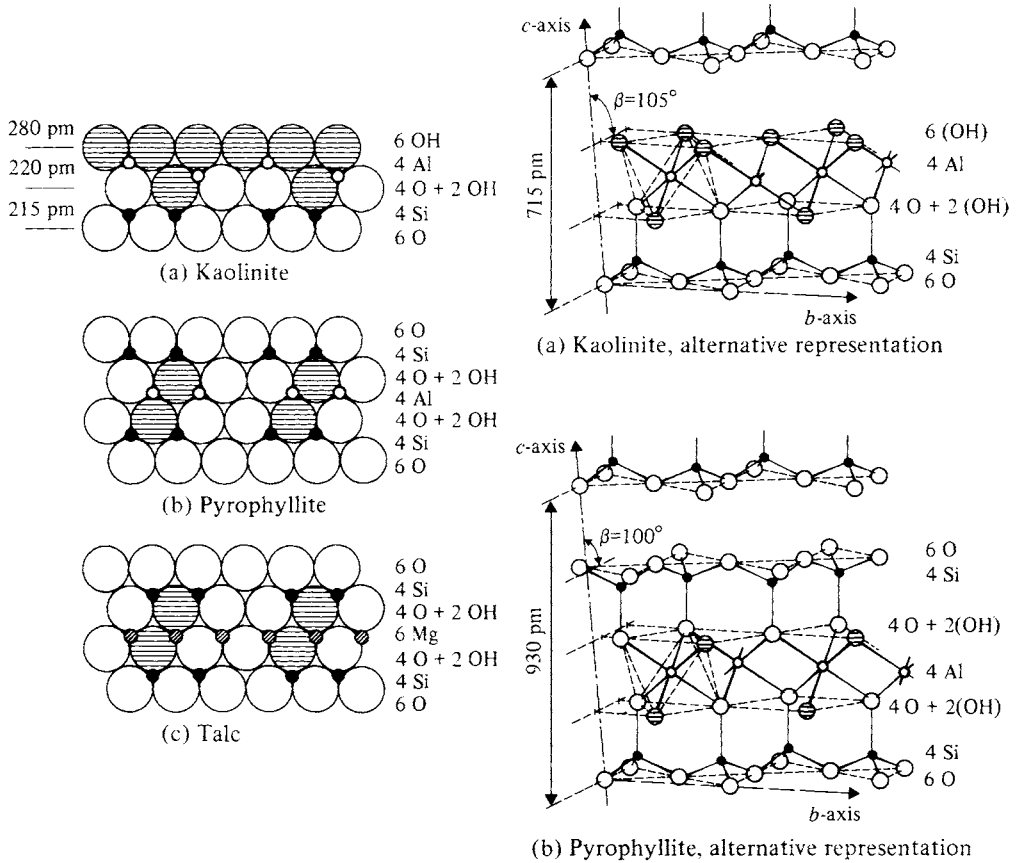

Figure 9.11 Alternative representations of the layer structures of (a) kaolinite, (b) pyrophyllite, and (c) talc. (After H. J. Emeléus and J. S. Anderson, 1960 and B. Mason and L. G. Berry, 1968.)

of which a typical formula is

$$[Mg_{0.32}(H_2O)_{4.32}]^{0.64+}{}_{+}$$

$$[(Mg_{2.36}Al_{0.16}Fe^{III}{}_{0.48})(OH)_2(Si_{2.72}Al_{1.20}O_{10})]^{0.64-}$$

total 3.00

When these minerals are heated they dehydrate in a remarkable way by extruding little worm-like structures as indicated by their name (Latin *vermiculus*, little worm); the resulting porous light-weight mass is much used for packing and insulation. The relationship between the various layer silicates is summarized with idealized formulae in Table 9.10 (on page 357).

Silicates with framework structures

The structural complexity of the 3D framework aluminosilicates precludes a detailed treatment here, but many of the minerals are of paramount importance. The group includes the feldspars (which are the most abundant of all minerals, and comprise ~60% of the earth's crust), the zeolites (which find major applications as molecular sieves, desiccants, ion exchangers and water softeners), and the ultramarines which, as their name implies, often have an intense blue colour. All are constructed from SiO_4 units in which each O atom is shared by 2 tetrahedra (as in the various forms of SiO_2 itself), but up to one-half of the Si

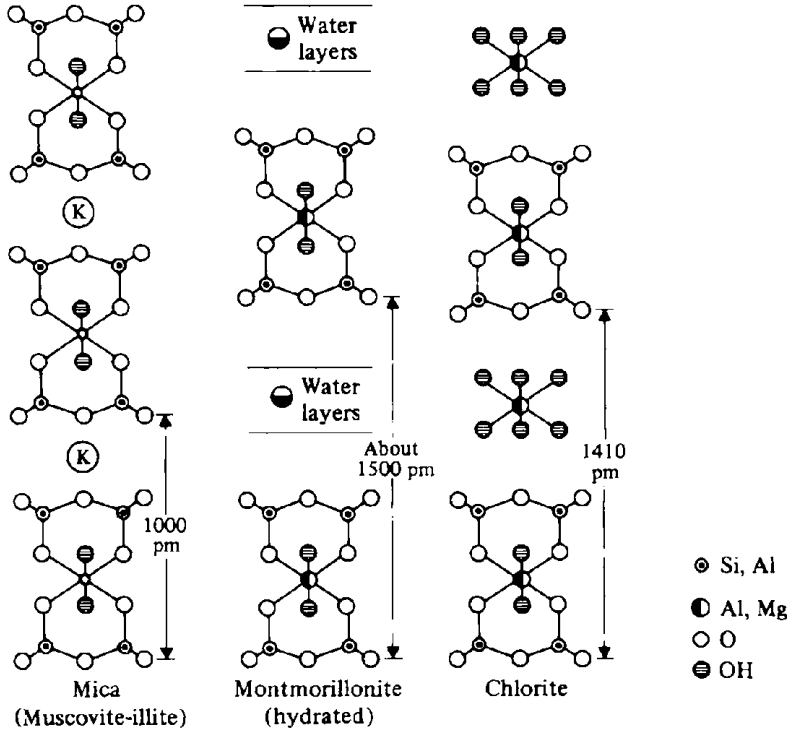

Figure 9.12 Schematic representation of the structures of muscovite mica, $[K_2Al_4(Si_6Al_2)O_{20}(OH)_4]$, hydrated montmorillonite, $[Al_4Si_8O_{20}(OH)_4].xH_2O$ and chlorite, $[Mg_{10}Al_2(Si_6Al_2)O_{20}(OH)_{16}]$, see text.

Clay Minerals and Related Aluminosilicates[1,52]

Clays are an essential component of soils, to which we owe our survival, and they are also the raw materials for some of mankind's most ancient and essential artefacts: pottery, bricks, tiles, etc. Clays are formed by the weathering and decomposition of igneous rocks and occur typically as very fine particles: e.g. kaolinite is formed as hexagonal plates of edge ~0.1–3 μm by the weathering of alkaline feldspar:

$$2[KAlSi_3O_8] + CO_2 + H_2O \xrightarrow{\text{idealized}} [Al_2(OH)_4Si_2O_5] + 4SiO_2 + K_2CO_3$$

When mixed with water, clays become soft, plastic and mouldable; the water of plasticity can be removed at ~100° and the clay then becomes rigid and brittle. Further heating (~500°) removes structural water of crystallization and results in the oxidation of any carbonaceous material or Fe^{II} (600–900°). Above about 950° mullite ($Al_6Si_2O_{13}$) begins to form and glassy phases appear. Common clay is mined on a huge scale (28 million tonnes in USA alone in 1991) and is used principally in the manufacture of bricks (12 Mt), portland cement (10 Mt) and concrete (2.4 Mt), as well as for paper filling and coating (3.7 Mt).

China clay or kaolin, which is predominantly kaolinite, is particularly valuable because it is essentially free from iron impurities (and therefore colourless). World production in 1991 was 24.7 Mt (USA 39%, UK 13%, Colombia, Korea and USSR ~7% each). In the USA over half of this vast tonnage is used for paper filling or paper coating and only 130 000 tonnes was used for china, crockery, and earthenware, which is now usually made from ball clay, a particularly fine-grained, highly plastic material which is predominantly kaolinite together with clay-mica and quartz. Some 800 000 tonnes of ball clay is used annually in the USA for white ware, table ware, wall and floor tiles, sanitary ware, and electrical porcelain.

Fuller's earth is a montmorillonite in which the principal exchangeable cation is calcium. It has a high absorbance and adsorptive capacity, and pronounced cation exchange properties which enable it to be converted to sodium-montmorillonite (bentonite). Nomenclature is confusing and, in American usage, the fibrous hydrated magnesium aluminosilicate attapulgite is also called fuller's earth. World production (1991) was 4.0 million tonnes (USA 68%, Germany 19%, UK 5%). Of the 2.74 Mt produced in the USA, two-thirds was used for what government statisticians coyly call "pet absorbant" and about one-eighth was for oil and grease absorbance.

Bentonite (sodium-montmorillonite) is extensively used as a drilling mud, but this apparently mundane application is based on the astonishing thixotropic properties of its aqueous suspensions. Thus, replacement of Ca by Na in the montmorillonite greatly enhances its ability to swell in one dimension by the reversible uptake of water; this effectively cleaves the clay particles causing a separation of the lamellar units to give a suspension of very finely divided, exceedingly thin plates. These plate-like particles have negative charges on the surface and positive charges on the edges and, even in a suspension of quite low solid content, the particles orient themselves negative to positive to give a jelly-like mass or gel; on agitation, however, the weak electrical bonds are broken and the dispersion becomes a fluid whose viscosity diminishes with the extent of agitation. This indefinitely reversible property is called thixotropy and is widely used in civil engineering applications, in oil-well drilling, and in non-drip paints. The plasticity of bentonite is also used in mortars, putties, and adhesives, in the pelletizing of iron ore and in foundry sands. World production was 9.3 Mt in 1991 (USA 37%, USSR 26% Greece 11%).

Micas occur as a late crystallization phase in igneous rocks. Usually the crystals are 1–5 mm on edge but in pegmatites (p. 108) they may considerably exceed this to give the valuable block mica. Uses of muscovite mica depend on its perfect basal cleavage, toughness, elasticity, transparency, high dielectric strength, chemical inertness and thermal stability to 500°. Phlogopite (Mg-mica) is less used except when stability to 850–1000° is required. Sheet mica is used for furnace windows, for electrical insulation (condensers, heating elements, etc.) and in vacuum tubes. Ground mica is used as a filler for rubber, plastics and insulating board, for silver glitter paints, etc. World production (excluding China) was ~240 000 tonnes in 1974 (USA 53%, India 20%, USSR 17%).

Talc, unlike the micas, consists of electrically neutral layers without the interleaving cations. It is valued for its softness, smoothness and dry lubricating properties, and for its whiteness, chemical inertness and foliated structure. Its most important applications are in ceramics, insecticides, paints and paper manufacture. The more familiar use in cosmetics and toilet preparations accounts for only 3% of world production which is about 5 Mt per annum. Half of this comes from Japan and the USA, and other major producers are Korea, the former Soviet Union, France and China. Talc and its more massive mineral form soapstone or steatite are widely distributed throughout the world and many countries produce it for domestic consumption either by open-cast or underground mining.

atoms have been replaced by Al, thus requiring the addition of further cations for charge-balance.

Most feldspars can be classified chemically as members of the ternary system $NaAlSi_3O_8$–$KAlSi_3O_8$–$CaAl_2Si_2O_8$. This is illustrated in Fig. 9.14, which also indicates the names of the mineral phases. Particularly notable

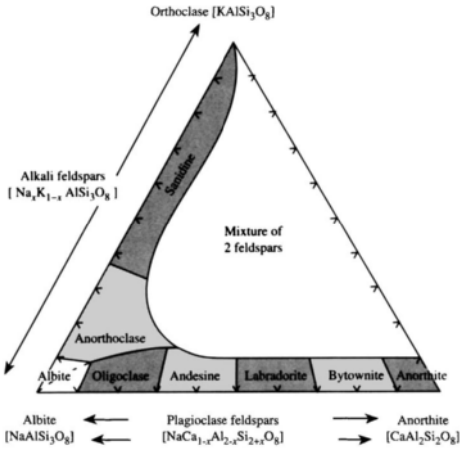

Figure 9.14 Ternary phase diagram for feldspars. The precise positions of the various phase boundaries depend on the temperature of formation.

is the continuous plagioclase series in which Na^{I} (102 pm) is replaced by Ca^{II} (100 pm) on octahedral sites, the charge-balance being maintained by a simultaneous substitution of Al^{III} for Si^{IV} on the tetrahedral sites. K^{I} (138 pm) is too disparate in size to substitute for Ca^{II} and 2-phase mixtures result, though orthoclase does form a continuous series of solid solutions with the Ba feldspar celsian $[BaAl_2Si_2O_8]$ (Ba^{II} 136 pm). Likewise, most of the alkaline feldspars are not homogeneous but tend to contain separate K-rich and Na-rich phases unless they have crystallized rapidly from solid solutions at high temperatures (above ~600°). Feldspars have tightly constructed aluminosilicate frameworks that generate large interstices in which the large M^{I} or M^{II} are accommodated in irregular coordination.[43] Smaller cations, which are common in the chain and sheet silicates (e.g. Li^{I}, Mg^{II}, Fe^{III}), do not occur as major constituents in feldspars presumably because they are unable to fill the interstices adequately.

Pressure is another important variable in the formation of feldspars and at sufficiently high pressures there is a tendency for Al to increase its coordination number from 4 to 6 with consequent destruction of the feldspar lattice.† For example:

† In some compounds of course, octahedrally coordinated Al is stable at normal atmospheric pressure, e.g. in Al_2O_3,

$$\underset{\text{albite (feldspar)}}{NaAl_tSi_3O_8} \xrightarrow{\text{pressure}} \underset{\text{jadeite (clinopyroxene)}}{NaAl_oSi_2O_6} + \underset{\text{quartz}}{SiO_2}$$

$$\underset{\text{albite}}{NaAl_tSi_3O_8} + \underset{\text{nepheline}}{NaAl_tSiO_4} \xrightarrow{\text{pressure}} \underset{\text{jadeite}}{2NaAl_oSi_2O_6}$$

$$\underset{\text{anorthite (feldspar)}}{3Ca(Al_t)_2Si_2O_8} \xrightarrow{\text{pressure}} \underset{\text{grossular (Ca garnet)}}{Ca_3(Al_o)_2(SiO_4)_3} + \underset{\text{kyanite}}{2(Al_o)_2SiO_5} + \underset{\text{quartz}}{SiO_2}$$

$$\underset{\text{anorthite}}{Ca(Al_t)_2Si_2O_8} + \underset{\text{gehlenite}}{Ca_2(Al_t)_2SiO_7} + \underset{\text{wollastonite}}{3CaSiO_3} \xrightarrow{\text{pressure}} \underset{\text{grossular}}{2Ca_3(Al_o)_2(SiO_4)_3}$$

Such reactions marking the disappearance of plagioclase feldspars may be responsible for the Mohorovicic discontinuity between the earth's crust and mantle: this implies that the crust and mantle are isocompositional, the crustal rocks above having phases characteristic of gabbro rock (olivine, pyroxene, plagioclase) whilst the mantle rocks below are an eclogite-containing garnet, Al-rich pyroxene and quartz. Not all geochemists agree, however.

Zeolites have much more open aluminosilicate frameworks than feldspars and this enables them to take up loosely bound water or other small molecules in their structure. Indeed, the name zeolite was coined by the mineralogist A. F. Cronstedt in 1756 (ζειν *zein*, to boil; λιθος *lithos*, stone) because the mineral appeared to boil when heated in the blow-pipe flame. Zeolite structures are characterized by the presence of tunnels or systems of interconnected cavities; these can be linked either in one direction giving fibrous crystals, or more usually in two or three directions to give lamellar and 3D structures respectively. Figure 9.15a shows the construction of a single cavity from 24 linked $\{SiO_4\}$ tetrahedra and Fig. 9.15b shows how this can be conventionally represented by a truncated cubo-octahedron formed by joining the Si atom positions. Several other types of polyhedron have also been observed. These are then linked in three dimensions to build the aluminosilicate framework. A typical structure is shown in Fig. 9.15c for the synthetic zeolite "Linde A" which has the formula $[Na_{12}(Al_{12}Si_{12}O_{48})].27H_2O$.[53] Other cavity frameworks are found in other zeolites such as faujasite, which has the idealized formula $[NaCa_{0.5}(Al_2Si_5O_{14})].10H_2O$, and chabazite $[Ca(Al_2Si_4)O_{12}].6H_2O$. There is great current interest in this field since it offers scope for the reproducible synthesis of structures having cavities, tunnels and pores of precisely defined dimensions on the atomic scale.[54] By

$Al(OH)_3$, and spinels such as $MgAl_2O_4$. Much higher pressures still are required to transform 4-coordinated Si to 6-coordinated (p. 343).

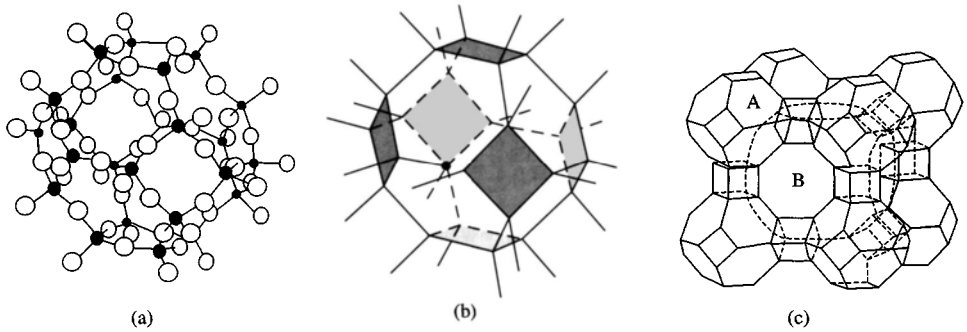

Figure 9.15 (a) 24 $\{SiO_4\}$ tetrahedra linked by corner sharing to form a framework surrounding a truncated cubo-octahedral cavity; (b) conventional representation of the polyhedron in (a); and (c) space-filling arrangement of the polyhedra A which also generates larger cavities B.

appropriate design such molecular sieves can be used to selectively remove water or other small molecules, to separate normal from branched-chain paraffins, to generate highly dispersed metal catalysts, and to promote specific size-dependent chemical reactions.[55] Zeolites are made commercially by crystallizing aqueous gels of mixed alkaline silicates and aluminates at 60–100°. Zeolite-A is being increasingly used as a detergent builder to replace sodium tripolyphosphate (p. 528).

The final group of framework aluminosilicates are the ultramarines which have alternate Si and Al atoms at the corners of the polyhedra shown in Fig. 9.15a and b and, in addition, contain substantial concentrations of anions such as Cl^-, SO_4^{2-} or S_2^{2-}. These minerals tend to be anhydrous, like the feldspars, and in contrast to the even more open zeolites. Examples are sodalite $[Na_8Cl_2(Al_6Si_6O_{24})]$, noselite $[Na_8(SO_4)(Al_6Si_6O_{24})]$ and ultramarine $[Na_8(S_2)(Al_6Si_6O_{24})]$. Sodalite is colourless if the supernumerary anions are all chloride, but partial replacement by sulfide gives the brilliant blue mineral lapiz lazuli. Further replacement gives ultramarine which is now manufactured synthetically as an important blue pigment for oil-based paints and porcelain, and as a "blueing" agent to mask yellow tints in domestic washing, paper making, starch, etc.† The colour is due to the presence of the sulfur radical anions S_2^- and S_3^- and shifts from green to blue as the ratio S_3^-/S_2^- increases; in ultramarine red the predominant species may be the neutral S_4 molecule though S_3^- and S_2^- are also present.[56]

9.3.6 Other inorganic compounds of silicon

This section briefly considers compounds in which Si is bonded to elements other than hydrogen, the halogens or oxygen, especially compounds in which Si is bonded to S, N or P. Silicon burns in S vapour at 100° to give SiS_2 which can be sublimed in a stream of N_2 to give long, white, flexible, asbestos-like fibres, mp 1090°, sublimation 1250°C. The structure consists of infinite chains of edge-shared tetrahedra (like W-silica, p. 343) and these transform at high temperature and pressure to a (corner-shared) cristobalite modification. The structural complexity of SiO_2 is not repeated, however. SiS_2 hydrolyses rapidly to SiO_2 and H_2S and is completely ammonolysed by liquid NH_3 to the imide

$$SiS_2 + 4NH_3 \longrightarrow Si(NH)_2 + 2NH_4SH$$

Sulfides of Na, Mg, Al and Fe convert SiS_2 into metal thiosilicates, and ethanol yields "ethylsilicate" $Si(OEt)_4$ and H_2S.‡ Volatile

† According to H. Remy the artificial production of ultramarine was first suggested by J. W. von Goethe in his *Italian Journey* (1786–8); it was first accomplished by L. Gmelin in 1828 and developed industrially by the Meissen porcelain works in the following year. It can be made by firing kaolin and sulfur with sodium carbonate; various treatments yield greens, reds and violets, as well as the deep blue, the colours being reminiscent of the highly coloured species obtained in nonaqueous solutions of S, Se and Te (pp. 664, 759).

[56] R. J. H. CLARK and D. G. COBBOLD, *Inorg. Chem.* **17**, 3169–74 (1978).

‡ $Si(OEt)_4$ is an important industrial chemical that is made on the kilotonne scale by the action of EtOH on $SiCl_4$. It has mp −77°, bp 168.5°, and d_{20} 0.9346 g cm^{-3}. Almost all uses depend on its controlled hydrolysis to produce silica in an adhesive or film-producing form. It is also a source of

thiohalides have been reported from the reaction of SiX_4 with H_2S at red heat; e.g. $SiCl_4$ yields $S(SiCl_3)_2$, cyclic $Cl_2Si(\mu\text{-}S)_2SiCl_2$ and crystalline $(SiSCl_2)_4$. The first normal thiocyanate derivative of Si, $RMe_2Si\text{–}SCN$, [R = $-C(SiMe_3)_2\{SiMe_2(OMe)\}$] was prepared from the corresponding chloride by treatment with AgSCN; it is more readily solvolysed than its isothiocyanate isomer, $RMe_2Si\text{–}NCS$.[57]

The elusive Si=S grouping has been synthesized by reaction between solid Si and H_2S at 1200°C to give monomeric SiS; this high-temperature molecule can itself be reacted with Cl_2 or HCl in an argon matrix to yield monomeric $S{=}SiCl_2$ and S=SiHCl.[58] Synthesis of stable organosilanethiones, RR′Si=S has been achieved by using the strategem of imparting additional stabilization through intramolecular coordination via an amine function; e.g. [(α-naphthyl)(8-$Me_2\overline{NCH_2C_{10}H_8}\overline{Si}{=}S$] was prepared by heating the corresponding silane $RR'SiH_2$ with S_8; the Si=S distance of 201.3 pm was noticeably shorter than the normal single bond Si–S distance of 216 pm.[59]

The most important nitride of Si is Si_3N_4; this is formed by direct reaction of the elements above 1300° or more economically by heating SiO_2 and coke in a stream of N_2/H_2 at 1500°. The compound is of considerable interest as an engineering material since it is almost completely inert chemically, and retains its strength, shape and resistance to corrosion and wear even above 1000°.[60] Its great hardness (Mohs 9), high dissociation temperature (1900°, 1 atm) and high density (3.185 g cm^{-3}) can all be related to its compact structure which resembles that of phenacite (Be_2SiO_4, p. 347). It is an insulator with a resistivity at room temperature $\sim 6.6 \times 10^{10}$ ohm cm. Another refractory, Si_2N_2O, is formed when $Si + SiO_2$ are heated to 1450° in a stream of Ar containing 5% N_2. The structure comprises puckered hexagonal nets of alternating Si and N atoms interlinked by nonlinear Si–O–Si bonds to similar nets on either side; the Si atoms are thus each 4-coordinate and the N atoms 3-coordinate.

Volatile silylamides are readily prepared by reacting a silyl halide with NH_3, RNH_2 or R_2NH in the vapour phase or in Et_2O, e.g.:

$$3SiH_3Cl + 4NH_3 \longrightarrow N(SiH_3)_3 + 3NH_4Cl$$

$$SiH_3Br + 2Me_2NH \longrightarrow SiH_3NMe_2 + Me_2NH_2Br$$

$$4SiH_3I + 5N_2H_4 \longrightarrow (SiH_3)_2NN(SiH_3)_2 + 4N_2H_5I$$

Silicon-substituted derivatives may require the use of lithio or sodio reagents, e.g.:

$$Me_3SiCl + NaN(SiMe_3)_2 \longrightarrow N(SiMe_3) + NaCl$$

$$Ph_3SiLi + R_2NH \longrightarrow Ph_3SiNR_2 + LiH$$

The N atom is always tertiary in these compounds and no species containing the SiH–NH group is stable at room temperature. Apart from this restriction, innumerable such compounds have been prepared including cyclic and polymeric analogues, e.g. [cyclo-$\{Me_2SiN(SiMe_3)_2\}$] and [cyclo-$(Me_2SiNH)_4$]. Interest has focused on the stereochemistry of the N atom which is often planar, or nearly so.[61] Thus $N(SiH_3)_3$ features a planar N atom and this has been ascribed to p_π-d_π interaction between the "nonbonding" pair of electrons on N and the "vacant" d_π orbitals on Si as shown schematically in Fig. 9.16. Consistent with this trisilylamines are notably weaker ligands than their tertiary amine analogues though replacement of one or two SiH_3 by CH_3 enhances the donor power again; e.g. $N(SiH_3)_3$ forms no adduct with BH_3 even at low temperature;

metal-free silica for use in phosphors in fluorescent lamps and TV tubes. In partly hydrolysed form it is used as a paint vehicle, a protective coating for porous stone, and as a vehicle for zinc-containing galvanic corrosion-preventing coatings. Many other orthoesters $Si(OR)_4$ are known but none are commercially important.

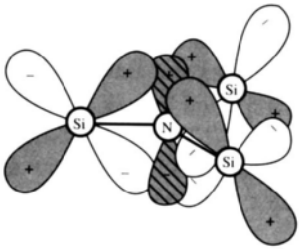

Figure 9.16 Symmetry relation between p_π orbital on N and d_π orbitals on the 3 Si atoms in planar $\{NSi_3\}$ compounds such as $N(SiH_3)_3$.

$MeN(SiH_3)_2$ forms a 1:1 adduct with BH_3 at −80° but this decomposes when warmed; $Me_2N(SiH_3)$ gives a similar adduct which decomposes at room temperature into Me_2NBH_2 and SiH_4 (cf. the stability of Me_3NBH_3, p. 165). The linear skeleton of H_3SiNCO and H_3SiNCS has also been interpreted in terms of $p_\pi-d_\pi$ $N \rightleftharpoons Si$ bonding.

Compounds containing an Si=N double bond are of very recent provenance. The first stable silanimine, $Bu^t_2Si{=}N{-}SiBu^t_3$, was prepared in 1986 as pale yellow crystals, mp 85° (decomp.);[62] it features a short Si=N distance (156.8 pm, cf. Si–N 169.5 pm) and almost linear coordination about the N atom (177.8°), suggesting some electronic delocalization as described above. The compound was made by reacting the azidosilane $Bu^t_2SiCl(N_3)$ with $NaSiBu^t_3$ in Bu_2O at −78°. The related compound $Pr^i_2Si{=}NR$ (R = 2,4,6-$Bu^t_3C_6H_2^-$) forms stable orange crystals, mp 98°.[63]

Unusual Si/P compounds are also beginning to appear, for example, the tetrasilahexaphospha-adamantane derivative $[(Pr^iSi)_4(PH)_6]$ (1), which is made by reacting Pr^iSiCl_3 with $Li[Al(PH_2)_4]$.[64] Again, reaction of white phosphorus, P_4, with tetramesityldisilene, $Mes_2Si{=}SiMes_2$, in toluene at 40° gives an 87% yield of the yellow bicyclo $(Mes_2Si)_2P_2$: this has a "butterfly" structure in which the "hinge" P atoms retain electron donor properties to give adducts such as the bis-$W(CO)_5$ complex (2) (P–P 234.2 pm; Si–P 224.4, 226.7 pm; P–W 256.0 pm; Si···Si 324.4 pm; angle Si–P–Si 91.9°).[65] The now extensive field of phosphorus-rich silaphosphanes has been reviewed.[66] Silaphosphenes, RR'Si=PAr are also known.[67]

9.3.7 Organosilicon compounds and silicones

Well over 100 000 organosilicon compounds have been synthesized. Of these, during the past few decades, silicone oils, elastomers and resins have become major industrial products. Many organosilicon compounds have considerable thermal stability and chemical inertness; e.g. $SiPh_4$ can be distilled in air at its bp 428°, as can Ph_3SiCl (bp 378°) and Ph_2SiCl_2 (bp 305°). These, and innumerable similar compounds, reflect the considerable strength of the Si–C bond which is, indeed, comparable with that of the C–C bond (p. 338). A further illustration is the compound SiC which closely resembles diamond in its properties (p. 334). Catenation and the formation of multiple bonds are further similarities with carbon chemistry, though these features are less prominent in organosilicon chemistry and much of the work in these areas is of recent

origin (e.g. pp. 338 and below). For example, although the word "silicone" was coined by F. S. Kipping in 1901 to indicate the similarity in *formula* of Ph_2SiO with that of the ketone benzophenone, Ph_2CO, he stressed that there was no chemical resemblance between them and that Ph_2SiO was polymeric.[68] It is now recognized that the great thermal and chemical stability of the silicones derives from the strength both of the Si–C bonds and of the Si–O–Si linkages. Many general reviews of the vast subject of organosilicon chemistry are available (e.g. refs 1, 2, 69–74) and only some of the salient or topical features will be touched on here. An interesting subset comprises the carbosilanes, that is compounds with a skeleton of alternating C and Si atoms.[75] These include chains, rings and polycyclic compounds, many of which can be made on a multigram or even larger scale by controlled thermolysis or by standard organometallic syntheses.

Transient reaction species containing Si=C bonds have been known since about 1966 and can be generated thermally, photolytically, or even chemically. A decade later $Me_2Si{=}CHMe$ was isolated in low-temperature matrices[76] but, despite concerted and well-planned attempts over many years, it was not until 1981 that a stable silene was reported.[77] A. G. Brook and his group prepared 2-adamantyl-2-trimethylsiloxy-1,1-bis(trimethylsilyl)-1-silaethene as very pale yellow needles, mp 92°:

$$(Me_3Si)_3SiC(O)(C_{10}H_{15}) \overset{\text{ether}/h\nu}{\rightleftharpoons} (Me_3Si)_2Si{=}C(OSiMe_3)(\text{adamantyl})$$

The solid silaethene was stable indefinitely at room temperature in the absence of air or other reagents but in solution it slowly reverted (over several days) to the isomeric acylsilane starting material. An X-ray analysis confirmed the structure and revealed a short >Si=C< bond (176.4 pm, cf. 187–191 pm for single-bonded Si–C) and a planar disposition of *ipso* atoms, the two planes being slightly twisted with respect to each other (14.6°). The use of bulky groups to enhance the stability of the silaethene is also notable, though this is not a necessary feature, at least at the Si centre, since $Me_2Si{=}C(SiMe_3)(SiMeBu^t_2)$ is stable as colourless crystals at room temperature (>Si=C< distance 170.2 pm, Si–C 189.0 pm and a planar $C_2Si{=}CSi_2$ skeleton).[78] The not unrelated planar heterocyclic compounds silabenzene, C_5SiH_6,[15] and silatoluene, C_5H_5SiMe,[16] should also be recalled.

Disilenes, containing the grouping >Si=Si<, can be isolated as thermally stable yellow or orange crystalline compounds provided that the substituents are sufficiently large to prevent

polymerization (e.g. mesityl, *t*-butyl, etc.)[79] The first such compound, Si_2Mes_4, was isolated in 1981 as orange crystals, mp 176°, following photolysis of the trisilane $SiMes_2(SiMe_3)_2$.[80] The Si=Si distance in several such compounds falls in the range 214–216 pm, which is about 10% shorter than the normal single-bonded Si–Si distance. Disilenes are chemically very reactive. Halogens and HX molecules give 1,2-addition products, e.g. $Mes_2Si(Cl)Si(Cl)Mes_2$, whilst aldehydes and ketones undergo [2 + 2] cyclo-addition reactions to give 1,2,3-oxadisilenanes, $\overline{OSi(Mes)_2Si(Mes)_2CHR}$. Controlled oxidation gives predominantly the 1,2-dioxetane $\overline{OSiR_2SiR_2O}$ (80%), plus the 1,3-cyclodisiloxane $\overline{OSiR_2OSiR_2}$ as a minor product. Numerous other novel heterocyles have been prepared by controlled reactions of disilenes with chalcogens, N_2O, P_4 and organic nitro-, nitroso-, azo- and azido-compounds.[81] Transition metal complexes can give η^2-disilene adducts such as $[Pt(PR_3)_2)(\eta^2\text{-}Si_2Mes_4)]$.[79,82]

Another fertile area of current interest is the synthesis of stable homocyclic polysilane derivatives.[83] Typical examples are cyclo-$(SiMe_2)_7$,[84] (cyclo-Si_5Me_9)-$(SiMe_2)_n$-(cyclo-Si_5Me_9), $n = 2–5$,[85] and several new permethylated polycylic silanes such as the colourless crystalline compounds bicyclo[3.2.1]-Si_8Me_{14} (mp 245°), bicyclo[3.3.1]-Si_9Me_{16} (mp ≥330°) and bicyclo[4.4.0]-$Si_{10}Me_{18}$ (mp 165°.[86] Analogues of cubane and tetrahedrane have also been synthesized. Thus, the one-step condensation of $Br_2RSiSiRBr_2$ or even $RSiBr_3$ with Na in toluene at 90° gave yields of up to 72% of the cubane $(SiR)_8$ ($R = SiMe_2Bu^t$) as bright yellow, air-sensitive crystals which are stable up to at least 400°C.[87] The synthesis of a molecular tetrasila-tetrahedrane has also finally been achieved by the following ingenious route ($R = SiBu^t_3$):[88]

$$2SiH_2Cl_2 \xrightarrow{2NaR} 2RSiH_2Cl \xrightarrow{2Na} RSiH_2SiH_2R \longrightarrow RSiBr_2SiBr_2R$$

$$2RSiBr_2SiBr_2R + 4NaR \longrightarrow Si_4R_4 + 4RBr + 4NaBr$$

The product, $Si_4(SiBu^t_3)_4$, forms intensely orange crystals that are stable to heat, light, water and air, and do not melt below 350°. The Si–Si distances within the *closo*-Si_4 cluster are 232–234 pm and the *exo* Si–Si distances are slightly longer, 235–237 pm (cf. Si–Si 235.17 in crystalline Si). Comparison with the *closo*-anion Si_4^{4-}, which occurs in several metal silicides (p. 337) and is isoelectronic with the P_4 molecule, is also appropriate.

There are three general methods for forming Si–C bonds. The most convenient laboratory method for small-scale preparations is by the reaction of $SiCl_4$ with organolithium, Grignard or organoaluminium reagents. A second attractive route is the hydrosilylation of alkenes, i.e. the catalytic addition of Si–H across C=C double bonds; this is widely applicable except for the crucially important methyl and phenyl silanes. Industrially, organosilanes are made by the direct reaction of RX or ArX with a fluidized bed of Si in the presence of about 10% by weight of metallic Cu as catalyst (cf. the direct preparation of organo compounds of

Ge, Sn, and Pb, pp. 396ff). The method was patented by E. G. Rochow in 1945 and ensured the commercial viability of the now extensive silicone industry.[2,69,72]

$$2MeCl + Si \xrightarrow[\sim 300^\circ]{\text{Cu powder}} Me_2SiCl_2 \quad (70\%\ \text{yield})$$

By-products are $MeSiCl_3$ (12%) and Me_3SiCl (5%) together with 1–2% each of $SiCl_4$, $SiMe_4$, $MeSiHCl_2$, etc. Relative yields can readily be altered by modifying the reaction conditions or by adding HCl (which increases $MeSiHCl_2$ and drastically reduces Me_2SiCl_2). The overall reaction is exothermic and heat must be removed from the fluidized bed. Because of their very similar bps, careful fractionation is necessary if pure products are required: Me_3SiCl 57.7°, Me_2SiCl_2 69.6°, $MeSiCl_3$ 66.4°. Mixtures of ethylchlorosilanes or phenylchlorosilanes (or their bromo analogues) can be made similarly. All these compounds are mobile, volatile liquids (except Ph_3SiCl, mp 89°, bp 378°).

Innumerable derivatives have been prepared by the standard techniques of organic chemistry.[2,69–75] The organosilanes tend to be much more reactive than their carbon analogues, particularly towards hydrolysis, ammonolysis, and alcoholysis. Further condensation to cyclic oligomers or linear polymers generally ensues, e.g.:

$$Ph_2SiCl_2 \xrightarrow{H_2O} Ph_2Si(OH)_2 \text{ white crystals, mp } \sim 132^\circ \text{ (d)}$$

$$\xrightarrow{>100^\circ} \tfrac{1}{n}(Ph_2SiO)_n + H_2O \qquad n = 3(\text{cyclo}), 4(\text{cyclo}), \text{ or } \infty$$

$$Me_2SiCl_2 \xrightarrow{NH_3/-35^\circ} \{Me_2Si(NH_2)_2\} \longrightarrow [\text{cyclo-}(Me_2SiNH)_3] + [\text{cyclo-}(Me_2SiNH)_4]$$

(not isolated)

For both economic and technical reasons, commercial production of such polymers is almost entirely restricted to the methyl derivatives (and to a lesser extent the phenyl derivatives) and hydrolysis of the various methylchlorosilanes has, accordingly, been much studied. Hydrolysis of Me_3SiCl yields trimethylsilanol as a volatile liquid (bp 99°); it is noticeably more acidic than the corresponding Bu^{t}OH and can be converted to its Na salt by aqueous NaOH (12M). Condensation gives hexamethyldisiloxane which has a very similar bp (100.8°):

$$2Me_3SiCl \xrightarrow[(-2HCl)]{+2H_2O} 2Me_3SiOH \xrightarrow{-H_2O} [O(SiMe_3)_2]$$

Hydrolysis of Me_2SiCl_2 usually gives high polymers, but under carefully controlled conditions leads to cyclic dimethylsiloxanes $[(Me_2SiO)_n]$ ($n = 3, 4, 5, 6$). Linear siloxanes have also been made by hydrolysing Me_2SiCl_2 in the presence of varying amounts of Me_3SiCl as a "chain-stopping" group, i.e. $[Me_3SiO(Me_2SiO)_xSiMe_3]$ ($x = 0, 1, 2, 3, 4$), etc. Cross-linking is achieved by hydrolysis and condensation in the presence of $MeSiCl_3$ since this generates a third Si–O function in addition to the two required for polymerization:

$$Me_3SiCl \xrightarrow{H_2O} Me_3Si{-}O{-} \quad \text{terminal group}$$

$$Me_2SiCl_2 \xrightarrow{H_2O} {-}O{-}SiMe_2{-}O{-} \quad \text{chain-forming group}$$

$$MeSiCl_3 \xrightarrow{H_2O} MeSi(-O-)_3 \quad \text{branching and bridging group}$$

Comparison with the mineral silicates is instructive since there is a 1:1 correspondence between the two sets of compounds, the methyl groups in the silicones being replaced by the formally isoelectronic O^- in the silicates (see p. 366). This reminds us of the essentially covalent nature of the Si–O–Si linkage, but the analogy should not be taken to imply identity of structures in detail, particularly for the more highly condensed polymers. Some aspects of the technology of silicones are summarized in the concluding Panel.

While siloxanes and silicones are generally regarded as being unreactive, it is well to remember that they do indeed react with fluorinating agents and with concentrated hydroxide solutions. In certain cases they can even be employed as mild selective reagents for specific syntheses. For example, $(Me_3Si)_2O$ is a useful reagent for the convenient high-yield

Silicone Polymers[1,2]

Silicones have good thermal and oxidative stability, valuable resistance to high and low temperatures, excellent water repellency, good dielectric properties, desirable antistick and antifoam properties, chemical inertness, prolonged resistance to ultraviolet irradiation and weathering, and complete physiological inertness. They can be made as fluids (oils), greases, emulsions, elastomers (rubbers) and resins.

Silicone oils are made by shaking suitable proportions of [$O(SiMe_3)_2$] and [cyclo-$(Me_2SiO)_4$] with a small quantity of 100% H_2SO_4; this randomizes the siloxane links by repeatedly cleaving the Si–O bonds to form HSO_4 esters and then reforming new Si–O bonds by hydrolysing the ester group:

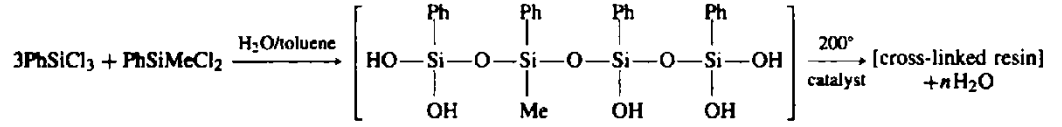
$$\equiv Si-O-Si\equiv + H_2SO_4 \longrightarrow \equiv Si-O-SO_3H + \equiv Si-OH$$

$$\equiv Si-OH + HO_3S-O-Si\equiv \longrightarrow \equiv Si-O-Si\equiv + H_2SO_4$$

The molecular weight of the resulting polymer depends only on the initial proportion of the chain-ending groups (Me_3SiO- and Me_3Si-) and the chain-building groups ($-Me_2SiO-$) from the two components. Viscosity at room temperature is typically in the range 50–300 000 times that of water and it changes only slowly with temperature. These liquids are used as dielectric insulating media, hydraulic oils and compressible fluids for liquid springs. Pure methylsilicone oils are good lubricants at light loads but cannot be used for heavy-duty steel gears and shafts since they contain no polar film-forming groups and so are too readily exuded under high pressure. The introduction of some phenyl groups improves performance, and satisfactory greases can be made by thickening methyl phenyl silicone oil with Li soaps. Other uses are as heat transfer media in heating baths and as components in car polish, sun-tan lotion, lipstick and other cosmetic formulations. Their low surface tension leads to their extensive use as antifoams in textile dyeing, fermentation processes and sewage disposal: about 10^{-2} to 10^{-4}% is sufficient for these applications. Likewise their complete non-toxicity allows them to be used to prevent frothing in cooking oils, the processing of fruit juices and the production of potato crisps.

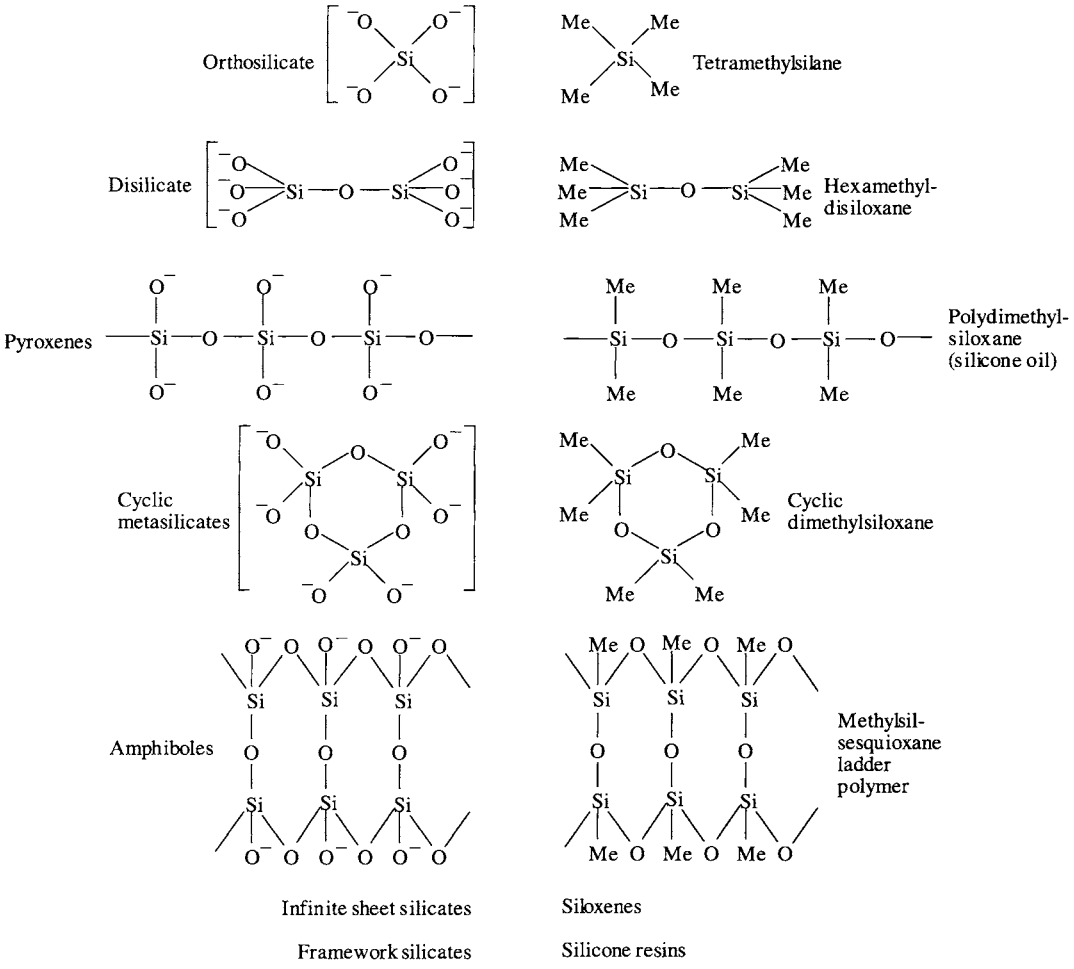
Silicone elastomers (rubbers) are reinforced linear dimethylpolysiloxanes of exceedingly high molecular weight (5×10^5–10^7). The reinforcing agent, without which the viscous gum is useless, is usually fumed silica (p. 345). Polymerization can be acid-catalysed but KOH produces a rubber with superior physical properties; in either case scrupulous care must be taken to avoid the presence of precursors of chain-blocking groups [Me_3Si-O-] or cross-linking groups [$MeSi(-O-)_3$]. The reinforced silicone rubber composition can be "vulcanized" by oxidative cross-linking using 1–3% of benzoyl peroxide or similar reagents; the mixture is heated to 150° for 10 min at the time of pressing or moulding and then cured for 1–10 h at 250°. Alternatively, and more elegantly, the process can be achieved at room temperature or slightly above by incorporating a small controlled concentration of Si–H groups which can be catalytically added across pre-introduced $Si-CH=CH_2$ groups in adjacent chains. Again, the cross-linking of 1-component silicone rubbers containing acetoxy groups can be readily effected at room temperature by exposure to moisture: Such rubbers generally have 1 cross-link for every 100–1000 Si atoms and are unmatched by any other synthetic or natural rubbers in retaining their inertness, flexibility, elasticity and strength up to 250° and down to −100°. They find use in cable-insulation sleeving, static and rotary seals, gaskets, belting, rollers, diaphragms, industrial sealants and adhesives, electrical tape insulation, plug-and-socket connectors, oxygen masks, medical tubing, space suits, fabrication of heart-valve implants, etc. They are also much used for making accurate moulds and to give rapid, accurate and flexible impressions for dentures and inlays.

Silicone resins are prepared by hydrolysing phenyl substituted dichloro- and trichloro-silanes in toluene. The Ph groups increase the heat stability, flexibility, and processability of the resins. The hydrolysed mixture is washed with water to remove HCl and then partly polymerized or "bodied" to a carefully controlled stage at which the resin is still soluble. It is in this form that the resins are normally applied, after which the final cross-linking to a 3D siloxane network is effected by heating to 200° in the presence of a heavy metal or quaternary ammonium catalyst to condense the silanol groups, e.g.:



a typical intermediate species

Silicone resins are used in the insulation of electrical equipment and machinery, and in electronics as laminates for printed circuit boards; they are also used for the encapsulation of components such as resistors and integrated circuits by means of transfer moulding. Non-electrical uses include high-temperature paints and the resinous release coatings familiar on domestic cooking ware and industrial tyre moulds. When one recalls the very small quantities of silicones needed in many of these individual applications, the global production figures are particularly impressive: they have grown from a few tonnes in the mid-1940s to over 100 000 tonnes in 1969 and an estimated production of 350 000 tonnes in 1982. About half of this is in the USA, distributed so that some 65–70% is as fluid silicones, 25–30% as elastomers, and 5–10% as resins. Over 1000 different silicone products are commercially available.



preparation of oxyhalide derivatives of Mo and W.[89] Thus, in CH_2Cl_2 solution, $(Me_3Si)_2O$ converts a suspension of WCl_6 quantitatively to red crystals of $W(O)Cl_4$ in less than 1 h at room temperature, and $W(O)Cl_4$ can then itself be converted to yellow $W(O)_2Cl_2$ in 95% yield (light petroleum, 100°, overnight). Likewise, $Mo(O)Cl_4$ when treated with $(Me_3Si)_2O$ in CH_2Cl_2 gives $Mo(O)_2Cl_2$ in 97% yield at r.t. Even silicone high-vacuum grease has been found unexpectedly to react with the potassium salt of an organoindium hydride to give crystals of the pseudo-crown ether complex $[cyclo\text{-}(Me_2SiO)_7K^+](K^+)_3[HIn(CH_2CMe_3)_3^-]_4$.[90]

Germanium, Tin and Lead

10.1 Introduction

Germanium was predicted as the missing element of a triad between silicon and tin by J. A. R. Newlands in 1864, and in 1871 D. I. Mendeleev specified the properties that "ekasilicon" would have (p. 29). The new element was discovered by C. A. Winkler in 1886 during the analysis of a new and rare mineral argyrodite, Ag_8GeS_6;[1] he named it in honour of his country, Germany.† By contrast, tin and lead are two of the oldest metals known to man and both are mentioned in early books of the Old Testament. The chemical symbols for the elements come from their Latin names *stannum* and *plumbum*. Lead was used in ancient Egypt for glazing pottery (7000–5000 BC); the Hanging Gardens of Babylon were floored with sheet lead to retain moisture and the Romans used lead extensively for water-pipes and plumbing; they extracted some 6–8 million tonnes in four centuries with a peak annual production of 60 000 tonnes. Production of tin, though equally influential, has been on a more modest scale and dates back to 3500–3200 BC. Bronze weapons and tools containing 10–15% Sn alloyed with Cu have been found at Ur, and Pliny described solder as an alloy of Sn and Pb in AD 79.

Germanium and Sn are non-toxic (like C and Si). Lead is now recognized as a heavy-metal poison;[2] it acts by complexing with oxo-groups

[1] M. E. WEEKS, *Discovery of the Elements*, 6th edn., Journal of Chemical Education Publ. 1956, 910 pp. Germanium, pp. 683–93; Tin and lead, pp. 41–7.

† The astonishing correspondence between the predicted and observed properties of Ge (p. 29) has tempted later writers to overlook the fact that Winkler thought he had discovered a metalloid like As and Sb and he originally identified Ge with Mendeleev's (incorrectly) predicted "eka-stibium" between Sb and Bi; Mendeleev himself thought it was "eka-cadmium", which he had (again incorrectly) predicted as a missing element between Cd and Hg. H. T. von Richter thought it was "eka-silicon"; so did Lothar Meyer, and they proved to be correct. This illustrates the great difficulties encountered by chemists working only 100 y ago, yet three decades before the rationale which stemmed from the work of Moseley and Bohr.

Freeman, San Francisco, 1973. See also R. M. HARRISON and D. P. H. LAXEN, *Lead Pollution*, Chapman and Hall, London, 1981, 175 pp; T. C. HUTCHINSON and K. N. MEEMA (eds.), *Lead, Mercury, Cadmium and* (ctd.)

in enzymes and affects virtually all steps in the process of haem synthesis and porphyrin metabolism. It also inhibits acetylcholine-esterase, acid phosphatase, ATPase, carbonic anhydrase, etc. and inhibits protein synthesis probably by modifying transfer-RNA. In addition to O complexation (in which it resembles Tl^{I}, Ba^{II} and Ln^{III}), Pb^{II} also inhibits SH enzymes (though less strongly than Cd^{II} and Hg^{II}), especially by interaction with cysteine residues in proteins. Typical symptoms of lead poisoning are cholic, anaemia, headaches, convulsions, chronic nephritis of the kidneys, brain damage and central nervous-system disorders. Treatment is by complexing and sequestering the Pb using a strong chelating agent such as edta, $\{-CH_2N(CH_2CO_2H)_2\}_2$, or BAL i.e. British anti-Lewisite, $HSCH_2CH(SH)CH_2OH$.

10.2 The Elements

10.2.1 Terrestrial abundance and distribution

Germanium and Sn appear about half-way down the list of elements in order of abundance in crustal rocks, together with several other elements in the region of 1–2 ppm:

Element	Br	U	**Sn**	Eu	Be	As
PPM	2.5	2.3	**2.1**	2.1	2	1.8
Order	46	47	**48**	=48	50	51
Element	Ta	**Ge**	Ho	Mo	W	Tb
PPM	1.7	**1.5**	1.4	1.2	1.2	1.2
Order	52	**53**	54	55	=55	=55

Germanium minerals are extremely rare but the element is widely distributed in trace amounts (like its neighbour Ga). Recovery has been achieved from coal ash but is now normally from the flue dusts of smelters processing Zn ores.

Tin occurs mainly as cassiterite, SnO_2, and this has been the only important source of the element from earliest times. Julius Caesar recorded the presence of tin in Britain, and Cornwall remained the predominant supplier for European needs until the present century (apart from a minor flourish from Bohemia between 1400 and 1550).[3] Today (1990s) world production approaches 200 000 tonnes per annum (see next section), of which the UK contributes less than 1%.[4]

Lead (13 ppm) is by far the most abundant of the heavy elements, being approached amongst these only by thallium (8.1 ppm) and uranium (2.3 ppm). This abundance is related to the fact that 3 of the 4 naturally occurring isotopes of lead (206, 207 and 208) arise primarily as the stable end products of the natural radioactive series. Only ^{204}Pb (1.4%) is non-radiogenic in origin. The variation in isotopic composition of Pb with its origin also accounts for the variability of atomic weight and the limited precision with which it can be quoted (p. 19). The most important Pb ore is the heavy black mineral galena, PbS. Other ore minerals are anglesite ($PbSO_4$), cerussite ($PbCO_3$), pyromorphite ($Pb_5(PO_4)_3Cl$) and mimetesite ($Pb_5(AsO_4)_3Cl$). Some 25 other minerals are known but are not economically important; all contain Pb^{II} in contrast to tin minerals which are invariably Sn^{IV} compounds. Lead ores are widely distributed and commercial deposits are worked in over fifty countries. Primary production (from mines) was 3.3 million tonnes (as Pb) in 1991 of which four-fifths came from the half dozen main producers: Australia 17.4%, USA 14.3%, the former Soviet Union 13.8%, China 9.6%, Canada 8.3% and Peru 6.0%.[4] Secondary production (from the resmelting of scrap) produces a further 5.6 Mtpa i.e. nearly two-thirds of the world's supply in 1991. The average price in 1992 was £306.4/tonne ($542/t).

10.2.2 Production and uses of the elements

Recovery of Ge from flue dusts is complicated, not only because of the small concentration of Ge but also because its amphoteric properties are similar to those of Zn from which it is being separated.[5] Leaching with H_2SO_4, followed by addition of aqueous NaOH, results in the coprecipitation of the 2 elements at pH ~5 and enrichment of Ge from ~2 to 10%: GeO_2 begins to precipitate at pH 2.4, is 90% precipitated at pH 3, and 98% precipitated at pH 5. $Zn(OH)_2$ begins to precipitate at pH 4 and is completely precipitated at pH 5.5. The concentrate is heated with HCl/Cl_2 to drive off $GeCl_4$, bp 83.1° (cf. $ZnCl_2$, bp 756°). After further fractionation of $GeCl_4$, hydrolysis affords purified GeO_2, which can be slowly reduced to the element by H_2 at ~530°. Final purification for semiconductor-grade Ge is effected by zone refining. World production of Ge in 1991 was 80 000 kg (80 tonnes), about 10% less than a decade earlier. The largest use is in transistor technology and, indeed, transistor action was first discovered in this element (p. 331). This use is now diminishing somewhat whilst that in optics is growing — Ge is transparent in the infrared and is used in infrared windows, prisms and lenses. Magnesium germanate is a useful phosphor, and other small-scale applications are in special alloys, strain gauges and superconductors. Despite its spectacular increase in availability during the past few decades from a laboratory rarity to a general article of commerce Ge and its compounds are still relatively expensive. Zone-refined Ge was quoted at $850 per kg in 1991 and GeO_2 at $500 per kg.

The ready reduction of SnO_2 by glowing coals accounts for the knowledge of Sn and its alloys in the ancient world. Modern technology uses a reverberatory furnace at 1200–1300°.[6] The main chemical problem in reducing SnO_2 comes from the presence of Fe in the ores which leads to a hard product with unacceptable properties. Reference to Ellingham-type diagrams of the sort shown on p. 308 shows that $-\Delta G(SnO_2)$ is very close to that for FeO/Fe_3O_4 and only about 80 kJ mol^{-1} above the line for reducing FeO to Fe at 1000–2000°. It is therefore essential to reduce cassiterite/iron oxide ores at an oxygen pressure sufficiently high to prevent extensive reduction to Fe. This is achieved in a two-stage process, the impure molten Sn from the initial carbon reduction being stirred vigorously in contact with atmospheric O_2 to oxidize the iron — a process that can be effected by "poling" with long billets of green wood — or, alternatively, by use of steam or compressed air. The price of tin was formerly regulated by The International Tin Council, but the market became progressively less stable and the suspension of buffer stock interventions in October 1985 precipitated on immediate collapse in the market from which it has not yet recovered. The ITC was superseded by The Association of Tin Producing Countries which attempts to limit production by the member countries. In 1991 there was an excess of tin on the world market for the 11th successive year and primary production was limited to 95 850 tonnes (Malaysia 29.8%, Indonesia 29.6%, Thailand 17.9%, Bolivia 13.2%, Australia 7.2%, Zaire 1.4%, Nigeria 0.9%). Additional production by China (43 000 t), the former USSR (13 500 t) and other countries brought the primary production of Sn in concentrates in 1991 to 196 700 tonnes. Prices hovered around $5700 per tonne, about half that of a few years earlier.[7,8] The many uses of metallic tin and its alloys are summarized in the Panel overleaf.

Lead is normally obtained from PbS. This is first concentrated from low-grade ores by froth flotation then roasted in a limited supply of air

Uses of Metallic Tin and Its Alloys

Because of its low strength and high cost, Sn is seldom used by itself but its use as a coating, and as alloys, is familiar in a variety of domestic and technological applications. Tin-plate accounts for almost 27% of tin used — it provides a non-toxic corrosion-resistant cover for sheet steel and can be applied either by hot dipping in molten Sn or more elegantly and controllably by electrolytic tinning. The layer is typically 0.4–25 μm thick. In addition to extensive use in food packaging, tin-plate is used increasingly for distributing beer and other drinks. In the USA alone 35 000 million of the 130 000 million drink cans sold annually are tin-plate, the rest being Al: this is a staggering per capita consumption of 500 pa.

The main alloys of tin together with an indication of the percentage of total Sn production for these alloys in the USA (1991) are:

Solder (37%)	(Sn/Pb) typically containing 33% Sn by weight but varying between 2–63% depending on use; sometimes Cd, Ga, In or Bi are added for increased fusibility.
Bronze (7%)	(Cu/Sn) typically 5–10% Sn often with added P or Zn to aid casting and impart superior elasticity and strain resistance. Gun metal is ~85% Cu, 5% Sn, 5% Zn and 5% Pb. Coinage metal and brass also often contain small amounts of Sn. World production of bronzes approaches 500 000 tonnes pa.
Babbitt (2%)	(heavy duty bearing metal introduced by I. Babbitt in 1839). The two main compositions are 80–90% Sn, 0–5% Pb, 5% Cu; and 75% Pb, 12% Sn, 13% Sb, 0–1% Cu. They have the characteristics of a hard compound embedded in a soft matrix and are used mainly in railway wagons, diesel locomotives, etc.
Pewter (3%)	(90–95% Sn, 1–8% Sb, 0.5–3% Cu); a decorative and servicable alloy that can be cast, bent, spun or formed into any shape; it is much used for coffee and tea services, trays, plates, jugs, tankards, candelabra, bowls and trophies. A related alloy of 90–95% Sn with Pb and other elements is highly prized and much used for organ pipes because of its tonal qualities, e.g. the Royal Albert Hall organ in London has 10 000 pipes containing some 150 tonnes Sn.

Other specialized uses of Sn and its alloys are as type metal, as the molten-metal bath in the manufacture of float glass and as the alloy Nb_3Sn in superconducting magnets. The many industrial and domestic uses of tin compounds are discussed in later sections; these compounds account for about 15% of the tin produced worldwide.

to give PbO which is then mixed with coke and a flux such as limestone and reduced in a blast furnace:[9]

$$PbS + 1.5O_2 \longrightarrow PbO + SO_2$$

$$PbO + C \longrightarrow Pb(liq) + CO;$$

$$PbO + CO \longrightarrow Pb(liq) + CO_2$$

Alternatively, the carbon reduction can be replaced by reduction of the roasted ore with fresh galena:

$$PbS + 2PbO \longrightarrow 3Pb(liq) + SO_2(g)$$

In either case the Pb contains numerous undesirable metal impurities, notably Cu, Ag, Au, Zn, Sn, As and Sb, some of which are clearly valuable in themselves. Copper is first removed by liquation: the Pb bullion is melted and held just above its freezing point when Cu rises to the surface as an insoluble solid which is skimmed off. Tin, As and Sb are next removed by preferential oxidation in a reverberatory furnace and skimming off the oxides; alternatively, the molten bullion is churned with an oxidizing flux of molten $NaOH/NaNO_3$ (Harris process). The softened Pb may still contain Ag, Au and perhaps Bi. Removal of the first two depends on their preferential solubility in Zn: the mixed metals are cooled slowly from 480° to below 420° when the Zn (now containing nearly all the Ag and Au) solidifies as a crust which is skimmed off; the

Uses of Lead Alloys and Chemicals

Although much lead is used as an inert material in cast, rolled or extruded form, a far greater tonnage is consumed as alloys. Its major application is in storage batteries where an alloy of 91% Pb, 9% Sb forms the supporting grid for the oxidizing agent (PbO_2) and the reducing agent (spongy Pb).[10] Over 70% of this Pb is recovered and recycled. In addition, its use (with Sn) in solders, fusible alloys, bearing metals (babbitt) and type metals has been summarized on p. 370. Other mechanical as distinct from chemical applications are in ammunition, lead shot, lead weights and ballast.

The pattern of chemical usage of Pb compounds in a particular country depends very much on whether organolead compounds are allowed as antiknock additives in petrol for cars (gasoline for automobiles). In a growing number of developed countries such additives are considered to be wasteful, dangerous and unnecessary and environmental legislation is gradually achieving the elimination of $PbEt_4$ and $PbMe_4$ as antiknocks.[2] The presence of Pb additives in petrol also interferes with the catalytic converters that are being developed to reduce or eliminate CO, NO_x and hydrocarbons from exhaust fumes, and this has likewise encouraged the change to other antiknocks.

World production of mined lead was 3 331 000 tonnes in 1991 and a further 5 558 000 tonnes was refined by reprocessing. In the same year US consumption of Pb in metal products was 1 125 000 tonnes (including 967 000 tonnes in storage batteries). In addition, some 57 250 tonnes of other oxides and 29 750 tonnes of miscellaneous Pb-containing products were consumed. The US market price of Pb dropped from $1.05/kg in 1990 to $0.40/kg in 1993 due in part to the collapse in use of $PbEt_4$ in petrol.

Lead pigments are widely used as rust-inhibiting priming paints for iron and steel. Red lead (Pb_3O_4) is the traditional primer but Ca_2PbO_4 is finding increasing use, particularly for galvanized steel. Lead chromate, $PbCrO_4$, is a strong yellow pigment extensively used in yellow paints for road markings and as an ingredient (with iron blues) in many green paints and coloured plastics. Other pigments include $PbMoO_4$ (red-orange), litharge PbO (canary yellow), and white lead, $\sim 2PbCO_3.Pb(OH)_2$. Lead compounds are also used for ceramic glazes, e.g. $PbSi_2O_5$ (colourless), in crown glass manufacture, and as polyvinylchloride plastic stabilizers, e.g. "tribasic lead sulfate", $3PbO.PbSO_4.H_2O$. See also p. 386.

excess of dissolved Zn is then removed either by oxidation in a reverberatory furnace, or by preferential reaction with gaseous Cl_2, or by vacuum distillation. Final purification (which also removes any Bi) is by electrolysis using massive cast Pb anodes and an electrolyte of acid $PbSiF_6$ or a sulfamate;[10] this yields a cathode deposit of 99.99% Pb which can be further purified by zone refining to <1 ppm impurity if required. Total world production figures and the current price were given at the end of the preceding section, and the various uses for lead alloys and chemicals are summarized in the Panel.

10.2.3 Properties of the elements

The atomic properties of Ge, Sn and Pb are compared with those of C and Si in Table 10.1. Trends noted in previous groups are again apparent. The pairwise similarity in the ionization energies of Si and Ge (which can be related to the filling of the $3d^{10}$ shell) and of Sn and Pb (which is likewise related to the filling of the $4f^{14}$ shell) are notable (Fig. 10.1). Tin has more stable isotopes than any other element (why?) and one of these, ^{119}Sn (nuclear spin $\frac{1}{2}$), is particularly valuable both for nmr experiments[11] and for Mössbauer spectroscopy.[12]

Some physical properties of the elements are compared in Table 10.2. Germanium forms brittle, grey-white lustrous crystals with the diamond structure; it is a metalloid with a similar electrical resistivity to Si at room temperature but with a substantially smaller band gap. Its mp, bp and associated enthalpy changes are also lower than for Si and this trend continues for Sn and Pb which are both very soft, low-melting metals.

Tin has two allotropes: at room temperature the stable modification is white, tetragonal

LIVE GRAPH

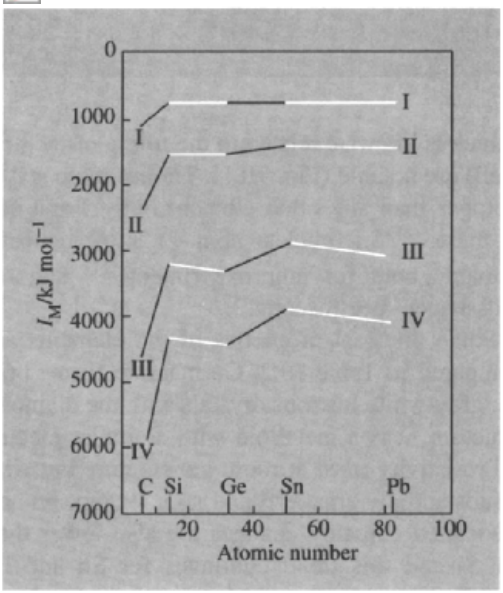

Figure 10.1 Successive ionization energies for Group 14 elements showing the influence of the $3d^{10}$ shell between Si and Ge and the $4f^{14}$ shell between Sn and Pb.

β-Sn, but at low temperatures this transforms into grey α-Sn which has the cubic diamond structure. The transition temperature is 13.2° but the transformation usually requires prolonged exposure at temperatures well below this. The reverse transition from α→β involves a structural distortion along the *c*-axis and is remarkable for the fact that the density increases by 26% in the high-temperature form. This arises because, although the Sn–Sn distances increase in the α→β transition, the CN increases from 4 to 6 and the distortion also permits a closer approach of the 12 next-nearest neighbours:

Modification	α (grey, diamond)	β (white, tetragonal)
Bond angles	6 at 109.5°	4 at 94° 2 at 149.6°
Nearest neighbours	4 at 280 pm	4 at 302 pm 2 at 318 pm
Next nearest neighbours	12 at 459 pm	4 at 377 pm 8 at 441 pm

A similar transformation to a metallic, tetragonal β-form can be effected in Si and Ge by subjecting them to pressures of ~200 and ~120 kbar respectively along the *c*-axis, and again the density increases by ~25% from the value at atmospheric pressure. Lead is familiar as a blue-grey, malleable metal with a fairly high density (nearly 5 times that of Si and twice those of Ge and Sn, but only half that of Os and Ir).

10.2.4 Chemical reactivity and group trends

Germanium is somewhat more reactive and more electropositive than Si: it dissolves slowly in hot concentrated H_2SO_4 and HNO_3 but does not react with water or with dilute acids or alkalis unless an oxidizing agent such as H_2O_2 or NaOCl is present; fused alkalis react with incandescence to give germanates. Germanium is oxidized to GeO_2 in air at red heat and both H_2S and gaseous S yield GeS_2; Cl_2 and Br_2 yield GeX_4 on moderate heating and HCl gives both $GeCl_4$ and $GeHCl_3$. Alkyl halides react with heated Ge (as with Si) to give the corresponding organogermanium halides.

Tin[13] is notably more reactive and electropositive than Ge though it is still markedly amphoteric in its aqueous chemistry. It is stable towards both water and air at ordinary temperatures but reacts with steam to give SnO_2 plus H_2 and with air or oxygen on heating to give SnO_2. Dilute HCl and H_2SO_4 show little, if any, reaction but dilute HNO_3 produces $Sn(NO_3)_2$ and NH_4NO_3. Hot concentrated HCl yields $SnCl_2$ and H_2 whereas hot concentrated H_2SO_4 forms $SnSO_4$ and SO_2. The occurrence of Sn^{II} compounds in these reactions is notable. By contrast, the action of hot aqueous alkali yields hydroxostannate(IV) compounds, e.g.:

$$Sn + 2KOH + 4H_2O \longrightarrow K_2[Sn(OH)_6] + 2H_2$$

Tin reacts readily with Cl_2 and Br_2 in the cold and with F_2 and I_2 on warming to give SnX_4. It reacts vigorously with heated S and Se, to form Sn^{II} and Sn^{IV} chalcogenides depending on the proportions used, and with Te to form SnTe.

Finely divided Pb powder is pyrophoric but the reactivity of the metal is usually greatly diminished by the formation of a thin, coherent, protective layer of insoluble product such as oxide, oxocarbonate, sulfate or chloride. This inertness has been exploited as one of the main assets of the metal since early times: e.g. a temperature of 600–800° is needed to form PbO in air and Pb is widely used for handling hot concentrated H_2SO_4. Aqueous HCl does, in fact, react slowly to give the sparingly soluble $PbCl_2$ (<1% at room temperature) and nitric acid reacts quite rapidly to liberate oxides of nitrogen and form the very soluble $Pb(NO_3)_2$ (~50 g per 100 cm^3, i.e. 1.5 M). Organic acids such as acetic acid also dissolve Pb in the presence of air to give $Pb(OAc)_2$, etc.; this precludes contact with the metal when processing or storing wine, fruit juices and other drinks. The familiar soft metal protective caps covering the cork on quality wines is Pb-foil laminated between thin outer layers of non-toxic Sn metal to which coloured decorative finishes can be applied. Fluorine reacts at room temperatures to give PbF_2 and Cl_2 gives $PbCl_2$ on heating.

Molten Pb reacts with the chalcogens to give PbS, PbSe and PbTe.

The steady trend towards increasing stability of M^{II} rather than M^{IV} compounds in the sequence Ge, Sn, Pb is an example of the so-called "inert-pair effect" which is well established for the heavier post-transition metals. The discussion on p. 226 is relevant here. A notable exception is the organometallic chemistry of Sn and Pb which is almost entirely confined to the M^{IV} state (pp. 399–405).

Catenation is also an important feature of the chemistry of Ge, Sn and Pb though less so than for C and Si. The discussion on p. 341 can be extended by reference to the bond energies in Table 10.3 from which it can be seen that there is a steady decrease in the M–M bond strength. In general, with the exception of M–H bonds, the strength of other M–X bonds diminishes less noticeably, though the absence of Ge analogues of silicone polymers speaks for the lower stability of the Ge–O–Ge linkage.

The structural chemistry of the Group 14 elements affords abundant illustrations of the trends to be expected from increasing atomic size, increasing electropositivity and increasing tendency to form M^{II} compounds, and these will become clear during the more detailed treatment of the chemistry in the succeeding sections. The often complicated stereochemistry of M^{II} compounds (which arises from the presence of a nonbonding electron-pair on the metal) is particularly revealing as also is the propensity of Sn^{IV} to become 5- and 6-coordinate.[14] The ability of both Sn and Pb to form polyatomic cluster anions of very low formal oxidation state, (e.g. M_5^{2-}, M_9^{4-}, etc.) reflects the now well-established tendency of the heavier post-transition elements to form chain, ring or cluster homopolyatomic ions:[18] this was first established for the polyhalide anions and for Hg_2^{2+} but is also prevalent in Groups 14, 15 and 16, e.g. Pb_9^{4-} is isoelectronic with Bi_9^{5+} (see Section 10.3.6, p. 391).

Table 10.3 Approximate average bond energies/kJ mol^{-1}[a]

M–	–M	–C	–H	–F	–Cl	–Br	–I
C	356	356	416	490	325	279	216
Si	226	360	323	596	400	325	248
Ge	188	255	289	471	339	281	216
Sn	151	226	253	—	315	261	187
Pb	98	130	205	411	308	—	—

[a]These values often vary widely (by as much as 50–100 kJ mol^{-1}) depending on the particular compound considered and the method of computation used. Individual values are thus less significant than general trends. The data represent a collation of values for typical compounds gleaned from refs 15–17.

10.3 Compounds

10.3.1 Hydrides and hydrohalides

Germanes of general formula Ge_nH_{2n+2} are known as colourless gases or volatile liquids for $n = 1$–5 and their preparation, physical properties, and chemical reactions are very similar to those of silanes (p. 337). Thus GeH_4 was formerly made by the inefficient hydrolysis of Mg/Ge alloys with aqueous acids but is now generally made by the reaction of $GeCl_4$ with $LiAlH_4$ in ether or even more conveniently by the reaction of GeO_2 with aqueous solutions of $NaBH_4$. The higher germanes are prepared by the action of a silent electric discharge on GeH_4; mixed hydrides such as SiH_3GeH_3 can be prepared similarly by circulating a mixture of SiH_4 and GeH_4 but no cyclic or unsaturated hydrides have yet been prepared. The germanes are all less volatile than the corresponding silanes (see Table) and, perhaps surprisingly,

noticeably less reactive. Thus, in contrast to SiH_4 and SnH_4, GeH_4 does not ignite in contact with air and is unaffected by aqueous acid or 30% aqueous NaOH. It acts as an acid in liquid NH_3 forming NH_4^+ and GeH_3^- ions and reacts with alkali metals in this solvent (or in $MeOC_2H_4$-OMe) to give $MGeH_3$. Like the corresponding $MSiH_3$, these are white, crystalline compounds of considerable synthetic utility. X-ray diffraction analysis shows that $KGeH_3$ and $RbGeH_3$ have the NaCl-type structure, implying free rotation of GeH_3^-, and $CsGeH_3$ has the rare TlI structure (p. 242). The derived "ionic radius" of 229 pm emphasizes the similarity to SiH_3^- (226 pm) and this is reinforced by the bond angles deduced from broad-line nmr experiments: SiH_3^- 94 ± 4° (cf. isoelectronic PH_3, 93.5°); GeH_3^- 92.5 ± 4° (cf. isoelectronic AsH_3, 91.8°).[19]

The germanium hydrohalides GeH_xX_{4-x} (X = Cl, Br, I; x = 1, 2, 3) are colourless, volatile, reactive liquids. Preparative routes include reaction of Ge, GeX_2 or GeH_4 with HX. The compounds are valuable synthetic intermediates (cf. SiH_3I). For example, hydrolysis of GeH_3Cl yields $O(GeH_3)_2$, and various metatheses can be effected by use of the appropriate Ag salts or, more effectively, Pb^{II} salts, e.g. GeH_3Br with PbO, $Pb(OAc)_2$, and $Pb(NCS)_2$ affords $O(GeH_3)_2$, $GeH_3(OAc)$, and $GeH_3(SCN)$. Treatment of this latter compound with MeSH or $[Mn(CO)_5H]$ yields GeH_3SMe and $[Mn(CO)_5(GeH_3)]$ respectively. An extensive phosphinogermane chemistry is also known, e.g. $R_nGe(PH_2)_{4-n}$, R = alkyl or H. The novel germaimine $CF_3N{=}GeH_2$ has been obtained as a colourless gas by reacting a 1:1 mixture of GeH_4 and CF_3NO in a sealed tube at 120° (the other product being H_2O). Addition of HI to the Ge=N double bond gave CF_3NHGeH_2I.[20]

Binary Sn hydrides are much less stable. Reduction of $SnCl_4$ with ethereal $LiAlH_4$ gives SnH_4 in 80–90% yield; $SnCl_2$ reacts similarly with aqueous $NaBH_4$. SnH_4 (mp − 146°, bp −52.5°) decomposes slowly to Sn and H_2 at room temperature; it is unattacked by dilute aqueous acids or alkalis but is decomposed by more concentrated solutions. It is a potent reducing agent. Sn_2H_6 is even less stable, and higher homologues have not been obtained. By contrast, organotin hydrides are more stable, and catenation up to $H(SnPh_2)_6H$ has been achieved by thermolysis of Ph_2SnH_2. Preparation of R_nSnH_{4-n} is usually by $LiAlH_4$ reduction of the corresponding organotin chloride.

PbH_4 is the least well-characterized Group 14 hydride and it is unlikely that it has ever been prepared except perhaps in trace amounts at high dilution; methods which successfully yield MH_4 for the other Group 14 elements all fail even at low temperatures. The alkyl derivatives R_2PbH_2 and R_3PbH can be prepared from the corresponding halides and $LiAlH_4$ at −78° or by exchange reactions with Ph_3SnH, e.g.:

$$Bu^n_3PbX + Ph_3SnH \longrightarrow Bu^n_3PbH + Ph_3SnX$$

Me_3PbH (mp ~ −106°, decomp above −30°) and Et_3PbH (mp ~ −145°, decomp above −20°) readily add to alkenes and alkynes (hydroplumbation) to give stable tetraorganolead compounds.

10.3.2 Halides and related complexes

Germanium, Sn and Pb form two series of halides: MX_2 and MX_4. PbX_2 are more stable than PbX_4, whereas the reverse is

[19] G. Thirase, E. Weiss, H. J. Henning and H. Lechert, *Z. anorg. allg. Chem.* **417**, 221–8 (1975).

[20] H. G. Ang and F. Klee, *J. Chem. Soc., Chem. Commun.*, 310–12 (1989).

true for Ge, consistent with the steady increase in stability of the dihalides in the sequence $CX_2 \ll SiX_2 < GeX_2 < SnX_2 < PbX_2$. Numerous complex halides are also known for both oxidation states.

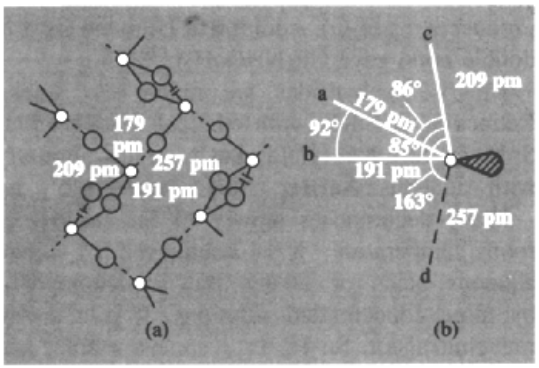

Figure 10.2 Crystal structure of GeF_2: (a) projection along the chains, and (b) environment of Ge (pseudo trigonal bipyramidal). The bond to the unshared F is appreciably shorter (179 pm) than those in the chain and there is a weaker interaction (257 pm) linking the chains into a 3D structure.

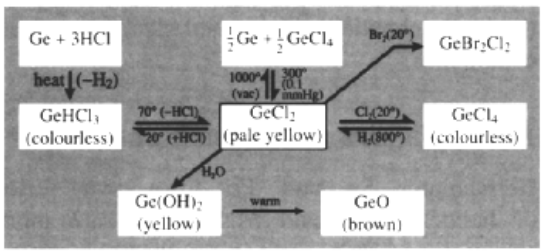
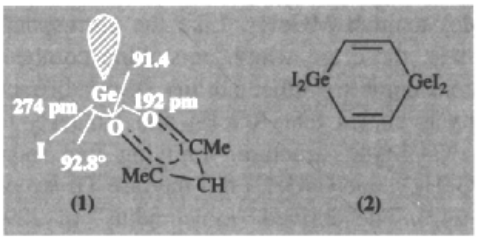
Germanium halides

GeF_2 is formed as a volatile white solid (mp 110°) by the action of GeF_4 on powdered Ge at 150–300°; it has a unique structure in which trigonal pyramidal $\{GeF_3\}$ units share 2 F atoms to form infinite spiral chains (Fig. 10.2). Pale-yellow $GeCl_2$ can be prepared similarly at 300° or by thermal decomposition of $GeHCl_3$ at 70°. Typical reactions are summarized in the scheme:



$GeBr_2$ is made by reduction of $GeBr_4$ or $GeHBr_3$ with Zn, or by the action of HBr on an excess of Ge at 400°; it is a yellow solid, mp 122°, which disproportionates to Ge and $GeBr_4$ at 150°, adds HBr at 40°, and hydrolyses to the unstable yellow $Ge(OH)_2$. GeI_2 is best prepared by reduction of GeI_4 with aqueous H_3PO_2 in the presence of HI to prevent hydrolysis; it sublimes to give bright orange-yellow crystals, is stable in dry air and disproportionates only when heated above ~550°. The structure of the lemon-yellow, monomeric, pyramidal 3-coordinate Ge^{II} complex [Ge(acac)I] (1) has been determined.[21] GeI_2 is oxidized to GeI_4 in aqueous KI/HCl; it forms numerous adducts with nitrogen ligands, and reacts with C_2H_2 at 140° to give a compound that was originally formulated as a 3-membered heterocycle  but which was subsequently shown by mass spectroscopy to have the unusual dimeric structure (2).



The ternary Ge^{II} halides, $MGeX_3$ (M = Rb, Cs; X = Cl, Br, I) are polymorphic with various distorted perovskite-like (p. 963) structures which reflect the influence of the "non-bonding" pair of electrons on the Ge^{II} centre.[22] Thus, at room temperature, rhombohedral $CsGeI_3$ has three Ge–I at 275 pm and three at 327 pm whereas in the high-temperature cubic form (above 277°C) there are six Ge–I distances at 320 pm as a result of position changes of the Ge atoms (reversible order–disorder transition). Again, $RbGeI_3$ has a lemon-yellow, orthorhombic form below −92°; an intermediate, bordeaux-red orthorhombic perovskite form (−92° to −52°); a black rhombohedral form (−52° to −29°); and

[22] G. Thiele, H. W. Rotter and K. D. Schmidt, *Z. anorg. allg. Chem.* **545**, 148–56 (1987); **571**, 60–8 (1989).

a black, cubic perovskite form between −29° and the decomposition temperature, +61°. In the yellow form there is one Ge–I at 281 pm, four at 306 pm and one at 327 pm, whereas in the red form there are three Ge–I at 287 pm and three at 324 pm. All the compounds are readily made simply by heating $Ge(OH)_2$ with MX in aqueous HX solutions.

Germanium tetrahalides are readily prepared by direct action of the elements or via the action of aqueous HX on GeO_2. The lighter members are colourless, volatile liquids, but GeI_4 is an orange solid (cf. CX_4, SiX_4). All hydrolyse readily and $GeCl_4$ in particular is an important intermediate in the preparation of organogermanium compounds via LiR or RMgX reagents. Many mixed halides and hydrohalides are also known, as are complexes of the type GeF_6^{2-}, $GeCl_6^{2-}$, *trans*-L_2GeCl_4 and L_4GeCl_4 (L = tertiary amine or pyridine). The curious mixed-valency complex Ge_5F_{12}, i.e. $[(GeF_2)_4GeF_4]$ has been shown to feature distorted square pyramids of $\{:Ge^{II}F_4\}$ with the "lone-pair" of electrons pointing away from the 4 basal F atoms which are at 181, 195, 220, and 245 pm from the apical Ge^{II}; the Ge^{IV} atom is at the centre of a slightly distorted octahedron (Ge^{IV}–F 171–180 pm, angle F–Ge–F 87.5–92.5°) and the whole structure is held together by F bridges.[23]

Tin halides

The structural chemistry of Sn^{II} halides is particularly complex, partly because of the stereochemical activity (or non-activity) of the nonbonding pair of electrons and partly because of the propensity of Sn^{II} to increase its CN by polymerization into larger structural units such as rings or chains. Thus, the first and second ionization energies of Sn (p. 372) are very similar to those of Mg (p. 111), but Sn^{II} rarely adopts structures typical of spherically symmetrical ions because the nonbonding pair of electrons, which is $5s^2$ in the free gaseous ion, readily distorts in the condensed phase; this can be described in terms of ligand-field distortions or the adoption of some "p character". Again, the "nonbonding" pair can act as a donor to vacant orbitals, and the "vacant" third 5p orbital and 5d orbitals can act as acceptors in forming further covalent bonds. A good example of this occurs with the adducts $[SnX_2(NMe_3)]$ (X = Cl, Br, I): the Sn^{II} atom, which has accepted a pair of electrons from the ligand NMe_3, can itself donate its own lone-pair to a strong Lewis acid to form a double adduct of the type $[BF_3\{\leftarrow SnX_2(\leftarrow NMe_3)\}]$ (X = Cl, Br, I).[24] Further examples, including more complicated interactions, are described later in this subsection.

SnF_2 (which is obtained as colourless monoclinic crystals by evaporation of a solution of SnO in 40% aqueous HF) is composed of Sn_4F_8 tetramers interlinked by weaker Sn–F interactions;[25] the tetramers are puckered 8-membered rings of alternating Sn and F as shown in Fig. 10.3 and each Sn is surrounded by a highly distorted octahedron of F (1 Sn–F_t at ~205 pm, 2 Sn–F_μ at ~218 pm, and 3 much longer Sn···F in the range 240–329 pm, presumably due to the influence of the nonbonding pair of electrons. In aqueous solutions containing F^- the predominant species is the very stable pyramidal complex SnF_3^- but crystallization is attended by further condensation. For example, crystallization of SnF_2 from aqueous solutions containing NaF does not give $NaSnF_3$ as previously supposed but

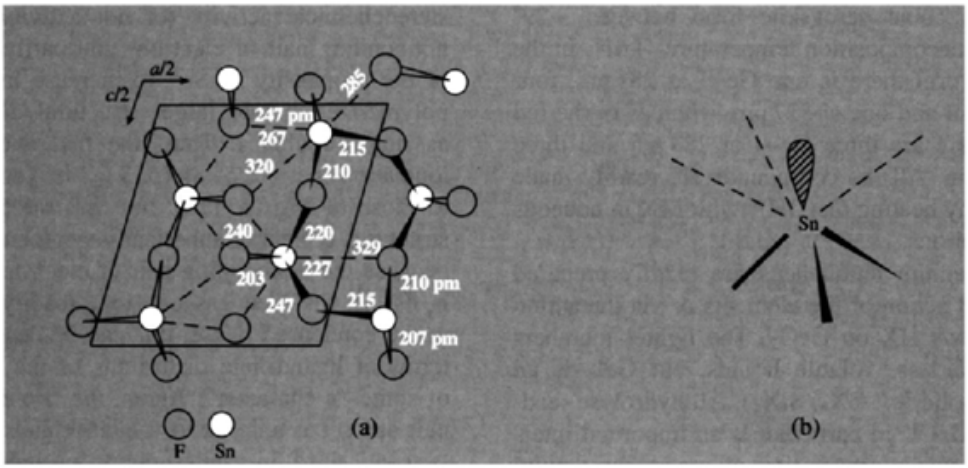

Figure 10.3 Structure of SnF_2 showing (a) interconnected rings of $\{Sn_4F_4(F_4)\}$, and (b) the unsymmetrical 3 + 3 coordination around Sn.

$NaSn_2F_5$ or $Na_4Sn_3F_{10}$ depending on conditions. The $\{Sn_2F_5\}$ unit in the first compound can be thought of as a discrete ion $[Sn_2F_5]^-$ or as an F^- ion coordinating to 2 SnF_2 molecules (Fig. 10.4a): each Sn is trigonal pyramidal with two close F_t, one intermediate F_μ, and 3 more distant F at 253, 298, and 301 pm. By contrast the compound $Na_4Sn_3F_{10}$ features 3 corner-shared square-pyramidal $\{SnF_4\}$ units (Fig. 10.4b) though the wide range of Sn–F distances could be taken to indicate incipient formation of a central SnF_4^{2-} weakly bridged to two terminal SnF_3^- groups. In the corresponding system with KF the compound

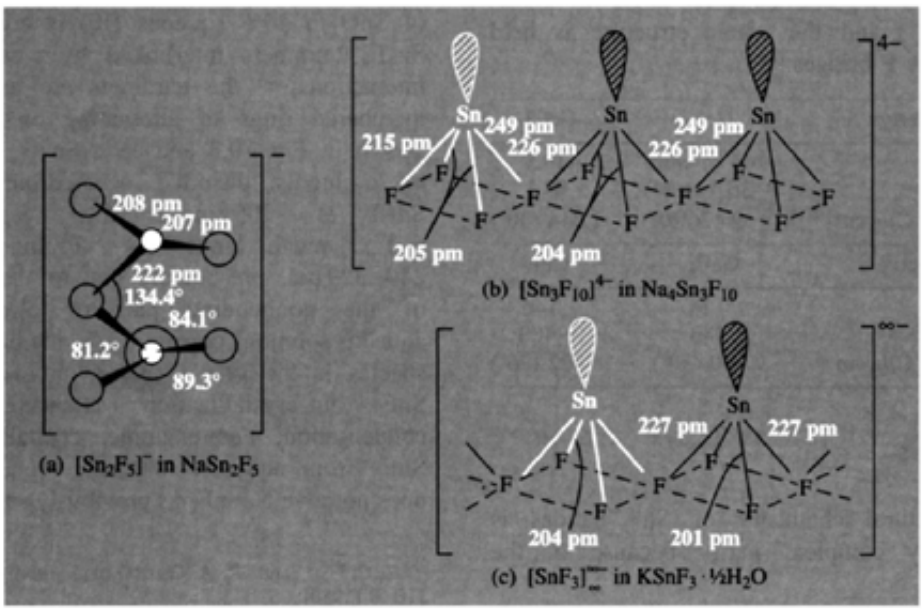

Figure 10.4 Structure of some fluoro-complexes of Sn^{II}.

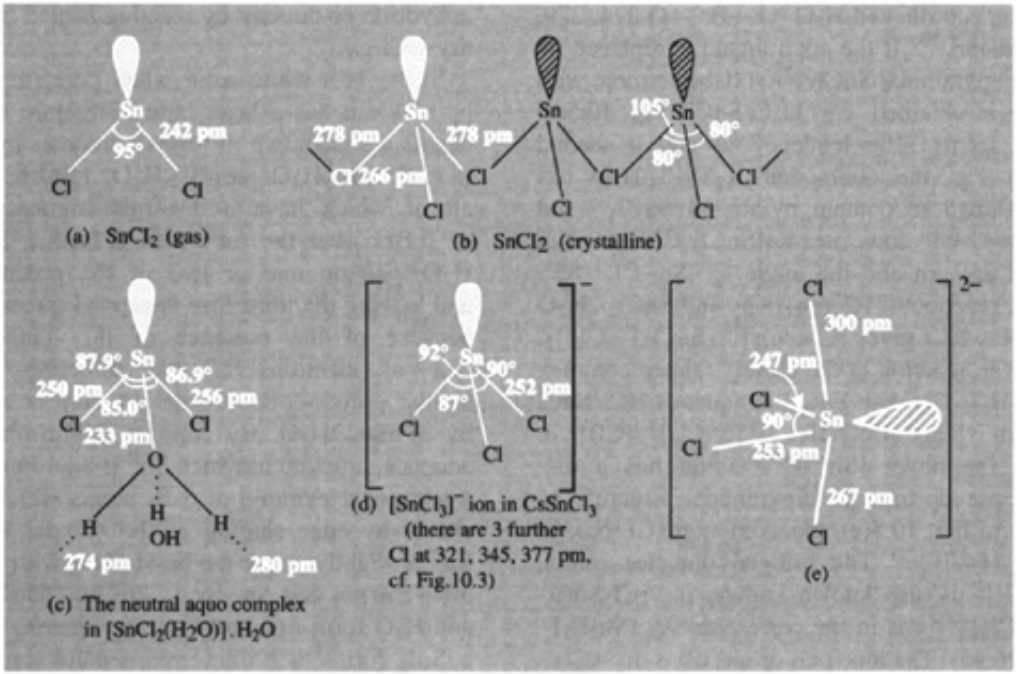

Figure 10.5 Structure of $SnCl_2$ and some chloro complexes of Sn^{II}.

that crystallizes is $KSnF_3.\frac{1}{2}H_2O$ in which the bridging of square pyramids is extended to give infinite chain polymers (Fig. 10.4c). (The main commercial application of SnF_2 is in toothpaste and dental preparations where it is used to prevent demineralization of teeth and to lessen the development of dental caries.)

SnF_4 is described on p. 381. There are also some intriguing mixed valence compounds such as Sn_3F_8 (i.e. $Sn^{II}_2Sn^{IV}F_8$) which is formed when solutions of SnF_2 in anhydrous HF are oxidized at room temperature with F_2, O_2 or even SO_2; the structure features nearly regular $\{Sn^{IV}F_6\}$ octahedra *trans*-bridged to $\{Sn^{II}F_3\}$ pyramids which themselves form polymeric $Sn^{II}F$ chains: Sn^{IV}–F 196 pm and Sn^{II}–F 210, 217, 225 pm with weaker $Sn^{II}\cdots F$ interactions in the range 255–265 pm.[26] Another example is α-Sn_2F_6 (i.e. $Sn^{II}Sn^{IV}F_6$) which transforms to β-Sn_2F_6 at 112° and to γ-Sn_2F_6 at 197°. High-temperature neutron diffraction studies[27] have shown that this latter phase has the cubic ordered ReO_3-type structure (p. 1047) with octahedral coordination of both types of Sn atoms by F (Sn^{II}–F 229 pm, Sn^{IV}–F 186 pm). The β-phase also features octahedral coordination in a structure closely related to that of rhombohedral $LiSbF_6$.

Tin(II) chlorides are similarly complex (Fig. 10.5). In the gas phase, $SnCl_2$ forms bent molecules, but the crystalline material (mp 246°, bp 623°) has a layer structure with chains of corner-shared trigonal pyramidal $\{SnCl_3\}$ groups. The dihydrate also has a 3-coordinated structure with only 1 of the H_2O molecules directly bonded to the Sn^{II} (Fig. 10.5c); the neutral aquo complexes are arranged in double layers with the second H_2O molecules interleaved between them to form a two-dimensional H-bonded network

[26] M. F. A. Dove, R. King and T. J. King, *J. Chem. Soc., Chem. Commun.*, 944–5 (1973).

[27] M. Ruchaud, C. Mirambet, L. Fournes, J. Grannec and J. L. Soubeyroux, *Z. anorg. allg. Chem.* **590**, 173–80 (1990).

with the coordinated H_2O (O—H···O 274, 279, and 280 pm.[28] If the aquo ligand is replaced by Cl^- the pyramidal $SnCl_3^-$ ion (isoelectronic with $SbCl_3$) is obtained, e.g. in $CsSnCl_3$ Fig. 10.5d). There seems little tendency to add a second ligand: e.g. the compound $K_2SnCl_4.H_2O$ has been shown to contain pyramidal $SnCl_3^-$ and "isolated" Cl^- ions, i.e. $K_2[SnCl_3]Cl.H_2O$ with Sn–Cl 259 pm and the angle Cl–Sn–Cl ~85°. Again, reaction of $[Co(en)_3]Cl_3$ and $SnCl_2.2H_2O$ in excess HCl gives $[Co(en)_3]^{3+}[SnCl_3]^-(Cl^-)_2$. However, reaction of the closely related complex $[Co(NH_3)_6]Cl_3$ with $SnCl_2$ in aqueous HCl/NaCl solution yields $[Co(NH_3)_6]^{3+}[SnCl_4]^{2-}(Cl)^-$ in which the novel $[SnCl_4]^{2-}$ anion has a distorted pseudo-trigonal bipyramidal structure as shown in Fig. 10.5(e), the axial angle Cl–Sn–Cl being 164.7°.[29] The bridged dinuclear anion $[Sn_2Cl_5]^-$ is also known known, i.e. $[Cl_2Sn(\mu\text{-}Cl)SnCl_2]^-$[30] as in the corresponding $[Sn_2F_5]^-$ (Fig. 10.4a). The lone pair of electrons in $SnCl_3^-$ can itself act as a ligating bond: for example, $SnCl_3^-$ can replace PPh_3 from the central Au atom in the cluster cation $[Au_8(PPh_3)_8]^{2+}$ to give $[Au_8(PPh_3)_7(SnCl_3)]^+$.[31] Another interesting system involves crown complexes (p. 96) such as $[Sn(18\text{-crown-}6)Cl]^+[SnCl_3]^-$ in which the cation features 7-coordinate hexagonal-pyramidal Sn^{II}.[32]

Apart from its structural interest, $SnCl_2$ is important as a widely used mild reducing agent in acid solution. The dihydrate is commercially available for use in electrolytic tin-plating baths, as a sensitizer in silvering mirrors and in the plating of plastics, and as a perfume stabilizer in toilet soaps. The anhydrous material can be obtained either by dehydration using acetic anhydride or directly by reacting heated Sn with dry HCl gas.

$SnBr_2$ is a white solid when pure (mp 216°, bp 620°); it has a layer-lattice structure but the details are unknown. It forms numerous hydrates (e.g. $3SnBr_2.H_2O$, $2SnBr_2.H_2O$, $6SnBr_2.5H_2O$) all of which have a distorted trigonal prism of 6 Br about the Sn^{II} with a further Br and H_2O capping one or two of the prism faces and leaving the third face uncapped (presumably because of the presence of the nonbonding pair of electrons in that direction).[33] A similar pseudo-9-coordinate structure is adopted by $3PbBr_2.2H_2O$. By contrast, $NH_4SnBr_3.H_2O$ adopts a structure in which Sn^{II} is coordinated by a tetragonal pyramid of 5 Br atoms which form chains by edge sharing of the 4 basal Br; the Sn^{II} is slightly above the basal plane with Sn–Br 304–350 pm and Sn–Br_{apex} 269 pm. The NH_4^+ and H_2O form rows between the chains.

SnI_2 forms as brilliant red needles (mp 316°, bp 720°) when Sn is heated with I_2 in 2 M hydrochloric acid. It has a unique structure in which one-third of the Sn atoms are in almost perfect octahedral coordination in rutile-like chains (2 Sn–I 314.7 pm, 4 Sn–I 317.4 pm, and no significant distortions of angles from 90°); these chains are in turn cross-linked by double chains containing the remaining Sn atoms which are themselves 7-coordinate (5 Sn–I all on one side at 300.4–325.1 and 2 more-distant I at 371.8 pm).[34] There is an indication here of reduced distortion in the octahedral site and this has been observed more generally for compounds with the heavier halides and chalcogenides in which the nonbonding electron pair on Sn^{II} can delocalize into a low-lying band of the crystal. Accordingly, SnTe is a metalloid with cubic NaCl structure. Likewise, $CsSn^{II}Br_3$ has the ideal cubic perovskite structure (p. 963);[35] the compound forms black lustrous crystals with a semi-metallic

conductivity of $\sim 10^3$ ohm^{-1} cm^{-1} at room temperature due, it is thought, to the population of a low-lying conduction band formed by the overlap of "empty" t_2 5d orbitals on Br. In this connection it is noteworthy that $Cs_2Sn^{IV}Br_6$ has a very similar structure to $CsSn^{II}Br_3$ (i.e. $Cs_2Sn^{II}_2Br_6$) but with only half the Sn sites occupied — it is white and non-conducting since there are no high-energy nonbonding electrons to populate the conduction band which must be present. Similarly, yellow $CsSn^{II}I_3$, $CsSn^{II}_2Br_5$, $Cs_4Sn^{II}Br_6$ and compositions in the system $CsSn^{II}_2X_5$ (X = Cl, Br) all transform to black metalloids on being warmed, and even yellow monoclinic $CsSnCl_3$ (Fig. 10.5d) transforms at 90° to a dark-coloured cubic perovskite structure. In solutions of SnX_2 in aqueous HX, however, the pyramidal SnX_3^- ions are formed and, by suitable mixtures of halides followed by extraction into Et_2O, all ten trihalogenostannate(II) anions $[SnCl_xBr_yI_z]^-$ ($x + y + z = 3$) have been observed and characterized by ^{119}Sn nmr spectroscopy.[36]

Tin(IV) halides are more straightforward. SnF_4 (prepared by the action of anhydrous HF on $SnCl_4$) is an extremely hygroscopic, white crystalline compound which sublimes above 700°. The structure (unlike that of CF_4, SiF_4 and GeF_4) is polymeric with octahedral coordination about Sn: the $\{SnF_6\}$ units are joined into planar layers by edge-sharing of 4 equatorial F atoms (Sn–F_μ 202 pm) leaving 2 further (terminal) F in *trans* positions above and below each Sn (Sn–F_t 188 pm). The other SnX_4 can be made by direct action of the elements and are unremarkable volatile liquids or solids comprising tetrahedral molecules. Similarities with the tetrahalides of Si and Ge are obvious. The compounds hydrolyse readily but definite hydrates can also be isolated from acid solution, e.g. $SnCl_4.5H_2O$, $SnBr_4.4H_2O$. Complexes with a wide range of organic and inorganic ligands are known, particularly the 6-coordinate *cis-* and *trans-* L_2SnX_4 and occasionally the 1:1 complexes $LSnX_4$. Stereochemistry has been deduced by infrared and Mössbauer spectroscopy and, when possible, by X-ray crystallography. The octahedral complexes SnX_6^{2-} (X = Cl, Br, I) are also well characterized for numerous cations. Five-coordinate trigonal bipyramidal complexes are less common but have been established for $SnCl_5^-$ and $Me_2SnCl_3^-$. A novel rectangular pyramidal geometry for Sn^{IV} has been revealed by X-ray analysis of the spirocyclic dithiolato complex anion $[(MeC_6H_3S_2)_2SnCl]^-$: the Cl atom occupies the apical position and the Sn atom is slightly above the plane of the 4 S atoms (mean angle Cl–Sn–Cl 103°).[37] A similar stereochemistry has also been established for Si^{IV} (p. 335) and for Ge^{IV} in $[(C_6H_4O_2)_2GeCl]^-$.

Lead halides

Lead continues the trends outlined in preceding sections, PbX_2 being much more stable thermally and chemically than PbX_4, Indeed, the only stable tetrahalide is the yellow PbF_4 (mp 600°); $PbCl_4$ is a yellow oil (mp −15°) stable below 0° but decomposing to $PbCl_2$ and Cl_2 above 50°; $PbBr_4$ is even less stable and PbI_4 is of doubtful existence (cf. discussion on TlI_3, p. 239). Stability can be markedly increased by coordination: e.g.

1980–3 (1975); see also J. D. DONALDSON and J. SILVER, *J. Chem. Soc., Dalton Trans.*, 666–9 (1973).

[36] J. M. CODDINGTON and M. J. TAYLOR, *J. Chem. Soc., Dalton Trans.*, 2223–7 (1989).

[37] A. C. SAU, R. O. DAY and R. R. HOLMES, *Inorg. Chem.* **20**, 3076–81 (1981); *J. Am. Chem. Soc.* **102**, 7972–3 (1980).

direct chlorination of $PbCl_2$ in aqueous HCl followed by addition of an alkali metal chloride gives stable yellow salts M_2PbCl_6 (M = Na, K, Rb, Cs, NH_4) which can serve as a useful source of Pb^{IV}. By contrast, PbX_2 are stable crystalline compounds which can readily be prepared by treating any water-soluble Pb^{II} salt with HX or halide ions to precipitate the insoluble PbX_2. As with Sn, the first two ionization energies of Pb are very similar to those of Mg; moreover, the 6-coordinate radius of Pb^{II} (119 pm) is virtually identical with that of Sr^{II} (118 pm) and there is less evidence of the structurally distorting influence of the nonbonding pair of electrons. Thus α-PbF_2, $PbCl_2$, and $PbBr_2$ all form colourless orthorhombic crystals in which Pb^{II} is surrounded by 9 X at the corners of a tricapped trigonal prism. There are, in fact, never 9 equidistant X neighbours but a range of distances in which one can discern 7 closer and 2 more distant neighbours. This (7 + 2)-coordination is also a feature of the structures of BaX_2 (X = Cl, Br, I), $EuCl_2$, CaH_2, etc.; see also hydrated tin(II) bromides, p. 380.

The high-temperature β-form of PbF_2 has the cubic fluorite (CaF_2) structure with 8-coordinated Pb^{II}. PbI_2 (yellow) has the CdI_2 hexagonal layer lattice structure. Like many other heavy-metal halides, $PbCl_2$ and $PbBr_2$ are photo-sensitive and deposit metallic Pb on irradiation with ultraviolet or visible light. PbI_2 is a photoconductor and decomposes on exposure to green light (λ_{max} 494.9 nm). Many mixed halides have also been characterized, e.g. PbFCl, PbFBr, PbFI, $PbX_2.4PbF_2$, etc. Of these PbFCl is an important tetragonal layer-lattice structure type frequently adopted by large cations in the presence of 2 anions of differing size;[38] its sparing solubility in water (37 mg per 100 cm^3 at 25°C) forms the basis of a gravimetric method of determining F. It is also interesting to note that PbF_2 was the first ionically conducting crystalline compound to be discovered (Michael Faraday, 1838).

Pb^{II} apparently forms complexes with an astonishing range of stoichiometries,[39] but structural information is frequently lacking. Cs_4PbX_6 (X = Cl, Br, I) have the K_4CdCl_6 structure with discrete $[Pb^{II}X_6]^{4-}$ units. $CsPb^{II}X_3$ also feature octahedral coordination (in perovskite-like structures, cf. p. 963) but there is sometimes appreciable distortion as in the yellow, low-temperature form of $CsPbI_3$ which adopts the NH_4CdCl_3 structure with three Pb–I distances, 301, 325, and 342 pm. Note also the orange-yellow crystalline compound of overall composition $[Co(en)_3PbCl_5.1.5H_2O]$ which in fact features a novel chain anion $[Pb_2Cl_9]_n^{5n-}$ and should be formulated $[Co(en)_3]_2[Pb_2Cl_9]$-$Cl.3H_2O$.[40] There are also many ternary solid state compounds, e.g. $Pb^{II}_{13}O_{10}Br_6$.[41]

10.3.3 Oxides and hydroxides

GeO is obtained as a yellow sublimate when powdered Ge and GeO_2 are heated to 1000°, and dark-brown crystalline GeO is obtained on further heating at 650°. The compound can also be obtained by dehydrating $Ge(OH)_2$

[39] E. W. ABEL, Lead, Chap. 18 in *Comprehensive Inorganic Chemistry*, Vol. 2, pp. 105–46, Pergamon Press, Oxford, 1973.

[40] A. AQUILINO, M. CANNAS, A. CHRISTINI and G. MARONGIU, *J. Chem. Soc., Chem. Commun.*, 347–8 (1978).

[41] H.-J. RIEBE and H.-L. KELLER, *Z. anorg. allg. Chem.* **571**, 139–47 (1989).

(p. 376) but neither compound is particularly well characterized. Both are reducing agents and GeO disproportionates rapidly to Ge and GeO_2 above 700°. Much more is known about GeO_2 and there is an impressive resemblance between the oxide chemistry of Ge^{IV} and Si^{IV}. Thus hexagonal GeO_2 has the 4-coordinated β-quartz structure (p. 342), tetragonal GeO_2 has the 6-coordinated rutile-like structure of stishovite (p. 343), and vitreous GeO_2 resembles fused silica. Similarly, Ge analogues of all the major types of silicates and aluminosilicates (pp. 347–59) have been prepared. Be_2GeO_4 and Zn_2GeO_4 have the phenacite and willemite structures with "isolated" $\{GeO_4\}$ units; $Sc_2Ge_2O_7$ has the thortveitite structure; $BaTiGe_3O_9$ has the same type of cyclic ion as benitoite, and $CaMgGe_2O_6$ has a chain structure similar to diopside. Further, the two crystalline forms of Ca_2GeO_4 are isostructural with two forms of Ca_2SiO_4, and Ca_3GeO_5 crystallizes in no fewer than 4 of the known structures of Ca_3SiO_5. The reaction chemistry of the two sets of compounds is also very similar.

SnO exists in several modifications. The commonest is the blue-black tetragonal modification formed by the alkaline hydrolysis of Sn^{II} salts to the hydrous oxide and subsequent dehydration in the absence of air. The structure features square pyramids of $\{SnO_4\}$ arranged in parallel layers with Sn^{II} at the apex and alternately above and below the layer of O atoms as shown in Fig. 10.6. The Sn–Sn distance between tin atoms in adjacent layers is 370 pm, very close to the values in β-Sn (p. 372). The structure can also be described as a fluorite lattice with alternate layers of anions missing. A metastable, red modification of SnO is obtained by heating the white hydrous oxide; this appears to have a similar structure and it can be transformed into the blue-black form by heating, by pressure, by treatment with strong alkali or simply by contact with the stable form. Both forms oxidize to SnO_2 with incandescence when heated in air to ~300° but when heated in the absence of O_2, the compound disproportionates like GeO. Various mixed-valence oxides have also been reported of which the best characterized is Sn_3O_4, i.e. $Sn^{II}_2Sn^{IV}O_4$.

SnO and hydrous tin(II) oxide are amphoteric, dissolving readily in aqueous acids to give Sn^{II} or its complexes, and in alkalis to give the pyramidal $Sn(OH)_3^-$; at intermediate values of pH, condensed basic oxide–hydroxide species form, e.g. $[(OH)_2SnOSn(OH)_2]^{2-}$ and $[Sn_3(OH)_4]^{2+}$, etc. Analytically, the hydrous oxide frequently has a composition close to $3SnO.H_2O$ and an X-ray study shows it to

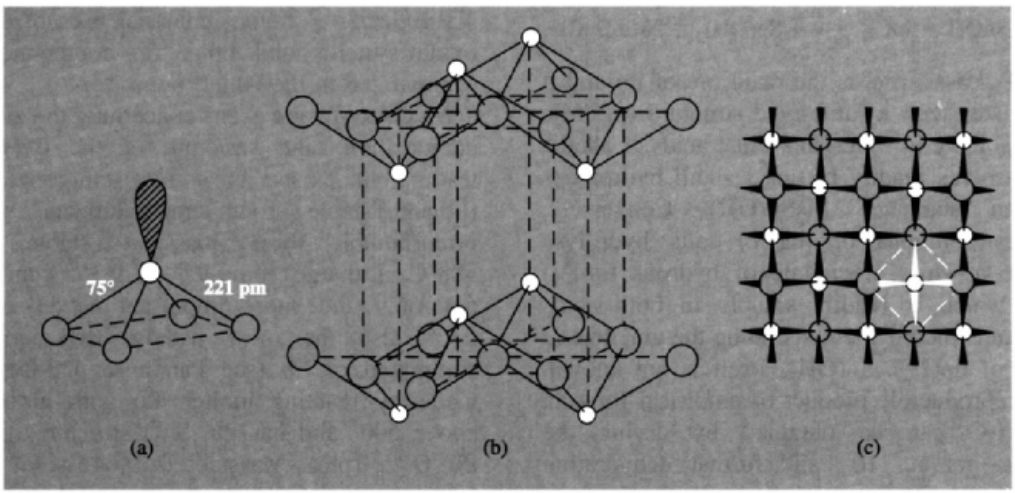

Figure 10.6 Structure of tetragonal SnO (and PbO) showing (a) a single square-based pyramid $\{:SnO_4\}$, (b) the arrangement of the pyramids in layers, and (c) a plane view of a single layer.

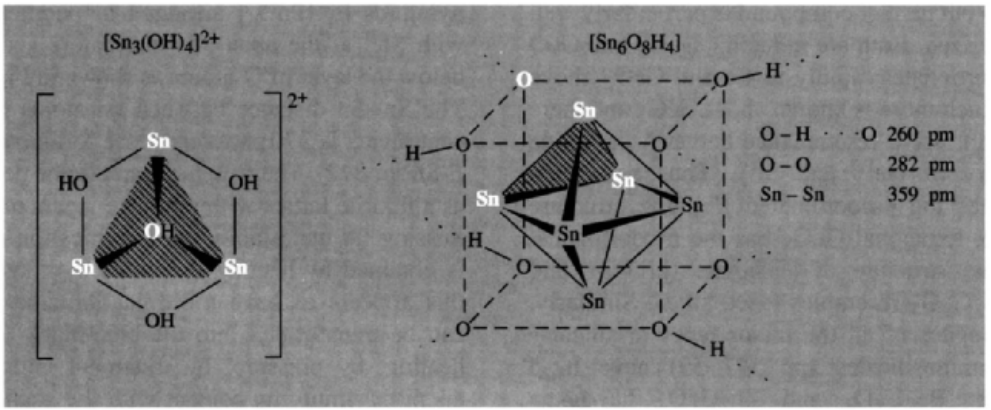

contain pseudo-cubic Sn_6O_8 clusters resembling $Mo_6Cl_8^{4+}$ (p. 1022) with 8 oxygen atoms centred above the faces of an Sn_6 octahedron and joined in infinite array by H bonds, i.e. $Sn_6O_8H_4$; the compound can be thought of as being formed by the deprotonation and condensation of $2[Sn_3(OH)_4]^{2+}$ units as the pH is raised:

$$2[Sn_3(OH)_4]^{2+} + 4OH^- \longrightarrow [Sn_6O_8H_4] + 4H_2O$$

(Hydrolysis of Pb^{II} salts leads to different structures, p. 395.) It seems unlikely that pure $Sn(OH)_2$ itself has ever been prepared from aqueous solutions but it can be obtained as a white, amorphous solid by an anhydrous organometallic method:[42]

$$2Me_3SnOH + SnCl_2 \xrightarrow{thf} Sn(OH)_2 + 2Me_3SnCl$$

SnO_2, cassiterite, is the main ore of tin and it crystallizes with a rutile-type structure (p. 961). It is insoluble in water and dilute acids or alkalis but dissolves readily in fused alkali hydroxides to form "stannates" $M^I_2Sn(OH)_6$. Conversely, aqueous solutions of tin(IV) salts hydrolyse to give a white precipitate of hydrous tin(IV) oxide which is readily soluble in both acids and alkalis thereby demonstrating the amphoteric nature of tin(IV). $Sn(OH)_4$ itself is not known, but a reproducible product of empirical formula $SnO_2.H_2O$ can be obtained by drying the hydrous gel at 110°, and further dehydration at temperatures up to 600° eventually yields crystalline SnO_2. Similarly, thermal dehydration of $K_2[Sn(OH)_6]$, i.e. "$K_2SnO_3.3H_2O$", yields successively $K_2SnO_3.H_2O$, $3K_2SnO_3.2H_2O$ and, finally, anhydrous K_2SnO_3; this latter compound also results when K_2O is heated directly with SnO_2, and variations in the ratio of the two reactants yield K_4SnO_4 and $K_2Sn_3O_7$. The structure of K_2SnO_3 does not have 6-coordinate Sn^{IV} but chains of 5-coordinate Sn^{IV} of composition $\{SnO_3\}$ formed by the edge sharing of tetragonal pyramids of $\{SnO_5\}$ as shown in Fig. 10.7. The colourless compound $RbNa_3SnO_4$, formed by heating RbSn and Na_2O_2 at 750° has tetrahedral SnO_4^{4-} units (Sn–O 196 pm); it is isotypic with $NaLi_3SiO_4$ and $NaLi_3GeO_4$.[43] Some industrial uses of tin(IV) oxide systems and other tin compounds are summarized in the Panel (opposite).

Much confusion exists concerning the number, composition, and structure of the oxides of lead. PbO exists as a red tetragonal form (litharge) stable at room temperature and a yellow orthorhombic form (massicot) stable above 488°C. Litharge (mp 897°, d 9.355 g cm^{-3}) is not only the most important oxide of Pb, it is also the most widely used inorganic compound of Pb (see Panel on p. 386); it is made by reacting molten Pb with air or O_2 above 600° and has the SnO structure (p. 383, Pb–O 230 pm). Massicot (d 9.642 g cm^{-3}) has

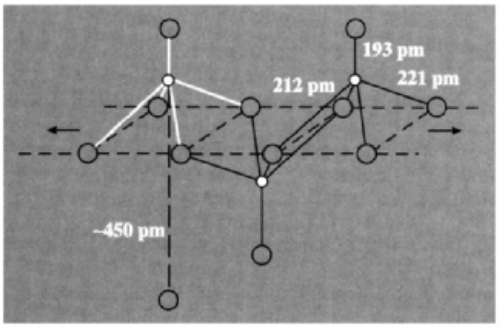

Figure 10.7 $\{SnO_3\}$ chain in the structure of K_2SnO_3 (and K_2PbO_3).

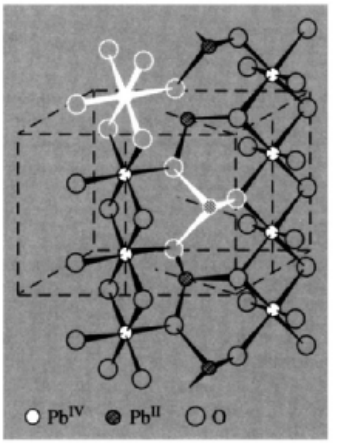

Figure 10.8 Portion of the crystal structure of Pb_3O_4 showing chains of edge-shared $Pb^{IV}O_6$ octahedra joined by pyramids of $Pb^{II}O_3$; the mean $O-Pb^{II}-O$ angle is 76° as in PbO.

a distorted version of the same structure. The mixed-valency oxide Pb_3O_4 (red lead, minium, d 8.924 g cm^{-3}) is made by heating PbO in air in a reverberatory furnace at 450–500° and is important commercially as a pigment and primer (see Panel on p. 386). Its structure (Fig. 10.8) consists of chains of $Pb^{IV}O_6$ octahedra (Pb–O 214 pm) sharing opposite edges, these chains being linked by the Pb^{II} atoms which themselves

Some Industrial Uses of Tin Compounds

Tin(IV) oxide is much used an the ceramics industry as an opacifier for glazes and enamels. Because of its insolubility (or, rather, slow solubility) in glasses and glazes it also serves as a base for pigments, e.g. SnO_2/V_2O_5 yellows, SnO_2/Sb_2O_5 blue-greys and SnO_2/Cr_2O_3 pinks. These latter, which can vary from a delicate pale pink to a dark maroon, probably involve substitutional incorporation of Cr^{III} for Sn^{IV} with concomitant oxide-ion vacancies, i.e. $[Sn^{IV}_{1-2x}Cr^{III}_{2x}O^{-II}_{2-x}(\square_-)_x]$. The vanadium- and antimony-tin glazes, on the other hand, probably involve reductive substitution without vacant sites, e.g. $[Sn^{IV}_{1-3x}Sn^{II}_{x}Sb^{V}_{2x}O^{-II}_{2}]$. Some 3500 tonnes of SnO_2 are consumed annually for ceramic glazes.

A related application is the use of $SnCl_4$ vapour to toughen freshly fabricated glass bottles by deposition of an invisible transparent film of SnO_2 (<0.1 μm) which is then incorporated in the surface structure of the glass. This increases the strength of the glass and improves its abrasion resistance so that bottles so treated can be made considerably lighter without loss of robustness. When the thickness of the SnO_2 film is similar to the wavelength of visible light (0.1–1.0 μm), then thin-film interference effects occur and the glass acquires an attractive iridescence. Still thicker films give electrically conducting layers which, after suitable doping with Sb or F ions, can be used as electrodes, electro-luminescent devices (for low-intensity light panels and display signs, in aircraft, cinemas, etc.), fluorescent lamps, antistatic cover-glasses, transparent tube furnaces, deiceable windscreens (especially for aircraft), etc. Another property of these thicker films is their ability to reflect a high proportion of infrared (heat) radiation whilst remaining transparent to visible radiation — the application to heat insulation of windows is obvious.

Attention should be drawn to the use of tin oxide systems as heterogeneous catalysts. The oldest and most extensively patented systems are the mixed tin–vanadium oxide catalysts for the oxidation of aromatic compounds such as benzene, toluene, xylenes and naphthalene in the synthesis of organic acids and acid anhydrides. More recently mixed tin–antimony oxides have been applied to the selective oxidation and ammoxidation of propylene to acrolein, acrylic acid and acrylonitrile.

Homogeneous catalysis by tin compounds is also of great industrial importance. The use of $SnCl_4$ as a Friedel–Crafts catalyst for homogeneous acylation, alkylation and cyclization reactions has been known for many decades. The most commonly used industrial homogeneous tin catalysts, however, are the Sn(II) salts of organic acids (e.g. acetate, oxalate, oleate, stearate and octoate) for the curing of silicone elastomers and, more importantly, for the production of polyurethane foams. World consumption of tin catalysts for these last applications alone is over 1000 tonnes pa.

For uses of organotin compounds (i.e. compounds having at least one Sn–C bond), see p. 400.

The Oxides of Lead[9,10]

PbO (red, orange or yellow depending on the method of preparation) is amphoteric and dissolves readily in both acids and alkalis. It is much used in glass manufacture since a high Pb content leads to greater density, lower thermal conductivity, higher refractive index (greater brilliance), and greater stability and toughness. The replacement of the very mobile alkali ions by Pb also leads to high electrical capacities, comparable with mica. PbO is also used to form stable ceramic glazes and vitreous enamels (see SnO_2, p. 385). Electric storage batteries are the other major user of PbO (either as litharge or as "black oxide", i.e. PbO + Pb). The plates of the battery consist of an inactive grid or support onto which is applied a paste of PbO/H_2SO_4. The positive plates are activated by oxidizing PbO to PbO_2 and the negative plates by reducing PbO to Pb. Another use of PbO is in the production of pigments (p. 371).

Red lead (Pb_3O_4) is manufactured on the 20 000-tonne scale annually and is used primarily as a surface coating to prevent corrosion of iron and steel (check oxidation-reduction potentials). It is also used in the production of leaded glasses and ceramic glazes and, very substantially, as an activator, vulcanizing agent and pigment in natural and artificial rubbers and plastics.

PbO_2 is a strong oxidizing agent and, in addition to its *in situ* production in storage batteries, it is independently manufactured for use as an oxidant in the manufacture of chemicals, dyes, matches and pyrotechnics. It is also used in considerable quantity as a curing agent for sulfide polymers and in high-voltage lightning arresters. Because of the instability of Pb^{IV}, PbO_2 tends to give salts of Pb^{II} with liberation of O_2 when treated with acids, e.g.

$$PbO_2 + H_2SO_4 \xrightarrow{\text{warm}} PbSO_4 + H_2O + \tfrac{1}{2}O_2 \bullet$$

$$PbO_2 + 2HNO_3 \longrightarrow Pb(NO_3)_2 + H_2O + \tfrac{1}{2}O_2$$

Warm HCl reacts similarly but in the cold $PbCl_4$ is obtained. PbO_2 is produced commercially by the oxidation of Pb_3O_4 in alkaline slurry with Cl_2 and the technical product is marketed in 90-kg drums.

Mixed oxides of Pb^{IV} with other metals find numerous applications in technology and industry. They are usually made by heating PbO_2 (or PbO) in air with the appropriate oxide, hydroxide or oxoacid salt, the product formed being dependent on the stoichiometry used, e.g. $M^{II}Pb^{IV}O_3$, $M^{II}_2Pb^{IV}O_4$ (M^{II} = Ca, Sr, Ba). $CaPbO_3$ in particular is increasingly replacing Pb_3O_4 as a priming pigment to protect steel against corrosion by salt water. Mixed oxides of Pb^{II} are also important. Ferrimagnetic oxides of general formula $PbO.nFe_2O_3$ (n = 6, 5, 2.5, 1, 0.5) can be prepared by direct reaction but have not proved to be as attractive, commercially, as the hard ferrite $BaFe_{12}O_{19}$. By contrast, the ferroelectric behaviour (p. 57) of several mixed oxides with Pb^{II} has excited considerable interest. Many of these compounds have a distorted perovskite-type structure (p. 963); e.g. yellow $PbTiO_3$ (ferroelectric below 490°C), colourless $PbZrO_3$ (230°), and $PbHfO_3$ (215°, antiferroelectric). Others have a tetragonal tungsten-bronze-type structure (p. 1016), e.g. $PbNb_2O_6$ (ferroelectric up to 560°C), $PbTi_2O_6$ (~215°). The mode of action and uses of hard ferroelectrics has been discussed on p. 58, and the high Curie temperature of many Pb^{II} ferroelectrics makes them particularly useful for high-temperature applications.

are pyramidally coordinated by 3 oxygen atoms (2 at 218 pm and 1 at 213 pm). The dioxide normally occurs as the maroon-coloured PbO_2(I) which has the tetragonal, rutile structure (Pb^{IV}–O 218 pm, d 9.643 g cm^{-3}), but there is also a high-pressure, black, orthorhombic polymorph, PbO_2(II) (d 9.773 g cm^{-3}).

When PbO_2 is heated in air it decomposes as follows:[44]

$$PbO_2 \xrightarrow{293^\circ} Pb_{12}O_{19} \xrightarrow{351^\circ} Pb_{12}O_{17} \xrightarrow{374^\circ} Pb_3O_4 \xrightarrow{605^\circ} PbO$$

In addition, a sesquioxide Pb_2O_3 can be obtained as vitreous black monoclinic crystals (d 10.046 g cm^{-3}) by decomposing PbO_2 (or PbO) at 580–620° under an oxygen pressure of 1.4 kbar: in this compound the Pb^{II} atoms are situated between layers of distorted $Pb^{IV}O_6$ octahedra (mean Pb^{IV}–O 218 pm) with 3 Pb^{II}–O in the range 231–246 pm and 3 in the range 264–300 pm. The monoclinic compound $Pb_{12}O_{19}$ (i.e. $PbO_{1.583}$) forms dark-brown or black crystals which have a pseudocubic defect-fluorite structure with 10 ordered anion vacancies according to the formulation $[Pb_{24}O_{38}(\square_{-})_{10}]$ and no detectable variability of composition. It will be recalled that PbO can be considered as a defect fluorite structure in which each alternate layer

[44] W. B. White and R. Ray, *J. Am. Ceram. Soc.* **47**, 242–7 (1964) and references therein.

of O atoms in the (001) direction is missing (p. 383), i.e. $[Pb_{24}O_{24}(\square_{-})_{24}]$; it therefore seems reasonable to suppose that the anion vacancies in $[Pb_{24}O_{38}(\square_{-})_{10}]$ are also confined to alternate layers, though it is not clear why this structure should show no variability in composition. Further heating above 350° (or careful oxidation of PbO) yields $Pb_{12}O_{17}$ (i.e. $PbO_{1.417}$) which is also a stoichiometric ordered defect fluorite structure $[Pb_{24}O_{34}(\square_{-})_{14}]$. However, oxidation of this phase under increasing oxygen pressure leads to a nonstoichiometric phase of variable composition between $PbO_{1.42}$ and $PbO_{1.57}$ in which there appears to be a quasi-random array of anion vacancies.[45]

Lead does not appear to form a simple hydroxide, $Pb(OH)_2$, [cf. $Sn(OH)_2$, p. 384]. Instead, increasing the pH of solutions of Pb^{II} salts leads to hydrolysis and condensation, see $[Pb_6O(OH)_6]^{4+}$ (p. 395).

10.3.4 Derivatives of oxoacids

Oxoacid salts of Ge are usually unstable, generally uninteresting, and commercially unimportant. The tetraacetate $Ge(OAc)_4$ separates as white needles, mp 156°, when $GeCl_4$ is treated with TlOAc in acetic anhydride and the resulting solution is concentrated at low pressure and cooled. An unstable sulfate $Ge(SO_4)_2$ is formed in a curious reaction when $GeCl_4$ is heated with SO_3 in a sealed tube at 160°:

$$GeCl_4 + 6SO_3 \longrightarrow Ge(SO_4)_2 + 2S_2O_5Cl_2$$

Numerous oxoacid salts of Sn^{II} and Sn^{IV} have been reported and several basic salts are also known. Anhydrous $Sn(NO_3)_2$ has not been prepared but the basic salt $Sn_3(OH)_4(NO_3)_2$ can be made by reacting a paste of hydrous tin(II) oxide with aqueous HNO_3; the compound may well contain the oligomeric cation $[Sn_3(OH)_4]^{2+}$ illustrated on p. 384. $Sn(NO_3)_4$ can be obtained in anhydrous reactions of $SnCl_4$ with N_2O_5, $ClNO_3$ or $BrNO_3$; the compound readily oxidizes or nitrates organic compounds, probably by releasing reactive NO_3 radicals. Many phosphates and phosphato complexes have been described: typical examples for Sn^{II} are $Sn_3(PO_4)_2$, $SnHPO_4$, $Sn(H_2PO_4)_2$, $Sn_2P_2O_7$ and $Sn(PO_3)_2$. Examples with Sn^{IV} are $Sn_2O(PO_4)_2$, $Sn_2O(PO_4)_2.10H_2O$, SnP_4O_7, $KSn(PO_4)_3$, $KSnOPO_4$ and $Na_2Sn(PO_4)_2$. One remarkable compound is tin(IV) hypophosphite, $Sn(H_2PO_2)_4$ since it contains Sn^{IV} in the presence of the strongly reducing hypophosphorous anion; it has been suggested that the isolation of $Sn(H_2PO_2)_4$ (colourless crystals) by bubbling O_2 through a solution of SnO in hypophosphorous acid, $[H_2PO(OH)]$, may be due to a combination of kinetic effects and the low solubility of the product.

Treatment of SnO_2 with hot dilute H_2SO_4 yields the hygroscopic dihydrate $Sn(SO_4)_2.2H_2O$. In the Sn^{II} series $SnSO_4$ is a stable, colourless compound which is probably the most convenient laboratory source of Sn^{II} uncontaminated with Sn^{IV}; it is readily prepared by using metallic Sn to displace Cu from aqueous solutions of $CuSO_4$. $SnSO_4$ was at one time thought to be isostructural with $BaSO_4$ but this seemed unlikely in view of the very different sizes of the cations and the known propensity of Sn^{II} to form distorted structures; it is now known to consist of $\{SO_4\}$ groups linked into a framework by O–Sn–O bonds in such a way that Sn is pyramidally coordinated by 3 O atoms at 226 pm (O–Sn–O angles 77–79°); other Sn–O distances are much larger and fall in the range 295–334 pm.[46] A basic sulfate and oxosulfate are also known:

$$3Sn^{II}SO_4(aq) \xrightarrow{NH_3(aq)} [Sn^{II}_3(OH)_2O(SO_4)]$$

$$\xrightarrow{230°} [Sn^{II}_3O_2SO_4]$$

The crystal structures of the oxalates SnC_2O_4 and $K_2Sn(C_2O_4)_2.H_2O$ show interesting features[47]

[45] J. S. Anderson and M. Sterns, *J. Inorg. Nucl. Chem.* **11**, 272–85 (1959).

[46] J. D. Donaldson and D. C. Puxley, *Acta Cryst.* **28B**, 864–7 (1972).

[47] A. D. Christie, R. A. Howie and W. Moser, *Inorg. Chim. Acta.* **36**, L447–L448 (1979).

reminiscent of tetragonal SnO (Fig. 10.6). The organotin(IV) sulfate $(Me_3Sn)_2SO_4.2H_2O$ has trigonal bipyramidal Sn with *trans*-O_2SnMe_3 stereochemistry, i.e. $[H_2O-SnMe_3-(\mu\text{-}OSO_2O)-SnMe_3-OH_2]$; H-bonding between the two non-bridging O-atoms of the sulfate group and water molecules in neighbouring units produces a three-dimensional network.[48] In general, the product obtained by the thermal decomposition of Sn^{II} oxoacid salts depends on the coordinating strength of the oxoacid anion. For strong ligands such as formate, acetate and phosphite, other Sn^{II} compounds are formed (often SnO), whereas for less-strongly coordinating ligands such as the sulfate or nitrate internal oxidation to SnO_2 occurs, e.g.:

Strong ligands:

$$2Sn(HCO_2)_2 \xrightarrow{200^\circ} 2SnO + H_2CO + CO_2$$

$$Sn(MeCO_2)_2 \xrightarrow{240^\circ} SnO + Me_2CO + CO_2$$

$$5SnHPO_3 \xrightarrow{325^\circ} Sn^{II}_2P_2O_7 + Sn^{II}_3(PO_4)_2 + PH_3 + H_2$$

$$2SnHPO_4 \xrightarrow{395^\circ} Sn^{II}_2P_2O_7 + H_2O$$

Weak ligands:

$$2SnO \xrightarrow{350^\circ} SnO_2 + Sn$$

$$SnSO_4 \xrightarrow{378^\circ} SnO_2 + SO_2$$

$$Sn_3(OH)_4(NO_3)_2 \xrightarrow[\text{(explosive)}]{125^\circ} 3SnO_2 + 2NO + 2H_2O$$

Most oxoacid derivatives of lead are Pb^{II} compounds, though $Pb(OAc)_4$ is well known and is extensively used as a selective oxidizing agent in organic chemistry.[49] It can be obtained as colourless, moisture-sensitive crystals by treating Pb_3O_4 with glacial acetic acid. $Pb(SO_4)_2$ is also stable when dry and can be made by the action of conc H_2SO_4 on $Pb(OAc)_4$ or by electrolysis of strong H_2SO_4 between Pb electrodes. $PbSO_4$ is familiar as a precipitate for the gravimetric determination of sulfate (solubility 4.25 mg per 100 cm^3 at 25°C); $PbSeO_4$ is likewise insoluble. By contrast $Pb(NO_3)_2$ is very soluble in water (37.7 g per 100 cm^3 at 0°, 127 g at 100°). The diacetate is similarly soluble (19.7 and 221 g per 100 cm^3 at 0° and 50° respectively). Both compounds find wide use in the preparation of Pb chemicals by wet methods and are made simply by dissolving PbO in the appropriate aqueous acid. A large number of basic nitrates and acetates is also known. The thermal decomposition of anydrous $Pb(NO_3)_2$ above 400° affords a convenient source of N_2O_4 (see p. 456).

Other important Pb^{II} salts are the carbonate, basic carbonate, silicates, phosphates and perchlorate, but little new chemistry is involved. $PbCO_3$ occurs as cerussite; the compound is made as a dense white precipitate by treating the nitrate or acetate with CO_2 in the presence of $(NH_4)_2CO_3$ or Na_2CO_3, care being taken to keep the temperature low to avoid formation of the basic carbonate $\sim 2Pb(CO_3).Pb(OH)_2$. These compounds were formerly much used as pigments (white lead) but are now largely replaced by other white pigments such as TiO_2 which has higher covering power and lower toxicity. The highly soluble perchlorate [and even more the tetrafluoroborate $Pb(BF_4)_2$] are much used as electrolytic plating baths for the deposition of Pb to impart corrosion resistance or lubricating properties to various metal parts. Throughout the chemistry of the oxoacid salts of Pb^{II} the close correlation between anionic charge and aqueous solubility is apparent.

The complex coordination chemistry of Pb^{II} is also beginning to be actively explored and some unusual stereochemistries are emerging. Thus, the mononuclear (η^2-nitrato)bis(phenanthrolene)(*N*-thiocyanato) complex $[Pb(phen)_2(NCS)(\eta^2\text{-}NO_3)]$ has 7-coordinate Pb^{II} with a large vacancy

Next Page

in the coordination sphere, possibly indicating a stereochemically active lone pair.[50] Again, $[Pb(phen)_4(OClO_3)]ClO_4$ features 9-fold, capped square antiprismatic coordination about Pb,[51] whereas in $[Pb[tpy)_3][ClO_4]_2$ (tpy = 2, 2′:6′,2″-terpyridine) there is an unusual D_3 9-coordinate environment around the Pb^{II} centre.[52]

10.3.5 Other inorganic compounds

Few of the many other inorganic compounds of Ge, Sn and Pb call for special comment. Many pseudo-halogen derivatives of Sn^{IV}, Pb^{IV} and Pb^{II} have been reported, e.g. cyanides, azides, isocyanates, isothiocyanates, isoselenocyanates and alkoxides.[39,53]

All 9 chalcogenides MX are known (X = S, Se, Te). GeS and SnS are interesting in having layer structures similar to that of the isoelectronic black-P (p. 482). The former is prepared by reducing a fresh precipitate of GeS_2 with excess H_3PO_2 and purifying the resulting amorphous red-brown powder by vacuum sublimation. SnS is usually made by sulfide precipitation from Sn^{II} salts. PbS occurs widely as the black opaque mineral galena, which is the principal ore of Pb (p. 368). In common with PbSe, PbTe and SnTe, it has the cubic NaCl-type structure. Pure PbS can be made by direct reaction of the elements or by reaction of $Pb(OAc)_2$ with thiourea; the pure compound is an intrinsic semiconductor which, in the presence of impurities or stoichiometric imbalance, can develop either *n*-type or *p*-type semiconducting properties (p. 332). It is also a photoconductor (like PbSe and PbTe) and is one of the most sensitive detectors of infrared radiation; the photovoltaic effect in these compounds is also widely used in photoelectric cells, e.g. PbS in photographic exposure meters. The three compounds are also unusual in that their colour diminishes with increasing molecular weight: PbS is black, PbSe grey, and PbTe white.

Of the selenides, GeSe (mp 667°) forms as a dark-brown precipitate when H_2Se is passed into an aqueous solution of $GeCl_2$. SnSe (mp 861°) is a grey-blue solid made by direct reaction of the elements above 350°. PbSe (mp 1075°) can be obtained by volatilizing $PbCl_2$ with H_2Se, by reacting $PbEt_4$ with H_2Se in organic solvents, or by reducing $PbSeO_4$ with H_2 or C in an electric furnace; thin films for semiconductor devices are generally made by the reaction of $Pb(OAc)_2$ with selenourea, $(NH_2)_2CSe$. The tellurides are best made by heating Ge, Sn or Pb with the stoichiometric amount of Te.

Other chalcogenides that have been described include GeS_2, $GeSe_2$, Sn_2S_3 and $SnSe_2$, but these introduce no novel chemistry or structural principles. Of more interest, perhaps, is the polymeric anion $[Sn_5S_{12}^{4-}]_\infty$ (1) which occurs in $Cs_4Sn_5S_{12}.2H_2O$ and which contains both trigonal bipyramidal and octahedral Sn^{IV}.[54] The compound was prepared by hydrothermal reaction of Cs_2CO_3 with SnS_2 at 150°C. A similar reaction between Rb_2CO_3 and SnS_2 in saturated aqueous H_2S solution at 190°C afforded $Rb_2Sn_3S_7.2H_2O$ in which the polymeric $[Sn_3S_7^{2-}]_\infty$ anion (2) features both SnS_4 tetrahedra and SnS_6 octahedra.[55] Another new structural form, in which a *commo*-Sn atom joins a double cube, is found in the discrete $\{Sn_7S_6O_2\}$ cluster core (3) of $[\{Bu^tSn(S)L\}_3]_2Sn$; the diphosphinate ligand L = μ-η^2-O_2PPh_2 bridges the three non-*commo* Sn atoms in each of the cubes.[56] Examples of

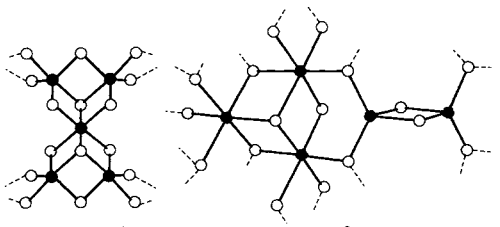
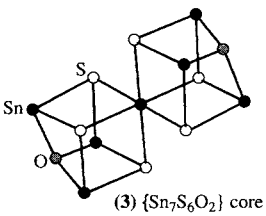
square-pyramidal 5-coordinate Sn^{IV} [57,58] and pentagonal bipyramidal 7-coordinate Sn^{IV} [59] have also been recently established in various thio-organotin complexes.



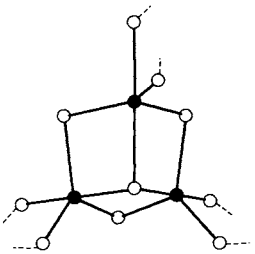
(1) $[Sn_5S_{12}^{4-}]_\infty$ (2) $[Sn_3S_7^{2-}]_\infty$



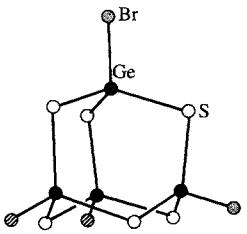
(3) $\{Sn_7S_6O_2\}$ core

The discrete anions $[Sn_2Se_6]^{4-}$ and $[Sn_2Te_6]^{4-}$ have the B_2H_6-type structure (p. 154) and are known in $Rb_4(Sn_2Se_6)$,[55] $[enH_2]_2[Sn_2Se_6]$[60] and $[NMe_4]_4[Sn_2Te_6]$.[61] By contrast, $[enH_2][Sn_3Se_7].\frac{1}{2}en$ features a sheet polymeric anion $[Sn_3Se_7^{2-}]_\infty$ (4) in which the basic elements are $SnSe_5$ trigonal bipyramids.[60] The adamantane-like anion $[Ge_4Te_{10}]^{4-}$ was identified by X-ray diffraction analysis of the black crystalline salt $[NEt_4]_4[Ge_4Te_{10}]$, prepared in 72% yield by extraction of the alloy of composition $K_4Ge_4Te_{10}$ with ethylene diamine in the presence of Et_4NBr[61a]

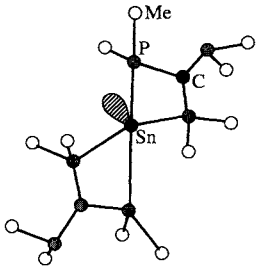
The first sulfide halide of Ge was made by the apparently straightforward reaction:



(4) $[Sn_3Se_7^{2-}]_\infty$



(5) $Ge_4S_6Br_4$



(6) $[Sn\{C(PMe_2)_3\}_2]$

$$4GeBr_4 + 6H_2S \xrightarrow{CS_2/Al_2Br_6} Ge_4S_6Br_4 + 12HBr$$

The unexpectedly complex product was isolated as an almost colourless air-stable powder, and a single-crystal X-ray analysis showed that it had the molecular adamantane-like structure (5).[62] This is very similar to the structure of the "iso-electronic" compound P_4O_{10} (p. 504).

There has been growing interest in the detailed structure and reaction chemistry of monomeric forms of two-coordinate derivatives of Ge^{II}, Sn^{II} and Pb^{II} since the first examples were unequivocally established in 1980.[63,64] Thus, treatment of the corresponding chlorides MCl_2 with lithium di-*tert*-butyl phenoxide derivatives in thf affords a series of yellow (Ge^{II}, Sn^{II}) and red (Pb^{II}) compounds $M(OAr)_2$ in high yield.[63] The O–M–O bond angle in $M(OC_6H_2Me\text{-}4\text{-}Bu^t_2\text{-}2,6)_2$ was 92° for Ge and 89° for Sn. Similar reactions

of MCl_2 with $LiNBu^t_2$ yielded the (less stable) monomeric di-*tert*-butylamide, $Ge(NBu^t_2)_2$ (orange), and $Sn(NBu^t_2)_2$ (maroon);[64] the more stable related bis(tetramethylpiperidino) compound $[Ge\{\overline{NCMe_2(CH_2)_3CMe_2}\}_2]$ was found to have a somewhat larger bond angle at Ge (N–Ge–N = 111°) and a rather long Ge–N bond (189 pm). More recent examples are $[Ge\{N(SiMe_3)_2\}_2]$[65] and $[\overline{GeN(Bu^t)CH{=}CHN}\text{-}(Bu^t)]$.[66] The first monomeric prochiral Sn^{II} complexes, $[Sn\{N(SiMe_3)_2\}X]$, have also been reported, where X is a bulky substituted phenoxy group or a tetramethylpiperidino moiety.[67] These are but illustrative examples of a large and burgeoning field.[68]

Turning finally to compounds with bonds from the heavier Group 14 elements to heavier Group 15 elements we may note compounds such as $[Sn\{C(PMe_2)_3\}_2]$ which has the pseudo trigonal bipyramidal structure (6). This complex, which has Sn bonded exclusively to four P atoms, is formed as yellow crystals by the reaction of $SnCl_2$ with $2Li\{C(PMe_2)_3\}$ in Et_2O at −78°C.[69] A notable feature of the structure is the substantial difference between the equatorial and axial Sn–P distances (260 pm *vs* 279 and 284 pm, respectively) and the small chelate bite angle of 62.9° at the Sn atom. The compound is fluxional in solution even at −90°C due to pseudorotation (p. 499) which equilibrates the axial and equatorial positions. Several similar compounds are known.[69] Germanium analogues of (6) such as the stable crystalline complexes $[Ge\{C(PMe_2)_3\}_2]$ and $[Ge\{C(PMe_2)_2(SiMe_3)\}_2]$ can be made by similar procedures, starting from $GeCl_2$.dioxane:[70] see also next section.

A range of shiny metallic compounds featuring trigonal planar anions SnX_3^{5-} (X = As, Sb, Bi) have been characterized with composition $M_6(SnX_3)O_{0.5}$ (M = Rb, Cs); the Sn and X atoms in SnX_3^{5-} (isostructural with CO_3^{2-}) are coordinated by trigonal prisms of $6M^+$, and the O^{2-} ions occupy octahedral sites in the M^+ lattice.[70a]

Rather different is the X-ray structural characterization of the 'bare' Sn^{2+} ion in $[Sn^{2+}][SbF_6^-]_2.2AsF_3$ (prepared by treating the product of the direct reaction between SnF_2 and SbF_5 with AsF_3).[71] The crystal packing is such that each Sn^{2+} is surrounded by nine F atoms (tricapped trigonal prism) and the average Sn–F distance is 257 pm (cf. the sum of the ionic radii, 251 pm). The Mössbauer spectrum (p. 371) shows zero quadrupole splitting and the highest known chemical shift for any tin(II) species, consistent with the 'bare ion' formulation.

10.3.6 Metal–metal bonds and clusters

The catenation of Group 14 elements has been discussed on pp. 337–42 and 374–5,

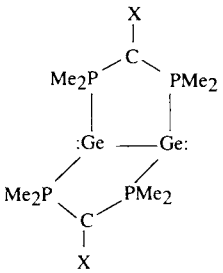
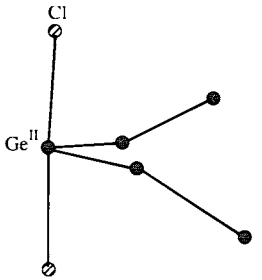
(7) $[Ge^{IV}\{C(PMe_2)_2X\}_2Cl_2]$



(8) $[Ge^{I}{}_2\{C(PMe_2)_2X\}_2]$



(9) $[Ge^{I}{}_2\{\mu\text{-}(PMe_2)_2CX\}_2]_2Ge^{II}Cl_2(core)$

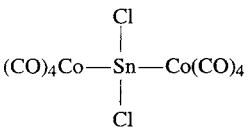
and further examples are in Section 10.3.7. In addition, when the reaction of $GeCl_2$.dioxane with $2Li[C\{(PMe_2)_2X\}_2]$ (mentioned above[70]) is varied by using a higher proportion of $GeCl_2$, concurrent redox disproportionation occurs to yield a mixture of $[Ge^{IV}\{C(PMe_2)_2X\}_2Cl_2]$ (7) and $[Ge^{I}_2\{C(PMe_2)_2X\}_2]$ (8) according to the optimized stoichiometry:[72]

$$3GeCl_2.diox + 4Li[\{C(PMe_2)_2X\}_2] = (7) + (8) + 4LiCl + 3C_4H_8O_2$$

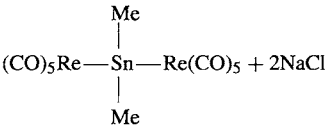
where $X + SiMe_3$ (or PMe_2). The Ge–Ge distance in (8) is 254 pm, i.e. about 10 pm longer than in polygermanes. The stereochemically active lone pairs of electrons on Ge^{I} in (8) can be used as electron-pair donors to a further $GeCl_2$ moiety to form the homonuclear (germanediyl donor)–(germanediyl acceptor) complex $[Ge_2\{\mu\text{-}(PMe_2)_2CX\}_2]_2GeCl_2$ which features a mixed-valent Ge_5 chain as shown schematically in (9). The Ge–Ge distances along the Ge^{I}–Ge^{I}–Ge^{II}–Ge^{I}–Ge^{I} chain are 249.2, 255.4, 256.2 and 248.5 pm, respectively.

Heteroatomic metal-metal bonds can be formed by a variety of synthetic routes as illustrated below for tin:

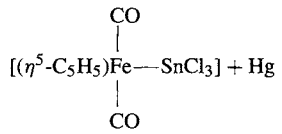
Insertion: $SnCl_2 + Co_2(CO)_8 \longrightarrow$



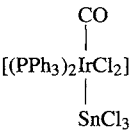
Metathesis: $Me_2SnCl_2 + 2NaRe(CO)_5 \longrightarrow$



Elimination: $SnCl_2 + [Fe(\eta^5\text{-}C_5H_5)(CO)_2HgCl] \longrightarrow$



Oxidative addition: $SnCl_4 + [Ir(CO)Cl(PPh_3)_2] \longrightarrow$



Some representative examples, all featuring tetrahedral Sn, are in Fig. 10.9.[53] Several reactions are known in which the Sn–M bond remains intact, e.g.:

$$Ph_3SnMn(CO)_5 + 3Cl_2 \longrightarrow Cl_3SnMn(CO)_5 + 3PhCl$$

$$Cl_2Sn\{Co(CO)_4\}_2 + 2RMgX \longrightarrow R_2Sn\{Co(CO)_4\}_2 + 2MgClX$$

Others result in cleavage, e.g.:

$$Me_3SnCo(CO)_4 + I_2 \longrightarrow Me_3SnI + Co(CO)_4I$$

$$Me_3SnMn(CO)_5 + Ph_2PCl \longrightarrow Me_3SnCl + \tfrac{1}{2}[Ph_2PMn(CO)_4]_2 + CO$$

$$Me_3SnMn(CO)_5 + C_2F_4 \longrightarrow Me_3SnCF_2CF_2Mn(CO)_4$$

[72] H. H. Karsch, B. Deubelly, J. Reide and G. Müller, *Angew. Chem. Int. Edn. Engl.* **26**, 674–6 (1987).

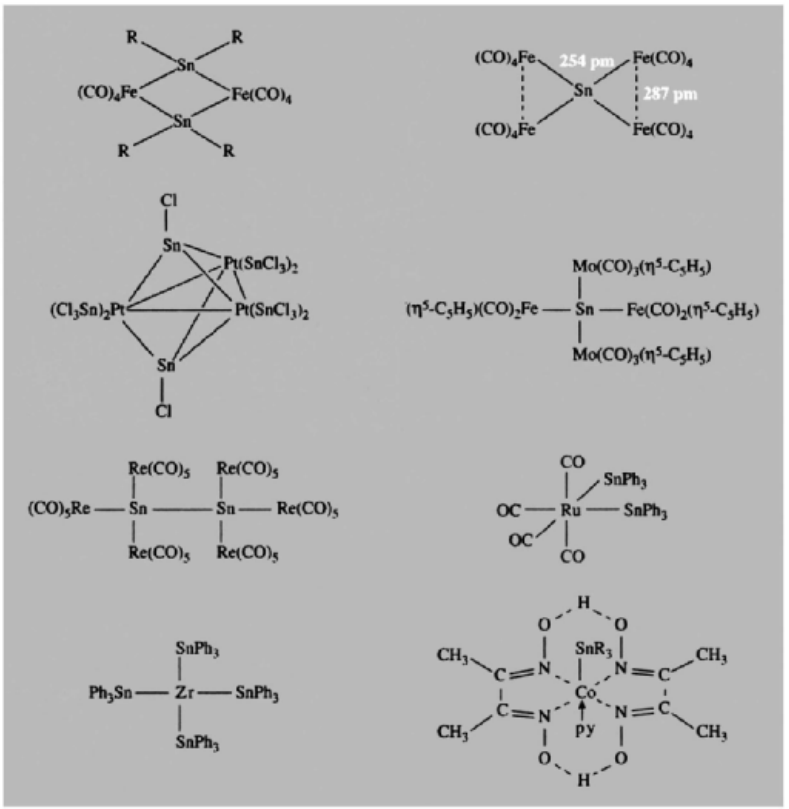


Figure 10.9 Some examples of metal sequences and metal clusters containing tin-transitional metal bonds.

A similar though less extensive range of Pb–M compounds has been established;[39] e.g. $[Ph_2Pb\{Mn(CO)_5\}_2]$, $[Ph_3PbRe(CO)_5]$, $[Ph_2Pb\{Co(CO)_4\}_2]$, $[(PPh_3)_2Pt(PbPh_3)_2]$, $[(CO)_3Fe(PbEt_3)_2]$, and the cyclic dimer $[(CO)_4Fe{-}PbEt_2]_2$. Reaction of these compounds with halogens results in fission of the Pb–M bonds. In the unique case of $[Pb\{Mn(\eta^5\text{-}C_5H_5)(CO)_2\}_2]$ the linear central MnPbMn core (177.2°) and short Mn–Pb distance (246.3 pm) suggest that this is the first example of multiple bonding between Pb and a transition metal, Mn=Pb=Mn.[73] The compound is obtained in 20% yield as air-stable reddish-brown crystals by the reaction of $PbCl_2$ with the substitutionally labile complex $[Mn(\eta^5\text{-}C_5H_5)(CO)_2(thf)]$.

It has been known since the early 1930s that reduction of Ge, Sn and Pb by Na in liquid ammonia gives polyatomic Group 14 metal anions, and crystalline compounds can be isolated using ethylenediamine, e.g. $[Na_4(en)_5Ge_9]$ and $[Na_4(en)_7Sn_9]$. A dramatic advance was achieved[74] in the 1970s by means of the polydentate cryptand ligand $[N\{(C_2H_4)O(C_2H_4)O(C_2H_4)\}_3N]$ (p. 98). Thus, reaction of cryptand in ethylenediamine with the alloys $NaSn_{1-1.7}$ and $NaPb_{1.7-2}$ gave red crystalline salts $[Na(crypt)]_2^+[Sn_5]^{2-}$ and $[Na(crypt)]_2^+[Pb_5]^{2-}$ containing the D_{3h} cluster anions illustrated in Fig. 10.10. If each Sn or Pb atom is thought to have 1 nonbonding pair of electrons then the

[73] W. A. HERRMANN, H.-J. KNEUPER and E. HERDTWECK, *Angew. Chem. Int. Edn. Engl.* **24**, 1062–3 (1985).

[74] P. A. EDWARDS and J. D. CORBETT, *Inorg. Chem.* **16**, 903–7 (1977). J. D. CORBETT and P. A. EDWARDS, *J. Am. Chem. Soc.* **99**, 3313–7 (1977).

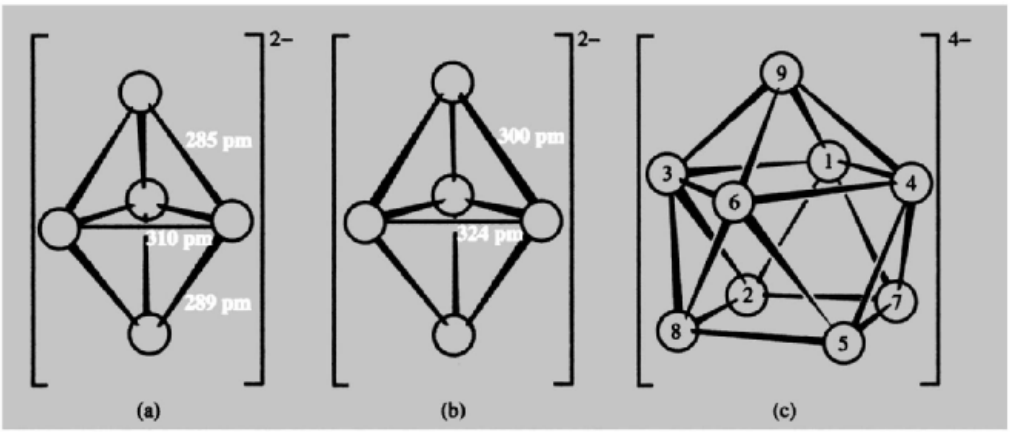

Figure 10.10 The structure of polystannide and polyplumbide anions: (a) the slightly distorted D_{3h} structure of $[Sn_5]^{2-}$, (b) the D_{3h} structure of $[Pb_5]^{2-}$, and (c) the unique C_{4v} structure of $[Sn_9]^{4-}$: all Sn–Sn distances are in the range 295–302 pm except those in the slightly longer upper square (1,3,6,4) which are in the range 319–331 pm; the angles within the two parallel squares are all 90° (±0.8°).

M_5^{2-} clusters have 12 framework bonding electrons as has $[B_5H_5]^{2-}$ (p. 161); the anions are also isoelectronic with the well-known cation $[Bi_5]^{3+}$. Similarly, the alloy $NaSn_{\sim 2.25}$ reacts with cryptand in ethylenediamine to give dark-red crystals of $[Na(crypt)]_4^+[Sn_9]^{4-}$; the anion is the first example of a C_{4v} unicapped Archimedian antiprism (Fig. 10.10c) and differs from the D_{3h} structure of the isoelectronic cation $[Bi_9]^{5+}$ which, in the salt $Bi^+[Bi_9]^{5+}[HfCl_6]_3^{2-}$ (p. 591), features a tricapped trigonal prism, as in $[B_9H_9]^{2-}$ (p. 153). The emerald green species $[Pb_9]^{4-}$, which is stable in liquid NH_3 solution, has not so far proved amenable to isolation via cryptand-complexed cations.

The influence of electron-count on cluster geometry has been very elegantly shown by a crystallographic study of the deep-red compound $[K(crypt)]_6^+[Ge_9]^{2-}[Ge_9]^{4-}.2.5en$, prepared by the reaction of KGe with cryptand in ethylenediamine. $[Ge_9]^{4-}$ has the C_{4v} unicapped square-antiprismatic structure (10.10c) whereas $[Ge_9]^{2-}$, with 2 less electrons, adopts a distorted D_{3h} structure which clearly derives from the tricapped trigonal prism (p. 153).[75] The field is one of great interest and activity, as evidenced by papers describing the synthesis of and structural studies on tetrahedral Ge_4^{2-} and Sn_4^{2-},[76] tricapped trigonal-prismatic $TlSn_8^{3-}$,[77] bicapped square-antiprismatic $TlSn_9^{3-}$,[77] and the two *nido*-series $Sn_{9-x}Ge_x^{4-}$ $(x = 0–9)$ and $Sn_{9-x}Pb_x^{4-}$ $(x = 0–9)$.[78] Other theoretical studies on many of these polymetallic-cluster anions have also been published.[79] Recent synthetic and structural work includes the characterization of the octahedral *closo*-$[Ge_2Co_4]$ grouping in $[1,6\text{-}\{(CO)_4COGe\}_2Co_4(CO)_{11}]$,[80]

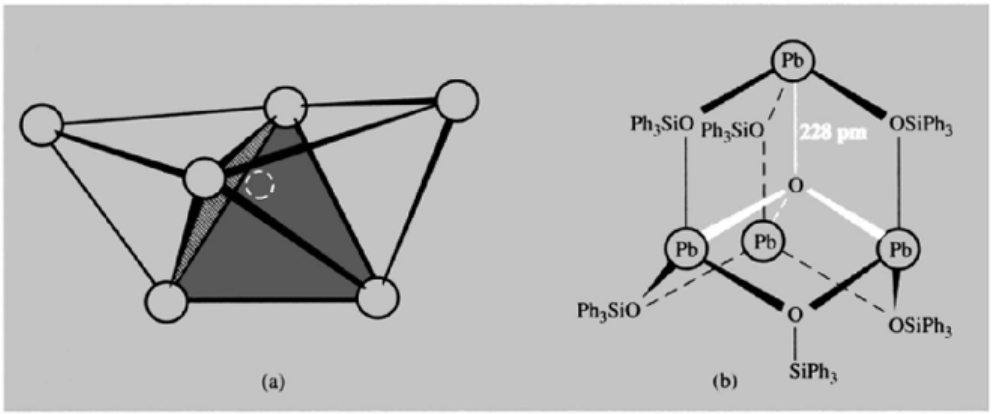

Figure 10.11 (a) The three face-sharing tetrahedra of Pb atoms in the $Pb_6O(OH)_6^{4+}$ cluster; only the unique 4-coordinate O atom at the centre of the central tetrahedron is shown (in white). (b) The adamantane-like structure of $[Pb_4O(OSiPh_3)_6]$ showing the fourfold coordination about the central O atom.

the *closo*-10 vertex cluster $[Sn_9Cr(CO)_3]^{4-}$[81] and encapsulated Ge and Sn atoms (E) in species such as $[Ni_{12}(\mu_{12}\text{-}E)(CO)_{22}]^{2-}$ and $[Ni(\mu_{10}\text{-}Ge)(CO)_{20}]^{2-}$.[82]

The polymeric cluster compound $[Sn_6O_4(OH)_4]$ formed by hydrolysis of Sn^{II} compounds has been mentioned on p. 384. Hydrolysis of Pb^{II} compounds also leads to polymerized species; e.g. dissolution of PbO in aqueous $HClO_4$ followed by careful addition of base leads to $[Pb_6O(OH)_6]^{4+}[ClO_4]_4^-H_2O$. The cluster cation (Fig. 10.11a) consists of 3 tetrahedra of Pb sharing faces; the central tetrahedron encompasses the unique O atom and the 6 OH groups lie on the faces of the 2 end tetrahedra.[83] The extent of direct Pb–Pb interaction within the overall cluster has not been established but it is noted that the distance between "adjacent" Pb atoms falls in the range 344–409 pm (average 381 pm) which is appreciably larger than in the Pb_5^{2-} anion. The distance from the central O to the 4 surrounding Pb atoms is 222–235 pm and the other Pb–O(H) distances are in the range 218–267 pm. The structure should be compared with the $[Sn_6O_4(OH)_4]$ cluster (p. 384), which also has larger Sn–Sn distances than in the polystannide anions in Fig. 10.10.

Another polycyclic structure in which a unique O atom is surrounded tetrahedrally by 4 Pb^{II} atoms is the colourless adamantane-like complex $[Pb_4O(OSiPh_3)_6]$, obtained as a 1:1 benzene solvate by reaction of Ph_3SiOH with $[Pb(C_5H_5)_2]$ (p. 404). The local geometry about Pb^{II} is also noteworthy: it comprises pseudo-trigonal bipyramidal coordination in which the bridging $OSiPh_3$ groups occupy the equatorial sites whilst the apical sites are occupied by the unique O atom and axially directed lone pairs of electrons.[84] The first heterometallic oxoalkoxide, $[Pb_6Nb_4O_4(OEt)_{24}]$, has also been prepared, by reacting $[Pb_4O(OEt)_6]$ and $[Nb_2(OEt)_{10}$ in ethanol at room temperature.[85] X-ray structural analysis shows an octahedral Pb_6 framework, four of whose faces are capped by a μ_4-oxo ligand connected to 3Pb atoms and an $\{Nb(OEt)_5\}$ moiety; the remaining

four faces of the Pb_6 octahedron are capped by (μ_3-OEt) groups. This leads, to the overall detailed formulation of the compound as $[Pb_6(\mu_4\text{-}O)_4\{Nb(OEt)_2\}_4(\mu_3\text{-}OEt)_4(\mu_2\text{-}OEt)_{12}]$. Alternatively the complex can be described as a tetradentate oxo ligand donating to $4\{Nb(OEt)_2(\mu_2\text{-}OEt)_3\}$ groups i.e. $[Pb_6O_4(OEt)_4\{Nb(OEt)_5\}_4]$.

10.3.7 Organometallic compounds[86]

Germanium[87]

Organogermanium chemistry closely resembles that of Si though the Ge compounds tend to be somewhat less thermally stable. They are also often rather more chemically reactive than their Si counterparts, e.g. in ligand scrambling reactions, Ge–C bond cleavage and hydrogermylation. However, GeR_4 compounds themselves are rather inert chemically and R_nGeX_{4-n} tend to be less prone to hydrolysis and condensation reactions than their Si analogues. Again, following expected group trends, germylenes (R_2Ge:) are more stable than silylenes. The table of comparative bond energies on p. 374 indicates that the Ge–C and Ge–H bonds are weaker than the corresponding bonds involving Si but are nevertheless quite strong; Ge–Ge is noticeably weaker. The electronegativity of both Si and Ge are similar to that of H, though the reactivity pattern towards organolithium reagents suggests a slight hydridic character ($H^{\delta-}$) for Ph_3SiH and some protic character ($H^{\delta+}$) for Ph_3GeH:

$$Ph_3Si\text{–}H + LiR \longrightarrow Ph_3Si\text{–}R + LiH$$

(metathesis)

$$Ph_3Ge\text{–}H + LiR \longrightarrow Ph_3Ge\text{–}Li + RH$$

(metallation)

In fact, the polarity of the Ge–H bond can readily be reversed (umpolung) by an appropriate choice of constituents, e.g.:

$$Et_3Ge^{\delta+}\text{–}H^{\delta-} + >C{=}O \longrightarrow H\text{–}\overset{|}{\underset{|}{C}}\text{–}OGeEt_3$$

(germoxane)

$$Cl_3Ge^{\delta-}\text{–}H^{\delta+} + >C{=}O \longrightarrow Cl_3Ge\text{–}\overset{|}{\underset{|}{C}}\text{–}OH$$

(germylcarbinol)

Preparative routes to organogermanium compounds parallel those for organosilicon compounds (p. 363) and most of the several thousand known organogermanes can be considered as derivatives of R_nGeX_{4-n} or Ar_nGeX_{4-n} where X = hydrogen, halogen, pseudohalogen, OR, etc. The compounds are colourless, volatile liquids, or solids. Attempts to prepare $(-R_2GeO-)_x$ analogues of the silicones (p. 364) show that the system is different: hydrolysis of Me_2GeCl_2 is reversible and incomplete, but extraction of aqueous solutions of Me_2GeCl_2 with petrol leads to the cyclic tetramer $[Me_2GeO]_4$, mp 92°; the compound is monomeric in water. Organodigermanes and -polygermanes have also been made by standard routes, e.g.:

$$2Me_3GeBr + 2K \xrightarrow{\text{reflux}} 2KBr + Ge_2Me_6$$

(mp −40°, bp 140°)

$$Et_3GeBr + NaGePh_3 \xrightarrow{\text{liq } NH_3} NaBr + Et_3GeGePh_3 \text{ (mp 90°)}$$

$$2Ph_3GeBr + 2Na \xrightarrow[\text{xylene}]{\text{boiling}} 2NaBr + Ge_2Ph_6$$

(mp 340°)

$$Ph_2GeCl_2 + 2NaGePh_3 \longrightarrow 2NaCl + Ge_3Ph_8$$

(mp 248°)

In general, the Ge–Ge bond is readily cleaved by Br_2 either at ambient or elevated temperatures but the compounds are stable to thermal cleavage at moderate temperatures. Ge_2R_6 compounds can even be distilled unchanged in air (like Si_2R_6 but unlike the more reactive Sn_2R_6) and are stable towards hydrolysis and ammonolysis.

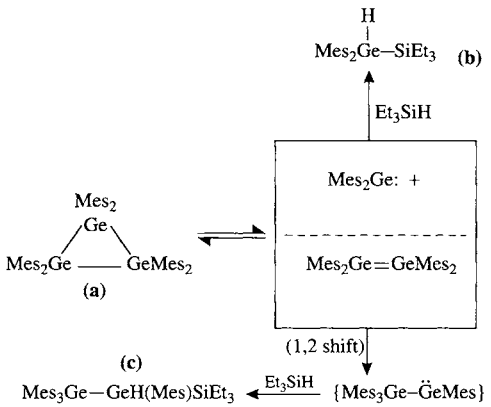
[87] P. RIVIÈRE, M. RIVIÈRE-BAUDET and J. SATGÈ, Chap. 10 in G. WILKINSON, F. G. A. STONE and E. W. ABEL (eds.) *Comprehensive Organometallic Chemistry*, Pergamon Press, Oxford, Vol. 2, pp. 399–518 (1982) (716 refs.).

Considerable recent attention has focused on the preparation, structure and stability of germenes (>Ge=C<), germylenes (R_2Ge:), cyclo and polyhedral oligopolygermanes, and Ge^{II} species with coordination numbers greater than 4 (especially 5 and 10). Thus, evidence for fugitive germene species has been known for some 20 years[88] but stable germenes, $R_2Ge{=}CR'_2$, were first reported only in 1987,[89,90] the stabilization being achieved by use of bulky groups both on Ge [e.g. R = mesityl or $-N(SiMe_3)_2$] and on C [e.g. R'_2 = $-B(Bu^t)C(SiMe_3)_2B(Bu^t)-$ or CR'_2 = fluorenylidene]. Numerous other stable germenes have since been characterized.[90]

The first germylene, R_2Ge: [R = $(SiMe_3)_2$-CH–], was reported in 1976. It can now be conveniently prepared from $GeCl_2$.diox and Grignard-type derivatives of the bulky bis(trimethylsilyl)methyl R group in Et_2O (e.g. ether complexes of RMgCl or MgR_2); gas-phase electron diffraction at 155°C shows it to be a V-shaped monomer with the angle CGeC 107°.[91] In the solid phase the compound forms bright yellow crystals (mp 182°C) of the centrosymmetric dimer Ge_2R_4 which has a *trans*-folded framework (see structure on p. 403) with a fold angle θ of 32° and a Ge–Ge distance of 235 pm.[92] By contrast, reductive coupling reactions of R_2GeX_2 with a mixture of Mg/$MgBr_2$ in thf affords colourless crystals of cyclotrigermanes or cyclotetragermanes in moderate or good yield:[93]

$$R_2GeCl_2 \xrightarrow{MgBr_2} R_2Ge(Cl)Br \xrightarrow{Mg} R_2Ge(Cl)MgBr \xrightarrow{\text{dil HCl}} (GeR_2)_n \quad n = 3, 4$$

Bulky R groups such as mesityl, xylyl or 2,6-diethylphenyl lead to Ge_3 rings whereas sterically less demanding groups such as Pr, Ph or Me_3SiCH_2 yield Ge_4 rings. Note that the compounds $(GeR_2)_n$ feature Ge with the coordination number 2, 3 or 4 depending on whether $n = 1$, 2, or ≥ 3, respectively. Mixed derivatives can also be made: e.g., reductive coupling of $Mes(Bu)GeCl_2$ at room temperature affords [{Ge(Mes)Bu}$_3$], mp 201°. Thermolysis of [{$Ge(Mes)_2$}$_3$], (a) in the presence of Et_3SiH at 105° yields a mixture of dimesityl(triethylsilyl)germane (b) and tetramesityl(triethylsilyl)digermane (c) according to the subjoined scheme:[94]



Polyhedral oligogermanes of varying complexity can be made by careful choice of the organo R group and the metal reductive coupling agent.[95] Thus, treatment of $\{(Me_3Si)_2CH\}GeCl_3$ with Li metal in thf gave thermochroic yellow-orange crystals of the hexamer $[Ge_6\{CH(SiMe_3)_2\}_6]$ which were unexpectedly stable to atmospheric

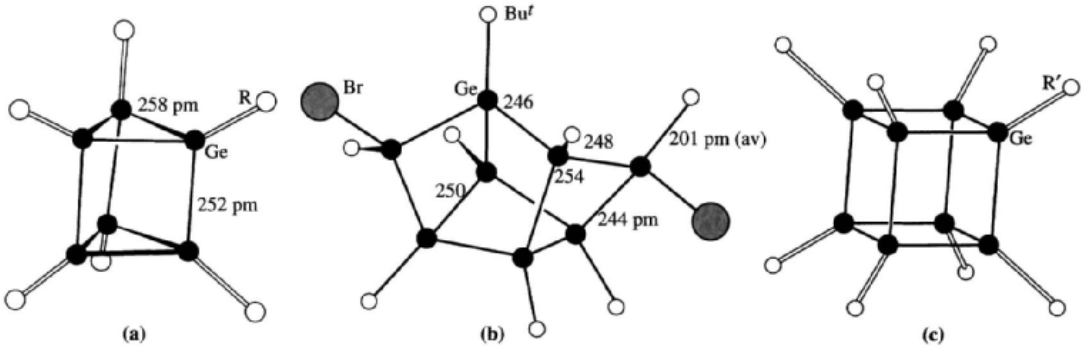

Figure 10.12 (a) Prismane structure of $[Ge_6\{CH(SiMe_3)_2\}_6]$ (for clarity only the *ipso* C atoms of the R groups are shown). (b) The tetracyclo structure of $[Ge_8Bu^t_8Br_2]$ with only the *ipso* C atoms of the Bu^t groups shown. (c) The cubane structure of $[Ge_8(CMeEt_2)_8]$ again with only the *ipso* C atoms of the *t*-hexyl groups shown.

O_2 and moisture.[96] X-ray analysis revealed a prismane structure (Fig. 10.12a) rather than a monocyclic benzenoid structure. The Ge–Ge distances within the two triangular faces (258 pm) are, perhaps surprisingly, longer than those in the prism quadrilateral edges (252 pm) and all the Ge–Ge distances are significantly longer than in other polygermanes (237–247 pm). Again, treatment of $GeBr_4$ with LiBu^t yields a mixture of $Bu^t_2GeBr_2$ and $Bu^tBr_2Ge{-}GeBr_2Bu^t$, and treatment of this latter with an excess of Li/naphthalene afforded the polycyclic octagermane. $Ge_8Bu^t_8Br_2$, in 50% yield.[97] As shown in Fig 10.12b, the molecule is chiral with C_2 skeletal symmetry. The octagermacubane $[Ge_8(CHMeEt_2)_8]$ (Fig. 10.12c) was obtained as yellow crystals (mp > 215°) by a simple coupling reaction of R_3GeCl with $Mg/MgBr_2$, and numerous other cyclic, ladder and cluster polygermanes have been described.[95]

The coordination number of Ge in organogermanes is not limited to 2, 3 or 4, and higher coordination numbers are well documented. Examples are 5-coordinate Ge^{II} in the cation of $[Ge(\eta^5\text{-}C_5Me_5)]^+[BF_4]^-$ (10),[98] 6-coordinate Ge^{II} in the corresponding chloride $[(\eta^5\text{-}C_5Me_5)GeCl]$ (11)[98] and 10-coordinate Ge^{II} in $[Ge(\eta^5\text{-}C_5H_5)_2]$ (12)[99] and its $(\eta^5\text{-}C_5R_5)$ analogues.[98] These species can now readily be prepared by standard reactions, and structural details are in the leading references cited. Thus, reaction of NaC_5H_5 with $GeCl_2$.diox in thf gives a 60% yield of (12) as colourless crystals, mp 78°C. The angle of aperture between the two C_5H_5 planes in (12) is 50.4° compared with 45.9° or 48.4° for stannocene.[99] By contrast, 5-coordinate Ge^{IV} adopts a structure midway between trigonal bipyramidal and rectangular pyramidal in phenyl-substituted anionic germanates such as $[PhGe(\eta^2\text{-}C_6H_4O_2)_2]^-$ (13), the precise geometry being dictated by the co-cation, e.g. $[NEt_4]^+$, $[N(Et)_3H]^+$ or $[AsPh_4]^+$.[100]

Finally, brief mention should be made of the growing range of heterocyclic organogermanium compounds. Compounds with 3–13(+) atoms in the ring have recently been reviewed.[101] Cyclic organogermapolysilanes are also known, e.g.

peralkyl-1-germa-2,3,4-trisilacyclobutanes.[102] Other variants include the novel telluradigermiranes, $Ar_2\overline{Ge-Te-Ge}Ar_2$,[103] a yellow phosphagermirene $Bu^t\overline{C=P-Ge}R_2$ [mp. 89° for R = $(Me_3Si)_2CH-$],[104] and a germaphosphetene featuring a $\overline{GeCCP}$ ring system.[105] The possibilities are clearly limitless.

Tin[106,107]

Organotin compounds have been much more extensively investigated than those of Ge and, as described in the Panel, many have important industrial applications.[108] Syntheses are by standard techniques (pp. 134, 259, 363) of which the following are typical:

Grignard: $SnCl_4 + 4RMgCl \longrightarrow SnR_4 + 4MgCl_2$ (also with ArMgCl)

Organo Al: $3SnCl_4 + 4AlR_3 \longrightarrow 3SnR_4 + 4AlCl_3$ (alkyl only)

Direct (Rochow)[†] $Sn + 2RX \longrightarrow R_2SnX_2$ (and R_nSnX_{4-n}) (alkyl only).

All three routes are used on an industrial scale and the Grignard route (or the equivalent organo-Li reagent) is convenient for laboratory scale. Rather less used is the modified Wurtz-type reaction ($SnCl_4 + 4RCl \xrightarrow{8\ Na} SnR_4 + 8NaCl$). Conversion of SnR_4 to the partially halogenated species is readily achieved by scrambling reactions with $SnCl_4$. Reduction of R_nSnX_{4-n} with $LiAlH_4$ affords the corresponding hydrides and hydrostannation (addition of Sn–H) to C–C double and triple bonds is an attractive route to unsymmetrical or heterocyclic organotin compounds.

Most organotin compounds can be regarded as derivatives of $R_nSn^{IV}X_{4-n}$ ($n = 1-4$) and even compounds such as SnR_2 or $SnAr_2$ are in fact cyclic oligomers $(Sn^{IV}R_2)_x$ (p. 402). The physical properties of tetraorganostannanes closely resemble those of the corresponding hydrocarbons or tetraorganosilanes but with higher densities, refractive indices, etc. They are colourless, monomeric, volatile liquids or solids. Chemically they resist hydrolysis or oxidation under normal conditions though when

[†] For example, with MeCl at 175° in the presence of catalytic amounts of CH_3I and NEt_3, the yields were Me_2SnCl_2 (39%), $MeSnCl_3$ (6.6%), Me_3SnCl (4.6%).

Uses of Organotin Compounds

Tin is unsurpassed by any other metal in the multiplicity of applications of its organometallic compounds. The first organotin compound was made in 1849 but large-scale applications have developed only recently; indeed, world production figures for organotin compounds increased more than 700-fold between 1950 and 1980:

Year	1950	1960	1965	1970	1975	1980
Tonnes pa	<50	2000	5000	15 000	25 000	35 000

The largest application for organotin compounds (75% by weight) is as stabilizers for PVC plastics; in their absence halogenated polymers are rapidly degraded by heat, light or oxygen to give discoloured, brittle products. The most effective stabilizers are R_2SnX_2, where R is an alkyl residue (typically *n*-octyl) and X is laurate, maleate, etc. For food packaging the *cis*-butenedioate polymer, $[Oct^i_2Sn-OC(O)CH{=}CHC(O)O]_n$, and the *S,S'*-bis-(*iso*-octyl mercaptoethanoate), $Oct^i_2Sn\{SCH_2C(O)OOct^i\}_2$ have been approved and are used when colourless non-toxic materials with high transparency are required. The compounds are thought to be such effective stabilizers because (i) they inhibit the onset of dehydrochlorination by exchanging their anionic groups X with reactive Cl sites in the polymer, (ii) they react with and hence scavenge the HCl which is produced and which would otherwise catalyse further elimination, and (iii) they act as antioxidants and thereby prevent breakdown of the polymer initiated by atmospheric O_2.

Another major use of organotin compounds is as curing agents for the room temperature "vulcanization" of silicones; the 3 most commonly used compounds are Bu_2SnX_2, where X is acetate, 2-ethylhexanoate or laurate. The same compounds are also used to catalyse the addition of alcohols to isocyanates to produce polyurethanes.

The next major use of organotin compounds (15–20%) is as agricultural biocides and here triorganotins are the most active materials; the importance of this application can readily be appreciated since, at present, over one-third of the world's food crops are lost annually to pests such as fungi, bacteria, insects or weeds. The great advantage of organotin compounds in these applications is that their toxic action is selective and there is little danger to higher (mammalian) life; furthermore, their inorganic degradation products are completely non-toxic. Bu^n_3SnOH and Ph_3SnOAc control fungal growths such as potato blight and related infections of sugar-beet, peanuts, and rice. They also eradicate red spider mite from apples and pears. Other R_3SnX are effective in controlling insects, either by acting as chemosterilants or by killing the larvae. Again, $O(SnBu^n_3)_2$ is an excellent wood preserver, and derivatives of Ph_3Sn- and $(cyclohexyl)_3Sn$- are also used for this. Related applications are as marine antifouling agents for timber-hulled boats; paints containing Bu^n_3Sn- or Ph_3Sn- derivatives slowly release these groups and provide long-term protection against attachment of barnacles or attack by Teredo woodworm borers. Cellulose and woollen fabrics are likewise protected against fungal attack or destruction by moths. R_3SnX are also used as bacteriostats to control slime in paper and wood-pulp manufacture.

Me_2SnCl_2 is now used as an alternative to $SnCl_4$ for coating glass with a thin film of SnO_2 since it is a non-corrosive solid which is easier to handle. The glass (or ceramic) surface is treated with Me_2SnCl_2 vapour at temperatures above 450° and, depending on the thickness of the oxide film produced, the glass is toughened and the surface can be rendered scratch-resistant, lustrous, or electroconductive (p. 385).

Organotin reagents and intermediates are finding increasing use in organic syntheses.[109]

ignited they burn to SnO_2, CO_2 and H_2O. Ease of Sn–C cleavage by halogens or other reagents varies considerably with the nature of the organic group and generally increases in the sequence Bu (most stable) < Pr < Et < Me < vinyl < Ph < Bz < allyl < CH_2CN < CH_2CO_2R (least stable). The lability of Sn–C bonds and the ease of redistribution in mixed organostannane systems frustrated early attempts to prepare optically active tin compounds and the first synthesis of a 4-coordinate Sn compound in which the metal is the sole chiral centre was only achieved in 1971 with the isolation and resolution of [MeSn(4-anisyl)(1-naphthyl)-$\{CH_2CH_2C(OH)Me_2\}$].[110]

The association of SnR_4 via bridging alkyl groups (which is such a notable feature of many organometallic compounds of Groups 1, 2 and 13) is not observed at all. However, many compounds of general formula R_3SnX or R_2SnX_2 are strongly associated via bridging X-groups

[109] M. PEREYE, J.-P. QUINTARD and A. RAHM, *Tin in Organic Synthesis*, Butterworths, London, 1987, 342 pp. J. K. STILLE, *Angew. Chem. Int. Edn. Engl.* **25**, 508–24 (1986).

[110] M. GIELEN, *Acc. Chem. Res.* **6**, 198–202 (1973).

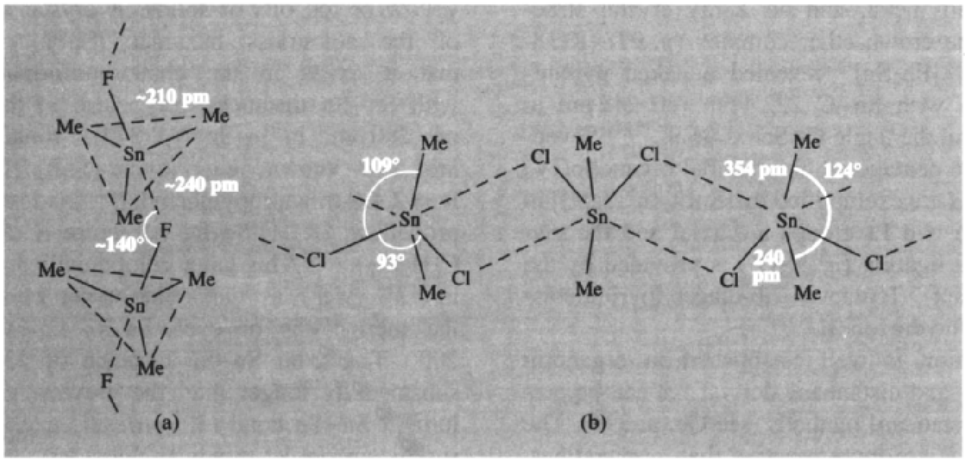

Figure 10.13 Crystal structure of (a) Me_3SnF, and (b) Me_2SnCl_2, showing tendency to polymerize via Sn—X···Sn bonds.

which thereby raise the coordination number of Sn to 5, 6 or even 7. As expected, F is more effective in this role than the other halogens (why?). For example, Ph_3SnF is a strictly linear polymer with 5-coordinate trigonal bipyramidal geometry about Sn; the angles Sn–F–Sn and F–Sn–F are both 180° and the Sn–F distances in the chain are identical (214.6 pm).[111] By contrast, Me_3SnF has a zig-zag chain structure (Fig. 10.13a) with unequal Sn–F distances and a pronounced bend at F (~140°). The volatile chlorine analogue (Me_3SnCl: mp 39.5°, bp 154°) also has a zig-zag chain structure with angle Sn–Cl–Sn 151° and essentially linear Cl–Sn–Cl (177°); The two Sn–Cl distances in the chain are 243 and 326 pm but even this longer distance is substantially shorter than the sum of the van der Waals radii (385 pm).[112] On the other hand crystalline Ph_3SnCl and Ph_3SnBr feature monomeric molecules with 4-coordinate Sn atoms.

Me_2SnF_2 has a layer structure with octahedral Sn and *trans*-Me groups above and below the F-bridged layers as in SnF_4 (p. 381). The weaker Cl bridging in Me_2SnCl_2 leads to the more distorted structure shown in Fig. 10.13b. The O atom is an even more effective ligand than F and, amongst the numerous compounds R_3SnOR' and $R_2Sn(OR')_2$ that have been studied by X-ray crystallography, the only ones with 4-coordinate tin (presumably because of the bulky ligands) are 1,4-$(Et_3SnO)_2C_6Cl_4$ and $[Mn(CO)_3\{\eta^5\text{-}C_5Ph_4(OSnPh_3)\}]$.

The converse of polymerization is heterolytic bond scission leading either to R_3Sn^+ or R_3Sn^- species. Tricoordinate organotin(IV) cations can readily be synthesized at room temperature by hydride or halide abstraction reactions in benzene or other solvents.[113] For example, with R = Me, Bu or Ph:

$$R_3SnH + Ph_3CClO_4 \longrightarrow [R_3Sn]^+[ClO_4]^- + Ph_3CH$$

$$R_3SnCl + AgClO_4 \longrightarrow [R_3Sn]^+[ClO_4]^- + AgCl$$

$$R_3SnH + B(C_6F_5)_3 \longrightarrow [R_3Sn]^+[B(C_6F_5)_3H]^-$$

The highly ionic nature of these (presumably planar) species is revealed by cryoscopy, electrical conductance and the diagnostically large downfield ^{119}Sn nmr chemical shift. Salts of the corresponding anionic species Ph_3Sn^- are easily generated by heating either Ph_3SnH or Sn_2Ph_6

[112] M. B. Hossain, J. L. Lefferts, K. C. Molloy, D. van der Helm and J. J. Zuckerman, *Inorg. Chim. Acta* **36**, L409–L410 (1979).

[113] J. B. Lambert and B. Kuhlmann, *J. Chem. Soc., Chem. Commun.*, 931–2 (1992).

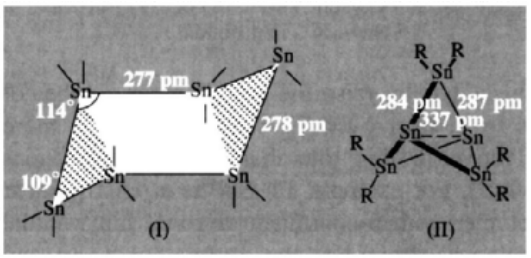
with alkali metal, and an X-ray crystal structure of the crown ether complex (p. 97) $[K(18\text{-crown-6})]^+[Ph_3Sn]^-$ revealed a naked pyramidal anion with Sn–C 222.4 pm (cf. 212 pm in $SnPh_4$) and the angle C–Sn–C 96.9°.[114] Seven-coordinate pentagonal bipyramidal organotin(IV) complexes are exemplified by $[SnEt_2(\eta^5\text{-dapt})]$ in which the two Et groups are axial and the planar 5-fold ligation (η^5-N_3O_2) is provided by the ligand (dapt), (H_2dapt = 2,6-diacetylpyridinebis-(2-thenoylhydrazone)].[115]

Catenation is well established in organotin chemistry and distannane derivatives can be prepared by standard methods (see Ge, p. 396). The compounds are more reactive than organodigermanes; e.g. Sn_2Me_6 (mp 23°) inflames in air at its bp (182°) and absorbs oxygen slowly at room temperature to give $(Me_2Sn)_2O$. Typical routes to higher polystannanes are:

$$2Me_3SnBr + NaMe_2SnSnMe_2Na \xrightarrow{\text{liq } NH_3} Me_3Sn(SnMe_2)_2SnMe_3 \text{ (oil)}$$

$$3Ph_3SnLi + SnCl_2 \longrightarrow [(Ph_3Sn)_3SnLi] \xrightarrow{Ph_3SnCl} Sn(SnPh_3)_4 (\text{mp} \sim 320°)$$

Unbranched chains up to at least Sn_6 are known, e.g. $Ph_3Sn(Bu^t_2Sn)_nSnPh_3$ ($n = 0$–4).[116] Cyclodialkyl stannanes(IV) can also be readily prepared, e.g. reaction of Me_2SnCl_2 with Na/liq NH_3 yields cyclo-$(SnMe_2)_6$ together with acyclic $X(SnMe_2)_nX$ ($n = 12$–20). Yellow crystalline cyclo-$(SnEt_2)_9$ is obtained almost quantitatively when Et_2SnH_2, dissolved in toluene/pyridine, is catalytically dehydrogenated at 100° in the presence of a small amount of Et_2SnCl_2. Similarly, under differing conditions, the following have been prepared:[34] $(SnEt_2)_6$, $(SnEt_2)_7$, $(SnBu^t_2)_4$, $(SnBu^i_2)_4$, $(SnBu^i_2)_6$, and $(SnPh_2)_5$. The compounds are highly reactive yellow or red oils or solids. A crystal structure of the colourless hexamer $(SnPh_2)_6$ shows that it exists in the chair conformation (I) with Sn–Sn distances very close to the value of 280 pm in α-Sn (p. 372). Small rings are also known, e.g. [cyclo-$(SnR_2)_3$] where R = 2,4,6-triisopropylphenyl,[117] and even the propellane [1.1.1]-Sn_5R_6 (structure II, R = 2,6-$C_6H_3Et_2$).[118] This latter compound was formed in 13% yield as dark blue-violet crystals by the thermolysis of cyclo-Sn_3R_6 in xylene at 200°. The axial Sn–Sn distance of 337 pm is substantially longer than the previously known longest Sn–Sn bond (305 pm) and may indicate significant singlet diradical character).



True monomeric organotin(II) compounds have proved rather elusive. The cyclopentadienyl compound $[Sn(\eta^5\text{-}C_5H_5)_2]$ (which is obtained as white crystals mp 105° from the reaction of NaC_5H_5 and $SnCl_2$ in thf) has a structure similar to that of germanocene (12 pp. 398–9) with the angle subtended at Sn by the midpoints of the C_5 rings 143.7° and 148.0° in the two independent molecules.[119] Interestingly, the mean value of 146° is 1° larger than the value for $[Sn(\eta^5\text{-}C_5Me_5)_2]$, suggesting that the angle is governed predominantly by electronic rather than steric factors. However, with the much more demanding η^5-C_5Ph_5 ligand, the two planar C_5 rings are exactly parallel and staggered, the opposed canting of the phenyl rings with respect to the C_5 rings giving overall

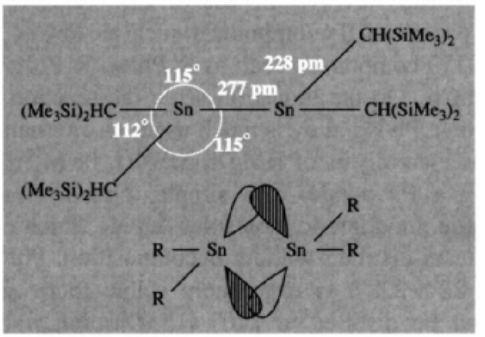
S_{10} symmetry.[120] Heterostannocenes such as the pyrrole analogue, $[Sn(\eta^5\text{-}C_4Bu^t_2H_2N)_2]$, (in which a CH group has been replaced by the isoelectronic N atom) have also been reported, the angle subtended by the ring centres at Sn being 142.5° in this case.[121] The related "half-sandwich" cation, *nido*-$[(\eta^5\text{-}C_5Me_5)Sn:]^+$, which is isostructural with *nido*-B_6H_{10} (p. 154), can be made in moderate yield by treating $[Sn(\eta^5\text{-}C_5Me_5)_2]$ with an ethereal solution of HBF_4. The product, $[(\eta^5\text{-}C_5Me_5)Sn]BF_4$, forms colourless crystals which are somewhat sensitive to air and moisture.[122] As its trifluoromethanesulfonate salt ($X^- = CF_3SO_3^-$), the cation undergoes a remarkable reaction with BI_3 which results in replacement of the apical Sn atom with the {BI} group to give a pentacarba analogue of *nido*-B_6H_{10}:[123]

$$\textit{nido}\text{-}[(\eta^5\text{-}C_5Me_5)Sn]^+X^- + BI_3 \longrightarrow \textit{nido}\text{-}[(\eta^5\text{-}C_5Me_5)BI]^+X^- + SnI_2$$

The stabilization of σ-bonded dialkyltin(II) compounds, R_2Sn:, (and also those of Ge and Pb) can be achieved by the use of bulky R groups. The first such compound, $[Sn\{CH(SiMe_3)_2\}_2]$, was prepared by direct reaction of $LiCH(SiMe_3)_2$ with $SnCl_2$ or $[Sn\{N(SiMe_3)_2\}_2]$ in ether, and was obtained as air-sensitive red crystals (mp 136°).[124,125] It is monomeric in the gas phase and in benzene solution, and behaves chemically as a "stannylene", displacing CO from $M(CO)_6$ to give orange $[Cr(CO)_5(SnR_2)]$ and yellow $[Mo(CO)_5(SnR_2)]$.[124,126] However, a crystal structure determination showed that the compound dimerizes in the solid state, perhaps by donation of the lone-pair of electrons on each Sn centre into the "vacant" orbital of its neighbour, to give a weak bent double bond as indicated schematically below;[125,127] this would interpret the orientation of the four $\{-CH(SiMe_3)_2\}$ groups.



A synthetic strategy which ensures retention of the monomeric form of SnR_2 even in the crystalline state is to use functionalized R groups which contain a chelating substituent, e.g. by replacing the H atom in $\{-CH(SiMe_3)_2\}$ with a 2-pyridyl group.[128]

Stable stannaethenes, >C=Sn<,[129] and stannaphosphenes, >Sn=P<,[130] have been reported and these, again, exploit the use of bulky groups to prevent oligomerization.

Lead[131]

The organic chemistry of Pb is much less extensive than that of Sn, though over 2000 organolead compounds are known and $PbEt_4$ has been produced on a larger tonnage than any other single organometallic compound (p. 371). The most useful laboratory-scale routes to organoleads involve the use of LiR, RMgX, or AlR_3 on lead(II) compounds such as $PbCl_2$, or lead(IV) compounds such as R'_2PbX_2, R'_3PbX, or K_2PbCl_6. On the industrial scale the reaction of RX on a Pb/Na alloy is much used; an alternative is the electrolysis of RMgX, M^IBR_4, or M^IAlR_4 using a Pb anode. The simple tetraalkyls are volatile, monomeric molecular liquids which can be steam-distilled without decomposition; $PbPh_4$ (mp 227–228°) is even more stable thermally: it can be distilled at 240° (15–20 mmHg) but decomposes above 270°. Diplumbanes Pb_2R_6 are much less stable and higher polyplumbanes are unknown except for the thermally unstable, reactive red solid, $Pb(PbPh_3)_4$.

The decreasing thermal stability of Group 14 organometallics with increasing atomic number of M reflects the decreasing M–C and M–M bond energies. This in turn is related to the increasing size of M and the consequent increasing interatomic distance (see table).

M	C	Si	Ge	Sn	Pb
M-C distance in MR_4/pm	154	194	199	217	227

Parallel with these trends and related to them is the increase in chemical reactivity which is further enhanced by the increasing bond polarity and the increasing availability of low-lying vacant orbitals for energetically favourable reaction pathways.

It is notable that the preparation of alkyl and aryl derivatives from Pb^{II} starting materials always results in Pb^{IV} organometallic compounds. The only well-defined examples of Pb^{II} organometallics are purple compound Pb[CH(SiMe$_3$)$_2$]$_2$ (see refs on p. 403) and the cyclopentadienyl compound $Pb(\eta^5\text{-}C_5H_5)_2$ and its ring-methyl derivative. Like the Sn analogue (p. 402) $Pb(\eta^5\text{-}C_5H_5)_2$ features non-parallel cyclopentadienyl rings in the gas phase, the angle subtended at Pb being $135 \pm 15°$. Two crystalline forms are known and the orthorhombic polymorph has the unusual chain-like structure shown in Fig. 10.14:[132] one C_5H_5 is between 2 Pb and perpendicular to the Pb–Pb vector whilst the other C_5H_5 is bonded (more closely) to only 1 Pb. The chain polymer can be thought to arise as a result of the interaction of the lone-pair of electrons on a given Pb atom with a neighbouring (chain) C_5H_5 ring; a 3-centre bond is constructed by overlapping 2 opposite sp^2 hybrids on 2 successive Pb atoms in the chain with the σMO (A''_2) of the C_5H_5 group: this forms one bonding, one nonbonding, and one antibonding MO of which the first 2 are filled and the third empty. By contrast, the deep red crystalline compound $[Pb(\eta^5\text{-}C_5Me_5)_2]$ (mp 100–105°) is monomeric;[119] the angle subtended by the ring centres at Pb is 151° (i.e. even larger than in the Sn analogue) and there is a slight ring slippage

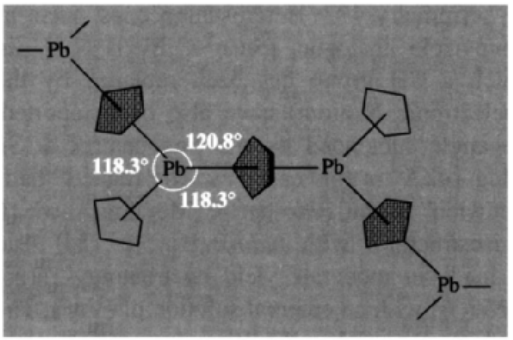

Figure 10.14 Schematic diagram of the chain structure of orthorhombic $Pb(\eta^5\text{-}C_5H_5)_2$. For the doubly coordinated C_5H_5 ring (shaded) Pb–C_{av} is 306 pm, and for the "terminal" C_5H_5 ring Pb–C_{av} is 276 pm; the Pb ··· Pb distance within the chain is 564 pm.

[132] C. Panattoni, G. Bombieri, and U. Croato, *Acta Cryst.* **21**, 823–6 (1966).

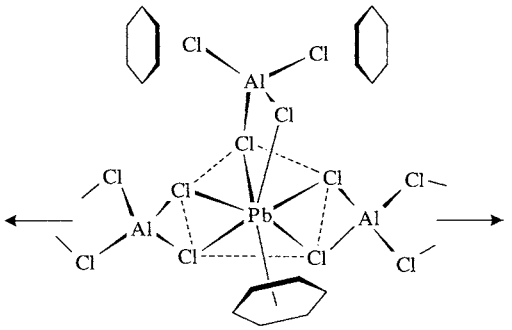

Figure 10.15 Schematic diagram of the chain structure of $[Pb^{II}(AlCl_4)_2(\eta^6\text{-}C_6H_6)].C_6H_6$: Pb–Cl varies from 285–322 pm, Pb–C_{av} (bound) 311 pm, Pb-centre of C_6H_6 (bound) 277 pm.

which leads to a range of Pb–C distances (269–290 pm) to the pentahapto rings.

Another unusual organo-Pb^{II} compound is the η^6-benzene complex $[Pb^{II}(AlCl_4)_2(\eta^6\text{-}C_6H_6)].C_6H_6$ in which Pb^{II} is in a distorted pentagonal bipyramidal site with 1 axial Cl and the other axial site occupied by the centre of the benzene ring (Fig. 10.15). The other C_6H_6 is a molecule of solvation far removed from the metal. One $\{AlCl_4\}$ group chelates the Pb in an axial-equatorial configuration and the other $\{AlCl_4\}$ chelates and bridges neighbouring Pb atoms to form a chain. There is a similar Sn^{II} compound with the same structure. The original paper should be consulted for a discussion of the bonding.[133]

The coordination chemistry of Pb^{II} with conventional ligands from groups 14–16 and with macrocyclic ligands has recently been reviewed.[134]

11 Nitrogen

11.1 Introduction

Nitrogen is the most abundant uncombined element accessible to man. It comprises 78.1% by volume of the atmosphere (i.e. 78.3 atom% or 75.5 wt%) and is produced industrially from this source on the multimegatonne scale annually. In combined form it is essential to all forms of life, and constitutes, on average, about 15% by weight of proteins. The industrial fixation of nitrogen for agricultural fertilizers and other chemical products is now carried out on a vast scale in many countries, and the number of moles of anhydrous ammonia manufactured exceeds that of any other compound. Indeed, of the top fifteen "high-volume" industrial chemicals produced in the USA, five contain nitrogen (Fig. 11.1).[1] This has important consequences, predominantly beneficial but occasionally detrimental, since of all man's recent interventions in the cycles of nature the industrial fixation of nitrogen is by far the most extensive. These aspects will be discussed further in later sections.

The "discovery" of nitrogen in 1772 is generally credited to Daniel Rutherford, though the gas was also isolated independently about the same time by both C. W. Scheele and H. Cavendish.[2] Rutherford (at the suggestion of his teacher Joseph Black who had earlier discovered CO_2, p. 269) was studying the properties of the residual "air" left after carbonaceous substances were burned in a limited supply of air; he removed the CO_2 by means of KOH and so obtained nitrogen which he thought was ordinary air that had taken up phlogiston from the combusted material. The elementary nature of nitrogen was disputed by some even as late as 1840 despite the work of A. L. Lavoisier. The name "nitrogen" was suggested by Jean-Antoine-Claude Chaptal in 1790 when it was realized that the element was a constituent of nitric acid and nitrates (Greek νίτρον, nitron; γεννᾶν, to form). Lavoisier preferred *azote* (Greek ἄζωτικός, no life) because

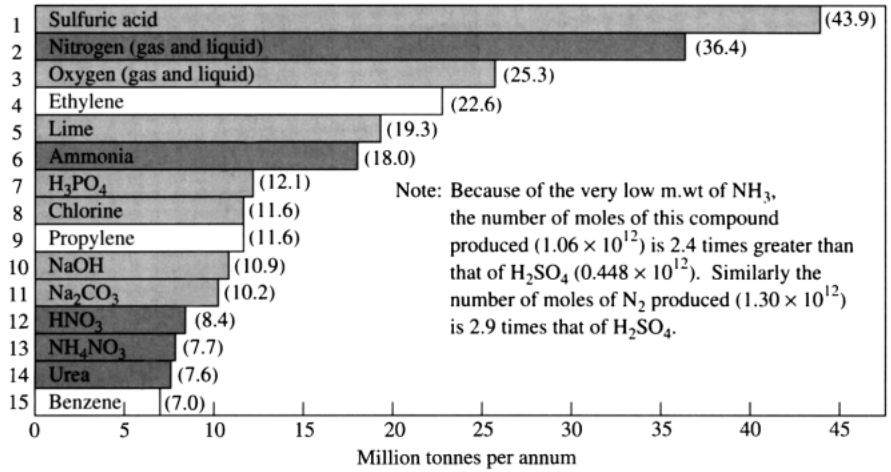

Figure 11.1 US production of the top 15 industrial chemicals (1996).

of the asphyxiating properties of the gas, and this name is still used in the French language and in such forms as azo, diazo, azide, etc. The German name *Stickstoff* refers to the same property (*sticken*, to choke or suffocate).

Compounds of nitrogen have an impressive history. Ammonium chloride was first mentioned in the *Historia* of Herodotus (fifth century BC)† and ammonium salts, together with nitrates, nitric acid and aqua regia, were well known to the early alchemists.(2) Some important dates in the subsequent development of the chemistry of nitrogen are given in the Panel on p. 408. Exciting discoveries are still being made at the present time and, indeed, the detailed mechanisms by which bacteria fix nitrogen at ambient temperatures and pressures is still an active area of research. Several recent reviews, monographs, and proceedings of symposia have been published.(3–6)

11.2 The Element

11.2.1 Abundance and distribution

Despite its ready availability in the atmosphere, nitrogen is relatively unabundant in the crustal rocks and soils of the earth. At 19 ppm it is equal 33rd with Ga in the order of abundance, and similar to Nb (20 ppm) and Li (18 ppm). The only major minerals are KNO_3 (nitre, saltpetre) and $NaNO_3$ (sodanitre, Chile saltpetre). Both occur widespread, usually in small amounts as evaporites in arid regions, often as an efflorescence on soils or in caverns. $NaNO_3$ is isomorphous with calcite (p. 109) whereas KNO_3 is isomorphous with aragonite (p. 109), thus reflecting the similar size of NO_3^- and CO_3^{2-}, and the fact that K^+ is considerably larger than Na^+ and Ca^{2+}. Major deposits of KNO_3 occur in India and there are smaller amounts in Bolivia, Italy, Spain and the former Soviet Union. There are vast deposits of $NaNO_3$ in the desert regions of northern Chile where it occurs with other evaporites such as NaCl, Na_2SO_4 and

† "There are pieces of salt in large lumps on the hills of Libya and the Ammonians who live there worship the god Ammon in a temple resembling that of the Theban Jupiter." (Greek Αμμων, the name of the Egyptian diety Amun, whence *sal ammoniac* from ἀμμωνιακόν, belonging to Ammon.)

Time Chart for Nitrogen Chemistry

1772 N_2 gas isolated by D. Rutherford (also by C. W. Scheele and H. Cavendish).
1772 N_2O prepared by J. Priestley who also showed it supported combustion
1774 NH_3 gas isolated by Priestley using mercury in a pneumatic trough.
1809 First donor-acceptor adduct (coordination compound) $NH_3.BF_3$ prepared by J. L. Gay Lussac (A. Werner's theory, 1891–5).
1811 NCl_3 prepared by P. L. Dulong who lost an eye and three fingers studying its properties.
1828 Urea made from NH_4CNO by F. Wöhler.
1832 Phosphonitrilic chloride $(NPCl_2)_x$ prepared by J. von Liebig by heating NH_3 or NH_4Cl with PCl_5.
1835 S_4N_4 first prepared by M. Gregory.
1862 Importance of N *in soil* for agriculture recognized (despite von Liebig having incorrectly maintained, in the face of fierce opposition, that it came from the atmosphere directly).
1864 Ability of liquid NH_3 to dissolve metals giving coloured solutions reported by W. Weyl.
1886 Atmospheric N_2 shown to be "fixed" by organisms in certain root nodules.
1887 Hydrazine, N_2H_4, first isolated by T. Curtius; he also first made HN_3 (from N_2H_4) in 1890.
1895 First industrial process involving atmospheric N_2 — the Frank–Caro process for calcium cyanamide.
1900 Birkeland–Eyde industrial oxidation of N_2 to NO and hence HNO_3 (now obsolete).
1906 Crystalline sulfamic acid, H_3NSO_3, first obtained by F. Raschig.
1907 Raschig's industrial oxidation of NH_3 to N_2H_4 using hypochlorite.
1908 Catalytic oxidation of NH_3 to HNO_3 (1901) developed on an industrial scale by W. Ostwald (awarded the 1909 Nobel Prize in Chemistry for his work on catalysis).
1909 F. Haber's catalytic synthesis of NH_3 developed in collaboration with C. Bosch into a large-scale industrial process by 1913. (Haber was awarded the 1918 Nobel Prize in Chemistry "for the synthesis of ammonia from its elements"; Bosch shared the 1931 Nobel Prize for "contributions to the invention and development of chemical high-pressure methods", the Haber synthesis of NH_3 being the first high-pressure industrial process.)
1926 Borazine, $(HBNH)_3$, analogous to benzene prepared by A. Stock and E. Pohland.
1928 NF_3 first prepared by O. Ruff and E. Hanke, 117 y after NCl_3.
1925–35 Spectrum of atomic N gradually analysed.
1929 Discovery of a nitrogen isotope ^{15}N by S. M. Naudé following the discovery of isotopes of O and C by others earlier in the same year.
1934 Microwave absorption in NH_3 (due to molecular inversion) first observed — this marks the start of microwave spectroscopy.
1950 Nuclear magnetic resonance in compounds, containing ^{14}N and ^{15}N first observed by W. E. Proctor and F. C. Yu.
1957 N_2F_4 first made by C. B. Colburn and A. Kennedy and later (1961) shown to be in dissociative equilibrium with paramagnetic NF_2 above 100°C.
1958 $NH_3.BH_3$ isoelectronic with ethane prepared by S. G. Shore and R. W. Parry (direct reaction of NH_3 and B_2H_6 gives $[BH_2(NH_3)_2]^+[BH_4]^-$).
1962 First "bent" NO complex encountered, viz. $[Co(NO)(S_2CNMe_2)_2]$ (P. R. H. Alderman, P. G. Owston and J. M. Rowe).
1965 First N_2 ligand complex prepared by A. D. Allan and C. V. Senoff.
1966 ONF_3 (isoelectronic with CF_4) discovered independently by two groups.
1968 N_2 recognized as a bridging ligand in $[(NH_3)_5RuN_2Ru(NH_3)_5]^{4+}$ by D. F. Harrison, E. Weissberger, and H. Taube. (H. Taube, 1983 Nobel Prize for chemistry "for his work on the mechanisms of electron transfer reactions especially in metal complexes").
1974 First thionitrosyl (NS) complex isolated by J. Chatt and J. R. Dilworth.
1975 $(SN)_x$ polymer, known since 1910, found to be metallic (and a superconductor at temperatures below 0.33 K).
1979 Trigonal prismatic 6-fold coordination of N (Table 11.1, p. 413).
1980–90 Square pyramidal and trigonal bipyramidal 5-fold coordination of N (Table 11.1).

KNO_3 on the eastern slopes of the coastal ranges at an elevation of 1200–2500 m. Because of the development of the synthetic ammonia and nitric acid industries these large deposits are no longer a major source of nitrates, though they played an important role in agriculture until the 1920s (as also did guano, the massive deposits of bird excreta on certain islands).

The continuous interchange of nitrogen between the atmosphere and the biosphere is called the nitrogen cycle. Global estimates are difficult to obtain and there are frequently regional and local impacts which vary greatly from the mean. However, some indication of the size of the various "reservoirs" of nitrogen in the atmosphere, on land, and in the seas is

given in Fig. 11.2 together with the estimated annual rate of transfer between these various pools.[7,8] Estimates frequently vary by a factor of 3 or more. Atmospheric nitrogen is fixed by biological action (p. 1035), industrial processes (p. 421), and to a significant extent by fires, lightning and other atmospheric discharges which produce NO_x. There is also a minute production (on the global scale) of NO_x from internal combustion engines and from coal-burning, though the local concentration in some urban environments can be very high and extremely unpleasant.[9–11] Absorption of fixed nitrogen by both terrestrial and aquatic plants leads to protein synthesis followed by death, decay, oxidation and denitrification by bacterial and other action which eventually returns the nitrogen to the seas and the atmosphere as N_2. An alternative sequence involves the digestion of plants by animals, the synthesis of animal proteins, excretion of nitrogenous material, and, again, ultimate death, decay and denitrification. Figure 11.2 indicates that the greatest anthropogenic impact on the cycle arises from the industrial fixation of nitrogen by the Haber and other processes. Much of this is used beneficially as fertilizers but the leaching of excess nitrogenous material can lead to eutrophication in freshwater systems, and the increased nitrate concentration in waters used for human consumption can pose a health hazard. Nevertheless, there is no doubt that the high yields of agriculture necessary to maintain even the present human population of the world cannot be achieved without the judicious application of manufactured nitrogenous fertilizers. Concern has also been expressed that increasing levels of N_2O following denitrification may eventually impoverish the ozone layer in the stratosphere. Much more data are required and the subject is being actively pursued by several international agencies as well as by national and local governments and individual scientists.

11.2.2 Production and uses of nitrogen

The only important large-scale process for producing N_2 is the liquefaction and fractional distillation of air[12] (see Panel on p. 411). Production has grown remarkably during the past few years, partly as a result of the increasing demand for its coproduct O_2 for steelmaking. For example, US domestic production has increased 250-fold in the past 25 y from 0.12 million tonnes in 1955 to 30 million tonnes in 1980. In 1991 world production was 56 million tonnes (USA 47%; Europe 35%; Asia 15%). Commercial N_2 is a highly purified product, typically containing less than 20 ppm O_2. Specially purified "oxygen-free" N_2, containing less than 2 ppm, is available commercially, and "ultrapure" N_2 (99.999%) containing less than 10 ppm Ar is also produced on the multitonne per day scale.

Laboratory routes to highly purified N_2 are seldom required. Thermal decomposition of sodium azide at 300°C under carefully controlled conditions is one possibility:

$$2NaN_3 \longrightarrow 2Na + 3N_2$$

Hot aqueous solutions of ammonium nitrite also decompose to give nitrogen though small amounts of NO and HNO_3 are also formed (p. 434) and must be removed by suitable absorbents such as dichromate in aqueous sulfuric acid:

$$NH_4NO_2 \xrightarrow{aq} N_2 + 2H_2O$$

Other routes are the thermal decomposition of $(NH_4)_2Cr_2O_7$, the reaction of NH_3 with bromine water, or the high-temperature reaction of NH_3

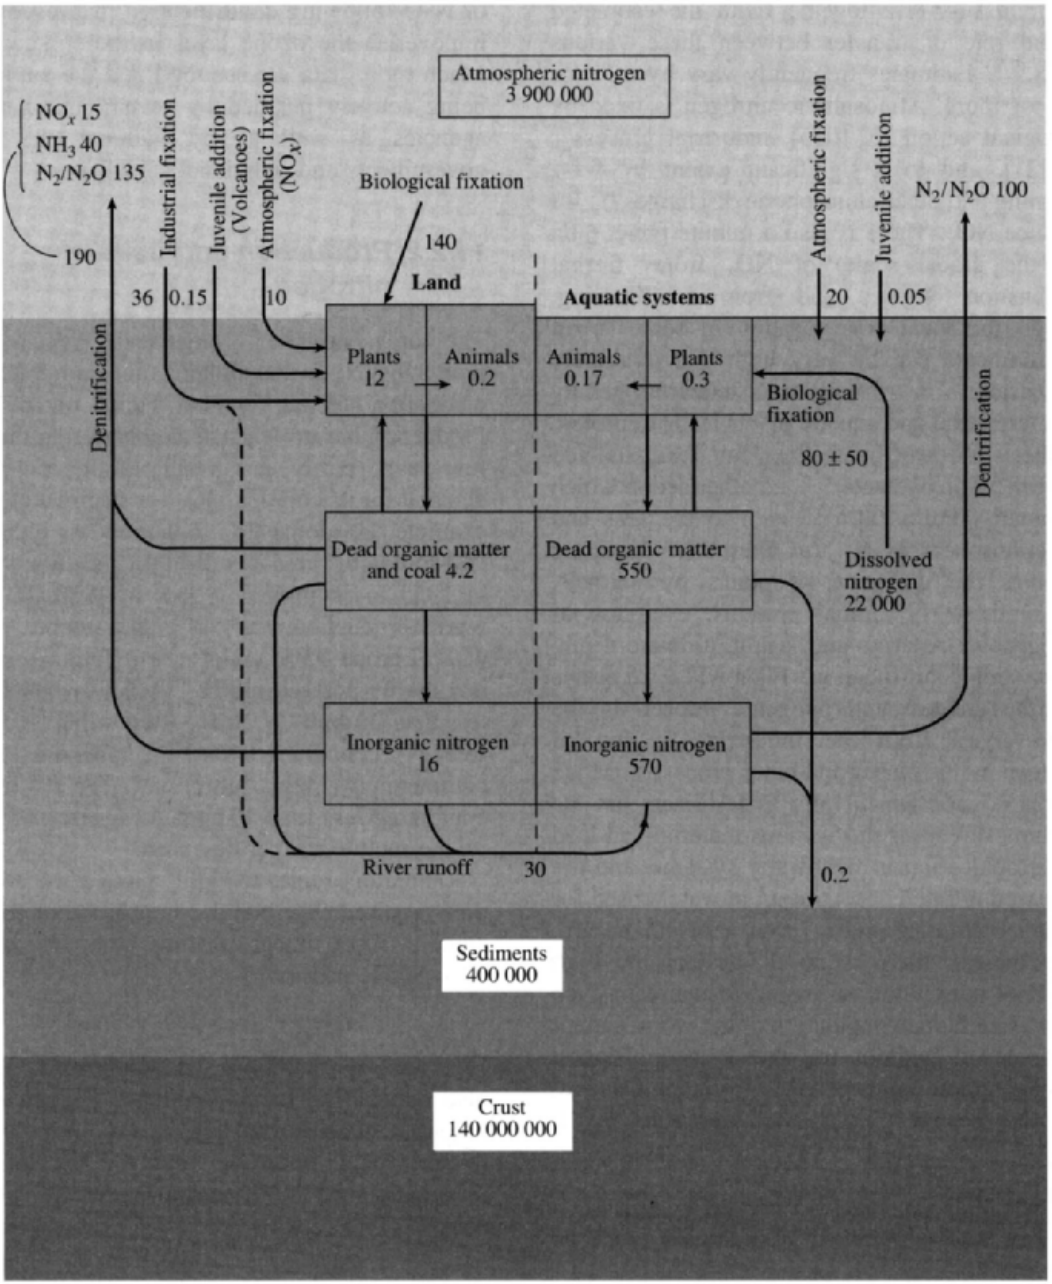

Figure 11.2 Distribution of nitrogen in the biosphere and annual transfer rates can be estimated only within broad limits. The two quantities known with high confidence are the amount of nitrogen in the atmosphere and the rate of industrial fixation. The inventories (within the boxes) are expressed in terms of 10^9 tonnes of N; the transfers (indicated by arrows) are in 10^6 tonnes of N. Taken from ref. 7 with some adjustments for more recent data.

Industrial Gases from Air

Air is the source of six industrial gases, N_2, O_2, Ne, Ar, Kr and Xe. As the mass of the earth's atmosphere is approximately 5×10^9 million tonnes, the supply is unlimited and the annual industrial production, though vast, is insignificant by comparison. The composition of air at low altitudes is remarkably constant, the main variable component being water vapour which ranges from ~4% by volume in tropical jungles to very low values in cold or arid climates. Other minor local variations result from volcanism or human activity. The main invariant part of the air has the following composition (% by volume, bp in parentheses):

N_2	**78.03 (77.2 K)**	CO_2	0.033 (194.7 K)	He	0.0005 (4.2 K)
O_2	**20.99 (90.1 K)**	Ne	**0.0015 (27.2 K)**	Kr	0.0001 **(119.6 K)**
Ar	**0.93 (87.2 K)**	H_2	0.0010 (20.2 K)	Xe	0.000008 **(165.1 K)**

Details of the production and uses of O_2 (p. 604) and the noble gases (p. 889) are in later chapters.

About two-thirds of the N_2 produced industrially is supplied as a gas, mainly in pipes but also in cylinders under pressure. The remaining one-third is supplied as liquid N_2 since this is also a very convenient source of the dry gas. The main use is as an inert atmosphere in the iron and steel industry and in many other metallurgical and chemical processes where the presence of air would involve fire or explosion hazards or unacceptable oxidation of products. Thus, it is extensively used as a purge in petrochemical reactors and other chemical equipment, as an inert diluent for chemicals, and in the float glass process to prevent oxidation of the molten tin (p. 370). It is also used as a blanketing gas in the electronics industry, in the packaging of processed foods and pharmaceuticals, and to pressurize electric cables, telephone wires, and inflatable rubber tyres, etc.

About 10% of the N_2 produced is used as a refrigerant. Typical of such applications are (a) freeze grinding of normally soft or rubbery materials, (b) low-temperature machining of rubbers, (c) shrink fitting and assembly of engineering components, (d) the preservation of biological specimens such as blood, semen, etc., and (e) as a constant low-temperature bath (−196°C). Liquid N_2 is also frequently used for convenience in applications where a very low temperature is not essential such as (a) food freezing (and hamburger meat grinding), (b) in-transit refrigeration, (c) freeze branding of cattle, (d) pipe-freezing for stopping flow in the absence of valves, and (e) soil-freezing for consolidating unstable ground in tunnelling or excavation.

The cost of N_2, like that of O_2, is particularly dependent on electricity costs, though plant maintenance and transport costs also obtrude. Typical prices in 1992 for N_2 in the USA were about $32 per tonne for bulk liquid (exclusive of transportation and handling charges). Costs for small-scale users of N_2 from gas cylinders are proportionately much higher.

with CuO; overall equations can be written as:

$$(NH_4)_2Cr_2O_7 \longrightarrow N_2 + Cr_2O_3 + 4H_2O$$

$$8NH_3 + 3Br_2 \xrightarrow{aq} N_2 + 6NH_4Br(aq)$$

$$2NH_3 + 3CuO \longrightarrow N_2 + 3Cu + 3H_2O$$

11.2.3 Atomic and physical properties

Nitrogen has two stable isotopes ^{14}N (relative atomic mass 14.003 07, abundance 99.634%) and ^{15}N (15.000 11, 0.366%); their relative abundance (272:1) is almost invariant in terrestrial sources and corresponds to an atomic weight of 14.006 74(7). Both isotopes have a nuclear spin and can be used in nmr experiments.[13] though the sensitivity at constant field is only one-thousandth that of ^1H. The ^{14}N nucleus has a spin quantum number of 1 and, in consequence, the spectra are broadened by quadrupole effects. The ^{15}N nucleus with spin $\frac{1}{2}$ does not have this difficulty though its low abundance poses problems.[14] Interestingly, the first chemical shift ever to be observed in nmr spectroscopy ("as an annoying ambiguity in the magnetic moment of ^{14}N") was in 1950 in an aqueous solution of NH_4NO_3.[15] Nowadays ^{14}N and ^{15}N nmr chemical shifts are widely used to probe the

[15] W. G. PROCTOR and F. C. YU, *Phys. Rev.* **77**, 717 (1950).

nature of bonding in N-containing compounds, to study structural features (e.g. linear, bent, encapsulated N), to determine the site of coordination or protonation, to follow kinetically the course of chemical reactions and to detect new species.

Isotopic enrichment of ^{15}N is usually effected by chemical exchange, and samples containing up to 99.5% ^{15}N have been obtained from the 2-phase equilibrium

$$^{15}NO(g) + {}^{14}NO_3^-(aq) \rightleftharpoons {}^{14}NO(g) + {}^{15}NO_3^-(aq)$$

Other exchange reactions that have been used are:

$$^{15}NH_3(g) + {}^{14}NH_4^+(aq) \rightleftharpoons {}^{14}NH_3(g) + {}^{15}NH_4^+(aq)$$

$$^{15}NO(g) + {}^{14}NO_2(g) \rightleftharpoons {}^{14}NO(g) + {}^{15}NO_2(g)$$

Fractional distillation of NO provides another effective route and, as the heavier isotope of oxygen is simultaneously enriched, the product has a high concentration of $^{15}N^{18}O$. Many key nitrogen compounds are now commercially available with ^{15}N enriched to 5%, 30% or 95%, e.g. N_2, NO, NO_2, NH_3, HNO_3 and several ammonium salts and nitrates. Fortunately the use of these compounds in tracer experiments is simplified by the absence of exchange with atmospheric N_2 under normal conditions, in marked contrast with labelled H, C and O compounds where contract with atmospheric moisture and CO_2 must be avoided.

The ground state electronic configuration of the N atom is $1s^2 2s^2 2p_x^1 2p_y^1 2p_z^1$ with three unpaired electrons (^4S). The electronegativity of N (~3.0) is exceeded only by those of F and O. Its "single-bond" covalent radius (~70 pm) is slightly smaller than those of B and C, as expected; the nitride ion, N^{3-}, is much larger and has been assigned a radius in the range 140–170 pm. Ionization energies and other properties are compared with those of the other Group 15 elements (P, As, Sb and Bi) on p. 550.

Molecular N_2, i.e. dinitrogen (see p. 34), (mp −210°C, bp −195.8°C) is a colourless, odourless, tasteless, diamagnetic gas. The short interatomic distance (109.76 pm) and very high dissociation energy (945.41 kJ mol^{-1}) are both consistent with multiple bonding. The free-energy change for the equilibrium $N_2 \rightleftharpoons 2N$ is $\Delta G = 911.13\,kJ\,mol^{-1}$ from which it is clear that the dissociation constant $K_p = [N]^2/[N_2]$ atm is negligible under normal conditions; it is 1.6×10^{-24} atm at 2000 K and still only 1.3×10^{-12} atm at 4000 K. Detailed tabulations of other physical properties of nitrogen are available.[16]

11.2.4 Chemical reactivity

Gaseous N_2 is rather inert at room temperature presumably because of the great strength of the N≡N bond and the large energy gap between the highest occupied molecular orbitals (HOMO) and the lowest unoccupied molecular orbitals (LUMO). Further contributory factors are the very symmetrical electron distribution in the molecule and the absence of bond polarity — when these are modified, as in the isoelectronic analogues CO, CN^- and NO^+, the reactivity is considerably enhanced. Nitrogen reacts readily with Li at room temperature (p. 76) and with several transition-element complexes (p. 414).

Reactivity increases rapidly with rising temperature and the element combines directly with Be, the alkaline earth metals, and B, Al, Si and Ge to give nitrides (p. 417); hydrogen yields ammonia (p. 421), and coke yields cyanogen, $(CN)_2$, when heated to incandescence (p. 320). Many finely divided transition metals also react directly at elevated temperatures to give nitrides of general formula MN (M = Sc, Y, lanthanoids; Zr, Hf; V; Cr, Mo, W; Th, U, Pu). Although not always directly preparable from N_2(g), many other nitrides are known (p. 417) and, indeed, nitrides as a class include some of the most stable compounds in the whole of chemistry. Nitrogen forms bonds with almost all elements in the periodic table, the only exceptions apparently being the noble gases (other than Xe and Kr, pp. 902, 904). A wide range of stereochemistries is observed and

[16] B. R. BROWN, Physical properties of nitrogen, in *Mellor's Comprehensive Treatise on Inorganic and Theoretical Chemistry*, Vol. 8, Suppl. 1, *Nitrogen*, Part 1, pp. 27–149, Longmans, London, 1964.

Table 11.1 Stereochemistry of nitrogen[a]

CN		Examples
0		N(g) in "active nitrogen"
1		N_2, NO, NNO, $[NNN]^-$, HNNN, RC≡N, XC≡N (X = Hal), $[OsO_3N]^-$
2	*Linear:*	$[NO_2]^+$, NNO, $[NNN]^-$, HNNN; η^1-N_2 complexes, e.g. $[Ru(N_2)(NH_3)_5]^{2+}$; η^1-NO complexes, e.g. $[Fe(CN)_5(NO)]^{2-}$; μ_2-N complexes, e.g. $[(H_2O)Cl_4RuNRuCl_4(OH_2)]^{3-}$ and $[Cl_5WNWCl_5]^{2-}$ (ref. 18)
	Bent:	NO_2, $[NO_2]^-$, $[NH_2]^-$, HNNN, HNCO, RNCO, XNCO, N_2F_2, *cyclo*-$\overline{CH_2NN}$, *cyclo*-$[NSF(O)]_3$ $[W(CO)_5OPPh_2NPPh_3]$ (ref. 19)
3	*Planar:*	$[NO_3]^-$, N_2O_4, XNO_2, $(HO)NO_2$, $K[ON(NO)(SO_3)]$, $K_2[ON(SO_3)_2]$ (Fremy's salt), $N(SiH_3)_3$, $NMe(SiMe_3)_2$ (ref. 20), $N(GeH_3)_3$, $N(PF_2)_3$, Si_3N_4, and Ge_3N_4 (Be_2SiO_4 structure, p. 347), μ_3-N complexes, e.g. $[\{H_2O(SO_4)_2Ir\}_3N]^{4-}$
	Pyramidal:	NH_3, NF_3, NH_2F, NHF_2, $(HO)NH_2$, N_2H_4, N_2F_4, $[N_4(CH_2)_6]$
	T-shaped:	$[Mo_3(\mu_3\text{-}N)O(\eta^5\text{-}C_5H_5)_3(CO)_4]$ (ref. 21)
4	*Tetrahedral:*	$[NH_4]^+$, $[NH_3(OH)]^+$, $[NF_4]^+$, H_3NBF_3 and innumerable other coordination complexes of NH_3, NR_3, en, edta, etc., including Me_3NO and sulfamic acid (H_3NSO_3). BN (layer structure and Zn blende-type), AlN (wurtzite-type), $[PhAlNPh]_4$ (cubane-type)
	See-saw:	$[\{Fe(CO)_3\}_4(\mu_4\text{-}N)]^-$ (refs. 22, 23)
5	*Square-pyramidal:*	$[Fe_5(CO)_{14}H(\mu_5\text{-}N)]$ (ref. 23), $[(\eta^5\text{-}C_5Me_5)_2Mo_2Co_3(CO)_{10}(\mu_5\text{-}N)]$ (ref. 24), *closo*-NB_9H_{10} (p. 211)
	Trig. bipyramidal:	$[N(AuPPh_3)_5]^{2+}$ (ref. 25)
6	*Octahedral:*	MN (interstitial nitrides with NaCl or hcp structure, e.g. M = Sc, La; Ce, Pr, Nd; Ti, Zr, Hf; V, Nb, Ta; Cr, Mo, W; Th, U), Ti_2N (anti-rutile TiO_2-type), Cu_3N (ReO_3-type), Ca_3N_2 (anti-Mn_2O_3)
	Trigonal prism:	$[NCo_6(CO)_{15}]^-$ (ref. 26), $[Rh_{12}H(N)_2(CO)_{23}]^{3-}$ (ref. 27)
	Pentagonal prism:	*closo*-$NB_{11}H_{12}$ (p. 211)
8	*Cubic:*	Ternary nitrides with anti-CaF_2 structure, e.g. BeLiN, $AlLi_3N_2$, $TiLi_5N_3$, $NbLi_7N_4$, and $CrLi_9N_5$
	Square antiprism:	$[Rh_{12}H(N)_2(CO)_{23}]^{3-}$ (ref. 27)

[a]For coordination numbers 1, 2, and 3 the CN is sometimes increased in the condensed phase as a result of H bonding (p. 52), e.g. HCN, NH_2^-, NH_3, N_2H_4, $NH_2(OH)$, $NO_2(OH)$.

typical examples of coordination numbers 0, 1, 2, 3, 4, 5, 6, and 8 are given in Table 11.1.

A particularly reactive form of nitrogen can be obtained by passing an electric discharge through N_2(g) at a pressure of 0.1–2 mmHg.[16,17] Atomic N is formed, and the process is accompanied by a peach-yellow emission which persists as an afterglow, often for several minutes after the discharge

has been stopped. Atoms of N in their ground state (^4S) have a relatively long lifetime since recombination involves either a 3-body collision on the surface of the vessel (first-order reaction in N at pressures below ~3 mmHg) or a termolecular homogeneous association reaction (second order in N at pressures above ~3 mmHg):

$$N(^4S) + N(^4S) \xrightarrow{M} N_2^* \longrightarrow N_2 + h\nu(\text{yellow}) \quad (1)$$

The molecules of N_2^* so formed are in an excited state ($B^3\Pi_g$) and give rise to the emission of the first positive band system of the spectrum of molecular N_2 in returning to the ground state ($A^3\Sigma_u^+$).

Several elements react with the N atoms in active nitrogen to form nitrides. The excited N_2 molecules are also highly reactive and can cause the dissociation of molecules that are normally stable to attack either by ordinary N_2 or even N atoms, e.g.:

$$N_2^* + CO_2 \longrightarrow N_2 + CO + O(^3P)$$

$$N_2^* + H_2O \longrightarrow N_2 + OH(^2\Pi) + H(^2S).$$

One of the most dramatic developments in the chemistry of N_2 during the past 30 years was the discovery by A. D. Allen and C. V. Senoff in 1965 that dinitrogen complexes such as $[Ru(NH_3)_5(N_2)]^{2+}$ could readily be prepared from aqueous $RuCl_3$ using hydrazine hydrate in aqueous solution.[28] Since that time virtually all transition metals have been found to give dinitrogen complexes and several hundred such compounds are now characterized.[5,29,30] Three general preparative methods are available:

(a) Direct replacement of labile ligands in metal complexes by N_2: such reactions proceed under mild conditions and are often reversible, e.g.:

$$[Ru(NH_3)_5(H_2O)]^{2+} + N_2 \overset{H_2O}{\rightleftharpoons} H_2O + [Ru(NH_3)_5(N_2)]^{2+} \text{ pale yellow}$$

$$[CoH_3(PPh_3)_3] + N_2 \overset{EtOH}{\rightleftharpoons} H_2 + [CoH(N_2)(PPh_3)_3] \text{ orange-red}$$

$$2[Cr(C_6Me_6)(CO)_3] + N_2 \xrightarrow{thf/h\nu} 2CO + [\{Cr(C_6Me_6)(CO)_2\}_2N_2] \text{ red-brown}$$

(b) Reduction of a metal complex in the presence of an excess of a suitable coligand under N_2, e.g.:

$$[MoCl_4(PMe_2Ph)_2] + 2N_2 \xrightarrow{Na/toluene/PMe_2Ph} cis\text{-}[Mo(N_2)_2(PMe_2Ph)_4]$$

$$[WCl_4(PMe_2Ph)_2] + 2N_2 \xrightarrow{(Na/Hg)/PMe_2Ph} cis\text{-}[W(N_2)_2(PMe_2Ph)_4] \text{ yellow}$$

$$[FeClH(depe)_2] + N_2 \xrightarrow{NaBH_4/Me_2CO} NaCl + trans\text{-}[Fe(depe)_2H(N_2)] \text{ orange}$$

$$2[Ni(acac)_2] + 4PCy_3 + N_2 \xrightarrow{AlMe_3} [\{Ni(N_2)(PCy_3)_2\}_2]$$

where depe is $Et_2PCH_2CH_2PEt_2$, acac is 3,5-pentanedionate, and PCy_3 is tris(cyclohexyl)phosphine. In some systems Mg/thf is a better reducing agent than Na, e.g.:

$$MoCl_5 + 4PMe_2PH + 2N_2 \xrightarrow{Mg/thf} cis\text{-}[Mo(N_2)_2(PMe_2Ph)_4]$$

(c) Conversion of a ligand with N–N bonds into N_2; in the early development of N_2 complex chemistry this was the most successful and widely used route, e.g.:

$$[Mn(\eta^5\text{-}C_5H_5)(CO)_2(N_2H_4)] + 2H_2O_2 \xrightarrow{Cu^{II}/thf/-40^\circ} 4H_2O + [Mn(\eta^5\text{-}C_5H_5)(CO)_2(N_2)] \text{ red-brown}$$

---

[28] A. D. Allen and C. V. Senoff, *Chem. Commun.*, 1965, 621–2. The unprecedented nature of the reaction can be gauged from the fact that this paper was rejected for publication by *J. Am. Chem. Soc.* on the grounds that it was impossible, before being accepted by *Chem. Commun.*, See also H. Taube, The researches of A. D. Allen — an appreciation, *Coord. Chem. Rev.* **26**, 1–5 (1978).

[29] A. D. Allen, R. O. Harris, B. R. Loescher, J. R. Stevens and R. N. Whiteley, *Chem. Revs.* **73**, 11–20 (1973).

[30] D. Sellmann, *Angew. Chem. Int. Edn. Engl.* **13**, 639–49 (1974).

$$[(PPh_3)_2Cl_2Re{-}N{=}N{-}CPh(O)] + 2PPh_3 \xrightarrow{MeOH} HCl + PhCO_2Me + \textit{trans}\text{-}[ReCl(N_2)(PPh_3)_4]\ \text{yellow}$$

$$[RuCl(das)_2(N_3)]PF_6 + NOPF_6 \longrightarrow [RuCl(das)_2(N_2)]\ \text{white, plus byproducts}$$

(das = $Ph_2AsCH_2CH_2AsPh_2$)

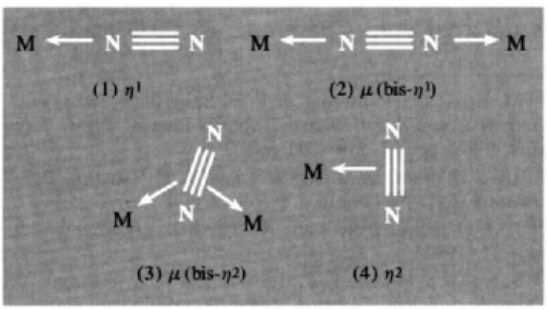
$$\textit{trans}\text{-}[Ir(CO)Cl(PPh_3)_2] + PhCON_3 \xrightarrow{CHCl_3/0^\circ} \textit{trans}\text{-}[IrCl(N_2)(PPh_3)_2]\ \text{yellow}$$

A related example is the reaction of $NbCl_5$ and thf with $(Me_3Si)_2NN(SiMe_3)_2$ in CH_2Cl_2 to give an 80% yield of $[(\mu\text{-}N_2)\{NbCl_3(thf)_2\}_2]$.[31] Occasionally an N≡N triple bond can be formed within a metal complex, e.g. by reaction of coordinated NH_3 with HNO_2, but this method is of limited application, e.g.:

$$[Os(N_2)(NH_3)_5]^{2+} + HNO_2 \longrightarrow 2H_2O + \textit{cis}\text{-}[Os(N_2)_2(NH_3)_4]$$

Frequently dinitrogen complexes have colours in the range white-yellow-orange-red-brown but other colours are known, e.g. $[\{Ti(\eta^5\text{-}C_5H_5)_2\}_2(N_2)]$ is blue.

Dinitrogen might coordinate to metals in at least 4 ways,[32] but only the end-on modes, structures (1) and (2), are well established as common bonding modes by numerous well-defined examples:



The side-on structure (3) has been established in two dinickel complexes which have very complicated structures involving lithium atoms also in association with the bridging N_2.[33] It also occurs in the first fully characterized N_2 complex of a lanthanide element, $[(\mu\text{-}\eta^2\text{:}\eta^2\text{-}N_2)\{Sm(\eta^5\text{-}C_5Me_5)_2\}_2]$[34] The "side-on" η^2 mode (structure 4) was at one time thought to be exemplified by the rhodium(I) complex $[RhCl(N_2)(PPr^i_3)_2]$ but a reinvestigation of the X-ray structure by another group[35] showed conclusively that the N_2 ligand was coordinated in the "end-on" mode (1) — an instructive example of mistaken conclusions that can initially be drawn from this technique. The side on structure (4) has been postulated for the zirconium(III) complex $[Zr(\eta^5\text{-}C_5H_5)(N_2)R]$ on the basis of its ^{15}N nmr spectrum.[36] A unique triply-coordinated bridging mode (μ_3-N_2) has also recently been established by X-ray crystallography.[37]

Complexes are known which feature more than one N_2 ligand, e.g. *cis*-$[W(N_2)_2(PMe_2Ph)_4]$ and *trans*-$[W(N_2)_2(diphos)_2]$ (where diphos = $Ph_2PCH_2CH_2PPh_2$) and some complexes feature more than one bonding mode, e.g.:[38]

$$[(\eta^5\text{-}C_5Me_5)_2(\eta^1\text{-}N_2)Zr{\leftarrow}N{\equiv}N{\rightarrow}Zr(\eta^1\text{-}N_2)\text{-}(\eta^5\text{-}C_5Me_5)_2]$$

The first example of a tris-N_2 complex is the yellow crystalline compound *mer*-$[Mo(\eta^1\text{-}N_2)_3(PPr^n_2Ph)_3]$.[39]

X-ray structural studies have shown that for N_2 complexes with structure (1), the M–N–N group is linear or nearly so (172–180°); the N–N internuclear distance is usually in the range 110–113 pm, only slightly longer than in gaseous N_2 (109.8 pm). Such complexes have a strong sharp, infrared absorption in the range 1900–2200 cm^{-1}, corresponding to the Raman-active band at 2331 cm^{-1} in free N_2. Similarly, in complexes with structure (2), when both transition metals have a closed d-shell, the N–N distance falls in the range 112–120 pm and ν(N–N) often occurs near 2100 cm^{-1}, i.e. little altered from that of the corresponding complexes of structure (1). On the other hand, if one of the M is a transition metal with a closed d-shell and the other is either a main-group metal such as Al in $AlMe_3$ or an open-shell transition metal such as Mo in $MoCl_4$, then the N–N bond is greatly lengthened and the N–N stretching frequency is lowered even to 1600 cm^{-1}. Compounds with structure (3) have N–N ~134–136 pm, and this very substantial lengthening has been attributed to interaction with the Li atoms in the structure.[33]

As implied above, N_2 is isoelectronic with both CO and C_2H_2, and the detailed description of the bonding in structures 1–4 follows closely along the lines indicated on pp. 927 and 932 though there are some differences in the detailed sequences of orbital energies. Crystallographic and vibrational spectroscopic data have been taken to indicate that N_2 is weaker than CO in both its σ-donor and π-acceptor functions. Theoretical studies suggest that σ donation is more important for the formation of the M–N bond than is π back-donation, which mainly contributes to the weakening of the N–N bond, and end-on (η^1) donation is more favourable than side-on (η^2).[40]

The chemical reactivity of coordinated N_2 has been extensively studied because of its potential relevance to the catalytic and biological fixation of N_2 to NH_3 (p. 1035). For other recent work on the reactions of coordinated dinitrogen see refs. 41–44

To conclude this section on the chemical reactivity of nitrogen it will be helpful to compare the element briefly with its horizontal neighbours C and O, and also with the heavier elements in Group 15, P, As, Sb and Bi. The diagonal relationship with S is vestigial. Nitrogen resembles oxygen in its high electronegativity and in its ability to form H bonds (p. 52) and coordination complexes (p. 198) by use of its lone-pair of electrons. Catenation is more limited than for carbon, the longest chain so far reported being the N_8 unit in PhN=N—N(Ph)—N=N—N(Ph)—N=NPh.

Nitrogen shares with C and O the propensity for multiple bonding via p_π–p_π interactions both with another N atom or with a C or O atom. In this it differs sharply from its Group 15 congeners which have no analogues of the oxides of nitrogen, nitrites, nitrates, nitro-, nitroso-, azo- and diazo-compounds, azides, cyanates, thiocyanates or imino-derivatives. Conversely, there are no nitrogen analogues of the various oxoacids of phosphorus (p. 510).

11.3 Compounds

This section deals with the binary compounds that nitrogen forms with metals, and then describes the extensive chemistry of the hydrides, halides, pseudohalides, oxides and oxoacids of the element. The chemistry of P–N compounds is deferred until Chapter 12 (p. 531) and S–N

compounds are discussed in Chapter 15 (p. 721). Compounds with B (p. 207) and C (p. 319) have already been treated.

11.3.1 Nitrides, azides and nitrido complexes

Nitrogen forms binary compounds with almost all elements of the periodic table and for many elements several stoichiometries are observed, e.g. MnN, Mn_6N_5, Mn_3N_2, Mn_2N, Mn_4N and Mn_xN ($9.2 < x < 25.3$). Nitrides are frequently classified into 4 groups: "salt-like", covalent, "diamond-like" and metallic (or "interstitial"). The remarks on p. 64 concerning the limitations of such classifications are relevant here. The two main methods of preparation are by direct reaction of the metal with N_2 or NH_3 (often at high temperatures) and the thermal decomposition of metal amides, e.g.:

$$3Ca + N_2 \longrightarrow Ca_3N_2$$

$$3Mg + 2NH_3 \xrightarrow{900^\circ} Mg_3N_2 + 3H_2$$

$$3Zn(NH_2)_2 \longrightarrow Zn_3N_2 + 4NH_3$$

Common variants include reduction of a metal oxide or halide in the presence of N_2 and the formation of a metal amide as an intermediate in reactions in liquid NH_3:

$$Al_2O_3 + 3C + N_2 \longrightarrow 2AlN + 3CO$$

$$2ZrCl_4 + N_2 + 4H_2 \longrightarrow 2ZrN + 8HCl$$

$$3Ca + 6NH_3 \xrightarrow{-3H_2} \{3Ca(NH_2)_2\} \longrightarrow Ca_3N_2 + 4NH_3$$

Metal nitrides have also been prepared by adding KNH_2 to liquid-ammonia solutions of the appropriate metal salts in order to precipitate the nitride, e.g. Cu_3N, Hg_3N_2, AlN, Tl_3N and BiN.

"Salt-like" nitrides are exemplified by Li_3N (mp 548°C, decomp) and M_3N_2 (M = Be, Mg, Ca, Sr, Ba). It is possible to write ionic formulations of these compounds using the species N^{3-} though charge separation is unlikely to be complete, particularly for the corresponding compounds of Groups 11 and 12, i.e. Cu_3N, Ag_3N, and M_3N_2 (M = Zn, Cd, Hg). The N^{3-} ion has been assigned a radius of 146 pm, slightly larger than the value for the isoelectronic ions O^{2-} (140 pm) and F^- (133 pm), as expected. Stability varies widely; e.g. Be_3N_2 melts at 2200°C whereas Mg_3N_2 decomposes above 271°C. The existence of Na_3N is doubtful and the heavier alkali metals appear not to form analogous compounds, perhaps for steric reasons (p. 76). However the azides NaN_3 and KN_3 are well characterized as colourless crystalline salts which can be melted with little decomposition; they feature the symmetrical linear N_3^- group as do $Sr(N_3)_2$ and $Ba(N_3)_2$. The corresponding "B subgroup" metal azides such as AgN_3, $Cu(N_3)_2$, and $Pb(N_3)_2$ are shock-sensitive and detonate readily; they are far less ionic and have more complex structures. Further discussion of azides is on p. 433. Other stoichiometries are also known, e.g. Ca_2N (anti-$CdCl_2$ layer structure), Ca_3N_4, and $Ca_{11}N_8$.

The covalent binary nitrides are more conveniently treated under the appropriate element. Examples include cyanogen $(CN)_2$ (p. 320), P_3N_5 (p. 531), S_2N_2 (p. 725) and S_4N_4 (p. 722). The Group 13 nitrides MN (M = B, Al, Ga, In, Tl) are a special case since they are isoelectronic with graphite, diamond, SiC, etc., to which they are structurally related (p. 255). Their physical properties suggest a gradation of bond-type from covalent, through partially ionic, to essentially metallic as the atomic number increases. Si_3N_4 and Ge_3N_4 are also known and have the phenacite (Be_2SiO_4)-type structure. Si_3N_4, in particular, has excited considerable interest in recent years as a ceramic material with extremely desirable properties: high strength and wear resistance, high decomposition temperature and oxidation resistance, excellent thermal-shock properties and resistance to corrosive environments, low coefficient of friction, etc. Unfortunately it is extremely difficult to fabricate and sinter suitably shaped components, and considerable efforts have therefore been spent on developing related nitrogen ceramics by forming

solid solutions between Si_3N_4 and Al_2O_3 to give the "sialons" (SiAlON) of general formula $Si_{6-0.75x}Al_{0.67x}O_xN_{8-x}(0 < x < 6)$.[45]

The most extensive group of nitrides are the metallic nitrides of general formulae MN, M_2N, and M_4N in which N atoms occupy some or all of the interstices in cubic or hcp metal lattices (examples are in Table 11.1, p. 413). These compounds are usually opaque, very hard, chemically inert, refractory materials with metallic lustre and conductivity and sometimes having variable composition. Similarities with borides (p. 145) and carbides (p. 297) are notable. Typical mps (°C) are:

TiN	ZrN	HfN	VN	NbN	TaN
2950	2980	2700	2050	2300	3090
CrN	ThN	UN			
d1770	2630	2800			

Hardness on the Mohs scale is often above 8 and sometimes approaches 10 (diamond). These properties commend nitrides for use as crucibles, high-temperature reaction vessels, thermocouple sheaths and related applications. Several metal nitrides are also used as heterogeneous catalysts, notably the iron nitrides in the Fischer-Tropsch hydriding of carbonyls. Few chemical reactions of metal nitrides have been studied; the most characteristic (often extremely slow but occasionally rapid) is hydrolysis to give ammonia or nitrogen:

$$2AlN + (n+3)H_2O \longrightarrow Al_2O_3.nH_2O + 2NH_3$$

$$2VN + 3H_2SO_4 \longrightarrow V_2(SO_4)_3 + N_2 + 3H_2$$

The crystal chemistry of metal nitrides has been reviewed[45a] and there have recently been some intriguing developments in our understanding of the stoichiometries and structures of ternary and quaternary metal nitrides.[45b]

The nitride ion N^{3-} is an excellent ligand, particularly towards second- and third-row transition metals.[46] It is considered to be by far the strongest π donor known, the next strongest being the isoelectronic species O^{2-}. Nitrido complexes are usually prepared by the thermal decomposition of azides (e.g. those of phosphine complexes of V^V, Mo^{VI}, W^{VI}, Ru^{VI}, Re^V) or by deprotonation of NH_3 (e.g. $[OsO_4 \rightarrow OsO_3N]^-$). Most involve a terminal $\{\equiv N\}^{3-}$ group as in $[VCl_3N]^-$, $[MoO_3N]^-$, $[WCl_5N]^{2-}$, $[ReN(PR_3)_3X_2]$ and $[RuN(OH_2)X_4]^-$. The M–N distance is much shorter (by 40–50 pm) than the "normal" σ-(M–N) distance, consistent with strong multiple bonding. Other bonding modes feature linear symmetrical bridging as in $[(H_2O)Cl_4Ru{-}N{-}RuCl_4(OH_2)]^{3-}$, trigonal planar μ_3 bridging as in $[\{(H_2O)(SO_4)_2Ir\}_3N]^{4-}$, and tetrahedral coordination as in $[(MeHg)_4N]^+$ (Fig. 11.3). The nitrido ligand has a strong *trans* influence, e.g. in $[Os^{VI}NCl_5]^{2-}$ (p. 1085); likewise, in the octahedral complex. $[Tc^VNCl_2(PMe_2Ph)_3]$, the Tc–Cl distance *trans* to N is 266.5 pm whereas that *cis* to N is only 244.1 pm.[47]

Azidotrifluoromethylmethane, CF_3N_3, (mp −152°, bp −285°) is a colourless gas which is thermally stable at room temperature. It can be prepared in 90% yield by reacting CF_3NO with hydrazine in MeOH at −78° and then treating the product with HCl gas.[48]

$$CF_3NO + H_2NNH_2 \longrightarrow CF_3{-}N{=}NNH_2 \longrightarrow CF_3NNN$$

The molecule has an almost linear N_3 group and an angle C–N–N of 112.4° (Fig. 11.4a).[49] The (linear) azide ion, N_3^-, is isoelectronic with N_2O, CO_2, OCN^-, etc. and forms numerous coordination complexes by standard ligand replacement reactions. Various coordination modes have been established, including end-on η^1, bridging

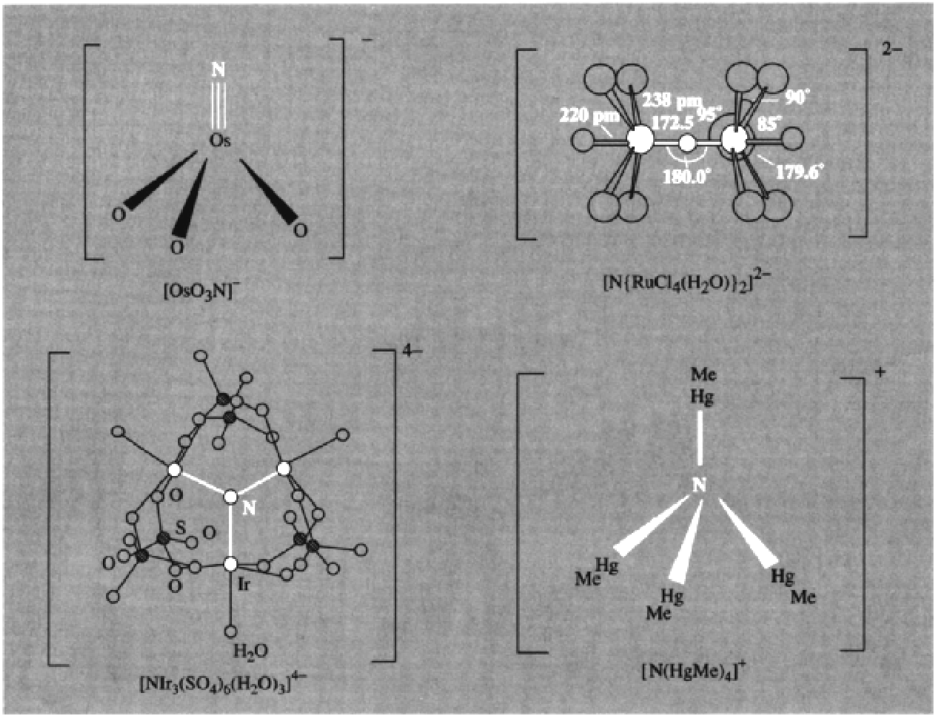

Figure 11.3 Structures of some nitrido complexes.[24]

μ,η^1 and bridging $\mu,\eta^1{:}\eta^1$ (Fig. 11.4).[50,51] The binuclear complex $[Mo_2Cl_2N_{20}]^{2-}$ features a terminal nitrido ligand, $N\equiv^-$, as well as terminal and bridging azido ligands, i.e. $[\{(MoCl(N)(\eta^1\text{-}N_3)_2(\mu,\eta^1\text{-}N_3)\}_2]^{2-}$.[52]

Concatenations larger than N_3 are rare. The planar bridging $N_4{}^{4-}$ occurs in the binuclear W^{VI} dianion, $[Cl_5W(\mu,\eta^1{:}\eta^1\text{-}N_4)WCl_5]^{2-}$; this is formed during the thermolytic interconversion of $[W(N_3)Cl_5]$ to the corresponding nitrido complex $WNCl_3$ in the presence of Ph_4AsCl, the nitride reacting as it is formed with unreacted azide still present according to the simple stoichiometry:[53]

$$2Ph_4AsCl + WNCl_3 + W(N_3)Cl_5 \longrightarrow [Ph_4AsCl]_2[Cl_5W(\mu\text{-}N_4)WCl_5]$$

It will be noted that $N_4{}^{4-}$ is isosteric with the tetradeprotonated urea molecule, $(H_2N)_2C{=}O$, and is also isoelectronic and isostructural with $CO_3{}^{2-}$ and $NO_3{}^-$. An X-ray analysis of the red single crystals shows that N(central)-N_μ is long (149 pm) and that N(central)-N_t is short (123 pm). Unbranched N-catenation is observed in 2-tetrazenes such as $(Me_3Si)_2N{-}N{=}N{-}N(SiMe_3)_2$ (mp 46°) and its derivatives, e.g.

$$\underbrace{Me_3Si{-}N{-}N{=}N{-}N}_{SiMe_2}{-}N(SiMe_3)_2 \qquad \text{(mp 40°)}$$

and $(Me_3Si)_2N{-}\underbrace{N{-}N{=}N{-}N}_{SiMe_2}{-}N(SiMe_3)_2$ [54]

11.3.2 Ammonia and ammonium salts

NH_3 is a colourless, alkaline gas with a unique, penetrating odour that is first perceptible at concentrations of about 20–50 ppm. Noticeable irritation to eyes and the nasal passages begins at about 100–200 ppm, and higher concentrations can be dangerous.[55] NH_3 is prepared industrially in larger amounts (number of moles) than any other single compound (p. 407) and the production of synthetic ammonia is of major importance for several industries (see Panel).

In the laboratory NH_3 is usually obtained from cylinders unless isotopically enriched species such as $^{15}NH_3$ or ND_3 are required. Pure dry $^{15}NH_3$ can be prepared by treating an enriched $^{15}NH_4^+$ salt with an excess of KOH and drying the product gas over metallic Na. Reduction of $^{15}NO_3^-$ or $^{15}NO_2^-$ with Devarda's alloy (50% Cu, 45% Al, 5% Zn) in alkaline solution provides an alternative route as does the hydrolysis of a nitride, e.g.:

$$3Ca + {}^{15}N_2 \longrightarrow Ca_3{}^{15}N_2 \xrightarrow{6H_2O} 2{}^{15}NH_3 + 3Ca(OH)_2$$

ND_3 can be prepared similarly using D_2O, e.g.:

$$Mg_3N_2 + 6D_2O \longrightarrow 2ND_3 + 3Mg(OD)_2$$

[55] T. A. Czuppon, S. A. Knez and J. M. Rovner, Ammonia, *Kirk-Othmer Encyclopedia of Chemical Technology*, 4th edn., Vol. 2, pp. 638–91, Wiley, New York, 1992

Industrial Production of Synthetic Ammonia[55–57]

The first industrial production of NH_3 began in 1913 at the BASF works in Ludwigshaven-Oppau, Germany. The plant, which had a design capacity of 30 tonnes per day, involved an entirely new concept in process technology; it was based on the Haber-Bosch high-pressure catalytic reduction of N_2 with H_2 obtained by electrolysis of water. Modern methods employ the same principles for the final synthesis but differ markedly in the source of hydrogen, the efficiency of the catalysts, and the scale of operations, many plants now having a capacity of 1650 tonnes per day or more. Great ingenuity has been shown not only in plant development but also in the application of fundamental thermodynamics to the selection of feasible chemical processes. Except where electricity is unusually cheap, reduction by electrolytic hydrogen has now been replaced either by coke/H_2O or, more recently, by natural gas (essentially CH_4) or naphtha (a volatile aliphatic petrol-like fraction of crude oil). The great advantages of modern hydrocarbon reduction methods over coal-based processes are that, comparing plant of similar capital costs, they occupy one-third the land area, use half the energy, and require one-tenth the manpower, yet produce 4 times the annual tonnage of NH_3.

The operation of a large synthetic ammonia plant based on natural gas involves a delicately balanced sequence of reactions. The gas is first *desulfurized* to remove compounds which will poison the metal catalysts, then compressed to ~30 atm and reacted with steam over a nickel catalyst at 750°C in the *primary steam reformer* to produce H_2 and oxides of carbon:

$$CH_4 + H_2O \overset{\text{Ni/750°}}{\rightleftharpoons} CO + 3H_2; \quad CH_4 + 2H_2O \overset{\text{Ni/750°}}{\rightleftharpoons} CO_2 + 4H_2$$

Under these conditions the issuing gases contain some 9% of unreacted methane; sufficient air is injected via a compressor to give a final composition of 1 : 3 N_2 : H_2 and the air burns in the hydrogen thereby heating the gas to ~1100°C in the *secondary reformer:*

$$2H_2 + \underset{\text{air}}{(O_2 + 4N_2)} \overset{1100°}{\rightleftharpoons} 2H_2O + 4N_2; \quad CH_4 + H_2O \overset{\text{Ni/1000°}}{\rightleftharpoons} CO + 3H_2$$

The emerging gas, now containing only 0.25% CH_4, is cooled in heat exchangers which generate high-pressure steam for use first in the turbine compressors and then as a reactant in the primary steam reformer. Next, the CO is converted to CO_2 by the *shift reaction* which also produces more H_2:

$$CO + H_2O \overset{\text{(a) + (b)}}{\rightleftharpoons} CO_2 + H_2$$

Maximum conversion occurs by equilibration at the lowest possible temperature so the reaction is carried out sequentially on two beds of catalyst: (a) iron oxide (400°C) which reduces the CO concentration from 11% to 3%; (b) a copper catalyst (200°) which reduces the CO content to 0.3%. Removal of CO_2 (~18%) is effected in a *scrubber* containing either a concentrated alkaline solution of K_2CO_3 or an amine such as ethanolamine:

$$CO_2 + H_2O + K_2CO_3 \underset{\text{regeneration (heat)}}{\overset{\text{absorption}}{\rightleftharpoons}} 2KHCO_3$$

Remaining trace quantities of CO (which would poison the iron catalyst during ammonia synthesis) are converted back to CH_4 by passing the damp gas from the scrubbers over a Ni *methanation catalyst* at 325°: $CO + 3H_2 \rightleftharpoons CH_4 + H_2O$. This reaction is the reverse of that occurring in the primary steam reformer. The *synthesis gas* now emerging has the approximate composition H_2 74.3%, N_2 24.7%, CH_4 0.8%, Ar 0.3%, CO 1–2 ppm. It is *compressed* in three stages from 25 atm to ~200 atm and then passed over a *promoted iron catalyst* at 380–450°C:

$$N_2 + 3H_2 \overset{\text{Fe/400°/200 atm}}{\rightleftharpoons} 2NH_3$$

The gas leaving the catalyst beds contains about 15% NH_3; this is condensed by refrigeration and the remaining gas mixed with more incoming synthesis gas and recycled. Variables in the final reaction are the synthesis pressure,

Panel continues

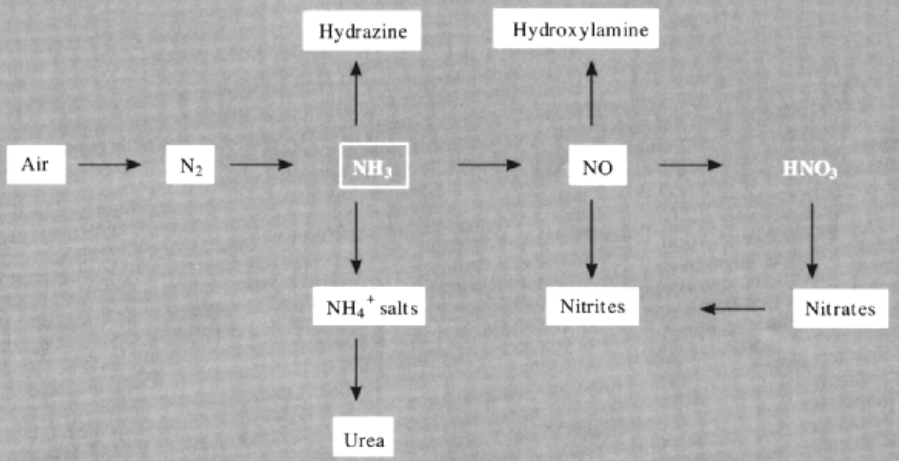
[56] S. P. S. ANDREW, in R. THOMPSON (ed.), *The Modern Inorganic Chemicals Industry,* pp. 201–31, The Chemical Society, London, 1977.

[57] S. D. LYON, *Chem. Ind.* 731–9 (1975).

synthesis temperature, gas composition, gas flow rate† and catalyst composition and particle size. Since the earliest days the "promoted" Fe catalysts have been prepared by fusing magnetite (Fe_3O_4) on a table with KOH in the presence of a small amount of mixed refractory oxides such as MgO, Al_2O_3 and SiO_2; the solidified sheet is broken up into chunks 5–10 mm in size. These chunks are then reduced inside the ammonia synthesis converter to give the active catalyst which consists of Fe crystallites separated by the amorphous refractory oxides and partly covered by the alkali promotor which increases its activity by at least an order of magnitude.

World production of synthetic ammonia has increased dramatically particularly during the period 1950–80. Production in 1950 was little more than 1 million tonnes; though this was huge when compared with the production of most other compounds, it is dwarfed by today's rate of production which exceeds 120 million tonnes pa. In 1990 world production capacity was 119.6 million tonnes distributed as follows: Asia 35.4%, the former Soviet Union 21.5%, North America 13.8%, Western Europe 11.3%, Eastern Europe 9.7% Latin America 5.3%, Africa 3.0%, The price of NH_3 (FOB Gulf Coast plants, USA) was $107/tonne in 1990.

The applications of NH_3 are dominated (over 85%) by its use in various forms as a fertilizer. Of these, direct application is the most common (28.7%), followed by urea (22.4%), NH_4NO_3 (15.8%), ammonium phosphates (14.6%), and $(NH_4)_2SO_4$ (3.4%). Industrial uses include (a) commercial explosives — such as NH_4NO_3, nitroglycerine, TNT and nitrocellulose, which are produced from NH_3 via HNO_3 — and (b) fibres/plastics e.g. in the manufacture of caprolactam for nylon-6, hexamethylenediamine for nylon-6,6, polyamides, rayon and polyurethanes. Other uses include a wide variety of applications in refrigeration, wood pulping, detinning of scrap-metal and corrosion inhibition; it is also used as a rubber stabilizer, pH controller, in the manufacture of household detergents, in the food and beverage industry, pharmaceuticals, water purification and the manufacture of numerous organic and inorganic chemicals. Indeed, synthetic ammonia is the key to the industrial production of most inorganic nitrogen compounds, as indicated in the subjoined Scheme.



†Flow rate is usually quoted as "space velocity", i.e. the ratio of volumetric rate of gas at STP to volume of catalyst; typical values are in the range 8000–60 000 h^{-1}.

The chemical fixation of N_2 to NH_3 under less extreme conditions than those used industrially is a continuing area of active research and considerable progress has been made in elucidating mechanisms involving N_2 coordinated to Mo, W, V and other centres.[5,6,58–63]

Some physical and molecular properties of NH_3 are in Table 11.2. The influence of H

[a]1 centipoise = 10^{-3} kg m^{-1} s^{-1}. [b]1 Debye = 10^{-18} esu = $3.335\,64\times10^{-30}$ C m. [c]1 GHz = 10^9 s^{-1}.

bonding on the bp and other properties has already been noted (p. 53). It has been estimated that 26% of the H bonding in NH_3 breaks down on melting, 7% on warming from the mp to the bp, and the final 67% on transfer to the gas phase at the bp. The low density, viscosity and electrical conductivity, and the high dielectric constant of liquid ammonia are also notable. Liquid NH_3 is an excellent solvent and a valuable medium for chemical reactions (p. 424); its high heat of vaporization (23.35 kJ mol^{-1} at the bp) makes it relatively easy to handle in simple vacuum flasks. The molecular properties call for little comment except to note that the rapid inversion frequency with which the N atom moves through the plane of the 3 H atoms has a marked effect on the vibrational spectrum of the molecule. The inversion itself occurs in the microwave region of the spectrum at 23.79 GHz (corresponding to a wavelength of 1.260 cm) and was, in fact, the first microwave absorption spectrum to be detected (C. E. Cleeton and N. H. Williams, 1934). The associated energy ($hc\bar{\nu}$) is 0.7935 cm^{-1} i.e. 9.49 J mol^{-1}. Inversion also occurs in ND_3 at a frequency of 1.591 GHz, i.e. less than for NH_3 by a factor of 14.95. The inversion can be stopped in NH_3 by increasing the pressure to ~2 atm. The corresponding figure for ND_3 is ~90 mmHg (i.e. again a factor of about 15).

Ammonia is readily absorbed by H_2O with considerable evolution of heat (~37.1 kJ per mol of NH_3 gas). Aqueous solutions are weakly basic due to the equilibrium

$$NH_3(aq) + H_2O \overset{H_2O}{\rightleftharpoons} NH_4^+(aq) + OH^-(aq);$$

$$K_{298.2} = [NH_4^+][OH^-]/[NH_3] = 1.81\times10^{-5}\ \text{mol l}^{-1}$$

The equilibrium constant at room temperature corresponds to $pK_b = 4.74$ and implies that a 1 molar aqueous solution of NH_3 contains only 4.25 mmol l^{-1} of NH_4^+ (or OH^-). Such solutions do not contain the undissociated "molecule" NH_4OH, though weakly bonded hydrates have been isolated at low temperature:

$NH_3.H_2O$ (mp 194.15 K) and $2NH_3.H_2O$ (mp 194.32 K)

These hydrates are not ionically dissociated but contain chains of H_2O molecules cross-linked by NH_3 molecules into a three-dimensional H-bonded network.

Ammonia burns in air with difficulty, the flammable limits being 16–25 vol%. Normal combustion yields nitrogen but, in the presence of a Pt or Pt/Rh catalyst at 750–900°C, the reaction proceeds further to give the thermodynamically less-favoured products NO and NO_2:

$$4NH_3 + 3O_2 \xrightarrow{\text{burn}} 2N_2 + 6H_2O$$

$$4NH_3 + 5O_2 \xrightarrow{\text{Pt/800°}} 4NO + 6H_2O$$

$$2NO + O_2 \xrightarrow{\text{Pt/800°}} 2NO_2$$

These reactions are very important industrially in the production of HNO_3 (p. 466). See also the industrial production of HCN by the Andrussov process (p. 321): $2NH_3 + 3O_2 + 2CH_4 \longrightarrow 2HCN + 6H_2O$.

Gaseous NH_3 burns with a greenish-yellow flame in F_2 (or ClF_3) to produce NF_3 (p. 439). Chlorine yields several products depending on conditions: NH_4Cl, NH_2Cl, $NHCl_2$, NCl_3, $NCl_3.NH_3$, N_2 and even small amounts of N_2H_4. The reaction to give chloramine, NH_2Cl, is important in urban and domestic water purification systems. Reactions with other non-metals and their halides or oxides are equally complex and lead to a variety of compounds, many of which are treated elsewhere (pp. 497, 501, 506, 535, 723, etc.). At red heat carbon reacts with NH_3 to give $NH_4CN + H_2$, whereas phosphorus yields PH_3 and N_2, and sulfur gives H_2S and N_4S_4. Metals frequently react at higher temperature to give nitrides (p. 417). Of particular importance is the attack on Cu in the presence of oxygen (air) at room temperature since this precludes the use of this metal and its alloys in piping and valves for handling either liquid or gaseous NH_3. Corrosion of Cu and brass by moist NH_3/air mixtures and by air-saturated aqueous solutions of NH_3 is also rapid. Contact with Ni and with polyvinylchloride plastics should be avoided for the same reason.

Liquid ammonia as a solvent[64–67]

Liquid ammonia is the best-known and most widely studied non-aqueous ionizing solvent. Its most conspicuous property is its ability to dissolve alkali metals to form highly coloured, electrically conducting solutions containing solvated electrons, and the intriguing physical properties and synthetic utility of these solutions have already been discussed (p. 77). Apart from these remarkable solutions, much of the chemistry in liquid ammonia can be classified by analogy with related reactions in aqueous solutions. Accordingly, we briefly consider in turn, solubility relationships, metathesis reactions, acid-base reactions, amphoterism, solvates and solvolysis, redox reactions and the preparation of compounds in unusual oxidation states. Comparison of the physical properties of liquid NH_3 (p. 423) with those of water (p. 623) shows that NH_3 has the lower mp, bp, density, viscosity, dielectric constant and electrical conductivity; this is due at least in part to the weaker H bonding in NH_3 and the fact that such bonding cannot form cross-linked networks since each NH_3 molecule has only 1 lone-pair of electrons compared with 2 for each H_2O molecule. The ionic self-dissociation constant of liquid NH_3 at $-50°C$ is $\sim 10^{-33}\,mol^2\,l^{-2}$.

Most ammonium salts are freely soluble in liquid NH_3 as are many nitrates, nitrites, cyanides and thiocyanates. The solubilities of halides tend to increase from the fluoride to the iodide; solubilities of salts of multivalent ions are generally low suggesting that (as in aqueous systems) lattice-energy and entropy effects outweigh solvation energies. The possibility of H-bond formation also influences solubility and, in the case of NH_4I, an X-ray single-crystal analysis of the monosolvate shows the presence of an H-bonded cation $N_2H_7^+$ with an N–H···N distance of 269 ± 5 pm.[68] Some typical solubilities at 25°C expressed as g per 100 g solvent are: NH_4OAc 253.2, NH_4NO_3 389.6, $LiNO_3$ 243.7, $NaNO_3$ 97.6, KNO_3 10.4, NaF 0.35, NaCl 3.0, NaBr 138.0, NaI 161.9, NaSCN 205.5. Some of these solubilities are astonishingly high, particularly when expressed as the number of moles of solute per 10 mol

NH_3, e.g.: NH_4NO_3 8.3, $LiNO_3$ 6.1, NaSCN 4.3. Further data at 25° and other temperatures are in ref. 69.

Metathesis reactions are sometimes the reverse of those in aqueous systems because of the differing solubility relations. For example because AgBr forms the complex ion $[Ag(NH_3)_2]^+$ in liquid NH_3 it is readily soluble, whereas $BaBr_2$ is not, and can be precipitated:

$$Ba(NO_3)_2 + 2AgBr \xrightarrow{\text{liq } NH_3} BaBr_2\downarrow + 2AgNO_3$$

Reactions analogous to the precipitation of AgOH and of insoluble oxides from aqueous solution are:

$$AgNO_3 + KNH_2 \xrightarrow{\text{liq } NH_3} AgNH_2\downarrow + KNO_3$$

$$3HgI_2 + 6KNH_2 \xrightarrow{\text{liq } NH_3} Hg_3N_2\downarrow + 6KI + 4NH_3$$

Acid-base reactions in many solvent systems can be thought of in terms of the characteristic cations and anions of the solvent (see also p. 831)

$$\text{solvent} \rightleftharpoons \text{characteristic cation (acid)} + \text{characteristic anion (base)}$$

$$2H_2O \rightleftharpoons H_3O^+ + OH^-$$

$$2NH_3 \rightleftharpoons NH_4^+ + NH_2^-$$

On this basis NH_4^+ salts can be considered as solvo-acids in liquid NH_3 and amides as solvo-bases. Neutralization reactions can be followed conductimetrically, potentiometrically or even with coloured indicators such as phenolphthalein:

$$\underset{\text{solvo-acid}}{NH_4NO_3} + \underset{\text{solvo-base}}{KNH_2} \xrightarrow{\text{liq } NH_3} \underset{\text{salt}}{KNO_3} + \underset{\text{solvent}}{2NH_3}$$

Likewise, amphoteric behaviour can be observed. For example $Zn(NH_2)_2$ is insoluble in liquid NH_3 (as is $Zn(OH)_2$ in H_2O), but it dissolves on addition of the solvo-base KNH_2 due to the formation of $K_2[Zn(NH_2)_4]$; this in turn is decomposed by NH_4^+ salts (solvo-acids) with reprecipitation of the amide:

$$K_2[Zn(NH_2)_4] + 2NH_4NO_3 \xrightarrow{\text{liq } NH_3} Zn(NH_2)_2 + 2KNO_3 + 4NH_3$$

Solvates are perhaps less prevalent in compounds prepared from liquid ammonia solutions than are hydrates precipitated from aqueous systems, but large numbers of ammines are known, and their study formed the basis of Werner's theory of coordination compounds (1891–5). Frequently, however, solvolysis (ammonolysis) occurs (cf. hydrolysis).[65] Examples are:

$$M^IH + NH_3 \longrightarrow MNH_2 + H_2$$

$$M^I_2O + NH_3 \longrightarrow MNH_2 + MOH$$

$$SiCl_4 \xrightarrow[\text{temp}]{\text{low}} [Si(NH_2)_4] \xrightarrow{0^\circ} Si(NH)(NH_2)_2 \xrightarrow{1200^\circ} Si_3N_4$$

Amides are one of the most prolific classes of ligand and the subject of metal and metalloid amides has been extensively reviewed.[70]

Redox reactions are particularly instructive. If all thermodynamically allowed reactions in liquid NH_3 were kinetically rapid, then no oxidizing agent more powerful than N_2 and no reducing agent more powerful than H_2 could exist in this solvent. Using data for solutions at 25°:[64]

Acid solutions (1 M NH_4^+)

$NH_4^+ + e^- = NH_3 + \frac{1}{2}H_2$ $\quad E^\circ = 0.0\,V$

$3NH_4^+ + \frac{1}{2}N_2 + 3e^- = 4NH_3$ $\quad E^\circ = -0.04\,V$

Basic solutions (1 M NH_2^-)

$NH_3 + e^- = NH_2^- + \frac{1}{2}H_2$ $\quad E^\circ = 1.59\,V$

$2NH_3 + \frac{1}{2}N_2 + 3e^- = 3NH_2^-$ $\quad E^\circ = 1.55\,V$

Obviously, with a range of only 0.04 V available very few species are thermodynamically stable. However, both the hydrogen couple and the nitrogen couple usually exhibit "overvoltages" of ~1 V, so that in acid solutions the practical range of potentials for solutes is from +1.0 to −1.0 V. Similarly in basic solutions the practical range

[69] K. JONES, Nitrogen, Chap. 19 in *Comprehensive Inorganic Chemistry* Vol. 2, pp. 147–388, Pergamon Press, Oxford, 1973.

[70] M. F. LAPPERT, P. P. POWER, A. R. SANGER and R. C. SRIVASTAVA, *Metal and Metalloid Amides*, Ellis Horwood Ltd., Chichester, 1980, 847 pp. (approximately 3000 references).

extends from 2.6 to 0.6 V. It is thus possible to work in liquid ammonia with species which are extremely strong reducing agents (e.g. alkali metals) and also with extremely strong oxidizing agents (e.g. permanganates, superoxides and ozonides; p. 609). For similar reasons the NO_3^- ion is effectively inert towards NH_3 in acid solution but in alkaline solutions N_2 is slowly evolved:

$$3K^+ + 3NH_2^- + 3NO_3^- \longrightarrow 3KOH\downarrow + N_2 + 3NO_2^- + NH_3$$

The use of liquid NH_3 to prepare compounds of elements in unusual (low) oxidation states is exemplified by the successive reduction of $K_2[Ni(CN)_4]$ with Na/Hg in the presence of an excess of CN^-: the dark-red dimeric Ni^I complex $K_4[Ni_2(CN)_6]$ is first formed and this can be further reduced to the yellow Ni^0 complex $K_4[Ni(CN)_4]$. The corresponding complexes $[Pd(CN)_4]^{4-}$ and $[Pt(CN)_4]^{4-}$ can be prepared similarly, though there is no evidence in these latter systems for the formation of the M^I dimer. A ditertiaryphosphine complex of Pd^0 has also been prepared:

$$[Pd\{1,2\text{-}(PEt_2)_2C_6H_4\}_2]Br_2 \xrightarrow{Na/NH_3} [Pd\{1,2\text{-}(PEt_2)_2C_6H_4\}_2] + 2NaBr$$

$[Co^{III}(CN)_6]^{3-}$ yields the pale-yellow complex $[Co^I(CN)_4]^{3-}$ and the brown-violet complex $[Co_2^0(CN)_8]^{8-}$ (cf. the dimeric carbonyl $[Co_2(CO)_8]$).

Liquid NH_3 is also extensively used as a preparative medium for compounds which are unstable in aqueous solutions, e.g.:

$$2Ph_3GeNa + Br(CH_2)_xBr \xrightarrow{\text{liq } NH_3} Ph_3Ge(CH_2)_xGePh_3 + 2NaBr$$

$$Me_3SnX + NaPEt_2 \xrightarrow{\text{liq } NH_3} Me_3SnPEt_2 + 2NaX$$

Alkali metal acetylides M_2C_2, MCCH and MCCR can readily be prepared by passing C_2H_2 or C_2HR into solutions of the alkali metal in liquid NH_3, and these can be used to synthesize a wide range of transition-element acetylides,[71] e.g.:

$$Ni(SCN)_2.6NH_3 + 5KC_2Ph \xrightarrow{\text{liq } NH_3} K_2[Ni(C_2Ph)_4].2NH_3 + 2KSCN + 4NH_3$$

$$K_2[Ni(C_2Ph)_4].2NH_3 \xrightarrow{vac} K_2[Ni^{II}(C_2Ph)_4] + 2NH_3$$
yellow

Other examples are orange-red $K_3[Cr^{III}(C_2H)_6]$, rose-pink $Na_2[Mn^{II}(C_2Me)_4]$, dark-green $Na_4[Co^{II}(C_2Me)_6]$, orange $K_4[Ni^0(C_2H)_4]$, yellow $K_6[Ni_2^I(C_2Ph)_6]$. Such compounds are often explosive, though the analogues of Cu^I and Zn^{II} are not, e.g. yellow $Na[Cu(C_2Me)_2]$, colourless $K_2[Cu(C_2H)_3]$, and colourless $K_2[Zn(C_2H)_4]$.

Ammonium halides have been used as versatile reagents in low-temperature solid-state redox and acid-base reactions.[72] For example, direct reaction with the appropriate metal at 270–300° yields the ammonium salts of $ZnCl_4^{2-}$, $LaCl_5^{2-}$, YCl_6^{3-}, YBr_6^{3-}, $CuCl_3^{2-}$, etc., whereas Y_2O_3 yields either $(NH_4)_3YBr_6$ or YOBr depending on the stoichiometric ratio of the reagents. Solid-state reactions of ammonium sulfate, nitrate, phosphates and carbonate have also been studied.

11.3.3 Other hydrides of nitrogen

Nitrogen forms more than 20 binary compounds with hydrogen[73] of which ammonia (NH_3, p. 420), hydrazine (N_2H_4, p. 427) and hydrogen azide (N_3H, p. 432) are by far the most important. Hydroxylamine, $NH_2(OH)$, is closely related in structure and properties to both ammonia, $NH_2(H)$, and hydrazine, $NH_2(NH_2)$ and it will be convenient to discuss this compound in the present section also (p. 431). Several protonated cationic species such as NH_4^+, $N_2H_5^+$, etc, and deprotonated anionic species such as NH_2^-, $N_2H_3^-$, etc. also exist but ammonium hydride, NH_5, is unknown. Among

Density (liquid at 25°)/g cm^{-3}	1.00	$\Delta H_f^\circ(25°)/\text{kJ mol}^{-1}$	50.6
$\eta(25°)$/centipoise[a]	0.9	$\Delta G_f^\circ(25°)/\text{kJ mol}^{-1}$	149.2
Refractive index n_D^{25}	1.470	$S°(25°)/\text{J K}^{-1}\text{ mol}^{-1}$	121.2

[a] 1 centipoise = 10^{-3} kg m^{-1} s^{-1}.

the less familiar (and less stable) neutral radicals which have been well characterized are the imidogen (NH), amidogen (NH_2), diazenyl (N_2H) and hydrazyl (N_2H_3) radicals. Such species are important in atmospheric chemistry and in combustion reactions. Of the neutral compounds the following can be mentioned:[73]

N_2H_2: *trans*-diazene, HN=NH (yellow), and its 1:1 isomer, $H_2N{=}N$

N_3H: hydrogen azide (p. 432) and cyclotriazene (triazairine). $\overline{N{=}N{-}NH}$

N_3H_3: triazene, $HN{=}N{-}NH_2$ and cyclotriazane (triaziridene) c-$(NH)_3$

N_3H_5: triazane (aminohydrazine), $H_2NN(H)$-NH_2

N_4H_4: *trans*-2-tetrazene, $H_2N{-}N{=}N{-}NH_2$, (colourless, low-melting crystals, N–N 143 pm, N=N 121 pm). and ammonium azide, NH_4N_3 (white crystals, subl. 133°C, *d* 1.350 g cm^{-3})

N_4H_6: tetrazane, $H_2NN(H)N(H)NH_2$, (bright yellow solid)

N_5H_5: hydrazinium azide, $N_2H_5N_3$, (explosive white crystals)

N_6H_2: Probably a cyclic dimer of N_3H

N_7H_9: hydrazinium azide monohydrazinate, $N_2H_5N_3.N_2H_4$

N_9H_3: cyclic trimer of N_3H, i.e. 1,3,5-$N_6(NH)_3$

Hydrazine[74]

Anhydrous N_2H_4 is a fuming, colourless liquid with a faint ammoniacal odour which is first detectable at a concentration of 70–80 ppm. Many of its physical properties (Table 11.3) are remarkably similar to those of water (p. 623); comparisons with NH_3 (p. 423) H_2O_2 (p. 634) are also instructive, and the influence of H bonding is apparent. In the gas phase four conformational isomers are conceivable (Fig. 11.5) but the large dipole (1.85 D) clearly eliminates the staggered *trans*-conformation; electron diffraction data (and infrared) indicate the *gauche*-conformation with an angle of rotation of 90–95° from the eclipsed position.

The most effective preparative routes to hydrazine are still based on the process introduced by F. Raschig in 1907: this involves the reaction of ammonia with an alkaline solution of sodium hypochlorite in the presence of gelatin or glue. The overall reaction can be written as

$$2NH_3 + NaOCl \xrightarrow{\text{aqueous alkali}} N_2H_4 + NaCl + H_2O \quad (1)$$

but it proceeds in two main steps. First there is a rapid formation of chloramine which proceeds to completion even in the cold:

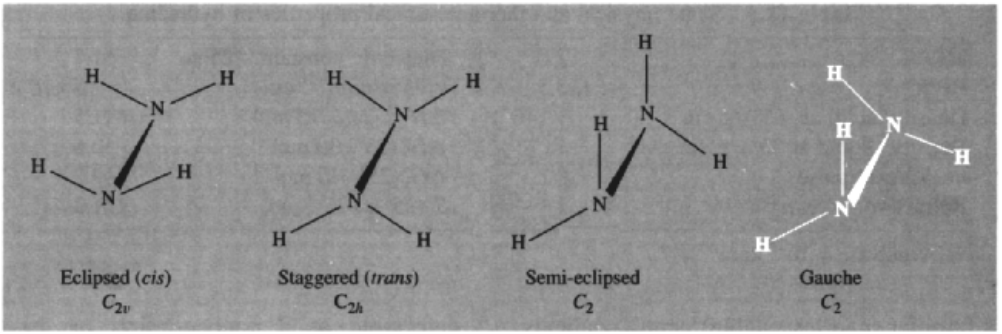
$$NH_3 + OCl^- \longrightarrow NH_2Cl + OH^- \quad (2)$$

The chloramine then reacts further to produce N_2H_4 either by slow nucleophilic attack of NH_3 (3a) and subsequent rapid neutralization (3b), or by preliminary rapid formation of the chloramide ion (4a) followed by slow nucleophilic attack of NH_3 (4b):

$$NH_2Cl + NH_3 \xrightarrow{\text{slow}} N_2H_5^+ + Cl^- \quad (3a)$$

$$N_2H_5^+ + OH^- \xrightarrow{\text{fast}} N_2H_4 + H_2O \quad (3b)$$

[74] E. W. SCHMIDT, *Hydrazine and its Derivatives, Preparation, Properties, Application* Wiley, Chichester, 1984, 1059 pp. (over 4400 references).



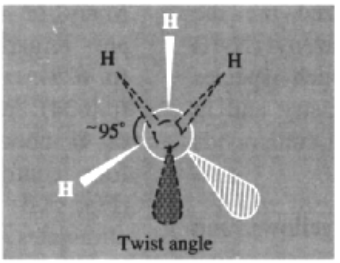


Figure 11.5 Possible conformations of N_2H_4 with pyramidal N. Hydrazine adopts the gauche C_2 form with N–N 145 pm, H–N–H 108°, and a twist angle of 95° as shown in the lower diagram.

$$NH_2Cl + OH^- \xrightarrow{\text{fast}} NHCl^- + H_2O \qquad (4a)$$

$$NHCl^- + NH_3 \xrightarrow{\text{slow}} N_2H_4 + Cl^- \qquad (4b)$$

In addition there is a further rapid but undesirable reaction with chloramine which destroys the N_2H_4 produced:

$$N_2H_4 + 2NH_2Cl \xrightarrow{\text{fast}} 2NH_4Cl + N_2 \qquad (5)$$

This reaction is catalysed by traces of heavy metal ions such as Cu^{II} and the purpose of the gelatin is to suppress reaction (5) by sequestering the metal ions; it is probable that gelatin also assists the hydrazine-forming reactions between ammonia and chloramine in a way that is not fully understood. The industrial preparation and uses of N_2H_4 are summarized in the Panel.

At room temperature, pure N_2H_4 and its aqueous solutions are kinetically stable with respect to decomposition despite the endothermic nature of the compound and its positive free energy of formation:

$$N_2(g) + 2H_2(g) \longrightarrow N_2H_4(l);\ \Delta H_f^\circ = 50.6\,kJ\,mol^{-1}$$

$$\Delta G_f^\circ = 149.2\,kJ\,mol^{-1}$$

When ignited, N_2H_4 burns rapidly and completely in air with considerable evolution of heat (see Panel):

$$N_2H_4(l) + O_2(g) \longrightarrow N_2(g) + 2H_2O;$$

$$\Delta H = -621.5\,kJ\,mol^{-1}$$

In solution, N_2H_4 is oxidized by a wide variety of oxidizing agents (including O_2) and it finds use as a versatile reducing agent because of the variety of reactions it can undergo. Thus the thermodynamic reducing strength of N_2H_4 depends on whether it undergoes a 1-, 2-, or 4-electron oxidation and whether this is in acid or alkaline solution. Typical examples in acid solution are as follows:†

1-electron change (e.g. using Fe^{III}, Ce^{IV}, or MnO_4^-):

† See p. 435 for discussion of standard electrode potentials and their use. It is conventional to write the half-reactions as (oxidized form) + ne^- = (reduced form). Since $\Delta G = -nE^\circ F$ at unit activities, it follows that the reactions will occur spontaneously in the reverse direction to that written when E° is negative, i.e. hydrazine is oxidized by the reagents listed.

Industrial Production and Uses of Hydrazine[75]

Hydrazine is usually prepared in a continuous process based on the Raschig reaction. Solutions of ammonia and sodium hypochlorite (30:1) are mixed in the cold with a gelatin solution and then passed rapidly under pressure through a reactor at 150° (residence time 1 s). This results in a 60% conversion based on hypochlorite and produces a solution of ~0.5% by weight of N_2H_4. The excess of NH_3 and steam are stripped off in stages and the solution finally distilled to give pure hydrazine hydrate $N_2H_4.H_2O$ (mp −51.7°, bp 118.5°, d 1.0305 g cm^{-3} at 21°). In the Olin Mathieson variation of this process, NH_2Cl is preformed from $NH_3 + NaOCl$ (3:1) and then anhydrous NH_3 is injected to a ratio of ~30:1; this simultaneously raises the temperature and pressure in the reactor. An alternative industrial route, which is economical only for smaller plants, uses urea instead of ammonia in a process very similar to Raschig's:

$$(NH_2)_2CO + NaOCl + 2NaOH \xrightarrow[\text{protein inhibitor}]{\text{rapid heat/}} N_2H_4.H_2O + NaCl + Na_2CO_3$$

Hydrazine hydrate contains 64.0% by weight of N_2H_4 and is frequently preferred to the pure compound not only because it is cheaper but also because its much lower mp avoids problems of solidification. Anhydrous N_2H_4 can be obtained from concentrated aqueous solutions by distillation in the presence of dehydrating agents such as solid NaOH or KOH. Alternatively, hydrazine sulfate can be precipitated from dilute aqueous solutions using dilute H_2SO_4 and the precipitate treated with liquid NH_3 to liberate the hydrazine:

$$N_2H_4(aq) + H_2SO_4(aq) \longrightarrow N_2H_6SO_4 \xrightarrow[\text{(anhydr)}]{2NH_3} N_2H_4 + (NH_4)_2SO_4$$

World production capacity of hydrazine solutions in 1995 (expressed as N_2H_4) was about 40 000 tonnes, predominantly in USA 16 500 t, Germany 6400 t, Japan 6600 t and France 6100 t. In addition some 3200 t of anhydrous N_2H_4 was manufactured in USA for rocket fuels.

The major use (non-commercial) of anhydrous N_2H_4 and its methyl derivatives $MeNHNH_2$ and Me_2NNH_2 is as a rocket fuel in guided missiles, space shuttles, lunar missions, etc. For example the Apollo lunar modules were decelerated on landing and powered on blast-off for the return journey by the oxidation of a 1:1 mixture of $MeNHNH_2$ and Me_2NNH_2 with liquid N_2O_4; the landing required some 3 tonnes of fuel and 4.5 tonnes of oxidizer, and the relaunching about one-third of this amount. Other oxidants used are O_2, H_2O_2, HNO_3, or even F_2. Space vehicles propelled by anhydrous N_2H_4 itself include the Viking Lander on Mars, the Pioneer and Voyager interplanetary probes and the Giotto space probe to Halley's comet.

The major commercial applications of hydrazine solutions are as blowing agents (~40%), agricultural chemicals (~25%), medicinals (~5%), and — increasingly — in boiler water treatment now as much as 20%. The detailed pattern of usage, of course, depends to some extent on the country concerned.

Aqueous solutions of N_2H_4 are versatile and attractive reducing agents. They have long been used to prepare silver (and copper) mirrors, to precipitate many elements (such as the platinum metals) from solutions of their compounds, and in other analytical applications. A major application as noted above is now in the treatment of high-pressure boiler water: this was first introduced in about 1945 and has the following advantages over the previously favoured Na_2SO_3:

(a) N_2H_4 is completely miscible with H_2O and reacts with dissolved O_2 to give merely N_2 and H_2O:
$N_2H_4 + O_2 \longrightarrow N_2 + 2H_2O$
(b) N_2H_4 does not increase the dissolved solids (cf. Na_2SO_3) since N_2H_4 itself and all its reaction and decomposition products are volatile.
(c) These products are either alkaline (like N_2H_4) or neutral, but never acidic.
(d) N_2H_4 is also a corrosion inhibitor (by reducing Fe_2O_3 to hard, coherent Fe_3O_4) and it is therefore useful for stand-by and idle boilers.

The usual concentration of O_2 in boiler feed water is ~0.01 ppm so that, even allowing for a twofold excess, 1 kg N_2H_4 is sufficient to treat 50 000 tonnes of feed water (say ~4 days' supply at the rate of 500 tonnes per hour).

Hydrazine and its derivatives find considerable use in the synthesis of biologically active materials, dyestuff intermediates and other organic derivatives. Reactions of aldehydes to form hydrazides ($RCH{=}NNH_2$) and azines ($RCH{=}NN{=}CHR$) are well known in organic chemistry, as is the use of hydrazine and its derivatives in the synthesis of heterocyclic compounds.

[75] Hydrazine and its derivatives, *Kirk–Othmer Encyclopedia of Chemical Technology*, 4th edn., Vol. 13, pp. 560–606 (1995).

$$NH_4^+ + \tfrac{1}{2}N_2 + H^+ + e^- = N_2H_5^+; \quad E^\circ = -1.74\,V$$

2-electron change (e.g. using H_2O_2 or HNO_2):

$$\tfrac{1}{2}NH_4^+ + \tfrac{1}{2}HN_3 + \tfrac{5}{2}H^+ + 2e^- = N_2H_5^+; \quad E^\circ = +0.11\,V$$

4-electron change (e.g. using IO_3^- or I_2):

$$N_2 + 5H^+ + 4e^- = N_2H_5^+; \quad E^\circ = -0.23\,V$$

For basic solutions the corresponding reduction potentials are:

$$NH_3 + \tfrac{1}{2}N_2 + H_2O + e^- = N_2H_4 + OH^-; \quad E^\circ = -2.42\,V$$

$$\tfrac{1}{2}NH_3 + \tfrac{1}{2}N_3^- + \tfrac{5}{2}H_2O + 2e^- = N_2H_4 + \tfrac{5}{2}OH^-; \quad E^\circ = -0.92\,V$$

$$N_2 + 4H_2O + 4e^- = N_2H_4 + 4OH^-; \quad E^\circ = -1.16\,V$$

In the 4-electron oxidation of acidified N_2H_4 to N_2, it has been shown by the use of N_2H_4 isotopically enriched in ^{15}N that both the N atoms of each molecule of N_2 originated in the same molecule of N_2H_4. This reaction is also the basis for the most commonly used method for the analytical determination of N_2H_4 in dilute aqueous solution:

$$N_2H_4 + KIO_3 + 2HCl \xrightarrow{H_2O/CCl_4} N_2 + KCl + ICl + 3H_2O$$

The IO_3^- is first reduced to I_2 which is subsequently oxidized to ICl by additional IO_3^-; the end-point is detected by the complete discharge of the iodine colour from the CCl_4 phase.

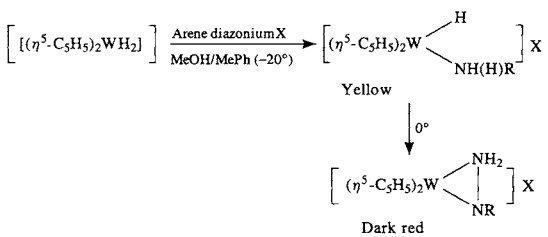
As expected, N_2H_4 in aqueous solutions is somewhat weaker as a base than is ammonia (p. 423):

$$N_2H_4(aq) + H_2O = N_2H_5^+ + OH^-; \quad K_{25^\circ} = 8.5 \times 10^{-7}\,mol\,l^{-1}$$

$$N_2H_5^+(aq) + H_2O = N_2H_6^{2+} + OH^-; \quad K_{25^\circ} = 8.9 \times 10^{-16}\,mol\,l^{-1}$$

The hydrate $N_2H_4.H_2O$ is an H-bonded molecular adduct and is not ionically dissociated. Two series of salts are known, e.g. N_2H_5Cl and $N_2H_6Cl_2$. (It will be noticed that $N_2H_6^{2+}$ is isoelectronic with ethane.) H bonding frequently influences the crystal structure and this is particularly noticeable in $N_2H_6F_2$ which features a layer lattice similar to CdI_2 though the structure is more open and the fluoride ions are not close packed. Sulfuric acid forms three salts, $N_2H_4.nH_2SO_4$ ($n = \frac{1}{2}$, 1, 2), i.e. $[N_2H_5]_2SO_4$, $[N_2H_6]SO_4$ and $[N_2H_6][HSO_4]_2$.

Hydrazido(2−)-complexes of Mo and W have been prepared by protonating dinitrogen complexes with concentrated solutions of HX and by ligand exchange.[76] For example several dozen complexes of general formulae $[MX_2(NNH_2)L_3]$ and *trans*-$[MX(NNH_2)L_4]$ have been characterized for M = Mo; X = halogen; L = phosphine or heterocyclic-N donor. Similarly, *cis*-$[W(N_2)_2(PMe_2Ph)_4]$ afforded *trans*-$[WF(NNH_2)(PMe_2Ph)_4][BF_4]$ when treated with HF/MeOH in a borosilicate glass vessel. Side-on coordination of a phenylhydrazido(1−) ligand has also been established in compounds such as the dark-red $[W(\eta^5\text{-}C_5H_5)_2(\eta^2\text{-}H_2NNPh)][BF_4]$;[77] these are synthesized by the ready isomerization of the first-formed yellow η^1-arylhydrazido(2−) tungsten hydride complex above −20° (X = BF_4, PF_6):



In these reactions R = Ph, *p*-$MeOC_6H_4$, *p*-MeC_6H_4 or *p*-FC_6H_4. Further bonding modes are as an isodiazene (i.e. M←N=NMe_2 rather than M=N–NMe_2)[78] and as a bridging diimido

group (M···N–N=M).[79] Both hydrazine itself and its dianion, $HNNH^{2-}$, act as bridging ligands in the pale yellow dinuclear tungsten(VI) complex shown in Fig. 11.6.[80] A selection of further recent work on the various coordination modes of substituted hydrazido, diazenido and related ligands is appended.[81]

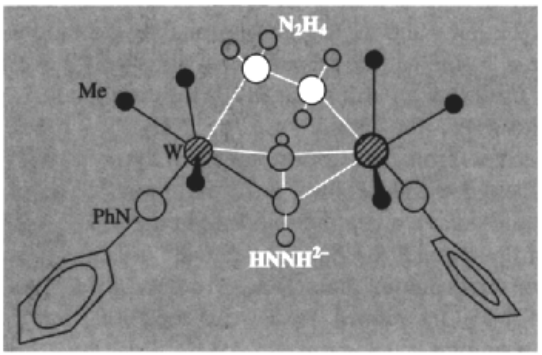

Figure 11.6 Structure of $[\{W(NPh)Me_3\}_2(\mu\text{-}\eta^1,\eta^1\text{-}NH_2NH_2)(\mu\text{-}\eta^2,\eta^2\text{-}NHNH)]$.

Hydroxylamine

Anhydrous NH_2OH is a colourless, thermally unstable hygroscopic compound which is usually handled as an aqueous solution or in the form of one of its salts. The pure compound (mp 32.05°C, d 1.204 g cm^{-3} at 33°C) has a very high dielectric constant (77.63–77.85) and a vapour pressure of 10 mmHg at 47.2°. It can be regarded as water in which 1 H has been replaced by the more electronegative NH_2 group or as NH_3 in which 1 H has been replaced by OH. Aqueous solutions are less basic than either ammonia or hydrazine:

$$NH_2OH(aq) + H_2O = NH_3OH^+ + OH^-;$$
$$K_{25°} = 6.6 \times 10^{-9}\ \text{mol l}^{-1}$$

Hydroxylamine can be prepared by a variety of reactions involving the reduction of nitrites, nitric acid or NO, or by the acid hydrolysis of nitroalkanes. In the conventional Raschig synthesis, an aqueous solution of NH_4NO_2 is reduced with HSO_4^-/SO_2 at 0° to give the hydroxylamido-*N*,*N*-disulfate anion which is then hydrolysed stepwise to hydroxylammonium sulfate:

$$NH_4NO_2 + 2SO_2 + NH_3 + H_2O \longrightarrow [NH_4]_2[N(OH)(OSO_2)_2]$$

$$[NH_4]^+{}_2[N(OH)(OSO_2)_2]^{2-} + H_2O \longrightarrow [NH_4][NH(OH)(OSO_2)] + [NH_4][HSO_4]$$

$$2[NH_4]^+[NH(OH)(OSO_2)]^- + 2H_2O \longrightarrow [NH_3(OH)]_2[SO_4] + [NH_4]_2[SO_4]$$

Aqueous solutions of NH_2OH can then be obtained by ion exchange, or the free compound can be prepared by ammonolysis with liquid NH_3; insoluble ammonium sulfate is filtered off and the excess of NH_3 removed under reduced pressure to leave solid NH_2OH.

Alternatively, hydroxylammonium salts can be made either (a) by the electrolytic reduction of aqueous nitric acid between amalgamated lead electrodes in the presence of H_2SO_4/HCl, or (b) by the hydrogenation of nitric oxide in acid solutions over a Pt/charcoal catalyst:

$$\text{(a)}\ HNO_3(aq) + 6H^+(aq) \xrightarrow{6e^-} 2H_2O + NH_2OH \xrightarrow{HCl(g)} [NH_3(OH)]Cl(s)$$

$$\text{(b)}\ 2NO(g) + 3H_2(g) + H_2SO_4(aq) \xrightarrow{Pt/C} [NH_3(OH)]_2SO_4$$

A convenient laboratory route involves the reduction of an aqueous solution of nitrous acid or potassium nitrite with bisulfite under carefully

controlled conditions: The hydroxylamidodisulfate first formed, though stable in alkaline solution, rapidly hydrolyses to the monosulfate in acid solution and this can then subsequently be hydrolysed to the hydroxylammonium ion by treatment with aqueous HCl at 100° for 1 h:

$$HNO_2 + 2HSO_3^- \longrightarrow [N(OH)(OSO_2)_2]^{2-} + H_2O$$

$$\xrightarrow{\text{fast}} [NH(OH)(OSO_2)]^- + [HSO_4]^-$$

$$[NH(OH)(OSO_2)]^- + H_3O^+ \xrightarrow{100°/1\,h}$$

$$[NH_3(OH)]^+ + [HSO_4]^-$$

Anhydrous NH_2OH can be prepared by treating a suspension of hydroxylammonium chloride in butanol with NaOBu:

$$[NH_3(OH)]Cl + NaOBu \longrightarrow NH_2OH + NaCl + BuOH$$

The NaCl is removed by filtration and the NH_2OH precipitated by addition of Et_2O and cooling.

NH_2OH can exist as 2 configurational isomers (*cis* and *trans*) and in numerous intermediate *gauche* conformations as shown in Fig. 11.7. In the crystalline form, H bonding appears to favour packing in the *trans* conformation. The N–O distance is 147 pm consistent with its formulation as a single bond. Above room temperature the compound decomposes (sometimes explosively) by internal oxidation-reduction reactions into a complex mixture of N_2, NH_3, N_2O and H_2O. Aqueous solutions are much more stable, particularly acid solutions in which the compound is protonated, $[NH_3(OH)]^+$. Such solutions can act as oxidizing agents particularly when acidified but are more generally used as reducing agents, e.g. as antioxidants in photographic developers, stabilizers of monomers, and for reducing Cu^{II} to Cu^{I} in the dyeing of acrylic fibres. Comparisons with the redox chemistry of H_2O_2 and N_2H_4 are also instructive (see, for example, pp. 272–3 of ref. 69). The ability of NH_2OH to react with N_2O, NO and N_2O_4 under suitable conditions (e.g. as the sulfate adsorbed on silica gel) makes it useful as an absorbent in combustion analysis. However, the major use of NH_2OH, which derives from its ability to form oximes with aldehydes and ketones, is in the manufacture of caprolactam, a key intermediate in the production of polyamide-6 fibres such as nylon. This consumes more than 97% of world production of NH_2OH, which is at least 650 000 tonnes per annum.

The extensive chemistry of the hydroxylamides of sulfuric acid is discussed later in the context of other H–N–O–S compounds (pp. 740–6).

Hydrogen azide

Aqueous solutions of HN_3 were first prepared in 1890 by T. Curtius who oxidized aqueous hydrazine with nitrous acid:

$$N_2H_5^+ + HNO_2 \longrightarrow HN_3 + H^+ + 2H_2O$$

Other oxidizing agents that can be used include nitric acid, hydrogen peroxide, peroxydisulfate, chlorate and the pervanadyl ion. The anhydrous

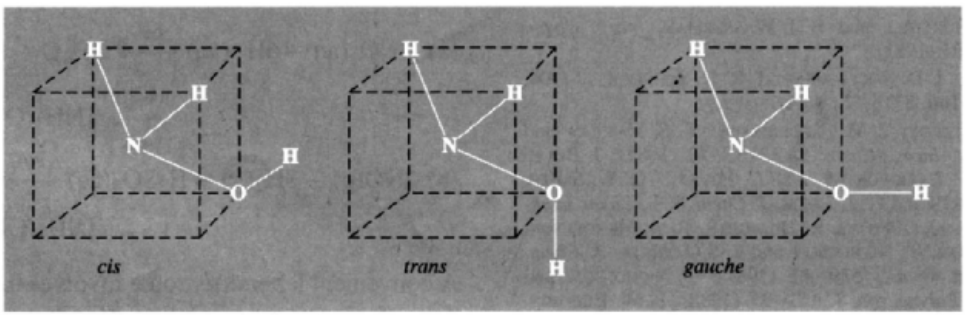

Figure 11.7 Configurations of NH_2OH.

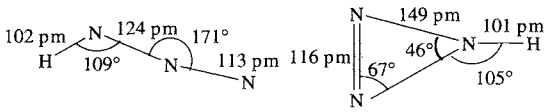
compound is extremely explosive and even dilute solutions should be treated as potentially hazardous. Pure HN_3 is best prepared by careful addition of H_2SO_4 to NaN_3; it is a colourless liquid or gas (mp $\sim -80°$, estimated bp 35.7°, d 1.126 g cm^{-3} at 0°). Its large positive enthalpy and free energy of formation emphasize its inherent instability: ΔH_f°(1, 298 K) 269.5, ΔG_f° (1, 298 K) 327.2 kJ mol^{-1}. It has a repulsive, intensely irritating odour and is a deadly (though non-cumulative) poison; even at concentrations less than 1 ppm in air it can be dangerous. In the gas phase the 3 N atoms are (almost) colinear, as expected for a 16 valence-electron species, and the angle HNN is 109°; the two N–N distances are appreciably different, as shown in structure (1). The structure and dimensions of the isomeric molecule cyclotriazene are given in (2) for comparison; the N–H bond is tilted out of the plane of the N_3 ring by 74°.



(1) (2)

Similar differences are found for organic azides (e.g. MeN_3). In ionic azides (p. 417) the N_3^- ion is both linear and symmetrical (both N–N distances being 116 pm) as befits a 16-electron species isoelectronic with CO_2 (cf. also the cyanamide ion NCN^{2-}, the cyanate ion NCO^-, the fulminate ion CNO^- and the nitronium ion NO_2^+).

Aqueous solutions of HN_3 are about as strongly acidic as acetic acid:

$$HN_3(aq) = H^+(aq) + N_3^-(aq);\ K_a\ 1.8 \times 10^{-5},\ pK_a\ 4.77 \text{ at } 298\text{ K}$$

Numerous metal azides have been characterized (p. 417) and covalent derivatives of non-metals are also readily preparable by simple metathesis using either NaN_3 or aqueous solutions of HN_3[82,83]. In these compounds the N_3 group behaves as a pseudohalogen (p. 319) and, indeed, the unstable compounds FN_3, ClN_3, BrN_3, IN_3 and NCN_3 are known, though potential allotropes of nitrogen such as $N_3–N_3$ (analogous to Cl_2) and $N(N_3)_3$ (analogous to NCl_3) have not been isolated. More complex heterocyclic compounds are, however, well established, e.g. cyanuric azide $\{-NC(N_3)-\}_3$, *B,B,B*-triazidoborazine $\{-NB(N_3)-\}_3$ and even the azidophosphazene derivative $\{-NP(N_3)_2-\}_3$.

Most preparative routes to HN_3 and its derivatives involve the use of NaN_3 since this is reasonably stable and commercially available. NaN_3 can be made by adding powdered $NaNO_3$ to fused $NaNH_2$ at 175° or by passing N_2O into the same molten amide at 190°:

$$NaNO_3 + 3NaNH_2 \longrightarrow NaN_3 + 3NaOH + NH_3$$

$$N_2O + 2NaNH_2 \longrightarrow NaN_3 + NaOH + NH_3$$

The latter reaction is carried out on an industrial scale using liquid NH_3 as solvent; a variant uses Na/NH_3 without isolation of the $NaNH_2$:

$$3N_2O + 4Na + NH_3 \longrightarrow NaN_3 + 3NaOH + 2N_2$$

A remarkable new covalent azide is the pale yellow nitrosyl NNNNO, prepared by reacting gaseous NOCl (p. 441) with solid NaN_3 at low temperature.[84] $NNNN(SO_2F)_2$ has also very recently been made by a similar route from $(SO_2F)_2NCl$; it is a volatile yellow liquid which sometimes decomposes explosively.[84a]

The major use of inorganic azides exploits the explosive nature of heavy metal azides. $Pb(N_3)_2$ in particular is extensively used in detonators because of its reliability, especially in damp conditions; it is prepared by metathesis between $Pb(NO_3)_2$ and NaN_3 in aqueous solution.

11.3.4 Thermodynamic relations between N-containing species

The ability of N to exist in its compounds in at least 10 different oxidation states from -3 to $+5$ poses certain thermodynamic and mechanistic problems that invite systematic treatment. Thus, in several compounds N exists in more than one oxidation state, e.g. $[N^{-III}H_4]^+[N^{III}O_2]^-$, $[N^{-III}H_4]^+[N^{V}O_3]^-$, $[N^{-II}{}_2H_5]^+[N^{V}O_3]^-$, $[N^{-III}H_4]^+[N^{-\frac{1}{3}}{}_3]^-$, etc. Furthermore, we have seen (p. 423) that, under appropriate conditions, NH_3 can be oxidized by O_2 to yield N_2, NO or NO_2, whereas oxidation by OCl^- yields N_2H_4 (p. 427). Likewise, using appropriate reagents, N_2H_4 can be oxidized either to N_2 or to HN_3 (in which the "average" oxidation number of N is $-\frac{1}{3}$). The thermodynamic relations between these various hydrido and oxo species containing N can be elegantly codified by means of their standard reduction potentials, and these can be displayed pictorially using the concept of the "volt equivalent" of each species (see Panel).

The standard reduction potentials in acidic aqueous solution are given in Table 11.4; these are shown diagrammatically in Fig. 11.8 (p. 437) which also includes the corresponding data for alkaline solutions. The reduction potentials are readily converted to volt equivalents (by multiplying by the appropriate oxidation state) and these are plotted against oxidation state in Fig. 11.9. This latter diagram is particularly valuable in giving a visual representation of the redox chemistry of the element. Thus, it follows from the definition of "volt equivalent" that the reduction potential of any couple is the *slope* of the line joining the two points: the greater the positive slope the stronger the oxidizing potential and the greater the negative slope the stronger the reducing power. Any pair of points can be joined. For example in acid solution N_2H_4 is a

Table 11.4 Standard reduction potentials for nitrogen species[a] in acidic aqueous solution (pH 0, 25°C)

Couple	E°/V	Corresponding half-reaction
N_2/HN_3	−3.09	$\frac{3}{2}N_2 + H^+(aq) + e^- \longrightarrow HN_3(aq)$
$N_2/N_2H_5^+$	−0.23	$N_2 + 5H^+ + 4e^- \longrightarrow N_2H_5^+$
$H_2N_2O_2/NH_3OH^+$	+0.387	$H_2N_2O_2 + 6H^+ + 4e^- \longrightarrow 2NH_3OH^+$
HN_3/NH_4^+	+0.695	$HN_3 + 11H^+ + 8e^- \longrightarrow 3NH_4^+$
$NO/H_2N_2O_2$	+0.712	$2NO + 2H^+ + 2e^- \longrightarrow H_2N_2O_2$
NO_3^-/N_2O_4	+0.803	$2NO_3^- + 4H^+ + 2e^- \longrightarrow N_2O_4 + 2H_2O$
$HNO_2/H_2N_2O_2$	+0.86	$2HNO_2 + 4H^+ + 4e^- \longrightarrow H_2N_2O_2 + 2H_2O$
NO_3^-/HNO_2	+0.94	$NO_3^- + 3H^+ + 2e^- \longrightarrow HNO_2 + H_2O$
NO_3^-/NO	+0.957	$NO_3^- + 4H^+ + 3e^- \longrightarrow NO + 2H_2O$
HNO_2/NO	+0.983	$HNO_2 + H^+ + e^- \longrightarrow NO + H_2O$
N_2O_4/NO	+1.035	$N_2O_4 + 4H^+ + 4e^- \longrightarrow 2NO + 2H_2O$
N_2O_4/HNO_2	+1.065	$N_2O_4 + 2H^+ + 2e^- \longrightarrow 2HNO_2$
$N_2H_5^+/NH_4^+$	+1.275	$N_2H_5^+ + 3H^+ + 2e^- \longrightarrow 2NH_4^+$
HNO_2/N_2O	+1.29	$2HNO_2 + 4H^+ + 4e^- \longrightarrow N_2O + 3H_2O$
NH_3OH^+/NH_4^+	+1.35	$NH_3OH^+ + 2H^+ + 2e^- \longrightarrow NH_4^+ + H_2O$
$NH_3OH^+/N_2H_5^+$	+1.42	$2NH_3OH^+ + H^+ + 2e^- \longrightarrow N_2H_5^+ + 2H_2O$
HN_3/NH_4^+	+1.96	$HN_3 + 3H^+ + 2e^- \longrightarrow NH_4^+ + N_2$
$H_2N_2O_2/N_2$	+2.65	$H_2N_2O_2 + 2H^+ + 2e^- \longrightarrow N_2 + 2H_2O$

[a] All the half-reactions listed in this table have only (Ox), H^+ and e^- on the left-hand side of the half-reaction. Others, such as $N_2/NH_3OH^+ - 1.87$ (i.e. $N_2 + 2H_2O + 4H^+ + 2e^- \longrightarrow 2NH_3OH^+$) can readily be calculated by appropriate combinations (in this case, for example, $N_2/N_2H_5^+ - NH_3OH^+/N_2H_5^+$). There are also simple electron addition reactions, e.g. NO^+/NO, $E^\circ + 1.46$ V (i.e. $NO^+ + e^- \longrightarrow NO$) and more complex electron additions, e.g. $NO_3^-, NO/NO_2^-$, $E^\circ + 0.49$ V (i.e. $NO_3^- + NO + e^- \longrightarrow 2NO_2^-$), etc.

Standard Reduction Potentials and Volt Equivalents

Chemical reactions can often formally be expressed as the sum of two or more "half-reactions" in which electrons are transferred from one chemical species to another. Conventionally these are now almost always represented as equilibria in which the forward reaction is a reduction (addition of electrons):

$$\text{(oxidized form)} + ne^- \rightleftharpoons \text{(reduced form)}$$

The electrochemical reduction potential (E volts) of such an equilibrium is given by

$$E = E^\circ - \frac{2.3026RT}{nF} \log_{10} \frac{a(\text{red})}{a(\text{ox})} \tag{1}$$

where E° is the "standard reduction potential" at unit activity a, R is the gas constant (8.3144 J mol^{-1} K^{-1}), T is the absolute temperature, F is the Faraday constant (96 485 C mol^{-1}) and 2.3026 is the constant $\ln_e 10$ required to convert from natural to decadic logarithms. At 298.15 K (25°C) the factor $2.3026RT/F$ has the value 0.059 16 V and, replacing activities by concentrations, one obtains the approximate expression

$$E \approx E^\circ - \frac{0.059\ 16}{n} \log_{10} \frac{[\text{red}]}{[\text{ox}]} \tag{2}$$

By convention, E° for the half-reaction (3) is taken as zero, i.e. $E^\circ(H^+/\frac{1}{2}H_2) = 0.0$ V:

$$H^+(\text{aq}, a = 1) + e^- \rightleftharpoons \tfrac{1}{2}H_2(\text{g}, 1\text{ atm}) \tag{3}$$

Remembering that $\Delta G = -nEF$, it follows that the standard free energy change for the half reaction is $\Delta G^\circ = -nE^\circ F$, e.g.:

$$Fe^{3+}(\text{aq}) + e^- \rightleftharpoons Fe^{2+}(\text{aq}); \quad E^\circ(Fe^{3+}/Fe^{2+}) = 0.771\text{ V} \tag{4}$$
$$\Delta G^\circ = -74.4\text{ kJ mol}^{-1}$$

Coupling the half-reactions (3) and (4) gives the reaction (5) {i.e.(4) − (3)} which, because ΔG is negative, proceeds spontaneously from left to right as written:

$$Fe^{3+}(\text{aq}) + \tfrac{1}{2}H_2(\text{g}) \rightleftharpoons Fe^{2+}(\text{aq}) + H^+(\text{aq}); \quad E^\circ = 0.771\text{ V} \tag{5}$$
$$\Delta G^\circ = -74.4\text{ kJ mol}^{-1}$$

Again, $E^\circ(Zn^{2+}/Zn) = -0.763$ V, hence reaction (6) occurs spontaneously in the reverse direction:

$$Zn^{2+}(\text{aq}) + H_2(\text{g}) \rightleftharpoons Zn(\text{s}) + 2H^+(\text{aq}); \quad E^\circ = -0.763\text{ V};$$
$$\Delta G^\circ = +147.5\text{ kJ mol}^{-1} \text{ (note the factor of 2 for } n) \tag{6}$$

In summary, at pH 0 a reaction is spontaneous from left to right if $E^\circ > 0$ and spontaneous in the reverse direction if $E^\circ < 0$. At other H-ion concentrations eqn. (2) indicates that the potential of the H electrode (3) will be

$$E = -0.05916 \log \frac{\{P_{H_2}/\text{atm}\}^{\frac{1}{2}}}{\{[H^+(\text{aq})]/\text{mol l}^{-1}\}}\text{ V}$$

and, in general, the potential of any half-reaction changes with the concentration of the species involved according to the Nernst equation (7):

$$E = E^\circ - \frac{0.05916}{n} \log Q \tag{7}$$

where Q has the same form as the equilibrium constant but is a function of the actual activities of the reactants and products rather than those of the equilibrium state. Note also that the potential is independent of the coefficients of the half-reaction whereas the free energy is directly proportional to these, e.g.:

Panel continues

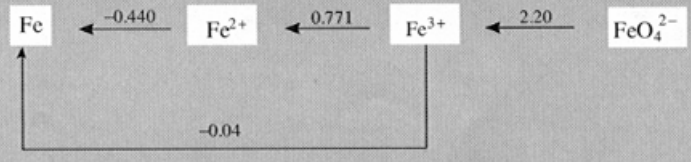
$$\tfrac{1}{2}I_2 + e^- \rightleftharpoons I^-; \quad E^\circ = 0.536\ V; \quad \Delta G^\circ = -51.5\ kJ\ mol^{-1}$$

$$I_2 + 2e^- \rightleftharpoons 2I^-; \quad E^\circ = 0.536\ V; \quad \Delta G^\circ = -103.0\ kJ\ mol^{-1}$$

It is vital to remember that, when half-reactions are added or subtracted, one should not add or subtract the corresponding E° values but rather nE°. (We shall return to this point later.)

Lists of standard reduction potentials are given in many books[85] and are extensively quoted throughout this text. Almost all lists now use the IUPAC sign conventions employed above, though some earlier American books (including, unfortunately, the classic early text on the subject[86] use the opposite sign convention. When standard reduction potentials are listed in sequence from the most negative to the most positive the strongest reducing agents are at the top of the list and a reducing agent should, in principle, be capable of reducing all oxidizing agents lying below it in the table. Conversely, the oxidizing agents are listed in order of *increasing* strength and a given oxidizing agent should be able to oxidize all reducing agents lying above it in the table. Such lists are an extremely compact way of summarizing a great deal of predictive information. For example a list of 100 independent reduction potentials enables the free energy change for $100 \times 99/2 = 4950$ reactions to be calculated and indicates the direction in which a hypothetical reaction would occur under appropriate conditions (which might involve the use of a catalyst).

When an element can exist in several oxidation states it is sometimes convenient to display the various reduction potentials diagramatically, the corresponding half-reactions under standard conditions being implied. Thus, in acidic aqueous solutions



Note that the value of $E^\circ(Fe^{3+}/Fe) = -0.04$ V is equivalent to $\{(2 \times -0.44) + 0.77\}/3$. Because the quantity nE° is used in these calculations (rather than E°) it is convenient to define the "volt equivalent" of a species; the volt equivalent of a compound or ion is the reduction potential of the species relative to the element in its standard state multiplied by the oxidation state of the element in the compound (including its sign). The oxidation state is the number of electrons that must be added to an atom of an element to regain electroneutrality when all other atoms in the compound (ion) have been removed as their "normal" ions. For example the oxidation state of Fe is +6 in FeO_4^{2-}:

$$FeO_4^{2-} \xrightarrow{-4O^{2-}} Fe^{6+} \xrightarrow{+6e^-} Fe$$

It follows that, in the above example, the volt equivalents of Fe^{2+} and Fe^{3+} are −0.88 and −0.11 respectively and that of FeO_4^{2-} is +6.49 {i.e. $(2 \times -0.44) + 0.77 + (3 \times 2.20)$}. This leads to $E^\circ(FeO_4^{2-}/Fe) = +1.08$ V.

The power of these various concepts in codifying and rationalizing the redox chemistry of the elements is illustrated for the case of nitrogen in the present section. Standard reduction potentials and plots of volt equivalents against oxidation state for other elements are presented in later chapters.

stronger reducing agent than H_2 (slope of tie-line −0.23 V) and NH_2OH is even stronger (slope −1.87 V). By contrast, the couple N_2O/NH_3OH^+ has virtually the same reducing power as H_2 (slope −0.05 V).

It also follows that, when three (or more) oxidation states lie approximately on a straight line in the volt-equivalent diagram, they tend to form an equilibrium mixture rather than a reaction going to completion (provided that the attainment of thermodynamic equilibrium is not hindered kinetically). This is because the slopes joining the several points are almost the same, so that E° for the various couples (and hence ΔG°) are the same; there is consequently approximately zero change in free energy and a balanced

[86] W. M. LATIMER, *The Oxidation States of the Elements and their Potentials in Aqueous Solutions*, 2nd edn., Prentice-Hall, New York, 1952, 392 pp.

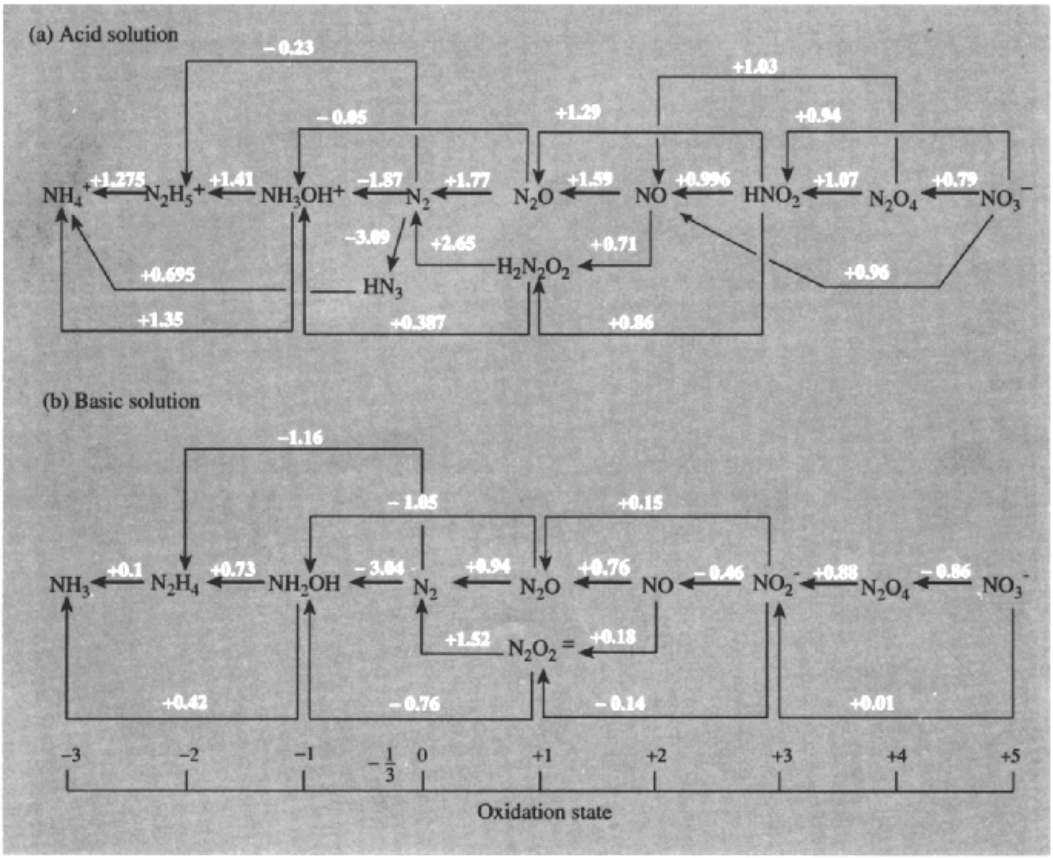

Figure 11.8 Oxidation states of nitrogen showing standard reduction potentials in volts: (a) in acid solution at pH 0, and (b) in basic solution at pH 14.

equilibrium is maintained between the several species. Indeed, the volt-equivalent diagram is essentially a plot of free energy versus oxidation state (as indicated by the right-hand ordinate of Fig. 11.9).

Two further points follow from these general considerations:

(a) a compound will tend to disproportionate into a higher and a lower oxidation state if it lies above the line joining the 2 compounds in these oxidation states, i.e. disproportionation is accompanied by a decrease in free energy and will tend to occur spontaneously if not kinetically hindered. Examples are the disproportionation of hydroxylamine in acidic solutions (slow) and alkaline solutions (fast):

$$4NH_3OH^+ \longrightarrow N_2O + 2NH_4^+ + 3H_2O + 2H^+$$

$$3NH_2OH \longrightarrow N_2 + NH_3 + 3H_2O$$

(b) Conversely, a compound can be formed by conproportionation of compounds in which the element has a higher and lower oxidation state if it lies below the line joining these two states. A particularly important example is the synthesis of $HN_3^{-\frac{1}{3}}$ by reacting $N_2^{-\mathrm{II}}H_5^+$ and $HN^{+\mathrm{III}}O_2$ (p. 432). It will be noted that the reduction potential of HN_3 (−3.09 V) is more negative than that of any other reducing agent in acidic aqueous solution so it is thermodynamically impossible to synthesize HN_3 by reduction of N_2 or any of its compounds in such media unless the reducing agent itself contains N (as does hydrazine).

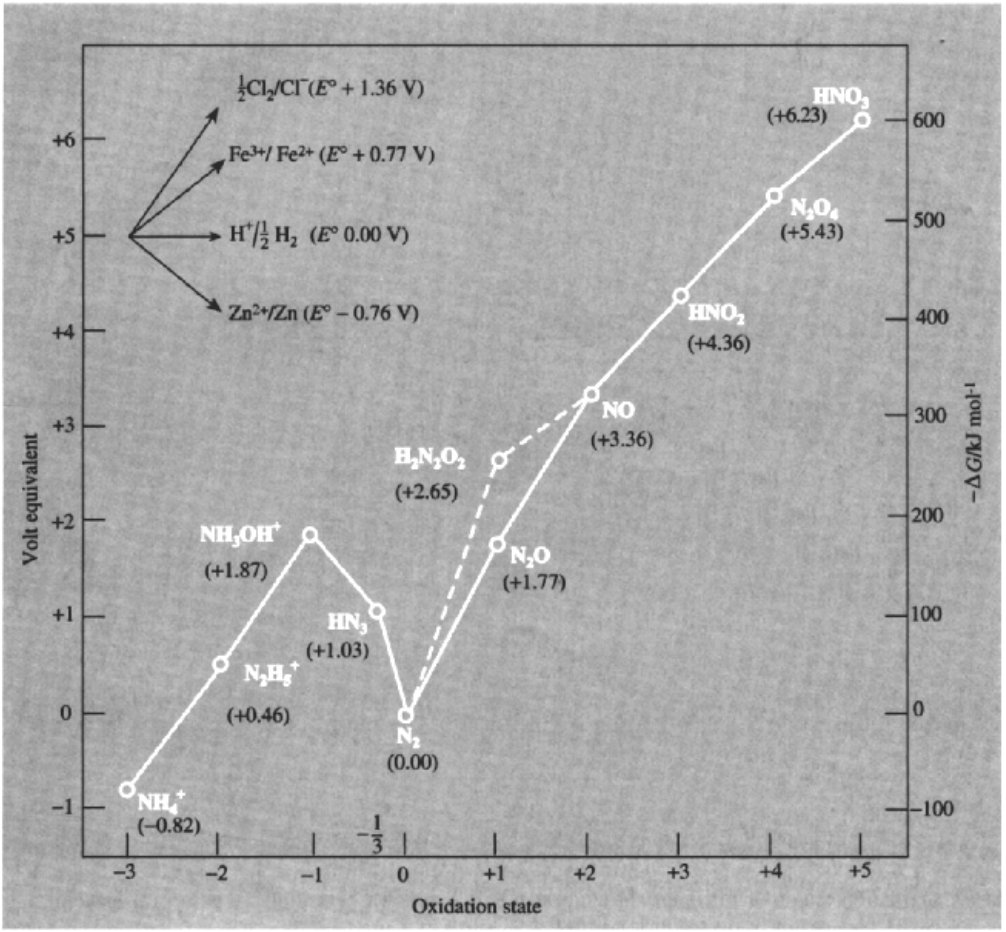

Figure 11.9 Plot of volt equivalent against oxidation state for various compounds or ions containing N in acidic aqueous solution. Note that values of $-\Delta G$ refer to N_2 as standard (zero) but are quoted per mol of N atoms and per mol of N_2; they refer to reactions in the direction (ox) + ne^- → (red). Slopes corresponding to some common oxidizing and reducing agents are included for comparison.

In basic solutions a different set of redox equilibria obtain and a different set of reduction potentials must be used. For example:

	$E°$/V
$N_2 + 4H_2O + 2e^- = 2NH_2OH + 2OH^-$	−3.04
$N_2 + 4H_2O + 4e^- = N_2H_4 + 4OH^-$	−1.16
$N_2O + 5H_2O + 4e^- = 2NH_2OH + 4OH^-$	−1.05
$N_2O_2^{2-} + 6H_2O + 4e^- = 2NH_2OH + 6OH^-$	−0.73
$NO_3^- + H_2O + 2e^- = NO_2^- + 2OH^-$	+0.01
$N_2H_4 + 4H_2O + 2e^- = 2NH_4^+ + 4OH^-$	+0.11
$2NH_2OH + 2e^- = N_2H_4 + 2OH^-$	+0.73

A more complete compilation is summarized in Fig. 11.8. It is instructive to use these data to derive a plot of volt equivalent versus oxidation state in basic solution and to compare this with Fig. 11.9 which refers to acidic solutions.

11.3.5 Nitrogen halides and related compounds [69]

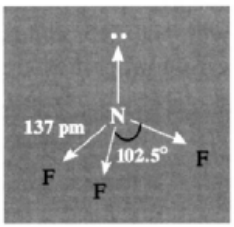
It is a curious paradox that NF_3, the most stable binary halide of N, was not prepared until 1928, more than 115 y after the highly unstable

NCl_3 was prepared in 1811 by P. L. Dulong (who lost three fingers and an eye studying its properties). Pure NBr_3 explodes even at $-100°$ and was not isolated until 1975[87] and NI_3 has not been prepared, though the explosive adduct $NI_3.NH_3$ was first made by B. Courtois in 1813 and several other ammines are known. In all, there are now 5 binary fluorides of nitrogen (NF_3, N_2F_4, *cis*- and *trans*-N_2F_2 and N_3F) and these, together with the cations NF_4^+ and $N_2F_3^+$ and various mixed halides, hydride halides and oxohalides are discussed in this section.

NF_3 was first prepared by Otto Ruff's group in Germany by the electrolysis of molten NH_4F/HF and this process is still used commercially. An alternative is the controlled fluorination of NH_3 over a Cu metal catalyst.

$$4NH_3 + 3F_2 \xrightarrow{Cu} NF_3 + 3NH_4F$$

NF_3 is a colourless, odourless, thermodynamically stable gas (mp $-206.8°$, bp $-129.0°$, $\Delta G^\circ_{298} - 83.3\,kJ\,mol^{-1}$). The molecule is pyramidal with an F–N–F angle of 102.5°, but the dipole moment (0.234 D) is only one-sixth of that of NH_3 (1.47 D) presumably because the N–F bond moments act in the opposite direction to that of the lone-pair moment:



The gas is remarkably unreactive (like CF_4) being unaffected by water or dilute aqueous acid or alkali; at elevated temperatures it acts as a fluorinating agent and with Cu, As, Sb or Bi in a flow reactor it yields N_2F_4 ($2NF_3 + 2Cu \rightarrow N_2F_4 + 2CuF$). As perhaps expected (p. 198) NF_3 shows little tendency to act as a ligand, though NF_4^+ is known[88] and also the surprisingly stable isoelectronic species ONF_3 (mp $-160°$, bp $-87.6°$):

$$NF_3 + 2F_2 + SbF_3 \xrightarrow{200°/100\ atm} [NF_4]^+[SbF_6]^-$$

$$2NF_3 + O_2 \xrightarrow[-196°]{\text{electric discharge/}} 2ONF_3$$

$$3FNO + 2IrF_6 \xrightarrow{20°} ONF_3 + 2[NO]^+[IrF_6]^-$$

ONF_3 was discovered independently by two groups in 1966.[89] Although isoelectronic with BF_4^-, CF_4 and NF_4^+ it has excited interest because of the short N–O distance (115.8 pm), which implies some multiple bonding, and the correspondingly long N–F distances (143.1 pm). Similar partial double bonding to O and highly polar bonds to F have also been postulated for the analogous ion $[OCF_3]^-$ in $Cs[OCF_3]$.[90]

FN_3 is one of the most explosive and thermally unstable covalent azides known. It can be prepared by reacting HN_3 with F_2 and is best handled as a gas at low pressure.[91] The molecular parameters (microwave) are N–F 144.4 pm, N_α–N_β 125.3 pm, N_α–N_ω 113.2 pm, and angles FNN 103.8°, NNN 170.9° (cf HN_3 p. 433) The species NF is known only as a ligand, in the octahedral complex $[ReF_5(NF)]$[92] the complex is made by treating ReF_4N or ReF_3N with XeF_2 and X-ray structural analysis revealed a linear Re–N–F group (178°) with N–F 126 pm.

Dinitrogen tetrafluoride, N_2F_4, is the fluorine analogue of hydrazine and exists in both the staggered (*trans*) C_{2h} and *gauche* C_2 conformations

[92] J. Fawcett, R. D. Peacock and D. R. Russell, *J. Chem. Soc., Dalton Trans.*, 567–71 (1987).

(p. 428). It was discovered in 1957 and is now made either by partial defluorination of NF_3 (see above) or by quantitative oxidation of NF_2H with alkaline hypochlorite:

$$(NH_2)_2CO(aq) \xrightarrow[(70\%\ \text{yield})]{F_2/N_2} NH_2CONF_2$$

$$\xrightarrow[(100\%\ \text{yield})]{\text{conc } H_2SO_4} NF_2H \xrightarrow[(100\%\ \text{yield})]{\text{NaOCl (pH 12)}} \tfrac{1}{2}N_2F_4$$

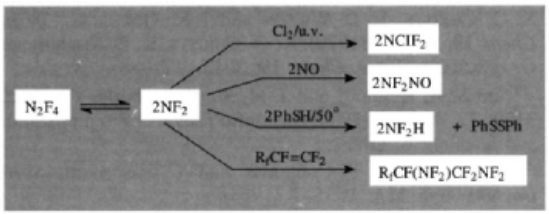
N_2F_4 is a colourless reactive gas (mp $-164.5°$, bp $-73°$, $\Delta G^\circ_{298} + 81.2\,\text{kJ mol}^{-1}$) which acts as a strong fluorinating agent towards many substances, e.g.:

$$SiH_4 + N_2F_4 \xrightarrow{25°} SiF_4 + N_2 + 2H_2$$

$$10Li + N_2F_4 \xrightarrow{-80 \text{ to } +250°} 4LiF + 2Li_3N$$

$$S + N_2F_4 \xrightarrow{110-140°} SF_4 + SF_5NF_2 + \ldots$$

It forms adducts with strong fluoride-ion acceptors such as AsF_5 which can be formulated as salts, e.g. $[N_2F_3]^+[AsF_6]^-$. However, its most intriguing property is an ability to dissociate at room temperature and above to give the free radical NF_2. Thus, when N_2F_4 is frozen out from the warm gas at relatively low pressures the solid is dark blue whereas when it is frozen out from the cold gas at moderate pressures it is colourless. At 150°C the equilibrium constant for the dissociation $N_2F_4 \rightleftharpoons 2NF_2$ is $K = 0.03$ atm and the enthalpy of dissociation is $83.2\,\text{kJ mol}^{-1}$.[93] Such a dissociation, which interprets much of the reaction chemistry of N_2F_4,[94] is reminiscent of the behaviour of N_2O_4 (p. 455) but is not paralleled in the chemistry of N_2H_4:

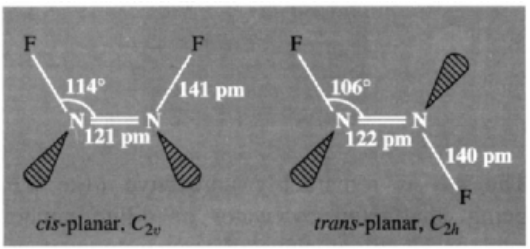


Dinitrogen difluoride, N_2F_2, was first identified in 1952 as a thermal decomposition product of the azide N_3F and it also occurs in small yield during the electrolysis of NH_4F/HF (p. 439), and in the reactions of NF_3 with Hg or with NF_3 in a Cu reactor (p. 439). Fluorination of NaN_3 gives good yields on a small scale but the compound is best prepared by the following reaction sequence:

$$KF + NF_2H \xrightarrow{-80°} KF.NF_2H$$

$$\xrightarrow[\sim 100\%\ \text{yield}]{20°} N_2F_2 + KHF_2$$

All these methods give mixtures of the *cis*- and *trans*-isomers; these are thermally interconvertible but can be separated by low-temperature fractionation. The *trans*-form is thermodynamically more unstable than the *cis*-form but it can be stored in glass vessels whereas the *cis*-form reacts completely within 2 weeks to give SiF_4 and N_2O. *Trans*-N_2F_2 can be prepared free of the *cis*-form by the low-temperature reaction of N_2F_4 with $AlCl_3$ or MCl_2 (M = Mn, Fe, Co, Ni, Sn); thermal isomerization of *trans*-N_2F_2 at 70–100° yields an equilibrium mixture containing ~90% *cis*-N_2F_2 (ΔH_{isom} $12.5\,\text{kJ mol}^{-1}$). Pure *cis*-N_2F_2 can be obtained by selective complexation with AsF_5; only the *cis*-form reacts at room temperature to give $[N_2F]^+[AsF_6]^-$ and this, when treated with NaF/HF, yields pure *cis*-N_2F_2. Some characteristic properties are listed below.



Isomer	MP/°C	BP/°C	ΔH_f°/kJ mol^{-1}	μ/Debye
cis-N_2F_2	< −195	−105.7	69.5	0.18
trans-N_2F_2	−172	−111.4	82.0	0.00

[93] F. H. JOHNSON and C. B. COLBURN, *J. Am. Chem. Soc.* **83**, 3043–7 (1961).

[94] C. L. BAUMGARDNER and E. L. LAWTON, *Acc. Chem. Res.* **7**, 14–20 (1974).

Several mixed halides and hydrohalides of nitrogen are known but they tend to be unstable, difficult to isolate pure, and of little interest. Examples are[69] $NClF_2$, NCl_2F, $NBrF_2$, NF_2H, NCl_2H and $NClH_2$. The cation $NH_2F_2^+$ has also been prepared as its salts with AsF_6^- and SbF_6^-.[95]

The well known compound NCl_3 is a dense, volatile, highly explosive liquid (mp −40°, bp +71°, d(20°) 1.65 g cm^{-3}, μ 0.6 D) with physical properties which often closely resemble those of CCl_4 (p. 301). It is much less hazardous as a dilute gas and, indeed, is used industrially on a large scale for the bleaching and sterilizing of flour; for this purpose it is prepared by electrolysing an acidic solution of NH_4Cl at pH 4 and the product gas is swept out of the cell by means of a flow of air for immediate use. NCl_3 is rapidly hydrolysed by moisture and in alkaline solution can be used to prepare ClO_2:

$$NCl_3 + 3H_2O \longrightarrow NH_3 + 3HOCl \text{ (bleach, etc.)}$$

$$NCl_3 + 3H_2O + 6NaClO_2 \longrightarrow 6ClO_2 + 3NaCl + 3NaOH + NH_3$$

$$2NCl_3 + 6NaClO_2 \longrightarrow 6ClO_2 + 6NaCl + N_2$$

The elusive NBr_3 was finally prepared as a deep-red, very temperature-sensitive, volatile solid by the low-temperature bromination of bistrimethylsilylbromamine with BrCl:

$$(Me_3Si)_2NBr + 2BrCl \xrightarrow{\text{pentane/}-87^\circ} NBr_3 + 2MeSiCl$$

It reacts instantly with NH_3 in CH_2Cl_2 solution at −87° to give the dark-violet solid $NBrH_2$; under similar conditions I_2 yields the red-brown solid NBr_2I. The ligands NCl and NBr have been characterized in the purple complexes $[ReF_5(NCl)]$ (mp ~80°, N–Cl 156 pm, angle Re–N–Cl 177°) and $[ReF_5(NBr)]$ (mp ~140°); The preparation parallels that of $[ReF_5(NF)]$ (p. 439), the reagent XeF_2 being replaced by ClF_3 and BrF_3, respectively.[92] The complexes $[VCl_3(NX)]$ (X = Cl, Br, I) have also been characterized.[96]

Pure NI_3 has not been isolated, but the structure of its well-known extremely shock-sensitive adduct with NH_3 has been elucidated — a feat of considerable technical virtuosity.[97] Unlike the volatile, soluble, molecular solid NCl_3, the involatile, insoluble compound $[NI_3.NH_3]_n$ has a polymeric structure in which tetrahedral NI_4 units are corner-linked into infinite chains of –N–I–N–I– (215 and 230 pm) which in turn are linked into sheets by I–I interactions (336 pm) in the c-direction; in addition, one I of each NI_4 unit is also loosely attached to an NH_3 (253 pm) that projects into the space between the sheets of tetrahedra. The structure resembles that of the linked SiO_4 units in chain metasilicates (p. 349). A further interesting feature is the presence of linear or almost linear N–I–N groupings which suggest the presence of 3-centre, 4-electron bonds (pp. 63, 64) characteristic of polyhalides and xenon halides (pp. 835–8, 897).

Nitrogen forms two series of oxohalides — the nitrosyl halides XNO and the nitryl halides XNO_2. There are also two halogen nitrates $FONO_2$ (bp −46°) and $ClONO_2$ (bp 22.3°), but these do not contain N–X bonds and can be considered as highly reactive derivatives of nitric acid, from which they can be prepared by direct halogenation:

$$HNO_3 + F_2 \longrightarrow FONO_2 + HF$$

$$HNO_3 + ClF \longrightarrow ClONO_2 + HF$$

The nitrosyl halides are reactive gases that feature bent molecules; they can be made by direct halogenation of NO with X_2, though fluorination of NO with AgF_2 has also been used and ClNO can be more conveniently made by passing N_2O_4 over moist KCl:

$$2NO + X_2 \longrightarrow 2XNO$$

[95] K. O. CHRISTE, *Inorg. Chem.* **14**, 2821–4 (1975).

[96] J. STRÄHLE and K. DEHNICKE, *Z. anorg. allg. Chem.* **338**, 287–98 (1965). K. DEHNICKE and W. LIEBETT, *Z. anorg. allg. Chem.* **453**, 9–13 (1979).

[97] J. JANDER, Recent chemistry and structure investigation of NI_3, NBr_3, NCl_3 and related compounds, *Adv. Inorg. Chem. Radiochem.* **19**, 1–63 (1976).

$$NO + AgF_2 \longrightarrow FNO + AgF$$

$$N_2O_4 + KCl \longrightarrow ClNO + KNO_3$$

Some physical properties are in Table 11.5. FNO is colourless, ClNO orange-yellow and BrNO red. The compounds, though generally less reactive than the parent halogens, are nevertheless extremely vigorous reagents. Thus FNO fluorinates many metals ($nFNO + M \rightarrow MF_n + nNO$) and also reacts with many fluorides to form salt-like adducts such as $NOAsF_6$, $NOVF_6$, and $NOBF_4$. ClNO acts similarly and has been used as an ionizing solvent to prepare complexes such as $NOAlCl_4$, $NOFeCl_4$, $NOSbCl_6$, and $(NO)_2SnCl_6$.[98] Aqueous solutions of XNO are particularly potent solvents for metals (like aqua regia, HNO_3/HCl) since the HNO_2 formed initially, reacts to give HNO_3:

$$XNO + H_2O \longrightarrow HNO_2 + HX$$

$$3HNO_2 \longrightarrow HNO_3 + 2NO + H_2O$$

Alkaline solutions contain a similar mixture:

$$4XNO + 3H_2O \longrightarrow HNO_3 + HNO_2 + 2NO + 4HX$$

$$4XNO + 6NaOH \longrightarrow NaNO_3 + NaNO_2 + 2NO + 4NaX + 3H_2O$$

With alcohols, however, the reaction stops at the nitrite stage:

$$XNO + ROH \longrightarrow RONO + HX$$

Nitryl fluoride and chloride, XNO_2, like their nitrosyl analogues, are reactive gases; they feature planar molecules, analogous to the isoelectronic nitrate anion, NO_3^-. Some physical properties are in Table 11.6. FNO_2 can be prepared by direct reaction of F_2 with NO_2 or $NaNO_2$ or by fluorination of NO_2 using CoF_3 at 300°. $ClNO_2$ can not be made by direct chlorination of NO_2 but is conveniently synthesized in high yield by reacting anhydrous nitric acid with chlorosulfuric acid at 0°C:

$$HNO_3 + ClSO_3H \longrightarrow ClNO_2 + H_2SO_4$$

Reactions of XNO_2 often parallel those of XNO; e.g. FNO_2 readily fluorinates many metals and reacts with the fluorides of non-metals to give nitryl "salts" such as NO_2BF_4, NO_2PF_6, etc. Likewise, $ClNO_2$ reacts with many chlorides in liquid Cl_2 to give complexes such as NO_2SbCl_6. Hydrolysis yields aqueous solutions of nitric and hydrochloric acids, whereas ammonolysis in liquid ammonia yields chloramine and ammonium nitrite:

$$ClNO_2 + H_2O \longrightarrow \{HOCl + HNO_2\} \longrightarrow HNO_3 + HCl$$

$$ClNO_2 + 2NH_3 \longrightarrow ClNH_2 + NH_4NO_2$$

Table 11.5 Some physical properties of XNO[a]

Property	FNO	ClNO	BrNO
MP/°C	−132.5	−59.6	−56
BP/°C	−59.9	−6.4	~0
ΔH_f°(298 K)/kJ mol^{-1}	−66.5	+51.7	+82.2
ΔG_f°(298 K)/kJ mol^{-1}	−51.1	+66.0	+82.4
Angle X–N–O	110°	113°	117°
Distance N–O/pm	113	114	115
Distance N–X/pm	152	198	214
μ/D	1.81	0.42	—

[a]BrNO dissociates reversibly into NO and Br, the extent of dissociation being ~7% at room temperature and 1 atm pressure. A similar reversible dissociation occurs with ClNO at higher temperatures.

Table 11.6 Some physical properties of XNO_2

Property	FNO_2	$ClNO_2$	Property	FNO_2	$ClNO_2$

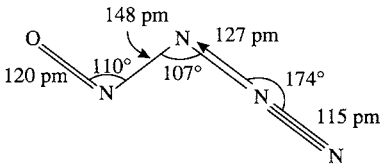
11.3.6 Oxides of nitrogen

Nitrogen is unique among the elements in forming no fewer than 8 molecular oxides, 3 of which are paramagnetic and all of which are thermodynamically unstable with respect to decomposition into N_2 and O_2. In addition there is evidence for fugitive species such as nitryl azide, N_3NO_2, but this decomposes rapidly below room temperature[99] and will not be considered further. Three of the oxides (N_2O, NO and NO_2) have been known for over 200 y and were, in fact, amongst the very first gaseous compounds to be isolated and identified (J. Priestley and others in the 1770s). The most recent addition, nitrosyl azide N_4O (p. 433), was isolated in 1993 as a pale yellow solid whose vibration spectrum at −110° is consistent with the optimized computed structure (3).[84]



(3)

The physiological effects of N_2O (laughing gas, anaesthetic) and NO_2 (acrid, corrosive fumes) have been known from the earliest days, and the environmental problems of "NO_x" from automobile exhaust fumes and as a component in photochemical smog are well known in all industrial countries.[100,101] NO is now recognized as a key neuro transmitter in humans and other animals and its biologically triggered synthesis is implicated in cardiovascular pharmacology, hypertension, impotence, immunology and other vital functions.[102] NO and NO_2 are important in the commercial production of nitric acid (p. 466) and nitrate fertilizers and N_2O_4 has been used extensively as the oxidizer in rocket fuels for space missions (p. 429).

The oxides of nitrogen played an important role in exemplifying Dalton's law of multiple proportions which led up to the formulation of his atomic theory (1803–8), and they still pose some fascinating problems in bonding theory. Their formulae, molecular structure, and physical appearance are briefly summarized in Table 11.7 and each compound is discussed in turn in the following sections.

Nitrous oxide (Dinitrogen monoxide), N_2O

Nitrous oxide can be made by the careful thermal decomposition of molten NH_4NO_3 at about 250°C:

$$NH_4NO_3 \xrightarrow{\Delta} N_2O + 2H_2O$$

Although the reaction has the overall stoichiometry of a dehydration it is more complex than this and involves a mutual redox reaction between N^{-III} and N^{V}. This is at once explicable in terms of the volt-equivalent diagram in Fig. 11.9 which also interprets why NO and N_2 are formed simultaneously as byproducts. It is probable that the mechanism involves dissociation of NH_4NO_3 into NH_3 and HNO_3, followed by autoprotolysis of HNO_3 to give NO_2^+, which is the key intermediate:

$$NH_4NO_3 \rightleftharpoons NH_3 + HNO_3$$

$$2HNO_3 \rightleftharpoons NO_2^+ + H_2O + NO_3^-$$

$$NH_3 + NO_2^+ \longrightarrow \{H_3NNO_2\}^+$$

$$\longrightarrow NNO + H_3O^+, \text{ etc.}$$

Consistent with this ^{15}NNO can be made from $^{15}NH_4NO_3$, and $N^{15}NO$ from $NH_4{}^{15}NO_3$. Alternative preparative routes (Fig. 11.9) are the reduction of aqueous nitrous acid with either hydroxylamine or hydrogen azide:

Table 11.7 The oxides of nitrogen (See also structure 3, p. 443)

Formula	Name	Structure	Description
N_2O	Dinitrogen monoxide (nitrous oxide)	 linear ($C_{\infty v}$)	Colourless gas (bp −88.5°) (cf. isoelectronic CO_2, NO_2^+, N_3^-)
NO	(Mono) nitrogen monoxide		Colourless paramagnetic gas (bp −151.8°); liquid and solid are also colourless when pure
N_2O_3	Dinitrogen trioxide	 planar (C_s)	Blue solid (mp −100.7°), dissociates reversibly in gas phase into NO and NO_2
NO_2	Nitrogen dioxide	 bent (C_{2v})	Brown paramagnetic gas, dimerizes reversibly to N_2O_4
N_2O_4	Dinitrogen tetroxide	 planar D_{2h}	Colourless liquid (mp −11.2°) dissociates reversibly in gas phase to NO_2
N_2O_5	Dinitrogen pentoxide	 $[NO_2]^+[NO_3]^-$ planar C_{2v} ($\sim D_{2h}$)	Colourless ionic solid; sublimes at 32.4° to unstable molecular gas (angle N–O–N ~180°)
NO_3	Nitrogen trioxide	 planar (D_{3h})	Unstable paramagnetic radical

$$HNO_2 + NH_2OH \xrightarrow{aq} N_2O + 2H_2O$$

$$HNO_2 + HN_3 \xrightarrow{aq} N_2O + N_2 + H_2O$$

Thermal decomposition of nitramide, H_2NNO_2, or hyponitrous acid $H_2N_2O_2$ (both of which have the empirical formula $N_2O.H_2O$) have also been used. The mechanisms of these and other reactions involving simple inorganic compounds of N have been reviewed.[103]

[103] G. STEDMAN, *Adv. Inorg. Chem. Radiochem.* **22**, 114–70 (1979). See also F. T. BONNER and N.-Y. WANG, *Inorg. Chem.* **25**, 1858–62 (1986).

However, though N_2O can be made in this way it is not to be regarded as the anhydride of hyponitrous acid since $H_2N_2O_2$ is not formed when N_2O is dissolved in H_2O (a similar relation exists between CO and formic acid).

Nitrous oxide is a moderately unreactive gas comprised of linear unsymmetrical molecules, as expected for a 16-electron triatomic species (p. 433). The symmetrical structure N–O–N is precluded on the basis of orbital energetics. Some physical properties are in Table 11.8: it will be seen that the N–N and N–O distances are

Table 11.8 Some physical properties of N_2O

MP/°C	−90.86	μ/D	0.166
BP/°C	−88.48	Distance (N–N)/pm	112.6
ΔH_f°(298 K)/kJ mol^{-1}	82.0	Distance (N–O)/pm	118.6
ΔG_f°(298 K)/kJ mol^{-1}	104.2		

both short and calculations[104] give the bond orders as N–N 2.73 and N–O 1.61. N_2O is thermodynamically unstable and when heated above ~600°C it dissociates by fission of the weaker bond ($N_2O \rightarrow N_2 + \frac{1}{2}O_2$). However, the reaction is much more complex than this simple equation might imply and the process involves a "forbidden" singlet-triplet transition in which electron spin is not conserved.[105] The activation energy for the process is high (~250 kJ mol^{-1}) and at room temperature N_2O is relatively inert: e.g. it does not react with the halogens, the alkali metals or even ozone. At higher temperatures reactivity increases markedly: H_2 gives N_2 and H_2O; many other non-metals (and some metals) react to form oxides, and the gas supports combustion. Perhaps its most remarkable reaction is with molten alkali metal amides to yield azides, the reaction with $NaNH_2$ being the commercial route to NaN_3 and hence all other azides (p. 433):

$$NaNH_2(l) + N_2O(g) \xrightarrow{200^\circ} NaN_3 + H_2O(g)$$

$$NaNH_2 + H_2O \longrightarrow NaOH + NH_3(g)$$

It is also notable that N_2O (like N_2 itself) can act as a ligand by displacing H_2O from the aquo complex $[Ru(NH_3)_5(H_2O)]^{2+}$:[106]

$$[Ru(NH_3)_5(H_2O)]^{2+} + N_2O(aq) \longrightarrow [Ru(NH_3)_5(N_2O)]^{2+} + H_2O$$

The formation constant K is 7.0 mol^{-1} l for N_2O and 3.3×10^4 mol^{-1} l for N_2.

[106] J. N. ARMOR and H. TAUBE, *J. Am. Chem. Soc.* **91**, 6874–6 (1969). A. A. DIAMANTIS and G. J. SPARROW, *J. Chem. Soc., Chem. Commun.*, 819–20 (1970). J. N. ARMOR and H. TAUBE, *J. Chem. Soc., Chem. Commun.*, 287–8 (1971).

Notwithstanding the fascinating reaction chemistry of N_2O it is salutory to remember that its largest commercial use is as a propellant and aerating agent for "whipped" ice-cream — this depends on its solubility under pressure in vegetable fats coupled with its non-toxicity in small concentrations and its absence of taste. It was also formerly much used as an anaesthetic.

Nitric oxide (Nitrogen monoxide), NO

Nitric oxide is the simplest thermally stable odd-electron molecule known and, accordingly, its electronic structure and reaction chemistry have been very extensively studied.[107] The compound is an intermediate in the production of nitric acid and is prepared industrially by the catalytic oxidation of ammonia (p. 466). On the laboratory scale it can be synthesized from aqueous solution by the mild reduction of acidified nitrites with iodide or ferrocyanide or by the disproportionation of nitrous acid in the presence of dilute sulfuric acid:

$$KNO_2 + KI + H_2SO_4 \xrightarrow{aq} NO + K_2SO_4 + H_2O + \tfrac{1}{2}I_2$$

$$KNO_2 + K_4[Fe(CN)_6] + 2MeCO_2H \longrightarrow NO + K_3[Fe(CN)_6] + H_2O + 2MeCO_2K$$

$$6NaNO_2 + 3H_2SO_4 \longrightarrow 4NO + 2HNO_3 + 2H_2O + 3Na_2SO_4$$

The dry gas has been made by direct reduction of a solid mixture of nitrite and nitrate with chromium(III) oxide ($3KNO_2 + KNO_3 + Cr_2O_3 \rightarrow 4NO + 2K_2CrO_4$) but is now more conveniently obtained from a cylinder.

Nitric oxide is a colourless, monomeric, paramagnetic gas with a low mp and bp (Table 11.9). It is thermodynamically unstable and decomposes into its elements at elevated temperatures (1100–1200°C), a fact which militates against its direct synthesis from N_2 and O_2. At high pressures and moderate temperatures

[107] pp. 323–5 of ref. 69.

Table 11.9 Some physical properties of NO

MP/°C	−163.6	μ/D	0.15
BP/°C	−151.8	Distance (N–O)/pm	115
ΔH_f° (298 K)/ kJ mol^{-1}	90.2	Ionization energy/eV	9.23
ΔG_f° (298 K)/ kJ mol^{-1}	86.6	Ionization energy/ kJ mol^{-1}	890.6

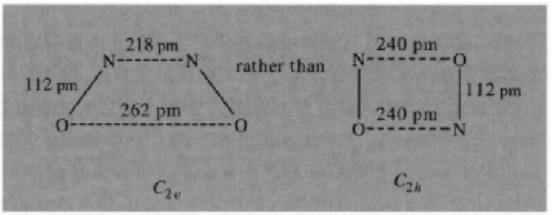
(~50°) it rapidly disproportionates:

$$3NO \longrightarrow N_2O + NO_2;\ -\Delta H = 3 \times 51.8\,\text{kJ mol}^{-1}$$
$$-\Delta G = 3 \times 34.7\,\text{kJ mol}^{-1}$$

However, when the gas is occluded by zeolites the disproportionation takes a different course:

$$4NO \longrightarrow N_2O + N_2O_3;\ -\Delta H = 4 \times 48.8\,\text{kJ mol}^{-1}$$
$$-\Delta G = 4 \times 25.7\,\text{kJ mol}^{-1}$$

The molecular orbital description of the bonding in NO is similar to that in N_2 or CO (p. 927) but with an extra electron in one of the π^* antibonding orbitals. This effectively reduces the bond order from 3 to ~2.5 and accounts for the fact that the interatomic N–O distance (115 pm) is intermediate between that in the triple-bonded NO^+ (106 pm) and values typical of double-bonded NO species (~120 pm). It also interprets the very low ionization energy of the molecule (9.25 eV, compared with 15.6 eV for N_2, 14.0 eV for CO, and 12.1 eV for O_2). Similarly, the notable reluctance of NO to dimerize can be related both to the geometrical distribution of the unpaired electron over the entire molecule and to the fact that dimerization to O=N—N=O leaves the total bond order unchanged ($2 \times 2.5 = 5$). When NO condenses to a liquid, partial dimerization occurs, the *cis*-form being more stable than the *trans*-. The pure liquid is colourless, not blue as sometimes stated: blue samples owe their colour to traces of the intensely coloured N_2O_3.[108] Crystalline nitric oxide is also colourless (not blue) when pure,[108] and X-ray diffraction data are best interpreted in terms of weak association into dimeric units. It seems probable that the dimers adopt the *cis*-(C_{2v}) structure[109] rather than the rectangular C_{2h} structure which was at one time favoured,[110] i.e.:



In either case each dimer has two possible orientations, and random disorder between these accounts for the residual entropy of the crystal (6.3 J mol^{-1} of dimer). More recently[111] an asymmetric dimer  has been characterized; this forms as a red species when NO is condensed in the presence of polar molecules such as HCl or SO_2, or Lewis acids such as BX_3, SiF_4, $SnCl_4$ or $TiCl_4$. Reaction of NO with either $[Pt(PPh_3)_3]$ or $[Pt(PPh_3)_4]$ yields $[Pt(NO)_2(PPh_3)_2]$ which has been shown by X-ray diffraction analysis to be an unstable planar *cis*-hyponitrite complex, $[(PPh_3)_2Pt—ON=NO]$, with an N=N distance of 121 pm and N–O 132 and 139 pm.[112]

The reactivity of NO towards atoms, free radicals, and other paramagnetic species has been much studied, and the chemiluminescent reactions with atomic N and O are important in assaying atomic N (p. 414). NO reacts rapidly with molecular O_2 to give brown NO_2, and this gas is the normal product of reactions which produce NO if these are carried out in air. The oxidation is unusual in following third-order reaction kinetics and, indeed, is the classic

[108] J. MASON, *J. Chem. Educ.* **52**, 445–7 (1975).

[111] J. R. OLSEN and J. LAANE, *J. Am. Chem. Soc.* **100**, 6948–55 (1978).

[112] S. BHADURI, B. F. G. JOHNSON, A. PICKARD, P. R. RAITHBY, G. M. SHELDRICK and C. I. ZUCCARO, *J. Chem. Soc., Chem. Commun.*, 354–5 (1977).

example of such a reaction (M. Bodenstein, 1918). The reaction is also unusual in having a negative temperature coefficient, i.e. the rate becomes progressively slower at higher temperatures. For example the rate drops by a factor of 2 between room temperature and 200°. This can be accounted for by postulating that the mechanism involves the initial equilibrium formation of an unstable dimer which then reacts with oxygen:

$$2NO \rightleftharpoons N_2O_2 \xrightarrow{O_2} 2NO_2$$

As the equilibrium concentration of N_2O_2 decreases rapidly with increase in temperature the decrease in rate is explained. However alternative mechanisms have also been suggested.[107]

Nitric oxide reacts with the halogens to give XNO (p. 441). Some other facile reactions are listed below:

$$ClNO_2 + NO \longrightarrow ClNO + NO_2$$

(?Cl transfer or O transfer)

$$NCl_3 + 2NO \longrightarrow ClNO + N_2O + Cl_2$$

(stepwise at $-150°$)

$$XeF_2 + 2NO \longrightarrow 2FNO + Xe$$

(occurs stepwise; also with XeF_4)

$$I_2O_5 + 5NO \longrightarrow \tfrac{5}{2}N_2O_4 + I_2$$

(N_2O_5 is also produced)

Reactions with sulfides, polysulfides, sulfur oxides and the oxoacids of sulfur are complex and the products depend markedly on reaction conditions (see also p. 745 for blue crystals in chamber acid). Some examples are:

$$SO_2 + 2NO \longrightarrow N_2O + SO_3$$

$$2SO_3 + NO \longrightarrow (SO_3)_2NO$$

$$2H_2SO_3 + 2NO \longrightarrow 2H_2SO_3NO \xrightarrow{-H_2SO_3}$$

$$H_2SO_3(NO)_2 \longrightarrow N_2O + H_2SO_4$$

$$K_2SO_3(aq) + NO \xrightarrow{0°}$$

$$K_2[ONSO_3] \xrightarrow{NO} K_2[ONSO_3]$$

radical anion

NO white crystals

Under alkaline conditions disproportionation reactions predominate. Thus with Na_2O the dioxonitrate(II) first formed, disproportionates into the corresponding nitrite(III) and dioxodinitrate(*N*–*N*)(I) :

$$4Na_2O + 4N^{II}O \xrightarrow{100°C} 4Na_2N^{II}O_2 \longrightarrow$$

$$2Na_2O + 2NaN^{III}O_2 + Na_2N_2^{I}O_2$$

With alkali metal hydroxides, both N_2O and N_2 are formed in addition to the nitrite:

$$2MOH + 4N^{II}O \longrightarrow 2MN^{III}O_2 + N_2^{I}O + H_2O$$

$$4MOH + 6N^{II}O \longrightarrow 4MN^{III}O_2 + N_2^{(0)} + 2H_2O$$

Nitric oxide complexes. NO readily reacts with many transition metal compounds to give nitrosyl complexes and these are also frequently formed in reactions involving other oxo-nitrogen species. Classic examples are the "brown-ring" complex $[Fe(H_2O)_5NO]^{2+}$ formed during the qualitative test for nitrates, Roussin's red and black salts (p. 1094), and sodium nitroprusside, $Na_2[Fe(CN)_5NO].2H_2O$. The field has been extensively reviewed[113–115] and only the salient features need be summarized here. A variety of preparative routes is available (see Panel). Most nitrosyl complexes are highly coloured — deep reds, browns, purples, or even black. Apart from the intrinsic interest in the structure and bonding of these compounds there

Synthetic Routes to NO Complexes[114]

The coordination chemistry of NO is often compared to that of CO but, whereas carbonyls are frequently prepared by reactions involving CO at high pressures and temperatures, this route is less viable for nitrosyls because of the thermodynamic instability of NO and its propensity to disproportionate or decompose under such conditions (p. 446). Nitrosyl complexes can sometimes be made by transformations involving pre-existing NO complexes, e.g. by ligand replacement, oxidative addition, reductive elimination or condensation reactions (reductive, thermal or photolytic). Typical examples are:

$$[Mn(CO)_3(NO)(PPh_3)] + PPh_3 \longrightarrow [Mn(CO)_2(NO)(PPh_3)_2] + CO$$

$$2[Cr(\eta^5\text{-}C_5H_5)Cl(NO)_2] \xrightarrow{BH_4^-} [\{Cr(\eta^2\text{-}C_5H_5)(NO)_2\}_2]$$

$$2[Mn(CO)_4(NO)] \xrightarrow{h\nu} [Mn_2(CO)_7(NO)_2]$$

$$[\{Mn(\eta^5\text{-}C_5H_5)(CO)(NO)\}_2] \xrightarrow{h\nu} [Mn_3(\eta^5\text{-}C_5H_5)_3(NO)_4]$$

Syntheses which *increase* the number of coordinated NO molecules can be classified into more than a dozen types, of which only the first three use free NO gas.

1. *Addition of NO to coordinatively unsaturated complexes:*

$$[CoCl_2L_2] + NO \longrightarrow [CoCl_2L_2(NO)]$$

$$[Co(OPPh_3)_2X_2] + 2NO \longrightarrow [Co(NO)_2(OPPh_3)_2X_2]$$

2. *Substitution (ligand replacement)*

Very frequently in these reactions 2NO replace 3CO. Alternatively, 1NO can replace 2CO with simultaneous formation of a metal-metal bond, or 1NO can replace CO + a halogen atom:

$$[Co(CO)_3(NO)] + 2NO \longrightarrow [Co(NO)_3] + 3CO$$

$$[Fe(CO)_5] + 2NO \longrightarrow [Fe(CO)_2(NO)_2] + 3CO$$

$$[Cr(CO)_6] + 4NO \longrightarrow [Cr(NO)_4] + 6CO$$

$$[CO(\eta^5\text{-}C_5H_5)(CO)_2] + NO \longrightarrow \tfrac{1}{2}[\{Co(\eta^5\text{-}C_5H_5)(NO)\}_2] + 2CO$$

$$[Mn(CO)_5I] + 3NO \longrightarrow [Mn(CO)(NO)_3] + 4CO + \{I\}$$

$$\tfrac{1}{2}[\{Mn(CO)_4I\}_2] + 3NO \longrightarrow [Mn(CO)(NO)_3] + 3CO + \{I\}$$

3. *Reductive nitrosylation* (cf. $MF_6 + NO \rightarrow NO^+MF_6^-$ for Mo, Tc, Re, Ru, Os, Ir, Pt)

$$CoCl_2 + 3NO + B + ROH \longrightarrow \tfrac{1}{2}[\{CoCl(NO)_2\}_2] + BH^+ + RONO$$

where B is a proton acceptor such as an alkoxide or amine.

4. *Addition of or substitution by NO^+*

This method uses $NOBF_4$, $NOPF_6$, or $NO[HSO_4]$ in MeOH or MeCN, e.g.:

$$[Rh(CNR)_4]^+ + NO^+ \longrightarrow [Rh(CNR)_4(NO)]^{2+}$$

$$[Ir(CO)ClL_2] + NO^+ \longrightarrow [Ir(CO)ClL_2(NO)]^+$$

$$[Ni(CO)_2L_2] + NO^+ \longrightarrow [Ir(CO)L_2(NO)]^+ + CO$$

$$[Cr(CO)_4(diphos)] + 2NO^+ \xrightarrow{MeCN} [Cr(NO)_2(MeCN)_4]^{2+} + 4CO + diphos$$

5. *Oxidative addition of XNO*

The reaction may occur with either coordinatively unsaturated or saturated complexes, e.g.:

$$[PtX_4]^{2-} + ClNO \longrightarrow [PtCl(NO)(X)_4]^{2-} (X = Cl, CN, NO_2)$$

Panel continues

$$[Ni(PPh_3)_4] + ClNO \longrightarrow [Ni(Cl)(NO)(PPh_3)_2] + 2PPh_3$$

6. *Reaction of metal hydride complexes with N-nitrosoamides,* e.g. *N*-methyl-*N*-nitrosourea:

$$[Mn(CO)_5H] + MeN(NO)CONH_2 \longrightarrow [Mn(CO)_4(NO)] + CO + MeNHCONH_2$$

7. *Transfer of coordinated NO* (especially from dimethylglyoximate complexes)

$$[Co(dmg)_2(NO)] + [MClL_n] \longrightarrow [CoCl(dmg)_2] + [M(NO)L_n]$$

$$[Ru(NO)_2(PPh_3)_2] + [RuCl_2(PPh_3)_3] \xrightarrow[\text{dust}]{Zn} 2[RuCl(NO)(PPh_3)_2] + PPh_3$$

8. *Use of NH_2OH in basic solution* (especially for cyano complexes)

The net transformation can be considered as the replacement of CN^- (or X^-) by NO^- and the reaction can be formally represented as

$$2NH_2OH \longrightarrow NH_3 + H_2O + \{NOH\} \longrightarrow NO^- + H^+(\text{removed by base})$$

Examples are:

$$[Ni(CN)_4]^{2-} + 2NH_2OH \xrightarrow{MOH} [Ni(CN)_3(NO)]^{2-} + NH_3 + 2H_2O + MCN$$

$$[Cr(CN)_6]^{3-} + 2NH_2OH \xrightarrow{MOH} [Cr(CN)_5(NO)]^{3-} + NH_3 + 2H_2O + MCN$$

9. *Use of acidified nitrites* (i.e. $NO_2^- + 2H^+ \longrightarrow NO^+ + H_2O$), e.g.:

$$K[Fe(CO)_3(NO)] + KNO_2 + CO_2 + H_2O \longrightarrow [Fe(CO)_2(NO)_2] + 2KHCO_3$$

$$Na[Fe(CO)_4H] + 2NaNO_2 + 3MeCO_2H \longrightarrow [Fe(CO)_2(NO)_2] + 2CO + 2H_2O + 3MeCO_2Na$$

10. *Use of (acidified) nitrites RONO* (i.e. $RONO + H^+ \rightleftharpoons NO^+ + ROH$) e.g.:

$$[Fe(CO)_3(PPh_3)_2] + RONO + H^+ \longrightarrow [Fe(CO)_2(NO)(PPh_3)_2]^+ + CO + ROH$$

Alternatively in aprotic solvents such as benzene:

$$[\{Mn(CO)_4(PPh_3)\}_2] \xrightarrow{RONO} 2[Mn(CO)_3(NO)(PPh_3)] + 2CO$$

11. *Use of concentrated nitric acid* (i.e. $2HNO_3 \rightleftharpoons NO^+ + NO_3^- + H_2O$)

Some of these reactions result, essentially, in the oxidative addition of $NO^+NO_3^-$ to coordinatively unsaturated metal centres whereas in others ligand replacement by NO^+ occurs — this is a favoured route for producing "nitroprusside", i.e. nitrosylpentacyanoferrate(II):

$$[Pt(en)_2]^{2+} \xrightarrow{HNO_3} [Pt(en)_2(NO)(NO_3)]^{2+}$$

$$[Fe(CN)_6]^{4-} \xrightarrow{HNO_3} [Fe(CN)_5(NO)]^{2-}$$

12. *Oxide ion abstraction from coordinated NO_2,* i.e.

$$[ML_x(NO_2)]^{n+} + H^+ \longrightarrow [ML_x(NO)]^{(n+2)+} + OH^-$$

e.g.
$$cis\text{-}[Ru(bipy)_2(NO_2)X] \underset{2OH^-}{\overset{2H^+}{\rightleftharpoons}} cis\text{-}[Ru(bipy)_2(NO)X]^{2+} + H_2O$$

$$[Fe(CN)_5(NO_2)]^{4-} \xrightarrow{2H^+} [Fe(CN)_5(NO)]^{2-} + H_2O$$

13. *Oxygen atom abstraction*

$$[Fe(CO)_5] + KNO_2 \longrightarrow K[Fe(CO)_3(NO)] + CO + CO_2$$

Many variations on these synthetic routes have been devised and the field is still being actively developed.

The reactions of NO coordinated to transition metals have been extensively reviewed.[114]

is much current interest in their potential use as homogeneous catalysts for a variety of chemical reactions.[115] See also p. 443.[102]

NO shows a wide variety of coordination geometries (linear, bent, doubly bridging, triply bridging and quadruply bridging — see p. 453) and sometimes adopts more than one mode within the same complex. NO has one more electron than CO and often acts as a 3-electron donor — this is well illustrated by the following isoelectronic series of compounds in which successive replacement of CO by NO is compensated by a matching decrease in atomic number of the metal centre:

$[Ni(CO)_4]$	$[Co(CO)_3(NO)]$	$[Fe(CO)_2(NO)_2]$
mp −25°	−11°	+18.4°
(colourless)	(red)	(deep red)
$[Mn(CO)(NO)_3]$	$[Cr(NO)_4]$	
+27°	decomp > rt	
(dark green)	(red-black)	

For the same reason 3CO can be replaced by 2NO; e.g.:

$$[Co(CO)_3(NO)] \longrightarrow [Co(NO)_3]$$

$$[Fe(CO)_5] \longrightarrow [Fe(CO)_2(NO)_2]$$

$$[Mn(CO)_4(NO)] \longrightarrow [Mn(CO)(NO)_3]$$

$$[Cr(CO)_6] \longrightarrow [Cr(NO)_4]$$

In these and analogous compounds the M–N–O group is linear or nearly so, the M–N and N–O distances are short, and the N–O infrared stretching modes usually occur in the range 1650–1900 cm^{-1}. The bonding in such compounds is sometimes discussed in terms of the preliminary transfer of 1 electron from NO to the metal and the coordination of NO^+ to the reduced metal centre as a "2-electron σ donor, 2-electron π acceptor" analogous to CO (p. 926). This formal scheme, though useful in emphasizing similarities and trends in the coordination behaviour of NO^+, CO and CN^-, is unnecessary even for the purpose of "book-keeping" of electrons; it is also misleading in implying an unacceptably large separation of electronic charge in these covalent complexes and in leading to uncomfortably low oxidation states for many metals. e.g. Cr(−IV) in $[Cr(NO)_4]$, Mn(−III) in $[Mn(CO)(NO)_3]$, etc. Many physical techniques (such as ESCA, Mössbauer spectroscopy, etc.) suggest a much more even distribution of charge and there is accordingly a growing trend to consider linear NO complexes in terms of molecular orbital energy level schemes in which an almost neutral NO contributes 3 electrons to the bonding system via orbitals of σ and π symmetry.[116] Nitrogen-15 nmr spectroscopy has also been developed as a powerful tool for characterizing and distinguishing between linear and bent nitrosyl complexes and, where appropriate for studying their interconversion.[117]

Compounds in which the {M–N–O} group is nominally linear often feature a slightly bent coordination geometry and M–N–O bond angles in the range 165–180° are frequently encountered. However, another group of compounds is known in which the angle M–N–O is close to 120°. The first example, $[Co(NO)(S_2CNMe)_2]$, appeared in 1962[118] though there were problems in refining the structure, and a second example was found in 1968[119] when the cationic complex $[Ir(CO)Cl(NO)(PPh_3)_2]^+$ was found to have a bond angle of 124° (Fig. 11.10); values in the range 120–140° have since been observed in several other compounds (Table 11.10). The related complex $[RuCl(NO)_2(PPh_3)_2]^+$, in which the CO ligand has been replaced by a second NO molecule, is interesting in having both

mnt = maleonitriledithiolate. diars = 1,2-bis(dimethylarsino)benzene. diphos = $Ph_2PCH_2CH_2PPh_2$.

[a] Value imprecise because of crystal twinning (see ref. 118).

linear and bent {M–NO} groups: as can be seen in Fig. 11.10 the nonlinear coordination is associated with a lengthening of the Ru–N and N–O distances. This is consistent with a weakening of these bonds and it is significant that the N–O infrared stretching mode in such compounds tends to occur at lower wave numbers (1525–1690 cm^{-1}) than for linearly coordinated NO (1650–1900 cm^{-1}). In such systems neutral NO can be thought of as a 1-electron donor, as in the analogous (bent) nitrosyl halides, XNO (p. 442); it is unnecessary to consider the ligand as an NO^- 2-electron donor. The implication is that the other pair of electrons on NO is placed in an essentially non-bonding orbital on N (which is thus approximately described as an sp^2 hybrid) rather than being donated to the metal as in the linear, 3-electron-donor mode (Fig. 11.11). Consistent with this, non-linear coordination is generally observed with the later transition elements in which the low-lying orbitals on the metal are already filled, whereas linear coordination tends to occur with earlier transition elements which can more readily accommodate the larger number of electrons supplied by the ligand. However, the energetics are frequently finely balanced and other factors must also be considered — a good example is supplied by the two "isoelectronic" complexes shown in Fig. 11.12: $[Co(diars)_2(NO)]^{2+}$ has a linear NO equatorially coordinated to a trigonal bipyramidal cobalt atoms whereas $[IrCl_2(NO)(PPh_3)_2]$ has a bent NO axially coordinated to a square-pyramidal iridium atom, even though both Co and Ir are in the same group in the periodic table. Indeed, the complex cation $[Ir(\eta^3\text{-}C_3H_5)(NO)(PPh_3)_2]^+$ shows a facile equilibrium (in CH_2Cl_2 or MeCN solutions) between the linear and the bent NO modes of coordination and, with appropriate counter anions, either the linear –NO (light brown) or bent –NO (red-brown) isomer can be crystallized.[120] Some further examples of the two coordination geometries are in Table 11.10.

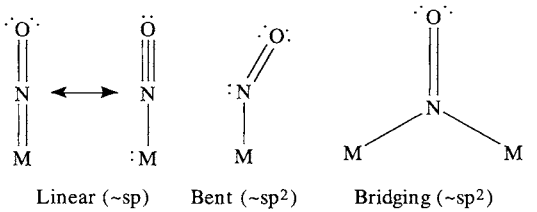

Figure 11.11 Schematic representation of the bonding in NO complexes. Note that bending would withdraw an electron-pair from the metal centre to the N atom thus creating a vacant coordination site: this may be a significant factor in the catalytic activity of such complexes.[115,121].

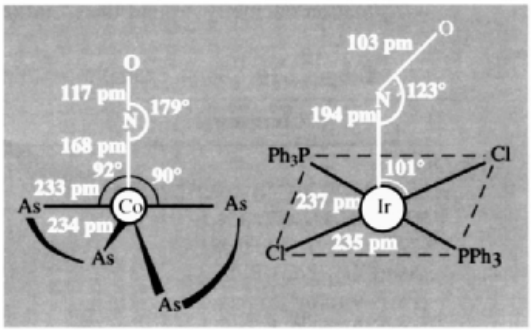

Figure 11.12 Comparison of the coordination geometries of $[Co(diars)_2(NO)]^{2+}$ and $[IrCl_2(NO)(PPh_3)]$; diars = 1,2-bis(dimethylarsino)benzene.

Like CO, nitric oxide can also act as a bridging ligand between 2 or 3 metals. Examples are the Cr and Mn complexes in Fig. 11.13. In $[\{Cr(\eta^5\text{-}C_5H_5)(NO)(\mu_2\text{-}NO)\}_2]$ the linear terminal NO has an infrared band at 1672 cm^{-1} whereas for the doubly bridging NO the vibration drops to 1505 cm^{-1}. In both geometries NO can be considered as a 3-electron donor and there is also a Cr–Cr bond thereby completing an 18-electron configuration around each Cr atom. In $[Mn_3(\eta^5\text{-}C_5H_5)_3(\mu_2\text{-}NO)_3(\mu_3\text{-}NO)]$ the 3 Mn

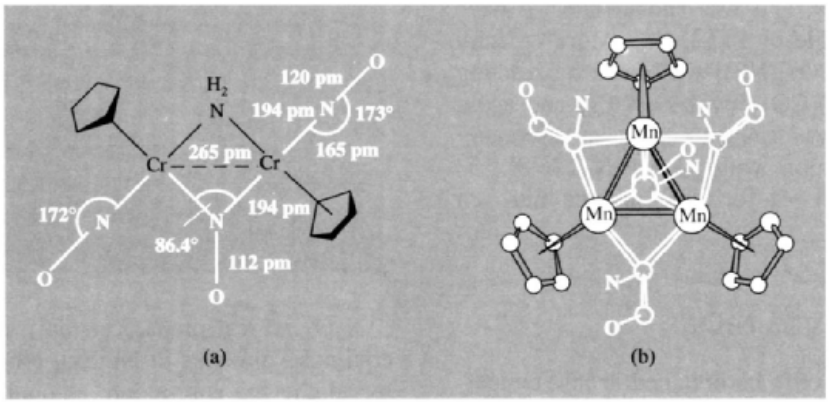

Figure 11.13 Structures of polynuclear nitrosyl complexes: (a) $[\{Cr(\eta^5\text{-}C_5H_5)(NO)\}_2(\mu_2\text{-}NH_2)(\mu_2\text{-}NO)]$ showing linear-terminal and doubly bridging NO; and (b) $[Mn_3(\eta^5\text{-}C_5H_5)_3(\mu_2\text{-}NO)_3(\mu_3\text{-}NO)]$ showing double-and triply-bridging NO; the molecule has virtual C_{3v} symmetry and the average Mn–Mn distance is 250 pm (range 247–257 pm).

form an equilateral triangle each edge of which is bridged by an NO group (ν 1543, 1481 cm^{-1}); the fourth NO is normal to the MN_3 plane and bridges all 3 Mn to form a triangular pyramid; the N–O stretching vibration moves to even lower wave numbers (1328 cm^{-1}). Again, each metal is associated with 18 valency electrons if each forms Mn Mn bonds with its 2 neighbours and each NO is a 3-electron donor.

An unprecedented quadruply bridging mode for NO has been established in the violet cluster anion $[\{Re_3(\mu\text{-}H)_3(CO)_{10}\}_2(\mu_4\text{-}\eta^2\text{-}NO)]^-$ (see Fig. 11.14a).[122] The complex was isolated as its $[NEt_4]^+$ salt after its formation by reaction of $NOBF_4$ with the trinuclear hydrido anion $[Re_3(\mu\text{-}H)_4(CO)_{10}]^-$. The rather long N–O distance (132–135 pm) is consistent with its formulation as NO^-. Another novel complex is $[Os(CO)Cl_2(HNO)(PPh_3)_2]$ (Fig. 11.14b) which is formed by direct reaction of HCl with $[Os(CO)(NO)(PPh_3)_2]$.[123] The complex is the first to contain the HNO ligand which is itself thermally unstable as a free molecule. The ligand is *N*-coordinated and coplanar with the $[Os(Co)Cl_2]$ moiety and has H–N 94 pm, N–O 119 pm and angle HNO 99°.

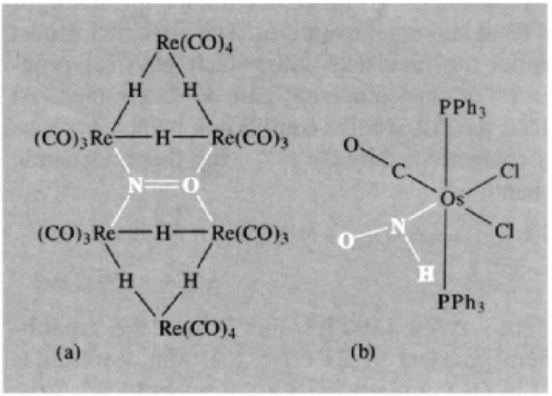

Figure 11.14 (a) Quadruply bridging NO in the anion $[\{Re_3(\mu\text{-}H)_3(CO)_{10}\}_2(\mu_4\text{-}\eta^2\text{-}NO)]^-$. (b) The neutral complex $[Os(CO)Cl_2(HNO)(PPh_3)_2]$.

In contrast to the numerous complexes of NO which have been prepared and characterized, complexes of the thionitrosyl ligand (NS) are virtually unknown, as is the free ligand itself. The first such complex $[Mo(NS)(S_2CNMe_2)_3]$ was obtained as orange-red air-stable crystals by treating $[MoN(S_2CNMe_2)_3]$ with sulfur in

[122] T. Beringhelli, G. Ciani, G. D'Alfonso, H. Molinari, A. Sironi and M. Freni, *J. Chem. Soc., Chem. Commun.*, 1327–9 (1984).

refluxing MeCN, and was shown later to have an M–N–S angle of 172.1°.[124] More recently $[Cr(\eta^5\text{-}C_5H_5)(CO)_2(NS)]$ was made by reacting $Na[Cr(\eta^5\text{-}C_5H_5)(CO)_3]$ with $S_3N_3Cl_3$ and again the NS group was found to adopt an essentially linear coordination with Cr–N–S 176.8°.[125] See also pp. 721–46 for other sulphur–nitrogen species.

Dinitrogen trioxide, N_2O_3

Pure N_2O_3 can only be obtained at low temperatures because, above its mp (−100.1°C), it dissociates increasingly according to the equilibria:

$$\underset{\text{Blue}}{N_2O_3} \rightleftharpoons \underset{\text{Colourless}}{NO} + \underset{\text{Brown}}{NO_2};$$

$$\underset{\text{Brown}}{2NO_2} \rightleftharpoons \underset{\text{Colourless}}{N_2O_4}$$

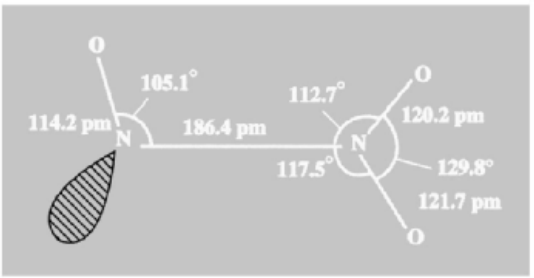
The solid is pale blue; the liquid is an intense blue at low temperatures but the colour fades and becomes greenish due to the presence of NO_2 at higher temperatures. The dissociation also limits the precision with which physical properties of the compound can be determined. At 25°C the dissociative equilibrium in the gas phase is characterized by the following thermodynamic quantities:

$$N_2O_3(g) \rightleftharpoons NO(g) + NO_2(g);\ \Delta H = 40.5\,kJ\,mol^{-1};$$

$$\Delta G = -1.59\,kJ\,mol^{-1}$$

Hence $\Delta S = 139\,J\,K^{-1}\,mol^{-1}$ and the equilibrium constant $K(25°C) = 1.91$ atm. Molecules of N_2O_3 are planar with C_s symmetry.

Structural data are in the diagram; these data were obtained from the microwave spectrum of the gas at low temperatures. The long (weak) N–N bond is notable (cf. 145 pm in hydrazine, p. 428). In this N_2O_3 resembles N_2O_4 (p. 455).



N_2O_3 is best prepared simply by condensing equimolar amounts of NO and NO_2 at −20°C or by adding the appropriate amount of O_2 to NO in order to generate the NO_2 *in situ*:

$$2NO + N_2O_4 \xrightarrow{\text{cool}} 2N_2O_3$$

$$4NO + O_2 \longrightarrow 2N_2O_3$$

Alternative preparations involve the reduction of 1:1 nitric acid by As_2O_3 at 70°, or the reduction of fuming HNO_3 with SO_2 followed by hydrolysis:

$$2HNO_3 + 2H_2O + As_2O_3 \longrightarrow N_2O_3 + 2H_3AsO_4$$

$$2HNO_3 + 2SO_2 \longrightarrow 2NOHSO_4 \xrightarrow{2H_2O} N_2O_3 + H_2SO_4$$

However, these methods do not yield a completely anhydrous product and dehydration can prove difficult.

Studies of the chemical reactivity of N_2O_3 are complicated by its extensive dissociation into NO and NO_2 which are themselves reactive species. With water N_2O_3 acts as the formal anhydride of nitrous acid and in alkaline solution it is converted essentially quantitatively to nitrite:

$$N_2O_3 + H_2O \xrightarrow{\text{aq}} 2HNO_2$$

$$N_2O_3 + 2OH^- \longrightarrow 2NO_2^- + H_2O$$

Reaction with concentrated acids provides a preparative route to nitrosyl salts such as $NO[HSO_4]$, $NO[HSeO_4]$, $NO[ClO_4]$, and $NO[BF_4]$, e.g.:

$$N_2O_3 + 3H_2SO_4 \longrightarrow 2NO^+ + H_3O^+ + 3HSO_4^-$$

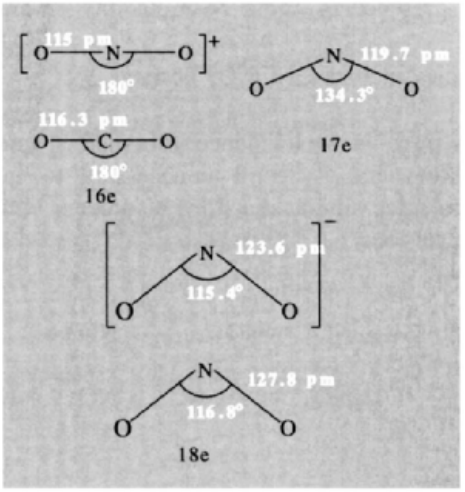
Nitrogen dioxide, NO_2, and dinitrogen tetroxide, N_2O_4

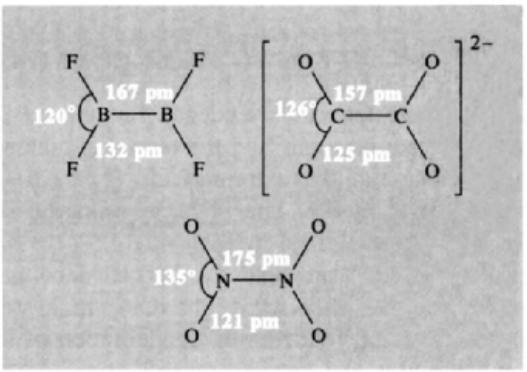
The facile equilibrium $N_2O_4 \rightleftharpoons 2NO_2$ makes it impossible to study the pure individual compounds in the temperature range $-10°$ to $+140°$ though the *molecular* properties of each species in the equilibrium mixture can often be determined. At all temperatures below the freezing point ($-11.2°$) the solid consists entirely of N_2O_4 molecules but the liquid at this temperature has 0.01% NO_2. At the bp (21.5°C) the liquid contains 0.1% NO_2 but the gas is more extensively dissociated and contains 15.9% NO_2 at this temperature and 99% NO_2 at 135°. The increasing dissociation can readily be followed by a deepening of the brown colour due to NO_2 and an increase in the paramagnetism; the thermodynamic data for the dissociation of $N_2O_4(g)$ at 25°C are:

$$\Delta H^\circ \ 57.20\,\text{kJ mol}^{-1};\ \Delta G^\circ \ 4.77\,\text{kJ mol}^{-1};$$
$$\Delta S^\circ \ 175.7\,\text{J K}^{-1}\text{mol}^{-1}$$

The unpaired electron in NO_2 appears to be more localized on the N atom than it is in NO and this may explain the ready dimerization. NO_2 is also readily ionized either by loss of an electron (9.91 eV) to give the nitryl cation NO_2^+ (isoelectronic with CO_2) or by gain of an electron to give the nitrite ion NO_2^- (isoelectronic with O_3). These changes are accompanied by a dramatic diminution in bond angle and an increase in N–O distance as the number of valence electrons increases from 16 to 18 (top diagram).

The structure of N_2O_4 in the gas phase is planar (D_{2h}) with a remarkably long N–N bond, and these features persist in both the monoclinic crystalline form near the mp and the more stable low-temperature cubic form. Data for the monoclinic form are in the lower diagram† together with those for the isoelectronic species B_2F_4 and





the oxalate ion $C_2O_4^{2-}$. The trends in bond angles and terminal bond distances are clear but the long central bond in N_2O_4 is not paralleled in the other 2 molecules where the B–B distance (p. 148) and C–C distance (p. 292) are normal. However, the B–B bond in B_2Cl_4 is also long (175 pm).

In addition to the normal homolytic dissociation of N_2O_4 into $2NO_2$, the molecule sometimes reacts as if by heterolytic fission: thus in media of high dielectric constant the compound often reacts as though dissociated according to the equilibrium $N_2O_4 \rightleftharpoons NO^+ + NO_3^-$ (see p. 457). This has sometimes been taken to imply

† Values for the gas phase are similar but there is a noticeable contraction in the cubic crystalline form (in parentheses). N–N 175 pm (164 pm), N–O 118 pm (117 pm), angle O–N–O 133.7° (126°). In addition, infrared studies on N_2O_4 isolated in a low-temperature matrix at liquid nitrogen temperature (–196°C) have been interpreted in terms of a twisted (non-planar) molecule $O_2N\text{–}NO_2$, and similar experiments at liquid helium temperature (–269°C) have been interpreted in terms of the unstable oxygen-bridged species $ONONO_2$.

the presence in liquid N_2O_4 of oxygen-bridged species such as $ONONO_2$ or even  but there is no evidence for such species in solution and it seems unnecessary to invoke them since similar reactions also occur with the oxalate ion:

Thus

$$N_2O_4 \longrightarrow NO^+ + NO_3^- \xrightarrow{2H^+} NO^+ +$$
$$H_2NO_3^+ \xrightarrow{H^+} NO^+ + NO_2^+ + H_3O^+$$

Compare

$$C_2O_4^{2-} \longrightarrow CO + CO_3^{2-} \xrightarrow{2H^+} CO +$$
$$H_2CO_3 \xrightarrow{H^+} CO + CO_2 + H_3O^+$$

There is no noticeable tendency for pure N_2O_4 to dissociate into ions and the electrical conductivity of the liquid is extremely low (1.3×10^{-13} $ohm^{-1}\,cm^{-1}$ at 0°). The physical properties of N_2O_4 are summarized in Table 11.11.

N_2O_4 is best prepared by thermal decomposition of rigorously dried $Pb(NO_3)_2$ in a steel reaction vessel, followed by condensation of the effluent gases and fractional distillation:

$$2Pb(NO_3)_2 \xrightarrow{\sim 400^\circ} 4NO_2 + 2PbO + O_2$$

Other methods (which are either more tedious or more expensive) include the reaction of nitric acid with SO_2 or P_4O_{10} and the reaction of nitrosyl chloride with $AgNO_3$:

$$2HNO_3 + SO_2 \longrightarrow N_2O_4 + H_2SO_4$$
$$4HNO_3 + P_4O_{10} \longrightarrow 2N_2O_4 + O_2 + 4HPO_3$$
$$NOCl + AgNO_3 \longrightarrow N_2O_4 + AgCl$$

The compound is also formed when NO reacts with oxygen:

$$2NO + O_2 \rightleftharpoons 2NO_2 \underset{\text{warm}}{\overset{\text{cool}}{\rightleftharpoons}} N_2O_4$$

These equilibria limit the temperature range in which reactions of N_2O_4 and NO_2 can be studied since dissociation of N_2O_4 into NO_2 is extensive above room temperature and is virtually complete by 140° whereas decomposition of NO_2 into NO and O_2 becomes significant above 150° and is complete at about 600°.

N_2O_4/NO_2 react with water to form nitric acid (p. 466) and the moist gases are therefore highly corrosive:

$$N_2O_4 + H_2O \longrightarrow HNO_3 + HNO_2;$$
$$3HNO_2 \longrightarrow HNO_3 + 2NO + H_2O$$

The oxidizing action of NO_2 is illustrated by the following:

$$NO_2 + 2HCl \longrightarrow NOCl + H_2O + \tfrac{1}{2}Cl_2$$
$$NO_2 + 2HX \xrightarrow{\text{heat}} NO + H_2O + X_2 \quad (X = Cl, Br)$$
$$2NO_2 + F_2 \longrightarrow 2FNO_2$$
$$NO_2 + CO \longrightarrow NO + CO_2$$

N_2O_4 has been extensively studied as a nonaqueous solvent system[126] and it is uniquely useful for preparing anhydrous metal nitrates and nitrato complexes (p. 468). Much of the chemistry can be rationalized in terms of a self-ionization equilibrium similar to that observed for

[126] C. C. ADDISON, in G. JANDER, H. SPANDAU and C. C. ADDISON (eds.), *Chemistry in Non-aqueous Ionizing Solvents*, Vol. 3, Part 1, pp. 1–78, Pergamon Press, London, 1967. C. C. ADDISON, *Chem. Rev.* **80**, 21–39 (1980).

Table 11.11 Some physical properties of N_2O_4

liquid ammonia (p. 425):

$$\underset{\text{Solvent}}{N_2O_4} \rightleftharpoons \underset{\text{Solvo-acid}}{NO^+} + \underset{\text{Solvo-base}}{NO_3^-}$$

As noted above, there is no physical evidence for this equilibrium in pure N_2O_4, but the electrical conductivity is considerably enhanced when the liquid is mixed with a solvent of high dielectric constant such as nitromethane ($\varepsilon \approx 37$), or with donor solvents (D) such as $MeCO_2Et$, Et_2O, Me_2SO, or Et_2NNO (diethylnitrosamine):

$$N_2O_4 + nD \rightleftharpoons \{D_n.N_2O_4\} \rightleftharpoons [D_nNO]^+ + NO_3^-$$

Typical solvent system reactions are summarized below together with the analogous reactions from the liquid ammonia solvent system:

"Neutralization"

$$NOCl + AgNO_3 \xrightarrow{N_2O_4} AgCl + N_2O_4$$

$$NH_4Cl + NaNH_2 \xrightarrow{NH_3} NaCl + 2NH_3$$

"Acid"

$$2NOCl + Sn \xrightarrow{N_2O_4} SnCl_2 + 2NO$$

$$2NH_4Cl + Sn \xrightarrow{NH_3} SnCl_2 + 2NH_3 + H_2$$

"Base/amphoterism"

$$2[EtNH_3][NO_3] + 2N_2O_4 + Zn \xrightarrow{N_2O_4} [EtNH_3]_2[Zn(NO_3)_4] + 2NO$$

$$2NaNH_2 + 2NH_3 + Zn \xrightarrow{NH_3} Na_2[Zn(NH_2)_4] + H_2$$

"Solvolysis"

$$CaO + 2N_2O_4 \xrightarrow{N_2O_4} Ca(NO_3)_2 + N_2O_3$$

$$Na_2O + NH_3 \xrightarrow{NH_3} NaNH_2 + NaOH$$

Similarly :

$$ZnCl_2 + N_2O_4 \xrightarrow{N_2O_4} Zn(NO_3)_2 + 2NOCl$$

Such reactions provide an excellent route to anhydrous metal nitrates, particularly when metal bromides or iodides are used, since then the nitrosyl halide decomposes and this prevents the possible formation of nitrosyl compounds, e.g.:

$$TiI_4 + 4N_2O_4 \rightleftharpoons Ti(NO_3)_4 + 4NO + 2I_2$$

Many carbonyls react similarly, e.g.:

$$[Mn_2(CO)_{10}] + N_2O_4 \longrightarrow [Mn(CO)_5(NO_3)] + [Mn(CO)_x(NO)_y]$$

$$[Fe(CO)_5] + 4N_2O_4 \longrightarrow [Fe(NO_3)_3.N_2O_4] + 5CO + 3NO$$

Solvates are frequently formed in these various reactions, e.g.:

$$Cu + 3N_2O_4 \xrightarrow{MeNO_2} [Cu(NO_3)_2.N_2O_4] + 2NO$$

Some of these may contain undissociated solvent molecules N_2O_4 but structural studies have revealed that often such "solvates" are actually nitrosonium nitrato-complexes. For example it has been shown[127] that $[ScNO_3)_3.2N_2O_4]$ is, in fact, $[NO]_2^+[Sc(NO_3)_5]^{2-}$. Similarly, X-ray crystallography revealed[128] that $[Fe(NO_3)_3.1\frac{1}{2}N_2O_4]$ is $[NO]^+{}_3[Fe(NO_3)_4]^-{}_2[NO_3]^-$, in which there is a fairly close approach of 3 NO^+ groups to the "uncoordinated" nitrate ion to give a structural unit of stoichiometry $[N_4O_6]^{2+}$ (see also p. 472).

In contrast to the wealth of reactions in which N_2O_4 tends to behave as $NO^+NO_3^-$, there is no evidence for reactions based on the alternative heterolytic dissociation $NO_2^+NO_2^-$.[129] Earlier claims[129a] to have identified BF_3 adducts such as $[NO_2]^+[ONOBF_3]^-$ have been shown to be incorrect and the predominant products of the reaction of BF_3 with N_2O_4 (and also with N_2O_3 and with N_2O_5) are, in fact, $NO^+BF_4^-$ and $NO_2^+BF_4^-$.[129b] This latter compound had

earlier (1956) been introduced by G. A. Olah as a powerful, stable nitrating agent in organic chemistry and it has been widely used since then.[130]

N_2O_4 has also been used extensively as a hypogolic oxidizer for hydrazine-based fuels in spacecraft. For example, the Apollo manned lunar landing modules (1969–72) used 5.0 tonnes of liquid N_2O_4 during descent to the lunar surface and 1.5 tonnes during the return ascent, the fuel being a 1:1 mixture of $MeNHNH_2$ and Me_2NNH_2.

Dinitrogen pentoxide, N_2O_5, and nitrogen trioxide, NO_3

N_2O_5 is the anhydride of nitric acid and is obtained as a highly reactive deliquescent, light-sensitive, colourless, crystalline solid by carefully dehydrating the concentrated acid with P_4O_{10} at low temperatures:

$$4HNO_3 + P_4O_{10} \xrightarrow{-10^\circ} 2N_2O_5 + 4HPO_3$$

The solid has a vapour pressure of 100 mmHg at 7.5°C and sublimes (1 atm) at 32.4°C, but is thermally unstable both as a solid and as a gas above room temperature. Thermodynamic data at 25°C are:

	ΔH_f°/kJ mol^{-1}	ΔG_f°/kJ mol^{-1}	S°/J K^{-1} mol^{-1}
N_2O_5 (cryst)	−43.1	113.8	178.2
N_2O_5 (g)	11.3	115.1	355.6

X-ray diffraction studies show that solid N_2O_5 consists of an ionic array of linear NO_2^+ (N–O 115.4 pm) and planar NO_3^- (N–O 124 pm). In the gase phase and in solution (CCl_4, $CHCl_3$, $OPCl_3$) the compound is molecular; the structure is not well established but may be $O_2N–O–NO_2$ with a central N–O–N angle close to 180°. The molecular form can also be obtained in the solid phase by rapidly quenching the gas to − 180°, but it rapidly reverts to the more stable ionic form on being warmed to −70°. [cf. ionic and covalent forms of $BF_3.2H_2O$ (p. 198), $AlCl_3$ (p. 234), PCl_5 (p. 498), etc.]

N_2O_5 is readily hydrated to nitric acid and reacts with H_2O_2 to give pernitric acid as a coproduct:

$$N_2O_5 + H_2O \longrightarrow 2HONO_2$$

$$N_2O_5 + H_2O_2 \longrightarrow HONO_2 + HOONO_2$$

It reacts violently as an oxidizing agent towards many metals, non-metals and organic substances, e.g.:

$$N_2O_5 + Na \longrightarrow NaNO_3 + NO_2$$

$$N_2O_5 + NaF \longrightarrow NaNO_3 + FNO_2$$

$$N_2O_5 + I_2 \longrightarrow I_2O_5 + N_2$$

Like N_2O_4 (p. 457) it dissociates ionically in strong anhydrous acids such as HNO_3, H_3PO_4, H_2SO_4, HSO_3F and $HClO_4$, and this affords a convenient source of nitronium ions and hence a route to nitronium salts, e.g.:

$$N_2O_5 + 3H_2SO_4 \longrightarrow 2NO_2^+ + H_3O^+ + 3HSO_4^-$$

$$N_2O_5 + HSO_3F \longrightarrow [NO_2]^+[FSO_3]^- + HNO_3$$

$$N_2O_5 + 2SO_3 \longrightarrow [NO_2]^+_2[S_2O_7]^{2-}$$

In the gas phase, N_2O_5 decomposes according to a first-order rate law which can be explained by a dissociative equilibrium followed by rapid reaction according to the scheme

$$N_2O_5 \rightleftharpoons NO_2 + \{NO_3\} \longrightarrow NO_2 + O_2 + NO$$

$$N_2O_5 + NO \rightleftharpoons 3NO_2$$

The fugitive, paramagnetic species $\{NO_3\}$ is also implicated in several other gas-phase reactions involving the oxides of nitrogen and, in the N_2O_5-catalysed decomposition of ozone, its concentration is sufficiently high for its absorption spectrum to be recorded, thereby establishing its integrity as an independent chemical species. Such reactions are the subject of considerable current interest for environmental reasons. NO_3 probably has a symmetrical planar structure (like NO_3^-) but it has not been isolated as a pure compound.

11.3.7 Oxoacids, oxoanions and oxoacid salts of nitrogen

Nitrogen forms numerous oxoacids, though several are unstable in the free state and are known only in aqueous solution or as their salts. The principal species are summarized in Table 11.12; of these by far the most stable is nitric acid and this compound, together with its salts the nitrates, are major products of the chemical industry (p. 466).

Hyponitrous acid and hyponitrites [131]

Hyponitrous acid crystallizes from ether solutions as colourless crystals which readily decompose

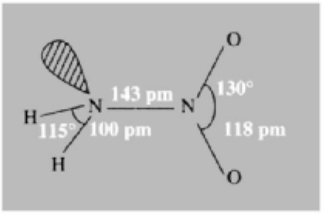
[131] M. N. HUGHES, *Q. Rev.* **22**, 1–13 (1968).

Table 11.12 Oxoacids of nitrogen and related species

Formula	Name	Remarks
$H_2N_2O_2$	Hyponitrous acid	Weak acid HON=NOH, isomeric with nitramide, $H_2N{-}NO_2$;[a] salts are known (p. 460)
{HNO}	Nitroxyl	Reactive intermediate (p. 461), salts are known (see also p. 453).
$H_2N_2O_3$	Hyponitric acid [trioxodinitric(II) acid]	Known in solution and as salts, e.g. Angeli's salt $Na_2[ON{=}NO_2]$ (p. 460)
$H_4N_2O_4$	Nitroxylic (hydronitrous) acid	Explosive; sodium salt known $Na_4[O_2NNO_2]$[b]
HNO_2	Nitrous acid	Unstable weak acid, HONO (p. 461); stable salts (nitrites) are known
HOONO	Peroxonitrous acid	Unstable, isomeric with nitric acid; some salts are more stable[c]
HNO_3	Nitric acid	Stable strong acid $HONO_2$; many stable salts (nitrates) are known (p. 465)
HNO_4	Peroxonitric acid	Unstable, explosive crystals, $HOONO_2$; no solid salts known. (For "orthonitrates", NO_4^{3-}, i.e. salts of the unknown orthonitric acid H_3NO_4, see p. 471–2)

[a] The structure of nitramide is as shown, the dihedral angle between NH_2 and NNO_2 is 52°. Nitramide is a weak acid pK_1 6.6 (K_1 2.6×10^{-7}) and it decomposes into N_2O and H_2O by a base-catalysed mechanism:

$$H_2NNO_2 + B \xrightarrow{\text{slow}} BH^+ + [HNNO_2]^- \xrightarrow{\text{fast}} N_2O + OH^-$$



[b] Sodium nitroxylate can be prepared as a yellow solid by reduction of sodium nitrite with Na/NH_3(liq.):

$$2NaNO_2 + 2Na \xrightarrow{NH_3} Na_4\left[\begin{array}{c} O \\ \diagup \\ O \end{array} N{-}N \begin{array}{c} \diagdown \\ O \end{array} O\right]$$

[c] Peroxonitrous acid is formed as an unstable intermediate during the oxidation of acidified aqueous solutions of nitrites to nitrates using H_2O_2; such solutions are orange-red and are more highly oxidizing than either H_2O_2 or HNO_3 alone (e.g. they liberate Br_2 from Br^-). Alkaline solutions are more stable but the yellow peroxonitrites M[OONO] have not been isolated pure. The chemistry of peroxonitrites has recently been reviewed J. O. EDWARDS and R. C. PLUMB, in K. D. KARLIN (ed). *Progr. Inorg. Chem.* **41**, 599–635 (1994).

(explosively when heated). Its structure has not been determined but the molecular weight indicates a double formula $H_2N_2O_2$, i.e. HON=NOH; consistent with this the compound yields N_2O when decomposed by H_2SO_4, and hydrazine when reduced. The free acid is obtained by treating $Ag_2N_2O_2$ with anhydrous HCl in ethereal solution. It is a weak dibasic acid: pK_1 6.9, pK_2 11.6. Aqueous solutions are unstable between pH 4–14 due to base catalysed decomposition via the hydrogen-hyponitrite ion:

$$HONNOH \xrightarrow{\text{base}} [HONNO]^- \xrightarrow[\text{(minutes)}]{\text{fast}} N_2O + OH^-$$

At higher acidities (lower pH) decomposition is slower ($t_{1/2}$ days or weeks) and the pathways are more complex. The stoichiometry, kinetics and mechanisms of several other reactions of $H_2N_2O_2$ with, for example, NO and with HNO_2 have also been studied.[132]

Hyponitrites can be prepared in variable (low) yields by several routes of which the commonest are reduction of aqueous nitrite solutions using sodium (or magnesium) amalgam, and condensation of organic nitrites with hydroxylamine in NaOEt/EtOH:

$$2NaNO_3 + 8Na/Hg + 4H_2O \longrightarrow Na_2N_2O_2 + 8NaOH + 8Hg$$

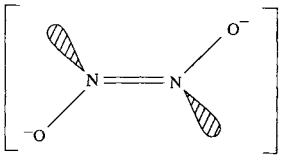
$$2AgNO_3 + 2NaNO_2 + 4Na/Hg + 2H_2O \longrightarrow Ag_2N_2O_2 + 2NaNO_3 + 4NaOH + 4Hg$$

$$Ca(NO_3)_2 + 4Mg/Hg + 4H_2O \longrightarrow CaN_2O_2 + 4Mg(OH)_2 + 4Hg$$

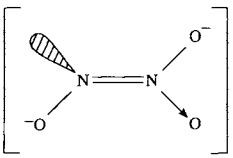
$$NH_2OH + RONO + 2NaOEt \xrightarrow{EtOH} Na_2N_2O_2 + ROH + 2EtOH$$

Vibrational spectroscopy indicates that the hyponitrite ion has the *trans*- (C_{2h}) configuration (1) in the above salts.

As implied by the preparative methods employed, hyponitrites are usually stable towards



(1)



(2)

reducing agents though under some conditions they can be reduced (p. 434). More frequently they themselves act as reducing agents and are thereby oxidized, e.g. the analytically useful reaction with iodine:

$$[ONNO]^{2-} + 3I_2 + 3H_2O \longrightarrow [NO_3]^- + [NO_2]^- + 6HI$$

There is also considerable current environmental interest in hyponitrite oxidation because it is implicated in the oxidation of ammonia to nitrite, an important step in the nitrogen cycle (p. 410). Specifically, it seems likely that the oxidation proceeds from ammonia through hydroxylamine and hyponitrous acid to nitrite (or N_2O).

With liquid N_2O_4 stepwise oxidation of hyponitrites occurs to give $Na_2N_2O_x$ ($x = 3$–6):

$$Na_2N_2O_2 \xrightarrow{\text{fast}} Na_2N_2O_3 \xrightarrow{\text{slow}} Na_2N_2O_5 \xrightarrow[100°]{\text{slow}} Na_2N_2O_6$$

Angeli's salt $Na_2N_2O_3$ has been shown by vibration spectroscopy to contain the trioxodinitrate(II) anion structure (2). Its decomposition and reactions in aqueous solutions have been extensively studied by ^{15}N nmr spectroscopy and other techniques.[133]

In contrast to the stepwise oxidation of sodium hyponitrite in liquid N_2O_4, the oxidation goes rapidly to the nitrate ion in an inert solvent of high dielectric constant such as nitromethane:

$$[ON{=}NO]^{2-} + 2N_2O_4 \xrightarrow{MeNO_2} 2[NO_3]^- + \{ONON{=}NONO\} \longrightarrow N_2 + 2NO_2$$

[132] M. N. Hughes *et al.*, *Inorg. Chem.* **24**, 1934–5 (1985); *J. Chem. Soc., Dalton Trans.*, 527–32 and 533–7 (1989).

[133] M. J. Akhtar, C. A. Lutz and F. T. Bonner, *Inorg. Chem.* **18**, 2369–75 (1979). F. T. Bonner, H. Degani and M. J. Akhtar, *J. Am. Chem. Soc.* **103**, 3739–42 (1981). D. A. Bazylinski and T.C. Hollocher, *Inorg. Chem.* **24**, 4285–8 (1985).

More recently it has been found that the hyponitrite ion can act as a bidentate ligand in either a bridging or a chelating mode. Thus, the controversy about the nature of the black and red isomers of nitrosyl pentammine cobalt(III) complexes has been resolved by X-ray crystallographic studies which show that the black chloride $[Co(NH_3)_5NO]Cl_2$ contains a mononuclear octahedral Co^{III} cation with a linear Co–N–O group whereas the red isomer, in the form of a mixed nitrate-bromide, is dinuclear with a bridging *cis*-hyponitrite-(*N*,*O*) group as shown in Fig. 11.15.[134] The *cis*-configuration is probably adopted for steric reasons since this is the only configuration that allows the bridging of two $\{Co(NH_3)_5\}$ groups by an ONNO group without steric interference between them. The *cis*-chelating mode (*O*,*O*) was found in the air-sensitive yellow crystalline complex $[Pt(O_2N_2)(PPh_3)_2]$ which has already been mentioned on p. 446. The presence of the *cis*-configuration in this complex invites speculation as to whether *cis*-$[ON–NO]^{2-}$ can also exist in simple hyponitrites. Likely candidates appear to be the "alkali metal nitrosyls" MNO prepared by the action of NO on Na/NH_3; infrared data suggest they are not $M^+[NO]^-$ and might indeed contain the *cis*-hyponitrite ion. They would therefore not be salts of nitroxyl HNO which has often been postulated as an intermediate in reactions which give N_2O and which is well known in the gas phase. Nitroxyl can be prepared by the action of atomic H or HI on NO and decomposes to N_2O and H_2O. As expected, the molecule is bent (angle H—N=O 109°). See also Fig. 11.14(b), p. 453.

Nitrous acid and nitrites

Nitrous acid, HNO_2, has not been isolated as a pure compound but it is a well known and important reagent in aqueous solutions and has also been studied as a component in gas-phase equilibria. Solutions of the free acid can readily be obtained by acidification of cooled aqueous nitrite solutions but even at room temperature disproportionation is noticeable:

$$3HNO_2(aq) \rightleftharpoons H_3O^+ + NO_3^- + 2NO$$

It is a fairly weak acid with pK_a 3.35 at 18°C, i.e. intermediate in strength between acetic (4.75) and chloroacetic (2.85) acids at 25°, and very similar to formic (3.75) and sulfanilic (3.23) acids. Salt-free aqueous solutions can be made by choosing combinations of reagents which give insoluble salts, e.g.:

$$Ba(NO_2)_2 + H_2SO_4 \xrightarrow{aq} 2HNO_2 + BaSO_4$$

$$AgNO_2 + HCl \xrightarrow{aq} HNO_2 + AgCl$$

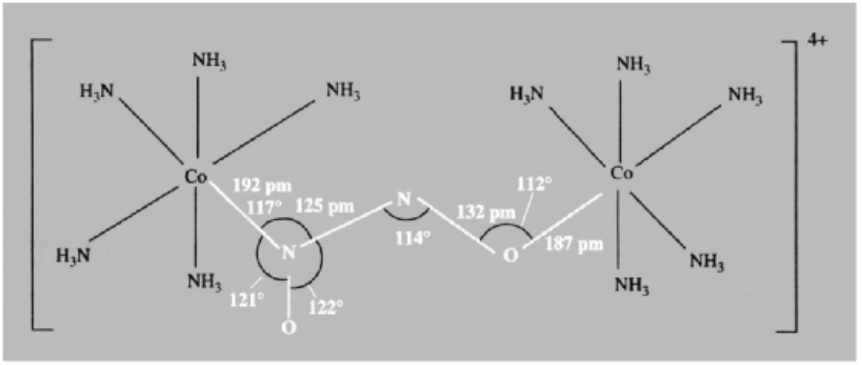

Figure 11.15 Structure of the dinuclear cation in the red isomer $[\{Co(NH_3)_5NO\}_2](Br)_{2.5}(NO_3)_{1.5}.2H_2O$; (mean Co–$NH_3$ 194 ± 2 pm, mean angle 90 ± 4°).

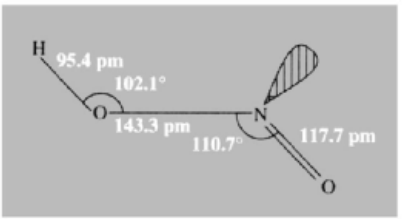
When the presence of salts in solution is unimportant, the more usual procedure is simply to acidify $NaNO_2$ with hydrochloric acid below 0°.

In the gas phase, an equilibrium reaction producing HNO_2 can be established by mixing equimolar amounts of H_2O, NO and NO_2:

$$2HNO_2(g) \rightleftharpoons H_2O(g) + NO(g) + NO_2(g);$$

$$\Delta H°(298\,K)\ 38\,kJ/2\,mol\ HNO_2;$$

$$K_p(298\,K)\ 8.0 \times 10^5\ N\,m^{-2}\ (7.9\ atm)$$



Microwave spectroscopy shows that the gaseous compound is predominantly in the *trans*-planar (C_s) configuration with the dimensions shown. The differences between the two N–O distances is notable. Despite the formal single-bond character of the central bond the barrier to rotation is 45.2 kJ mol^{-1}. Infrared data suggest that the *trans*-form is ~2.3 kJ mol^{-1} more stable ($\Delta G°$) than the *cis*- form at room temperature.

Nitrites are usually obtained by the mild reduction of nitrates, using C, Fe or Pb at moderately elevated temperatures, e.g.:

$$NaNO_3 + Pb \xrightarrow{\text{melt}} NaNO_2 + PbO$$

On the industrial scale, impure $NaNO_2$ is made by absorbing "nitrous fumes" in aqueous alkali or carbonate solutions and then recrystallizing the product:

$$NO + NO_2 + 2NaOH\ (\text{or } Na_2CO_3) \xrightarrow{aq} 2NaNO_2 + H_2O\ (\text{or } CO_2)$$

The sparingly soluble $AgNO_2$ can be obtained by metathesis, and simple variants yield the other stable nitrites, e.g.:

$$NaNO_2 + AgNO_3 \xrightarrow{aq} AgNO_2 + NaNO_3$$

$$NaNO_2 + KCl \xrightarrow{aq} KNO_2 + NaCl$$

$$2NH_3 + H_2O + N_2O_3 \longrightarrow 2NH_4NO_2$$

$$Ba(OH)_2 + NO + NO_2 \xrightarrow{aq} Ba(NO_2)_2 + H_2O$$

Many stable metal nitrites (Li, Na, K, Cs, Ag, Tl^I, NH_4, Ba) contain the bent $[O–N–O]^-$ anion (p. 413) with N–O in the range 113–123 pm and the angle 116–132°. Nitrites of less basic metals such as Co(II), Ni(II) and Hg(II) are often highly coloured and are probably essentially covalent assemblages. Solubility (g per 100 g H_2O at 25°) varies considerably, e.g. $AgNO_2$ 0.41, $NaNO_2$ (hygroscopic) 85.5, KNO_2 (deliquescent) 314. Thermal stability also varies widely: e.g. the alkali metal nitrites can be fused without decomposition (mp $NaNO_2$ 284°, KNO_2 441°C), whereas $Ba(NO_2)_2$ decomposes when heated above 220°, $AgNO_2$ above 140° and $Hg(NO_2)_2$ above 75°. Such trends are a general feature of oxoacid salts (pp. 469, 863, 868). NH_4NO_2 can decompose explosively.

The aqueous solution chemistry of nitrous acid and nitrites has been extensively studied. Some reduction potentials involving these species are given in Table 11.4 (p. 434) and these form a useful summary of their redox reactions. Nitrites are quantitatively oxidized to nitrate by permanganate and this reaction is used in titrimetric analysis. Nitrites (and HNO_2) are readily reduced to NO and N_2O with SO_2, to $H_2N_2O_2$ with Sn(II), and to NH_3 with H_2S. Hydrazinium salts yield azides (p. 432) which can then react with further HNO_2:

$$HNO_2 + N_2H_5^+ \longrightarrow HN_3 + H_2O + H_3O^+$$

$$HNO_2 + HN_3 \longrightarrow N_2O + N_2 + H_2O$$

This latter reaction is most unusual in that it simultaneously involves an element (N) in four different oxidation states. Use of ^{15}N-enriched reagents shows that all the N from HNO_2 goes quantitatively to the internal N of N_2O:[135]

$$HN_3 + HO^{15}NO \xrightarrow{-H_2O} \{NNN^{15}NO\} \longrightarrow NN + N^{15}NO$$

[135] K. CLUSIUS and H. KNOFF, *Chem. Ber.* **89**, 681–5 (1956).

$NaNO_2$ is mildly toxic (tolerance limit ~100 mg/kg body weight per day, i.e. 4–8 g/day for humans). $NaNO_2$ (or a precursor such as $NaNO_3$, which is itself harmless) has been much used for curing meat and for treating preserved foods stuffs to prevent bacterial spoilage and consequent poisoning by the (often deadly) toxins produced by *Clostridium botulinum* etc., (normal dietary intake of NO_2^- 10–15 μg per day). $NaNO_2$ is used industrially on a large scale for the synthesis of hydroxylamine (p. 431), and in acid solution for the diazotization of primary *aromatic* amines:

$$ArNH_2 + HNO_2 \xrightarrow{HCl/aq} [ArNN]Cl + 2H_2O$$

The resulting diazo reagents undergo a wide variety of reactions including those of interest in the manufacture of azo dyes and pharmaceuticals. With primary *aliphatic* amines the course of the reaction is different: N_2 is quantitatively evolved and alcohols usually result:

$$RNH_2 + HNO_2 \xrightarrow{-H_2O} RNHNO \dashrightarrow RN{=}NOH$$
$$\xrightarrow{OH^-} RN_2^+ \dashrightarrow N_2 + R^+ \dashrightarrow \text{products}$$

The reaction is generally thought to involve carbonium-ion intermediates but several puzzling features remain.[136] Secondary aliphatic amines give nitrosamines without evolution of N_2:

$$R_2NH + HONO \longrightarrow R_2NNO + H_2O$$

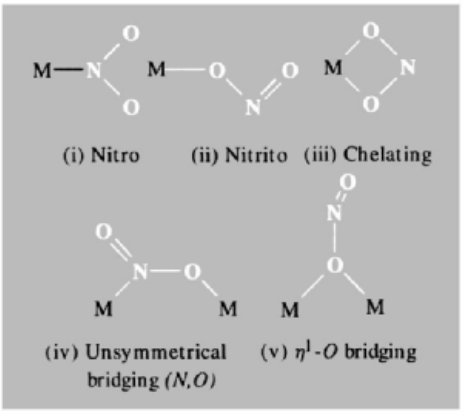
Tertiary aliphatic amines react in the cold to give nitrite salts and these decompose on warming to give nitrosamines and alcohols:

$$R_3N + HNO_2 \xrightarrow{\text{cold}} [R_3NH][NO_2]$$
$$\xrightarrow{\text{warm}} R_2NNO + ROH$$

In addition to their general use in synthetic organic chemistry, these various reactions afford the major route for introducing ^{15}N into organic compounds by use of $Na^{15}NO_2$.

[136] C. J. Collins, *Acc. Chem. Res.* **4**, 315–22 (1971).

The nitrite ion, NO_2^-, is a versatile ligand and can coordinate in at least five different ways (i)–(v):



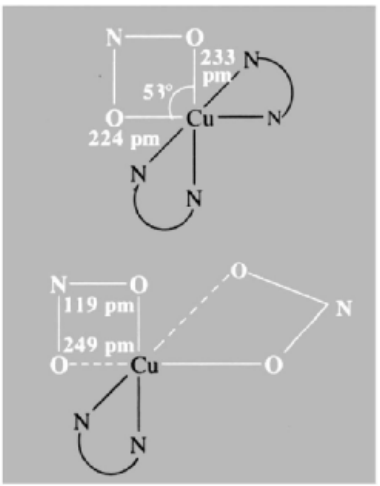
Nitro-nitrito isomerism (i), (ii), was discovered by S. M. Jörgensen in 1894–9 and was extensively studied during the classic experiments of A. Werner (p. 912); the isomers usually have quite different colours, e.g. $[Co(NH_3)_5(NO_2)]^{2+}$, yellow, and $[Co(NH_3)_5(ONO)]^{2+}$, red. The nitrito form is usually less stable and tends to isomerize to the nitro form. The change can also be effected by increase in pressure since the nitro form has the higher density. For example application of 20 kbar pressure converts the violet nitrito complex $[Ni(en)_2(ONO)_2]$ to the red nitro complex $[Ni(en)_2(NO_2)_2]$ at 126°C, thereby reversing the change from nitro to nitrito which occurs on heating the complex from room temperature at atmospheric pressure.[137] An X-ray study of the thermally induced nitrito → nitro isomerization and the photochemically induced nitro → nitrito isomerization of Co(III) complexes has shown that both occur intra-molecularly by rotation of the NO_2 group in its own plane, probably via a 7-coordinated cobalt intermediate.[138] Similarly, the base-catalysed nitrito → nitro isomerization of $[M^{III}(NH_3)_5(ONO)]^{2+}$(M = Co,

[137] J. R. Ferraro and L. Fabbrizzi, *Inorg. Chim. Acta* **26**, L15–L17 (1978).

[138] I. Grenthe and E. Nordin, *Inorg. Chem.* **18**, 1109–16 and 1869–74 (1979).

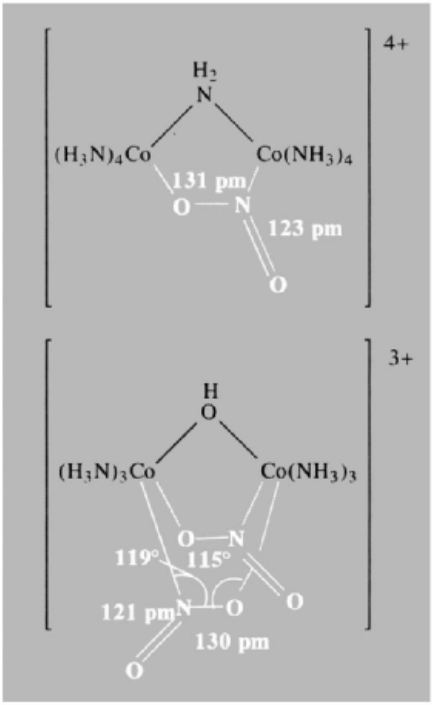
Rh, Ir) is intramolecular and occurs without ^{18}O exchange of the coordinated ONO^- with $H_2{}^{18}O$, $^{18}OH^-$ or "free" $N^{18}O_2{}^-$.[139] However, an elegant ^{17}O nmr study using specifically labelled $[Co(NH_3)_5(^{17}ONO)]^{2+}$ and $[Co(NH_3)_5(ON^{17}O)]^{2+}$ established that spontaneous intramolecular O-to-O exchange in the nitrite ligand occurs at a rate comparable to that of the spontaneous *O*-to-*N* isomerization.[140]

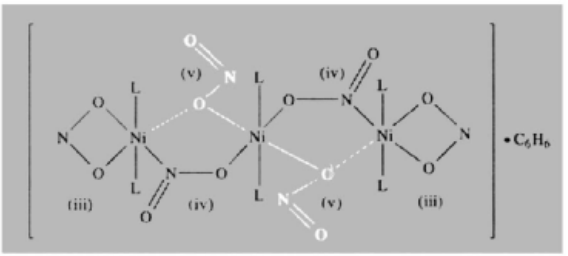
A typical value for the N–O distance in nitro complexes is 124 pm whereas in nitrito complexes the terminal N–O (121 pm) is shorter than the internal N–O(M) ~129 pm. In the bidentate chelating mode (iii) the 2 M–O distances may be fairly similar as in $[Cu(bipy)_2(O_2N)]NO_3$ or quite different as in $[Cu(bipy)(O_2N)_2]$:



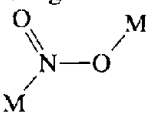
Examples of the unsymmetrical bridging mode (iv) are shown in the top diagram.

The oxygen-bridging mode (v) is less common but occurs together with modes (iii) and (iv) in the following centrosymmetrical trimeric Ni complex and related compounds.[141]





It is possible that a sixth (symmetrical bridging) mode M—O, O—M, N occurs in some complexes such as $Rb_3Ni(NO_2)_5$ but this has not definitely been established; an unsymmetrical bridging mode with a *trans*-configuration of metal atoms is also possible, i.e.



[compare with (iv)].

The familiar problem of misleading stoichiometries, and the frequent impossibility of deducing the correct structural formula from the empirical composition is well illustrated by the

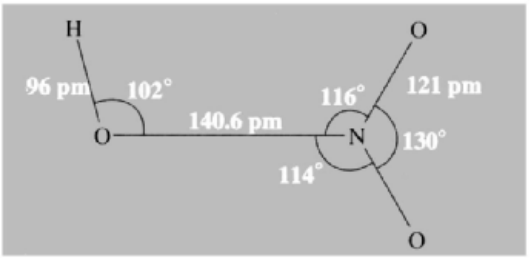
recent synthesis of the novel alkali metal oxide nitrites $Na_4N_2O_5$ (yellow) and $K_4N_2O_5$ (red).[142] These compounds are made by heating powdered mixtures of M_2O and MNO_2 at 340° for 8 days in a silver crucible and have an anti-K_2NiF_4 type structure, $[(NO_2)_2OM_4]$, i.e $M_4O(NO_2)_2$, with N–O 122.1 pm, angle O–N–O 114.5° and octahedrally coordinated O^{2-} (i.e OM_6 with K–O 260 pm.



with the dimensions shown (microwave). The difference in N–O distances, the slight but real tilt of the NO_2 group away from the H atom by 2°, and the absence of free rotation are notable features. The same general structure obtains in the solid state but detailed data are less reliable. Physical properties are shown in Table 11.13. Despite its great thermodynamic stability (with respect to the elements) pure HNO_3 can only be obtained in the solid state; in the gas and liquid phases the compound decomposes spontaneously to NO_2 and this occurs more rapidly in daylight (thereby accounting for the brownish colour which develops in the acid on standing):

$$2HNO_3 \rightleftharpoons 2NO_2 + H_2O + \tfrac{1}{2}O_2$$

Nitric acid and nitrates

Nitric acid is one of the three major acids of the modern chemical industry and has been known as a corrosive solvent for metals since alchemical times in the thirteenth century.[143,144] It is now invariably made by the catalytic oxidation of ammonia under conditions which promote the formation of NO rather than the thermodynamically more favoured products N_2 or N_2O (p. 423). The NO is then further oxidized to NO_2 and the gases absorbed in water to yield a concentrated aqueous solution of the acid. The vast scale of production requires the optimization of all the reaction conditions and present-day operations are based on the intricate interaction of fundamental thermodynamics, modern catalyst technology, advanced reactor design, and chemical engineering aspects of process control (see Panel). Production in the USA alone now exceeds 7 million tonnes annually, of which the greater part is used to produce nitrates for fertilizers, explosives and other purposes (see Panel).

Anhydrous HNO_3 can be obtained by low-pressure distillation of concentrated aqueous nitric acid in the presence of P_4O_{10} or anhydrous H_2SO_4 in an all-glass, grease-free apparatus in the dark. The molecule is planar in the gas phase

In addition, the liquid undergoes self-ionic dissociation to a greater extent than any other nominally covalent pure liquid (cf. $BF_3.2H_2O$, p. 198); initial autoprotolysis is followed by rapid loss of water which can then react with a further molecule of HNO_3:

$$2HNO_3 \rightleftharpoons H_2NO_3^+ + NO_3^- \rightleftharpoons H_2O + [NO_2]^+ + [NO_3]^-$$

$$HNO_3 + H_2O \rightleftharpoons [H_3O]^+ + [NO_3]^-$$

Production and Uses of Nitric Acid[56,145,146]

Before 1900 the large-scale production of nitric acid was based entirely on the reaction of concentrated sulfuric acid with $NaNO_3$ and KNO_3 (p. 407). The first successful process for making nitric acid directly from N_2 and O_2 was devised in 1903 by E. Birkeland and S. Eyde in Norway and represented the first industrial fixation of nitrogen:

$$\tfrac{1}{2}N_2 + 1\tfrac{1}{4}O_2 + \tfrac{1}{2}H_2O(l) \longrightarrow HNO_3(l); \quad \Delta H^\circ(298\,K) - 30.3\,kJ\,mol^{-1}$$

The overall reaction is exothermic but required the use of an electric arc furnace which, even with relatively cheap hydroelectricity, made the process very expensive. The severe activation energy barrier, though economically regrettable, is in fact essential to life since, in its absence, all the oxygen in the air would be rapidly consumed and the oceans would be a dilute solution of nitric acid and its salts. [Dilution of $HNO_3(l)$ to $HNO_3(aq)$ evolves a further $33.3\,kJ\,mol^{-1}$ at 25°C.]

The modern process for manufacturing nitric acid depends on the catalytic oxidation of NH_3 over heated Pt to give NO in preference to other thermodynamically more favoured products (p. 423). The reaction was first systematically studied in 1901 by W. Ostwald (Nobel Prize 1909) and by 1908 a commercial plant near Bochum, Germany, was producing 3 tonnes/day. However, significant expansion in production depended on the economical availability of synthetic ammonia by the Haber–Bosch process (p. 421). The reactions occurring, and the enthalpy changes per mole of N atoms at 25°C are:

$$NH_3 + 1\tfrac{1}{4}O_2 \longrightarrow NO + 1\tfrac{1}{2}H_2O(l); \quad \Delta H^\circ - 292.5\,kJ\,mol^{-1}$$

$$NO + \tfrac{1}{2}O_2 \longrightarrow NO_2; \quad \Delta H^\circ - 56.8\,kJ\,mol^{-1}$$

$$NO_2 + \tfrac{1}{3}H_2O(l) \longrightarrow \tfrac{2}{3}HNO_3(l) + \tfrac{1}{3}NO; \quad \Delta H^\circ - 23.3\,kJ\,mol^{-1}$$

Whence, multiplying the second and third reactions by $\frac{3}{2}$ and adding:

$$NH_3(g) + 2O_2(g) \longrightarrow HNO_3(l) + H_2O(l); \quad \Delta H^\circ - 412.6\,kJ\,mol^{-1}$$

In a typical industrial unit a mixture of air with 10% by volume of NH_3 is passed very rapidly over a series of gauzes (Pt, 5–10% Rh) at ~850°C and 5 atm pressure; contact time with the catalyst is restricted to ≤ 1 ms in order to minimize unwanted side reactions. Conversion efficiency is ~96% (one of the most efficient industrial catalytic reactions known) and the effluent gases are passed through an absorption column to yield 60% aqueous nitric acid at about 40°C. Loss of platinum metal from the catalyst under operating conditions is reduced by alloying with Rh but tends to increase with pressure from about 50–100 mg/tonne of HNO_3 produced at atmospheric pressure to about 250 mg/tonne at 10 atm; though this is not a major part of the cost, the scale of operations means that about 0.5 tonne of Pt metals is lost annually in the UK from this cause and more than twice this amount in the USA.

Concentration by distillation of the 60% aqueous nitric acid produced in most modern ammonia-burning plants is limited by the formation of a maximum-boiling azeotrope (122°) at 68.5% by weight; further concentration to 98–9% can be effected by countercurrent dehydration using concentrated H_2SO_4, or by distillation from concentrated $Mg(NO_3)_2$ solutions. Alternatively 99% pure HNO_3 can be obtained directly from ammonia oxidation by incorporating a final oxidation of N_2O_4 with the theoretical amounts of air and water at 70°C and 50 atm over a period of 4 h:

$$N_2O_4 + \tfrac{1}{2}O_2 + H_2O \longrightarrow 2HNO_3$$

The largest use of nitric acid (~75%) is in the manufacture of NH_4NO_3 and of this, about 75% is used for fertilizer production. Many plants have a capacity of 2000 tonnes/day or more and great care must be taken to produce the NH_4NO_3 in a readily handleable form (e.g. prills of about 3 mm diameter); about 1% of a "conditioner" is usually added to improve storage and handling properties. NH_4NO_3 is thermally unstable (p. 469) and decomposition can become explosive. For this reason a temperature limit of 140°C is imposed on the neutralization step and pH is strictly controlled. The decomposition is catalysed by many inorganic materials including chloride, chromates, hypophosphites, thiosulfates and powdered metals (e.g. Cu, Zn, Hg). Organic materials (oil, paper, string, sawdust, etc.) must also be rigorously excluded during neutralization since their oxidation releases additional heat. Indeed, since the mid-1950s NH_4NO_3 prills mixed with fuel oil have been extensively used as a direct explosive in mining and quarrying operations (p. 469) and this use now accounts for up to 15% of the NH_4NO_3 produced.

[146] S. I. CLARKE and W. J. MAZZAFRO Nitric acid, in *Kirk–Othmer Encyclopedia of Chemical Technology*, 4th edn., Vol. 17, pp. 80–107 (1996).

Some 8–9% of HNO_3 goes to make cyclohexanone, the raw material for adipic acid and ε-caprolactam, which are the monomers for nylon-6,6 and nylon-6 respectively. A further 7–10% is used in other organic nitration reactions to give nitroglycerine, nitrocellulose, trinitrotoluene and numerous other organic intermediates. Minor uses (which still consume large quantities of the acid) include the pickling of stainless steel, the etching of metals, and its use as the oxidizer in rocket fuels. In Europe nitric acid is sometimes used to replace sulfuric acid in the treatment of phosphate rock to give nitrophosphate fertilizers according to the idealized equation:

$$Ca_{10}(PO_4)_6F_2 + 14HNO_3 \longrightarrow 3Ca(H_2PO_4)_2 + 7Ca(NO_3)_2 + 2HF$$

Another minority use is in the manufacture of nitrates (other than NH_4NO_3) for use in explosives, propellants, and pyrotechnics generally; typical examples are:

explosives: gun powder, KNO_3/S/powdered C (often reinforced with powdered Si)
white smokes: ZnO/$CaSi_2$/KNO_3/C_2Cl_6
incendiary agents: Al/$NaNO_3$/methylmethacrylate/benzene
local heat sources: Al/Fe_3O_4/$Ba(NO_3)_2$; Mg/$Sr(NO_3)_2$/SrC_2O_4/thiokol polysulfide
photoflashes: Mg/$NaNO_3$
flares (up to 10 min): Mg/$NaNO_3$/CaC_2O_4/polyvinyl chloride/varnish; Ti/$NaNO_3$/boiled linseed oil
coloured flares: Mg/$Sr(NO_3)_2$/chlorinated rubber (red); Mg($Ba(NO_3)_2$)/chlorinated rubber (green).

These equilibria effect a rapid exchange of N atoms between the various species and only a single ^{15}N nmr signal is seen at the weighted average position of HNO_3, $[NO_2]^+$ and $[NO_3]^-$. They also account for the high electrical conductivity of the "pure" (stoichiometric) liquid (Table 11.13), and are an important factor in the chemical reactions of nitric acid and its non-aqueous solutions see below.

The phase diagram HNO_3–H_2O shows the presence of two hydrates, $HNO_3.H_2O$ mp −37.68°, and $HNO_3.3H_2O$ mp −18.47°. A further hemihydrate, $2HNO_3.H_2O$, can be extracted into benzene or toluene from 6 to 16 M aqueous solutions of nitric acid, and a dimer hydrate, $2HNO_3.3H_2O$, is also known, though neither can be crystallized. The structure of the two crystalline hydrates is dominated by hydrogen bonding as expected; e.g. the monohydrate is $[H_3O]^+[NO_3]^-$ in which there are puckered layers comprising pyramidal $[H_3O]^+$ hydrogen bonded to planar $[NO_3]^-$ so that there are 3 H bonds per ion. The trihydrate forms a more complex three-dimensional H-bonded framework. (See also p. 468 for the structure of hydrogen-nitrates.)

The solution chemistry of nitric acid is extremely varied. Redox data are summarized in Table 11.4 and Fig. 11.9 (pp. 434–8). In dilute aqueous solutions (<2 M) nitric acid is extensively dissociated into ions and behaves as a typical strong acid in its reactions with metals, oxides, carbonates, etc. More concentrated aqueous solutions are strongly oxidizing and attack most metals except Au, Pt, Rh and Ir, though some metals which react at lower concentrations are rendered passive, probably because of the formation of an oxide film (e.g. Al, Cr, Fe, Cu). Aqua regia (a mixture of concentrated hydrochloric and nitric acids in the ratio of ~3:1 by volume) is even more aggressive, due to the formation of free Cl_2 and ClNO and the superior complexing ability of the chloride ion; it has long been known to "dissolve" both gold and the platinum metals, hence its name. In concentrated H_2SO_4 the chemistry of nitric acid is dominated by the presence of the nitronium ion (pp. 458, 465):

$$HNO_3 + 2H_2SO_4 \rightleftharpoons NO_2^+ + H_3O^+ + 2HSO_4^-;$$

$$K \sim 22 \text{ mol l}^{-1}$$

Such solutions are extensively used in aromatic nitration reactions in the heavy organic chemicals industry. See also pp. 457–8.

Anhydrous nitric acid has been studied as a nonaqueous ionizing solvent, though salts tend to be rather insoluble unless they produce NO_2^+ or

NO_3^- ions.[147] Addition of water to nitric acid at first diminishes its electrical conductivity by repressing the autoprotolysis reactions mentioned above. For example, at $-10°$ the conductivity decreases from 3.67×10^{-2} ohm^{-1} cm^{-1} to a minimum of 1.08×10^{-2} ohm^{-1} cm^{-1} at 1.75 molal H_2O (82.8% N_2O_5) before rising again due to the increasing formation of the hydroxonium ion according to the acid-base equilibrium

$$HNO_3 + H_2O \rightleftharpoons H_3O^+ + NO_3^-$$

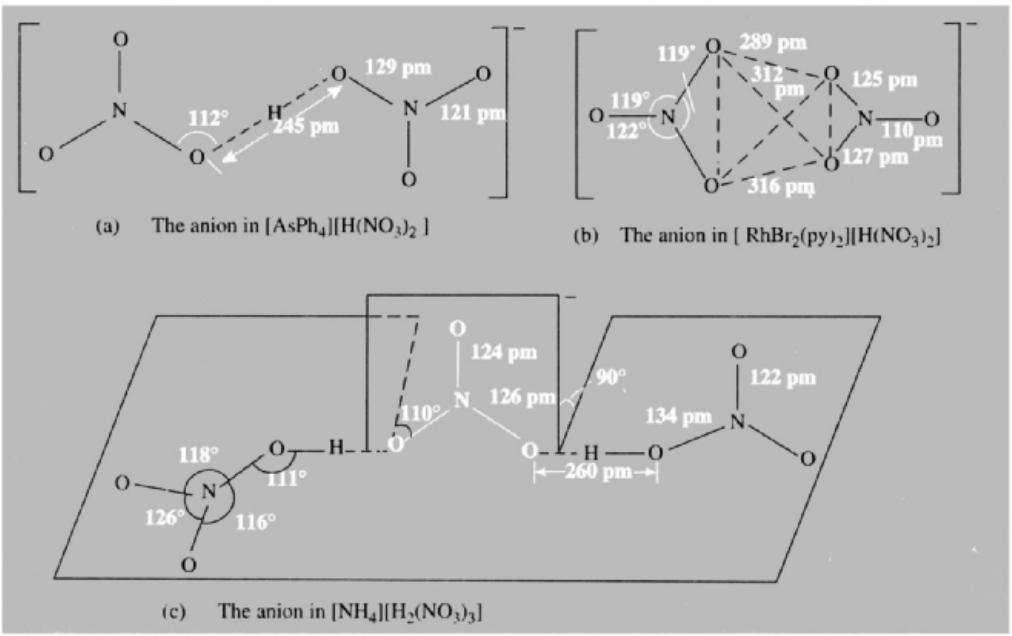
By contrast, Raman spectroscopy and conductivity measurements show that N_2O_4 ionizes almost completely in anhydrous HNO_3 to give NO^+ and NO_3^- and such solutions show no evidence for the species N_2O_4, NO_2^+ or NO_2^-.[126] N_2O_5 is also extremely soluble in anhydrous nitric acid in which it is completely ionized as $NO_2^+NO_3^-$.

Nitrates, the salts of nitric acid, can readily be made by appropriate neutralization of the acid, though sometimes it is the hydrate which crystallizes from aqueous solution. Anhydrous nitrates and nitrato complexes are often best prepared by use of donor solvents containing N_2O_4 (p. 456). The reaction of liquid N_2O_5 with metal oxides and chlorides affords an alternative route, e.g.:

$$TiCl_4 + 4N_2O_5 \longrightarrow Ti(NO_3)_4 + 2N_2O_4 + 2Cl_2$$

Many nitrates are major items of commerce and are dealt with under the appropriate metal (e.g. $NaNO_3$, KNO_3, NH_4NO_3, etc.). In addition, various hydrogen dinitrates and dihydrogen trinitrates are known of formula $M[H(NO_3)_2]$ and $M[H_2(NO_3)_3]$ where M is a large cation such as K, Rb, Cs, NH_4 or $AsPh_4$. In $[AsPh_4][H(NO_3)_2]$ 2 coplanar NO_3^- ions are linked by a short H bond as shown in (a) whereas [*trans*-$RhBr_2(py)_4$][$H(NO_3)_2$] features a slightly distorted tetrahedral group of 4 oxygen atoms in which the position of the H atom is not obvious [structure (b)]. In $[NH_4][H_2(NO_3)_3]$ there is a more extended system of H bonds in which 2 coplanar molecules of HNO_3 are symmetrically bridged by an NO_3^- ion at right angles as shown in (c).

[147] W. H. LEE, in J. J. LAGOWSKI (ed.), *The Chemistry of Non-aqueous Solvents*, Vol. 2, pp. 151–89, Academic Press, New York, 1967.



(a) The anion in $[AsPh_4][H(NO_3)_2]$

(b) The anion in $[RhBr_2(py)_2][H(NO_3)_2]$

(c) The anion in $[NH_4][H_2(NO_3)_3]$

As with the salts of other oxoacids, the thermal stability of nitrates varies markedly with the basicity of the metal, and the products of decomposition are equally varied.[148] Thus the nitrates of Group 1 and 2 metals find use as molten salt baths because of their thermal stability and low mp (especially as mixtures). Representative values of mp and the temperature (T_d) at which the decomposition pressure of O_2 reaches 1 atm are:

M	Li	Na	K	Rb	Cs	Ag	Tl
MP of MNO_3/°C	255	307	333	310	414	212	206
T_d/°C	474	525	533	548	584	–	–

The product of thermolysis is the nitrite or, if this is unstable at the temperature employed, the oxide (or even the metal if the oxide is also unstable):[149]

$$2NaNO_3 \longrightarrow 2NaNO_2 + O_2$$ (see p. 462)

$$2KNO_3 \longrightarrow K_2O + N_2 + \tfrac{5}{2}O_2$$

$$Pb(NO_3)_2 \longrightarrow PbO + 2NO_2 + \tfrac{1}{2}O_2$$ (see p. 456)

$$2AgNO_3 \longrightarrow Ag + 2NO_2 + O_2$$

As indicated in earlier sections, NH_4NO_3 can be exploded violently at high temperatures or by use of detonators (p. 466), but slow controlled thermolysis yields N_2O (p. 443):

$$2NH_4NO_3 \xrightarrow{>300°} 2N_2 + O_2 + 4H_2O$$

$$NH_4NO_3 \xrightarrow{200-260°} N_2O + 2H_2O$$

The presence of organic matter or other reducible material also markedly affects the thermal stability of nitrates and the use of KNO_3 in gunpowder has been known for centuries (p. 645).

The nitrate group, like the nitrite group, is a versatile ligand and numerous modes of coordination have been found in nitrato complexes.[150] The "uncoordinated" NO_3^- ion (isoelectronic with BF_3, BO_3^{3-}, CO_3^{2-}, etc.) is planar with N–O near 122 pm; this value increases to 126 pm in $AgNO_3$ and 127 pm in $Pb(NO_3)_2$. The most common mode of coordination is the symmetric bidentate mode Fig. 11.16a, though unsymmetrical bidentate coordination (b) also occurs and, in the limit, unidentate coordination (c). Bridging modes include the *syn-syn* conformation (d) (and the *anti-anti* analogue), and also geometries in which a single O atom bridges 2 or even 3 metal atoms (e), (f). Sometimes more than one mode occurs in the same compound.

Symmetrical bidentate coordination (a) has been observed in complexes with 1–6 nitrates coordinated to the central metal, e.g. $[Cu(NO_3)(PPh_3)_2]$; $[Cu(NO_3)_2]$, $[Co(NO_3)_2(OPMe_3)_2]$; $[Co(NO_3)_3]$ in which the 6 coordinating O atoms define an almost regular octahedron (Fig. 11.17a), $[La(NO_3)_3(bipy)_2]$; $[Ti(NO_3)_4]$, $[Mn(NO_3)_4]^{2-}$, $[Fe(NO_3)_4]^-$ and $[Sn(NO_3)_4]$, which feature dodecahedral coordination about the metal; $[Ce(NO_3)_5]^{2-}$ in which the 5 bidentate nitrate groups define a trigonal bipyramid leading to tenfold coordination of cerium (Fig. 11.17b); $[Ce(NO_3)_6]^{2-}$ and $[Th(NO_3)_6]^{2-}$, which feature nearly regular icosahedral (p. 141) coordination of the metal by 12 O atoms; and many lanthanide and uranyl $[UO_2]^{2+}$ complexes. It seems, therefore, that the size of the metal centre is not necessarily a dominant factor.

Unsymmetrical bidentate coordination (Fig. 11.16b) is observed in the high-spin d^7 complex $[Co(NO_3)_4]^{2-}$ (Fig. 11.17c), in $[SnMe_2(NO_3)_2]$ and also in several Cu^{II} complexes of formula $[CuL_2(NO_3)_2]$, where L is MeCN, H_2O, py or 2-MeC_5H_4N (α-picoline). An example of unidentate coordination is furnished by $K[Au(NO_3)_4]$ as shown in Fig. 11.18(a), and further examples are in *cis*-$[Pd(NO_3)_2(OSMe_2)_2]$, $[Re(CO)_5(NO_3)]$, $[Ni(NO_3)_2(H_2O)_4]$, $[Zn(NO_3)_2(H_2O)_4]$ and several Cu^{II} complexes such as $[CuL_2(NO_3)_2]$ where L is pyridine *N*-oxide or 1,4-diazacycloheptane. It appears that a combination of steric effects and the limited availability of coordination sites in these already highly coordinated late-transition-metal complexes restricts each nitrate group to one coordination site. When more

[150] C. C. Addison, N. Logan, S. C. Wallwork and C. D. Garner, *Q. Rev.* **25**, 289–322 (1971).

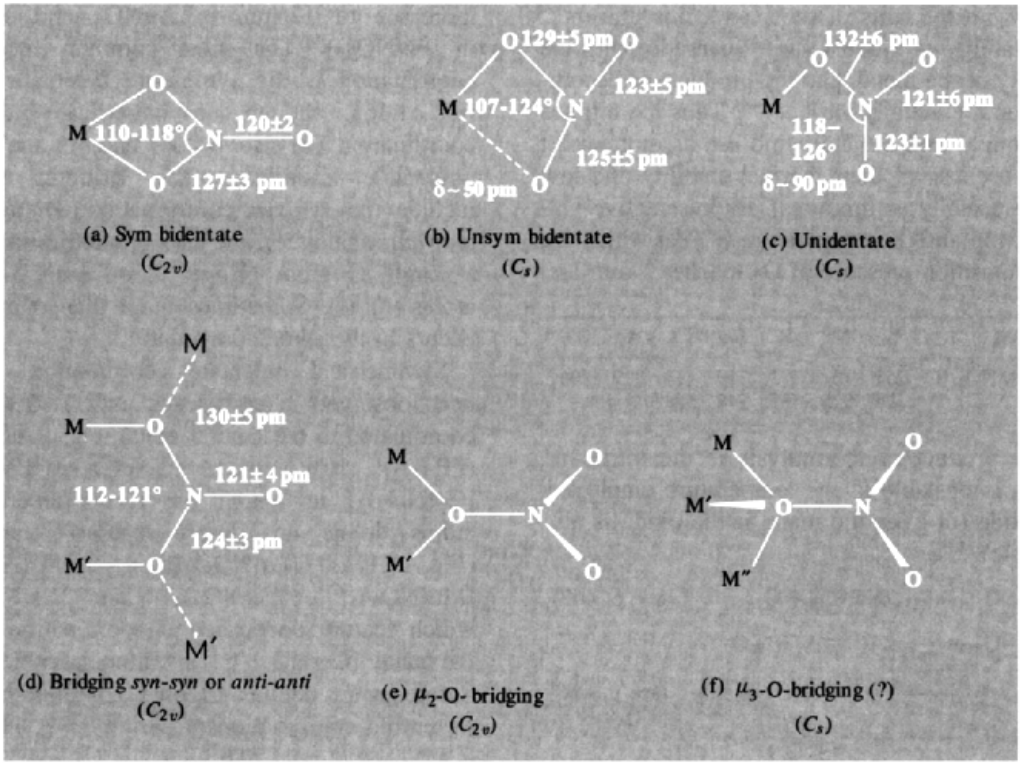

Figure 11.16 Coordination geometries of the nitrate group showing typical values for the interatomic distances and angles. Further structural details are in ref. 150.

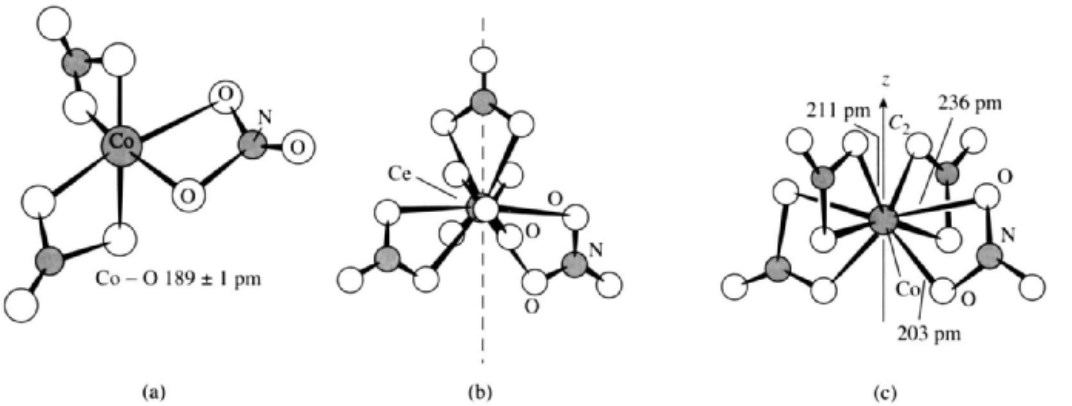

Figure 11.17 Structures of (a) $Co(NO_3)_3$, (b) $[Ce(NO_3)_5]^{2-}$ and (c) $[Co(NO_3)_4]^{2-}$

sites become available, as in $[Ni(NO_3)_2(H_2O)_2]$ and $[Zn(NO_3)_2(H_2O)_2]$, or when the co-ligands are less bulky, as in $[CuL_2(NO_3)_2]$, where L is H_2O, MeCN or $MeNO_2$, then the nitrate groups become bidentate bridging (mode d in Fig. 11.16) and a further example of this is seen in $[\alpha\text{-}Cu(NO_3)_2]$, which forms a more extensive network of bridging nitrate groups, as

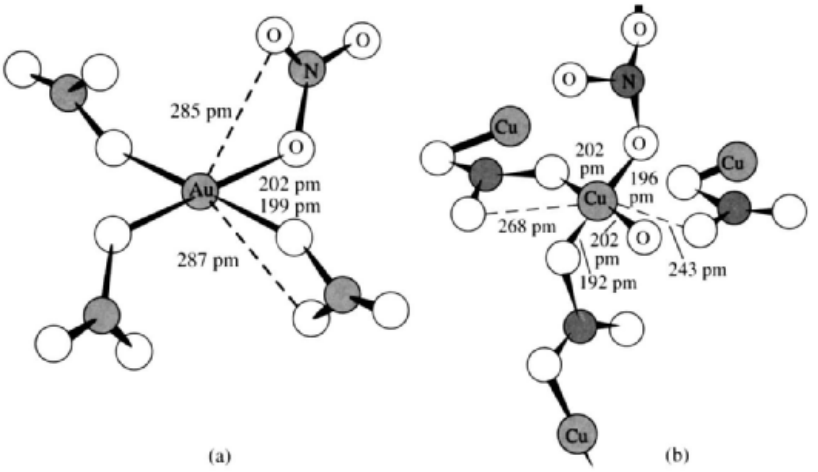

Figure 11.18 (a) Structure of $[Au(NO_3)_4]^-$, (b) α-$Cu(NO_3)_2$.

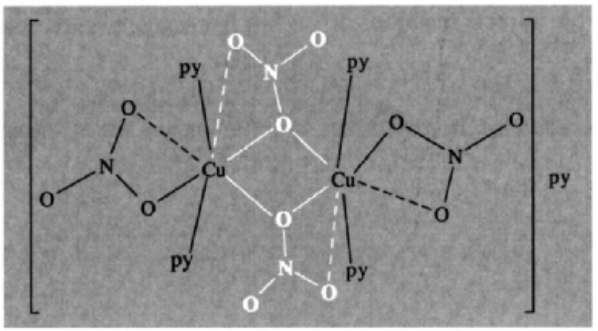

Figure 11.19 Schematic diagram of the centrosymmetric dimer in $[Cu_2(NO_3)_4(py)_4]py$ showing the two bridging nitrato groups each coordinated to the 2 Cu atoms by a single O atom; the dimer also has an unsymmetrical bidentate nitrate group on each Cu.

shown in Fig. 11.18(b). The single oxygen atom bridging mode (e) occurs in $[Cu(NO_3)_2(py)_2]_2py$ (Fig. 11.19) and the triple-bridge (f) may occur in $[Cu_4(NO_3)_2(OH)_6]$ though there is some uncertainty about this structure and further refinement would be desirable. Finally, the structure of the unique yellow solvate of formula $[Fe(NO_3)_3.1\frac{1}{2}N_2O_4]$ (p. 457) has been shown[128] to be $[N_4O_6]^{2+}[Fe(NO_3)_4]^-_2$. Each anion has 4 symmetrically bidentate NO_3 groups in which the coordinating O atoms lie at the corners of a trigonal dodecahedron, as is commonly found in tetranitrato species (N-O_t 120 pm, N-O(Fe) 127 pm, angles O-N-O 113.4° and O-Fe-O 60.0°). The $[N_4O_6]^{2+}$ cation comprises a central planar nitrate group (N-O 123 pm) surrounded by 3 NO groups at distances which vary from 241 to 278 pm (Fig. 11.20); the interatomic distance in the NO groups is very short (90–99 pm) implying NO^+ and the distances of these to the central NO_3 group are slightly less than the sum of the van der Waals radii for N and O.

Orthonitrates, $M^I_3NO_4$

There is no free acid H_3NO_4 analogous to orthophosphoric acid H_3PO_4 (p. 516), but the alkali metal orthonitrates Na_3NO_4 and K_3NO_4

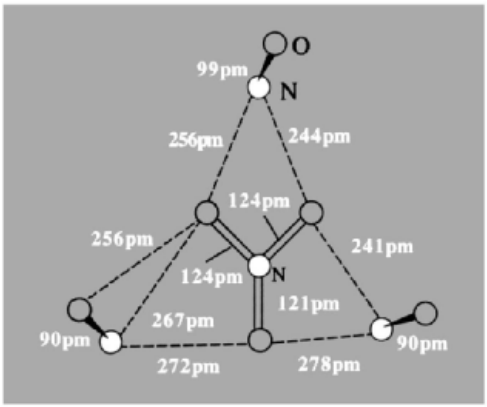

Figure 11.20 The $[N_4O_6]^{2+}$ cation.

have been synthesized by direct reaction at elevated temperatures, e.g.:[151,152]

$$NaNO_3 + Na_2O \xrightarrow[300°C \text{ for } 7 \text{ days}]{\text{Ag crucible}} Na_3NO_4$$

The compound forms white crystals that are very sensitive to atmospheric moisture and CO_2:

$$Na_3NO_4 + H_2O + CO_2 \longrightarrow NaNO_3 + NaOH + NaHCO_3$$

X-ray structural analyses have shown that the NO_4^{3-} ion has regular T_d symmetry with the unexpectedly small N-O distance of 139 pm. This suggests that substantial polar interactions are superimposed on the N-O single bonds since the d_π orbitals on N are too high in energy to contribute significantly to multiple covalent bonding. It further implies that $d_\pi - p_\pi$ interactions need not necessarily be invoked to explain the observed short interatomic distance in the isoelectronic oxoanions PO_4^{3-}, SO_4^{2-} and ClO_4^-.

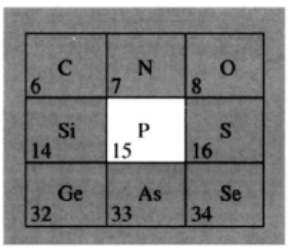
12 Phosphorus

12.1 Introduction

Phosphorus has an extensive and varied chemistry which transcends the traditional boundaries of inorganic chemistry not only because of its propensity to form innumerable covalent "organophosphorus" compounds, but also because of the numerous and crucial roles it plays in the biochemistry of all living things. It was first isolated by the alchemist Hennig Brandt in 1669 by the unsavoury process of allowing urine to putrify for several days before boiling it down to a paste which was then reductively distilled at high temperatures; the vapours were condensed under water to give the element as a white waxy substance that glowed in the dark when exposed to air.[1] Robert Boyle improved the process (1680) and in subsequent years made the oxide and phosphoric acid; he referred to the element as "aerial noctiluca", but the name phosphorus soon became generally accepted (Greek φως *phos*, light; Greek φορος *phoros*, bringing).

As shown in the Panel on the next page, phosphorus is probably unique among the elements in being isolated first from animal (human) excreta, then from plants, and only a century later being recognized in a mineral.



In much of its chemistry phosphorus stands in relation to nitrogen as sulfur does to oxygen. For example, whereas N_2 and O_2 are diatomic gases, P and S have many allotropic modifications which reflect the various modes of catenation adopted. Again, the ability of P and S to form multiple bonds to C, N and O, though it exists, is less highly developed than for N (p. 416), whereas the ability to form extended networks of –P–O–P–O– and –S–O–S–O– bonds is greater; this is well illustrated by comparing the oxides and oxoanions of N

[1] M. E. WEEKS, *Discovery of the Elements*, Journal of Chemical Education Publ., Easton, Pa., 1956; Phosphorus, pp. 109–39.

Time Chart for Phosphorus Chemistry

1669 Phosphorus isolated from urine by H. Brandt.
1680 R. Boyle improved the process and showed air was necessary for the phosphorescence of P.
1688 Phosphorus first detected in the vegetable kingdom (by B. Albino).
1694 P_4O_{10} and H_3PO_4 first made by R. Boyle.
1769 Phosphorus shown by J. G. Gahn and C. W. Scheele to be an essential constituent in the bones of man and animals, thereby revealing a plentiful source of fertilizers.
1779 Phosphorus first discovered in a mineral by J. G. Gahn (pyromorphite, a lead phosphate); subsequently found in the much more abundant apatite by T. Bergman and J. L. Proust.
1783 PH_3 first prepared by P. Gengembre (and independently in 1786 by R. Kirwan).
1808 PCl_3 and PCl_5 made by J. L. Gay Lussac and L. J. Thenard (and by H. Davy).
1811 N. L. Vauquelin isolated the first organic P compound (lethicin) from brain fat; it was characterized as a phospholipid by Gobbley in 1850.
1816 P. L. Dulong first clearly demonstrated the existence of two oxides of P.
1820 First synthesis of an organo-P compound by J. L. Lassaigne who made alkyl phosphites from H_3PO_4 + ROH.
1833 T. Graham (who later became the first President of the Chemical Society) classified phosphates as ortho, pyro or meta, following J. J. Berzelius's preparation of pyrophosphoric acid by heat.
1834 $(PNCl_2)_n$ made by F. Wöhler and J. von Liebig (originally formulated as $P_3N_2Cl_5$).
1843 J. Murray patented his production of "superphosphate" fertilizer (a name coined by him for the product of H_2SO_4 on phosphate rock).
1844 A. Albright started the manufacture of elemental P in England (for matches); 0.75 tonne in 1844, 26.5 tonnes in 1851.
1845 Polyphosphoric acids made by T. Fleitmann and W. Henneberg.
1848 Red (amorphous) P discovered by A. Schrötter.
1850 First commercial production of "wet process" phosphoric acid.
1868 E. F. Hoppe-Seyler and F. Miescher isolated "nuclein", the first nucleic acid, from pus.
1880 Modern cyclic formulation of tetrametaphosphate anion suggested by A. Glatzel. (Ring structure of metaphosphate definitely established by L. Pauling and J. Sherman 1937.)
1888 Electrothermal process for manufacturing P introduced by J. B. Readman (Edinburgh).
1898 "Strike-anywhere" matches devised by H. Sévène and E. D. Cahen in France; previously the brothers Lundström had exhibited "safety matches" in 1855, and the first P-containing striking match had been invented by F. Dérosne in 1812.
1929 C. H. Fiske and Y. Subbarow discovered adenosine triphosphate (ATP) in muscle fibre; it was synthesized some 20 y later by A. Todd *et al.* (Nobel Prize 1957).
1932 Elucidation of the glycolysis process (by G. Embden and by O. Meyerhof) followed by the glucose oxidation process (H. A. Krebs, 1937) established the intimate involvement of P compounds in many biochemical reactions.
1935 Radioactive ^{32}P made by (n,γ) reaction on ^{31}P.
~1940 Highly polymeric phosphate esters (nucleic acids) present in all cells and recognized as essential constituents of chromosomes.
1951 First ^{31}P nmr chemical shifts measured by W. C. Dickinson (for $POCl_3$, PCl_3, etc. relative to aq. H_3PO_4).
1952 Detergents (using polyphosphates) overtake soap as main washing agent in the USA. (Heavy duty liquid detergents with polyphosphates introduced in 1955.)
1953 F. H. C. Crick, J. B. Watson and M. H. F. Wilkins (with Rosalind Franklin) establish the double helix structure of nucleic acids (Nobel Prize 1962).
1960 Concept of "pseudorotation" introduced by R. S. Berry to interpret the stereochemical non-rigidity of trigonal bipyramidal PF_5 (and SF_4, ClF_3); the 5 F atoms are equivalent (1953) due to interconversion via a square pyramidal intermediate.
1961 First 2-coordinate compound of P prepared by A. B. Burg ($Me_3P{=}PCF_3$). First 1-coordinate P compound ($HC{\equiv}P$) made by T. E. Gier.

and P. "Valency expansion" is another point of difference between the elements of the first and second periods of the periodic table for, although compounds in which N has a formal oxidation state of +5 are known, no simple "single-bonded" species such as NF_5 or NCl_6^- have been prepared, analogous to PF_5 and PCl_6^-. This finds interpretation in the availability of 3d orbitals for bonding in P (and S) but not for N (or O). The extremely important Wittig reaction for olefin synthesis (p. 545) is another manifestation of this property. Discussion of more extensive group trends in which N and P are compared with the other Group 15 elements As, Sb and Bi, is deferred until the next chapter (pp. 550–4).

Because of the great importance of phosphorus and its compounds in the chemical industry, several books and reviews on their preparation and uses are available.[2–10] Some of these applications reflect the fact that P is a vital element for the growth and development of all plants and animals and is therefore an important constituent in many fertilizers. Phosphorus compounds are involved in energy transfer processes (such as photosynthesis (p. 126), metabolism, nerve function and muscle action), in heredity (via DNA), and in the production of bones and teeth.[11–14] Topics in phosphorus chemistry are regularly reviewed.[15]

12.2 The Element

12.2.1 Abundance and distribution

Phosphorus is the eleventh element in order of abundance in crustal rocks of the earth and it occurs there to the extent of ~1120 ppm (cf. H ~1520 ppm, Mn ~1060 ppm). All its known terrestrial minerals are orthophosphates though the reduced phosphide mineral schreibersite $(Fe,Ni)_3P$ occurs in most iron meteorites. Some 200 crystalline phosphate minerals have been described, but by far the major amount of P occurs in a single mineral family, the apatites, and these are the only ones of industrial importance, the others being rare curiosities.[16] Apatites (p. 523) have the idealized general formula $3Ca_3(PO_4)_2.CaX_2$, that is $Ca_{10}(PO_4)_6X_2$, and common members are fluorapatite $Ca_5(PO_4)_3F$, chloroapatite $Ca_5(PO_4)_3Cl$, and hydroxyapatite $Ca_5(PO_4)_3(OH)$. In addition, there are vast deposits of amorphous phosphate rock, phosphorite, which approximates in composition to fluoroapatite.[11,17] These deposits are widely

Australasia	Queensland, Nauru, Makatea	0.4
Total		9.1

spread throughout the world as indicated in Table 12.1 and reserves (1982 estimates) are adequate for several centuries with present technology. The phosphate content of commercial phosphate rock generally falls in the range $(72 \pm 10)\%$ BPL [i.e. "bone phosphate of lime", $Ca_3(PO_4)_2$] corresponding to $(33 \pm 5)\%$ P_4O_{10} or 12–17% P. The USA is the principal producer, having produced one-third of the total world output in 1985, and Morocco is the largest exporter, mainly to the UK and continental Europe. World production is a staggering 151 million tonnes of phosphate rock per annum (1985), equivalent to some 20 million tonnes of contained phosphorus (p. 480).

Phosphorus also occurs in all living things and the phosphate cycle, including the massive use of phosphatic fertilizers, is of great current interest.[18–20] The movement of phosphorus through the environment differs from that of the other non-metals essential to life (H, C, N, O and S) because it has no volatile compounds that can circulate via the atmosphere. Instead, it circulates via two rapid biological cycles on land and sea (weeks and years) superimposed on a much slower primary geological inorganic cycle (millions of years). In the inorganic cycle, phosphates are slowly leached from the igneous or sedimentary rocks by weathering, and transported by rivers to the lakes and seas where they are precipitated as insoluble metal phosphates or incorporated into the aquatic food chain. The solubility of metal phosphates clearly depends on pH, salinity, temperature, etc., but in neutral solution $Ca_3(PO_4)_2$ (solubility product $\sim 10^{-29}$ mol^5 l^{-5}) may first precipitate and then gradually transform into the less soluble hydroxyapatite [$Ca_5(PO_4)_3(OH)$], and, finally, into the least-soluble member, fluoropatite (solubility product $\sim 10^{-60}$ mol^9 l^{-9}). Sedimentation follows and eventually, on a geological time scale, uplift to form a new land mass. Some idea of actual concentrations of ions involved may be obtained from the fact that in sea water there is one phosphate group per million water molecules; at a salinity of 3.3%, pH 8 and 20°C, 87% of the inorganic phosphate exist as $[HPO_4]^{2-}$, 12% as $[PO_4]^{3-}$ and 1% as $[H_2PO_4]^-$. Of the $[PO_4]^{3-}$ species, 99.6% is complexed with cations other than Na^+.[21]

The secondary biological cycles stem from the crucial roles that phosphates and particularly organophosphates play in all life processes. Thus organophosphates are incorporated into the backbone structures of DNA and RNA which regulate the reproductive processes of cells, and they

[21] E. T. DEGENS, *Topics in Current Chem.* **64**, 1–112 (1976).

are also involved in many metabolic and energy-transfer processes either as adenosine triphosphate (ATP) (p. 528) or other such compounds. Another role, restricted to higher forms of life, is the structural use of calcium phosphates as bones and teeth. Tooth enamel is nearly pure hydroxyapatite and its resistance to dental caries is enhanced by replacement of OH^- by F^- (fluoridation) to give the tougher, less soluble $[Ca_5(PO_4)_3F]$. It is also commonly believed that the main inorganic phases in bone are hydroxyapatite and an amorphous phosphate, though many crystallographers favour an isomorphous solution of hydroxyapatite and the carbonate–apatite mineral dahlite, $[(Na,Ca)_5(PO_4,CO_3)_3(OH)]$, as the main crystalline phase with little or no amorphous material. Young bones also contain brushite, $[CaHPO_4.2H_2O]$, and the hydrated octacalcium phosphate $[Ca_8H_2(PO_4)_6.5H_2O]$ which is composed, essentially, of alternate layers of apatite and water oriented parallel to (001).[21]

The land-based phosphate cycle is shown in Fig. 12.1.[22] The amount of phosphate in untilled soil is normally quite small and remains fairly stable because it is present as the insoluble salts of Ca^{II}, Fe^{III} and Al^{III}. To be used by plants, the phosphate must be released as the soluble $[H_2PO_4]^-$ anion, in which form it can be taken up by plant roots. Although acidic soil conditions will facilitate phosphate absorption, phosphorus is the nutrient which is often in shortest supply for the growing plant. Most mined phosphate is thus destined for use in fertilizers and this accounts for up to 75% of phosphate rock in technologically advanced countries and over 90% in less advanced (more

[22] J. Emsley, *Chem. Br.* **13**, 459–63 (1977).

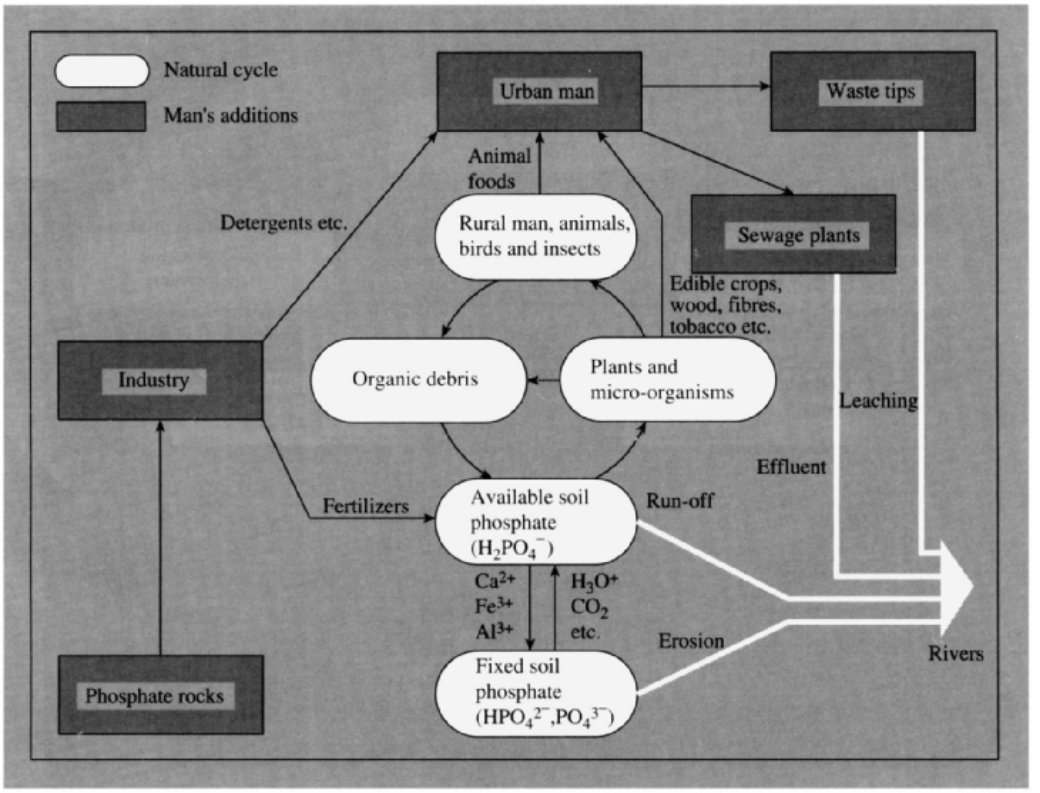

Figure 12.1 The land-based phosphate cycle.

agriculturally based) countries. Moderation in all things, however: excessive fertilization of natural waters due to detergents and untreated sewage in run-off water can lead to heavy overgrowth of algae and higher plants, thus starving the water of dissolved oxygen, killing fish and other aquatic life, and preventing the use of lakes for recreation, etc. This unintended over-fertilization and its consequences has been termed eutrophication (Greek εὖ, *eu*, well; τρέφειν, *trephein*, to nourish) and is the subject of active environmental legislation in several countries. Reclamation of eutrophied lakes can best be effected by addition of soluble Al^{III} salts to precipitate the phosphates.

As just implied, the land-based phosphorus cycle is connected to the water-based cycle via the rivers and sewers. It has been estimated that, on a global scale, about 2 million tonnes of phosphate are washed into the seas annually from natural processes and rather more than this amount is dumped from human activities. For example in the UK some 200 000 tonnes of phosphate enters the sewers each year: 100 000 tonnes from detergents (now decreasing), 75 000 from human excreta, and 25 000 tonnes from industrial processes. Details of the subsequent water-based phosphate cycle are shown schematically in Fig. 12.2. The water-based cycle is the most rapid of the three phosphate cycles and can be completed within weeks (or even days). The first members of the food chain are the algae and experiments with radioactive ^{32}P (p. 482) have shown that, within minutes of entering an aquatic environment, inorganic phosphate is absorbed by algae and bacteria (50% uptake in 1 min. 80% in 3 min). In the seas and oceans the various phosphate anions

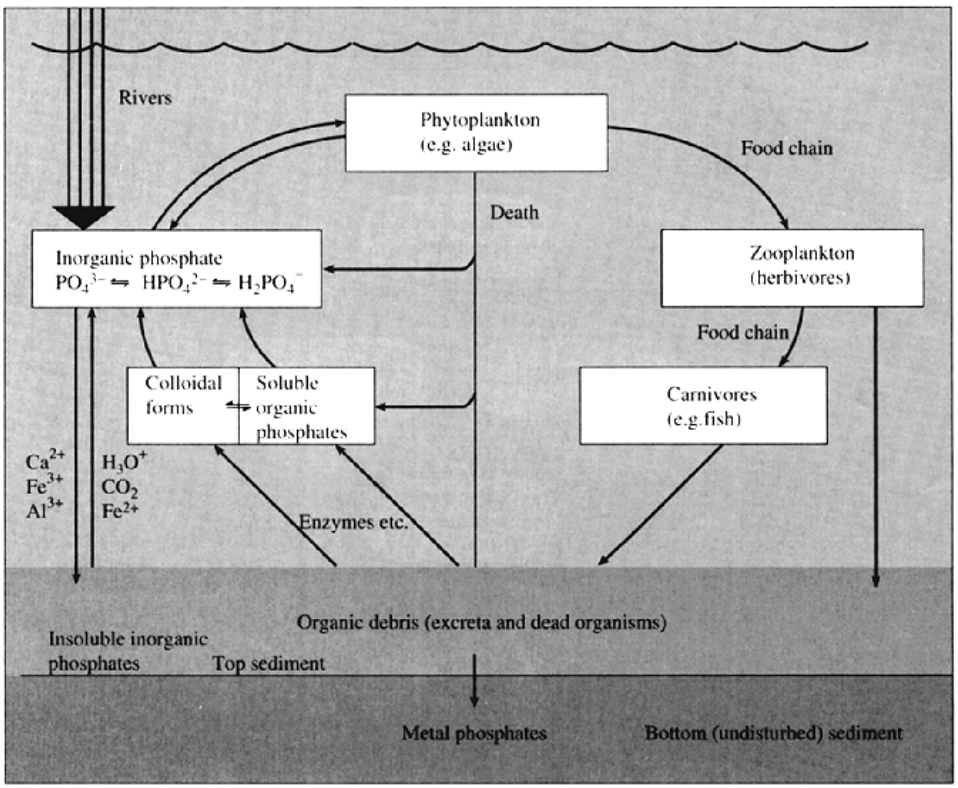

Figure 12.2 The water-based phosphate cycle.[22]

form insoluble inorganic phosphates which gradually sink to the sea bed. The concentration of phosphate therefore increases with depth (down to about 1000 m, below which it remains fairly constant); by contrast the sunlight, which is necessary for the primary photosynthesis in the food chain, is greatest at the surface and rapidly diminishes with depth. It is significant that those regions of the sea where the deeper phosphate-rich waters come welling up to the surface support by far the greatest concentration of the world's fish population; such regions, which occur in the mid-Pacific, the Pacific coast of the Americas, Arabia and Antarctica, account for only 0.1% of the sea's surface but support 50% of the world's fish population.

12.2.2 Production and uses of elemental phosphorus

For a century after its discovery the only source of phosphorus was urine. The present process of heating phosphate rock with sand and coke was proposed by E. Aubertin and L. Boblique in 1867 and improved by J. B. Readman who introduced the use of an electric furnace. The reactions occurring are still not fully understood, but the overall process can be represented by the idealized equation:

$$2Ca_3(PO_4)_2 + 6SiO_2 + 10C \xrightarrow[1500°]{1400-} 6CaSiO_3 + 10CO + P_4; \quad \Delta H = -3060\,\text{kJ/mol } P_4$$

The presence of silica to form slag which is vital to large-scale production was perceptively introduced by Robert Boyle in his very early experiments. Two apparently acceptable mechanisms have been proposed and it is possible that both may be occurring. In the first, the rock is thought to react with molten silica to form slag and P_4O_{10} which is then reduced by the carbon:

$$2Ca_3(PO_4)_2 + 6SiO_2 \longrightarrow 6CaSiO_3 + P_4O_{10}$$

$$P_4O_{10} + 10C \longrightarrow 10CO + P_4$$

In the second possible mechanism, the rock is considered to be directly reduced by CO and the CaO so formed then reacts with the silica to form slag:

$$2Ca_3(PO_4)_2 + 10CO \longrightarrow 6CaO + 10CO_2 + P_4$$

$$6CaO + 6SiO_2 \longrightarrow 6CaSiO_3$$

$$10CO_2 + 10C \longrightarrow 20CO$$

Whatever the details, the process is clearly energy intensive and, even at 90% efficiency, requires ~15 MWh per tonne of phosphorus (see Panel).

12.2.3 Allotropes of phosphorus[23]

Phosphorus (like C and S) exists in many allotropic modifications which reflect the variety of ways of achieving catenation. At least five crystalline polymorphs are known and there are also several "amorphous" or vitreous forms (see Fig. 12.3). All forms, however, melt to give the same liquid which consists of symmetrical P_4 tetrahedral molecules, P–P 225 pm. The same molecular form exists in the gas phase (P–P 221 pm), but at high temperatures (above ~800°C) and low pressures P_4 is in equilibrium with the diatomic form P≡P (189.5 pm). At atmospheric pressure, dissociation of P_4 into $2P_2$ reaches 50% at ~1800°C and dissociation of P_2 into 2P reaches 50% at ~2800°.

The commonest form of phosphorus, and the one which is usually formed by condensation from the gaseous or liquid states, is the waxy, cubic, white form α-P_4 (d 1.8232 g cm^{-3} at 20°C). This, paradoxically, is also the most volatile and reactive solid form and thermodynamically the least stable. It is the slow phosphorescent oxidation of the vapour above these crystals that gives white phosphorus its most characteristic property. Indeed, the emission of yellow-green light from the oxidation of P_4 is one of the earliest recorded examples of chemiluminescence, though the details of the reaction

[23] D. E. C. CORBRIDGE, *The Structural Chemistry of Phosphorus*, Elsevier, Amsterdam, 1974, 542 pp.

Production of White Phosphorus[3,11,17]

A typical modern phosphorus furnace (12 m diameter) can produce some 4 tonnes per hour and is rated at 60–70 MW (i.e. 140 000 A at 500 V). Three electrodes, each weighing 60 tonnes, lead in the current. The amounts of raw material required to make 1 tonne of white phosphorus depend on their purity but are typically 8 tonnes of phosphate rock, 2 tonnes of silica, 1.5 tonnes of coke, and 0.4 tonnes of electrode carbon. The phosphorus vapour is driven off from the top of the furnace together with the CO and some H_2; it is passed through a hot electrostatic precipitator to remove dust and then condensed by water sprays at about 70° (P_4 melts at 44.1°). The byproduct CO is used for supplementary heating.

As most phosphate rock approximates in composition to fluoroapatite, $[Ca_5(PO_4)_3F]$, it contains 3–4 wt% F. This reacts to give the toxic and corrosive gas SiF_4 which must be removed from the effluent. The stoichiometry of phosphate rock might suggest that about 1 mole of SiF_4 is formed for each 3 moles of P_4, but only about 20% of the fluorine reacts in this way, the rest being retained in the slag. Nevertheless, since a typical furnace can produce over 30 000 tonnes of phosphorus per year this represents a substantial waste of a potentially useful byproduct (~5000 tonnes SiF_4 yearly per furnace). In some plants the SiF_4 is recovered by treatment with water and soda ash (Na_2CO_3) to give Na_2SiF_6 which can be used in the fluoridation of drinking water.

Another troublesome impurity in phosphate rock (1–5%) is Fe_2O_3 which is reduced in the furnace to "ferrophosphorus", an impure form of Fe_2P. This is a dense liquid at the reaction temperature; it sinks beneath the slag and can be drained away at intervals. As every tonne of ferrophosphorus contains ~0.25 tonne of P, this is a major loss, but is unavoidable since the Fe_2O_3 cannot economically be removed beforehand. The few uses of ferrophosphorus depend on its high density (~6.6 g cm^{-3}). It can be mixed with dynamite for blasting or used as a filler in high-density concrete and in radiation shields for nuclear reactors. It is also used in the manufacture of special steels and cast-irons, especially for non-sparking railway brake-shoes. The other substantial byproduct, $CaSiO_3$ slag, has little economic use and is sold as hard core for road-fill or concrete aggregate; about 7–9 tonnes are formed per tonne of P produced.

World capacity for the production of elemental P is ~1.5 million tonnes per year. Some figures for 1984 are as follows:

Country	USSR	USA	Germany	Netherlands	Canada	France
ktonne/y	615	412	95	90	90	39
Country	**China**	**Japan**	**Mexico**	**India**	**South Africa**	
ktonne/y	35	20	10	10	6	

About 80–90% of the elemental P produced is reoxidized to (pure) phosphoric acid (p. 521). The rest is used to make phosphorus oxides (p. 503), sulfides (p. 506), phosphorus chlorides and oxochloride (p. 496), and organic P compounds. A small amount is converted to red phosphorus (see below) for use in the striking surface of matches for pyrotechnics and as a flame retarding agent (in polyamides). Bulk price for P_4 is ~$2.00/kg.

mechanism are still not fully understood: the primary emitting species in the visible region of the spectrum are probably $(PO)_2$ and HPO; ultraviolet emission from excited states of PO also occurs.[24] At −76.9° and atmospheric pressure the α-form of P_4 converts to the very similar white hexagonal β-form (d 1.88 g cm^{-3}), possibly by loss of rotational disorder; $\Delta H(\alpha \rightarrow \beta)$ −15.9 kJ (mol P_4)$^{-1}$. White phosphorus is insoluble in water but exceedingly soluble (as P_4) in CS_2 (~880 g per 100 g CS_2 at 10°C). It is also very soluble in PCl_3, $POCl_3$, liquid SO_2, liquid NH_3 and benzene, and somewhat less soluble in numerous other organic solvents. The β-form can be maintained as a solid up to 64.4°C under a pressure of 11 600 atm, whereas the α-form melts at 44.1°C. White phosphorus is highly toxic and ingestion, inhalation or even contact with skin must be avoided; the fatal dose when taken internally is about 50 mg.

Amorphous red phosphorus was first obtained in 1848 by heating white P_4 out of contact with air for several days, and is now made on a commercial scale by a similar process at 270°–300°C. It is denser than white P_4 (~2.16 g cm^{-3}), has a much higher m.p.

[24] R. J. VAN ZEE and A. U. KHAN, *J. Am. Chem. Soc.* **96**, 6805–6 (1974).

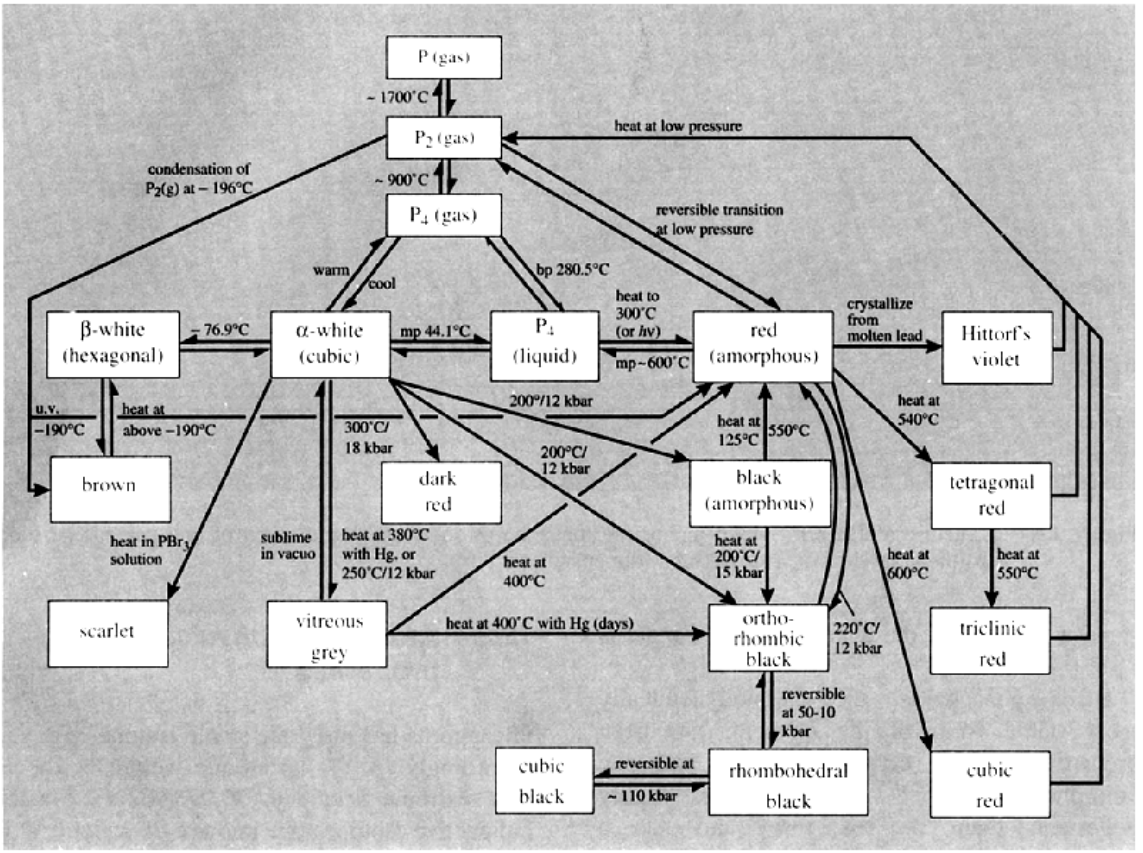

Figure 12.3 Interconversion of the various forms of elemental phosphorus (1 kbar = 10^8 Pa = 987.2 atm).

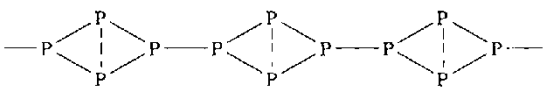
(~600°C), and is much less reactive; it is therefore safer and easier to handle, and is essentially non-toxic. The amorphous material can be transformed into various crystalline red modifications by suitable heat treatment, as summarized on the right hand side of Fig. 12.3. It seems likely that all are highly polymeric and contain three-dimensional networks formed by breaking one P–P bond in each P_4 tetrahedron and then linking the remaining P_4 units into chains or rings of P atoms each of which is pyramidal and 3 coordinate as shown schematically below:



This is well illustrated by the crystal structure of Hittorf's violet monoclinic allotrope (d 2.35 g cm^{-3}) which was first made in 1865 by crystallizing phosphorus in molten lead. The structure is exceedingly complex[25] and consists of P_8 and P_9 groups linked alternately by pairs of P atoms to form tubes of pentagonal cross-section and with a repeat unit of 21P (Fig. 12.4). These tubes, or complex chains, are stacked (without direct covalent bonding) to form sheets and are linked by P–P bonds to similar chains which lie at right angles to the first set in an adjacent parallel layer. These pairs of composite parallel sheets are then stacked to form the crystal. The average P···P distance is 222 pm (essentially the

[25] VON H. THURN and H. KREBS. *Acta Cryst.* **B25**, 125–35 (1969).

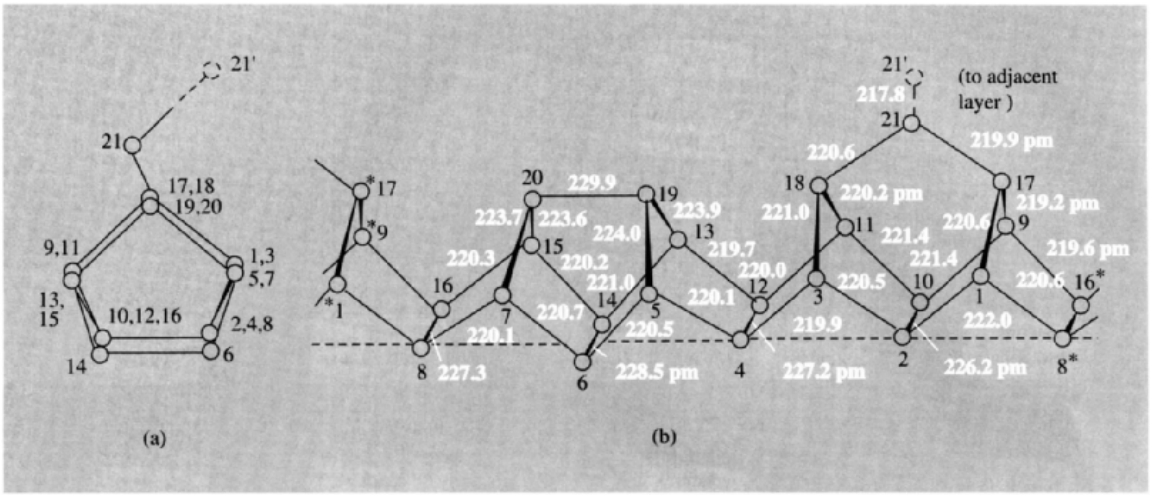


Figure 12.4 Structure of Hittorf's violet monoclinic phosphorus showing (a) end view of one pentagonal tube, (b) the side view of a single tube (dimensions in pm).

same as in P_4) but the average P- P- P angle is 101° (instead of 60°).

Black phosphorus, the thermodynamically most stable form of the element, has been prepared in three crystalline forms and one amorphous form. It is even more highly polymeric than the red form and has a correspondingly higher density (orthorhombic 2.69, rhombohedral 3.56, cubic 3.88 g cm^{-3}). Black phosphorus (orthorhombic) was originally made by heating white P_4 to 200° under a pressure of 12 000 atm (P. W. Bridgman, 1916). Higher pressures convert it successively to the rhombohedral and cubic forms (Fig. 12.3). Orthorhombic black P (mp ~610°) has a layer structure which is based on a puckered hexagonal net of 3-coordinate P atoms with 2 interatomic angles of 102° and 1 of 96.5° (P–P 223 pm). The relation of this form to the rhombohedral and cubic forms is shown in Fig. 12.5. Comparison with the rhombohedral forms of As, Sb and Bi is also instructive in showing the increasing tendency towards octahedral coordination and metallic properties (p. 551). Black P is semiconducting but its electrical properties are probably significantly affected by impurities introduced during its preparation.

12.2.4 Atomic and physical properties[26]

Phosphorus has only one stable isotope, $^{31}_{15}P$, and accordingly (p. 17) its atomic weight is known with extreme accuracy, 30.973 762(4). Sixteen radioactive isotopes are known, of which ^{32}P is by far the most important; it is made on the multikilogram scale by the neutron irradiation of $^{32}S(n,p)$ or $^{31}P(n,\gamma)$ in a nuclear reactor, and is a pure β-emitter of half life 14.26 days, E_{max} 1.709 MeV, E_{mean} 0.69 MeV. It finds extensive use in tracer and mechanistic studies. The stable isotope ^{31}P has a nuclear spin quantum number of $\frac{1}{2}$ and this is much used in nmr spectroscopy.[27] Chemical shifts and coupling constants can both be used diagnostically to determine structural information.

In the ground state, P has the electronic configuration $[Ne]3s^2 3p_x^1 3p_y^1 3p_z^1$ with 3 unpaired

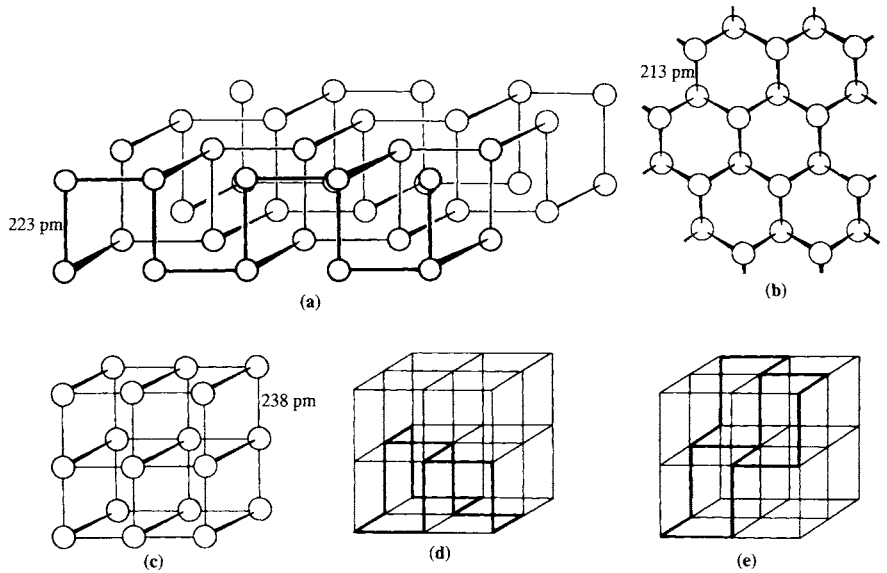

Figure 12.5 The structures of black phosphorus: (a) portion of one layer of orthorhombic P (idealized), (b) rhombohedral form, portion of one hexagonal layer, (c) cubic form, 4 unit cells, (d) distortion of (a) to the cubic form, and (e) distortion of (b) to the cubic form.

electrons; this, together with the availability of low-lying vacant 3d orbitals, accounts for the predominant oxidation states III and V in phosphorus chemistry. Ionization energies, electronegativity, and atomic radii are compared with those of N, As, Sb and Bi on p. 550. White phosphorus (α-P_4) has mp 44.1° (or 44.25° when ultrapure), bp 280.5° and a vapour pressure of 0.122 mmHg at 40°C. It is an insulator with an electrical resistivity of $\sim 10^{11}$ ohm cm at 11°C, a dielectric constant of 4.1 (at 20°) and a refractive index n_D (29.2°) 1.8244. The heat of combustion of P_4 to P_4O_{10} is $-2971\,kJ\,mol^{-1}$ and the heat of transition to amorphous red phosphorus is -29 kJ (mol P_4)$^{-1}$.

12.2.5 Chemical reactivity and stereochemistry

The spontaneous chemiluminescent reaction of white phosphorus with moist air was the first property of the element to be observed and was the origin of its name (p. 473); its spontaneous ignition temperature in air is ~35°. We have already seen (p. 481) that the reactivity of phosphorus depends markedly upon which allotrope is being studied and that increasing catenation of the polymeric red and black forms notably diminishes both reactivity and solubility. The preference of phosphorus for these forms rather than for the gaseous form P_2, which is its most obvious distinction from nitrogen, can be rationalized in terms of the relative strengths of the triple and single bonds for the 2 elements. Reliable values are hard to obtain but generally accepted values are as follows:

E(N≡N)/kJ per mol of N	946	E(P≡P)/kJ per mol of P	490
E(>N–N<)/kJ per mol of N	159 (or 296)	E(>P–P<)/kJ per mol of P	200
Ratio	5.95 (or 3.20)	Ratio	2.45

It is clear that, for nitrogen, the triple bond is preferred since it has more than 3 times the energy of a single bond, whereas for phosphorus the triple-bond energy is less than 3 times the single-bond energy and so allotropes having 3 single bonds per P atom are more stable than that with a triple bond.

Table 12.2 Stereochemistry of phosphorus

CN	Geometry	Examples
0	—	P(g) — in equilibrium with P_2(g) above 2200°C
1	—	P_2(g) — in equilibrium with P_4(g) above 800°C; HC≡P; FC≡P; MeC≡P (p. 544)
2	Bent[28]	$HP{=}CH_2$,[29] $[P(CN)_2]^-$,[30] $[\{C_6H_4S(NR)C\}_2P]^+X^-$ (p. 544), *cyclo*-C_5H_5P, 2,4,6-$Ph_3C_5H_2P$; $Me_3P{=}PCF_3$; P_7^{3-} anion[31] (isoelectronic with P_4S_3) in Sr_3P_{14}; P_{11}^{3-} anion in Na_3P_{11}; diazaphospholes[32]
3	Planar	$[PhP\{Mn(\eta^5\text{-}C_5H_5)(CO)_2\}_2]$[33], [(fluorenyl)=P{=C($SiMe_3$)$_2$}]$^-$[33a]
	Pyramidal	P_4, PH_3, PX_3, P_4O_6, $[PhP\{Co(CO)_4\}_2]$[34]
4	Tetrahedral	PH_4^+, Cl_3PO, P_4O_{10}, PO_4^{3-}, polyphosphates, MP (zinc-blende type, M = B, Al, Ga, In), $[Co_3(CO)_9(\mu_3\text{-}PPh)]$,[35] $[(P_4)Ni\{(Ph_2PCH_2CH_2)_3N\}]$;[36] many complexes of PR_3 etc., with metal centres
	Local C_{2v}	PBr_4^-, $[PBr_2(CN)_2]^-$.[37] $[\mu(\eta^3\text{-}P_3)\{Ni(triphos)\}_2]^{2+}$[38]
5	Trigonal bipyramidal	PF_5, PPh_5
	Square pyramidal	$[Co_4(CO)_8(\mu\text{-}CO)_2(\mu_4\text{-}PPh)_2]$, $[Os_5(CO)_{15}(\mu_4\text{-}POMe)]$[39]
6	Octahedral	PF_6^-, PCl_6^-, MP (NaCl-type, M = La, Sm, Th, U etc.)
	Trigonal primsatic	Rh_4P_3, Hf_3P_2 (also contains seven- and eight-fold coordination of P by M), $[(\mu_6\text{-}P)\{Os(CO)_3\}_6]^-$[40]
	Irregular (4 + 2)	$[Co_6(CO)_{14}(\mu\text{-}CO)_2P]^-$
7	Capped trigonal prismatic	Ta_2P, Hf_2P (contains P in seven-, eight-, and nine-fold coordination by M)
8	Cubic	M_2P (antifluorite type (p. 118), M = Ir, Rh)
	Bicapped trigonal prismatic	Hf_2P
9	Tricapped trigonal prismatic	M_3P (M = Ti, V, Cr, Mn, Fe, Ni, Zr, Nb, Ta) M_2P ($PbCl_2$-type, M = Fe, Co, Ru)
	Monocapped square antiprismatic	$[Rh_9(CO)_{21}P]^{2-}$[41]

Phosphorus forms binary compounds with all elements except Sb, Bi and the noble gases. It reacts spontaneously with O_2 and the halogens at room temperature, the mixtures rapidly reaching incandescence. Sulfur and the alkali metals also react vigorously with phosphorus on warming, and the element combines directly with all metals (except Bi, Hg, Pb) frequently with incandescence (e.g. Fe, Ni, Cu, Pt). White phosphorus (but not red) also reacts readily with heated aqueous solutions to give a variety of products (pp. 493 and 513ff), and with many other aqueous and nonaqueous reagents.

The stereochemistry and bonding of P are very varied as will become apparent in later sections: the element is known in at least 14 coordination geometries with CN up to 9, though the most frequently met have CN 3, 4, 5 and 6. Some typical coordination geometries are summarized in Table 12.2 and illustrated in Fig. 12.6. Many of these compounds will be more fully discussed in later sections.

The great propensity of P atoms to catenate into chains, rings and clusters, P_n, has already been noted during the discussion on allotropy (pp. 479–83). These groupings and other similar ones also feature in the structures of metal phosphides (p. 489), polyphosphanes (p. 492) and organopolyphosphanes (p. 542). Moreover, neutral or charged groupings, P_n, ($n = 2$–6, 10) can also serve as ligands[42–44], as can isolated P atoms in anions such as $[(\mu_6\text{-P})\{Os(CO)_3\}_6]^-$[40] and other structures shown at the foot of Fig. 12.6. Two decades ago virtually nothing was known about this aspect of phosphorus chemistry, but it is now a burgeoning field, and the substantial progress which has been made in recent years now permits a general overview to be given.

The P_2 group is isoelectronic with ethyne (p. 932) and with N_2 (pp. 414–6) and As_2. It has emerged as a versatile ligand with several well characterized coordination modes as shown schematically in Fig 12.7. The first compound containing the P_2 ligand, $[(Co(CO)_3]_2(\mu,\eta^2\text{-}P_2)]$, was isolated as a red oil in 1973 and was clearly similar to the already known alkyne and As_2 complexes $[\{Co(CO)_3\}_2\{\mu,\eta^2\text{-}(CR)_2\}]$ and $[\{Co(CO)_3\}_2(\mu,\eta^2\text{-}As_2)]$. It was formed by reaction of $Na[Co(CO)_4]$ with PCl_3 or PBr_3 in thf. The tetrahedrane-like core (Fig. 12.7a) was confirmed by X-ray analysis on the related PPh_3 derivative $[Co_2(CO)_5(PPh_3)(\mu,\eta^2\text{-}P_2)]$.[45] Direct action of P_4 with appropriate carbonyl, cyclopentadienyl or alkoxide derivatives of Cr, Mo, W, etc. has yielded a wide range of such compounds of P_2 acting as a 4e-donor, in all of which the two ML_n vertices can be considered as 15e-acceptors (i.e $d^{10} + 5e$, "isoelectronic" with P in Group 15) e.g., $\{Cr(Cp)(CO)_2\}$,[46] $\{Mo(Cp)(CO)_2\}$, $\{W(py)(OPr^i)_2(\mu\text{-}OPr^i)\}$[47], etc., where Cp is $(\eta^5\text{-}C_5H_5)$ or one of its derivatives. With 14e or 16e metal–vertex acceptors the core adopts the more open "butterfly" configuration (Fig 12.7b) without direct M–M bonding, e.g $[\{Ni(Et_2PCH_2CH_2PEt_2)\}_2(\mu,\eta^2\text{-}P_2)]$[48] and its $\{Ni(PEt_3)_2\}$ and $[Pt(PEt_3)_2]$ analogues. Further electron-pair donation from one or both of the P atoms can also occur to give compounds such as $[Cr_2(\eta^5\text{-}C_5H_5)_2(CO)_4(\mu,\eta^2\text{-}P_2)\{M(CO)_5\}_{1\text{ or }2}]$ (M = Cr, Mo, W) (see Figs. 12.7 c, d).[49] In these, the P_2 group acts as a 6e or 8e donor, and bridges 3 or 4 M atoms respectively. See below — p. 488 — for examples cf. bis-P_2, i.e. pseudo-P_4 complexes.)

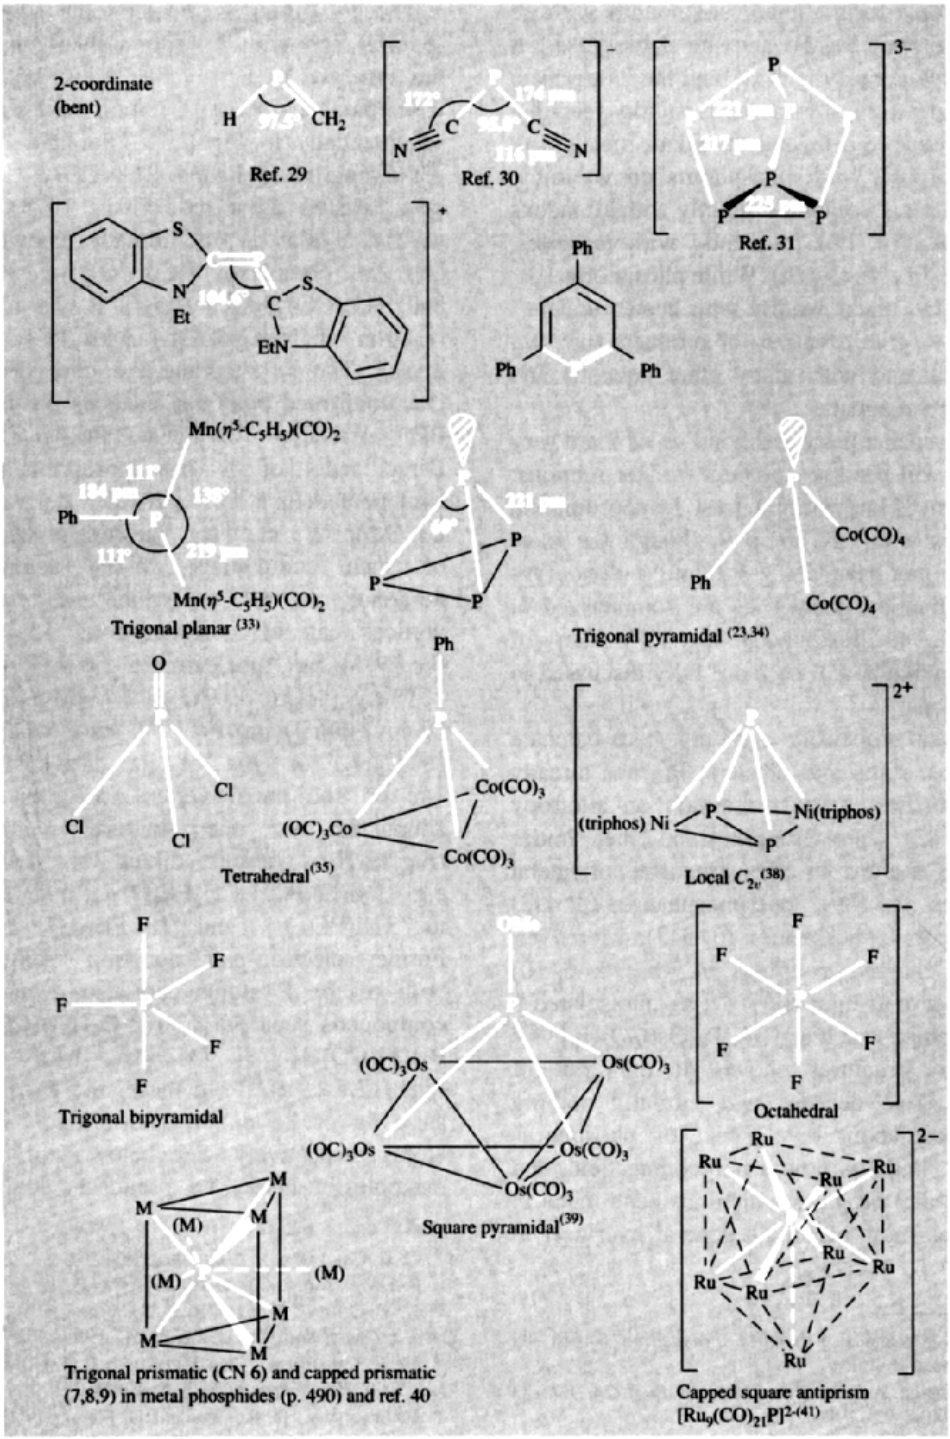

Figure 12.6 Schematic representation of some of the coordination geometries of phosphorus.

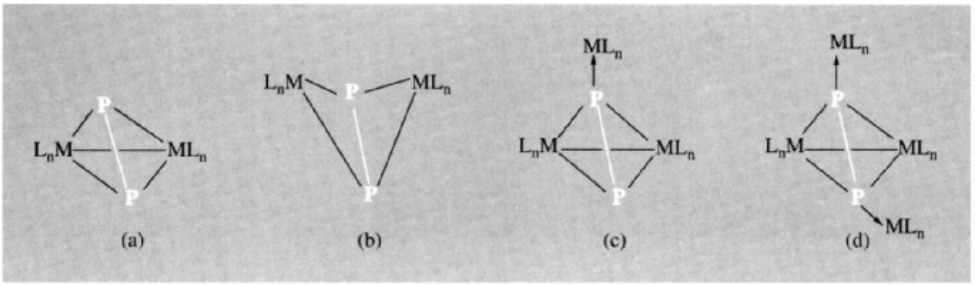

Figure 12.7 (a) (μ,η^2-P_2) 4e-donor to 15e ML_n vertices. (b) (μ,η^2-P_2)4e-donor to 14e or 16e ML_n. (c) Triply bridging (μ_3,η^2-P_2), a formal 6e-donor. (d) Quadruply bridging (μ_4,η^2-P_2) 8e-donor.

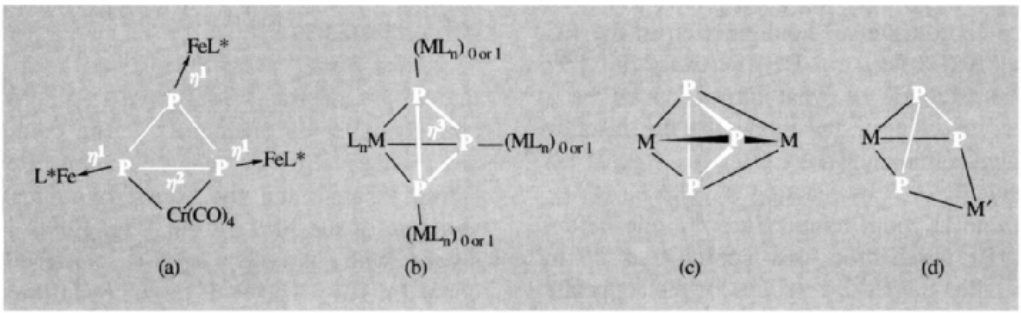

Figure 12.8 (a) *Cyclo*-P_3 as an η^1 and η^2 donor (see text). (b) *Cyclo*-P_3 as an η^3 donor; addition of η^1 donation to 1, 2 or 3 further metal centres is possible. (c) Bis-η^3 ligation of *cyclo*-P_3 to coordinated metal centres $M(L_n)$. (d) More open η^2,η^3 coordination of P_3 to different metal centres, e.g. M = {Ni(triphos)}^{1}, M′ = {Pt(PPh_3)$_2$} (see text).

The *cyclo*-P_3 ligand can act in either the η^1,η^2 or η^3 mode as shown schematically in Fig. 12.8(a)–(c).[42,50] Each of the three P atoms in 8(b) can also have a further pendant ML_n group attached thereby making the *cyclo*-P_3 ligand μ_2, μ_3 or μ_4. In addition, the more open structure 8(d) is known in the binuclear cation $[(triphos)Ni\{P_3Pt(PPh_3)_2\}]^+$, where triphos is 1,1,1-tris(diphenylphosphinomethyl)-ethane, $\{CH_3C(CH_2PPh_2)_3\}$.[42] The η^1 and η^2 modes in Fig. 12.8(a) have only recently been established (in $[\{(\eta^5\text{-}C_5Me_5)(CO)_2Fe\text{-}P\}_3\text{-}Cr(CO)_4]$)[50] but the η^3 mode in Fig. 12.8(b) has been known since 1976 when it was found that one of the main products of the reaction between P_4 and $[Co_2(CO)_8]$ was the reactive pale-yellow solid $[Co(CO)_3(\eta^3\text{-}P_3)]$.[51] Numerous other examples featuring Co, Rh and Ir, and the isoelectronic cationic metal centres with Ni, Pd and Pt are now known. Metals in earlier groups require more electron donation from pendant ligands to achieve the 15-electron vertex configuration isolobal with the subrogated P atom in P_4, e.g. $\{Mo(\eta^5\text{-}C_5Me_5)(CO)_2\}$. The binuclear η^3,η^3 mode of *cyclo*-P_3 (Fig. 12.8c) and its As_3 homologues were extensively studied by L. Sacconi and others in the early 1980s.[38,42,43]

As a ligand, P_4 can adopt various geometries,[42,43] including the P_4 tetrahedron, planar *cyclo*-P_4 (both square and trapezoidal), and a planar zig-zag chain. In principle, the tetrahedral cluster P_4 could ligate in η^1,η^2 and η^3 modes,

[50] L. Weber, U. Sonnenberg, H.-G. Stammler and B. Neumann, *Z. anorg. allg. Chem.* **605**, 87–99 (1991).

[51] A. Vizi-Orosz *J. Organomet. Chem.* **111**, 61–4 (1976).

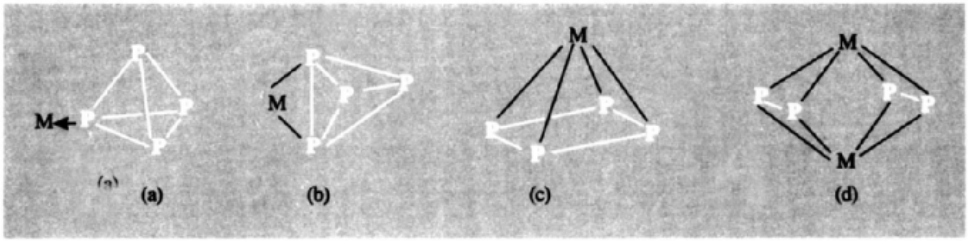

Figure 12.9 Schematic representation of various coordination modes: (a) η^1-P_4; (b) η^2-P_4; (c) η^4-*cyclo*-P_4; (d) (μ, η^2-P_2)$_2$ (see text).

though only the first two have so far been established (Fig. 12.9 (a), (b)). [Note, however, the face-coordinated η^3 configuration in the Bi_4 complex $[(CO)_4Fe(\mu_4,\eta^3\text{-}Bi_4)\{Fe(CO)_3\}_3]^{2-}$.][52] The first example of what turned out to be a complex involving the η^1 mode was the unstable red-brown compound $[\{Fe(CO)_4\}_3(\mu_3\text{-}P_4)]$ which was made in 1977 by reacting P_4 with $Fe_2(CO)_9$ in benzene at room temperature:[53] one vertex of the P_4 tetrahedron was coordinated η^1 to one of the $\{Fe(CO)_4\}$ groups while opposite edges of the P_4 cluster were bonded η^2 to the other two $\{Fe(CO)_4\}$ groups. The first η^1-P_4 complex to be characterized by X-ray structural analysis was $[(\eta^3\text{-}np_3)Ni(\eta^1\text{-}P_4)]$,[54] formed by direct reaction of white P_4 with the Ni^0 complex $[Ni(\eta^4\text{-}np_3)]$ in thf at 0°C where np_3 is $N(CH_2CH_2PPh_2)_3$. Coordination results in a slight elongation of the tetrahedron with $P_{basal}-P_{apical}$ 220 pm and $P_{basal}-P_{basal}$ 209 pm (cf. 221 pm in α-P_4. The η^2-P_4 mode of coordination is featured in many complexes with Rh, Ir, etc., for example $[RhCl(\eta^2\text{-}P_4)(PPh_3)_2]$,[55] formed by direct reaction of P_4 with $[RhCl(PPh_3)_3]$ in CH_2Cl_2 at −78°C. The coordinated edge is almost perpendicular to the $\{RhClL_2\}$ plane and is lengthened by about 25 pm to 246.2 pm, whereas the other P–P distances are essentially unchanged from those in uncoordinated P_4.[56]

Square planar *cyclo*-P_4 features as a ligand in $[Nb(\eta^5\text{-}C_5H_3Bu^t_2\text{-}1,3)(CO)_2(\eta^4\text{-}P_4)]$[57] and the corresponding Ta analogue.[58] The compounds are formed by uv photolysis of P_4 with $[M(cp^*)(CO)_4]$ and the square-pyramidal *nido* structure of the MP_4 cluster (Fig. 12.9c) is consistent with its 14e ($2n+4$) cluster-electron count (p. 161). The P–P distances in the coplanar P_4 ligand are in the range 214–218 pm for the Nb complex, with Nb–P_4(centre) being 142 pm and the basal PPP angles being 92.6° and 88.4°. In the Ta complex, the P–P distances are 215–217 pm. A co-product of the photolysis reaction is the related bis-(P_2) complex $[\{Ta(C_5H_3Bu^t_2)(CO)(\mu,\eta^2\text{-}P_2)\}_2]$, Fig. 12.9d, in which the P–P distance is 212 pm within each P_2 ligand and 357 pm between the coplanar P_2 ligands. Several similar binuclear bis-(P_2) complexes are known, including Rh/Rh, and mixed metal species involving Nb/Ta and Ta/Co.[58]

A still more open configuration occurs in the zig-zag P_4 chain shown in Fig. 12.10(a).[59] This was found in the dianion of the deep

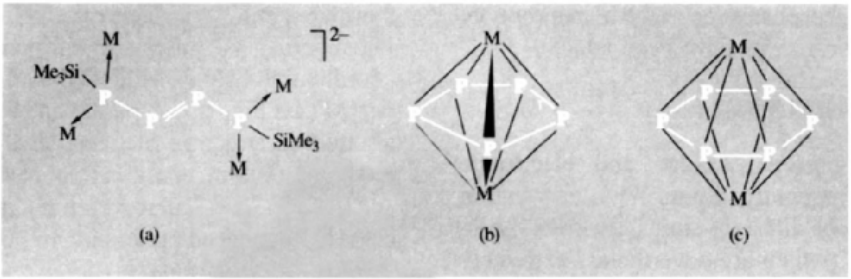

Figure 12.10 (a) Zig-zag P_4 chain, M = $\{Cr(CO)_5\}$; (b) η^5-*cyclo*-P_5, M various; (c) η^6-*cyclo*-P_6, M various (see text).

red crystalline compound $[Li(dme)_3]^+{}_2[(SiMe_3)\{Cr(CO)_5\}_2P{-}P{=}P{-}P\{Cr(CO)_5\}_2(SiMe_3)]^{2-}$ which was obtained by reacting $Li[P(SiMe_3)_2\{Cr(CO)_5\}]$ with $BrCH_2CH_2Br$ in 1,2-dimethoxyethane (dme). The interatomic distances P–P 221.9 pm and P=P 202.5 pm reflect the bond orders indicated.

Because *cyclo*-P_5 and *cyclo*-P_6 can be considered as isoelectronic with C_5H_5 and C_6H_6 their appearance as ligands is not entirely unexpected, but the recent synthesis and characterization of such complexes was nevertheless a noteworthy achievement.[43] Typical examples are $[(Mn(CO)_3(\eta^5\text{-}P_5)]$[60] (formed by the direct action of KP_5 on $[Mn(CO)_5Br]$ in dmf at 155°C) and $[Fe(\eta^5\text{-}C_5H_5)(\mu{:}\eta^5,\eta^5\text{-}P_5)Fe(\eta^5\text{-}C_5Me_4R)]$[43] (Fig. 12.10(b)) for *cyclo*-P_5; and $[\{Mo(\eta^5\text{-}C_5Me_5)\}_2(\mu{:}\eta^5,\eta^5\text{-}P_6)]$[43] (Fig. 12.10(c)) for planar *cyclo*-P_6. Several *cyclo*-As_5 and -As_6 analogues are also known. The complex $[\{Ti(\eta^5\text{-}C_5Me_5)\}_2(\mu{:}\eta^3,\eta^3\text{-}P_6)]$ features a puckered P_6 ring in the chair conformation, so that the overall cluster core has a distorted cubane geometry.[61]

The most complex P_n ligand so far characterized is the astonishing μ_5 hexadentate P_{10} unit in $[\{Cr(\eta^5\text{-}C_5H_5)(CO)_2\}_5P_{10}]$ (see ref. 62 for details).

12.3 Compounds

12.3.1 Phosphides[63–65]

Phosphorus forms stable binary compounds with almost every element in the periodic table and those with metals are called phosphides. Like borides (p. 145) they are known in a bewilderingly large number of stoichiometries, and typical formulae are M_4P, M_3P, $M_{12}P_5$, M_7P_3, M_2P, M_7P_4, M_5P_3, M_3P_2, M_4P_3, M_5P_4, M_6P_5, MP, M_3P_4, M_2P_3, MP_2, M_3P_7, M_2P_5, MP_3, M_3P_{11}, M_3P_{14}, MP_5, M_3P_{16}, M_4P_{26}, MP_7, M_2P_{16} and MP_{15}. Many metals (e.g. Ti, Ta, W, Rh) form as many as 5 or 6 phosphides and Ni has at least 8 (Ni_3P, Ni_5P_2, $Ni_{12}P_5$, NiP_2, Ni_5P_4, NiP, NiP_2 and NiP_3). Ternary and more complex metal phosphides are also known.

The most general preparative route to phosphides (Faraday's method) is to heat the metal with the appropriate amount of red P at high temperature in an inert atmosphere or an evacuated sealed tube:

$$nM + mP \xrightarrow{\text{heat}} M_nP_m$$

An alternative route (Andrieux's method) is the electrolysis of fused salts such as molten

alkali-metal phosphates to which appropriate metal oxides or halides have been added:

$$\{(NaPO_3)_n/NaCl/WO_3\}\ \text{fused} \xrightarrow{\text{electrol}} W_3P$$

Variation in current, voltage and electrolyte composition frequently results in the formation of phosphides of different stoichiometries. Less-general routes (which are nevertheless extremely valuable in specific instances) include:

(a) Reaction of PH_3 with a metal, metal halide or sulfide, e.g.:

$$PH_3 + 2Ti \xrightarrow{800°} Ti_2P$$

$$2PH_3 + 3Ni(O_2CMe)_2 \xrightarrow{H_2O} Ni_3P_2$$

$$+ 6HOAc \xrightarrow[\text{reaction}]{\text{further}} Ni_5P_2$$

(b) Reduction of a phosphate such as apatite with C at high temperature, e.g.:

$$Ca_3(PO_4)_2 + 8C \xrightarrow{1200°} Ca_3P_2 + 8CO$$

(c) Reaction of a metal phosphide with further metal or phosphorus to give a product of different stoichiometry, e.g.:

$$Th_3P_4 + Th \xrightarrow{900°} 4ThP$$

$$4RuP + P_4(g) \xrightarrow{650°} 4RuP_2$$

$$4IrP_2 \xrightarrow[\text{(low press)}]{1150°} 2Ir_2P + 1\tfrac{1}{2}P_4(g)$$

Phosphides resemble in many ways the metal borides (p. 145), carbides (p. 297), and nitrides (p. 417), and there are the same difficulties in classification and description of bonding. Perhaps the least-contentious procedure is to classify according to stoichiometry, i.e. (a) metal-rich phosphides (M/P > 1), (b) monophosphides (M/P = 1), and (c) phosphorus-rich phosphides (M/P < 1):

(a) *Metal-rich phosphides* are usually hard, brittle, refractory materials with metallic lustre, high thermal and electrical conductivity, great thermal stability and general chemical inertness. Phosphorus is often in trigonal prismatic coordination being surrounded by 6 M, or by 7, 8 or 9 M (see Fig. 6.7 on p. 148 and Fig. 12.6). The antifluorite structure of many M_2P also features eightfold (cubic) coordination of P by M. The details of the particular structure adopted in each case are influenced predominantly by size effects.

(b) *Monophosphides* adopt a variety of structures which appear to be influenced by both size and electronic effects. Thus the Group 3 phosphides MP adopt the zinc-blende structure (p. 1210) with tetrahedral coordination of P, whereas SnP has the NaCl-type structure (p. 242) with octahedral coordination of P, VP has the hexagonal NiAs-type structure (p. 556) with trigonal prismatic coordination of isolated P atoms by V, and MoP has the hexagonal WC-type structure (p. 299) in which both Mo and P have a trigonal prismatic coordination by atoms of the other kind. More complicated arrangements are also encountered, e.g.:[65]

TiP, ZrP, HfP: half the P trigonal prismatic and half octahedral;

MP (M = Cr, Mn, Fe, Co, Ru, W): distorted trigonal prismatic coordination of P by M plus two rather short contacts to P atoms in adjacent trigonal prisms, thus building up a continuous chain of P atoms; NiP is a distortion of this in which the P atoms are grouped in pairs rather than in chains (or isolated as in VP).

(c) *Phosphorus-rich phosphides* are typified by lower mps and much lower thermal stabilities when compared with monophosphides or metal-rich phosphides. They are often semiconductors rather than metallic conductors and feature increasing catenation of the P atoms (cf. boron rich borides, p. 148). P_2 units occur in FeP_2, RuP_2 and OsP_2 (marcasite-type, p. 680) and in PtP_2 (pyrites type, p. 680) with P–P 217 pm. Planar P_4 rings (square or rectangular) occur in several MP_3 (M = Co, Ni, Rh, Pd, Ir) with P–P typically 223 pm in the square ring of RhP_3. Structures are also known in which the P atoms form chains (PdP_2, NiP_2, CdP_2, BaP_3),

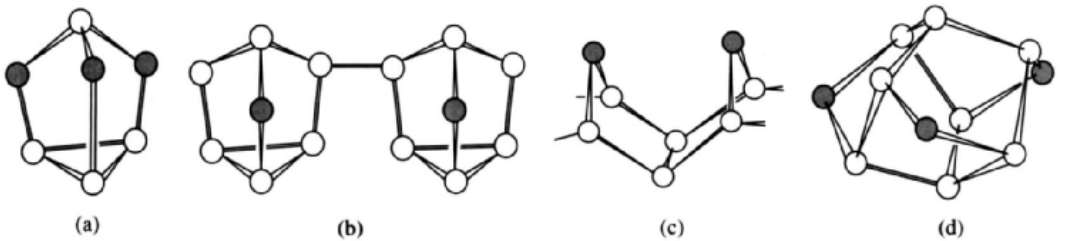

Figure 12.11 Schematic representation of the structures of polycyclic polyphosphide anions (open circles P, shaded circles P^-) (a) P_7^{3-}, (b) $(P_7^-)_x$, (c) $\not\equiv P_8^{2-} \not\equiv_x$, (d) P_{11}^{3-}.

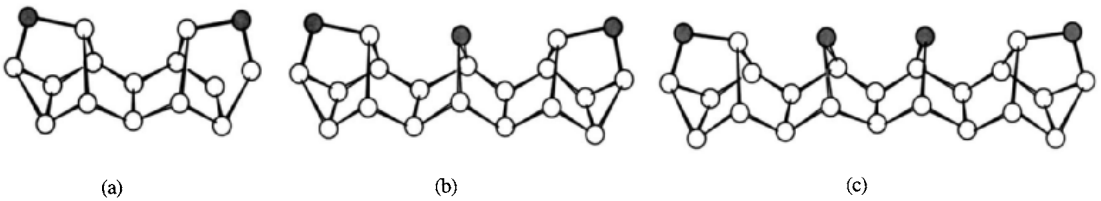

Figure 12.12 Schematic representation of the structures of (a) P_{16}^{2-}, (b) P_{21}^{3-}, (c) P_{26}^{4-}, (open circles P, shaded circles P^-)

double chains ($ZnPbP_{14}$, $CdPbP_{14}$, $HgPbP_{14}$), or layers (CuP_2, AgP_2, CdP_4); in the last 3 phosphides the layers are made up by a regular fusion of puckered 10-membered rings of P atoms with the metal atoms in the interstices. The double-chained structure of $MPbP_{14}$ is closely related to that of violet phosphorus (p. 482).

In addition, phosphides of the electropositive elements in Groups 1, 2 and the lanthanoids form phosphides with some degree of ionic bonding. The compounds Na_3P_{11} and Sr_3P_{14} have already been mentioned (p. 484) and other somewhat ionic phosphides are M_3P (M = Li, Na), M_3P_2 (M = Be, Mg, Zn, Cd), MP (M = La, Ce) and Th_3P_4. However, it would be misleading to consider these as fully ionized compounds of P^{3-} and there is extensive metallic or covalent interaction in the solids. Such compounds are characterized by their ready hydrolysis by water or dilute acid to give PH_3.

Recent extensive structural studies by X-ray crystallography and by ^{31}P nmr spectroscopy have revealed an astonishing variety of *conjuncto*-polyphosphides with quasi-ionic cluster structures.[66,67] Thus, the yellow compound Li_3P_7 (which has been known since 1912) and its Na–Cs analogues have been found to contain the P_7^{3-} cluster shown schematically in Fig. 12.11(a). The cluster can be regarded as being related to the P_4 tetrahedron (p. 479) by the notional insertion of three 2-connected P^- atoms (cf. the structure of P_4S_3, p. 507, with which it is precisely isoelectronic). Substitution of P by As leads to a series of closely related anions $[P_{7-x}As_x]^{3-}$ $x = 1$–5, (?6),[68] and As_7^{3-} is also known for Na, Rb, Cs). Catenation of the P_7^{3-} unit, as shown in Fig. 12.11(b), leads to the stoichiometry $M^+P_7^-$. The repeating unit $=P_8=$, which is clearly related to a segment in the structure of Hittorf's allotrope (p. 482), is shown in Fig. 12.11(c). A more complex

[66] H. G. VON SCHNERING, in A. H. COWLEY (ed.) *Rings, Clusters and Polymers of the Main Group Elements*, ACS Symposium Series No. **232**, Washington D. C. 1983, pp. 69–80.

[67] M. BAUDLER, *Angew. Chem. Int. Edn. Engl.* **21**, 492–512 (1982); **26**, 419–41 (1987).

[68] W. HÖNLE and H. G. VON SCHNERING, *Angew. Chem. Int. Edn. Engl.* **25**, 352–3 (1986).

cluster occurs in the yellow/orange compounds $M_3^+P_{11}^{3-}$ (Fig. 12.11d): P_{11}^{3-} can be thought of as comprising two axial PP_3 tetrahedra joined by a central belt of three 2-connected P^- atoms, so that the sequence of cluster planes contains 1,3,(3),3,1 P atoms, respectively.

Even more complex *conjuncto*-polyphosphide anions can be constructed, such as those of stoichiometry P_{16}^{2-}, P_{21}^{3-} and P_{26}^{4-}, Fig. 12.12(a)(b)(c).[66,67] These bear an obvious structural relationship to $=P_8=$ (Fig. 12.11c) and to Hittorf's phosphorus (Fig. 12.4) and can be viewed as ladders of P atoms with alternate P–P and $P(P^-)P$ rungs, terminated at each end by a ring-closing $P(P^-)$ unit. The P–P distances and PPP angles in these various species are much as expected. These cluster anions, and those mentioned in the preceding paragraphs, can be partially or completely protonated (see next subsection) and they also occur in neutral organopolyphosphanes (p. 495).

A completely different structural motif has very recently been found in the red-brown phosphide Ca_5P_8, formed by direct fusion of Ca metal and red P in the correct atom ratio in a corundum crucible at 1000°C.[69] The structure comprises Ca^{2+} cations and P_8^{10-} anions, the latter adopting a staggered ethane conformation. (Note that P^+ is isolobal with C and P^{2-} with H so that $C_2H_6 = [(P^+)_2(P^{2-})_6] = P_8^{10-}$.) The internal P–P distance is 230.1 pm and the terminal P–P distances 214.9–216.9 pm, while the internal PPP angles are 104.2–106.4° and the outer angles are 103.4–103.7°.

Few industrial uses have so far been found for phosphides. "Ferrophosphorus" is produced on a large scale as a byproduct of P_4 manufacture, and its uses have been noted (p. 480). Phosphorus is also much used as an alloying element in iron and steel, and for improving the workability of Cu. Group 3 monophosphides are valuable semiconductors (p. 255) and Ca_3P_2 is an important ingredient in some navy sea-flares since its reaction with water releases spontaneously flammable phosphines. By contrast the phosphides of Nb, Ta and W are valued for their chemical inertness, particularly their resistance to oxidation at very high temperatures, though they are susceptible to attack by oxidizing acids or peroxides.

12.3.2 Phosphine and related compounds

The most stable hydride of P is phosphine (phosphane), PH_3. It is the first of a homologous open-chain series P_nH_{n+2} ($n = 1–9$) the members of which rapidly diminish in thermal stability, though P_2H_4 and P_3H_5 have been isolated pure. There are ten other (unstable) homologous series: P_nH_n ($n = 3–10$), P_nH_{n-2} ($n = 4–12$), and P_nH_{n-4} ($n = 5–13$) and so on up to P_nH_{n-18} ($n = 19–22$)[67]; in all of these there is a tendency to form cyclic and condensed polyphosphanes at the expense of open-chain structures. Some 85 phosphanes have so far been identified and structurally characterized by nmr spectroscopy and other techniques, although few have been obtained pure because of problems involving thermal instability, ready disproportionation, light-sensitivity and great chemical reactivity.[67,70,71] Phosphorane, PH_5, has not been prepared or even detected, despite numerous attempts, although HPF_4, H_2PF_3 and H_3PF_2 have recently been well characterized.[72,73]

PH_3 is an extremely poisonous, highly reactive, colourless gas which has a faint garlic odour at concentrations above about 2 ppm by volume. It is intermediate in thermal stability between NH_3 (p. 421) and AsH_3 (p. 557). Several convenient routes are available for its preparation:

1. Hydrolysis of a metal phosphide such as AlP or Ca_3P_2; the method is useful even

[73] A. BECHERS, *Z. anorg. allg. Chem.* **619**, 1869–79 (1993).

up to the 10-mole scale and can be made almost quantitative

$$Ca_3P_2 + 6H_2O \longrightarrow 2PH_3 + 3Ca(OH)_2$$

2. Pyrolysis of phosphorous acid at 205–210°; under these conditions the yield of PH_3 is 97% though at higher temperatures the reaction can be more complex (p. 512)

$$4H_3PO_3 \xrightarrow{200^\circ} PH_3 + 3H_3PO_4$$

3. Alkaline hydrolysis of PH_4I (for very pure phosphine):

$$P_4 + 2I_2 + 8H_2O \longrightarrow 2PH_4I + 2HI + 2H_3PO_4$$

$$PH_4I + KOH(aq) \longrightarrow PH_3 + KI + H_2O$$

4. Reduction of PCl_3 with $LiAlH_4$ or LiH:

$$PCl_3 + LiAlH_4 \xrightarrow{Et_2O/\ <0^\circ} PH_3 + \ldots$$

$$PCl_3 + 3LiH \xrightarrow{warm} PH_3 + 3LiCl$$

5. Alkaline hydrolysis of white P_4 (industrial process):

$$P_4 + 3KOH + 3H_2O \longrightarrow PH_3 + 3KH_2PO_2$$

Phosphine has a pyramidal structure, as expected, with P–H 142 pm and the H–P–H angle 93.6° (see p. 557). Other physical properties are mp −133.5°, bp −87.7°, dipole moment 0.58 D, heat of formation ΔH_f° −9.6 kJ mol^{-1} (uncertain) and mean P–H bond energy 320 kJ mol^{-1}. The free energy change (at 25°C) for the reaction $\frac{1}{4}P_4(\alpha\text{-white}) + \frac{3}{2}H_2(g) = PH_3(g)$ is −13.1 kJ mol^{-1}, implying a tendency for the elements to combine, though there is negligible reaction unless H_2 is energized photolytically or by a high-current arc. The inversion frequency of PH_3 is about 4000 times less than for NH_3 (p. 423); this reflects the substantially higher energy barrier to inversion for PH_3 which is calculated to be ~155 kJ mol^{-1} rather than 24.7 kJ mol^{-1} for NH_3.

Phosphine is rather insoluble in water at atmospheric pressure but is more soluble in organic liquids, and particularly so in CS_2 and CCl_3CO_2H. Some typical values are:

Solvent (T°C)	H_2O (17°)	CH_3CO_2H (20°)	C_6H_6 (22°)
Solubility/ml PH_3 (g) per 100 ml solvent	26	319	726
Solvent (T°C)	CS_2(21°)	CCl_3CO_2H	
Solubility/ml PH_3 (g) per 100 ml solvent	1025	1590	

[Note: 1 ml PH_3(g) ≃ 1.5 mg]

Aqueous solutions are neutral and there is little tendency for PH_3 to protonate or deprotonate:

$$PH_3 + H_2O \rightleftharpoons PH_2^- + H_3O^+; \quad K_A = 1.6 \times 10^{-29}$$

$$PH_3 + H_2O \rightleftharpoons PH_4^+ + OH^-; \quad K_B = 4 \times 10^{-28}$$

In liquid ammonia, however, phosphine dissolves to give $NH_4^+PH_2^-$ and with potassium gives KPH_2 in the same solvent. Again, phosphine reacts with liquid HCl to give the sparingly soluble $PH_4^+Cl^-$ and this reacts further with BCl_3 to give PH_4BCl_4. The corresponding bromides and PH_4I are also known.

More generally, phosphine readily acts as a ligand to numerous Lewis acids and typical coordination complexes are $[BH_3(PH_3)]$, $[BF_3(PH_3)]$, $[AlCl_3(PH_3)]$, $[Cr(CO)_2(PH_3)_4]$, $[Cr(CO)_3(PH_3)_3]$, $[Co(CO)_2(NO)(PH_3)]$, $[Ni(PF_3)_2(PH_3)_2]$ and $[CuCl(PH_3)]$. Further details are in the Panel and other aspects of the chemistry of PH_3 have been extensively reviewed.[74]

Phosphine is also a strong reducing agent: many metal salts are reduced to the metal and PCl_5 yields PCl_3. The pure gas ignites in air at about 150° but when contaminated with traces of P_2H_4 it is spontaneously flammable:

$$PH_3 + 2O_2 \longrightarrow H_3PO_4$$

When heated with sulfur, PH_3 yields H_2S and a mixture of phosphorus sulfides. Probably the most important reaction industrially is

[74] E. FLUCK, Chemistry of phosphine, *Topics in Current Chem.* **35**, 1–64 (1973). A review with 493 references.

Phosphine and its Derivatives as Ligands[7,75–78]

A wide variety of 3-coordinate phosphorus(III) compounds are known and these have been extensively studied as ligands because of their significance in improving our understanding of the stability and reactivity of many coordination complexes. Among the most studied of these ligands are PH_3, PF_3 (p. 495), PCl_3 (p. 496), PR_3 (R = alkyl), PPh_3 and $P(OR)_3$, together with a large number of "mixed" ligands such as Me_2NPF_2, $PMePh_2$, etc., and many multidentate (chelating) ligands such as $Ph_2PCH_2CH_2PPh_2$, etc.

In many of their complexes PF_3 and PPh_3 (for example) resemble CO (p. 926) and this at one time encouraged the belief that their bonding capabilities were influenced not only by the factors (p. 198) which affect the stability of the σ P→M interaction which uses the lone-pair of electrons on P^{III} and a vacant orbital on M, but also by the possibility of synergic π back-donation from a "nonbonding" d_π pair of electrons on the metal into a "vacant" $3d_\pi$ orbital on P. It is, however, not clear to what extent, if any, the σ and π bonds reinforce each other, and more recent descriptions are based on an MO approach which uses all (σ and π) orbitals of appropriate symmetry on both the phosphine and the metal-containing moiety. To the extent that σ and π bonding effects on the stability of metal-phosphorus bonds can be isolated from each other and from steric factors (see below) the accepted sequence of effects is as follows:

σ bonding: $PBu^t_3 > P(OR)_3 > PR_3 \approx PPh_3 > PH_3 > PF_3 > P(OPh)_3$
π bonding: $PF_3 > P(OPh)_3 > PH_3 > P(OR)_3 > PPh_3 \approx PR_3 > PBu^t_3$
Steric interference: $PBu^t_3 > PPh_3 > P(OPh)_3 > PMe_3 > P(OR)_3 > PF_3 > PH_3$

Steric factors are frequently dominant, particularly with bulky ligands, and their influence on the course of many reactions is crucial. One measure of the "size" of a ligand in so far as it affects bond formation is C. A. Tolman's cone angle (1970) which is the angle at the metal atom of the cone swept out by the van der Waals radii of the groups attached to P. This will, of course, be dependent on the actual interatomic distance between M and P. For the particular case of Ni, for which a standard value of 228 pm was adopted for Ni–P, the calculated values for the cone angle are:

Ligand	PH_3	PF_3	$P(OMe)_3$	$P(OEt)_3$	PMe_3	$P(OPh)_3$	PCl_3
Cone angle	87°	104°	107°	109°	118°	121°	125°
Ligand	PEt_3	PPh_3	PPr^i_3	PBu^t_3	$P(o\text{-tol})_3$	$P(\text{mesityl})_3$	
Cone angle	132°	145°	160°	182°	195°	212°	

Bulky tertiary phosphine ligands exert both steric and electronic influences when they form complexes (since an increase in bulkiness of a substituent on P increases the inter-bond angles and this in turn can be thought of as an increase in "p-character" of the lone-pair of electrons on P). For example, the sterically demanding di-t-butylphosphines, PBu^t_2R (R = alkyl or aryl), promote spatially less-demanding features such as hydride formation, coordinative unsaturation at the metal centre, and even the stablization of unusual oxidation states, such as Ir^{II}. They also favour internal C– or O– metallation reactions for the same reasons. Indeed, the metallation of C–H and C–P bonds of coordinated tertiary phosphines can be considered as examples of intramolecular oxidative addition, and these have important mechanistic implications for homogeneous and heterogeneous catalysis.[79]

Other notable examples are the orthometallation (orthophenylation) reactions of many complexes of aryl phosphines (PAr_3) and aryl phosphites $P(OAr)_3$ with platinum metals in particular, e.g.:

$$[RuClH\{P(OPh)_3\}_4] \underset{H_2}{\overset{\text{heat}(-H_2)}{\rightleftharpoons}} (PhO)_2\overline{PO-C_6H_4-Ru}Cl\{P(OPh)_3\}_3$$

its hydrophosphorylation of formaldehyde in aqueous hydrochloric acid solution:

$$PH_3 + 4HCHO + HCl \longrightarrow [P(CH_2OH)_4]Cl$$

The tetrakis(hydroxymethyl)phosphonium chloride so formed is the major ingredient with urea-formaldehyde or melamine-formaldehyde resins for the permanent flame-proofing of cotton cloth.

Of the many other hydrides of phosphorus, diphosphane (diphosphine), P_2H_4, is the most studied. It is best made[71] by treating CaP with cold oxygen-free water. Passage of PH_3 through an electric discharge at 5–10 kV is an alternative method for small amounts. P_2H_4 is a colourless, volatile liquid (mp −99°) which is thermally unstable even below room temperature and is decomposed slowly by water. Its vapour pressure at 0°C is 70.2 mmHg but partial decomposition precludes precise determination of the bp (63.5° extrap); $d \simeq 1.014\,g\,cm^{-3}$ at 20°C. Electron-diffraction measurements on the gas establish the *gauche*-C_2 configuration (p. 428) with P–P 222 pm, P–H 145 pm, and the angle H–P–H 91.3°, though vibration spectroscopy suggests a *trans*-C_{2h} configuration in the solid phase. These results can be compared with those for the halides P_2X_4 on p. 498.

The next member of the open-chain series P_nH_{n+2} is P_3H_5, i.e. PH_2PHPH_2, a colourless liquid that can be stored in the dark at −80° for several days.[67,71] It can be made by disproportionation ($2P_2H_4 \longrightarrow P_3H_5 + PH_3$) but it is difficult to purify because of its own fairly ready disproportionation and reactivity, e.g. $2P_3H_5 \longrightarrow P_4H_6 + P_2H_4$; and $P_3H_5 + P_2H_4 \longrightarrow P_4H_6 + PH_3$. Tetraphosphane(6), P_4H_6, exists as an equilibrium mixture of the two structural isomers $H_2PPHPHPH_2$ (*n*) and $P(PH_2)_3$(*i*), and itself reacts with P_3H_5 at −20° according to the idealized stoichiometry $P_4H_6 + P_3H_5 \longrightarrow 2PH_3 + P_5H_5$, i.e. *cyclo*-$(PH)_5$. All members of the series *cyclo*-P_nH_n ($n = 3$–10) have been detected mass spectrometrically in the thermolysis products from P_2H_4.[70]

Polycyclic polyphosphanes are often best prepared by direct protonation of the corresponding polyphosphide anions (Figs. 12.11 and 12.12) with HX, though other routes are also available. Thus, treatment of P_7^{3-} yields P_7H^{2-}, $P_7H_2^-$ and P_7H_3 by sucessive protonation of the three 2-connected P^- sites. The alkyl derivatives are more stable than the parent polycyclic phosphanes and provide many examples of the elegant solution of complex conformational problems by the use of nmr spectroscopy.[67,70]

12.3.3 Phosphorus halides

Phosphorus forms three series of halides P_2X_4, PX_3 and PX_5. All 12 compounds may exist, although there is considerable doubt about PI_5.[80] Numerous mixed halides PX_2Y and PX_2Y_3 are also known as well as various pseudohalides such as $P(CN)_3$, $P(CNO)_3$, $P(CNS)_3$ and their mixed halogeno-counterparts. The compounds form an extremely useful extended series with which to follow the effect of progressive substitution on various properties, and the pentahalides are particularly significant in spanning the "ionic-covalent" border, so that they exist in various structural forms depending on the nature of the halogen, the phase of aggregation, or the polarity of the solvent. Some subhalides such as P_4X_2 and P_7X_3, and some curious polyhalides such as PBr_7 and PBr_{11} have also been characterized. Physical properties of the binary halides are summarized in Table 12.3 (on the next page). Ternary (mixed) halides tend to have properties intermediate between those of the parent binary halides.

Phosphorus trihalides

All 4 trihalides are volatile reactive compounds which feature pyramidal molecules. The fluoride is best made by the action of CaF_2, ZnF_2 or AsF_3 on PCl_3, but the others are formed by direct halogenation of the element. PF_3 is colourless, odourless and does not fume in air, but is very hazardous due to the formation of a complex with blood haemoglobin (cf.

[80] I. TORNIEPORTH-OETTING and T. KLAPÖTKE, *J. Chem. Soc., Chem. Commun.*, 132–3 (1990).

Table 12.3 Some physical properties of the binary phosphorus halides

Compound	Physical State at 25°C	MP/°C	BP/°C	P–X/pm	Angle X–P–X

CO, p. 1101). It is about as toxic as $COCl_2$. The similarity of PF_3 and CO as ligands was first noted by J. Chatt[81] and many complexes with transition elements are now known,[82] e.g. $[Ni(CO)_n(PF_3)_{4-n}]$ $(n = 0–4)$, $[Pd(PF_3)_4]$, $[Pt(PF_3)_4]$, $[CoH(PF_3)_4]$, $[Co_2(\mu\text{-}PF_2)_2(PF_3)_6]$, etc. Such complexes can be prepared by ligand replacement reactions, by fluorination of PCl_3 complexes, by direct reaction of PF_3 with metal salts or even by direct reaction of PF_3 with metals at elevated temperatures and pressures.

PF_3, unlike the other trihalides of phosphorus, hydrolyses only slowly with water, the products being phosphorous acid and HF: $PF_3 + 3H_2O \rightarrow H_3PO_3 + 3HF$.

The reaction is much more rapid in alkaline solutions, and in dilute aqueous $KHCO_3$ solutions the intermediate monofluorophosphorous acid is formed:

$$PF_3 + 2H_2O \xrightarrow{2\%\text{ aq } KHCO_3} O{=}PH(OH)F + 2HF$$

PCl_3 is the most important compound of the group and is made industrially on a large scale† by direct chlorination of phosphorus suspended in a precharge of PCl_3 — the reaction is carried out under reflux with continuous take-off of the PCl_3 formed. PCl_3 undergoes many substitution reactions, as shown in the diagram, and is the main source of organophosphorus compounds. Particularly notable are PR_3, PR_nCl_{3-n}, $PR_n(OR)_{3-n}$, $(PhO)_3PO$, and $(RO)_3PS$. Many of these compounds are made on the 1000-tonne scale pa, and the major uses are as oil additives, plasticizers, flame retardants, fuel additives and intermediates in the manufacture of insecticides.[83] PCl_3 is also readily oxidized to the important phosphorus(V) derivatives PCl_5, $POCl_3$ and $PSCl_3$. It is oxidized by As_2O_3 to P_2O_5 though this is not the commercial route to this compound (p. 505). It fumes in moist air and is more readily hydrolysed (and oxidized) by water than is PF_3. With cold N_2O_4 (−10°) it undergoes a curious oxidative coupling reaction to give $Cl_3P{=}N{-}POCl_2$,

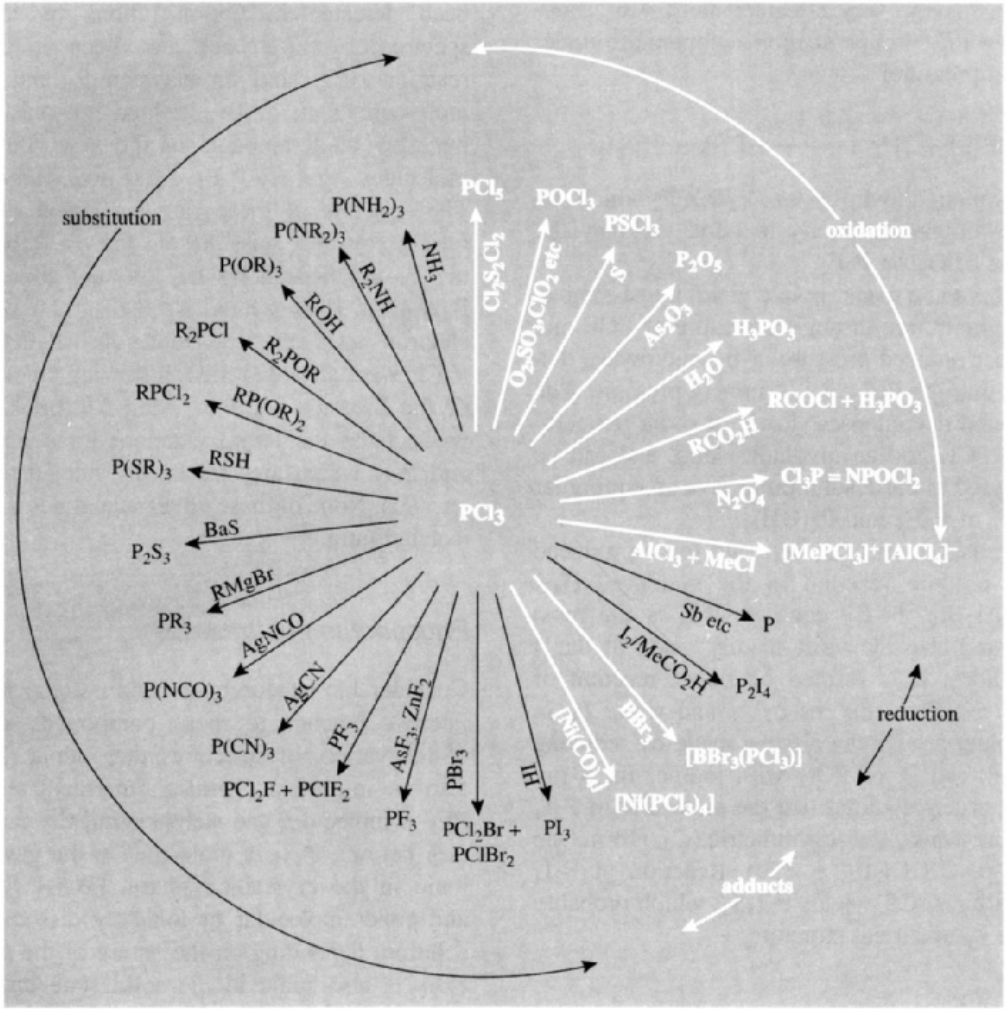
† World production exceeds one third of a million tonnes pa; of this USA produces ~155 000 tonnes, Western Europe ~115 000 and Japan ~35 000 tonnes pa.

[83] D. H. Chadwick and R. S. Watt, Chap. 19 in ref. 11, pp. 1221–79.



mp 35.5°; (note the presence of two different 4-coordinate P^V atoms).[84] Other notable reactions of PCl_3 are its extensive use to convert alcohols to RCl and carboxylic acids to RCOCl, its reduction to P_2I_4 by iodine, and its ability to form coordination complexes with Lewis acids such as BX_3 and Ni^0.

PI_3 is emerging as a powerful and versatile deoxygenating agent.[85] For example solutions of PI_3 in CH_2Cl_2 at or below room temperature convert sulfoxides (RR′SO) into diorganosulfides, selenoxides (RR′SeO) into selenides, aldehyde oximes (RCH=NOH) into nitriles, and primary nitroalkanes (RCH_2NO_2) into nitriles, all in high yield (75–95%). The formation of nitriles, RCN, in the last two reactions requires the presence of triethylamine in addition to the PI_3.

Diphosphorus tetrahalides and other lower halides of phosphorus

The physical properties of P_2X_4, in so far as they are known, are summarized in Table 12.3. P_2F_4 was first made in other than trace amounts in

[84] M. Becke-Goehring, A. Debo, E. Fluck and W. Goetze, *Chem. Ber.* **94**, 1383–7 (1961).

[85] J. N. Denis and A. Krief, *J. Chem. Soc., Chem. Commun.*, 544–5 (1980).

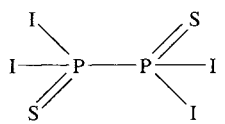
1966, using the very effective method of coupling two PF_2 groups at room temperature under reduced pressure:

$$2PF_2I + 2Hg \xrightarrow{86\%\text{ yield}} P_2F_4 + Hg_2I_2$$

The compound hydrolyses to F_2POPF_2 which can also be prepared directly in good yield by the reaction of O_2 on P_2F_4.

P_2Cl_4 can be made (in low yield) by passing an electric discharge through a mixture of PCl_3 and H_2 under reduced pressure or by microwave discharge through PCl_3 at 1–5 mmHg pressure. The compound decomposes slowly at room temperature to PCl_3 and an involatile solid, and can be hydrolysed in basic solution to give an equimolar mixture of P_2H_4 and $P_2(OH)_4$.

Little is known of P_2Br_4, said to be produced by an obscure reaction in the system C_2H_4–PBr_3–Al_2Br_6.[86] By contrast, P_2I_4 is the most stable and also the most readily made of the 4 tetrahalides; it is formed by direct reaction of I_2 and red P at 180° or by I_2 and white P_4 in CS_2 solution, and can also be made by reducing PI_3 with red P, or PCl_3 with iodine. Its X-ray crystal structure shows that the molecules of P_2I_4 adopt the *trans*-, centrosymmetric (C_{2h}) form (see N_2H_4, p. 428, N_2F_4, p. 439). Reaction of P_2I_4 with sulfur in CS_2 yields $P_2I_4S_2$, which probably has the symmetrical structure



but most reactions of P_2I_4 result in cleavage of the P–P bond, e.g. Br_2 gives $PBrI_2$ in 90% yield. Hydrolysis yields various phosphines and oxoacids of P, together with a small amount of hypophosphoric acid, $(HO)_2(O)PP(O)(OH)_2$.

Several ternary diphosphorus tetrahalides, $P_2X_nY_{4-n}$, (X, Y = Cl, Br, I) have recently been detected in CS_2 solutions by ^{31}P nmr spectroscopy.[87] It has also been found that reactions CS_2 solution between P_4 and half a mole-equivalent of Br_2 yielded not only P_2Br_4 but also small amounts of the new "butterfly" molecules *exo,exo*-P_4Br_2 and *exo,endo*-P_4Br_2. The structure of these can be viewed as being formed by the scission of one P–P bond in the P_4 tetrahedron by Br_2 (cf. the structure of B_4H_{10}, p. 154) which is also a 22 *valence*-electron species). The molecules P_4BrCl and P_4Cl_2 were also identified, following chlorination of the bromide solution using Me_3SnCl. Other products of the initial reactions included P_7Br_3 and P_7I_3 which are structurally related to P_7H_3 (p. 495). None of these novel subhalides has been isolated pure.[87]

Phosphorus pentahalides

Considerable theoretical and stereochemical interest attaches to these compounds because of the variety of structures they adopt; PCl_5 is also an important chemical intermediate. Thus, PF_5 is molecular and stereochemically non-rigid (see below), PCl_5 is molecular in the gas phase, ionic in the crystalline phase, $[PCl_4]^+[PCl_6]^-$, and either molecular or ionically dissociated in solution, depending on the nature of the solvent. PBr_5 is also ionic in the solid state but exists as $[PBr_4]^+[Br]^-$ rather than $[PBr_4]^+[PBr_6]^-$. The pentaiodide does not exist[80] (except perhaps as $PI_3.I_2$, but certainly not as $PI_4^+I^-$ as originally claimed[88]).

PF_5 is a thermally stable, chemically reactive gas which can be made either by fluorinating PCl_5 with AsF_3 (or CaF_2), or by thermal decomposition of $NaPF_6$, $Ba(PF_6)_2$ or the corresponding diazonium salts. Single-crystal X-ray analysis (at −164°C) indicates a trigonal bipyramidal structure with $P–F_{ax}$ (158.0 pm) being

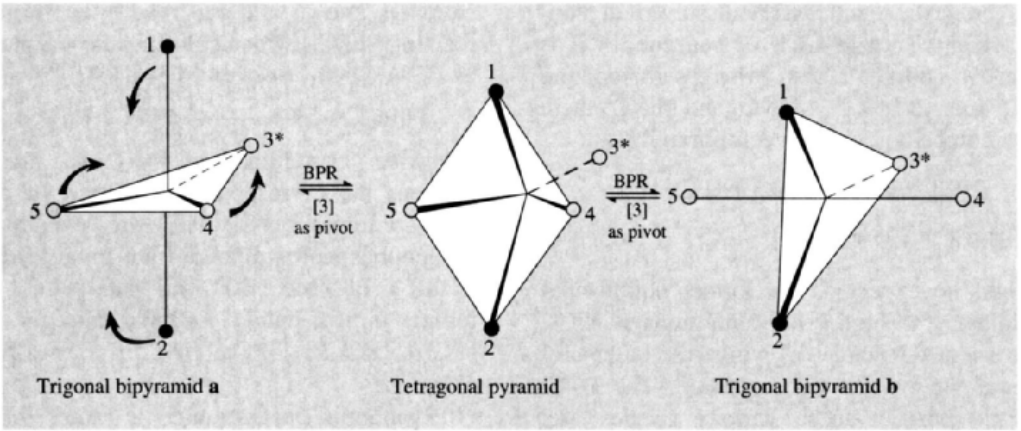

Figure 12.13 Interchange of axial and equatorial positions by Berry pseudorotation (BPR).

significantly longer than P–F_{eq} (152.2 pm).[89] This confirms the deductions from a gas phase electron-diffraction study (D_{3h}: P–F_{ax} 158 pm, P–F_{eq} 153 pm). However, the ^{19}F nmr spectrum, as recorded down to −100°C, shows only a single fluorine resonance peak (split into a doublet by ^{31}P–^{19}F coupling) implying that on this longer time scale (milliseconds, as distinct from "instantaneous" for electron diffraction) all 5 F atoms are equivalent. This can be explained if the axial and equatorial F atoms interchange their positions more rapidly than this, a process termed "pseudorotation" by R. S. Berry (1960); indeed, PF_5 was the first compound to show this effect.[90] The proposed mechanism is illustrated in Fig. 12.13 and is discussed more fully in ref. 91; the barrier to notation has been calculated as 16 ± 2 kJ mol^{-1}.[92]

The mixed chlorofluorides PCl_4F (mp −59°, bp +67°) and PCl_3F_2 (mp −63°) are also trigonal bipyramidal with axial F atoms; likewise PCl_2F_3 (mp −125°, bp +7.1°) has 2 axial and 1 equatorial F atoms and $PClF_4$ (mp −132°, bp −43.4°) has both axial positions occupied by F atoms.[93] These compounds are obtained by addition of halogen to the appropriate phosphorus(III) chlorofluoride, but if PCl_5 is fluorinated in a polar solvent, ionic isomers are formed, e.g. $[PCl_4]^+[PCl_4F_2]^-$ (colourless crystals, subl 175°) and $[PCl_4]^+[PF_6]^-$ (white crystals, subl 135° with decomposition). The crystalline hemifluoride $[PCl_4]^+[PCl_5F]^-$ has also been identified. The analogous parallel series of covalent and ionic bromofluorides is less well characterized but PBr_2F_3 is known both as an unstable molecular liquid (decomp 15°) and as a white crystalline powder $[PBr_4]^+[PF_6]^-$ (subl 135° decomp). It can be noted that $PF_3(NH_2)_2$ is a trigonal bipyramidal molecule with C_{2v} symmetry (i.e. equatorial NH_2 groups),[94] whereas the most stable form of tetra-arylfluorophosphoranes is ionic, $[PR_4]^+F^-$, although molecular monomers R_4PF and an ionic dimer $[PR_4]^+[PR_4F_2]^-$ also exist.[95]

PCl_5 is even closer to the ionic-covalent borderline than is PF_5, the ionic solid $[PCl_4]^+[PCl_6]^-$ melting (or subliming) to give a covalent molecular

liquid (or gas). Again, when dissolved in non-polar solvents such as CCl_4 or benzene, PCl_5 is monomeric and molecular, whereas in ionizing solvents such as MeCN, $MeNO_2$ and $PhNO_2$ there are two competing ionizing equilibria:[96]

$$2PCl_5 \rightleftharpoons [PCl_4]^+ + [PCl_6]^-$$

$$PCl_5 \rightleftharpoons [PCl_4]^+ + Cl^-$$

As might be expected, the former equilibrium predominates at higher concentrations of PCl_5 (above about 0.03 mol l^{-1}) whilst the latter predominates below this concentration. The P–Cl distances (pm) in these various species are: PCl_5 214 (axial), 202 (equatorial); $[PCl_4]^+$ 197; $[PCl_6]^-$ 208 pm. Ionic isomerism is also known and, in addition to $[PCl_4]^+[PCl_6]^-$, another (metastable) crystalline phase of constitution $[PCl_4]_2^+[PCl_6]^-Cl^-$ can be formed either by application of high pressure or by crystallizing PCl_5 from solutions of dichloromethane containing Br_2 or SCl_2.[97] When gaseous PCl_5 (in equilibrium with $PCl_3 + Cl_2$) is quenched to 15 K the trigonal-bipyramidal molecular structure is retained; this forms an ordered molecular crystalline lattice on warming to ~130 K, but further warming towards room temperature results in chloride-ion transfer to give $[PCl_4]^+[PCl_6]^-$.[98] The first alkali metal salt of $[PCl_6]^-$, $CsPCl_6$, has only recently been made.[99]

The delicate balance between ionic and covalent forms is influenced not only by the state of aggregation (solid, liquid, gas) or the nature of the solvent, but also by the effect of substituents. Thus $PhPCl_4$ is molecular with Ph equatorial whereas the corresponding methyl derivative is ionic, $[MePCl_3]^+Cl^-$. Despite this the $[PhPCl_3]^+$ cation is known and can readily be formed by reacting $PhPCl_4$ with a chlorine ion acceptor such as BCl_3, $SbCl_5$, or even PCl_5 itself:[100]

$$PhPCl_4 + PCl_5 \longrightarrow [PhPCl_3]^+[PCl_6]^-$$

Likewise crystalline Ph_2PCl_3 is molecular whereas the corresponding Me and Et derivatives are ionic $[R_2PCl_2]^+Cl^-$. However, all 3 triorganophosphorus dihalides are ionic $[R_3PCl]^+Cl^-$(R = Ph, Me, Et). The pale-yellow, crystalline mixed halide P_2BrCl_9 appears to be $[PCl_4]_6^+[PCl_3Br]_2^+[PCl_6]_4^-[Br]_4^-$ (i.e. $P_{12}Br_6Cl_{54}$).[101]

Phosphorus pentabromide is rather different. The crystalline solid is $[PBr_4]^+Br^-$ but this appears to dissociate completely to PBr_3 and Br_2 in the vapour phase; rapid cooling of this vapour to 15 K results in the formation of a disordered lattice of PBr_3 and PBr_7 (i.e. $[PBr_4]^+[Br_3]^-$) and this mixture reverts to $[PBr_4]^+Br^-$ on being warmed to 180 K.[98] The corresponding trichloride, $[PBr_4]^+[Cl_3]^-$ is also known.[102] $[PI_4]^+$ has been identified only as its salt $[PI_4]^+[AsF_6]^-$.[80]

PCl_5 is made on an industrial scale by the reaction of Cl_2 on PCl_3 dissolved in an equal volume of CCl_4. World production probably exceeds 20 000 tonnes pa. On the laboratory scale Cl_2 gas (or liquid) can be passed directly into PCl_3. PCl_5 reacts violently with water to give HCl and H_3PO_4 but in equimolar amounts the reaction can be moderated to give $POCl_3$:

$$PCl_5 + H_2O \longrightarrow POCl_3 + 2HCl$$

PCl_5 chlorinates alcohols to alkyl halides and carboxylic acids to the corresponding RCOCl. When heated with NH_4Cl the phosphonitrilic chlorides are obtained (p. 536). These and other reactions are summarized in the diagram.[8]

The chlorination of phosphonic and phosphinic acids and esters are of considerable importance. PCl_5 can also act as a Lewis acid to give 6-coordinate P complexes, e.g. $pyPCl_5$, and $pyz\text{-}PCl_5$, where py = C_5H_5N (pyridine) and pyz = *cyclo*-1,4-$C_4H_4N_2$ (pyrazine).[103]

Pseudohalides of phosphorus(III)

Paralleling the various phosphorus trihalides are numerous pseudohalides and mixed pseudohalide-halides of which the various isocyanates and isothiocyanates are perhaps the best known. Most are volatile liquids, e.g.

Compound	$P(NCO)_3$	$PF(NCO)_2$	$PF_2(NCO)$
MP/°C	−2	−55	~ −108
BP/°C	169.3	98.7	12.3

Compound	$PCl(NCO)_2$	$PCl_2(NCO)$	$P(NCS)_3$
MP/°C	−50	−99	−4
BP/°C	134.6	104.5	~120/1 mmHg
Compound	$PF_2(NCS)$	$PCl_2(NCS)$	
MP/°C	−95	−76	
BP/°C	90.3	148(decomp)	

The corresponding phosphoryl and thiophosphoryl pseudohalides are also known, i.e. $PO(NCO)_3$, $PS(NCO)_3$, etc. Preparations are by standard procedures such as those on the diagram for PCl_3 (p. 497). As indicated there, $P(CN)_3$ has also been made: it is a highly reactive white crystalline solid mp 203° which reacts violently with water to give mainly phosphorous acid and HCN.

12.3.4 Oxohalides and thiohalides of phosphorus

The propensity of phosphorus(III) compounds to oxidize to phosphorus(V) by formation of an additional P=O bond is well illustrated by the

$PS(NCS)_3$	—	123/0.3 mmHg	$PS(NCS)F_2$	—	90

ease with which the trihalides are converted to their phosphoryl analogues POX_3. Thus, PCl_3 reacts rapidly with pure O_2 (less rapidly with air) at room temperature or slightly above and this reaction is used on an industrial scale. Alternatively, a slurry of P_4O_{10} in PCl_3 can be chlorinated, the PCl_5 so formed reacting instantaneously with the P_4O_{10}:

$$P_4O_{10} + 6PCl_5 \longrightarrow 10POCl_3$$

$POBr_3$ can be made by similar methods, but POF_3 is usually made by fluorination of $POCl_3$ using a metal fluoride (e.g. M = Na, Mg, Zn, Pb, Ag, etc.). POI_3 was first made in 1973 by iodinating $POCl_3$ with LiI, or by reacting $ROPI_2$ with iodine ($ROPI_2 + I_2 \rightarrow RI + POI_3$).[104] Mixed phosphoryl halides, POX_nY_{3-n}, and pseudohalides (e.g. X = NCO, NCS) are known, as also are the thiophosphoryl halides PSX_3, e.g.:

$$P_2S_5 + 3PCl_5 \longrightarrow 5PSCl_3$$

$$PCl_3 + S \xrightarrow{AlCl_3} PSCl_3; \quad PI_3 + S \xrightarrow{CS_2/dark} PSI_3$$

Most of the phosphoryl and thiophosphoryl compounds are colourless gases or volatile liquids though $PSBr_3$ forms yellow crystals, mp 37.8°, POI_3 is dark violet, mp 53°, and PSI_3 is red-brown, mp 48°. All are monomeric tetrahedral (C_{3v}) or pseudotetrahedral. Some physical properties are in Table 12.4. The P–O interatomic distance in these compounds generally falls in the range 154–158 pm, the small value being consistent with considerable "double-bond character". Likewise the P–S distance is relatively short (185–194 pm).

The phosphoryl and thiophosphoryl halides are reactive compounds that hydrolyse readily on contact with water. They form adducts with Lewis acids and undergo a variety of substitution reactions to form numerous organophosphorus derivatives and phosphate esters. Thus, alcohols give successively $(RO)POCl_2$, $(RO)_2POCl$ and $(RO)_3PO$; phenols react similarly but more slowly. Likewise, amines yield $(RNH)POCl_2$, $(RNH)_2POCl$ and $(RNH)_3PO$ whereas Grignard reagents yield R_nPOCl_{3-n} ($n = 1$–3). Many of these compounds find extensive use as oil additives, insecticides, plasticizers, surfactants or flame retardants, and are manufactured on the multikilotonne scale.

In addition to the monophosphorus phosphoryl and thiophosphoryl compounds discussed above, several poly-phosphoryl and -thiophosphoryl halides have been characterized. Pyrophosphoryl fluoride, $O{=}PF_2{-}O{-}P{(=}O)F_2$ (mp −0.1°, bp 72° extrap) and the white crystalline cyclic tetramer $[O{=}P(F){-}O]_4$ were obtained by subjecting equimolar mixtures of PF_3 and O_2 to a silent electric discharge at −70°. Pyrophosphoryl chloride, $O{=}PCl_2{-}O{-}P{(=}O)Cl_2$ is conveniently prepared by passing Cl_2 into a boiling suspension

[104] A. V. KIRSANOV, ZH. K. GORBATENKO and N. G. FESHCHENKO, *Pure Appl. Chem.* **44**, 125–39 (1975).

of P_4O_{10} in PCl_3 diluted with CCl_4:

$$P_4O_{10} + 4PCl_3 + 4Cl_2 \longrightarrow 2P_2O_3Cl_4 + 4POCl_3$$

It is a colourless, odourless, non-fuming, oily liquid, mp −16.5°, bp 215° (decomp), with reactions similar to those of $POCl_3$. Sealed-tube reactions between P_4O_{10} and $POCl_3$ at 200–230° give more highly condensed cyclic and open-chain polyphosphoryl chlorides. A rather different structural motif occurs in $P_2S_4F_4$; this compound is obtained by fluorinating P_4S_{10} with an alkali-metal fluoride to give the anion $[S_2PF_2]^-$ which is then oxidized by bromine to $P_2S_4F_4$ (bp 60° at 10 mmHg). Vibrational and nmr spectra are consistent with the structure $F_2(S)PSSP(S)F_2$.

Bromination of P_4S_7 in cold CS_2 yields, in addition to PBr_3 and $PSBr_3$, two further thiobromides $P_2S_6Br_2$ (mp 118° decomp) and $P_2S_5Br_4$ (mp 90° decomp). The first of these has the cyclic structure shown in which the ring adopts a skew-boat configuration. An even more complex, bicyclic arrangement is found in the orange-yellow compound $P_4S_3I_2$ (mp 120° decomp) which is formed (together with several other products) when equiatomic amounts of P, S and I are allowed to react. The P and S atoms are arranged in two 5-membered rings having a common P–S–P group as shown; in each there is a P–P group and the I atoms are bonded in *cis*-configuration to the P atoms not common to the two rings. The orange compound $P_2S_2I_4$ (mp 94°) was mentioned on p. 498.

[107] H. BOK, M. KREMER, B. SOLOUKI, M. BINNEWIES and M. MEISEL, *J. Chem. Soc., Chem. Commun.*, 9–11 (1992).

By contrast to the plethora of simple oxo-halides and thiohalides of P^V, the corresponding derivatives of P^{III} are fugitive species that require matrix isolation techniques for preparation and characterization:[105] ClPO, BrPO, FPS and BrPS all form non-linear triatomic molecules, as expected. The corresponding oxosulfide, BrP(O)S,[106] and its thio-analogue, FP(S)S,[107] have also recently been isolated.

12.3.5 Phosphorus oxides, sulfides, selenides and related compounds

The oxides and sulfides of phosphorus are amongst the most important compounds of the element. At least 6 binary oxides and 9 well-defined sulfides are known, together with a similar number of selenides and several oxo-sulfides. It will be convenient to discuss first the preparation and structure of each group of compounds and then to mention the chemical reactions of the more important members in so far as they are known. It is notable that, in contrast to the ubiquitous NO and its many complexes (pp. 445 ff), little is known about its analogue, PO (see p. 506), although it is probably the most abundant P-containing molecule in interstellar clouds.[108] The first complex with a PO ligand was first synthesized as recently as 1991, when dark green crystals of the square-based pyramidal hetero-atom cluster $[W(CO)_4\{Ni(\eta^5\text{-}C_5HPr^i_4)\}_2(\mu{:}\eta^2,\eta^2\text{-}P_2)]$ was oxidized with bis(trimethylsilyl) peroxide, $(Me_3Si)_2O_2$, to yield black crystals of the corresponding $[W(CO)_4\{Ni(\eta^5\text{-}C_5HPr^i_4)\}_2(\mu{:}\eta^2,\eta^2\text{-}PO)_2]$.[108]

Oxides

P_4O_6 is obtained by controlled oxidation of P_4 in an atmosphere of 75% O_2 and 25% N_2 at 90 mmHg and ~50° followed by distillation of the product from the mixture. Careful

[108] O. J. SCHERER, J. BRAUN, P. WALTHER, G. HECKMANN and G. WOLMERSHÄUSER, *Angew. Chem. Int. Edn. Engl.* **30**, 852–4. (1991).

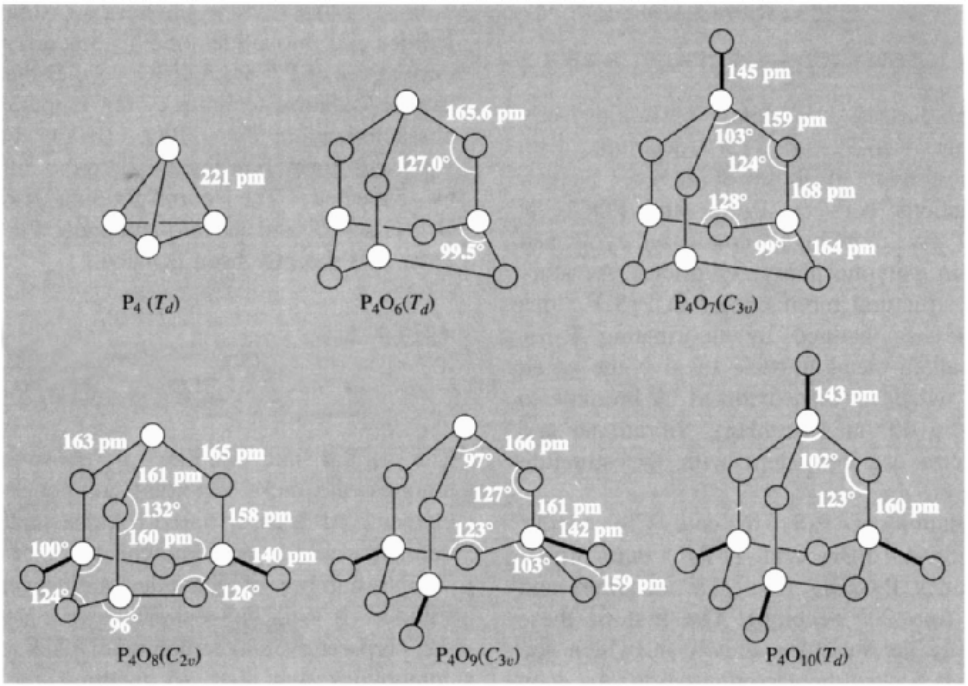

Figure 12.14 Molecular structures, symmetries and dimensions of the 5 oxides P_4O_{6+n} ($n = 0-4$) compared with α-P_4. The P···P distances in the oxides are ~280–290 pm, i.e. essentially nonbonding.

precautions are necessary if good yields are to be obtained.[109] It forms soft white crystals, mp 23.8°, bp 175.4°, and is soluble in many organic solvents. The molecular structure has tetrahedral symmetry and comprises 4 fused 6-membered P_3O_3 heterocycles each with the chair conformation as shown in Fig. 12.14.[110] When P_4O_6 is heated to 200–400° in a sealed, evacuated tube it disproportionates into red phosphorus and a solid-solution series of composition P_4O_n depending on conditions. The α-phase has a composition in the range $P_4O_{8.1}$–$P_4O_{9.2}$ and comprises a solid solution of oxides in which one or two of the "external" O atoms in P_4O_{10} have been removed. The β-phase has a composition range $P_4O_{8.0}$-$P_4O_{7.7}$ and appears to be a solid solution of P_4O_8 and P_4O_7, the latter compound having only one O atom external to the P_4O_6 cluster (C_{3v} symmetry). P_4O_7 is now best prepared from P_4O_6 dissolved in thf, using Ph_3PO as a catalyst (not an oxidant) at room temperature. The molecular structure and dimensions of P_4O_7 are given in Fig. 12.14 from which it is apparent that there is a gradual lengthening of P–O distances in the sequence P^V–$O_t < P^V - O_\mu < P^{III}$–$O_\mu$. Similar trends are apparent in the dimensions of the other members of the series P_4O_{6+n} shown in Fig. 12.14.[110] In addition, ring angles at P (96–103°) are always less than those at O (122–132°), as expected.

P_4O_6 hydrolyses in cold water to give H_3PO_3 i.e. $HP(O)(OH)_2$; this is interesting in view of the structure of P_4O_6 and implies an oxidative rearrangement of {P–OH} to {H–P=O} (p. 514). The oxide itself ignites and burns when heated in air; the progress of the reaction depends very much on the

Table 12.5 Some properties of crystalline polymorphs of P_2O_5

Polymorph	Density/g cm^{-3}	MP/°C	Pressure at triple pt/mmHg	ΔH_{subl}/kJ (mol P_4O_{10})$^{-1}$
H: hexagonal P_4O_{10}	2.30	420	3600	95
O: metastable $(P_2O_5)_n$	2.72	562	437	152
O′: stable $(P_2O_5)_n$	2.74–3.05	580	555	142

purity of the oxide and the conditions employed, and, when traces of elemental phosphorus are present in the oxide, the reaction is spontaneous even at room temperature. P_4O_6 reacts readily (often violently) with many simple inorganic and organic compounds but well-characterized products have rarely been isolated until recently.[109] It behaves as a ligand and successively displaces CO from $[Ni(CO)_4]$ to give compounds such as $[P_4O_6\{Ni(CO)_3\}_4]$, $[Ni(CO)_2(P_4O_6)_2]$ and $[Ni(CO)(P_4O_6)_3]$. With diborane adducts of formula $[P_4O_6(BH_3)_n]$ (n = 1–3) are obtained.

"Phosphorus pentoxide", P_4O_{10}, is the commonest and most important oxide of phosphorus. It is formed as a fine white smoke or powder when phosphorus burns in air and, when condensed rapidly from the vapour phase in this way, is obtained in the H (hexagonal) form comprising tetrahedral molecules as shown in Fig. 12.14. This compound and the other phosphorus oxides are the first we have considered that feature the $\{PO_4\}$ group as a structural unit; this group dominates most of phosphate chemistry and will recur repeatedly during the rest of this chapter. The common hexagonal form of P_4O_{10} is, in fact, metastable and can be transformed into several other modifications by suitable thermal or high-pressure treatment. A metastable orthorhombic (O) form is obtained by heating H for 2 h at 400° and the stable orthorhombic (O′) form is obtained after 24 h at 450°. Both consist of extensive sheet polymers of interlocking heterocyclic rings composed of fused $\{PO_4\}$ groups. There is also a high-pressure form and a glass, which probably consists of an irregular three-dimensional network of linked $\{PO_4\}$ tetrahedra. These polymeric forms are hard and brittle because of the P–O–P bonds throughout the lattice and, as expected, they are much less volatile and reactive than the less-dense molecular H form. For example, whilst the common H form hydrolyses violently, almost explosively, with evolution of much heat, the polymeric forms react only slowly with water to give, finally, H_3PO_4. Some properties of the various polymorphs are compared in Table 12.5. The limpid liquid obtained by rapidly heating the H form contains P_4O_{10} molecules but these rapidly polymerize and rearrange to layer or three-dimensional polymeric forms with a concomitant drop in the vapour pressure and an increase in the viscosity and mp.

Because of its avidity for water, P_4O_{10} is widely used as a dehydrating agent, but its efficacy as a desiccant is greatly impaired by the formation of a crusty surface film of hydrolysis products unless it is finely dispersed on glass wool. Its largest use is in the industrial production of ortho- and poly-phosphoric acids (p. 520) but it is also an intermediate in the production of phosphate esters. Thus, triethylphosphate is made by reacting P_4O_{10} with diethyl ether to form ethylpolyphosphates which, on subsequent pyrolysis and distillation, yield the required product:

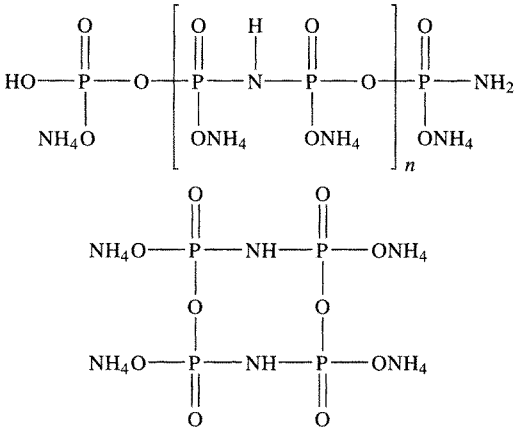
$$P_4O_{10} + 6Et_2O \xrightarrow{\text{heat}} 4PO(OEt)_3$$

Direct reaction with alcohols gives mixed mono- and di-alkyl phosphoric acids by cleavage of the P–O–P bonds:

$$P_4O_{10} + 6ROH \xrightarrow{65°} 2(RO)PO(OH)_2 + 2(RO)_2PO(OH)$$

Under less-controlled conditions P_4O_{10} dehydrates ethanol to ethene and methylarylcarbinols to the corresponding styrenes. H_2SO_4 is dehydrated to SO_3, HNO_3 gives N_2O_5 and amides

($RCONH_2$) yield nitriles (RCN). In each of these reactions metaphosphoric acid HPO_3 is the main P-containing product. P_4O_{10} reacts vigorously with both wet and dry NH_3 to form a range of amorphous polymeric powdery materials which are used industrially for water softening because of their ability to sequester Ca ions; composition depends markedly on the preparative conditions employed but most of the commercial products appear to be condensed linear or cyclic amidopolyphosphates which can be represented by formulae such as:



The annual production/consumption of P_4O_{10} in USA and Western Europe totals about 15 000 tonnes.

Other oxides of phosphorus are less well characterized though the suboxide PO and the peroxide P_2O_6 seem to be definite compounds. PO was obtained as a brown cathodic deposit when a saturated solution of Et_3NHCl in anhydrous $POCl_3$ was electrolysed between Pt electrodes at 0°. Alternatively it can be made by the slow reaction of $POBr_3$ with Mg in Et_2O under reflux:

$$2POBr_3 + 3Mg \longrightarrow 2PO + 3MgBr_2$$

Its structure is unknown but is presumably based on a polymeric network of P–O–P links. It reacts with water to give PH_3 and is quantitatively oxidized to P_2O_5 by oxygen at 300°. The peroxide P_2O_6 is thought to be the active ingredient in the violet solid obtained when P_4O_{10} and O_2 are passed through a heated discharge tube at low pressure. The compound has not been obtained pure but liberates I_2 from aqueous KI, hydrolyses to a peroxophosphoric acid, and liberates O_2 when heated to 130° under reduced pressure. Its structure may be $(O{=})_2P{-}O{-}O{-}P({=}O)_2$ or, in view of the variable composition of the product, it may be a mixture of P_4O_{11} and P_4O_{12} obtained by replacing P–O–P links by P–O–O–P in P_4O_{10}.

Sulfides[111]

The sulfides of phosphorus form an intriguing series of compounds which continue to present puzzling structural features. The compounds P_4S_{10}, P_4S_9, P_4S_7, α-P_4S_5, β-P_4S_5, α-P_4S_4, β-P_4S_4, P_4S_3 and P_4S_2 are all based on the P_4 tetrahedron but only P_4S_{10} (and possibly P_4S_9) is structurally analogous to the oxide. P_4S_6 is conspicuous by its absence. Structural data are summarized in Fig. 12.15 and some physical properties are in Table 12.6.

P_4S_3 is the most stable compound in the series and can be prepared by heating the required amounts of red P and sulfur above 180° in an inert atmosphere and then purifying the product by distillation at 420° or by recrystallization from toluene. The retention of a P_3 ring in the structure is notable. Its reactions and commercial application in match manufacture are discussed on p. 509.

The curious phase relations between phosphorus, sulfur and their binary compounds are worth noting. Because both P_4 and S_8 are stable molecules the phase diagram, if studied below 100°, shows only solid solutions with a simple eutectic at 10° (75 atom % P). By contrast, when the mixtures are heated above 200° the elements react and an entirely different phase diagram is obtained; however, as only the most stable compounds P_4S_3, P_4S_7 and P_4S_{10}

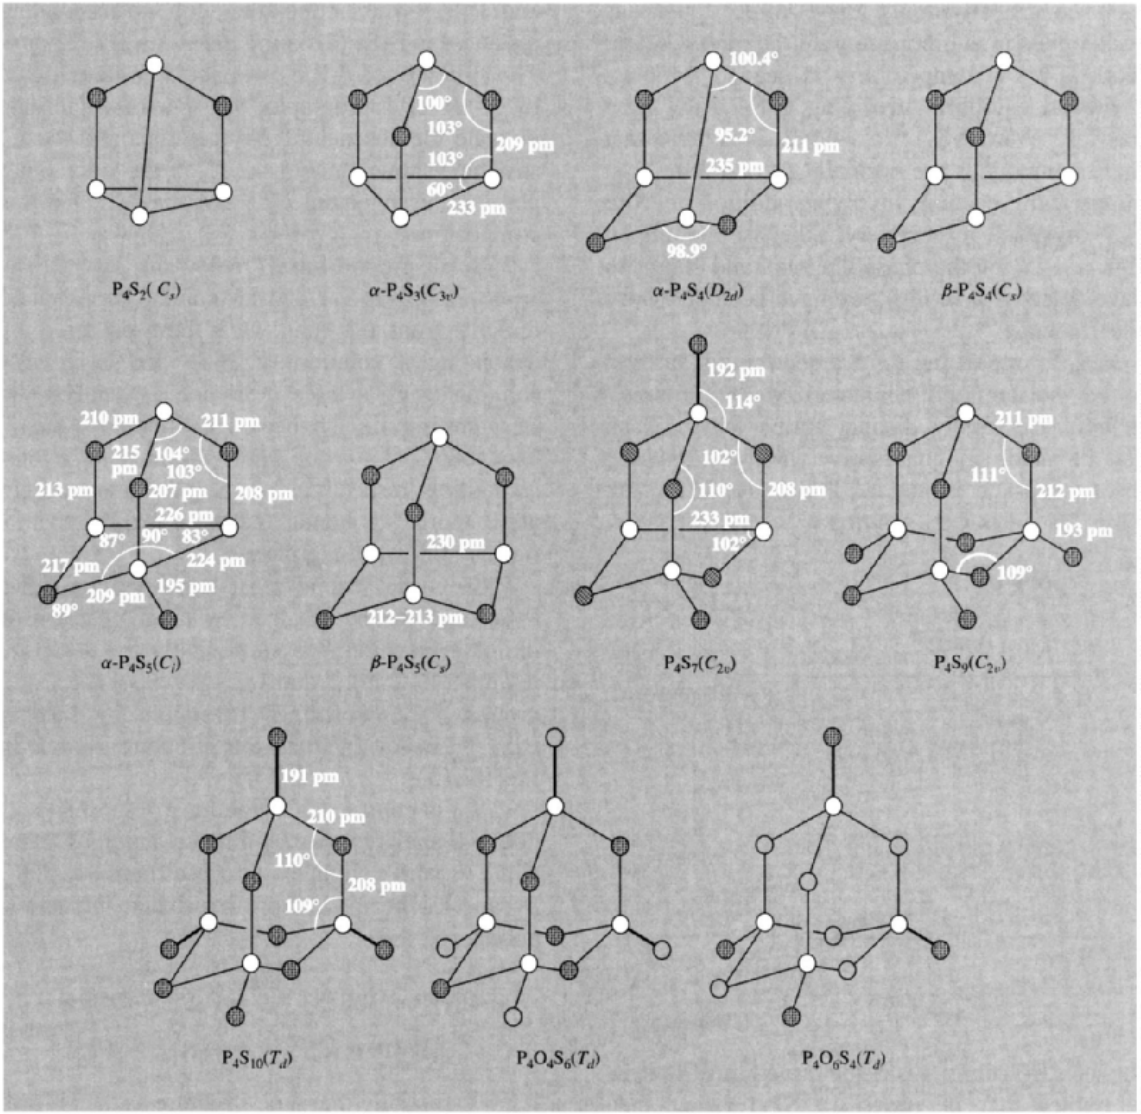

Figure 12.15 Structures of phosphorus sulfides and oxosulfides (schematic).

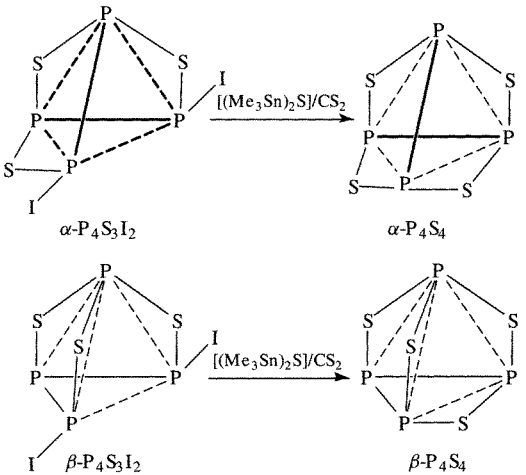
Table 12.6 Physical properties of some phosphorus sulfides

Property	α-P_4S_3	α-P_4S_4	α-P_4S_5	P_4S_7	P_4S_{10}
Colour	Yellow green	Pale yellow	Bright yellow	Very pale yellow	Yellow
MP/°C	174	230 (d)	170–220 (d)	308	288
BP/°C	408	—	—	523	514
Density/g cm^{-3}	2.03	2.22	2.17	2.19	2.09
Solubility in CS_2(17°)/ g per 100 g CS_2	100	sol	0.5	0.029	0.222

melt congruently, only these three appear as compounds in equilibrium with the melt. Careful work at lower temperatures is needed to detect peritectic equilibria involving P_4S_9, P_4S_5 (and possibly even P_4S_2),[112] and it is notable that these compounds are normally prepared by low-temperature reactions involving addition of 2S to P_4S_7 and P_4S_3 respectively. Likewise there is no sign of P_4S_4 on the phase diagram, and claims to have detected it in this way have been shown to be erroneous.[113]

P_4S_4 is one of the most recent binary sulfides to be isolated and characterized and it exists in two structurally distinct forms.[113,114] Each can be made in quantitative yield by reacting the appropriate isomer of $P_4S_3I_2$ (p. 503) with $[(Me_3Sn)_2S]$ in CS_2 solution:



As seen from Fig. 12.15 the structure of α-P_4S_4 resembles that of As_4S_4 (p. 579) rather than N_4S_4 (p. 723). The 4 P atoms are in tetrahedral array and the 4 S atoms form a slightly distorted square. The 2 P–P bonds are long (as also in P_4S_3 and P_4S_7) when compared with corresponding distances in P_4S_5 (225 pm) and P_4 itself (221 pm). The structure of β-P_4S_4 has not been determined by X-ray crystallography but spectroscopic data indicate the absence of P=S groups and the C_s structure shown in Fig. 12.15 is the only other possible arrangement of 3 coordinate P for this composition.

P_4S_5 disproportionates below its mp ($2P_4S_5 \rightleftharpoons P_4S_3 + P_4S_7$) and so cannot be obtained directly from the melt. It is best prepared by irradiating a solution of P_4S_3 and S in CS_2 solution using a trace of iodine as catalyst. Its structure is quite unexpected and features a single exocyclic P=S group and 3 fused heterocycles containing, respectively, 4, 5 and 6 atoms; there are 2 short P–P bonds and the 4-membered P_3S ring is almost square planar.

P_4S_7 is the second most stable sulfide (after P_4S_3) and can be obtained by direct reaction of the elements. Perhaps surprisingly the structure retains a P–P bond and has two exocyclic P=S groups. P_4S_9 is formed reversibly by heating $P_4S_7 + 2P_4S_{10}$ and has the structure shown in Fig. 12.15.

P_4S_{10} is commercially the most important sulfide of P and is formed by direct reaction of liquid white P_4 with a slight excess of sulfur above 300°. It can also be made from byproduct ferrophosphorus (p. 480).

$$4Fe_2P + 18FeS_2 \xrightarrow{\text{heat}} P_4S_{10} + 26FeS$$

$$4Fe_2P + 18S \longrightarrow P_4S_{10} + 8FeS$$

It has essentially the same structure as the H form of P_4O_{10} and hydrolyses mainly according to the overall equation

$$P_4S_{10} + 16H_2O \longrightarrow 4H_3PO_4 + 10H_2S$$

Presumably intermediate thiophosphoric acids are first formed and, indeed, when the hydrolysis is carried out in aqueous NaOH solution at 100°, substantial amounts of the mono- and di-thiophosphates are obtained. P–S bonds are also retained during reaction of P_4S_{10} with alcohols or phenols and the products formed are used extensively in industry for a wide variety of

Phosphorus Sulfides in Industry

The two compounds of importance are P_4S_3 and P_4S_{10}. The former is made on a large scale for use in "strike anywhere" matches according to a formula evolved by Sévène and Cahen in France in 1898. The ignition results from the violent reaction between P_4S_3 and $KClO_3$ which is initiated by friction of the match against glass paper (on the side of the box) or other abrasive material. A typical formulation for the match head is:

Reactants		Fillers (moderators)			Adhesives	
$KClO_3$	P_4S_3	Ground glass	Fe_2O_3	ZnO	Glue	Water
20%	9%	14%	11%	7%	10%	29%

Formulations of this type have completely replaced earlier "strike anywhere' matches based on (poisonous) white P_4, sulfur, and $KClO_3$, though "safety matches" still use a match head which is predominantly $KClO_3$ struck against the side of the match-box which has been covered with a paste of (non-toxic) red P (49.5%), antimony sulfide (27.6%), Fe_2O_3 (1.2%) and gum arabic (21.7%). About 10^{11} matches are used annually in the UK alone.

P_4S_{10} is made on an even larger scale than P_4S_3 and is the primary source of a very wide range of organic P–S compounds. World production of P_4S_{10} exceeds 250 000 tonnes annually of which about half is made in the USA, one-third in the UK/Europe, and the remaining 30 000 tonnes elsewhere (Japan, Romania, the former Soviet Union, Mexico, etc.). The most important reaction of P_4S_{10} is with alcohols or phenols to give dialkyl or diaryl dithiophosphoric acids:

$$P_4S_{10} + 8ROH \longrightarrow 4(RO)_2P(S)SH + 2H_2S$$

The zinc salts of these acids are extensively used as additives to lubricating oils to improve their extreme-pressure properties. The compounds also act as antioxidants, corrosion inhibitors and detergents. Short-chain dialkyl dithiophosphates and their sodium and ammonium salts are used as flotation agents for zinc and lead sulfide ores. The methyl and ethyl derivatives $(RO)_2P(S)SH$ and $(RO)_2P(S)Cl$ are of particular interest in the large-scale manufacture of pesticides such as parathion, malathion, dimethylparathion, etc.[83] For example parathion, which first went into production as an insecticide in Germany in 1947, is made by the following reaction sequence:

$$(EtO)_2P(S)SH + Cl_2 \longrightarrow HCl + S + (EtO)_2P(S)Cl$$

$$(EtO)_2P(S)Cl + NaOC_6H_4\text{-}p\text{-}NO_2 \longrightarrow (EtO)_2P(S)OC_6H_4\text{-}p\text{-}NO_2 \text{ (parathion)}$$

Methylparathion is the corresponding dimethyl derivative. Later (1952) malathion found favour because of its decreased toxicity to mammals; it is readily made in 90% yield by the addition of dimethyldithiophosphate to diethylmaleate in the presence of NEt_3 as a catalyst and hydroquinone as a polymerization inhibitor:

$$(MeO)_2P(S)SH + \begin{matrix} CHCO_2Et \\ \| \\ CHCO_2Et \end{matrix} \xrightarrow[60\%]{NEt_3\,/\,HQ} \begin{matrix} (MeO)_2P(S)SCHCO_2Et \\ | \\ CH_2CO_2Et \end{matrix} \quad \text{(malathion)}$$

The scale of manufacture of these organophosphorus pesticides can be guaged from data referring to the USA annual production in 1975 (tonnes): methylparathion 46 000, parathion 36 000 and malathion 16 000. In addition, some 15 other thioorganophosphorus insecticides are manufactured in the USA on a scale exceeding 2000 tonnes pa each.[4] They act by inhibiting cholinesterase, thus preventing the natural hydrolysis of the neurotransmitter acetylcholine in the insect.[20]

applications (see Panel). P_4S_{10} is also widely used to replace O by S in organic compounds to form, e.g., thioamides $RC(S)NH_2$, thioaldehydes RCHS and thioketones R_2CS. Methanolysis yields $(MeO)_2P(S)SH$ plus H_2S,[115] and the related anions $(RO)_2PS_2^-$ are known as versatile ligands with a remarkable variety of coordination modes.[116]

A rather different series of cyclic thiophosphate(III) anions $[(PS_2)_n]^{n-}$ is emerging from a study of the reaction of elemental phosphorus with polysulfidic sulfur. Anhydrous compounds

[115] P. Bourdauducq and M. C. Démarcq, *J. Chem. Soc., Dalton Trans.*, 1897–900 (1987).

[116] M. G. B. Drew, R. J. Hobson, P. P. E. M. Mumba and D. A. Rice, *J. Chem. Soc., Dalton Trans.*, 1569–71 (1987).

$M^I_5[cyclo\text{-}P_5S_{10}]$ and $M^I_6[cyclo\text{-}P_6S_{12}]$ were obtained using red phosphorus, whereas white P_4 yielded $[NH_4]_4[cyclo\text{-}P_4S_8].2H_2O$ as shiny platelets. This unique $P_4S_8^{4-}$ anion is the first known homocycle of 4 tetracoordinated P atoms and X-ray studies reveal that the P atoms form a square with rather long P–P distances (228 pm).[117]

The new planar anion PS_3^- (cf. the nitrate ion, NO_3^-) has been isolated as its tetraphenylarsonium salt, mp 183°, following a surprising reaction of P_4S_{10} with KCN/H_2S in MeCN, in which the coproduct was the known dianion $[(NC)P(S)_2\text{–}S\text{–}P(S)_2(CN)]^{2-}$.[118] The first sulfido heptaphosphane cluster anions, $[P_7(S)_3]^{3-}$ and $[HP_7(S)_2]^{2-}$ (cf. P_7^{3-}, p. 491), have also recently been characterized.[119]

Oxosulfides

When P_4O_{10} and P_4S_{10} are heated in appropriate proportions above 400°, $P_4O_6S_4$ is obtained as colourless hygroscopic crystals, mp 102°.

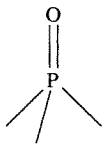
$$3P_4O_{10} + 2P_4S_{10} \longrightarrow 5P_4O_6S_4$$

The structure is shown in Fig. 12.15. The related compound $P_4O_4S_6$ is said to be formed by the reaction of H_2S with $POCl_3$ at 0° (A. Besson, 1897) but has not been recently investigated. An amorphous yellow material of composition $P_4O_4S_3$ is obtained when a solution of P_4S_3 in CS_2 or organic solvents is oxidized by dry air or oxygen. Other oxosulfides of uncertain authenticity such as $P_6O_{10}S_5$ have been reported but their structural integrity has not been established and they may be mixtures. However, the following series can be prepared by appropriate redistribution reactions: $P_4O_6S_n$ ($n = 1$–4), $P_4O_6Se_n$ ($n = 1$–3), P_4O_6SSe, $P_4O_7S_n$ ($n = 1$–3), P_4O_7Se, $P_4O_8S_n$ ($n = 1, 2$).[120] the crystal and molecular structures of $P_4O_6S_2$ and $P_4O_6S_3$ have recently been determined.[121] Two isomers each of β-$P_4S_2SeI_2$ and β-$P_4SSe_2I_2$, prepared by reaction of $P_4S_{3-n}Se_n$ with I_2 in CS_2 have been structurally identified by ^{31}P nmr spectroscopy.[122]

12.3.6 Oxoacids of phosphorus and their salts

The oxoacids of P are more numerous than those of any other element, and the number of oxoanions and oxo-salts is probably exceeded only by those of Si. Many are of great importance technologically and their derivatives are vitally involved in many biological processes (p. 528). Fortunately, the structural principles covering this extensive array of compounds are very simple and can be stated as follows:†

(i) All P atoms in the oxoacids and oxoanions are 4-coordinate and contain at least one P–O unit (1).



(1)

(ii) All P atoms in the oxoacids have at least one P–OH group (2a) and this often occurs in the anions also; all such groups are ionizable as proton donors (2b).

$M^{I}_{5}[cyclo\text{-}P_5S_{10}]$ and $M^{I}_{6}[cyclo\text{-}P_6S_{12}]$ were obtained using red phosphorus, whereas white P_4 yielded $[NH_4]_4[cyclo\text{-}P_4S_8].2H_2O$ as shiny platelets. This unique $P_4S_8^{4-}$ anion is the first known homocycle of 4 tetracoordinated P atoms and X-ray studies reveal that the P atoms form a square with rather long P–P distances (228 pm).[117]

The new planar anion PS_3^- (cf. the nitrate ion, NO_3^-) has been isolated as its tetraphenylarsonium salt, mp 183°, following a surprising reaction of P_4S_{10} with KCN/H_2S in MeCN, in which the coproduct was the known dianion $[(NC)P(S)_2–S–P(S)_2(CN)]^{2-}$.[118] The first sulfido heptaphosphane cluster anions, $[P_7(S)_3]^{3-}$ and $[HP_7(S)_2]^{2-}$ (cf. P_7^{3-}, p. 491), have also recently been characterized.[119]

Oxosulfides

When P_4O_{10} and P_4S_{10} are heated in appropriate proportions above 400°, $P_4O_6S_4$ is obtained as colourless hygroscopic crystals, mp 102°.

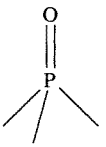
$$3P_4O_{10} + 2P_4S_{10} \longrightarrow 5P_4O_6S_4$$

The structure is shown in Fig. 12.15. The related compound $P_4O_4S_6$ is said to be formed by the reaction of H_2S with $POCl_3$ at 0° (A. Besson, 1897) but has not been recently investigated. An amorphous yellow material of composition $P_4O_4S_3$ is obtained when a solution of P_4S_3 in CS_2 or organic solvents is oxidized by dry air or oxygen. Other oxosulfides of uncertain authenticity such as $P_6O_{10}S_5$ have been reported but their structural integrity has not been established and they may be mixtures. However, the following series can be prepared by appropriate redistribution reactions: $P_4O_6S_n$ (n = 1–4), $P_4O_6Se_n$ (n = 1–3), P_4O_6SSe, $P_4O_7S_n$ (n = 1–3), P_4O_7Se, $P_4O_8S_n$ (n = 1, 2).[120] the crystal and molecular structures of $P_4O_6S_2$ and $P_4O_6S_3$ have recently been determined.[121] Two isomers each of β-$P_4S_2SeI_2$ and β-$P_4SSe_2I_2$, prepared by reaction of $P_4S_{3-n}Se_n$ with I_2 in CS_2 have been structurally identified by ^{31}P nmr spectroscopy.[122]

12.3.6 Oxoacids of phosphorus and their salts

The oxoacids of P are more numerous than those of any other element, and the number of oxoanions and oxo-salts is probably exceeded only by those of Si. Many are of great importance technologically and their derivatives are vitally involved in many biological processes (p. 528). Fortunately, the structural principles covering this extensive array of compounds are very simple and can be stated as follows:†

(i) All P atoms in the oxoacids and oxoanions are 4-coordinate and contain at least one P–O unit (1).



(1)

(ii) All P atoms in the oxoacids have at least one P–OH group (2a) and this often occurs in the anions also; all such groups are ionizable as proton donors (2b).

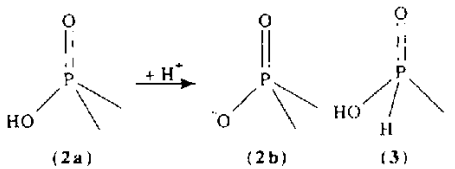
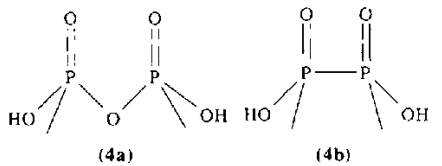
† Heteropolyacids containing P fall outside this classification and are treated, together with the isopolyacids and their salts, on pp. 1010–16. Organic esters such as $P(OR)_3$ are also excluded.

(iii) Some species also have one (or more) P–H group (3); such directly bonded H atoms are not ionizable.



(iv) Catenation is by P-O-P links (4a) or via direct P–P bonds (4b); with the former both open chain ("linear") and cyclic species are known but only corner sharing of tetrahedra occurs, never edge- or face-sharing.



(v) Peroxo compounds feature either P--OOH groups or POOP links.

It follows from these structural principles that each P atom is 5-covalent. However, the oxidation state of P is 5 only when it is directly bound to 4 O atoms; the oxidation state is reduced by 1 each time a P–OH is replaced by a P–P bond and by 2 each time a P–OH is replaced by a P-H. Some examples of phosphorus oxoacids are listed in Table 12.7 together with their recommended and common names. It will be seen that the numerous structural types and the variability of oxidation state pose several problems of nomenclature which offer a rich source of confusion in the literature.

The oxoacids of P are clearly very different structurally from those of N (p. 459) and this difference is accentuated when the standard reduction potentials (p. 434) and oxidation-state diagrams (p. 437) for the two sets of compounds are compared. Some reduction potentials (E°/V) in acid solution are in Table 12.8[123] (p. 513) and these are shown schematically below, together with the corresponding data for alkaline solutions.

The alternative presentation as an oxidation state diagram is in Fig. 12.16 which shows the dramatic difference to N (p. 438).

The fact that the element readily dissolves in aqueous media with disproportionation into PH_3 and an oxoacid is immediately clear from the fact that P lies above the line joining PH_3 and either H_3PO_2 (hypophosphorous acid), H_3PO_3 (phosphorous acid) or H_3PO_4 (orthophosphoric acid). The reaction is even

[a]Some acids are known only as their salts in which one or more −OH group has been replaced by O^-

[b]The number in parentheses after the formula indicates the maximum basicity, where this differs from the total number of H atoms in the formula.

more effective in alkaline solution. Similarly, $H_4P_2O_6$ disproportionates into H_3PO_3 and H_3PO_4. Figure 12.16 also illustrates that H_3PO_2 and H_3PO_3 are both effective reducing agents, being readily oxidized to H_3PO_4, but this latter compound (unlike HNO_3) is not an oxidizing agent.

A comprehensive treatment of the oxoacids and oxoanions of P is inappropriate but selected examples have been chosen to illustrate

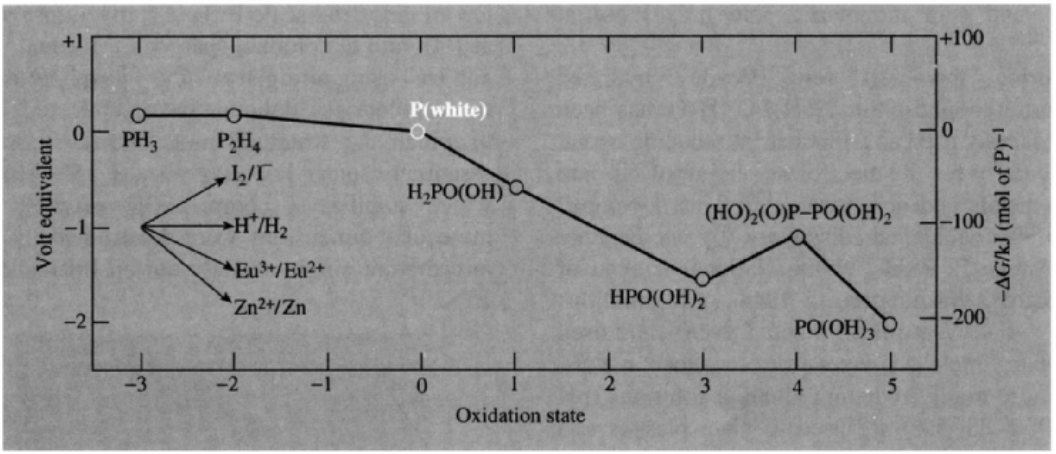

Figure 12.16 Oxidation state diagram for phosphorus. (Note that all the oxoacids have a phosphorus covalency of 5.)

interesting points of stereochemistry, reaction chemistry or technological applications. The treatment begins with the lower oxoacids and their salts (in which P has an oxidation state less than +5) and then considers phosphoric acid, phosphates and polyphosphates. The peroxoacids H_3PO_5 and $H_4P_2O_8$ and their salts will not be treated further[124] (except peripherally) nor will the peroxohydrates of orthophosphates, which are obtained from aqueous H_2O_2 solutions.[64]

Hypophosphorous acid and hypophosphites [$H_2PO(OH)$ and $H_2PO_2^-$]

The recommended names for these compounds (phosphinic acid and phosphinates) have not yet gained wide acceptance for inorganic compounds but are generally used for organophosphorus derivatives. Hypophosphites can be made by heating white phosphorus in aqueous alkali:

$$P_4 + 4OH^- + 4H_2O \xrightarrow[[NaOH/Ca(OH)_2]]{\text{warm}} 4H_2PO_2^- + 2H_2$$

Phosphite and phosphine are obtained as byproducts (p. 493) and the former can be removed via its insoluble calcium salt:

$$P_4 + 4OH^- + 2H_2O \xrightarrow{2Ca^{2+}} Ca(HPO_3)_2 + 2PH_3$$

Table 12.8 Some reduction potentials in acid solution (pH 0)[a]

Reaction	$E°$/V
$P + 3H^+ + 3e^- \rightleftharpoons PH_3(g)$	−0.063
$P + 2H^- + 2e^- \rightleftharpoons \frac{1}{2}P_2H_4(g)$	−0.097
$\frac{1}{2}P_2H_4 + H^+ + e^- \rightleftharpoons PH_3$	+0.006
$H_3PO_2 + H^+ + e^- \rightleftharpoons P + 2H_2O$	−0.508
$H_3PO_3 + 3H^+ + 3e^- \rightleftharpoons P + 3H_2O$	−0.502
$H_3PO_4 + 5H^+ + 5e^- \rightleftharpoons P + 4H_2O$	−0.411
$H_3PO_3 + 2H^+ + 2e^- \rightleftharpoons H_3PO_2 + H_2O$	−0.499
$H_3PO_4 + 2H^+ + 2e^- \rightleftharpoons H_3PO_3 + H_2O$	−0.276
$H_3PO_4 + H^+ + e^- \rightleftharpoons \frac{1}{2}H_4P_2O_6 + H_2O$	−0.933
$\frac{1}{2}H_4P_2O_6 + H^+ + e^- \rightleftharpoons H_3PO_3$	+0.380

[a] P refers to white phosphorus, $\frac{1}{4}P_4(s)$.

Free hypophosphorous acid is obtained by acidifying aqueous solutions of hypophosphites but the pure acid cannot be isolated simply by evaporating such solutions because of its ready oxidation to phosphorous and phosphoric acids and disproportionation to phosphine and phosphorous acid (Fig. 12.16). Pure H_3PO_2 is obtained by continuous extraction from aqueous solutions into Et_2O; it forms white crystals mp

[124] J. I. Creaser and J. O. Edwards, *Topics in Phosphorus Chemistry* **7**, 379–435 (1972).

26.5° and is a monobasic acid pK_a 1.244 at 25°.[125]

During the past few decades hydrated sodium hypophosphite, $NaH_2PO_2.H_2O$, has been increasingly used as an industrial reducing agent, particularly for the electroless plating of Ni onto both metals and non-metals.[126] This developed from an accidental discovery by A. Brenner and Grace E. Riddel at the National Bureau of Standards, Washington, in 1944. Acid solutions ($E \sim -0.40$ V at pH 4–6 and $T > 90°$) are used to plate thick Ni layers on to other metals, but more highly reducing alkaline solutions (pH 7–10; T 25–50°) are used to plate plastics and other non-conducting materials:

$$HPO_3^{2-} + 2H_2O + 2e^- \rightleftharpoons H_2PO_2^- + 3OH^-; \quad E \sim -1.57 \text{ V}$$

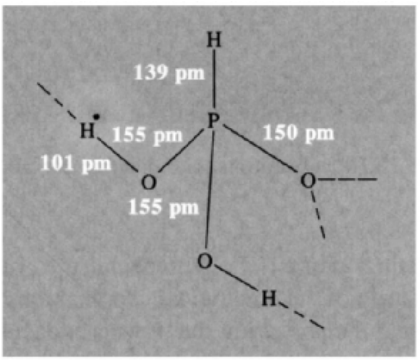
Typical plating solutions contain 10–30 g/l of nickel chloride or sulfate and 10–50 g/l NaH_2PO_2; with suitable pump capacities it is possible to plate up to 10 kg Ni per hour from such a bath (i.e. 45 m^2 surface to a thickness of 25 μm). Chemical plating is more expensive than normal electrolytic plating but is competitive when intricate shapes are being plated and is essential for non-conducting substrates. (See also the use of BH_4^- in this connection, p. 167.)

Phosphorous acid and phosphites [$HPO(OH)_2$ and HPO_3^{2-}]

Again, the recommended names (phosphonic acid and phosphonates) have found more general acceptance for organic derivatives such as RPO_3^{2-}, and purely inorganic salts are still usually called phosphites. The free acid is readily made by direct hydrolysis of PCl_3 in cold CCl_4 solution:

$$PCl_3 + 3H_2O \longrightarrow HPO(OH)_2 + 3HCl$$

On an industrial scale PCl_3 is sprayed into steam at 190° and the product sparged of residual water and HCl using nitrogen at 165°. Phosphorous acid forms colourless, deliquescent crystals, mp 70.1°, in which the structural units shown form four essentially linear H bonds (O···H 155–160 pm) which stabilize a complex 3D network. The molecular dimensions were determined by low-temperature single-crystal neutron diffraction at 15 K.[127]



In aqueous solutions phosphorous acid is dibasic (pK_1 1.257, pK_2 6.7)[125] and forms two series of salts: phosphites and hydrogen phosphites (acid phosphites), e.g.

"normal":	$[NH_4]_2[HPO_3].H_2O$, $Li_2[HPO_3]$, $Na_2[HPO_3].5H_2O$, $K_2[HPO_3]$
"acid":	$[NH_4][HPO_2(OH)]$, $Li[HPO_2(OH)]$, $Na[HPO_2(OH)].2\frac{1}{2}H_2O$, $K[HPO_2(OH)]$ and $M[HPO_2(OH)]_2$ (M = Mg, Ca, Sr).

Dehydration of these acid phosphites by warming under reduced pressure leads to the corresponding pyrophosphites $M^I_2[HP(O)_2-O-P(O)_2H]$ and $M^{II}[HP(O)_2-O-P(O)_2H]$.

Organic derivatives fall into 4 classes $RPO(OH)_2$, $HPO(OR)_2$, $R'PO(OR)_2$ and the phosphite esters $P(OR)_3$; this latter class has no purely inorganic analogues, though it is, of course, closely related to PCl_3. Some preparative routes have already been indicated. Reactions with alcohols depend on conditions:

$$PCl_3 + 3ROH \longrightarrow HPO(OR)_2 + RCl + 2HCl$$

[125] J. W. Larson and M. Pippin, *Polyhedron* **8**, 527–30 (1989).

[126] H. Niederprüm, *Angew. Chem. Int. Edn. Engl.* **14**, 614–20 (1975); G. A. Krulik, *Kirk–Othmer Encyclopedia of Chemical Technology*, 4th edn., Vol. 9, pp. 198–218, Wiley, New York, 1994.

[127] G. Becker, H.-D. Hausen, O. Mundt, W. Schwarz, C. T. Wagner and T. Vogt, *Z. anorg. allg. Chem.* **591**, 17–31 (1990).

$$PCl_3 + 3ROH + 3R'_3N \longrightarrow P(OR)_3 + 3R'_3NHCl$$

Phenols give triaryl phosphites $P(OAr)_3$ directly at ~160° and these react with phosphorous acid to give diaryl phosphonates:

$$2P(OAr)_3 + HPO(OH)_2 \longrightarrow 3HPO(OAr)_2$$

Trimethyl phosphite $P(OMe)_3$ spontaneously isomerizes to methyl dimethylphosphonate $MePO(OMe)_2$, whereas other trialkyl phosphites undergo the Michaelis–Arbusov reaction with alkyl halides via a phosphonium intermediate:

$$P(OR)_3 + R'X \longrightarrow \{[R'P(OR)_3]X\}$$
$$\longrightarrow R'PO(OR)_2 + RX$$

Further discussion of these fascinating series of reactions falls outside our present scope.[2]

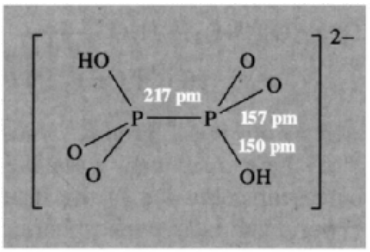
Hypophosphoric acid ($H_4P_2O_6$) *and hypophosphates*

There has been much confusion over the structure of these compounds but their diamagnetism has long ruled out a monomeric formulation, H_2PO_3. In fact, as shown in Table 12.7, isomeric forms are known: (a) hypophosphoric acid and hypophosphates in which both P atoms are identical and there is a direct P–P bond; (b) isohypophosphoric acid and isohypophosphates in which 1 P has a direct P–H bond and the 2 different P atoms are joined by a $P^{III}–O–P^{V}$ link.[23]

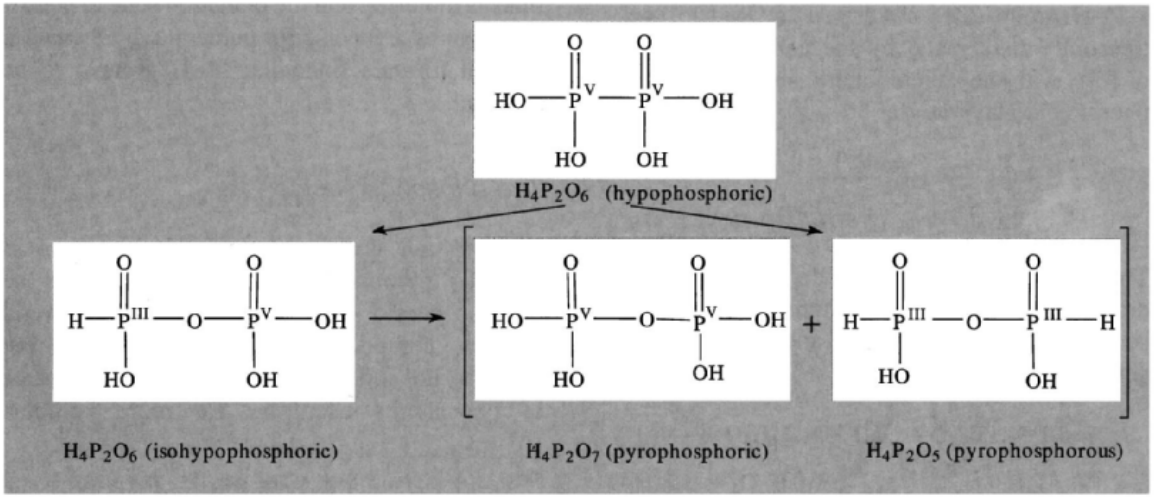
Hypophosphoric acid, $(HO)_2P(O)–P(O)(OH)_2$, is usually prepared by the controlled oxidation of red P with sodium chlorite solution at room temperature: the tetrasodium salt, $Na_4P_2O_6.10H_2O$, crystallizes at pH 10 and the disodium salt at pH 5.2:

$$2P + 2NaClO_2 + 8H_2O \longrightarrow Na_2H_2P_2O_6.6H_2O + 2HCl$$

Ion exchange on an acid column yields the crystalline "dihydrate" $H_4P_2O_6.2H_2O$ which is actually the hydroxonium salt of the dihydrogen hypophosphate anion $[H_3O]_2^+[(HO)P(O)_2–P(O)_2(OH)]^{2-}$; it is isostructural with the corresponding ammonium salt for which X-ray diffraction studies establish the staggered structure shown.



The anhydrous acid is obtained either by the vacuum dehydration of the dihydrate over P_4O_{10}



or by the action of H_2S on the insoluble lead salt $Pb_2P_2O_6$. As implied above, the first proton on each $-PO(OH)_2$ unit is more readily removed than the second and the successive dissociation constants at 25° are pK_1 2.2, pK_2 2.8, pK_3 7.3, pK_4 10.0. Both $H_4P_2O_6$ and its dihydrate are stable at 0° in the absence of moisture. The acid begins to melt (with decomposition) at 73° but even at room temperature it undergoes rearrangement and disproportionation to give a mixture of isohypophosphoric, pyrophosphoric, and pyrophosphorous acids as represented schematically on the previous page.

Hypophosphoric acid is very stable towards alkali and does not decompose even when heated with 80% NaOH at 200°. However, in acid solution it is less stable and even at 25° hydrolyses at a rate dependent on pH (e.g. $t_{\frac{1}{2}}$ 180 days in 1 M HCl, $t_{\frac{1}{2}} < 1$ h in 4 M HCl):

$$(HO)_2P(O)\text{–}P(O)(OH)_2 + H_2O \xrightarrow{pH < 0} HP(O)(OH)_2 + P(O)(OH)_3$$

The presence of P–H groups amongst the products of these reactions was one of the earlier sources of confusion in the structures of hypophosphoric and isohypophosphoric acids.

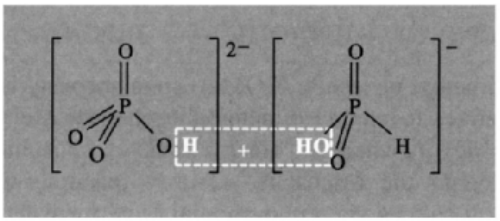
The structure of isohypophosphoric acid and its salts can be deduced from ^{31}P nmr which shows the presence of 2 different 4-coordinate P atoms, the absence of a P–P bond and the presence of a P–H group (also confirmed by Raman spectroscopy). It is made by the careful hydrolysis of PCl_3 with the stoichiometric amounts of phosphoric acid and water at 50°:

$$PCl_3 + H_3PO_4 + 2H_2O \xrightarrow{50°} iso\text{-}[H_3(HP_2O_6)] + 3HCl$$

The trisodium salt is best made by careful dehydration of an equimolar mixture of hydrated disodium hydrogen phosphate and sodium hydrogen phosphite at 180°:

$$Na_2HPO_4.12H_2O + NaH_2PO_3.2\tfrac{1}{2}H_2O \xrightarrow{180°} Na_3[HP_2O_6] + 15\tfrac{1}{2}H_2O$$

The structural relation between the reacting anions and the product is shown schematically below:



Other lower oxoacids of phosphorus

The possibility of P–H and P–P bonds in phosphorus oxoacids, coupled with the ease of polymerization via P–O–P linkages enables innumerable acids and their salts to be synthesized. Frequently mixtures are obtained and these can be separated by paper chromatography, paper electrophoresis, thin-layer chromatography, ion exchange or gel chromatography.[128] Much ingenuity has been expended in designing appropriate syntheses but no new principles emerge. A few examples are listed in Table 12.9 to illustrate both the range of compounds available and also the abbreviated notation, which proves to be more convenient than formal systematic nomenclature in this area. In this notation the sequence of P–P and P–O–P links is indicated and the oxidation state of each P is shown as a superscript numeral which enables the full formula (including P–H groups) to be deduced.

The phosphoric acids

This section deals with orthophosphoric acid (H_3PO_4), pyrophosphoric acid ($H_4P_2O_7$) and the polyphosphoric acids ($H_{n+2}P_nO_{3n+1}$). Several of these compounds can be isolated pure but their facile interconversion renders this area of phosphorus chemistry far more complex

[128] S. OHASHI, *Pure Appl. Chem.* **44**, 415–38 (1975).

Table 12.9 Some lower oxoacids of phosphorus (Superscript numerals in the abbreviated notation indicate oxidation states)

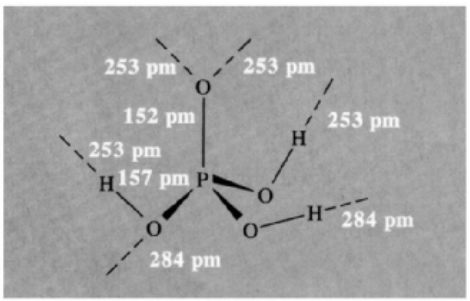
Formula (basicity)	Structure	Abbreviated notation	Formula (basicity)	Structure	Abbreviated notation
$H_4P_2O_4$ (2)		$^{2}P—^{2}P$	$H_5P_3O_9$ (5)		$^{5}P—O—^{4}P—^{4}P$
$H_4P_2O_5$ (3)		$^{2}P—^{4}P$	$H_6P_4O_{11}$ (6)		$^{4}P—^{4}P—O—^{4}P—^{4}P$
$H_4P_2O_6$ (3)		$^{3}P—O—^{5}P$	$H_4P_4O_{10}$ (10)		$(—^{4}P—^{4}P—O—)_2$ ring
$H_5P_3O_7$ (4)		$^{3}P—O—^{4}P—^{4}P$	$H_6P_6O_{12}$ (6)		$(—^{3}P—)_6$ ring
$H_5P_3O_8$ (5)		$^{4}P—^{3}P—^{4}P$			

than might otherwise appear. The corresponding phosphate salts are discussed in subsequent sections as also are the cyclic metaphosphoric acids $(HPO_3)_n$, the polymetaphosphoric acids $(HPO_3)_n$, and their salts.

Orthophosphoric acid is a remarkable substance: it can only be obtained pure in the crystalline state (mp 42.35°C) and when fused it slowly undergoes partial self-dehydration to diphosphoric acid:

$$2H_3PO_4 \rightleftharpoons H_2O + H_4P_2O_7$$

The sluggish equilibrium is obtained only after several weeks near the mp but is more rapid at higher temperatures. This process is accompanied by extremely rapid autoprotolysis (see below) which gives rise to several further (ionic) species in the melt. As the concentration of these various species builds up the mp slowly drops until at equilibrium it is 34.6°, corresponding to about 6.5 mole% of diphosphate.[129] Slow crystallization of stoichiometric molecular H_3PO_4 from this isocompositional melt gradually reverses the equilibria and the mp eventually rises again to the initial value. Crystalline H_3PO_4 has a hydrogen-bonded layer structure in which each $PO(OH)_3$ molecule is linked to 6 others by H bonds which are of two lengths, 253 and 284 pm. The shorter bonds link OH and O=P groups whereas the longer H bonds are between 2 OH groups on adjacent molecules.



Extensive H bonding persists on fusion and phosphoric acid is a viscous syrupy liquid that readily supercools. At 45°C (just above the mp) the viscosity is 76.5 centipoise (cP) and this increases to 177.7 cP at 25°. These values can be compared with 1.00 cP for H_2O at 20° and 24.5 cP for anhydrous H_2SO_4 at 25°. As shown in the Table[129] trideuterophosphoric acid has an even higher viscosity and deuteration also raises the mp and density.

Property	H_3PO_4	D_3PO_4
MP/°C	42.35	46.0
Density (25°C); supercooled/g cm^{-3}	1.8683	1.9083
η (25°C)/centipoise	177.5	231.8
κ/ohm^{-1} cm^{-1}	4.68×10^{-2}	2.82×10^{-2}

Property	$H_3PO_4 \cdot \frac{1}{2}H_2O$
MP/°C	29.30
Density (25°C); supercooled/g cm^{-3}	1.7548
η (25°C)/centipoise	70.64
κ/ohm^{-1} cm^{-1}	7.01×10^{-2}

Despite this enormous viscosity, fused H_3PO_4 (and D_3PO_4) conduct electricity extremely well and this has been shown to arise from extensive self-ionization (autoprotolysis) coupled with a proton-switch conduction mechanism for the $H_2PO_4^-$ ion:[129,130]

$$2H_3PO_4 \rightleftharpoons H_4PO_4^+ + H_2PO_4^- \qquad (1)$$

In addition, the diphosphate group is also deprotonated:

$$\left.\begin{aligned} 2H_3PO_4 &\rightleftharpoons H_2O + H_4P_2O_7 \\ &\rightleftharpoons H_3O^+ + H_3P_2O_7^- \\ H_3P_2O_7^- + H_3PO_4 &\rightleftharpoons H_4PO_4^+ \\ &\quad + H_2P_2O_7^{2-} \end{aligned}\right\}$$

i.e. $$3H_3PO_4 \rightleftharpoons H_3O^+ + H_4PO_4^+ + H_2P_2O_7^{2-} \qquad (2)$$

At equilibrium, the concentration of H_3O^+ and $H_2P_2O_7^{2-}$ are each ~0.28 molal and $H_2PO_4^-$ is ~0.26 molal, thereby implying a

[129] N. N. Greenwood and A. Thompson, *J. Chem. Soc.* 3485–92 and 3864–7 (1959).

[130] R. A. Munson, *J. Phys. Chem.* **68**, 3374–7 (1964).

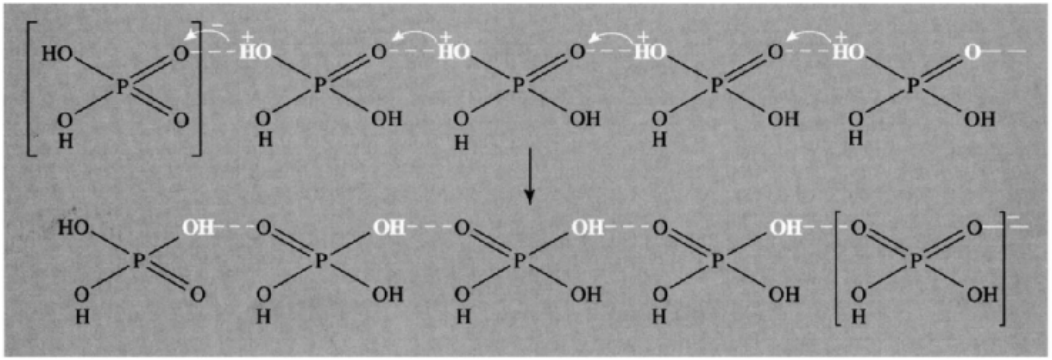


Figure 12.17 Schematic representation of proton-switch conduction mechanism involving $[H_2PO_4]^-$ in molten phosphoric acid.

concentration of 0.54 molal for $H_4PO_4^+$. These values are about 20–30 times greater than the concentrations of ions in molten H_2SO_4, namely $[HSO_4^-]$ 0.0178 molal, $[H_3SO_4^+]$ 0.0135 molal and $[HS_2O_7^-]$ 0.0088 molal (see p. 711). Because of the very high viscosity of molten H_3PO_4 electrical conduction by normal ionic migration is negligible and the high conductivity is due almost entirely to a rapid proton-switch followed by a relatively slow reorientation involving the $H_2PO_4^-$ ion, H-bonded to the solvent structure (Fig. 12.17).[129] Note that the tetrahedral $H_4PO_4^+$ ion, i.e. $[P(OH)_4]^+$, like the NH_4^+ ion in liquid NH_3, does not contribute to the proton-switch conduction mechanism in H_3PO_4 because, having no dipole moment, it does not orient preferentially in the applied electric field; accordingly any proton switching will occur randomly in all directions independently of the applied field and therefore will not contribute to the electrical conduction.

Addition of the appropriate amount of water to anhydrous H_3PO_4, or crystallization from a concentrated aqueous solution of syrupy phosphoric acid, yields the hemihydrate $2H_3PO_4.H_2O$ as a congruently melting compound (mp 29.3°). The crystal structure[131] shows the presence of 2 similar H_3PO_4 molecules which, together with the H_2O molecule, are linked into a three-dimensional H-bonded network: each of the nine O atoms participates in at least 1 relatively strong O–H···O bond (255–272 pm) and the interatomic distances P=O (149 pm) and P–OH (155 pm) are both slightly shorter than the corresponding distances in H_3PO_4. Hydrogen bonding persists in the molten compound, and the proton-switch conductivity is even higher than in the anhydrous acid (See Table on p. 518).

In dilute aqueous solutions H_3PO_4 behaves as a strong acid but only one of the hydrogens is readily ionizable, the second and third ionization constants decreasing successively by factors of $\sim 10^5$ (see p. 50). Thus, at 25°:

$$H_3PO_4 + H_2O \rightleftharpoons H_3O^+ + H_2PO_4^-;$$

$$K_1 = 7.11 \times 10^{-3}; \quad pK_1 = 2.15$$

$$H_2PO_4^- + H_2O \rightleftharpoons H_3O^+ + HPO_4^{2-};$$

$$K_2 = 6.31 \times 10^{-8}; \quad pK_2 = 7.20$$

$$HPO_4^{2-} + H_2O \rightleftharpoons H_3O^+ + PO_4^{3-};$$

$$K_3 = 4.22 \times 10^{-13}; \quad pK_3 = 12.37$$

Accordingly, the acid gives three series of salts, e.g. NaH_2PO_4, Na_2HPO_4, and Na_3PO_4 (p. 523). A typical titration curve in this system is shown in Fig. 12.18: there are three steps with two inflexions at pH 4.5 and 9.5. The first inflexion, corresponding to the formation of NaH_2PO_4, can be detected by an indicator such as methyl

[131] A. D. Mighell, J. P. Smith, and W. E. Brown, *Acta Cryst.* **B25**, 776–81 (1969).

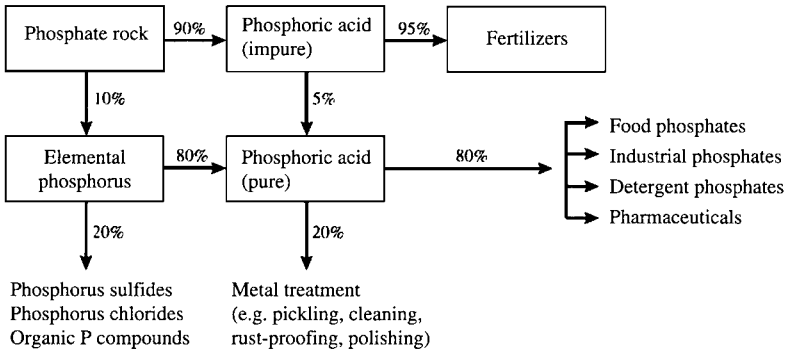
Industrial production and uses of H_3PO_4[3–5,8,9,11,132]

Phosphoric acid[132] is manufactured on a vast scale and is produced in a wide variety of concentrations and purities. It is therefore convenient to express production figures in terms of the amount of contained P_4O_{10} (the figures based on the equivalent amount of contained anhydrous H_3PO_4 can be obtained by multiplying by the factor 1.380, though these may be misleading if they are taken to imply that it is the anhydrous acid that is being produced). World production capacity in 1986 exceeded 43 million tonnes of contained P_4O_{10} and was distributed as follows:

Production capacity of phosphoric acid (million tonnes/year of contained P_4O_{10})

Region	North America	USSR & East.Eur.	Africa	Western Europe	Asia and Australasia	Central/S. America	Middle East
"P_4O_{10}"/Mtpa	13.1	10.6	6.1	5.0	3.9	2.4	1.5

Production is still increasing steadily in many countries "Thermal" acid (made by oxidation of phosphorus in the presence of water vapour) is about 3 times as expensive as "wet" acid (made by treating rock phosphate with sulfuric acid). The present approximate pattern of production and uses is shown in the following scheme:



Many of these uses have already been discussed, or will be in later sections (pp. 524, 527).

Applications of phosphoric acid in metal treatment date from 1869 when a British patent was granted for the prevention of rusting of corset stays by damp air or perspiration. Improvements followed the incorporation of certain metal ions in the phosphatizing solution (notably Mn, Fe and Zn), and today corrosion resistance is imparted in this way to innumerable metal objects such as nuts, bolts, screws, tools, car-engine parts, gears, etc. In addition, car-bodies, refrigerators, washing machines and other electrical applicances with painted or enamelled surfaces all use phosphatized undercoatings to prevent the paint from blistering or peeling. The simple immersion process may take up to 2 h at 90°C but can be accelerated 25-fold by adding small amounts of oxidizing agent such as $NaNO_3$ and $Cu(NO_3)_2$. A zinc phosphatized coating is usually about 0.6 μm thick (i.e. 2.2 g m^{-2}). Another important process is "bright dip" or chemical polishing of Al metal which has replaced chrome plating for car trims and other uses: the metal is immersed at 91–99°C in a solution containing 95 parts by weight of 85% H_3PO_4, 4 parts of 68% HNO_3, and 0.01% $Cu(NO_3)_2$, followed by electrolytic anodization to give the mirror-like surface a protective coating of transparent Al_2O_3.

Polyphosphoric acid supported on diatomaceous earth (p. 342) is a petrochemicals catalyst for the polymerization, alkylation, dehydrogenation, and low-temperature isomerization of hydrocarbons. Phosphoric acid is also used in the production of activated carbon (p. 274). In addition to its massive use in the fertilizer industry (p. 524) free phosphoric acid can be used as a stabilizer for clay soils: small additions of H_3PO_4 under moist conditions gradually leach out Al and Fe from the clay and these form polymeric phosphates which bind the clay particles together. An allied, though more refined use is in the setting of dental cements.

By far the greatest consumption of pure aqueous phosphoric acid is in the preparation of various salts for use in the food, detergent and tooth-paste industries (p. 524). When highly diluted the free acid is non-toxic and devoid of odour, and is extensively used to impart the sour or tart taste to many soft drinks ("carbonated beverages") such as the various colas (~0.05% H_3PO_4, pH 2.3), root beers (~0.01% H_3PO_4, pH 5.0), and sarsaparilla (~0.01% H_3PO_4, pH ~4.5).

[132]P. BECKER, *Phosphates and Phosphoric Acid*, Marcel Dekker, New York, 1988, 760 pp.

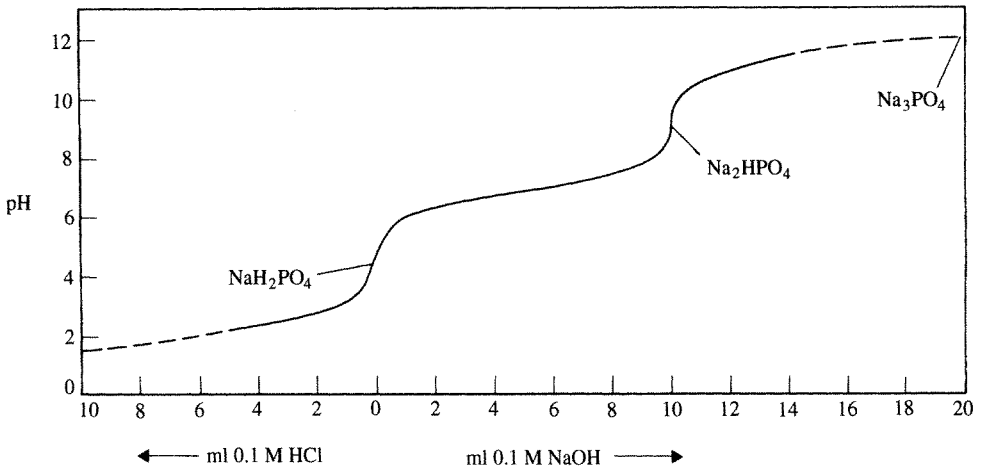


Figure 12.18 Neutralization curve for aqueous orthophosphoric acid. For technical reasons the curve shown refers to 10 cm^3 of 0.1 M NaH_2PO_4 titrated (to the left) with 0.1 M aqueous HCl and (to the right) with 0.1 M NaOH solutions. Extrapolations to points corresponding to 0.1 M H_3PO_4 (pH 1.5) and 0.1 M Na_3PO_4 (pH 12.0) are also shown.

orange (pK_i 3.5) and the second, corresponding to Na_2HPO_4, is indicated by the phenolphthalein end point (pK_i 9.5). The third equivalence point cannot be detected directly by means of a coloured indicator. Between the two inflexions the pH changes relatively slowly with addition of NaOH and this is an example of buffer action.† Indeed, one of the standard buffer solutions used in analytical chemistry comprises an equimolar mixture of Na_2HPO_4 and KH_2PO_4. Another important buffer, which has been designed to have a pH close to that of blood, consists of 0.030 43 M Na_2HPO_4 and 0.008 695 M KH_2PO_4, i.e. a mole ratio of 3.5:1 (pH 7.413 at 25°).

Concentrated H_3PO_4 is one of the major acids of the chemical industry and is manufactured on the multimillion-tonne scale for the production of phosphate fertilizers and for many other purposes (see Panel). Two main processes (the so-called "thermal" and "wet" processes) are used depending on the purity required. The "thermal" (or "furnace") process yields concentrated acid essentially free from impurities and is used in applications involving products destined for human consumption (see also p. 524); in this process a spray of molten phosphorus is burned in a mixture of air and steam in a stainless steel combustion chamber:

$$P_4 + 5O_2 \longrightarrow P_4O_{10} \xrightarrow{6H_2O} 4H_3PO_4$$

Acid of any concentration up to 84 wt% P_4O_{10} can be prepared by this method (72.42% P_4O_{10} corresponds to anhydrous H_3PO_4) but the usual commercial grades are 75–85% (expressed as anhydrous H_3PO_4). The hemihydrate (p. 518) corresponds to 91.58% H_3PO_4 (66.33% P_4O_{10}). The somewhat older "wet" (or "gypsum") process involves the treatment of rock phosphate (p. 476) with sulfuric acid, the idealized stoichiometry being:

$$Ca_5(PO_4)_3F + 5H_2SO_4 + 10H_2O \longrightarrow 3H_3PO_4 + 5CaSO_4.2H_2O + HF$$

† A buffer solution is one that resists changes in pH on dilution or on addition of acid or alkali. It consists of a solution of a weak acid (e.g. $H_2PO_4^-$) and its conjugate base (HPO_4^{2-}) and is most effective when the concentration of the two species are the same. For example at 25° an equimolar mixture of Na_2HPO_4 and KH_2PO_4 has pH 6.654 when each is 0.2 M and pH 6.888 when each is 0.01 M. The central section of Fig. 12.18 shows the variation in pH of an equimolar buffer of Na_2HPO_4 and NaH_2PO_4 at a concentration of 0.033 M (you should check this statement). Further discussion of buffer solutions is given in standard textbooks of volumetric analysis.

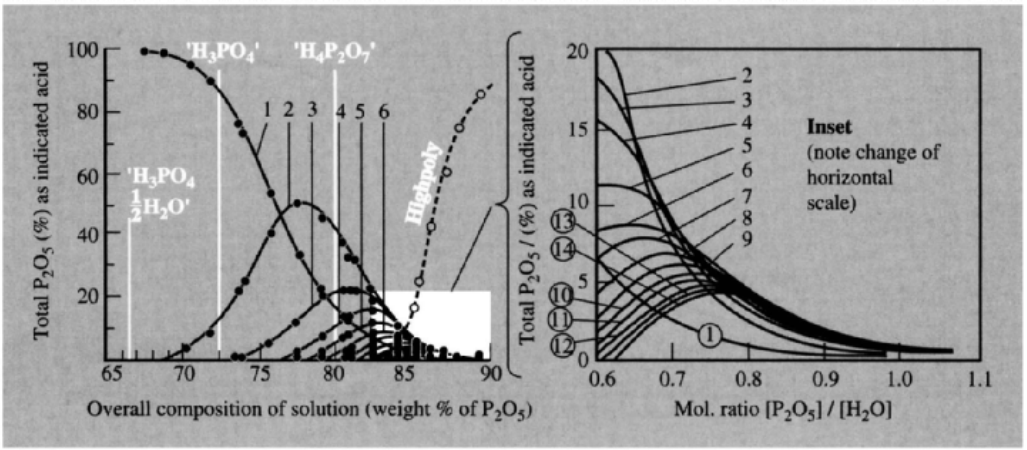

Figure 12.19 *The composition of the strong phosphoric acids shown as the weight per cent of P_2O_5 present in the form of each acid plotted against the overall stoichiometric composition of the mixture. The overall stoichiometries corresponding to the three congruently melting species $H_3PO_4.\frac{1}{2}H_2O$, H_3PO_4 and $H_4P_2O_7$ are indicated. Compositions above 82 wt P_2O_5 are shown on an expanded scale in the inset using the mole ratio $[P_2O_5]/[H_2O]$ as the measure of stoichiometry. (For comparison, $H_4P_2O_7$ corresponds to a mole ratio of 0.500, $H_5P_3O_{10}$ to a ratio 0.600, $H_6P_4O_{13}$ to 0.667, etc.). In both diagrams the curves labelled 1,2,3, ... refer to ortho-, di-, tri- ... phosphoric acids, and "highpoly" refers to highly polymeric material hydrolysed from the column.*

The gypsum is filtered off together with other insoluble matter such as silica, and the fluorine is removed as insoluble Na_2SiF_6. The dilute phosphoric acid so obtained (containing 35–70% H_3PO_4 depending on the plant used) is then concentrated by evaporation. It is usually dark green or brown in colour and contains many metal impurities (e.g. Na, Mg, Ca, Al, Fe, etc.) as well as residual sulfate and fluoride, but is suitable for the manufacture of phosphatic fertilizers, metallurgical applications, etc. (see Panel on p. 520).

Diphosphoric acid $H_4P_2O_7$ becomes an increasingly prevalent species as the system P_4O_{10}/H_2O becomes increasingly concentrated: indeed, the phase diagram shows that, in addition to the hemihydrate (mp 29.30°) and orthophosphoric acid (mp 42.35°) the only other congruently melting phase in the system is $H_4P_2O_7$. The compound is dimorphic with a metastable modification mp 54.3° and a stable form mp 71.5°, but in the molten state it comprises an isocompositional mixture of various polyphosphoric acids and their autoprotolysis products. Equilibrium is reached only sluggishly and the actual constitution of the melt depends sensitively both on the precise stoichiometry and the temperature (Fig. 12.19)[133] For the nominal stoichiometry corresponding to $H_4P_2O_7$ typical concentrations of the species $H_{n+2}P_nO_{3n+1}$ from $n = 1$ (i.e. H_3PO_4) to $n = 8$ are as follows:

n	1	2	3	4	5	6	7	8
mole%	35.0	42.6	14.6	5.0	1.8	0.7	0.3	0.1

Thus, although $H_4P_2O_7$ is marginally the most abundant species present, there are substantial amounts of H_3PO_4, $H_5P_3O_{10}$, $H_6P_4O_{13}$ and higher polyphosphoric acids. Note that the table indicates mole% of each molecular species present whereas the graphs in Fig. 12.19 plot weight percentage of P_2O_5 present as each acid shown.

In dilute aqueous solution $H_4P_2O_7$ is a somewhat stronger acid than H_3PO_4: the 4 dissociation constants at 25° are: $K_1 \sim 10^{-1}$,

[133] R. F. JAMESON, *J. Chem. Soc.* 752-9 (1959).

Table 12.10 Factors affecting the rate of polyphosphate degradation

Factor	Effect on rate	Factor	Effect on rate
Temperature	10^5–10^6 faster from 0° to 100°	Complexing cations	Often much faster
pH	10^3–10^4 faster from base to acid	Concentration	Roughly proportional
Enzymes	Up to 10^5–10^6 faster	Ionic environment in solution	Several-fold change
Colloidal gels	Up to 10^4–10^5 faster		

$K_2 \sim 1.5 \times 10^{-2}$, K_3 2.7×10^{-7} and K_4 2.4×10^{-10}, and the corresponding negative logarithms are: $pK_1 \sim 1.0$, $pK_2 \sim 1.8$, pK_3 6.57 and pK_4 9.62. The P—O—P linkage is kinetically stable towards hydrolysis in dilute neutral solutions at room temperature and the reaction half-life can be of the order of years. Such hydrolytic breakdown of polyphosphate is of considerable importance in certain biological systems and has been much studied. Some factors which affect the rate of degradation of polyphosphates are shown in Table 12.10.

Orthophosphates [23,64]

Phosphoric acid forms several series of salts in which the acidic H atoms are successively replaced by various cations; there is considerable commercial application for many of these compounds.

Lithium orthophosphates are unimportant and differ from the other alkali metal phosphates in being insoluble. At least 10 crystalline hydrated or anhydrous sodium orthophosphates are known and these can be grouped into three series:

$Na_3PO_4.nH_2O$ ($n = 0, \frac{1}{2}, 6, 8, 12$)
$Na_2HPO_4.nH_2O$ ($n = 0, 2, 7, 8, 12$)
$NaH_2PO_4.nH_2O$ ($n = 0, 1, 2$),
$NaH_2PO_4.H_3PO_4$ [i.e. $NaH_5(PO_4)_2$]
$NaH_2PO_4.Na_2HPO_4$ [i.e. $Na_3H_3(PO_4)_2$]
and $2NaH_2PO_4.Na_2HPO_4.2H_2O$

Likewise, there are at least 10 well-characterized potassium orthophosphates and several ammonium analogues. The presence of extensive H bonding in many of these compounds leads to considerable structural complexity and frequently confers important properties (see later). The mono- and di-sodium phosphates are prepared industrially by neutralization of aqueous H_3PO_4 with soda ash (anhydrous Na_2CO_3, p. 89). However, preparation of the trisodium salts requires the use of the more expensive NaOH to replace the third H atom. Careful control of concentration and temperature are needed to avoid the simultaneous formation of pyrophosphates (diphosphates). Some indication of the structural complexity can be gained from the compound $Na_3PO_4.12H_2O$ which actually crystallizes with variable amounts of NaOH up to the limiting composition $4(Na_3PO_4.12H_2O).NaOH$. The structure is built from octahedral $[Na(H_2O)_6]$ units which join to form "hexagonal" rings of 6 octahedra which in turn form a continuous two-dimensional network of overall composition $\{Na(H_2O)_4\}$; between the sheets lie $\{PO_4\}$ connected to them by H bonds.[134] Some industrial, domestic, and scientific applications of Na, K and NH_4 orthophosphates are given in the Panel.

Calcium orthophosphates are particularly important in fertilizer technology, in the chemistry of bones and teeth, and in innumerable industrial and domestic applications (see Panel). They are also the main source of phosphorus and phosphorus chemicals and occur in vast deposits as apatites and rock phosphate (p. 475). The main compounds occurring in the $CaO–H_2O–P_4O_{10}$ phase diagram are: $Ca(H_2PO_4)_2$, $Ca(H_2PO_4)_2.H_2O$, $Ca(HPO_4).nH_2O$ ($n = 0, \frac{1}{2}, 2$), $Ca_3(PO_4)_2$, $Ca_2PO_4(OH).2H_2O$, $Ca_5(PO_4)_3OH$ (i.e. apatite), $Ca_4P_2O_9$ [probably $Ca_3(PO_4)_2.CaO$] and $Ca_8H_2(PO_4)_6.5H_2O$.

In all of these alkali-metal and alkaline earth-metal orthophosphates there are discrete, approximately regular tetrahedral PO_4 units in

[134] E. TILLMANNS and W. H. BAUR, *Inorg. Chem.* **9**, 1957–8 (1970).

Uses of Orthophosphates[9]

Phosphates are used in an astonishing variety of domestic and industrial applications but their ubiquitous presence and their substantial impact on everyday life is frequently overlooked. It will be convenient first to indicate the specific uses of individual compounds and the properties on which they are based, then to conclude with a brief summary of many different types of application and their interrelation. The most widely used compounds are the various phosphate salts of Na, K, NH_4 and Ca. The uses of di-, tri- and poly-phosphates are mentioned on pp. 527–29.

Na_3PO_4 is strongly alkaline in aqueous solution and is thus a valuable constituent of scouring powders, paint strippers and grease saponifiers. Its complex with NaOCl [$(Na_3PO_4.11H_2O)_4.NaOCl$], is also strongly alkaline (a 1% solution has pH 11.8) and, in addition, it releases active chlorine when wetted; this combination of scouring, bleaching and bacteriocidal action makes the adduct valuable in formulations of automatic dishwashing powders.

Na_2HPO_4 is widely used as a buffer component (p. 521). The use of the dihydrate (~2% concentration) as an emulsifier in the manufacture of pasteurized processed cheese was patented by J. L. Kraft in 1916 and is still used, together with insoluble sodium metaphosphate or the mixed phosphate $Na_{15}Al_3(PO_4)_8$, to process cheese on the multikilotonne scale daily. Despite much study, the reason why phosphate salts act as emulsifiers is still not well understood in detail. Na_2HPO_4 is also added (~0.1%) to evaporated milk to maintain the correct Ca/PO_4 balance and to prevent gelation of the milk powder to a mush. Its addition at the 5% level to brine (15–20% NaCl solution) for the pickling of ham makes the product more tender and juicy by preventing the exudation of juices during subsequent cooking. Another major use in the food industry is as a starch modifier: small additions enhance the ability to form stable cold-water gels (e.g. instant pudding mixes), and the addition of 1% to farinaceous products raises the pH to slightly above 7 and provides "quick-cooking" breakfast cereals.

NaH_2PO_4 is a solid water-soluble acid, and this property finds use (with $NaHCO_3$) in effervescent laxative tablets and in the pH adjustment of boiler waters. It is also used as a mild phosphatizing agent for steel surfaces and as a constituent in the undercoat for metal paints.

K_3PO_4 (like Na_3PO_4) is strongly alkaline in aqueous solution and is used to absorb H_2S from gas streams; the solution can be regenerated simply by heating. K_3PO_4 is also used as a regulating electrolyte to control the stability of synthetic latex during the polymerization of styrenebutadiene rubbers. The buffering action of K_2HPO_4 has already been mentioned (p. 521) and this is the reason for its addition as a corrosion inhibitor to car-radiator coolants which otherwise tend to become acidic due to slow oxidation of the glycol antifreeze. KH_2PO_4 is a piezoelectric (p. 57) and finds use in submarine sonar systems. For many applications, however, the cheaper sodium salts are preferred unless there is a specific advantage for the potassium salt; one example is the specialist balanced commercial fertilizer formulation [$KH_2PO_4.(NH_4)_2HPO_4$] which contains 10.5% N, 53% P_2O_5 and 17.2% K_2O (i.e. N–P–K 10–53–17).

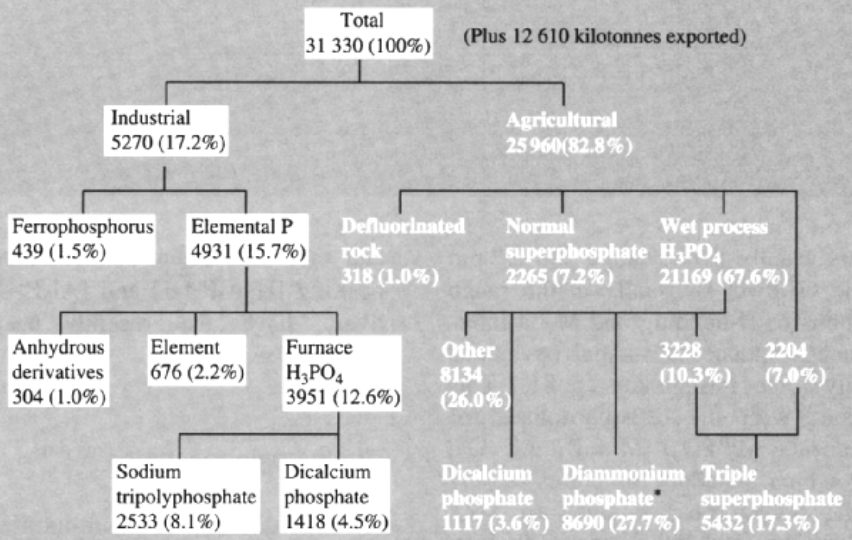
$(NH_4)_2HPO_4$ and $(NH_4)H_2PO_4$ can be used interchangeably as specialist fertilizers and nutrients in fermentation broths; though expensive, their high concentration of active ingredients ameliorate this, particularly in localities where transportation costs are high. Indeed, $(NH_4)_2HPO_4$ in granulated or liquid form consumes more phosphate rock than any other single end-product (over 8 million tonnes pa in the USA alone in 1974). Ammonium phosphates are also much used as flame retardants for cellulosic materials, about 3–5% gain in dry weight being the optimum treatment. Their action probably depends on their ready dissociation into NH_3 and H_3PO_4 on heating; the H_3PO_4 then catalyses the decomposition of cellulose to a slow-burning char (carbon) and this, together with the suppression of flammable volatiles, smothers the flame. As the ammonium phosphates are soluble, they are used mainly for curtains, theatre scenery and disposable paper dresses and costumes. The related compound urea phosphate ($NH_2CONH_2.H_3PO_4$) has also been used to flameproof cotton fabrics: the material is soaked in a concentrated aqueous solution, dried (15% weight gain) and cured at 160° to bond the retardant to the cellulose fibre. The advantage is that the retardant does not wash out, but the strength of the fabric is somewhat reduced by the process.

Calcium phosphates have a broad range of applications both in the food industry and as bulk fertilizers. The vast scale of the phosphate rock industry has already been indicated (p. 476) and this is further elaborated for the particular case of the USA in the Scheme on the page opposite (kilotonnes pa and %, 1974).

The crucial importance of Ca and PO_4 as nutrient supplements for the healthy growth of bones, teeth, muscle and nerve cells has long been recognized. The non-cellular bone structure of an average adult human consists of ~60% of some form of "tricalcium phosphate" [$Ca_5(PO_4)_3OH$]; teeth likewise comprise ~70% and average persons carry 3.5 kg of this material in their bodies. Phosphates in the body are replenished by a continuous cycle, and used P is carried by the blood to the kidneys and then excreted in urine, mainly as $Na(NH_4)HPO_4$. An average adult eliminates 3–4 g of PO_4 equivalent daily (cf. the discovery of P in urine by Brandt, p. 473).

Calcium phosphates are used in baking acids, toothpastes, mineral supplements and stock feeds. $Ca(H_2PO_4)_2$ was introduced as a leavening acid in the late nineteenth century (to replace "cream of tartar" $KHC_4H_4O_6$) but the monohydrate (introduced in the 1930s) finds more use today. "Straight baking powder", a mixture of $Ca(H_2PO_4)_2.H_2O$ and $NaHCO_3$ with some 40% starch coating, tends to produce CO_2 too quickly during dough mixing and so "combination baking

Panel continues



* Note that ammoniation of H_3PO_4 to give granulated or liquid ammonium phosphates consumes more phosphate rock in the USA than any other single end product.

powder", which also incorporates a slow-acting acid such as $NaAl(SO_4)_2$, is preferred. Nearly 90% of all US household baking powders now use such combinations, e.g.:

$$Ca(H_2PO_4)_2.H_2O + 2NaHCO_3 \longrightarrow 2CO_2 + 3H_2O + \text{'}Na_2Ca(HPO_4)_2\text{'}$$

$$NaAl(SO_4)_2 + 3NaHCO_3 \xrightarrow{H_2O} 3CO_2 + Al(OH)_3 + 2Na_2SO_4$$

A typical powder contains 28% $NaHCO_3$, 10.7% $Ca(H_2PO_4)_2.H_2O$, 21.4% $NaAl(SO_4)_2$ and 39.9% starch and the scale of manufacture approaches 10^5 tonnes pa.

In toothpastes, $CaHPO_4.2H_2O$ was first used to replace chalk as a mild abrasive and polishing agent in the early 1930s. It is still widely used provided the toothpaste does not also contain fluoride, since this would precipitate as CaF_2 and effectively eliminate the desired anion. Some 25 000 tonnes of $CaHPO_4.H_2O$ are used in this way annually in the USA and the compound typically comprises 50% by weight of the paste. The first important fluoride toothpaste contained 39% of the diphosphate $Ca_2P_2O_7$ which is the most insoluble and inert of all calcium phosphates. It is made by careful dehydration of $CaHPO_4.2H_2O$ at 150° and then above 400°. It was first used in Procter and Gamble's "Crest" which also contained 0.4% SnF_2 and 1% $Sn_2P_2O_7$.

Synthetic $Ca_5(PO_4)_3OH$ is added to table salt (1–2%) to impart free-flowing properties and it is likewise added to granulated sugar, baking powders and even fertilizers. It is prepared by adding H_3PO_4 to a slurry of hydrated lime — this is the reverse order of addition to that used for making $Ca(H_2PO_4)_2$ and $CaHPO_4$ since the aim is to deprotonate all three OH groups. The compound is extremely insoluble and precipitates as very fine particles (~0.5–3 μm diameter).

The idea of converting insoluble "tricalcium phosphate" or phosphate rock into soluble "monocalcium phosphate" $Ca(H_2PO_2)_2$ dates back to the 1830s when J. von Liebig observed that acidulated bones made good fertilizer. The limited supply of bones (including those from old battlefields!) was soon replaced by Suffolk coprolites and apatites, though the vast North African deposits were still unknown. The phosphate fertilizer industry originated in England (Lawes, 1843); it grew rapidly as shown by the dramatic increase in world production of phosphate rock, which leapt from 500 tonnes in 1847 to 500 kilotonnes in 1880, 3.1 million tonnes in 1900, and now exceeds 150 Mt (p. 476). This unprecedented demand for phosphatic fertilizers is, of course, closely related to the demand for food from an exploding world population of humans which reached 1 billion (10^9) in 1830, 2 billion in 1930, 3 billion in 1960, 4 billion in 1974 and will be over 8 billion by the end of the century.

"Superphosphate" is now made by the (highly exothermic) addition of H_2SO_4 to fine-ground phosphate rock:

$$2Ca_5(PO_4)_3F + 7H_2SO_4 + H_2O \longrightarrow 7CaSO_4 + 3Ca(H_2PO_4)_2.H_2O + 2HF$$

Panel continues

The $CaSO_4$ or its hydrate (gypsum) acts only as an unwanted diluent. Its presence can be avoided by using H_3PO_4 instead of H_2SO_4 for the acidulation, thus giving rise to "triple superphosphate"

$$Ca_5(PO_4)_3F + 7H_3PO_4 + H_2O \longrightarrow 5Ca(H_2PO_4)_2.H_2O + HF$$

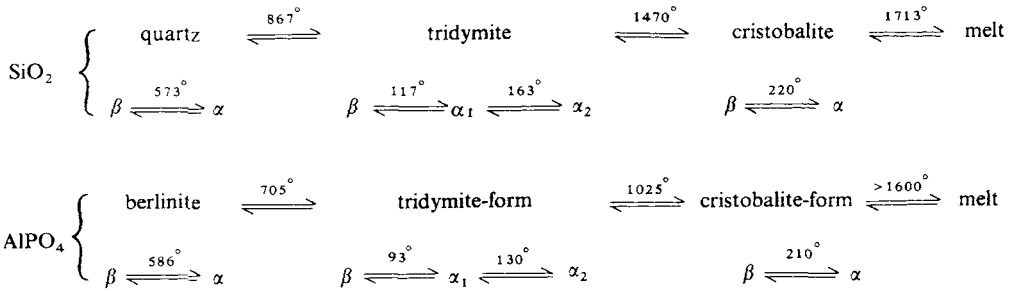
Commercial triple superphosphate contains almost 3 times the amount of available (soluble) P_2O_5 as ordinary superphosphate, hence its name (45–50 wt% vs. 18–20 wt%).

which P–O is usually in the range 153 ± 3 pm and the angle O–P–O is usually in the range $109 \pm 5°$. Extensive H-bonding and M–O interactions frequently induce substantial deviations from a purely ionic formulation (p. 81). This trend continues with the orthophosphates of tervalent elements $M^{III}PO_4$ (M = B, Al, Ga, Cr, Mn, Fe) which all adopt structures closely related to the polymorphs of silica (p. 342). $NaBePO_4$ is similar, and YPO_4 adopts the zircon ($ZrSiO_4$) structure. The most elaborate analogy so far revealed is for $AlPO_4$ which can adopt each of the 6 main polymorphs of silica as indicated in the scheme below. The analogy covers not only the structural relations between the phases but also the sequence of transformation temperatures (°C) and the fact that the α–β-transitions occur readily whilst the others are sluggish (p. 343). Similarly, the orthophosphates of B, Ga and Mn are known in the β-quartz and the α- and β-cristobalite forms whereas $FePO_4$ adopts either the α- or β-quartz structure. Numerous hydrated forms are also known. The Al–PO_4–H_2O system is used industrially as the basis for many adhesives, binders and cements.[135] Novel chain and sheet aluminium phosphate anions of composition $[H_2AlP_2O_8]$ and $[Al_5P_4O_{16}]^{3-}$, respectively, have also recently been structurally characterized.[136]

Chain polyphosphates [23,64]

A rather different structure-motif is observed in the chain polyphosphates: these feature corner-shared $\{PO_4\}$ tetrahedra as in the polyphosphoric acids (p. 522). The general formula for such anions is $[P_nO_{3n+1}]^{(n+2)-}$, of which the diphosphates, $P_2O_7^{4-}$, and tripolyphosphates, $P_3O_{10}^{5-}$, constitute the first two members. Chain polyphosphates have been isolated with n up to 10 and with n "infinite", but those of intermediate chain length ($10 < n < 50$) can only be obtained as glassy or amorphous mixtures. As the chain length increases, the ratio $(3n + 1)/n$ approaches 3.00 and the formula approaches that of the polymetaphosphates $[PO_3^-]_\infty$.

Diphosphates (pyrophosphates) are usually prepared by thermal condensation of dihydrogen



[135] J. H. Morris, P. G. Perkins, A. E. A. Rose and W. E. Smith, *Chem. Soc. Revs.* **6**, 173–94 (1977).

[136] J .M. Thomas *et al.*, *J. Chem. Soc., Chem. Commun.*, 1170–2 (1992), 929–31 and 1266–8 (1992). See also R. Kniep, *Angew. Chem. Int. Edn. Engl.* **25**, 525–34 (1986).

phosphates or hydrogen phosphates:

$$2MH_2PO_4 \xrightarrow{\Delta} M_2H_2P_2O_7 + H_2O$$

$$2M_2HPO_4 \xrightarrow{\Delta} M_4P_2O_7 + H_2O$$

They can also be prepared in specialized cases by (a) metathesis, (b) the action of H_3PO_4 on an oxide, (c) thermolysis of a metaphosphate, (d) thermolysis of an orthophosphate, or (e) reductive thermolysis, e.g.:

(a) $Na_4P_2O_7 + 4AgNO_3 \longrightarrow Ag_4P_2O_7\downarrow + 4NaNO_3$

(b) $2H_3PO_4 + PbO_2 \longrightarrow PbP_2O_7\downarrow + 3H_2O$

(c) $4Cr(PO_3)_3 \xrightarrow{\Delta} Cr_4(P_2O_7)_3 + 3P_2O_5$

(d) $2Hg_3(PO_4)_2 \xrightarrow{\Delta} 2Hg_2P_2O_7 + 2Hg + O_2$

(e) $2FePO_4 + H_2 \longrightarrow Fe_2P_2O_7 + H_2O$

Many diphosphates of formula $M^{IV}P_2O_7$, $M^{II}_2P_2O_7$ and hydrated $M^{I}_4P_2O_7$ are known and there has been considerable interest in the relative orientation of the two linked $\{PO_4\}$ groups and in the P–O–P angle between them.[137] For small cations the 2 $\{PO_4\}$ are approximately staggered whereas for larger cations they tend to be nearly eclipsed. The P–O–P angle is large and variable, ranging from 130° in $Na_4P_2O_7.10H_2O$ to 156° in α-$Mg_2P_2O_7$. The apparent colinearity in the higher-temperature (β) form of many diphosphates, which was previously ascribed to a P–O–P angle of 180°, is now generally attributed to positional disorder. Bridging P–O distances are invariably longer than terminal P–O distances, typical values (for $Na_4P_2O_7.10H_2O$) being P–O_μ 161 pm, P–O_t 152 pm. Note that bridging can also be via a peroxo group as in ammonium peroxodiphosphate[138] which features the zig-zag anion $[O_3P–O–O–PO_3]^{4-}$ with P–O_μ 165.8 pm, P–O_t 150.8 pm and O–O 150.1 pm (cf. 145.3 pm in H_2O_2 and 148–150 pm in $S_2O_5^{2-}$).

As diphosphoric acid is tetrabasic, four series of salts are possible though not all are always known, even for simple cations. The most studied are those of Na, K, NH_4 and Ca, e.g.:

$Na_4P_2O_7.10H_2O$(mp 79.5°), $Na_4P_2O_7$(mp 985°)

$$Na_3HP_2O_7.9H_2O \xrightarrow{30\text{–}35^\circ} Na_3HP_2O_7.H_2O \xrightarrow{150^\circ} Na_3HP_2O_7$$

$$Na_2H_2P_2O_7.6H_2O \xrightarrow{\sim 27^\circ} Na_2H_2P_2O_7$$

$NaH_3P_2O_7$(mp 185°)

Before the advent of synthetic detergents, $Na_4P_2O_7$ was much used as a dispersant for lime soap scum which formed in hard water, but it has since been replaced by the tripolyphosphate (see below). However, the ability of diphosphate ions to form a gel with soluble calcium salts has made $Na_4P_2O_7$ a useful ingredient for starch-type instant pudding which requires no cooking. The main application of $Na_2H_2P_2O_7$ is as a leavening acid in baking: it does not react with $NaHCO_3$ until heated, and so large batches of dough or batter can be made up and stored. $Ca_2P_2O_7$, because of its insolubility, inertness, and abrasive properties, is used as a toothpaste additive compatible with Sn^{II} and fluoride ions (see Panel on p. 525).

Of the tripolyphosphates only the sodium salt need be mentioned. It was introduced in the mid-1940s as a "builder" for synthetic detergents, and its production for this purpose is now measured in megatonnes per annum (see Panel on the next page). On the industrial scale $Na_5P_3O_{10}$ is usually made by heating an intimate mixture of powdered Na_2HPO_4 and NaH_2PO_4 of the required stoichiometry under carefully controlled conditions:

$$2Na_2HPO_4 + NaH_2PO_4 \longrightarrow Na_5P_3O_{10} + 2H_2O$$

The low-temperature form (I) converts to the high-temperature form (II) above 417°C and both forms react with water to give the crystalline hexahydrate. All three materials contain the

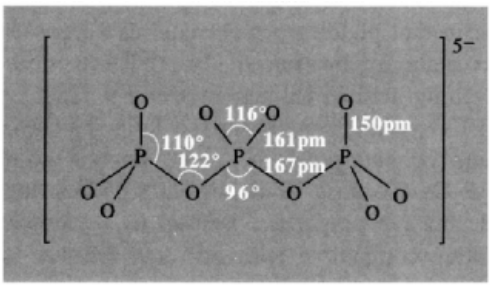
Uses of Sodium Tripolyphosphate

Many synthetic detergents contain 25–45% $Na_5P_3O_{10}$ though the amount is lower in the USA than in Europe because of the problems of eutrophication in some areas (p. 478). It acts mainly as a water softener, by chelating and sequestering the Mg^{2+} and Ca^{2+} in hard water. Indeed, the formation constants of its complexes with these ions are nearly one million-fold greater than with Na^+: ($NaP_3O_{10}^{4-}$ pK ~2.8; $MgP_3O_{10}^{3-}$ pK ~8.6; $CaP_3O_{10}^{3-}$ pK ~8.1). In addition, $Na_5P_3O_{10}$ increases the efficiency of the surfactant by lowering the critical micelle concentration, and by its ability to suspend and peptize dirt particles by building up a large negative charge on the particles by adsorption; it also furnishes a suitable alkalinity for cleansing action without irritating eyes or skin and it provides effective buffering action at these pHs. The dramatic growth of synthetic detergent powders during the 1950s was accompanied by an equally drametic drop in the use of soap powders.[11]

$Na_5P_3O_{10}$ is also used as a dispersing agent in clay suspensions used in oil-well drilling. Again, addition of <1% $Na_5P_3O_{10}$ to the slurries used in manufacturing cement and bricks enables much less water to be used to attain workability, and thus less to be removed during the setting or calcining processes.

tripolyphosphate ion $P_3O_{10}^{5-}$ with a *trans*-configuration of adjacent tetrahedra and a twofold symmetry axis; forms (I) and (II) differ mainly in the coordination of the sodium ions and the slight differences in the dimensions of the ion in the three crystals are probably within experimental error. Typical values are:



The complicated solubility relations, rates of hydrolysis, self-disproportionation and interconversion with other phosphates depends sensitively on pH, concentration, temperature and the presence of impurities.[139] Though of great interest academically and of paramount importance industrially these aspects will not be further considered here.[11,23,64,140] Triphosphates such as adenosine triphosphate (ATP) are also of vital importance in living organisms (see text books on biochemistry, and also ref. 141).

The stoichiometric formula of a chain-polyphosphate can sometimes be an unreliable guide to its structure. for example, the crystalline compound "$CaNb_2P_6O_{21}$" has been shown by X-ray crystal structure analysis to contain equal numbers of oxide(2−), diphosphate(4−) and tetraphosphate(6−) anions, i.e. $CaNb_2O[P_2O_7][P_4O_{13}]$.[142] By contrast, $CsM_2P_5O_{16}$ (M = V, Fe) does contain the anticipated homologous *catena*-pentaphosphate $[P_nO_{3n+1}]^{(n+2)-}$ anion (p. 512) with $n = 5$.[143]

Long-chain polyphosphates. $M^I_{n+2}P_nO_{3n+1}$, approach the limiting composition M^IPO_3 as $n \to \infty$ and are sometimes called linear metaphosphates to distinguish them from the cyclic metaphosphates of the same composition (p. 529). Their history extends back over 150 y to the time when Thomas Graham described the formation of a glassy sodium polyphosphate mixture now known as Graham's salt. Various heat treatments converted this to crystalline compounds known as Kurrol's salt, Maddrell's salt, etc., and it is now appreciated, as a result of X-ray crystallographic studies, that these and many related substances all feature unbranched chains of corner-shared $\{PO_4\}$ units which differ only in the mutual orientations and

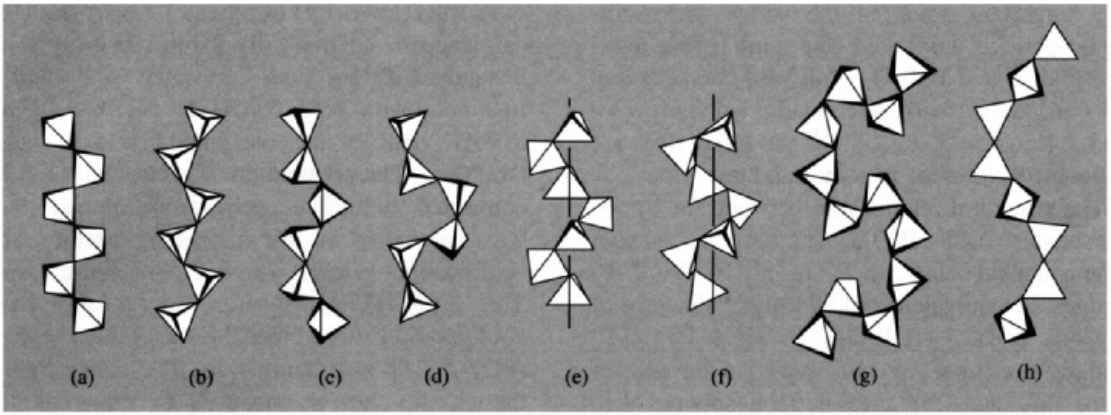

Figure 12.20 Types of polyphosphate chain configuration. The diagrams indicate the relative orientations of adjacent PO_4 tetrahedra, extended along the chain axes. (a) $(RbPO_3)_n$ and $(CsPO_3)_n$, (b) $(LiPO_3)_n$ low temp, and $(KPO_3)_n$, (c) $(NaPO_3)_n$ high-temperature Maddrell salt and $[Na_2H(PO_3)_3]_n$, (d) $[Ca(PO_3)_2]_n$ and $[Pb(PO_3)_2]_n$, (e) $(NaPO_3)_n$, Kurrol A and $(AgPO_3)_n$, (f) $(NaPO_3)_n$, Kurrol B, (g) $[CuNH_4(PO_3)_3]_n$ and isomorphous salts, (h) $[CuK_2(PO_3)_4]_n$ and isomorphous salts. Each crystalline form of Kurrol salt contains equal numbers of right-handed and left-handed spiralling chains.

repeat units of the constituent tetrahedra.[144] These, in turn, are dictated by the size and coordination requirements of the counter cations present (including H). Some examples are shown schematically in Fig. 12.20 and the geometric resemblance between these and many of the chain metasilicates (p. 350) should be noted. In most of these polyphosphates P–O_μ is 161 ± 5 pm, P–O_t 150 ± 2 pm, P–O_μ–P 125–135° and O_t–P–O_t 115–120° (i.e. very similar to the dimensions and angles in the tripolyphosphate ion, p. 528).

The complex preparative interrelationships occurring in the sodium polyphosphate system are summarized in Fig. 12.21 (p. 531). Thus anhydrous NaH_2PO_4, when heated to 170° under conditions which allow the escape of water vapour, forms the diphosphate $Na_2H_2P_2O_7$, and further dehydration at 250° yields either Maddrell's salt (closed system) or the cyclic trimetaphosphate (water vapour pressure kept low). Maddrell's salt converts from the low-temperature to the high-temperature form above 300°, and above 400° reverts to the cyclic trimetaphosphate. The high-temperature form can also be obtained (via Graham's and Kurrol's salts) by fusing the cyclic trimetaphosphate (mp 526°C) and then quenching it from 625° (or from 580° to give Kurrol's salt directly). All these linear polyphosphates of sodium revert to the cyclic trimetaphosphate on prolonged annealing at ~400°C.

Fuller treatments of the phase relations and structures of polyphosphates, and their uses as glasses, ceramics, refractories, cements, plasters and abrasives, are available.[144,145]

Cyclo-*polyphosphoric acids and* cyclo-*polyphosphates*[146]

These compounds were formerly called metaphosphoric acids and metaphosphates but the IUPAC *cyclo-* nomenclature is preferred as being structurally more informative. The only

two important acids in the series are *cyclo*-triphosphoric acid $H_3P_3O_9$ and *cyclo*-tetraphosphoric acid $H_4P_4O_{12}$, but well-characterized salts are known with heterocyclic anions $[cyclo\text{-}(PO_3)_n]^n$ ($n = 3$–8, 10),[147] and larger rings are undoubtedly present in some mixtures.

The structural relationship between the *cyclo*-phosphates and P_4O_{10} (p. 504) is shown schematically below. In P_4O_{10} all 10 P-O(-P) bridges are equivalent and hydrolytic cleavage of any one leads to "$H_2P_4O_{11}$" in which P-O(-P) bridges are now of two types. Cleavage of "type a" leads to *cyclo*-tetraphosphoric acid or its salts (as shown in the upper line of the scheme), whereas cleavage of any of the other bridges leads to a *cyclo*-triphosphate ring with a pendant -OP(O)OH group which can subsequently be hydrolysed off to leave $(HPO_3)_3$ or its salts (lower line of scheme). *Cyclo*-$(HPO_3)_4$ can, indeed, be made by careful hydrolysis of hexagonal P_4O_{10} with ice-water, and similar treatment with iced NaOH or $NaHCO_3$ gives a 75% yield of the corresponding salt *cyclo*-$(NaPO_3)_4$. The preparation of *cyclo*-$(NaPO_3)_3$ by controlled thermolytic dehydration of NaH_2PO_4 was mentioned in the preceding section and acidification yields *cyclo*-triphosphoric acid. The *cyclo*-$(PO_3)_3^{3-}$ anion adopts the chair configuration with dimensions as shown; *cyclo*-$(PO_3)_4^{4-}$ is also known in this configuration though this can be modified by changing the cation.

The crystal structure of the *cyclo*-hexaphosphate anion in $Na_6P_6O_{18}.6H_2O$ shows that all 6 P atoms are coplanar and that bond lengths are similar to those in the $P_3O_9^{3-}$ and $P_4O_{12}^{4-}$ anions. See ref. 147 for the structure of the hydrated *cyclo*-decaphosphate $K_{10}P_{10}O_{30}.4H_2O$. Higher *cyclo*-metaphosphates can be isolated by

chromatographic separation from Graham's salt in which they are present to the extent of ~1%.

12.3.7 Phosphorus–nitrogen compounds

The P–N bond is one of the most intriguing in chemistry and many of its more subtle aspects still elude a detailed and satisfactory description. It occurs in innumerable compounds, frequently of great stability, and in many of these the strength of the bond and the shortness of the interatomic distance have been interpreted in terms of "partial double-bond character". In fact, the conventional symbols P–N and P=N are more an aid to electron counting than a description of the bond in any given compound (see p. 538).

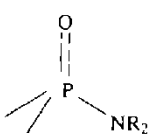
Many compounds containing the P–N link can be considered formally as derivatives of the oxoacids of phosphorus and their salts (pp. 510–31) in which there has been isoelectronic replacement of:

PH [or P(OH)] by $P(NH_2)$ or $P(NR_2)$;

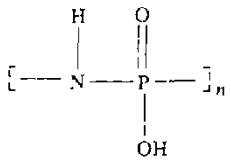
P=O [or P=S] by P=NH or P=NR;

P–O–P by P–NH–P or P–NR–P, etc.[148,149]

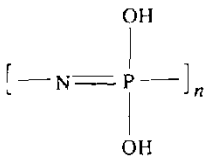
Examples are phosphoramidic acid, $H_2NP(O)(OH)_2$; phosphordiamidic acid, $(H_2N)_2P(O)(OH)$; phosphoric triamide, $(H_2N)_3PO$; and their derivatives. There are an enormous number of compounds featuring the 4-coordinate group shown in structure (1) including the versatile nonaqueous solvent hexamethylphosphoramide $(Me_2N)_3PO$; this is readily made by reacting $POCl_3$ with $6Me_2NH$, and dissolves metallic Na to give paramagnetic blue solutions similar to those in liquid NH_3 (p. 77).



(1)



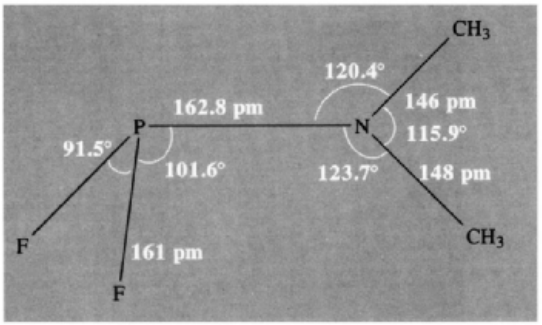
(2)



(3)

Another series includes the *cyclo*-metaphosphimic acids, which are tautomers of the *cyclo*-polyphosphazene hydroxides (p. 541). Similarly, halogen atoms in PX_3 or other P–X compounds can be successively replaced by the isoelectronic groups $-NH_2$, $-NHR$, $-NR_2$, etc., and sometimes a pair of halogens can be replaced by $=NH$ or $=NR$. These, in turn, can be used to prepare a large number of other derivatives as indicated schematically opposite for $P(NMe_2)_3$[2].

Although such compounds all formally contain P–N single bonds, they frequently display properties consistent with more extensive bonding. A particularly clear example is $PF_2(NMe_2)$ which features a short interatomic P–N distance and a *planar* N atom as indicated in the diagram below. (In the absence of this additional π bonding the P^{III}–N single-bond distance is close to 177 pm.) Again, the proton nmr of such compounds sometimes reveals restricted rotation about P–N at low temperatures and typical energy barriers to rotation (and coalescence temperatures of the non-equivalent methyl proton signals) are $PCl_2(NMe_2)$ 35 kJ mol^{-1} (−120°), $P(CF_3)_2(NMe_2)$ 38 kJ mol^{-1} (−120°), PClPh(NMe_2) 50 kJ mol^{-1} (−50°).



Other unusual P/N systems which have recently been investigated include the crystalline compound HPN_2, i.e. PN(NH), which is formed by ammonolysis of P_3N_5 at 580°C and which has a β-cristobalite (SiO_2) type structure;[150] PNO (cf. N_2O), which can be studied as a matrix-isolated species;[151] various phosphine azides, $RR'PN_3$, and their reactions;[152] and numerous substituted phosphonyl triphenylphosphazenes, $Ph_3P{=}N{-}PX_2$, (X=Cl, F, OPh, SEt, NEt_2, etc.).[153] The iminophosphenium ion, $[ArN{=}P]^+$ (Ar = 2,4,6-$Bu^t_3C_6H_2$) has been obtained as its pale yellow $AlCl_4^-$ salt by reaction of the corresponding covalently bonded chloride, ArN=PCl, with $AlCl_3$; the ion is notable

as the first stable species having a P≡N triple bond (P–N 148 pm, angle C–N–P 177°).[154] The coordination chemistry of phosphorane iminato complexes (containing the R_3PN^- ligand) of transition metals has been reviewed.[155]

Cyclophosphazanes

Many heterocyclic compounds contain formally single-bonded P–N groups, the simplest being the *cyclo*-diphosphazanes $(X_3PNR)_2$ and $\{X(O,S)PNR\}_2$. These contain P^V and have the structures shown in Fig. 12.22. A few phosph(III)azane dimers are also known, e.g. $(RPNR')_2$. A more complex example, containing fused heterocycles of alternating P^{III} and N atoms, is the interesting hexamethyl derivative $P_4(NMe)_6$ mp 122°. This stable compound (Fig. 12.23a) is readily obtained by reacting PCl_3 with $6MeNH_2$; it is isoelectronic with and isostructural with P_4O_6 (p. 504) and undergoes many similar reactions. The stoichiometrically similar compound $P_4(NPr^i)_6$ can be prepared in the non-adamantane-type structure shown in Fig. 12.23b, though it converts to structure-type a on being heated at 157° for 12 days.[156] A different sequence of atoms occurs in $P_2(NMe)_6$

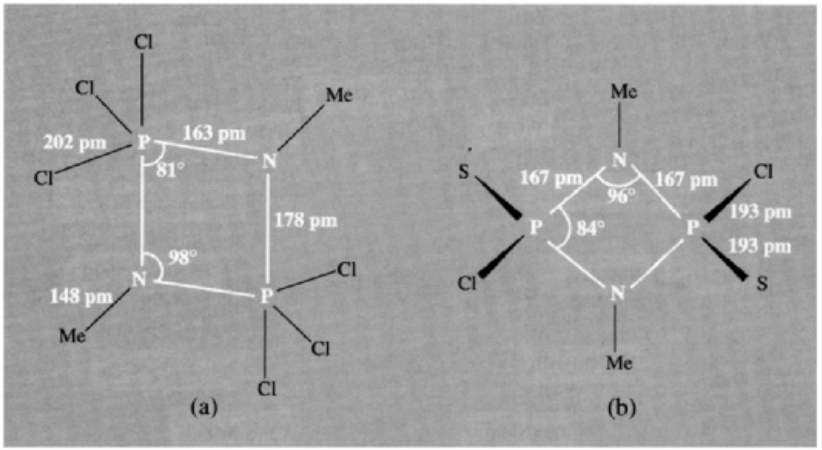

Figure 12.22 Structures of (a) $(Cl_3PNMe)_3$, and (b) $\{Cl(S)PNMe\}_2$. Note the difference in length of the axial P–N and equatorial P–N bonds (and of the axial and equatorial P–Cl bonds) about the trigonal bipyramidal P atoms in (a).

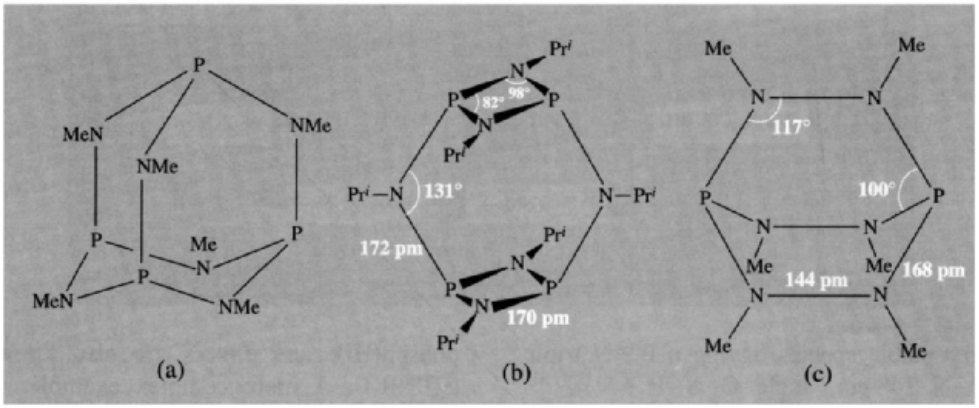

Figure 12.23 Structures of (a) $P_4(NMe)_6$, (b) $P_4(NPr^i)_6$, and (c) $P_2(NMe)_6$ (see text).

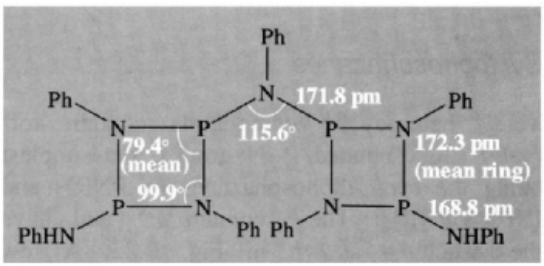
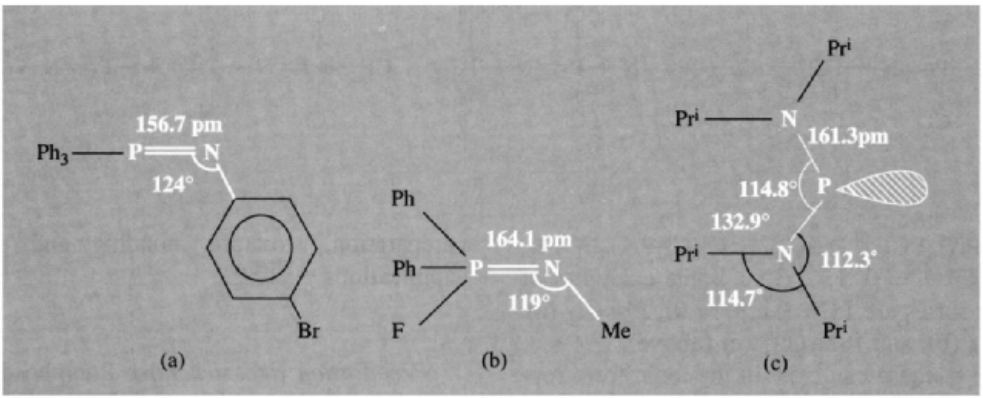
(Fig. 12.23c) and many other "saturated" heterocycles featuring either P^{III} or P^V have been made. A typical example, made by slow addition of PCl_3 to $PhNH_2$ in toluene at 0°, is $[PhNHP_2(NPh)_2]_2NPh$; the crystal structure of the 1:1 solvate of this compound with CH_2Cl_2 (mp 250°) reveals that all N atoms are essentially planar with distances to P as indicated in the following diagram.[157]



Phosphazenes

Formally "unsaturated" PN compounds are called phosphazenes and contain P^V in the

[157] M. L. Thompson, R. C. Haltiwanger, and A. D. Norman, *J. Chem. Soc., Chem. Commun.*, 647–8 (1979).



grouping $\rangle P{=}N-$. A few phosph(III)azenes are also known. Phosphazenes can be classified into monophosphazenes (e.g. $X_3P{=}NR$), diphosphazenes (e.g. $X_3P{=}N{-}P(O)X_2$), polyphosphazenes containing 2,3,4,... ∞ $-X_2P{=}N-$ units, and the *cyclo*-polyphosphazenes $[-X_2P{=}N-]_n$, $n = 3,4,5 \ldots 17$.

Monophosphazenes, particularly those with organic substituents, $R_3P{=}NR'$, derive great interest from being the N analogues of phosphorus ylides $R_3P{=}CR_2$ (p. 545). They were first made by H. Staudinger in 1919 by reacting an organic azide such as PhN_3 with PR_3 (R = Cl, OR, NR_2, Ar, etc.), e.g.:

$$PPh_3 + PhN_3 \longrightarrow N_2 + Ph_3P{=}NPh;\ \text{mp } 132^\circ$$

More recently they have been made via a reaction associated with the name of A. V. Kirsanov (1962), e.g.:

$$Ph_3PCl_2 + PhNH_2 \longrightarrow Ph_3P{=}NPh + 2HCl$$

As expected, the P–N distance is short and the angle at N is ~120°, e.g. (a) and (b) above. Over 600 such compounds are now known, especially those with the $Cl_3P{=}N-$ group.[158]

Diphosphazenes can be made by reacting PCl_5 with NH_4Cl in a chlorohydrocarbon solvent under mild conditions:

$$3PCl_5 + NH_4Cl \xrightarrow{\text{solvent}} 4HCl + [Cl_3P{=}N{-}PCl_3]^+PCl_6^-;\quad \text{mp } 310^\circ$$

$$[Cl_3P{=}N{-}PCl_3]^+PCl_6^- \xrightarrow{NH_4Cl} 4HCl + [Cl_3P{=}N{-}PCl_2{=}N{-}PCl_3]^+Cl^-$$

The inverse of these compounds are the phosphadiazene cations, prepared by halide ion abstraction from diaminohalophosphoranes in CH_2Cl_2 or SO_2 solution, e.g.:

$$(R_2N)_2PCl + AlCl_3 \longrightarrow [(R_2N)_2P]^+[AlCl_4]$$

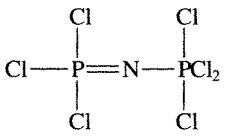
An X-ray crystal structure of the Pr^i_2N-derivative shows the presence of a bent, 2-coordinate P atom, equal P–N distances, and accurately planar 3-coordinate N atoms as in (c) above.[159] In liquid ammonia ammonolysis also occurs:

$$2PCl_5 + 16NH_3(\text{liq.}) \longrightarrow [(H_2N)_3P{=}N{-}P(NH_2)_3]^+Cl^- + 9NH_4Cl$$

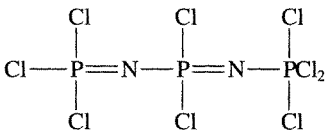
The P=N and P–N bonds are equivalent in these compounds and they could perhaps better be written as $[X_3P{=}N{=}PX_3]^+$, etc. Like the parent phosphorus pentahalides (p. 498), these diphosphazenes can often exist in ionic and covalent forms and they are part of a more extended group of compounds which can be classified into several general series $Cl(Cl_2PN)_nPCl_4$, $[Cl(Cl_2PN)_nPCl_3]^+Cl^-$,

[158] M. Bermann, *Topics in Phosphorus Chemistry* **7**, 311–78, 1972.

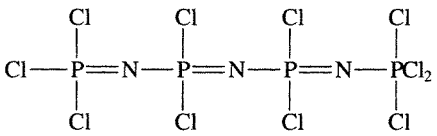
[159] A. H. Cowley, M. C. Cushner and J. S. Szobota, *J. Am. Chem. Soc.* **100**, 7784–6 (1978).



(a)



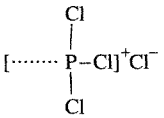
(b)



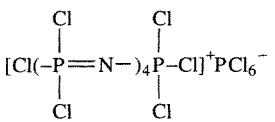
(c)

$[Cl(Cl_2PN)_nPCl_3]^+PCl_6^-$, $Cl(Cl_2PN)_nPOCl_2$, etc., where $n = 0, 1, 2, 3\ldots$. Some examples of the first series are PCl_5 (i.e. $n = 0$), P_2NCl_7 (a), $P_3N_2Cl_9$ (b), and $P_4N_3Cl_{11}$ (c) (above).

Some of these can exist in the ionic form represented by the second series (d):



(d)

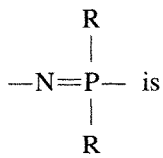


(e)

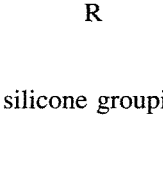
Likewise, the third series runs from $n = 0$ (i.e. $PCl_4^+PCl_6^-$) through P_3NCl_{12}, $P_4N_2Cl_{14}$, and $P_5N_3Cl_{16}$ to $P_6N_4Cl_{18}$ (e). In the limit, polymeric phosphazene dichlorides are formed $(-NPCl_2-)_n$, where n can exceed 10^4 and these polyphosphazenes and their *cyclo*-analogues form by far the most extensive range PN compounds.

Polyphosphazenes

The grouping



is isoelectronic with the silicone grouping



(p. 364)

and, after the silicones, the polyphosphazenes form the most extensive series of covalently bonded polymers with a non-carbon skeleton. This section will describe their preparation, structure, bonding and potential applications.[2,8,160,161]

Preparation and structure. Polyphosphazenes have a venerable history. $(NPCl_2)_n$ oligomers were first made in 1834 by J. von Liebig and F. Wöhler who reacted PCl_5 with NH_3, but their stoichiometry and structure were not elucidated until much later. The fluoro analogues $(NPF_2)_n$ were first made in 1956 and the bromo compounds $(NPBr_2)_n$ in 1960. The synthesis of $(NPCl_2)_n$ was much improved by R. Schenk and G. Römer in 1924 and their method remains the basis for present-day production on both the laboratory and industrial scales:

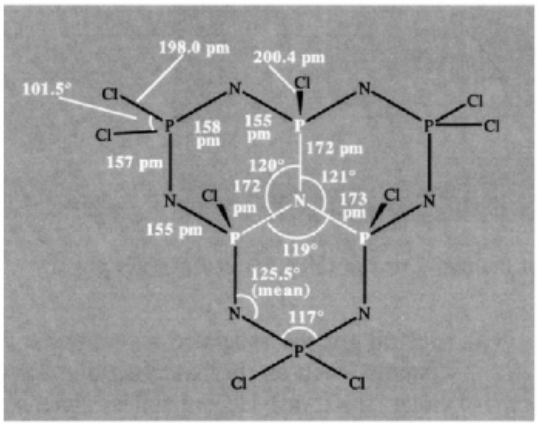
$$n PCl_5 + n NH_4Cl \xrightarrow[120-150^\circ]{\text{solvent}} (NPCl_2)_n + 4n HCl$$

Appropriate solvents are 1,1,2,2-tetrachloroethane (bp 146°), PhCl (bp 132°) and 1,2-dichlorobenzene (bp 179°). By varying the conditions, yields of the cyclic trimer or tetramer and other oligomers can be optimized and the compounds then separated by fractionation. Highly polymeric $(NPCl_2)_\infty$ can be made by heating *cyclo*-$(NPCl_2)_3$ to 150–300°, though heating to 350° induces depolymerization. Polycyclic compounds are rarely obtained in

[160] H. R. ALLCOCK, *Phosphorus Nitrogen Compounds,* Academic Press, New York, 1972, 498 pp.; H. R. ALLCOCK, *Chem. Rev.* **72,** 315–56 (1972) (475 refs.). H. R. ALLCOCK, Chap. 3 in A. H. COWLEY (ed.) *Rings, Clusters and Polymers of the Main Group Elements,* ACS Symposium Series No. **282,** Washington, DC, 49–67 (1982). H. R. ALLCOCK in J. E. MARK, R. WEST and H. R. ALLCOCK, *Inorganic Polymers,* Prentice Hall, 1991, 304 pp. H. R. ALLCOCK, Chap. 9 in R. STEUDEL (ed.) *The Chemistry of Inorganic Ring Systems,* Elsevier, Amsterdam, 145–69 (1992).

[161] S. S. KRISNAMURTHY, A. C. SAU and M. WOODS, *Adv. Inorg. Chem. Radiochem.* **21,** 41–112 (1978) (499 refs.).

these preparations, one exception being $N_7P_6Cl_9$, mp 237.5°, which can be obtained in modest yields from the direct thermolytic reaction of PCl_5 and NH_4Cl. The tricyclic structure is strongly distorted from planarity though the central NP_3 group features an accurately planar 3-coordinate N atom with much longer N···P bonds than those in the peripheral macrocycle. The 2 sorts of P–Cl bonds are also noticeably different in length and the 3 central Cl atoms are all on one side of the NP_3 plane with ∠NPCl 104°.



Many details of the preparative reaction mechanism remain unclear but it is thought that NH_4Cl partly dissociates into NH_3 and HCl, and that PCl_5 reacts in its ionic form $PCl_4^+PCl_6^-$ (p. 499). Nucleophilic attack by NH_3 on PCl_4^+ then occurs with elimination of HCl and the $\{HN{=}PCl_3\}$ attacks a second PCl_4^+ to give $[Cl_3P{=}N{-}PCl_3]^+$ and HCl. After 1 h the major (insoluble) intermediate product is $[Cl_3P{=}N{-}PCl_3]^+PCl_6^-$ (i.e. P_3NCl_{12}, p. 536) and this then slowly reacts with more NH_3 to give HCl and $\{Cl_3P{=}N{-}PCl_2{=}NH\}$, etc. It is probable that NH_4Br and $PBr_4^+Br^-$ react similarly to give $(NPBr_2)_n$ but NH_4F fluorinates PCl_5 to NH_4PF_4 and the fluoroanalogues $(NPF_2)_n$ are best prepared by fluorinating $(NPCl_2)_n$ with KSO_2F/SO_2 (i.e. KF in liquid SO_2). Similarly, standard substitution reactions lead to many derivatives in which all (or some) of the Cl atoms are replaced by OMe, OEt, OCH_2CF_3, OPh, NHPh, NMe_2, NR_2, R, Ar, etc. Partial replacement leads to geminal derivatives (in which both Cl atoms on 1 P atom are replaced) and to non-geminal derivatives which, in turn, can exist as *cis*- or *trans*- isomers.

The cyclic trimer $(NPF_2)_3$, mp 28°, has an accurately planar 6-membered ring (D_{3h} symmetry) in which all 6 P–N distances are equal (156 pm) and the angles NPN and PNP are all 120 ±1°. Most other trimers are also more-or-less planar with equal P–N distances: for example, $(NPCl_2)_3$ is almost planar (pseudo-chair with P–N 158 pm, P–Cl 197 pm, ∠NPN 118.4°, ∠PNP 121.4°, ∠ClPCl 102°. Perhaps surprisingly, the cyclic tetramer $(NPF_2)_4$, mp 30.4°, is also a planar heterocycle (D_{4h} symmetry) with even shorter P–N bonds (151 pm) and with ring angles of 122.7° and 147.4° at P and N respectively. However, other conformations are found in other derivatives, e.g. chair (C_{2h}), saddle (D_{2d}), boat (S_4), crown tetrameric (C_{4v}) and hybrid. Thus $(NPCl_2)_4$ exists in the metastable K form (in which it has the boat conformation) and the stable T form (chair configuration) as shown in Fig. 12.24. The remarkable diversity of molecular conformations observed for the 8-membered heterocycle $\{P_4N_4\}$ suggests that the particular structure adopted in each case results from a delicate balance of intra- and inter-molecular forces including the details of skeletal bonding, the orientation of substituents and their polar and steric nature, crystal-packing effects, etc. The mps for various series of *cyclo*-$(NPX_2)_n$ frequently show an alternation, with values for n even being greater than those for adjacent n odd. Some examples are in Fig. 12.25. The crystal structures of the four compounds $(NPMe_2)_{9-12}$ have recently been determined.[162]

Bonding. All phosphazenes, whether cyclic or chain, contain the formally unsaturated group  with 2-coordinate N and

[162] R. T. Oakley, S. J. Rettig, N. L. Paddock and J. Trotter, *J. Am. Chem. Soc.* **107**, 6923–36 (1985).

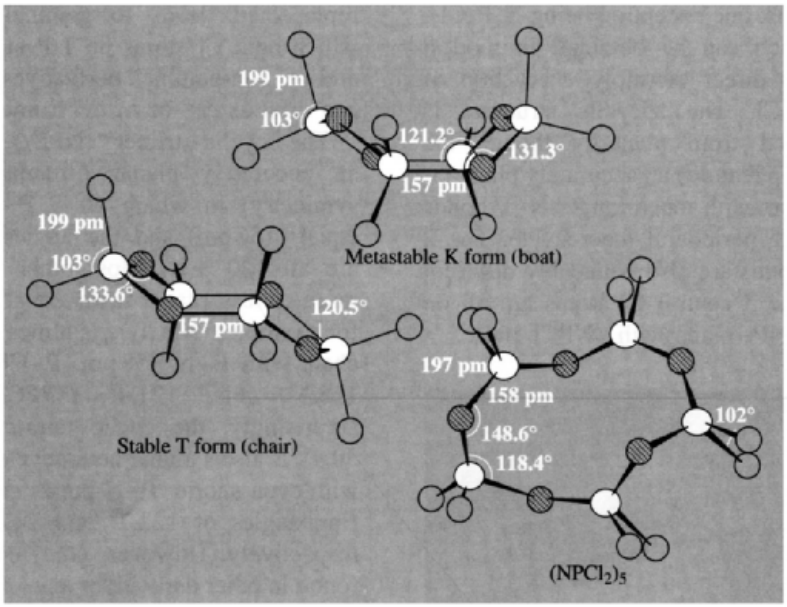


Figure 12.24 Molecular structure and dimensions of the two forms of $(NPCl_2)_4$ and of $(NPCl_2)_5$.

4-coordinate P. The experimental facts that have to be interpreted by any acceptable theory of bonding are:

(i) the rings and chains are very stable;
(ii) the skeletal interatomic distances are equal around the ring (or along the chain) unless there is differing substitution at the various P atoms;
(iii) the P--N distances are shorter than expected for a covalent single bond (~177 pm) and are usually in the range 158 ± 2 pm (though bonds as short as 147 pm occur in some compounds);
(iv) the N–P–N angles are usually in the range 120 ± 2° but the P--N--P angles in various compounds span the range from 120- 148.6°;
(v) skeletal N atoms are weakly basic and can be protonated or form coordination complexes, especially when there are electron-releasing groups on P;
(vi) unlike many aromatic systems the phosphazene skeleton is hard to reduce electrochemically;
(vii) spectral effects associated with organic π-systems (such as the bathochromic ultraviolet shift that accompanies increased electron delocalization) are not found.

LIVE GRAPH

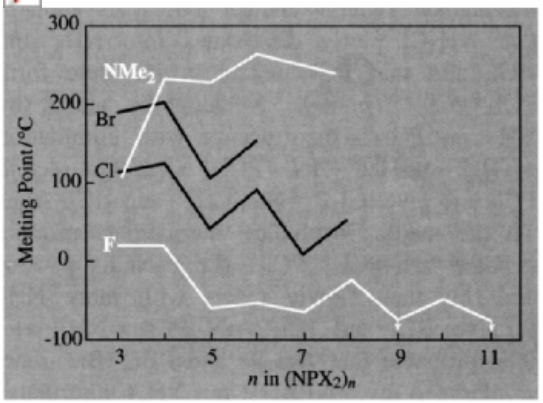

Figure 12.25 Melting points of various series of *cyclo*-polyphosphazenes $(NPX_2)_n$ showing the higher values for n even.

In short, the bonding in phosphazenes is not adequately represented by a sequence of alternating double and single bonds –N=P–N=P– yet it

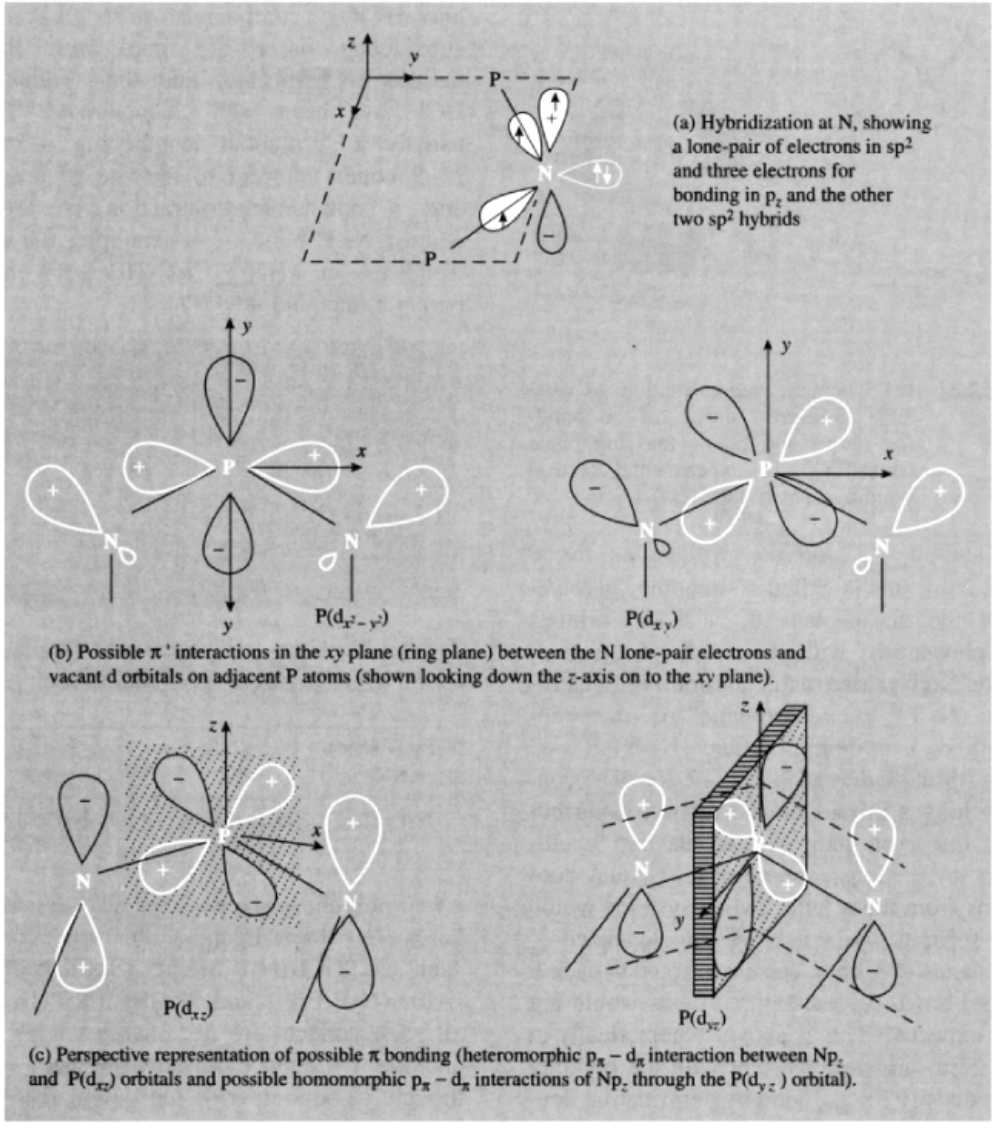

Figure 12.26 A possible description of bonding in phosphazenes.

differs from aromatic $\sigma-\pi$ system in which there is extensive electron delocalization via $p_\pi-p_\pi$ bonding. The possibility of $p_\pi-d_\pi$ bonding in N–P systems has been considered by many authors since the mid-1950s but there is still no consensus, and for nearly every argument that can be mounted in favour of P(3d)-orbital contributions another can be raised against it. It seems generally agreed that 2 electrons on N occupy an sp^2 lone-pair in the plane of the ring (or the plane of the local PNP triangle) as in Fig. 12.26a. The situation at P is less clear mainly because of uncertainties concerning the d-orbital energies and the radial extent (size) of these orbitals in the *bonding situation* (as distinct from the free atom). In so far as symmetry is concerned, the sp^2 lone-pair on each N can be involved in coordinate bonding in the xy plane

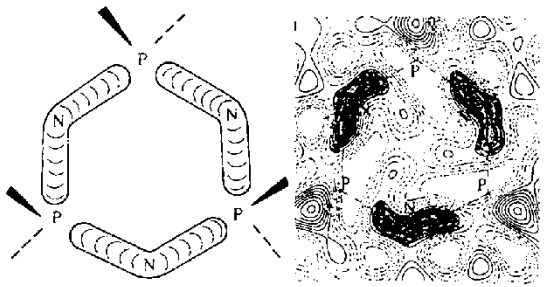

Figure 12.27 (a) Schematic representation of possible 3-centre islands of π bonding above and below the ring plane for $(NPX_2)_3$. (b) experimental electron bonding density (see text).

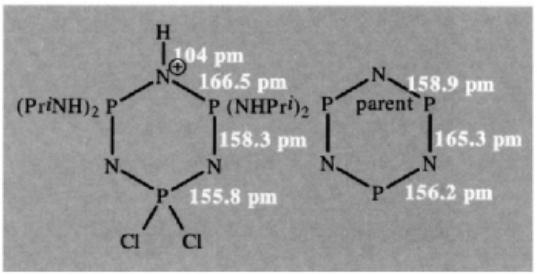
to "vacant" $d_{x^2-y^2}$ and d_{xy} orbitals on the P (Fig. 12.26b); this is called π'-bonding. Involvement of the out-of-plane d_{xz} and d_{yz} orbitals on the phosphorus with the singly occupied p_z orbital on N gives rise to the possibility of heteromorphic (N–P) "pseudoaromatic" $p_\pi - d_\pi$ bonding (with d_{xz}), or homomorphic (N–N) $p_\pi - p_\pi$ bonding (through d_{yz}) as in Fig. 12.26c. The controversy hinges in part on the relative contributions of the π' in-plane and of the two π out-of-plane interactions; approximately equal contributions from these latter two π systems would tend to separate the π orbitals into localized 3-centre islands of π character interrupted at each P atom, and broad delocalization effects would not then be expected. This is shown schematically in Fig. 12.27(a) and is consistent with the bonding electron density (b) as found by deformation density studies on the benzene clathrate of hexa(1-aziridinyl)cyclotriphosphazene, $2(CH_2CH_2N)_6P_3N_3.C_6H_6$.[163] The possibility of exocyclic π bonding between P(d_{z^2}) and appropriate orbitals on the substituents X has also been envisaged.

Reactions. The N atom in *cyclo*-polyphosphazenes can act as a weak Brønsted base (proton acceptor) towards such strong acids as HF and $HClO_4$; compounds with alkyl or NR_2 substituents on P are more basic than the halides, as expected, and their adducts with HCl have been well characterized. There is usually a substantial lengthening of the two N–P bonds adjacent to the site of protonation and a noticeable contraction of the next-nearest N–P bonds. For example, the relevant distances in $[HN_3P_3Cl_2(NHPr^i)_4]Cl$ and the parent compound are:[164]



Typical basicities (pK'_a measured against $HClO_4$ in $PhNO_2$) for ring-*N* protonation are:

$N_3P_3(NHMe)_6$	$N_3P_3(NEt_2)_6$	$N_3P_3Et_6$
8.2	8.2	6.4
$N_3P_3Ph_6$	$N_3P_3(OEt)_6$	*trans*-$N_3P_3Cl_3(NMe_2)_3$
1.5	−0.2	−5.4

Cyclo-polyphosphazenes can also act as Lewis bases (*N* donor-ligands) to form complexes such as $[TiCl_4(N_3P_3Me_6)]$, $[SnCl_4(N_3P_3Me_6)]$, $[AlBr_3(N_3P_3Br_6)]$ and $[2AlBr_3.(N_3P_3Br_6)]$. Not all such adducts are necessarily ring-*N* donors and the 1:1 adduct of $(NPCl_2)_3$ with $AlCl_3$ is thought to be a chloride ion donor, $[N_3P_3Cl_5]^+[AlCl_4]^-$. By contrast, the complex $[Pt^{II}Cl_2(\eta^2\text{-}N_4P_4Me_8)].MeCN$ features transannular bridging of 2 N atoms by the $PtCl_2$ moiety.[165] An intriguing example of a *cyclo*-polyphosphazene acting as a multidentate macrocyclic ligand occurs in the bright orange complex formed when $N_6P_6(NMe_2)_{12}$ reacts with equal amounts of $CuCl_2$ and CuCl. The crystal structure of

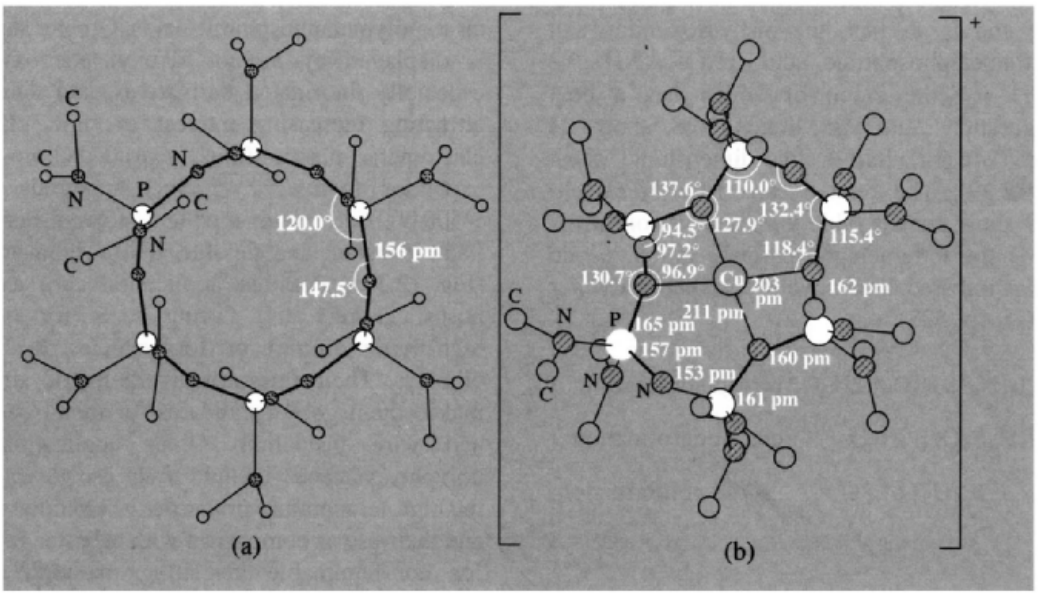

Figure 12.28 Structure of (a) the free ligand $N_6P_6(NMe_2)_{12}$, and (b) the η^4 complex cation $[CuCl\{N_6P_6(NMe_2)_{12}\}]^+$ showing changes in conformation and interatomic distances in the phosphazene macrocycle. The Cl is obscured beneath the Cu and can be regarded as occupying either the apical position of a square pyramid or, since ∠N(1)-Cu-N(1′) is large (160.9°), an equatorial position of a distorted trigonal bipyramid. Note that coordination tightens the ring, already somewhat crowded in the uncomplexed state, the mean angles at P being reduced from 120.0° to 107.5°, and the mean angles at N being reduced from 147.5° to 133.6°. The lengthening of the 8 P–N bonds contiguous to the 4 donor N atoms from 156 to 162 pm is significant, the other P–N distances (mean 156 pm) remaining similar to those in the free ligand.

the resulting $[N_6P_6(NMe_2)_{12}CuCl]^+[CuCl_2]^-$ has been determined (Fig. 12.28b) and detailed comparison with the conformation and interatomic distances in the parent heterocycle (Fig. 12.28a) gives important clues as to the relative importance of the various π and π' bonding interactions involving N (and P) atoms.[166] Incidentally, the compound also affords the first example of the linear 2-coordinate Cu^I complex $[CuCl_2]^-$. The related (and more extensive) organometallic chemistry of the phosphazenes has been reviewed.[167]

As P is isoelectronic with N, it has been found possible to prepare 8-membered diazahexaphosphocins such as $\overline{NPPh_2\mathbf{P}PPh_2NPPh_2\mathbf{P}PPh_2}$, analogous to $(NPPh_2)_4$.[168] The two subrogated **P** atoms can chelate to $PdCl_2$ to form a square planar complex.[169]

Many of the cyclic and chain dichloro derivatives $(NPCl_2)_n$ can be hydrolysed to *n*-basic acids and the lower members form well-defined salts frequently in the tautomeric metaphosphimic-acid form, e.g.:

The dihydrate of the tetramer is particularly stable and is, in fact, the bishydroxonium salt of tetrametaphosphimic acid $[H_3O]_2^+[(NH)_4P_4O_6(OH)_2]^{2-}$ the anion of which has a boat configuration and is linked by short H bonds (246 pm) into a two-dimensional sheet (Fig. 12.29). The related salts $M_4^I[NHPO_2)_4].nH_2O$ show considerable variation in conformation of the tetrametaphosphimate anion, as do the 8-membered heterocyclic tetraphosphazenes $(NPX_2)_4$ (p. 537), e.g.

$[NH_4]_4[N_4H_4P_4O_8].2H_2O$	boat conformation
$K_4[N_4H_4P_4O_8].4H_2O$	chair conformation
$Cs_4[N_4H_4P_4O_8].6H_2O$	saddle conformation.

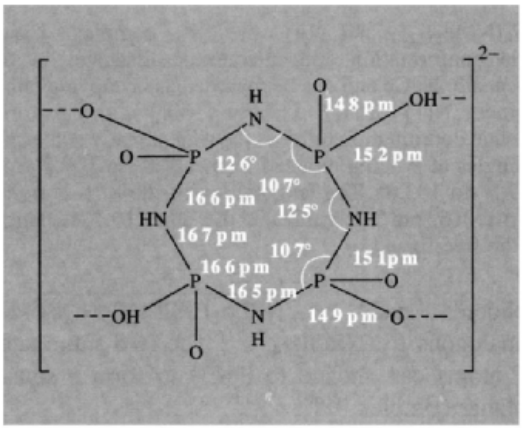

Figure 12.29 Schematic representation of the boat-shaped anion $[(NH)_4P_4O_6(OH)_2]^{2-}$ showing important dimensions and the positions of H bonds.

Applications. Many applications have been proposed for polyphosphazenes, particularly the non-cyclic polymers of high molecular weight, but those with the most desirable properties are extremely expensive and costs will have to drop considerably before they gain widespread use (cf. silicones, p. 365). The cheapest compounds are the chloro series $(NPCl_2)_n$ but these readily hydrolyse in moist air to polymetaphosphimic acids. Greater stability is displayed by amino, alkoxy, phenoxy and especially fluorinated derivatives, and these are attracting increasing interest as rigid plastics, elastomers, plastic films, extruded fibres and expanded foams.[160,170] Such materials (MW >500 000) are water-repellent, solvent-resistant, flame-resistant and flexible at low temperatures (Fig. 12.30). Possible applications are as fuel hoses, gaskets and O-ring seals for use in high-flying aircraft or for vehicles in Arctic climates. Their extraordinary dielectric strength makes them good candidates for metal coatings and wire insulation. Other applications of polyphosphazenes include their use to improve the high-temperature properties of phenolic resins and their use as composites with asbestos or glass for non-flammable insulating material. Some of the more reactive derivatives have been proposed as pesticides and even as ultra-high capacity fertilizers.

12.3.8 Organophosphorus compounds

A general treatment of the vast domain of organic compounds of phosphorus[171] falls outside the scope of this book though several important classes of compound have already been briefly mentioned, e.g. tertiary phosphine ligands (p. 494), alkoxyphosphines and their derivatives (p. 496), organophosphorus halides (p. 500), phosphate esters in life processes (p. 528) and organic derivatives of PN compounds (preceding section). There are also innumerable organic derivatives of the polycyclic polyphosphanes (p. 495),[67,70,172] and vast numbers of heterocyclic organophosphorus

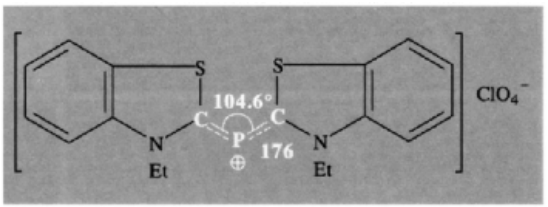
compounds.[173,174] Within the general realm of organic compounds of phosphorus it is convenient to distinguish organophosphorus compounds as a particular group, i.e. those which contain one or more direct P–C bond. In such compounds the coordination number of P can be 1, 2, 3, 4, 5 or 6 (p. 484). Examples of coordination number 1 were initially restricted to the relatively unstable compounds HCP, FCP and MeCP (cf. HCN, FCN and MeCN). HC≡P was first made in 1961 by subjecting PH_3 gas at 40 mmHg pressure to a low-intensity rotating arc struck between graphite electrodes;[175] it is a colourless, reactive gas, stable only below its triple point of −124° (30 mmHg). Monomeric HCP slowly polymerizes at −130° (more rapidly at −78°) to a black solid, and adds 2HCl at −110° to give $MePCl_2$ as the sole product. Both monomer and polymer are pyrophoric in air even at room temperature. More recently[176] MeCP was made by pyrolysing $MeCH_2PCl_2$ at 930° in a low-pressure flow reactor and trapping the products at −78°. Dramatic stabilization of a phospha-alkyne has been achieved by η^2-complexation to a metal centre:[177]

$$Bu^tC{\equiv}P + [Pt(C_2H_4)(PPh_3)_2] \xrightarrow[\text{room temp}]{C_6H_6} C_2H_4 + [Pt(\eta^2\text{-}Bu^tCP)(PPh_3)_2].C_6H_6$$

The translucent, cream-coloured benzene solvate was characterized by single-crystal X-ray analysis and by ^{31}P nmr spectroscopy. The first free phospha-alkyne stable to polymerization was $Bu^tC{\equiv}P$,[178] and its chemistry has been extensively investigated.[179,180] The similarly bulky ArC≡P (Ar = 2,4,6,-$Bu^t_3C_6H_2$) has been studied by X-ray crystallography[182] and the C–P distance found to be 152 pm, similar to the short C–P distance of 154 pm deduced from the microwave spectrum of HCP and MeCP. The most studied reactions of phospha-alkynes are cyclo-additions to give organo-P heterocycles,[179–181] and reactions with nucleophiles to give phospha-alkenes and 1,3-diphosphabutadienes.[182]

As with coordination number 1, the first 2-coordinate P compound also appeared in 1961:[183] $Me_3P{=}PCF_3$ was made as a white solid by cleaving *cyclo*-$[P(CF_3)]_{4\text{ or }5}$ with PMe_3; it is stable at low temperatures but readily dissociates into the starting materials above room temperature. More stable is the bent 2-coordinate phosphocation occurring in the orange salt[184]



The aromatic heterocycle phosphabenzene C_5H_5P (analogous to pyridine) was reported in 1971,[185] some years after its triphenyl derivative 2,4,6-$Ph_3C_5H_2P$. See also $HP{=}CH_2$[29] and $[P(CN)_2]^-$[30] (p. 484). The burgeoning field of heterocyclic phosphorus compounds featuring

2-coordinate and 3-coordinate P has been fully reviewed,[173,174] as has the equally active field of phospha-alkenes $\left(-P{=}C\right\rangle$ and diphosphenes $(-P{=}P-)$.[179,180,186,187]

The most common coordination numbers for organophosphorus compounds are 3 and 4 as represented by tertiary phosphines and their complexes, and quaternary cations such as $[PMe_4]^+$ and $[PPh_4]^+$. Also of great significance are the 4-coordinate P ylides† $R_3P{=}CH_2$; indeed, few papers have created so much activity as the report by G. Wittig and G. Geissler in 1953 that methylene triphenylphosphorane reacts with benzophenone to give Ph_3PO and 1,1-diphenylethylene in excellent yield.[188]

$$Ph_3P{=}CH_2 + Ph_2CO \longrightarrow Ph_3PO + Ph_2C{=}CH_2$$

The ylide $Ph_3P{=}CH_2$ can readily be made by deprotonating a quaternary phosphonium halide with *n*-butyllithium and many such ylides are now known:

$$[Ph_3PCH_3]^+Br^- \xrightarrow{LiBu^n} Ph_3P{=}CH_2 + LiBr + Bu^nH$$

$$[PMe_4]^+Br^- + NaNH_2 \xrightarrow{thf/0^\circ} Me_3P{=}CH_2 + NaBr + NH_3$$

The enormous scope of the Wittig reaction and its variants in affording a smooth, high-yield synthesis of C=C double bonds, etc., has been amply delineated by the work of Wittig and others and culminated in the award of the 1979 Nobel Prize for Chemistry (jointly with H. C. Brown for hydroboration, p. 166). The reaction of P ylides with many inorganic compounds has also led to some fascinating new chemistry.[189] The curious yellow compound $Ph_3P{=}C{=}PPh_3$ should also be noted:[190] unlike allene, $H_2C{=}C{=}CH_2$, which has a linear central carbon atom, the molecules are bent and the structure is strikingly unusual in having 2 crystallographically independent molecules in the unit cell which have substantially differing bond angles, 130.1° and 143.8°. The short P=C distances (163 pm as compared with 183.5 pm for P–C(Ph)) suggest double bonding, but the nonlinear P=C=P unit and especially the two values of the angle, are hard to rationalize (cf. the isoelectronic cation $[Ph_3P{=}N{=}PPh_3]^+$ which has various angles in different compounds).

Pentaorgano derivatives of P are rare. The first to be made (by G. Wittig and M. Rieber in 1948) was PPh_5:

$$Ph_3PO \xrightarrow[(2)\ HCl]{(1)\ LiPh} [PPh_4]^+Cl^- \xrightarrow{HI} [PPh_4]^+I^- \xrightarrow{LiPh} PPh_5 \text{ (d. 124°)}$$

Unlike $SbPh_5$ (which has a square-pyramidal structure p. 598), PPh_5 adopts a trigonal bipyramidal coordination with the axial P–C distances (199 pm) being appreciably longer than the equatorial P–C distances (185 pm). More recently (1976) $P(CF_3)_3Me_2$ and $P(CF_3)_2Me_3$ were obtained by methylating the corresponding chlorides with $PbMe_4$. There are also many examples of 5-coordinate P in which not all the directly bonded atoms are carbon. One such is the dioxaphenylspiro-phosphorane shown in Fig. 12.31; the local symmetry about P is essentially square pyramidal, and the factors which affect the choice between this geometry and trigonal bipyramidal is a topic of active

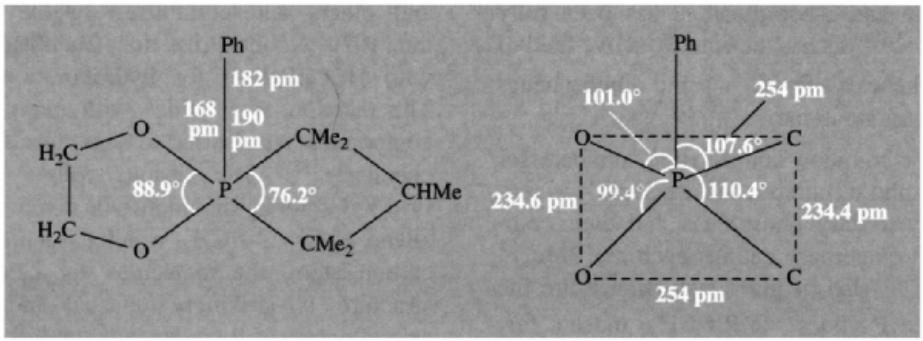

Figure 12.31 Schematic representation of the molecular structure of $[P(C_3HMe_5)(O_2C_2H_4)Ph]$ showing the rectangular-based pyramidal disposition of the 5 atoms bonded to P; the P atom is 44 pm above the C_2O_2 plane.

current interest.[39,191] It should also be noted that the compounds, Ph_3PBr_2 and Ph_3PI_2, which might have been thought to involve 5-coordinate P, feature instead 4-coordinate P and an unusual end-on bonding of the dihalogen moiety, i.e. $Ph_3P{-}Br{-}Br$,[192] and $Ph_3P{-}I{-}I$.[193] The corresponding interhalogen adducts Ph_3PIX (X = Cl, Br) appear to be 4-coordinate but ionic, i.e. $[Ph_3PI]^+X^-$.[194]

Many organophosphorus compounds are highly toxic and frequently lethal. They have been actively developed for herbicides, pesticides and more sinister purposes such as nerve gases which disorient, harass, paralyse or kill.[9]

Arsenic, Antimony and Bismuth

13.1 Introduction

The three elements arsenic, antimony and bismuth, which complete Group 15 of the periodic table, were amongst the earliest elements to be isolated and all were known before either nitrogen (1772) or phosphorus (1669) had been obtained as the free elements. The properties of arsenic sulfide and related compounds have been known to physicians and professional poisoners since the fifth century BC though their use is no longer recommended by either group of practitioners. Isolation of the element is sometimes credited to Albertus Magnus (AD 1193–1280) who heated orpiment (As_2S_3) with soap, and its name reflects its ancient lineage. [Arsenic, Latin *arsenicum* from Greek ἀρσενικόν (*arsenicon*) which was itself derived (with addition of όν) from Persian *az-zarnīkh*, yellow orpiment (*zar* = gold).] Antimony compounds were also known to the ancients and the black sulfide, stibnite, was used in early biblical times as a cosmetic to darken and beautify women's eyebrows; a rare Chaldean vase of cast antimony dates from 4000 BC and antimony-coated copper articles were used in Egypt 2500–2200 BC. Pliny (~AD 50) gave it the name *stibium* and writings attributed to Jabir (~AD 800) used the form *antimonium*; indeed, both names were used for both the element and its sulfide until the end of the eighteenth century (Lavoisier). The history of the element, like that of arsenic, is much obscured by the intentionally vague and misleading descriptions of the alchemists, though the elusive Benedictine monk Basil Valentine may have prepared it in 1492 (about the time of Columbus). N. Lémery published his famous *Treatise on Antimony* in 1707. Bismuth was known as the metal at least by 1480 though its previous history in the Middle Ages is difficult to unravel because the element was sometimes confused with Pb, Sn, Sb or even Ag. The Gutenberg printing presses (1440 onwards) used type that had been cut from brass or cast from Pb, Sn or Cu, but about 1450 a secret method of casting type from Bi alloys came into use and this particular use is still an important application of the element (p. 549). The name derives from the German *Wismut* (possibly white metal or meadow mines) and this was latinized to *bisemutum* by the sixteenth-century German scientist G. Bauer (Agricola) about 1530. Despite the difficulty of

assigning precise dates to discoveries made by alchemists, miners and metal workers (or indeed even discerning what those discoveries actually were), it seems clear that As, Sb and Bi became increasingly recognized in their free form during the thirteenth to fifteenth centuries; they are therefore contemporary with Zn and Co, and predate all other elements except the 7 metals and 2 non-metallic elements known from ancient times (Au, Ag, Cu, Fe, Hg, Pb, Sn; C and S).[1]

Arsenic and antimony are classed as metalloids or semi-metals and bismuth is a typical B subgroup (post-transition-element) metal like tin and lead.

13.2 The Elements

13.2.1 Abundance, distribution and extraction

None of the three elements is particularly abundant in the earth's crust though several minerals contain them as major constituents. As can be seen from Table 13.1, arsenic occurs about halfway down the elements in order of abundance, grouped with several others near 2 ppm. Antimony has only one-tenth of this abundance and Bi, down by a further factor of 20 or more, is about as unabundant as several of the commoner platinum metals and gold. In common with all the post-transition-element metals, As, Sb and Bi are chalcophiles, i.e. they occur in association with the chalcogens S, Se and Te rather than as oxides and silicates.

Arsenic minerals are widely distributed throughout the world and small amounts of the free element have also been found. Common minerals include the two sulfides realgar (As_4S_4) and orpiment (As_2S_3) and the oxidized form arsenolite (As_2O_3). The arsenides of Fe, Co and Ni and the mixed sulfides with these metals form another set of minerals, e.g. loellingite ($FeAs_2$), safforlite (CoAs), niccolite (NiAs), rammelsbergite ($NiAs_2$), arsenopyrite (FeAsS), cobaltite (CoAsS), enargite (Cu_3AsS_4), gersdorffite (NiAsS) and the quaternary sulfide glaucodot [(Co,Fe)AsS]. Elemental As is obtained on an industrial scale by smelting $FeAs_2$ or FeAsS at 650–700°C in the absence of air and condensing the sublimed element: FeAsS $\longrightarrow$ FeS + As(g) $\longrightarrow$ As(s). Residual As trapped in the sulfide residues can be released by roasting them in air and trapping the sublimed As_2O_3 in the flue system. The oxide can then either be used directly for chemical products or reduced with charcoal at 700–800° to give more As. As_2O_3 is also obtained in large quantities as flue dust from the smelting of Cu and Pb concentrates; because of the huge scale of these operations (pp. 1174, 371) this represents the most important industrial source of As. Some production figures and major uses of As and its compounds are listed in the Panel.

Stibnite, Sb_2S_3, is the most important ore of antimony and it occurs in large quantities in China, South Africa, Mexico, Bolivia and Chile. Other sulfide ores include ullmanite (NiSbS), livingstonite ($HgSb_4S_8$), tetrahedrite (Cu_3SbS_3), wolfsbergite ($CuSbS_2$) and jamesonite ($FePb_4Sb_6S_{14}$). Indeed, complex ores containing Pb, Cu, Ag and Hg are an important industrial source of Sb. Small amounts of oxide minerals formed by weathering are also known, e.g. valentinite (Sb_2O_3), cervantite (Sb_2O_4), and stibiconite ($Sb_2O_4.H_2O$), and minor finds of native Sb have occasionally been reported. Commercial ores have 5–60% Sb, and recovery methods depend on the

Production and Uses of Arsenic, Antimony and Bismuth[2]

Until the late 1980s the USA was the principal supplier of "white arsenic" (i.e. As_2O_3) but it now relies entirely on imports. World production has been steady for many years at about 52 000 tonnes pa and the main producers are France (10 000 tpa), Sweden (10 000 tpa), Russia (8 000 tpa) and Chile (7 000 tpa). The price of refined oxide was about $480 per tonne in 1989 and commercial grade As metal (99%+) was about $2.20/kg in 1990. High purity As (99.99%+) was $45.00/kg and zone-refined semiconductor grade even more expensive.

The main use of elemental As is in alloys with Pb and to a lesser extent Cu. Addition of small concentrations of As improves the properties of Pb/Sb for storage batteries (see below), up to 0.75% improves the hardness and castability of type metal, and 0.5–2.0% improves the sphericity of Pb ammunition. Automotive body solder is Pb (92%), Sb (5.0%), Sn (2.5%) and As (0.5%). Intermetallic compounds with Al, Ga and In give the III–V semiconductors (p. 255) of which GaAs and InAs are of particular value for light-emitting diodes (LEDs), tunnel diodes, infrared emitters, laser windows and Hall-effect devices (p. 258).

The use of As compounds as herbicides and pest controls in agriculture is now considerably restricted because of environmental considerations though arsenic acid itself, $AsO(OH)_3$, is still used in the formulation of wood preservatives. The oxide is widely used to decolorize glass.

World production capacity for antimony and its compounds (as contained Sb) was 116 000 tonnes in 1988, plus a similar amount of secondary (recycled) Sb obtained by smelting. However, actual production was somewhat below this. Typical prices (1988) were $3.50/kg for high-grade Sb_2O_3 and $2.30/kg for 99.5%+ Sb metal ($1.80/kg in 1990). Lead storage batteries use alloys containing 2.5–3% Sb and a trace of As, to minimize self-discharge, gassing and poisoning of the negative electrode. Other typical uses of Sb alloys in the USA, 1975 (tonnes of contained Sb), are shown in the Table.

Use	Sb/Pb batteries	Bearings	Ammunition	Solder	Type metal	Sheet pipe	Other metal	Non-metal products
Sb/tonnes	4143	365	216	121	68	55	144	6657
Percentage	35.2	3.5	1.8	1.0	0.6	0.5	1.2	56.5

As with arsenic, semiconductor grade Sb is prepared by chemical reduction of highly purified compounds. AlSb, GaSb and InSb have applications in infrared devices, diodes and Hall-effect devices. ZnSb has good thermoelectric properties. Applications of various *compounds* of Sb will be mentioned when the compounds themselves are discussed.

World annual production of bismuth and its compounds has hovered around 4000 tonnes of contained Bi for many years and a similar amount of secondary (refinery) Bi is also produced. Production has been dominated by China, Japan, Peru, Bolivia, Mexico, Canada, USA and Australia which, between them, account for almost of all supplies. Prices for the free element have fluctuated wildly since the 1970s, from <$4.00/kg to >$44.00/kg; at the end of 1990 it was $6.30/kg. Consumption of the metal and its compounds has also been unusual, usage in the USA dropping by a factor of 2 from 1973 to 1975, for example. The main uses are in pharmaceuticals, fusible alloys (including type metal, p. 547), and metallurgical additives.

No industrial poisoning by Bi metal has ever been reported but ingestion of compounds and inhalation of dust should be avoided.

grade. Low-grade sulfide ores (5–25% Sb) are volatilized as the oxide (any As_2O_3 being readily removed first by virtue of its greater volatility). The oxide can be reduced to the metal by heating it in a reverberatory furnace with charcoal in the presence of an alkali metal carbonate or sulfate as flux. Intermediate ores (25–40%) are smelted in a blast furnace and the oxide recovered from the flue system. Ores containing 40–60% Sb are liquated at 550–600° under reducing conditions to give Sb_2S_3 and then treated with scrap iron to remove the sulfide: $Sb_2S_3 + 3Fe \longrightarrow 2Sb + 3FeS$. Some complex sulfide ores are treated by leaching and electrowinning, e.g. the electrolysis of alkaline solutions of the thioantimonate Na_3SbS_4, and the element is also recovered from the flue dusts of Pb smelters. Impure Sb contains Pb, As, S, Fe and

[2] *Kirk–Othmer Encyclopedia of Chemical Technology*, 4th edn., Vol. 3, Wiley, New York, 1992; Arsenic and arsenic alloys (pp. 624–33); Arsenic compounds (633–59); Antimony and antimony alloys (367–81); Antimony compounds (382–412); Bismuth and bismuth alloys (Vol. 4, 1992 (pp. 237–45); Bismuth compounds (246–70).

Cu; the latter two can be removed by stibnite treatment or heating with charcoal/Na_2SO_4 flux; the As and S can be removed by an oxidizing flux of $NaNO_3$ and NaOH (or Na_2CO_3); Pb is hard to remove but this is unnecessary if the Sb is to be used in Pb alloys (see below). Electrolysis yields >99.9% purity and remaining impurities can be reduced to the ppm level by zone refining. The scale of production and the various uses of Sb and its compounds are summarized in the Panel.

Bismuth occurs mainly as bismite (α-Bi_2O_3), bismuthinite (Bi_2S_3) and bismutite [$(BiO)_2CO_3$]; very occasionally it occurs native, in association with Pb, Ag or Co ores. The main commercial source of the element is as a byproduct from Pb/Zn and Cu plants, from which it is obtained by special processes dependent on the nature of the main product.[2] Sulfide ores are roasted to the oxide and then reduced by iron or charcoal. Because of its low mp, very low solubility in Fe, and fairly high oxidative stability in air, Bi can be melted and cast (like Pb) in iron and steel vessels. Like Sb, the metal is too brittle to roll, draw, or extrude at room temperature, but above 225°C Bi can be worked quite well.

13.2.2 Atomic and physical properties

Arsenic and Bi (like P) each have only 1 stable isotope and this occurs with 100% abundance in all natural sources of the elements. Accordingly (p. 17) their atomic weights are known with great precision (Table 13.2). Antimony has 2 stable isotopes (like N); however, unlike N, which has 1 predominantly abundant isotope, the 2 isotopes of Sb are approximately equal in abundance (^{121}Sb 57.21%, ^{123}Sb 42.79%) and consequently (p. 17) the atomic weight is known with somewhat less accuracy. It is also noteworthy that ^{209}Bi is the heaviest stable isotope of any element; all nuclides beyond $^{209}_{83}$Bi are radioactive.

The ground-state electronic configuration of each element in the group is ns^2np^3 with an unpaired electron in each of the three p orbitals, and much of the chemistry of the group can be interpreted directly on this basis. However, smooth trends are sometimes modified (or even absent altogether), firstly, because of the lack of low-lying empty d orbitals in N, which differentiates it from its heavier congeners, and, secondly, because of the countervailing influence of the underlying filled d and f orbitals in As, Sb and Bi. Such perturbations are apparent when the various ionization energies in Table 13.2 are plotted as a function of atomic number. Table 13.2 also contains approximate data on the conventional covalent single-bond radii for threefold coordination though these values vary by about ±4 pm in various tabulations and should only be used as a rough guide. The 6-coordinate "effective ionic radii" for the +3 and +5

Table 13.2 Atomic properties of Group 15 elements

Property		N	P	As	Sb	Bi

(6-coordinate) (M^{V})/pm		(13)	38	46	60	76

oxidation states are taken from R. D. Shannon's tabulation,[3] but should not be taken to imply the presence of M^{3+} and M^{5+} cations in many of the compounds of these elements.

Arsenic, Sb and Bi each exist in several allotropic forms[4,5] though the allotropy is not so extensive as in P (p. 481). There are three crystalline forms of As, of which the ordinary, grey, "metallic", rhombohedral, α-form is the most stable at room temperature. It consists of puckered sheets of covalently bonded As stacked in layers perpendicular to the hexagonal *c*-axis as shown in Fig. 13.1. Within each layer each As has 3 nearest neighbours at 251.7 pm and the angle As–As–As is 96.7°; each As also has a further 3 neighbours at 312 pm in an adjacent layer. The α-forms of Sb and Bi are isostructural with α-As and have the dimensions shown in Table 13.3. It can be seen that there is a progressive diminution in the difference between intra-layer and inter-layer distances though the inter-bond angles remain almost constant.

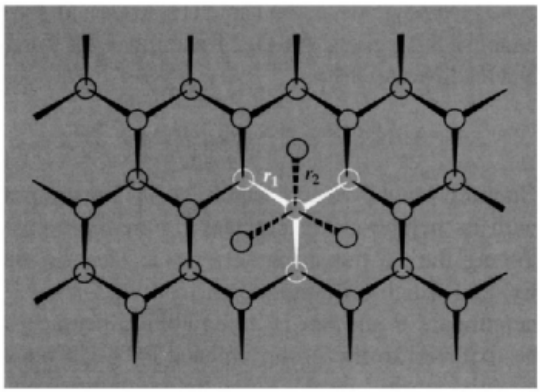

Figure 13.1 Puckered layer structure of As showing pyramidal coordination of each As to 3 neighbours at a distance r_1 (252 pm). The disposition of As atoms in the next layer (r_2 312 pm) is shown by dashed lines.

Table 13.3 Comparison of black P and α-rhombohedral As, Sb and Bi

	r_1/pm	r_2/pm	r_2/r_1	∠ M–M–M
Black P	223.1 (av)	332.4 (av)	1.490	2 at 96.3° (1 at 102.1°)
α-As	251.7	312.0	1.240	96.7°
α-Sb	290.8	335.5	1.153	96.6°
α-Bi	307.2	352.9	1.149	95.5°

In the vapour phase As is known to exist as tetrahedral As_4 molecules with (As–As 243.5 pm) and when the element is sublimed, a yellow, cubic modification is obtained which probably also contains As_4 units though the structure has not yet been determined because the crystals decompose in the X-ray beam. The mineral arsenolamprite is another polymorph, ε-As; it is possibly isostructural with "metallic" orthorhombic P.

Antimony exists in 5 forms in addition to the ordinary α-form which has been discussed above. The yellow form is unstable above −90°; a black form can be obtained by cooling gaseous Sb, and an explosive (impure?) form can be made electrolytically. The two remaining crystalline forms are made by high-pressure techniques: Form I has a primitive cubic lattice with a_0 296.6 pm: it is obtained from α-Sb at 50 kbar (5GPa, i.e. 5×10^9 N m^{-2}) by increasing the rhombohedral angle from 57.1° to 60.0° together with small shifts in atomic position so that each Sb has 6 equidistant neighbours. Further increase in pressure to 90 kbar yields Form II which is hcp with an interatomic distance of 328 pm for the 12 nearest neighbours.

Several polymorphs of Bi have been described but there is as yet no general agreement on their structures except for α-Bi (above) and ζ-Bi which forms at 90 kbar and has a bcc structure with 8 nearest neighbours at 329.1 pm.

The physical properties of the α-rhombohedral form of As, Sb and Bi are summarized in Table 13.4. Data for N_2 and P_4 are included for comparison. Crystalline As is rather volatile and the vapour pressure of the solid reaches 1 atm at 615° some 200° below its mp of 816°C (at 38.6 atm, i.e. 3.91 MPa). Antimony and Bi are

Table 13.4 Some physical properties of Group 15 elements

Property	N_2	P_4	α-As	α-Sb	α-Bi
MP/°C	−210.0	44.1	816 (38.6 atm)	630.7	271.4
BP/°C	−195.8	280.5	615 (subl)	1753	1564
Density (25°C)/g cm^{-3}	0.879 (−210°)	1.823	5.778[a]	6.684	9.808
Hardness (Mohs)	—	—	3.5	3–3.5	2.5
Electrical resistivity (20°C)/μohm cm	—	—	33.3	41.7	120
Contraction on freezing/%	—	—	10	0.8	−3.32

[a]Yellow As_4 has d_{25} 1.97 g cm^{-3}; cf. difference between the density of rhombohedral black P (3.56 g cm^{-3}) and white P_4 (1.823 g cm^{-3}) (p. 479).

much less volatile and also have appreciably lower mps than As, so that both have quite long liquid ranges at atmospheric pressure.

Arsenic forms brittle steel-grey crystals of metallic appearance. However, its lack of ductility and comparatively high electrical resistivity (33.3 μohm cm), coupled with its amphoterism and intermediate chemical nature between that of metals and non-metals, have led to its being classified as a metalloid rather than a "true" metal. Antimony is also very brittle and forms bluish-white, flaky, lustrous crystals of high electrical resistivity (41.7 μohm cm). These values of resistivity can be compared with those for "good" metals such as Ag (1.59), Cu (1.72), and Al (2.82 μohm cm), and with "poor" metals such as Sn (11.5) and Pb (22 μohm cm). Bismuth has a still higher resistivity (120 μohm cm) which even exceeds that of commercial resistors such as Nichrome alloy (100 μohm cm). Bismuth is a brittle, white, crystalline metal with a pinkish tinge. It is the most diamagnetic of all metals (mass susceptibility 17.0×10^{-9} m^3 kg^{-1} — to convert this SI value to cgs multiply by $10^3/4\pi$, i.e. 1.35×10^{-6} cm^3 g^{-1}). It also has the highest Hall effect coefficient of any metal and is unusual in expanding on solidifying from the melt, a property which it holds uniquely with Ga and Ge among the elements.

13.2.3 Chemical reactivity and group trends

Arsenic is stable in dry air but the surface oxidizes in moist air to give a superficial golden bronze tarnish which deepens to a black surface coating on further exposure. When heated in air it sublimes and oxidizes to As_4O_6 with a garlic like odour (poisonous). Above 250–300° the reaction is accompanied by phosphorescence (cf. P_4, p. 473). When ignited in oxygen, As burns brilliantly to give As_4O_6 and As_4O_{10}. Metals give arsenides (p. 554), fluorine enflames to give AsF_5 (p. 561), and the other halogens yield AsX_3 (p. 559). Arsenic is not readily attacked by water, alkaline solutions or non-oxidizing acids, but dilute HNO_3 gives arsenious acid (H_3AsO_3), hot conc HNO_3 yields arsenic acid (H_3AsO_4), and hot conc H_2SO_4 gives As_4O_6. Reaction with fused NaOH liberates H_2:

$$As + 3NaOH \longrightarrow Na_3AsO_3 + \tfrac{3}{2}H_2$$

One important property which As has in common with its neighbouring elements immediately following the 3d transition series (i.e. Ge, As, Se, Br) and which differentiates it from its Group 15 neighbours P and Sb, is its notable reluctance to be oxidized to the group valence of +5. Consequently As_4O_{10} and H_3AsO_4 are oxidizing agents and arsenates are used for this purpose in titrimetric analysis (p. 577).

The ground-state electronic structure of As, as with all Group 15 elements features 3 unpaired electrons ns^2np^3; there is a substantial electron affinity for the acquisition of 1 electron but further additions must be effected against considerable coulombic repulsion, and the formation of As^{3-} is highly endothermic. Consistent with this there are no "ionic" compounds containing the arsenide ion and

compounds such as Na_3As are intermetallic or alloy-like. However, despite the metalloidal character of the free element, the ionization energies and electronegativity of As are similar to those of P (Table 13.2) and the element readily forms strong covalent bonds to most non-metals. Thus AsX_3 (X = H, hal, R, Ar etc.) are covalent molecules like PX_3 and the tertiary arsines have been widely used as ligands to b-class transition elements (p. 909).[6] Similarly, As_4O_6 and As_4O_{10} resemble their P analogues in structure; the sulfides are also covalent heterocyclic molecules though their stoichiometry and structure differ from those of P.

Antimony is in many ways similar to As, but it is somewhat less reactive. It is stable to air and moisture at room temperature, oxidizes on being heated under controlled conditions to give Sb_2O_3, Sb_2O_4 or Sb_2O_5, reacts vigorously with Cl_2 and more sedately with Br_2 and I_2 to give SbX_3, and also combines with S on being heated. H_2 is without direct reaction and SbH_3 (p. 557) is both very poisonous and thermally very unstable. Dilute acids have no effect on Sb; concentrated oxidizing acids react readily, e.g. conc HNO_3 gives hydrated Sb_2O_5, aqua regia gives a solution of $SbCl_5$, and hot conc H_2SO_4 gives the salt $Sb_2(SO_4)_3$.

Bismuth continues the trend to electropositive behaviour and Bi_2O_3 is definitely basic, compared with the amphoteric oxides of Sb and As and the acidic oxides of P and N. There is also a growing tendency to form salts of oxoacids by reaction of either the metal or its oxide with the acid, e.g. $Bi_2(SO_4)_3$ and $Bi(NO_3)_3$. Direct reaction of Bi with O_2, S and X_2 at elevated temperatures yields Bi_2O_3, Bi_2S_3 and BiX_3 respectively, but the increasing size of the metal atom results in a steady decrease in the strength of covalent linkages in the sequence P > As > Sb > Bi. This is most noticeable in the instability of BiH_3 and of many organobismuth compounds (p. 599).

Most of the trends are qualitatively understandable in terms of the general atomic properties in Table 13.2 though they are not readily deducible from them in any quantitative sense. Again, the +5 oxidation state in Bi is less stable than in Sb for the reasons discussed on p. 226; not only is the sum of the 4th and 5th ionization energies for Bi greater than for Sb (9.78 vs. 9.63 MJ mol^{-1}) but the promotion energies of one of the ns^2 electrons to a vacant nd orbital is also greater for Bi (and As) than for Sb. The discussions on redox properties (p. 577) and the role of d orbitals (p. 222) are also relevant. Finally, Bi shows an interesting resemblance to La in the crystal structures of the chloride oxide, MOCl, and in the isomorphism of the sulfates and double nitrates; this undoubtedly stems from the very similar ionic radii of the 2 cations: Bi^{3+} 103, La^{3+} 103.2 pm.

All coordination numbers from 1–10 (and 12) are known for the sub-group, though 3, 4, 5 and 6 are by far the most frequently met. CN 1 is exemplified by RC≡As[7] (R = 2,4,6-$Bu^t_3C_6H_2$; cf RC≡P, p. 544) and by the isolated tetrahedral anions $SiAs_4^{8-}$ and $GeAs_4^{8-}$ (isoelectronic with SiO_4^{4-} and GeO_4^{4-}) which occur in the lustrous dark metallic Zintl phases Ba_4MAs_4.[8] CN 2 (bent) is quite common in heterocyclic organic compounds (p. 592) and in cluster anions such as As_7^{3-}, Sb_7^{3-} and As_{11}^{3-} and their derivates (p. 588). A rare example of linear 2-coordinate As was recently established in the bis(manganese) complex $[(\eta^5\text{-}C_5H_4Me)(CO)_2Mn{=}As{=}Mn(CO)_2(\eta^5\text{-}C_5H_4Me)]^+$, isolated as its dark brown salt with $CF_3SO_3^-$: the angle at As was found to be 176.3° and the As–Mn distance was 215 pm.[9] Likewise, examples of pyramidal 3-coordinate As, Sb and Bi are endemic, but planar CN 3 is extremely rare; examples occur in

compounds such as $[PhAs(Cr(CO)_5)_2]$ and $[PhSb(Mn(\eta^5\text{-}C_5H_5)(CO)_2)_2]$ (p. 597) See later, also, for examples of CN 4 (tetrahedral, flattened tetrahedral and see-saw), CN 5 (trigonal bipyramidal and square pyramidal) and CN 6 (octahedral, 3 + 3, and pentagonal pyramidal).

Higher coordination numbers are less common and are mainly confined to Bi. CN 7 has been found in the tetradendate crown-ether bismuth complex $[BiCl_3(12\text{-crown-}4)]$[10] and in the bismuth complex, [BiL], of the novel heptadentate anionic ligand of 'saltren', (H_3L), i.e. $(\mathbf{N}(CH_2CH_2\mathbf{N}{=}CHC_6H_4\mathbf{OH})_3)$.[11] The first example of CN 8 was found in the colourless 2:1 adduct $[2BiCl_3.18\text{-crown-}6]$ which was shown by X-ray analysis to involve an unexpected ionic structure featuring 8-coordinate Bi cations, viz. $[BiCl_2(18\text{-crown-}6)]^+{}_2[Bi_2Cl_8]^{2-}$.[10] CN 9 is represented by the discrete tris(tridentate) complex $[Bi(-\mathbf{O}-C(Bu^t){=}C-\mathbf{N}{=}C-C(Bu^t){=}\mathbf{O}{\rightarrow})_3]$ in which Bi has a face-capped, slightly-twisted trigonal-prismatic coordination environment.[12] Still higher coordination numbers are exemplified by encapsulated As and Sb atoms in rhodium carbonyl cluster anions: for example As is surrounded by a bicapped square antiprism of 10 Rh atoms in $[Rh_{10}As(CO)_{22}]^{3-}$,[13] and Sb is surrounded by an icosahedron of 12 Rh in $[Rh_{12}Sb(CO)_{27}]^{3-}$.[14] In each case the anion is the first example of a complex in which As or Sb acts as a 5-electron donor (cf. P as a 5-electron donor in $[Rh_9P(CO)_{21}]^{3-}$): all these clusters then have precisely the appropriate number of valence electrons for *closo* structures on the basis of Wade's rules (pp. 161, 174).

13.3 Compounds of Arsenic, Antimony and Bismuth[15]

13.3.1 Intermetallic compounds and alloys[16,17]

Most metals form arsenides, antimonides and bismuthides, and many of these command attention because of their interesting structures or valuable physical properties. Like the borides (p. 145), carbides (p. 297), silicides (p. 335), nitrides (p. 417) and phosphides (p. 489), classification is difficult because of the multitude of stoichiometries, the complexities of the structures and the intermediate nature of the bonding. The compounds are usually prepared by direct reaction of the elements in the required proportions and typical compositions are M_9As, M_5As, M_4As, M_3As, M_5As_2, M_2As, M_5As_3, M_3As_2, M_4As_3, M_5As_4, MAs, M_3As_4, M_2As_3, MAs_2 and M_3As_7. Antimony and bismuth are similar. Many of these intermetallic compounds exist over a range of composition, and nonstoichiometry is rife.

The (electropositive) alkali metals of Group 1 form compounds M_3E (E = As, Sb, Bi) and the metals of Groups 2 and 12 likewise form M_3E_2. These can formally be written as $M^+{}_3E^{3-}$ and $M^{2+}{}_3E^{3-}{}_2$ but the compounds are even less ionic than Li_3N (p. 76) and have many metallic properties. Moreover, other stoichiometries are found (e.g. LiBi, KBi_2, $CaBi_3$) which are not readily accounted for by the ionic model and, conversely, compounds M_3E are formed by many metals that are not usually thought of as univalent, e.g. Ti, Zr, Hf; V, Nb, Ta; Mn. There are clearly also strong additional interactions between unlike atoms as indicated by the structures adopted and the high mp of many of the compounds, e.g. Na_3Bi melts

at 840°, compared with Na 98° and Bi 271°C. Many of the M_3E compounds have the hexagonal Na_3As (anti-LaF_3) structure in which equal numbers of Na and As form hexagonal nets as in boron nitride and the remaining Na atoms are arranged in layers on either side of these nets. Each As has 5 Na neighbours at the corners of a trigonal bipyramid (3 at 294 and 2 at 299) and 6 other Na atoms at 330 pm form a trigonal prism (i.e. 11-coordinate). The Na atoms are of two sorts, both of high mixed CN to As and Na, and all the Na–Na distances (328–330 pm) are less than in Na metal (371.6 pm). The compounds show either metallic conductivity or are semiconductors. An even more compact metal structure (cubic) is adopted by β-Li_3Bi, β-Li_3Sb, and by M_3E, where M = Rb, Cs, and E = Sb, Bi.

Some of the alkali metal–group 15 element systems give compounds of stoichiometry ME. Of these, LiBi and NaBi have typical alloy structures and are superconductors below 2.47 K and 2.22 K respectively. Others, like LiAs, NaSb and KSb, have parallel infinite spirals of As or Sb atoms, and it is tempting to formulate them as $M^+{}_n(E_n)^{n-}$ in which the $(E_n)^{n-}$ spirals are isoelectronic with those of covalently catenated Se and Te (p. 752); however, their metallic lustre and electrical conductivity indicate at least some metallic bonding. Within the spiral chains As–As is 246 pm (cf. 252 pm in the element) and Sb–Sb is ~285 pm (cf. 291 pm in the element).

Compounds with Sc, Y, lanthanoids and actinoids are of three types. Those with composition ME have the (6-coordinated) NaCl structure, whereas M_3E_4 (and sometimes M_4E_3) adopt the body-centred thorium phosphide structure (Th_3P_4) with 8-coordinated M, and ME_2 are like $ThAs_2$ in which each Th has 9 As neighbours. Most of these compounds are metallic and those of uranium are magnetically ordered. Full details of the structures and properties of the several hundred other transition metal–Group 15 element compounds fall outside the scope of this treatment, but three particularly important structure types should be mentioned because of their widespread occurrence and relation to other structure types, namely $CoAs_3$, NiAs and structures related to those adopted by FeS_2 (marcasite, pyrites, loellingite, etc.).

$CoAs_3$ occurs in the mineral skutterudite; it is a diamagnetic semiconductor and has a cubic structure related to that of ReO_3 (p. 1047) but with a systematic distortion which results in the generation of well-defined *planar* rings of As_4. The same structure motif is found in MP_3 (M = Co, Ni, Rh, Pd), MAs_3 (M = Co, Rh, Ir) and MSb_3 (M = Co, Rh, Ir). The unit cell (Fig. 13.2) contains 8Co and 24As (i.e. $6As_4$), and it follows from the directions in which the various sets of atoms move, that 2 of the 8 original ReO_3 cells do not contain an As_4 group. Each As has a nearly regular tetrahedral arrangement of 2 Co and 2 As neighbours and each Co has a slightly distorted octahedral coordination group of 6 As. The planar As_4 groups are not quite square, the sides of the rectangle being 246 and 257 pm (cf. 244 pm in the tetrahedral As_4 molecule). The distortions from the ReO_3 structure (in which each As would have had 8 equidistant neighbours at about 330 pm) thus permit the closer approach of the As atoms in groups of 4 though this does not proceed so far as to form 6 equidistant As–As links as in the tetrahedral As_4 molecule. The P–P distances in the P_4 rectangles of the isostructural phosphides are 223 and 231 pm (cf. 225 pm in the tetrahedral P_4 molecule).

The NiAs structure is one of the commonest MX structure types, the number of compounds adopting it being exceeded only by those with the NaCl structure. It is peculiar to compounds formed by the transition elements with either As, Sb, Bi, the chalcogens (p. 748) or occasionally Sn. Examples with the Group 15 elements are Ti(As, Sb), V(P, Sb), CrSb, Mn(As, Sb, Bi), FeSb, Co(As, Sb), Ni(As, Sb, Bi), RhBi, Ir(Sb, Bi), PdSb, Pt(Sb, Bi). The structure is illustrated in Fig. 13.3a: each Ni is 8-coordinate, being surrounded by 6 As and by 2 Ni (which are coplanar with 4 of the As); the As atoms form a hcp lattice in which the interstices are occupied by Ni atoms in such a way that each As is surrounded by a trigonal prism of 6 Ni. Another important feature of the NiAs structure is the close approach of Ni atoms

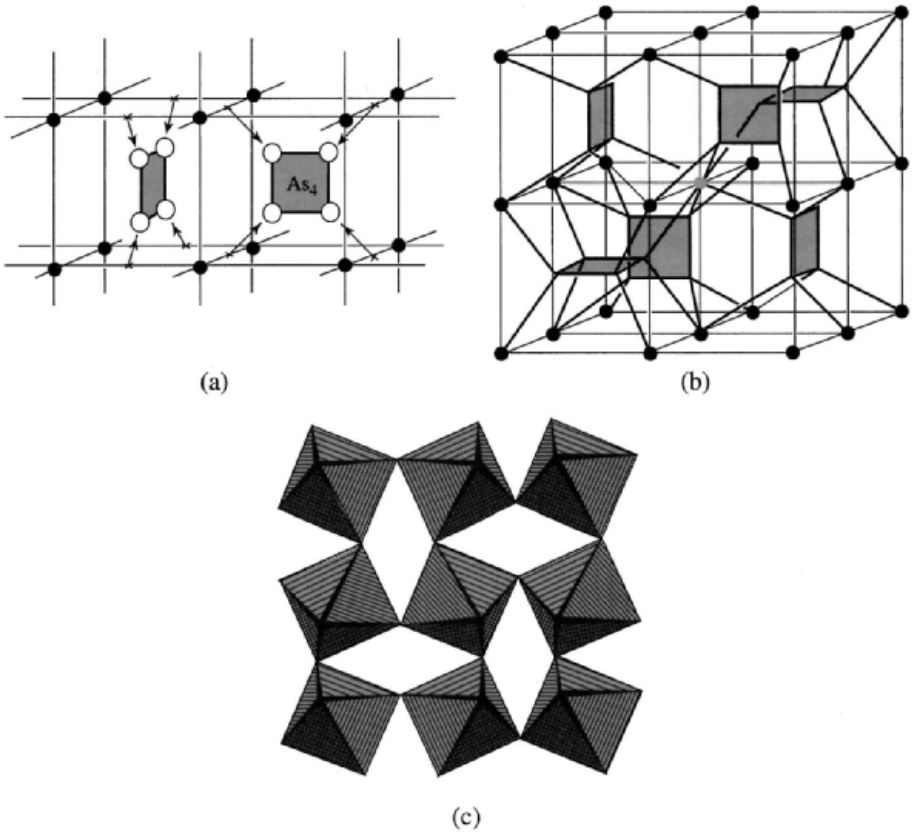

Figure 13.2 The cubic structure of skutterudite ($CoAs_3$). (a) Relation to the ReO_3 structure; (b) unit cell (only sufficient Co–As bonds are drawn to show that there is a square group of As atoms in only 6 of the 8 octants of the cubic unit cell, the complete 6-coordination group of Co is shown only for the atom at the body-centre of the cell); and (c) section of the unit cell showing $\{CoAs_6\}$ octahedra corner-linked to form As_4 squares.

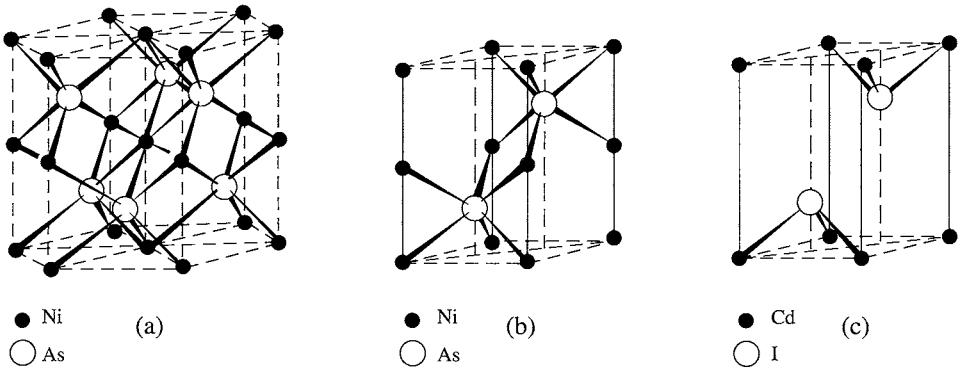

Figure 13.3 Structure of nickel arsenide showing (a) 3 unit cells, (b) a single unit cell Ni_2As_2 and its relation to (c) the unit cell of the layer lattice compound CdI_2 (see text).

in chains along the (vertical) *c*-axis. The unit cell (Fig. 13.3b) contains Ni_2As_2, and if the central layer of Ni atoms is omitted the CdI_2 structure is obtained (Fig. 13.3c). This structural relationship accounts for the extensive ranges of composition frequently observed in compounds with this structure, since partial filling of the intermediate layer gives compositions in the range $M_{1+x}X_2$ ($0 < x < 1$). With the chalcogens the range sometimes extends the whole way from ME to ME_2 but for As, Sb and Bi it never reaches ME_2 and intermetallic compounds of this composition usually have either the marcasite or pyrites structures of FeS_2 (p. 680) or the compressed marcasite (loellingite) structure of $FeAs_2$. All three structure types contain the E_2 group. Examples are:

marcasite type:	$NiAs_2$, $NiSb_2$
pyrites type:	$PdAs_2$, $PdSb_2$, $PtAs_2$, $PtSb_2$, $PtBi_2$, $AuSb_2$
loellingite type:	$CrSb_2$, FeP_2, $FeAs_2$, $FeSb_2$, RuP_2, $RuAs_2$, $RuSb_2$, OsP_2, $OsAs_2$, $OsSb_2$
ternary compounds:	CoAsS (i.e. "pyrites" $Co_2As_2S_2$), NiSbS {i.e. "pyrites" Ni(Sb-S)}, NiAsS (i.e. pyrites with random As and S on the S positions)

Compounds of As, Sb and Bi with the metals in Group 13 (Al, Ga, In, Tl) comprise the important III–V semiconductors whose structures, properties, and extensive applications have already been discussed (pp. 255–8). Group 14 elements also readily form compounds of which the following serve as examples: GeAs mp 737°C, $GeAs_2$ mp 732°C, SnAs (NaCl structure, superconductor below 3.5 K), Sn_4As_3 (defect NaCl structure, superconductor below 1.2 K). The many important industrial applications of dilute alloys of As, Sb and Bi with tin and lead were mentioned on pp. 370 and 371.

13.3.2 Hydrides of arsenic, antimony and bismuth

AsH_3, SbH_3 and BiH_3 are exceedingly poisonous, thermally unstable, colourless gases whose physical properties are compared with those of NH_3 (p. 423) and PH_3 (p. 492) in Table 13.5. The absence of H bonding is apparent; in addition, the proton affinity is very low and there is little tendency to form the onium ions MH_4^+ analogous to NH_4^+. However, very recently the thermally unstable salts $[AsH_4]^+[SbF_6]^-$ (decomp. −40°C), $[AsH_4]^+[AsF_6]^-$ (d. −75°) and $[SbH_4]^+[SbF_6]^-$ (d. −70°), have been isolated as colourless air- and moisture-sensitive crystals by protonation of the hydrides MH_3 with the appropriate superacids. HF/MF_5 (M = As, Sb).[18] The gradually increasing densities of the liquids near their bp is expected, as is the increase in M–H distance. There is a small diminution in the angle H–M–H with increasing molecular weight though the difference for AsH_3 and SbH_3 is similar to the experimental uncertainty. The rapid diminution in thermal stability is reflected in the standard heats of formation ΔH_f°; AsH_3 decomposes to the elements on being warmed to 250–300°, SbH_3 decomposes steadily

[18] R. MINKWITZ, A. KORNATH, W. SAWODNY and H. HÄRTNER, *Z. anorg. allg. Chem.* **620** 753–6 (1994).

Table 13.5 Comparison of the physical properties of AsH_3, SbH_3 and BiH_3 with those of NH_3 and PH_3

Property	NH_3	PH_3	AsH_3	SbH_3	BiH_3
MP/°C	−77.8	−133.5	−116.3	−88	—
BP/°C	−34.5	−87.5	−62.4	−18.4	+16.8 (extrap)
Density/g cm^{-3}(T°C)	0.683 (−34°)	0.746 (−90°)	1.640 (−64°)	2.204 (−18°)	—
ΔH_f°/kJ mol^{-1}	−46.1	−9.6(?)	66.4	145.1	277.8
Distance (M–H)/pm	101.7	141.9	151.9	170.7	—
Angle H–M–H	107.8°	93.6°	91.8°	91.3°	—

at room temperature, and BiH_3, cannot be kept above −45°.

Arsine, AsH_3, is formed when many As-containing compounds are reduced with nascent hydrogen and its decomposition on a heated glass surface to form a metallic mirror formed the basis of Marsh's test for the element. The low-temperature reduction of $AsCl_3$ with $LiAlH_4$ in diethyl ether solution gives good yields of the gas as does the dilute acid hydrolysis of many arsenides of electropositive elements (Na, Mg, Zn, etc.). Similar reactions yield stibine, e.g.:

$$Zn_3Sb_2 + 6H_3O^+ \xrightarrow[14\%\text{ yield}]{\text{aq HCl}} 2SbH_3 + 3Zn^{2+} + 6H_2O$$

$$SbO_3^{3-} + 3Zn + 9H_3O^+ \longrightarrow SbH_3 + 3Zn^{2+} + 12H_2O$$

$$SbCl_3(\text{in aq NaCl}) + NaBH_4 \longrightarrow SbH_3 \quad \text{(high yield)}$$

Both AsH_3 and SbH_3 oxidize readily to the trioxide and water, and similar reactions occur with S and Se. AsH_3 and SbH_3 form arsenides and antimonides when heated with metals and this reaction also finds application in semiconductor technology; e.g. highly purified SbH_3 is used as a gaseous *n*-type dopant for Si (p. 332).

Bismuthine, BiH_3, is extremely unstable and was first detected in minute traces by F. Paneth using a radiochemical technique involving $^{212}Bi_2Mg_3$. These experiments, carried out in 1918, were one of the earliest applications of radiochemical tracer experiments in chemistry. Later work using BH_4^- to reduce $BiCl_3$ was unsuccessful in producing macroscopic amounts of the gas and the best preparation (1961) is the disproportionation of $MeBiH_2$ at −45° for several hours; Me_2BiH can also be used:

$$Me_{3-n}BiH_n \xrightarrow{-45^\circ} \frac{n}{3}BiH_3 + \frac{3-n}{3}BiMe_3$$

Lower hydrides such as As_2H_4 have occasionally been reported as fugitive species but little is known of their properties (see p. 583; cf. also N_2H_4, p. 427; P_2H_4, p. 495). Recent fully optimized *ab initio* calculations (including relativistic core potentials) suggest that the double-bonded species HM=MH (M = P, As, Sb, Bi) should all exist as *trans* planar (C_{2v}) molecules;[19] close agreement with experimental interatomic distances in known organic diphosphenes (p. 544) and diarsenes adds confidence to the computed distances for −Sb=Sb− (260.8 pm) and −Bi=Bi− (271.9 pm) which are both about 9% shorter than the corresponding single-bond distances (cf. also −P=P− 200.5 pm and −As=As− 222.7 pm). The computed bond angles H−M−M in M_2H_2 (M = P, As, Sb, Bi) are 96.2°, 94.4°, 93.0° and 91.8°, respectively.

13.3.3 Halides and related complexes

The numerous halides of As, Sb and Bi show highly significant gradations in physical properties, structure, bonding and chemical reactivity. Distinctions between ionic, coordinate and covalent (molecular) structures in the halides and their complexes frequently depend on purely arbitrary demarcations and are often more a hindrance than a help in discerning the underlying structural and bonding principles. Alternations in the stability of the +5 oxidation state are also illuminating. It will be convenient to divide the discussion into five subsections dealing in turn with the trihalides MX_3, the pentahalides MX_5, other halides, halide complexes of M^{III} and M^V, and oxohalides.

Trihalides, MX_3

All 12 compounds are well known and are available commercially; their physical properties are summarized in Table 13.6 Comparisons with the corresponding data for NX_3 (p. 438) and PX_3 (p. 496) are also instructive. Trends in mp, bp and density are far from regular and reflect the differing structures and bond types.

[19] S. NAGASE, S. SUSUKI and T. KURAKAKE, *J. Chem. Soc., Chem. Commun.*, 1724–6 (1990).

Table 13.6 Some physical properties of the trihalides of arsenic, antimony and bismuth

Compound	Colour and state at 25°C	MP/°C	BP/°C	d/g cm^{-3} (T°C)	ΔH_f°/ kJ mol^{-1}
AsF_3	Colourless liquid	−6.0	62.8	2.666 (0°)	−956.5
$AsCl_3$	Colourless liquid	−16.2	130.2	2.205 (0°)	−305.0
$AsBr_3$	Pale-yellow crystals	+31.2	221	3.66 (15°)	−197.0
AsI_3	Red crystals	140.4	~400	4.39 (15°)	−58.2
SbF_3	Colourless crystals	290	~345	4.38 (25°)	−915.5
$SbCl_3$	White, deliquescent crystals	73.4	223	3.14 (20°)	−382.2
$SbBr_3$	White, deliquescent crystals	96.0	288	4.15 (25°)	−259.4
SbI_3	Red crystals	170.5	401	4.92 (22°)	−100.4
BiF_3	Grey-white powder	649[a]	900	~5.3	−900
$BiCl_3$	White, deliquescent crystals	233.5	441	4.75	−379
$BiBr_3$	Golden, deliquescent crystals	219	462	5.72	−276
BiI_3	Green-black crystals	408.6	~542 (extrap)	5.64	−150

[a] BiF_3 is sometimes said to be "infusible" or to have mp at varying temperatures in the range 725–770°, but such materials are probably contaminated with the oxofluoride BiOF (p. 572).

Thus AsF_3, $AsCl_3$, $AsBr_3$, $SbCl_3$ and $SbBr_3$ are clearly volatile molecular species, whereas AsI_3, SbF_3 and BiX_3 have more extended interactions in the solid state. Trends in the heats of formation from the elements are more regular being *ca.* −925 kJ mol^{-1} for MF_3, *ca.* −350 kJ mol^{-1} for MCl_3, *ca.* −245 kJ mol^{-1} for MBr_3 and *ca.* −100 kJ mol for MI_3. Within these average values, however, AsF_3 is noticeably more exothermic than SbF_3 and BiF_3, whereas the reverse is true for the chlorides; there is also a regular trend towards increasing stability in the sequence As < Sb < Bi for the bromides and for the iodides of these elements.

The trifluorides are all readily prepared by the action of HF on the oxide M_2O_3 (direct fluorination of M or M_2O_3 with F_2 gives MF_5, p. 561). Because AsF_3 hydrolyses readily, the reaction is best done under anhydrous conditions using H_2SO_4/CaF_2 or HSO_3F/CaF_2, but aqueous HF can be used for the others. The trichlorides, tribromides and triiodides of As and Sb can all be prepared by direct reaction of X_2 with M or M_2O_3, whereas the less readily hydrolysed BiX_3 can be obtained by treating Bi_2O_3 with the aqueous HX. Many variants of these reactions are possible: e.g., $AsCl_3$ can be made by chlorination of As_2O_3 with Cl_2, S_2Cl_2, conc HCl or H_2SO_4/MCl.

The trihalides of As are all pyramidal molecular species in the gas phase with angle X–As–X in the range 96–100°. This structure persists in the solid state, and with AsI_3 the packing is such that each As is surrounded by an octahedron of six I with 3 short and 3 long As–I distances (256 and 350 pm; ratio 1.37, mean 303 pm). The I atoms form a regular hcp lattice. A similar layer structure is adopted by SbI_3 and BiI_3 but with the metal atoms progressively nearer to the centre of the I_6 octahedra:

> 3 Sb–I at 287 pm and 3 at 332 pm; ratio 1.16, mean 310 pm
> all 6Bi–I at 310 pm; "ratio" 1.00

This is sometimes described as a trend from covalent, molecular AsI_3 through intermediate SbI_3 to ionic BiI_3, but this exaggerates the difference in bond-type. Arsenic, Sb and Bi have very similar electronegativities (p. 550) and it seems likely that the structural trend reflects more the way in which the octahedral interstices in the hcp iodine lattice are filled by atoms of gradually increasing size. The size of these interstices is about constant (see mean M–X distance) but only Bi is sufficiently large to fill them symmetrically.

Discrete molecules are apparent in the crystal structure of the higher trihalides of Sb, and,

Table 13.7 Structural data for antimony trihalides

	SbF_3	$SbCl_3$	α-$SbBr_3$	β-$SbBr_3$	SbI_3
Sb–X in gas molecule/pm	?	233	251	251	272
Three short Sb–X in crystal/pm	192	236	250	249	287
Three long Sb–X in crystal/pm	261	≥350	≥375	≥360	332
Ratio (long/short)	1.36	≥1.48	≥1.50	≥1.44	1.16
Angle X–Sb–X in crystal	87°	95°	96°	95°	96°

again, these pack to give 3 longer and 3 shorter interatomic distances (Table 13.7).

The structure of BiF_3 is quite different: β-BiF_3 has the "ionic" YF_3 structure with tricapped trigonal prismatic coordination of Bi by 9 F. $BiCl_3$ has an essentially molecular structure (like SbX_3) but there is a significant distortion within the molecule itself, and the packing gives 5 (not 3) further Cl at 322–345 pm to complete a *bi*capped trigonal prism. As a consequence of this structure $BiCl_3$ has smaller unit cell dimensions than $SbCl_3$ despite the longer Bi–Cl bond (250 pm, as against 236 pm for Sb–Cl). The eightfold coordination has been rationalized by postulating that the ninth position is occupied by the stereochemically active lone-pair of electrons on Bi^{III}. On this basis, the 3 long and 3 short M–X distances in octahedrally coordinated structures can also be understood, the lone-pair being directed towards the centre of the more distant triangle of 3X. However, it is hard to quantify this suggestion, particularly as the X–M–X angles are fairly constant at $97 \pm 2°$ (rather than 109.5° for sp^3 hybrids), implying little variation in hybridization and a lone-pair with substantial s^2 character. The effect is less apparent in SbI_3 and absent BiI_3 (see above) and this parallels the diminishing steric influence of the lone-pair in some of the complexes of the heavier halides with Sn^{II} (p. 380) and Te^{IV} (p. 757).

Many of the trihalides of As, Sb and Bi hydrolyse readily but can be handled without great difficulty under anhydrous conditions. AsF_3 and SbF_3 are important reagents for converting non-metal chlorides to fluorides. SbF_3 in particular is valuable for preparing organofluorine compounds (the Swarts reaction):

$$CCl_3CCl_3 + SbF_3 \longrightarrow CCl_2FCCl_2F$$

$$SiCl_4 + SbF_3 \longrightarrow SiCl_3F, SiCl_2F_2, SiClF_3$$

$$CF_3PCl_2 + SbF_3 \longrightarrow CF_3PF_2$$

$$R_3PS + SbF_3 \longrightarrow R_3PF_2$$

Sometimes the reagents simultaneously act as mild oxidants:

$$3PhPCl_2 + 4SbF_3 \longrightarrow 3PhPF_4 + 2Sb + 2SbCl_3$$

$$3Me_2P(S)P(S)Me_2 + 6SbF_3 \longrightarrow 6Me_2PF_3 + 2Sb + 2Sb_2S_3$$

AsF_3, though a weaker fluorinating agent than SbF_3, is preferred for the preparation of high-boiling fluorides since $AsCl_3$ (bp 130°) can be distilled off. SbF_3 is preferred for low-boiling fluorides, which can be readily fractionated from $SbCl_3$ (bp 223°). Selective fluorinations are also possible, e.g.:

$$[PCl_4]^+[PCl_6]^- + 2AsF_3 \longrightarrow [PCl_4]^+[PF_6]^- + 2AsCl_3$$

$AsCl_3$ and $SbCl_3$ have been used as non-aqueous solvent systems for a variety of reactions.[20,21] They are readily available, have convenient liquid ranges (p. 559), are fairly easy to handle, have low viscosities η, moderately high dielectric constants ε and good solvent properties (Table 13.8).

[20] D. S. PAYNE, Chap. 8 in T. C. WADDINGTON (ed.), *Nonaqueous Solvent Systems*, pp. 301–25, Academic Press, London, 1965.

[21] E. C. BAUGHAN, Chap. 5 in J. J. LAGOWSKI (ed.), *The Chemistry of Nonaqueous Solvents*, Vol. 4, pp. 129–65, Academic Press, London, 1976.

Table 13.8 Some properties of liquid $AsCl_3$ and $SbCl_3$

	η/centipoise	ε	κ/ohm^{-1} cm^{-1}
$AsCl_3$ at 20°C	1.23	12.8	1.4×10^{-7}
$SbCl_3$ at 75°C	2.58	33.2	1.4×10^{-6}

The low conductivities imply almost negligible self-ionization according to the formal scheme:

$$2MCl_3 \rightleftharpoons MCl_2^+ + MCl_4^-$$

Despite this, they are good solvents for chloride-ion transfer reactions, and solvo-acid–solvo-base reactions (p. 827) can be followed conductimetrically, voltametrically or by use of coloured indicators. As expected from their constitution, the trihalides of As and Sb are only feeble electron-pair donors (p. 198) but they have marked acceptor properties, particularly towards halide ions (p. 564) and amines.

AsX_3 and SbX_3 react with alcohols (especially in the presence of bases) and with sodium alkoxide to give arsenite and antimonite esters, $M(OR)_3$ (cf. phosphorus, (p. 515):

$$AsCl_3 + 3PhOH \longrightarrow As(OPh)_3 + 3HCl$$

$$SbCl_3 + 3Bu^tOH + 3NH_3 \longrightarrow Sb(OBu^t)_3 + 3NH_4Cl$$

$$SbCl_3 + 3NaOSiEt_3 \longrightarrow Sb(OSiEt_3)_3 + 3NaCl$$

Halide esters $(RO)_2MX$ and $(RO)MX_2$ can be made similarly:

$$AsCl_3 + 2NaOEt \longrightarrow (EtO)_2AsCl + 2NaCl$$

$$AsCl_3 + EtOH \xrightarrow{CO_2} (EtO)AsCl_2 + HCl$$

$$As(OPr)_3 + MeCOCl \longrightarrow (PrO)_2AsCl + MeCO_2Pr$$

Amino derivatives are obtained by standard reactions with secondary amines, lithium amides or by transaminations:

$$AsCl_3 + 6Me_2NH \longrightarrow As(NMe_2)_3 + 3[Me_2NH_2]Cl$$

$$SbCl_3 + 3LiNMe_2 \longrightarrow Sb(NMe_2)_3 + 3LiCl$$

$$As(NMe_2)_3 + 3Bu_2NH \longrightarrow As(NBu_2)_3 + 3Me_2NH$$

As with phosphorus (p. 533) there is an extensive derivative chemistry of these and related compounds.[15,16]

Pentahalides, MX_5

Until fairly recently only the pentafluorides and $SbCl_5$ were known, but the exceedingly elusive $AsCl_5$ was finally prepared in 1976 by ultraviolet irradiation of $AsCl_3$ in liquid Cl_2 at −105°C.[22] Some properties of the 5 pentahalides are given in Table 13.9.

The pentafluorides are prepared by direct reaction of F_2 with the elements (As, Bi) or their oxides (As_2O_3, Sb_2O_3). $AsCl_5$, as noted above, has only a fugitive existence and decomposes to $AsCl_3$ and Cl_2 at about −50°. $SbCl_5$ is more stable and is made by reaction of Cl_2 on $SbCl_3$. No pentabromides or pentaiodides have been characterized, presumably because M^V is too highly oxidizing for these heavier halogens (cf. TlI_3, p. 239). The relative instability of $AsCl_5$ when compared with PCl_5 and $SbCl_5$ is a further example of the instability of the highest valency state of p-block elements following the completion of the first (3d) transition series (p. 552). This can be understood in terms of incomplete shielding of the nucleus which leads to a "d-block contraction" and a consequent lowering of the energy of the 4s orbital in As and $AsCl_3$, thereby making it more difficult to promote one of the $4s^2$ electrons

[22] K. SEPPELT, *Angew. Chem. Int. Edn. Engl.* **15**, 377–8 (1976).

Table 13.9 Some properties of the known pentahalides

Property	AsF_5	SbF_5	BiF_5	$AsCl_5$	$SbCl_5$
MP/°C	−79.8	8.3	154.4	~ −50 (d)	4
BP/°C	−52.8	141	230	—	140 (d)
Density (T°C)/g cm^{-3}	2.33 (−53°)	3.11 (25°)	5.40 (25°)	—	2.35 (21°)

for the formation of $AsCl_5$. There is no evidence that the As–Cl bond strength itself, in $AsCl_5$, is unduly weak. The non-existence of $BiCl_5$ likewise suggests that it is probably less stable than $SbCl_5$, due the analogous "f-block contraction" following the lanthanide elements (p. 1232).

Evidence from vibration spectroscopy suggests that gaseous AsF_5, solid $AsCl_5$ and liquid $SbCl_5$ are trigonal bipyramidal molecules like PF_5 (D_{3h}), and this is confirmed for AsF_5 by a low-temperature X-ray crystal structure which also indicates that the As-F(axial) distances (171.9 pm) are slightly longer than the As-F (equatorial) distances (166.8 pm).[23] By contrast SbF_5 is an extremely viscous, syrupy liquid with a viscosity approaching 850 centipoise at 20°: the liquid features polymeric chains of *cis*-bridged $\{SbF_6\}$ octahedra in which the 3 different types of F atom (a, b, c) can be distinguished by low-temperature ^{19}F nmr spectroscopy.[24] As shown in Fig. 13.4(a), F_a are the bridging atoms and are *cis* to each other in any one octahedron; F_b are also *cis* to each other and are, in addition, *cis* to 1 F_a and *trans* to the other, whereas F_c are *trans* to each other and *cis* to both F_a. In the crystalline state the *cis* bridging persists but the structure has tetrameric molecular units (Fig. 13.4(b)) rather than high polymers.[25] There are two different Sb–F–Sb bridging angles, 141° and 170°, and the terminal Sb–F_t distances (mean 182 ± 5 pm) are noticeably less than the bridging Sb–F_μ distances (mean 203 ± 5 pm). (See p. 569 for the ionic structures of Sb_8F_{30}, i.e. $Sb^{V}{}_3Sb^{III}{}_5F_{30}$.) Yet another structure motif is adopted in BiF_5; this crystallizes in long white needles and has the α-UF_5 structure in which infinite linear chains of *trans*-bridged $\{BiF_6\}$ octahedra are stacked parallel to each other. The Bi-F-Bi bridging angle between adjacent octahedra in the chain is 180°.

The pentafluorides are extremely powerful fluorinating and oxidizing agents and they also have a strong tendency to form complexes with electron-pair donors. This latter property has already been presaged by the propensity of SbF_5 to polymerize and is discussed more fully on p. 569.

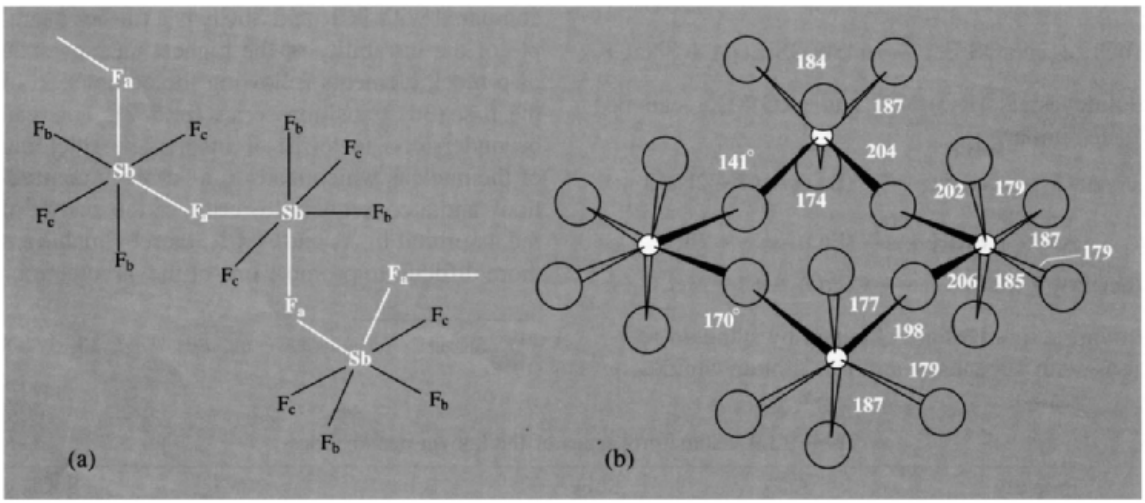

Figure 13.4 (a) The *cis*-bridged polymeric structure of liquid SbF_5 (schematic) showing the three sorts of F atom.[24] (b) Structure of the tetrameric molecular unit in crystalline $(SbF_5)_4$ showing the *cis*-bridging of 4 $\{SbF_6\}$ octahedra (distances in pm).[25]

See also "superacids" on p. 570. Some typical reactions of SbF_5 and $SbCl_5$ are as follows:

$$ClCH_2PCl_2 + SbF_5 \longrightarrow ClCH_2PF_4$$

$$Me_3As + SbCl_5 \longrightarrow Me_3AsCl_2 + SbCl_3$$

$$R_3P + SbCl_5 \longrightarrow [R_3PCl]^+[SbCl_6]^- \qquad (R = Ph, Et_2N, Cl)$$

$$SbCl_5 \xrightarrow{5NaOR} Sb(OR)_5 \xrightarrow{NaX} Na[Sb(OR)_5X] \qquad (X = OR, Cl)$$

Perhaps the most reactive compound of the group is BiF_5. It reacts extremely vigorously with H_2O to form O_3, OF_2 and a voluminous brown precipitate which is probably a hydrated bismuth(V) oxide fluoride. At room temperature BiF_5 reacts vigorously with iodine or sulfur; above 50° it converts paraffin oil to fluorocarbons; at 150° it fluorinates UF_4 to UF_6; and at 180° it converts Br_2 to BrF_3 and BrF_5, and Cl_2 to ClF.

Mixed halides and lower halides

Unlike phosphorus, which forms a large number of readily isolable mixed halides of both P^{III} and P^V, there is apparently less tendency to form such compounds with As, Sb and Bi, and few mixed halides have so far been characterized. AsF_3 and $AsCl_3$ are immiscible below 19°C, but at room temperature ^{19}F nmr indicates some halogen exchange; however equilibrium constants for the formation of AsF_2Cl and $AsFCl_2$ are rather small. Likewise, Raman spectra show the presence of $AsCl_2Br$ and $AsClBr_2$ in mixtures of the parent trihalides, though rapid equilibration prevents isolation of the mixed halides. It is said that $SbBrI_2$ (mp 88°) can be obtained by eliminating EtBr from $EtSbI_2Br_2$.

Mixed pentahalides are more readily isolated and are of at least three types: ionic, tetrameric, and less stable molecular trigonal-bipyramidal monomers. Thus, chlorination of a mixture of $AsF_3/AsCl_3$ with Cl_2, or fluorination of $AsCl_3$ with ClF_3 (p. 828) gives $[AsCl_4]^+[AsF_6]^-$ [mp 130°(d)] whose X-ray crystal structure has recently been redetermined.[26] Similarly, $AsCl_3 + SbCl_5 + Cl_2 \rightarrow [AsCl_4]^+[SbCl_6]^-$. It also appears that all members of the monomeric molecular series $AsCl_{5-n}F_n$ ($n = 1 - 4$) can be made either by thermolysis of $[AsCl_4]^+[AsF_6]^-$ or, in the case of $AsCl_3F_2$ (D_{3h}), by gas-solid reaction of $AsCl_2F_3$ (g) with $CaCl_2$ (s); the compounds were characterized as trigonal-bipyramidal molecules by low-temperature matrix ir and Raman spectra.[27] The mixed bromofluoride $[AsBr_4]^+[AsF_6]^-$, made by reaction of $AsBr_3$, Br_2 and AsF_5 at low temperature was also characterized by Raman spectroscopy.[28]

Antimony chloride fluorides have been known since the turn of the century but the complexity of the system, the tendency to form mixtures of compounds, and their great reactivity have conspired against structural characterization until fairly recently.[29] It is now clear that fluorination of $SbCl_5$ depends crucially on the nature of the fluorinating agent. Thus, with AsF_3 it gives $SbCl_4F$ (mp 83°) which is a *cis*-F-bridged tetramer as in Fig. 13.4(b) with the terminal F atoms replaced by Cl. Fluorination of $SbCl_5$ with HF also gives this compound but, in addition, $SbCl_3F_2$ mp 68° (*cis*-F-bridged tetramer) and $SbCl_2F_3$ mp 62°, which turns out to be $[SbCl_4]^+[Sb_2Cl_2F_9]^-$. The anion is F-bridged, i.e. $[ClF_4Sb{-}F{-}SbF_4Cl]^-$ with angle Sb–F–Sb 163°. Even more extensive fluorination occurs when $SbCl_5$ is reacted with SbF_5 and the product is $[SbCl_4]^+[Sb_2F_{11}]^-$. By contrast, fluorination of $(SbCl_4F)_4$ with SbF_5 in liquid SO_2 yields $Sb_4Cl_{13}F_7$ (mp ~ 50°) which is a *cis*-F-bridged tetramer of $SbCl_3F_2$ with two of the Sb atoms having a Cl atom partially replaced by F, i.e. $(Sb_2Cl_{6.5}F_{3.5})_2$ and bridge angles Sb–F–Sb of 166–168°.

The attention which has been paid to the mixed chloride fluorides of Sb^V is due not only to the intellectual problem of their structures but also to their importance as industrial fluorinating agents (Swarts reaction). Addition of small amounts of $SbCl_5$ to SbF_5 results in a dramatic decrease in viscosity (due to the breaking of Sb–F–Sb links) and a substantial increase in electrical conductivity (due to the formation of fluoro-complex ions). Such mixed halides are often more effective fluorinating agents than SbF_3, provided that yields are not lowered by oxidation, e.g. $SOCl_2$ gives SOF_2; $POCl_3$ gives $POFCl_2$; and hexachlorobutadiene is partially fluorinated and oxidized to give $CF_3CCl{=}CClCF_3$ which can then be further oxidized to CF_3CO_2H:

$$CCl_2{=}CClCCl{=}CCl_2 \xrightarrow{\text{“}SbF_3Cl_2\text{”}} CF_3CCl{=}CClCF_3$$

$$\xrightarrow[\text{KOH}]{KMnO_4/} 2CF_3CO_2H$$

The use of SbF_5 in the preparation of "superacids" such as $(HSO_3F + SbF_5 + SO_3)$ is described in the following subsection (p. 570).

The only well-established lower halide of As is As_2I_4 which is formed as red crystals (mp 137°) when stoichiometric amounts of the 2 elements are heated to 260° in a sealed tube in the presence of octahydrophenanthrene. The compound hydrolyses and oxidizes readily and disproportionates in warm CS_2 solution but is stable up to 150° in an inert atmosphere. Disproportionation is quantitative at 400°:

$$3As_2I_4 \longrightarrow 4AsI_3 + 2As$$

Sb_2I_4 is much less stable: it has been detected by emf or vapour pressure measurements on solutions of Sb in SbI_3 at 230° but has not been isolated as a pure compound.

The lower halides of Bi are rather different. The diatomic species BiX (X = Cl, Br, I) occur in the equilibrium vapour above heated Bi–BiX_3 mixtures. A black crystalline lower chloride of composition $BiCl_{1.167}$ is obtained by heating Bi–$BiCl_3$ mixtures to 325° and cooling them during 1–2 weeks to 270° before removing excess $BiCl_3$ by sublimation or extraction into benzene. The compound is diamagnetic and has an astonishing structure which involves cationic clusters of bismuth and 2 different chloro-complex anions:[30] $[(Bi_9^{5+})_2(BiCl_5^{2-})_4(Bi_2Cl_8^{2-})]$, i.e. $Bi_{24}Cl_{28}$ or Bi_6Cl_7. The Bi_9^{5+} cluster is a tricapped trigonal prism (p. 591); the anion $BiCl_5^{2-}$ has square pyramidal coordination of the 5 Cl atoms around Bi with the sixth octahedral position presumably occupied by the lone-pair of electrons, and $Bi_2Cl_8^{2-}$ has two such pyramids *trans*-fused at a basal edge (p. 565). The compound is stable in vacuum below 200° but disproportionates at higher temperatures. It also disproportionates in the presence of ligands which coordinate strongly to $BiCl_3$ and hydrolyses readily to the oxide chloride.

Bismuth also forms an intriguing family of subiodides, Bi_4I_4, $Bi_{14}I_4$ and $Bi_{18}I_4$, which comprise a series of infinite one-dimensional quasi-molecular ribbons of Bi atoms $[Bi_mI_4]_\infty$ of different width ($m = 4, 14, 18$). There are two sorts of Bi atom in these structures: "internal" atoms (Bi_{in}) surrounded by three other Bi atoms only, at 300–312 pm (cf. 307 pm in Bi metal), and "external" Bi_{ex}, connected to differing numbers of Bi and I atoms depending on m.[31] Bi_4Br_4 has a similar structure. The first unambiguous identification of Bi^+ in the solid state came in 1971 when the structure of the complex halide $Bi_{10}Hf_3Cl_{18}$ was shown by X-ray diffraction analysis[32] to be $(Bi^+)(Bi_9^{5+})(HfCl_6^{2-})_3$. The compound was made by the oxidation of Bi with $HfCl_4/BiCl_3$.

Halide complexes of M^{III} and M^V

The trihalides of As, Sb and Bi are strong halide-ion acceptors and numerous complexes have been isolated with a wide variety of compositions. They are usually prepared by direct reaction of the trihalide with the appropriate

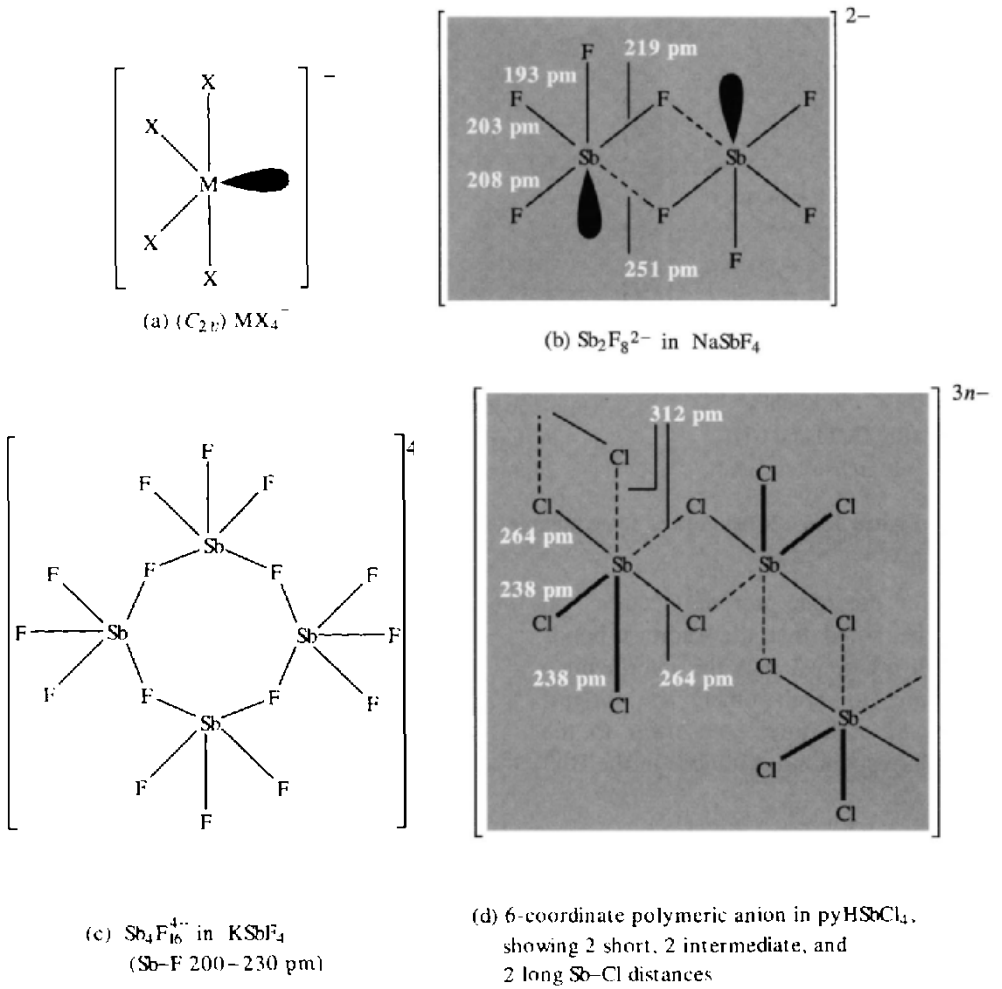

Figure 13.5 Structures of some complex halide anions of stoichiometry MX_4^-

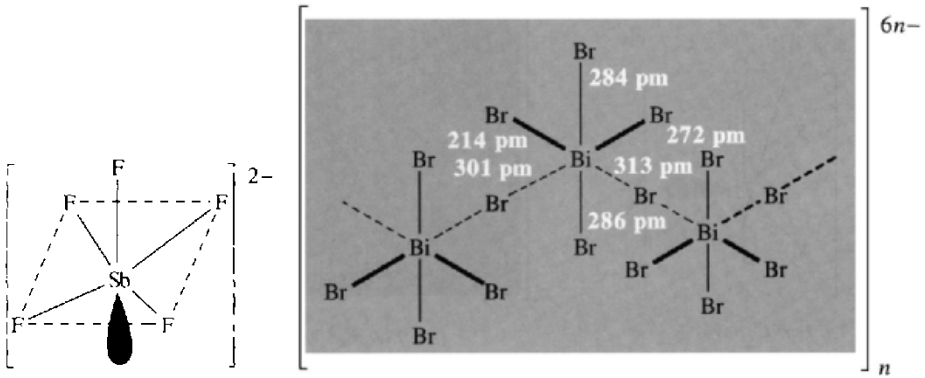
halide-ion donor. However, stoichiometry is not always a reliable guide to structure because of the possibility of oligomerization which depends both on the nature of M and X, and often also on the nature of the counter cation.[16,33] Thus the tetra-alkylammonium salts of MCl_4^-, MBr_4^-, and MI_4^- may contain the monomeric C_{2v} ion as shown in Fig. 13.5a (cf. isoelectronic SeF_4, p. 773), whereas in $NaSbF_4$ there is a tendency to dimerize by formation of subsidiary F···Sb interactions (Fig. 13.5b) cf. $Bi_2Cl_8^{2-}$ in the preceding subsection. With $KSbF_4$ association proceeds even further to give tetrameric cyclic anions (Fig. 13.5c). In both $NaSbF_4$ and $KSbF_4$ the Sb atoms are 5-coordinate but coordination rises to 6 in the polymeric chain anions of the pyridinium and 2-methylpyridinium salts $pyHSbCl_4$, $(2\text{-}MeC_5H_4NH)BiBr_4$ and $(2\text{-}MeC_5H_4NH)BiI_4$. The structure of $(SbCl_4)_n^{n-}$ is shown schematically in Fig. 13.5d and the three differing Sb–Cl distances reflect, in part,

[33] A. F. WELLS, *Structural Inorganic Chemistry*, 5th edn., pp. 879–88 and 894–9, Oxford University Press, Oxford, 1984.



(a) SbF_5^{2-} in K_2SbF_5 (Rb, Cs, Tl and NH_4 salt are isostructural)

(b) 6-coordinate polymeric anion in $(C_5H_{12}N)_2BiBr_5$, showing 2 short, 2 intermediate and 2 long Bi–Br distances

Figure 13.6 Structures of some complex halide anions of stoichiometry MX_5^{2-}

the influence of the lone-pair of electrons on Sb^{III}. It will be noted that the shortest bonds are *cis* to each other, whereas the intermediate bonds are *trans* to each other; the longest bonds are *cis* to each other and *trans* to the short bonds. Corresponding distances in the Bi^{III} analogues are:

$(BiBr_4)_n^{n-}$: short (2 at 264 pm); intermediate (283, 297 pm); long (308, 327 pm)

$(BiI_4)_n^{n-}$: short (2 at 289 pm); intermediate (2 at 310 pm); long (331, 345 pm).

Complexes of stoichiometry MX_5^{2-} can feature either discrete 5-coordinate anions as in K_2SbF_5 and $(NH_4)_2SbCl_5$ (Fig. 13.6a), or 6-coordinate polymeric anions as in the piperidinium salt $(C_5H_{10}NH_2)_2BiBr_5$ (Fig. 13.6b). In the discrete anion $SbCl_5^{2-}$ the $Sb-Cl_{apex}$ distance (236 pm) is shorter than the $Sb-Cl_{base}$ distances (2 at 258 and 2 at 269 pm) and the Sb atom is slightly below the basal plane (by 22 pm). The same structure is observed in K_2SbCl_5.

In addition to the various complex fluoroantimonate(III) salts M^ISbF_4 and $M^I_2SbF_5$ mentioned above, the alkali metals form complexes of stoichiometry $M^ISb_2F_7$, $M^ISb_3F_{10}$ and $M^ISb_4F_{13}$, i.e. $[SbF_4^-(SbF_3)_n]$ $(n = 1, 2, 3)$ but the mononuclear complexes $M^I_3SbF_6$ have not been found. The structure of $M^ISb_2F_7$ depends on the strength of the Sb-F···Sb bridge between the 2 units and this, in turn is influenced by the cation. Thus, in KSb_2F_7 there are distorted trigonal-bipyramidal SbF_4^- ions (Fig. 13.7a) and discrete pyramidal SbF_3 molecules (Sb–F 194 pm) with 2 (rather than 3) contacts between these and neighbouring SbF_4^- units of 241 and 257 pm (cf. SbF_3 itself, p. 560). By contrast $CsSb_2F_7$ has well-defined $Sb_2F_7^-$ anions (Fig. 13.7b) formed from 2 distorted trigonal bipyramidal $\{SbF_4\}$ groups sharing a common axial F atom with long bridge bonds.

Similar structural diversity characterizes the heavier halide complexes of the group. The

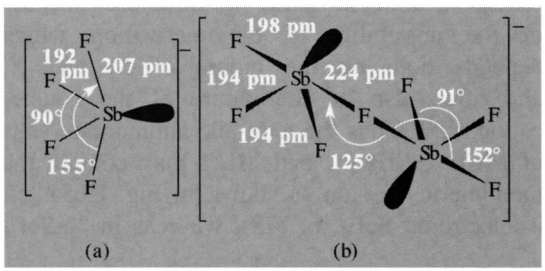


Figure 13.7 Structures of SbF_4^- and $Sb_2F_7^-$ ions in $KSbF_4(SbF_3)$ and $CsSb_2F_7$ respectively.
